I.2.2.18 Prevention of Experimentally Induced Myasthenia Gravis in Rats

PURPOSE AND RATIONALE

Myasthenia gravis is an organ specific autoimmune disease in man that results in skeletal muscles weakness. Typically, the sufferer has drooping eyelids, a blank facial expression, and weak, hesitant speech. This is due to the formation of autoantibodies against the nicotinic acetylcholine receptor (AChR). The formation of autoantibodies to acetylcholine's receptor leads to a gradual destruction of the receptors in skeletal muscles that receive nerve impulses and initiate muscle contractions. As a result, affected muscles fail to respond or react only weakly to nerve signals.

Experimental myasthenia gravis (EMG) can be induced in rats by injecting them with heterologous AChR, or with recombinant α subunits (two) of the AChR (portion of the AChR to which acetylcholine mainly binds) (Lennon et al. 1991). The animals display symptoms of myasthenia (electrophysiological evidence of altered neuromuscular function) and detectable antireceptor antibodies. The two α-subunits are plausible targets of pathogenic autoantibodies because they would allow mechanisms that depend on cross-linking, complement-mediated lysis, or hindrance of acetylcholine binding to the receptor (Schwartz 1993). The severity of the disease can vary, but most animals display, at the very least, a weakness and fatigability of foot grip. The disease gradually leads to abnormal gait and eventually the inability of the animals to walk or even right themselves.

PROCEDURE

Female rats of AO strain, 6–10 weeks old, are used. Three groups of rats are included in the experiment:

1. immunized with acetylcholine receptor (AChR)-protein and treated with test drug;
2. immunized with AChR-protein without drug, and
3. nonimmunized, nontreated control rats. The test drug is applied per os daily. First dose is administered on the day of immunization and the last on the day of sacrifice.

Immunization with AChR-Protein

AChR-protein isolated from Torpedo marmorata is emulsified with complete Freund's adjuvant and 100 µg/rat is injected intradermally in the hind foot pad. As additional adjuvant, 2.6×10^{10} *Bordetella pertussis* microorganisms is administered simultaneously by intramuscular injection in the hind leg.

Antibody Determination

Anti-AChR-protein antibodies are measured by enzyme linked immunosorbent assay (ELISA) as described by Norcross et al. (1980). AChR-protein is diluted to a final concentration of 2.5 µg/ml in 0.05 M carbonate buffer, pH 9.6. Two hundred ml of this solution is placed in each well of a microtitration plate (Flow Laboratories Inc.). After an over night incubation at 4°C, the plates are washed thoroughly with 0.01 M phosphate buffered saline (PBS) solution containing 0.05% Tween-20 (Sigma) subsequently referred to as PBS/T. Sera from all groups of rats are serially diluted in PBS/T and 200 µl is added to each micron well except in the background row (control row) and incubated at 4°C for 2 h. After washing, 200 µl of 1:1000 diluted peroxidase conjugated goat antirat immunoglobulin (Sera Lab. Sussex, England) in PBS/T are added to the micron wells and incubated for an additional 60 min at 4°C. After plates are washed, 200 µl of substrate-citrate buffer and 0.2 µl of 10% H_2O_2 are added and then incubated in the dark at room temperature for 30 min. The reaction is stopped by addition of 50 µl of 2M H_2SO_4 and the OD determined by using Titert Multiscan.

Two-color Flow Cytometry

Thymic cell suspensions are obtained by mincing tissue and passing it through 80 mm stainless mesh. After being washed three times in PBS, the cells are resuspended in PBS at a cell density of 10^7 viable cells/ml. The cell viability is determined by the trypan blue exclusion test. Erythrocytes are removed by addition of ammonium chloride. Cell staining and flow cytometric analyses are done as described by Itoyama et al. (1989). Thymocyte subsets expressing CD4 and/or CD8 molecules are defined by staining with monoclonal antibodies obtained from Serotec, Oxford, England: phycoerythrin (PE)-conjugated anti-W3/25 (CD4) and fluoresceinisothiocyanate (FITC)-conjugated anti-MRC OX8 (CD8). Two $\times 10^5$ to 1×10^6 cells suspended in 100 ml of PBS are exposed sequentially for 30 min to FITC-conjugated anti-CD8 and PE-conjugated anti-CD4 monoclonal antibodies. Isotype matched control monoclonal antibodies are used to prove the specificity of binding. Cell analysis is performed using FACScan flow cytometer from Becton Dickinson. One $\times 10^4$

events per sample are analyzed by Consort 30 and Lysis software. All data are collected and displayed on a log scale of increasing green and orange fluorescence intensity. This is presented as two-dimensional contour maps and as percentage of thymocytes by integrating counts in selected areas of the contour plots.

Stereologic Analysis of Thymuses

Thymuses of animals of all groups are prepared for light microscopic analysis. For this purpose thymus tissue is fixed in Carnoy's solution, embedded in paraffin and 3–5 µm thin sections are stained with hematoxylin and eosin. Cortex and medulla are analyzed stereologically using the point counting method described by Weible (1963). Volume density (*Vv*) of the examined structures is determined by the following equation: $Vv = Pi/Pt$, where *Pi* represents the number of points of the examined structure, and *Pt* the total number of points. *Vv* refers to the volume fraction i. e. volume of a feature per unit test volume (Williams 1981).

EVALUATION

EMG is evaluated clinically by daily examination of muscle weakness and scored as follows:

+ = weakness of grip with fatigability;
++ = abnormality of gait;
+++ = inability to walking and righting.

Immediately after appearance of clinical signs of EMG, rats are sacrificed, blood and thymuses are taken for determination of anti-AChR-protein antibodies, and histological analysis of thymuses and thymocyte subsets, respectively.

Statistical analysis of data is performed by Student's *t*-test (data of stereological analysis) and Mann-Whitney *U*-test (Results of flow cytometric analysis of thymocyte subsets).

MODIFICATIONS OF THE METHOD

McIntosh and Drachman (1987) described an *in vitro* suppressor assay using responder cells from the lymph nodes of Lewis rats immunized sc. with acetylcholine receptors emulsified in complete Freund's adjuvant and suppressor cells from spleens of rats immunized i.p. with acetylcholine receptors absorbed on bentonite. Antibodies were determined after stimulation with acetylcholine receptors from co-cultures of responder cells and putative suppressor cells treated previously with an immunosuppressant.

Araga and Blalock (1994) developed a method of altering B-cell-mediated autoimmune diseases by induction of anti-idiotypic antibodies by immunization with complementary peptides. A peptide encoded by RNA complementary to RNA for the Torpedo acetylcholine receptor main immunogenic region, AChR 67–16, was tested in the Lewis rat model of experimental autoimmune myasthenia gravis.

I.2.2.19 Glomerulonephritis Induced by Antibasement Membrane Antibody in Rats

PURPOSE AND RATIONALE

Masugi nephritis and other nephritis models of immunological origin in rats have been used for evaluation of immunosuppressive activity (Heymann et al. 1959; Shibata et al. 1966; Ito et al. 1983; Thoenes et al. 1989; Ogawa et al. 1990, 1991).

PROCEDURE

Preparation of Rabbit Antiserum against Rat Glomerular Basement Membrane

Glomeruli are separated from the homogenate of rat renal cortex by successive use of 3 metal sieves (150-, 180-, and 200-mesh). The basement membrane fraction is obtained by centrifugation and ultrasonic disruption. It is then digested with trypsin, dialyzed, and lyophilized. The resultant substance is employed as antigen. An emulsion of 1 mg of the antigen in 0.2 ml saline with 0.2 ml of complete Freund's adjuvant is injected intracutaneously into white rabbits once a week for 6 weeks. One week later, production of the antibasement membrane antibody is confirmed in guinea pigs by the passive cutaneous anaphylaxis test. Blood is collected from the carotid artery, incubated at 56°C for 30 min to inactivate components of the complement, and stored at –20°C until use.

Induction of Glomerulonephritis in Rats

Male Sprague-Dawley rats weighing about 300 g are injected with 0.5 ml of the rabbit antiserum via the tail vein. On the following day, they are further injected subcutaneously with an emulsion (0.25 ml) of physiological saline solution containing 5 mg of rabbit gamma-globulin in an identical volume of complete Freund's adjuvant.

Treatment

The rat antibasement antibody is injected 5 days before the start of administration of the test compound. Before the first dose, urinary total protein is determined and rats with nephritis are so assigned as to provide almost equal distribution of severity of the disease per group. The test compounds are administered orally for 14 days. The urine is collected at 7 and 14 days of treatment. After 14 days, the animals are sacrificed, blood is collected and thymus and kidneys are removed. Histopathological and immunohistochemical studies are performed in kidney tissue.

EVALUATION

Scores are given for **microscopic findings in the glomeruli:**

- cell proliferation in glomeruli
- PAS-positive granules in the epithelium of glomeruli
- fibrin deposits in Bowman's space
- adhesion to Bowman's capsule

and in **the tubuli:**

- hyaline cast
- dilation of tubuli

as well as for**immunofluorescence findings** for rat IgG, rat C3, and rabbit IgG.

Furthermore, total urinary protein, plasma total cholesterol, plasma fibrinogen, thymus/body weight ratio are compared between drug treated animals and controls by statistical means.

MODIFICATIONS OF THE METHOD

Lan et al. (1995) investigated the pathogenic role of interleukin-1 in the progression of established rat crescentic glomerulonephritis by administration of the interleukin-1 receptor antagonist IL-1ra.

Giménez et al. (1987), Thoenes et al. (1987) induced autoimmune tubulointerstitial nephritis in the brown Norway rat by injection of bovine tubular basement membrane.

Development of a systemic T-lymphocyte dependent autoimmune syndrome in brown Norway rats including glomerulonephritis with high proteinuria was induced with mercuric chloride by Baran et al. (1986), Aten et al. (1988), Lillevang et al. (1992).

Kokui et al. (1992) induced nephrosis with proteinuria in rats by intraperitoneal injection of puromycin aminonucleoside.

Lundstrom et al. (1993) studied the Heymann nephritis antigenic complex using a rat yolk sac carcinoma cell line that expresses glycoprotein 330, the main antigen in this autoimmune disease.

I.2.2.20 Auto-Immune Uveitis in Rats

PURPOSE AND RATIONALE

The mechanisms of certain types of uveitis have been studied in animals implicating autoimmunity. Uveitis has been produced in guinea pigs following injections with homologous uveal tissue.

The method is described in detail in the Sect. O.7.3.

I.2.2.21 Inhibition of Allogenic Transplant Rejection

PURPOSE AND RATIONALE

Transplantation of allogenic organs to recipients results in rejection of the transplants. This effect can be suppressed or delayed by immunosuppressive agents. Various organs are used for allogenic transplantation in animal experiments, such as skin pieces (Schorlemmer et al. 1993), kidney (Lee 1967; Küchle et al. 1991), rat heart, rat small intestine (Xiao et al. 1944) and corneal buttons (Coupland et al. 1994). The immunosuppressive activity can be evaluated either by using a major histocompatibility complex variant strain combination or a strong allogenic system.

PROCEDURE

For **skin transplantation** male animals of inbred strains of Fischer (F334), Lewis (LEW), Brown Norway (BN), Dark Agouti (DA) rats are used. Rat tail skin (donor) is cut into square pieces of 0.5 to 1.0 cm and transplanted to the tails of recipient rats. Rejection is defined as the day when the skin graft is of red-brown color and hard consistency. As strain combination with a major histocompatibility variant, transplantation from LEW to F334 is performed. Using a strong allogenic system, the high responder DA to LEW donor recipient combination is used. The immunosuppressive agents, e. g., cyclosporine or leflunomide are given orally up to 20 days. Ten animals are used for each group.

EVALUATION

The mean values of rejection time of treated groups are compared statistically with vehicle treated controls using Student's *t*-test or the Mann Whitney U-test.

MODIFICATIONS OF THE METHOD

Schorlemmer and Kurrle (1997) used Lewis (LEW, Rtl*l) rats as receivers and Balb/c mice as donors

in a xenotransplantation model of mouse-to-rat skin grafts. Rejection was defined as the day when the skin graft turned red-brown and became hard. For quantification of xenospecific IgM and IgG antibody titers, the test sera (dilution 1:10) were incubated with 1×10^6 purified T-cells (by sheep anti-mouse dynabeads, Deutsche Dynal GmbH, Hamburg, Germany) from Balb/c donor spleens for 30 min at 4°C. The cells were washed 3 times with phosphate buffered saline (pH 7.2) and then stained for IgG or IgM xenoantibodies; 50 µl of either FITC-conjugated goat antibodies, specific for the Fc-portion of rat IgG or specific for the µ-chain of rat IgM were added. After 30 min at 4°C the cells were washed twice and analyzed by flow cytometry.

Techniques for transplantation of several organs have been elaborated.

For **kidney transplantation** male rats, 5–7 months of age, are used as donors and recipients for the orthotopic right kidney transplantation as described by Lee (1967) with a modification of ureter-ureter anastomosis (Thoenes et al. 1974). Because bilateral nephrectomy is performed at transplantation, animal survival is dependent upon the allograft's function. All rats that do not excrete urine on the first postoperative day are excluded from further studies. As a control concerning long survival, syngeneically transplanted rats are maintained up to 300 days.

Engelbrecht et al. (1992) described a new rapid technique for renal transplantation in the rat. The method combines a special sleeve anastomotic technique for the renal artery, convential end-to-end anastomosis of the renal vein, and implantation of the ureter into the bladder.

A porcine renal transplant model has been used by Almond et al. (1992).

Peters et al. (1993) reviewed the therapeutic potential of tacrolimus in renal and hepatic transplantation.

For studying **heart transplantation**, heterotopic implantation of hearts from BN to LEW rats is performed (Williams et al. 1993). The diagnosis of rejection is established once the palpable cardiac allograft impulse ceases. Further studies with rat cardiac allografts have been performed by Hancock et al. (1990). The Fischer 344 rat (donor)/Long Evans rat (recipient) combination was used by Kahn et al. (1991). Walpoth et al. (1993) used magnetic resonance spectroscopy for assessing myocardial rejection in the transplanted rat heart.

Shiraishi et al. (1995) evaluated the effectiveness of the interleukin-1 receptor antagonist IL-1ra in the immune and inflammatory responses to rat heart allografts.

Cardiac transplantation between inbred rat strains that differ for weak histocompatibility antigens is associated with the development of arteriosclerosis in arteries of the donor graft myocardium (Carmer et al. 1990; Adams et al. 1992).

A heterotopic rat **heart-transplant model** and the influence of infection was described by Kobayashi et al. (1993).

The **hamster to rat cardiac xenograft** model has been used by several authors (de Masi et al. 1990; Steinbrüchel et al. 1991; van den Bogaerde et al. 1991; Woo et al. 1993; Fujino et al. 1994; Schuurman et al. 1994). The hearts from Syrian hamsters were implanted heterotopically in male Lewis rats, with anastomoses between the infrarenal abdominal aorta and inferior vena cava of the recipient and the donor aorta and right pulmonary artery, respectively.

Primate cardiac xenografts were performed by McManus et al. (1993) using cynomolgus monkeys (*Macaca fascicularis*) as donors and baboons (*Papio anubis*) as recipients.

Chronic rejection of rat **aortic allograft** was studied by Mennander et al. (1991). Administration of cyclosporin induced accelerated allograft arteriosclerosis.

Heterotopic transplantation of small intestine has been performed from BN to LEW rats. The mesenteric venous drainage is reconstructed either via the vena cava or the portal vein (Xiao et al. 1994). An isolated Thiry–Vella-loop was prepared by Xia and Kirkman (1990). Kellnar et al. (1990) described allogenic transplantation of fetal rat intestine with anastomosis to the normal bowel of the host. Langrehr et al. (1991) investigated under which circumstances graft versus host disease occurs following fully allogenic small bowel transplantation in the rat. Kirsch et al. (1991) studied the extent to which intestinal transplants in rats undergo functional and morphologic compensation.

Liver transplantation procedure has been described by Svensson et al. (1995) allowing measurement of bile secretion.

Orthotopic left **lung transplantation** was performed in inbred rats by Katayama et al. (1991).

Tracheal allografts were implanted into the abdomen of recipient rats (Davreux et al. 1993).

In vivo electrophysiology of rat **peripheral nerve transplants** was studied by Yu et al. (1990). A sciatic-tibial nerve graft was harvested from the donor rat between the sciatic notch and the ankle. In the recipient, the tibial nerve and the sural nerve were resected. The

nerve graft was placed along the natural course of the native tibial nerve. Nerve repair was performed using standard end-to-end epineural microsuture technique.

A model of neurovascularized rectus femoris **muscle transplantation** in rats was established by Muramatsu et al. (1994).

The orthotopic **transplantation of vascularized skeletal allografts** (rat distal femur and surrounding muscular cuff) has been described by Lee et al. (1995).

Long-term surviving of **limb allografts** in rats was studied by Kuroki et al. (1991). The donor and recipient limbs were prepared simultaneously by amputation at midfemur. The donor limb was fixed orthotopically by Kirschner wire. The donor and recipient femoral arteries, veins and sciatic nerves were anastomosed using a microsurgical technique.

For **cornea transplantation** Brown Norway rats ($RT1^{1xn}$) serve as donors and Lewis rats ($RT1^{1}$) as recipients (Coupland et al. 1994). Both the donor and recipient rats are anesthetized with xylazine hydrochloride and ketamine hydrochloride. Twenty min prior to surgery the recipient rats also receive 0.5 mg/kg atropine sc. and phenylephrine hydrochloride 5% eyedrops. Under sterile conditions and using an operation microscope, two donor corneal buttons (3.5 mm) are harvested from the donor rat using a trephine and curved Castroviejo scissors. The donor animals are then sacrificed by ether inhalation. The left eyes of the recipient rats are prepared by removing a central 3.0-mm button using a trephine and curved Castroviejo scissors. A drop of sterile methylcellulose (1%) is placed over the 3.0-mm corneal opening before the donor cornea is fixed with 10 interrupted sutures. The anterior chamber is not re-established following surgery. Prior to closure of the eyelids with 3 or 4 interrupted sutures, Polyspectran eyelid gel is placed over the operated eye. Forty-eight hours following surgery, the eyelid sutures are removed, allowing for the first time assessment of the cornea on the slit-lamp microscope. Slit-lamp evaluations are performed every 2–3 days under i.m. anesthesia with ketamine, with assessment of the cornea by scoring graft opacity, edema and vascularization.

J.1 Salivary Glands

J.1.0.1 Measurement of Salivation

PURPOSE AND RATIONALE

Symptoms of several human diseases are manifested as increased salivation (e. g., Parkinson's disease) or decreased salivation (e. g., xerosis). Studies to find and to evaluate sialagogues, such as substance P and its synthetic derivatives, as well as to search for salivation inhibitors are necessary. Saliva excretion is greatly influenced by anesthetics. Wagner et al. (1991) proposed a simple method to study saliva secretion in conscious rats and to evaluate sialagogues and sialagogue antagonists.

PROCEDURE

Fed, male Sprague-Dawley rats (200–300 g) are weighed and distributed randomly into groups of 6 animals. Conscious rats are injected i.v., via the lateral tail vein, with either the vehicle or the sialagogue, e. g., substance P (0.3–3 µg/kg in 1 ml saline/kg). The rat's oral cavity is swabbed immediately after i.v. injection by placing and holding a pre-weighed, absorbent foam cube (e. g., 5/16", Texwipe Company, Upper Saddle River, NJ) sublingually for 10 s using a Triceps foam pencil (Texwipe Company, Upper Saddle River, NJ). Conscious rats are restrained during the 10 s collection period by gently holding the animal and opening the mouth using a plastic coated snare, which is looped around the maxillary incisors and drawn back over the animal's head and the hand holding the rat, drawn around in front of the rat and looped around the mandibular incisors. Gentle pressure on the snare opens the rat's mouth allowing the placement of the absorbent cube. Foam cubes are re-weighed immediately after use. The difference between the initial weight of the cube and the weight of the cube after use represents saliva secreted.

EVALUATION

Data are analyzed with Dunnett's *t*-test that compares several treated groups with a control group. Regression analysis is used to determine dose response and relative potency.

MODIFICATIONS OF THE METHOD

Martinez et al. (1978, 1981) inserted appropriate plastic cannulae into the main excretory ducts of the two submandibular glands in **rats**.

Giuliani et al. (1988) studied the relative contributions of various neurokinin receptors (NK-1, NK-2, NK-3) to the sialogogic response after i.v. application in urethane-anesthetized rats.

Direct cannulation of the glandular duct with polyethylene tubing was performed by Bodner et al. (1983) and Kohn et al. (1992).

Bianciotti et al. (1994, 1996) cannulated the ducts of both the submaxillary and parotid glands in male Wistar rats anesthetized with 10% ethyl urethane. No basal flow of saliva was observed from either gland, however dose-response curves could be established after intravenous injection of sialogogic agents, such as methacholine (0.3 to 10.0 µg/kg), norepinephrine (3 to 60 µg/kg), isoproterenol (1 to 30 µg/kg), methoxamine (30 to 300 µg/kg), substance P (0.3 to 10.0 µg/kg). Atrial natriuretic factor enhanced the salivary response to methacholine, methoxamine and substance P.

Lohinai et al. (1997) determined salivary amylase secretion in conscious rats. Under ether anesthesia a catheter was introduced into the esophagus for salivary juice collection and a cannula was inserted into the jugular vein for infusions. After post-anesthesia recovery, submaximal carbachol infusion was given as a background to obtain steady secretion because of the low basal secretory rate. After application of drugs, volume and amylase were determined in saliva samples collected for 30 min.

Iwabuchi et al. (1994) studied salivary secretion after administration of a muscarinic agonist in MRL/lpr **mice**. Saliva were collected from the floor of the mouth of anesthetized rats with a capillary micropipette every 5 min for 60 min.

A method for the quantitative comparison of atropine substitutes on the salivary secretion of the **cat** has been published by Bülbring and Dawes (1945). Cats anesthetized with pentobarbitone were used. A cannula is tied into Wharton's duct and attached to

a bottle containing tap-water. The tap-water, displaced by the saliva, passes out of the bottle through a tube which actuates a drop timer.

Ekström et al. (1994) used morphometric analyses to study the parotid acinar degranulation in cats after stimulation of the parasympathetic auriculo-temporal nerve.

Izumi and Karita (1994, 1995a, b) investigated the secretory and vasodilator effects of nerve stimulation in the submandibular gland of cats. Cats of either sex were anesthetized with ketamine and a mixture of chloralose and urethane, paralyzed by intravenous injection of pancuronium bromide and artificially ventilated. Blood flow changes in the submaxillary glands and lips of the cats were measured using a laser-Doppler flowmeter. The duct of the submandibular gland was cannulated with a polyethylene cannula inserted distal to the intersection between the chorda lingual nerve and the duct. The amount of saliva secreted in response to nerve stimulation was determined gravimetrically by collecting the saliva in pre-weighed tubes.

Boldyreff (1925) described the preparation of salivary fistulae in the **dog**.

For preparing a **parotid fistula**, a fine sound is introduced through the orifice of the parotid duct, which is found opposite to the largest upper molar tooth, to the depth of 6–8 cm. Around the orifice and at a distance of about 0.5 cm from it, four sutures are laid on the mucosa at equal distances one from the other. After this, a round piece of mucosae, about 1 cm in diameter around the orifice, with the sutures at the edge of this piece, is cut out with small sharp scissors. The duct is then separated from surrounding tissues about 2 cm from the orifice in the direction of its length. Then an opening is made through the cheek into the mouth (from the point half way on the vertical line from the front or the back corner of the eye to the mouth) to the base of the prepared duct. The orifice of the duct is now led outside by pulling out with the forceps. Four sutures on the piece of mucosa are made around it. The piece of mucosa is sutured carefully to the skin with knot sutures. The wound inside the mouth is closed with a continuous suture. The piece of mucosa must be covered daily with vaseline to prevent drying. Sutures must be taken out slowly, beginning 3 days after operation. For the first 10 days after operation it is necessary to produce on the dog an intensive salivary secretion, twice a day, by introducing into the mouth of the animal, dry bread or meat powder or 0.5% solution of hydrochloric acid. Saliva is collected into graduated test tubes.

In a similar way, one can produce a **fistula of the submaxillary or sublingual glands**, usually a common fistula for both glands, because their ducts have a common orifice.

Ogawa et al. (2003) developed a model of chronic parotitis in rats by a direct injection of complete Freund's adjuvant into the unilateral parotid gland via the parotid duct without skin incision.

Lambert et al. (1994) **cultured acinar cells** from lacrimal and submandibular glands as well as epithelial cells from rat small intestine in supplemented, serum-free media and measured the secretory components after treatment with various agents by radioimmunoassay.

J.2 Esophagus

J.2.0.1 Tunica Muscularis Mucosae of Esophagus In Vitro

PURPOSE AND RATIONALE

The tunica muscularis mucosae preparation of the rat esophagus (Bieger and Triggle 1985; Ohia et al. 1992) has been recommended for evaluation of 5-HT_4 receptor ligands since it possesses a homogeneous population of 5-HT_4 receptors which mediates a well defined relaxant response to 5-HT (Baxter et al. 1991, 1992; Reeves et al. 1991; Waikar et al. 1992; Eglen et al. 1993, 1995; Yang et al. 1993; Gale et al. 1994; Monge et al. 1994; Sagrada et al. 1994; Elz and Keller 1995; Hegde et al. 1995; Cohen et al. 1996, 1998; Wong and Eglen 1996; Nagakura et al. 1999; Takeda et al. 1999).

PROCEDURE

Male Sprague Dawley rats (200–300 g) are sacrificed by asphyxiation with CO_2, and 2 cm segments of intrathoracic esophagus, proximal to the diaphragm, are excised and placed in Tyrode solution of the following composition (mM): NaCl 136, KCl 2.7, $MgCl_2 \cdot 6H_2O$ 1.0, NaH_2PO_4 0.4, glucose 5.6, $NaHCO_3$ 11.9, $CaCl_2$ 1.8, pH 7.4. The external muscularis propria, containing the outer longitudinal and circular muscle layers of the esophagus, is carefully removed in order to isolate the inner smooth muscle tube of the tunica muscularis mucosae. The tunica muscularis mucosae is suspended in a 10 ml tissue bath containing Tyrode solution at 37°C and aerated continuously with 95% O_2/5% CO_2. Tissues are placed under 2.5 mN tension and are left to equilibrate with Tyrode solution for 60 min (washing every 15 min) prior to starting the experiment. Responses are recorded isometrically using a Hugo Sachs Electronic (Biegestab K30) transducer coupled to a Graphtec (Linearcorder WR3310) 4-channel chart recorder.

Preparation of tunica muscularis mucosae are contracted with carbachol (3 µM, approximate EC_{50}). Concentration-effect curves (relaxation) to 5-HT (or other agonists) are constructed in a cumulative fashion, followed by washout, with a 60-min interval between the first and second curve.

In antagonist studies, the antagonist is incubated with the tissue for 60 min following washout and the second concentration-effect curve is constructed in the presence of the antagonist. Responses are measured as decreases in isometric tension and are expressed as percentage relaxation of the carbachol-induced tone.

EVALUATION

Concentration-Effect Curves and Agonist Potencies

All agonist concentration-effect curves are fitted using an nonlinear, iterative curve fitting program according to the following relationship (Parker and Waud 1971):

$$E = E_{\max}[A]^n / \left([A]^n + EC_{50}^n\right) .$$

This relationship describes curves with a maximal response $E_{\max}$, half-maximal response EC_{50} (both in terms of molar concentration), and a slope factor determined by the power n. [A] represents agonist concentration and E is response.

Antagonist Potencies

pA_2 estimates of test compounds vs. 5-HT in the rat tunica muscularis mucosae are determined by the method of Arunlakshana and Schild (1959) and computed using Statview II (Brain Power Inc., Calabassas, CA). Concentration ratios are determined using the iterated EC_{50} values in the absence and the presence of the test compounds.

All remaining pA_2 estimates are determined by the method of Furchgott (1972) using a single concentration of agonist. The method assumes a competitive interaction and is calculated as follows:

$$pA_2 = -\log([\text{antagonist}]/[\text{concentration ratio} - 1])$$

Statistics

CL (95%) and statistical significance of the difference between samples (single comparisons; unpaired Student's *t*-test) are determined using Statview II.

MODIFICATIONS OF THE METHOD

De Boer et al. (1993) divided the **rat** esophagus into two parts, cervical and thoracic, each of a length of 10–15 mm. Both parts were cut longitudinally and pinned on a silicon mat with the outer, striated muscle coat up. After dissection of the striated muscle, the remaining muscularis mucosae was divided into 4 (5×2 mm, thoracic part) and 6 (5×1.5 mm, cervical part) strips. Strips from different parts showed no differences in pharmacological behavior.

Cohen et al. (1994) found 5-HT_4 receptors in rat but not guinea pig, rabbit or dog esophageal smooth muscle.

Several authors (de Boer et al. 1993, 1995; Kelly and Houston 1996; Lezama et al. 1996; Oriowo 1997, 1998) showed that β_3-adrenoceptors mediate the relaxation of the rat esophageal muscularis mucosae.

Eglen et al. (1996) studied the functional interactions between muscarinic M_2 receptors and 5-hydroxytryptamine 5-HT_4 receptors and β_3-adrenoceptors in the isolated esophageal muscularis mucosae of the rat.

Goldhill et al. (1997) investigated the 5-HT_4 receptor modulation of tachykinergic excitation of rat esophageal tunica muscularis mucosae.

The tunica muscularis mucosae of **guinea pigs** was used by various authors:

Yoshida et al. (1993) studied the effect of a gastroprokinetic agent on electrically-evoked contractions in tunica muscularis from isolated guinea pig esophagus.

Watson et al. (1995) investigated the interactions between muscarinic M_2-receptors and β-adrenoceptors in guinea-pig esophageal muscularis mucosae.

Uchida et al. (1998a, b) examined the effect of Ba^{2+} on acetylcholine- and KCl-induced contractions and characterized the endothelin-induced contraction of the guinea-pig esophageal muscularis mucosae.

Malmberg et al. (1991) studied muscle activity of isolated muscle strips from the middle pharyngeal constrictor, the inferior pharyngeal constrictor, the cricopharyngeal muscle, and the cervical esophagus from **rabbits** in organ baths in response to drugs and electrical field stimulation.

Kohjitani et al. (1993, 1996) divided the lower esophagus of rabbits into 3 regions (lower esophagus, transitional zone, lower esophageal sphincter) and studied the influence of anesthetics and peptides on contractions induced by acetylcholine or electrical field stimulation.

Percy et al. (1997) studied the pharmacological characteristics of rabbit esophageal muscularis mucosae *in vitro*.

Based on studies by Bitar and Mahklouf (1982), Biancani et al. (1987), isolated smooth muscle cells of the lower esophageal sphincter from **cats** were used by Hillemeier et al. (1996) to investigate the influence of protein kinase C on spontaneous muscle tone. Esophagus and stomach from sacrificed cats were removed and opened along the lesser curvature. The location of the squamocolumnar junction was identified, the mucosa was peeled and removed by sharp dissection under a microscope. The underlying circular muscle layer was cut into slices 0.5 mm thick with a tissue slicer. The last slices containing the myenteric plexus, longitudinal muscle and serosa were discarded. The slices of circular muscle were placed flat on a wax surface, and tissue squares were made by cutting twice with a 2-mm blade block, the second cut at right angle of the first. Isolated smooth muscle cells were obtained by enzymatic digestion with collagenase. Agonist-induced contraction of isolated muscle cells was achieved by exposing them to IP_3 and a protein kinase C agonist. The cells were fixed in acrolein at a final concentration of 1%. The length of 30 consecutive intact cells encountered at random was measured with a phase-contrast microscope and a closed-circuit video camera.

Muscle strips from *cat* lower esophageal sphincter were used by Dobreva et al. (1994), Kortezova et al. (1994), Preiksaitis and Laurier (1998).

Uy Dong Sohn et al. (1995) investigated muscle-type-specific signal transduction pathways in esophageal and lower esophageal sphincter circular smooth muscle of cats.

Tokuhara et al. (1993) studied the influence of adrenoceptor agonists on the striated muscle portion of the esophagus by use of isolated strips from **dogs**.

Saha et al. (1993) examined the effects of nitric oxide-containing compounds on **opossum** esophageal longitudinal smooth muscle *in vitro*.

La Rocca et al. (1992) examined the effects of metoclopramide in transverse muscular strips from **pigeon** esophagus.

J.2.0.2 Esophageal Sphincter In Vivo

PURPOSE AND RATIONALE

Salapatek et al. (1992), Xue et al. (1996) studied the control of esophageal peristalsis and function of the lower esophageal sphincter in anesthetized cats.

PROCEDURE

Adult cats of either sex are fasted overnight. Anesthesia is induced with 15 mg/kg ketamine i.m. and maintained with i.v. infusion of 15 mg/kg/h. The cats can tolerate intubation while continuing to swallow spontaneously or with pharyngeal stimulation. Esophageal motility is continuously monitored by a multi-lumen catheter passed orally. The catheter has a sleeve (Dent 1976) which is positioned within the lower esophageal sphincter, with recording ports 2, 4, 6, and 8 cm above the lower esophageal sphincter and one port just below the sleeve. The recording catheter channels are continuously perfused with distilled water at 0.3 ml/min by means of a pressurized infusion pump. At the recording ports within the esophageal body, the system is able to record a pressure rise of 300 mm Hg/s. Pressures are recorded using transducers. Respiration is continuously monitored with a belt pneumograph placed around the animal's chest. All pressures are recorded on a Beckman eight-channel direct writing chart recorder with input couplers, preamplifiers and amplifiers while simultaneously taped on an eight channel FM tape recorder. Drugs are administered intravenously.

For each esophageal contraction, amplitude is measured at each esophageal level, using mean intraesophageal pressure as baseline. Onset of contraction is determined as the point of rapid upstroke at each level, and progression of the wave along the esophagus is expressed as the lag of time or delay (in seconds) between two adjacent recording sites. Basal lower esophageal sphincter pressure is measured using intragastric pressure as reference. Maximum lower esophageal sphincter relaxation and lower esophageal sphincter after-contraction are also assessed.

EVALUATION

Statistical analysis is performed by using one-way analysis of variance and a Student's *t*-test where appropriate.

MODIFICATIONS OF THE METHOD

Greenwood et al. (1992) used a similar multi-lumen catheter assembly system in **cats** and registered additionally the electromyogram of the mylohyoid muscle.

Further studies in cats were performed by Preiksaitis et al. (1994) and Lichtenstein et al. (1994).

Using a miniature perfused sleeve/sidehole catheter, Kawahara et al. (1994) measured gastric, lower esophageal sphincter and esophageal pressure in urethane anesthetized **rats**.

Rouzade et al. (1996) monitored manometrically esophageal, lower esophageal sphincter and fundus pressure in conscious **dogs**.

Blackshaw et al. (1995), Blackshaw and Dent (1997) measured responses of the lower esophageal sphincter in urethane-anesthetized **ferrets**.

Smid et al. (1998) studied lower esophageal sphincter function in a model of oesophagitis in ferrets. Oesophagitis was induced by acid (0.15 M HCl) and 1% pepsin infusions in anesthetized ferrets. Lower esophageal sphincter strip responses were measured *in vitro* after various agents and after electrical field stimulation.

Knudsen et al. (1994) measured esophageal pressured with a four-channel, perfused catheter assembly in lightly anesthetized **opossums**.

Further studies in opossums were performed by Harrington et al. (1991), de Arruda-Henry and Uchida-Athanasio (1994).

J.2.0.3 Permanent Fistula of the Esophagus in the Dog

PURPOSE AND RATIONALE

Esophagostomy was made for the first time by Pavlov (1902) for the purpose of obtaining pure gastric juice from a dog. Pure gastric juice can obtained in great quantities only after shame feeding from a gastric fistula, so it is necessary that the dog shall have two fistulae: esophageal and gastric fistula. The technique to prepare a permanent gastric fistula in the dog was described by Boldyreff (1925).

PROCEDURE

It is necessary to obtain beforehand a well nourished dog with a gastric fistula. The operation must be done aseptically with the usual anesthesia. The incision on the neck is made on a median line 2–3 cm below the larynx and is 12–15 cm long. The esophagus is found under the trachea and a little to the left. It is separated as little as possible from the surrounding tissue with a knife handle and pulled outside. The esophagus is now divided, cross-section, and the ends of the dissected esophagus are carefully sutured into the respective corners of the wound. In suturing the mucosa of the esophagus with the skin of the wound it is necessary to take into the suture the muscle layer of the esophagus also. After the ends of the esophagus are sutured into the corners of the wound, the part of the wound between them is closed. The wound should be covered with thick antiseptic ointment. After the operation it is necessary to examine the wound daily. The sutures must be taken out gradually beginning five or six days after the operation.

Oesophagotomy can be performed more simply, if the esophagus is not divided but a longitudinal incision, 12–15 cm long is made through its wall. The edges of this incision are sutured together with the edges of the wound in the neck. When the wound is healed this fistula can be temporarily closed during feeding by means of a bandage or with a special de-

vice. The dog can then eat and drink normally and the saliva is not lost through the fistula.

MODIFICATIONS OF THE METHODS

Boldyreff (1925) described also the preparation of crop fistulas in the **rooster**. A longitudinal incision 2–3 cm long is made through the skin in the middle part of the crop. Then, with the aid of a pair of surgical forceps the front wall of the crop is lifted up and an opening about 2 cm long is made in it with scissors. After this a fistular tube is introduced into the crop with the aid of a large hook and, if necessary, the opening of the crop is sutured with one suture tightly around the tube.

J.3 Gastric Function

J.3.1 Acid Secretion

J.3.1.1 Acid Secretion in Perfused Rat Stomach (Gosh and Schild Rat)

PURPOSE AND RATIONALE

Gosh and Schild (1958) introduced a method for the continuous recording of acid gastric secretion in the rat. The acid secretion can be stimulated by histamine, acetylcholine and gastrin. Moreover, the stimulated secretion can be inhibited by anti-ulcer drugs.

PROCEDURE
(MODIFIED AFTER GOSH AND SCHILD 1958)

Male Sprague-Dawley or Wistar rats weighing about 250 g are used. They are withheld from food, but not from water 18 h prior to the experiment. Four animals are used per dose of test drug or standard. Anesthesia is induced by i.p. injection of 5 ml/kg of 25% urethane solution. Body temperature is artificially stabilized by means of a rectal thermometer and a heating pad. The trachea is exposed and cannulated for artificial respiration. The jugular veins are then exposed and cannulated with polyethylene tubes bevelled at the tip. The abdomen is opened through a midline incision, the pyloro-duodenal junction exposed and a double perfusion cannula (with two lumina) is introduced through a cut in the duodenum up to the cardiac part of the stomach and secured firmly by placing a ligature around the pylorus, care being taken not to include blood vessels within the ligature. Using a peristaltic pump, the stomach is perfused continuously with 0.9% NaCl solution at 37°C. In the effluent, pH is measured with a pH-meter and continuously recorded. Gastric secretion is stimulated by continuous intravenous infusion of 100 µg/kg/h of pentagastrin or 3 mg/kg/h histamine hydrochloride or 30 µg/kg/h carbachol. As soon as acid secretion has reached a plateau, test substances or standard are injected intravenously.

EVALUATION

The maximal inhibition of acid secretion (AI_{max}) and the inhibition of acid secretion during 1 h (AI_t) are calculated.

$\boldsymbol{AI_{max}} = (pH_i - pH_s) \times (pH_b - pH_s)^{-1} \times 100$

$\boldsymbol{AI_t} = 100 - F_i \times F_s^{-1} \times 100$ whereby,

$\mathbf{pH_b}$ = pH value at basal H^+ secretion

$\mathbf{pH_s}$ = pH value at stimulated H^+ secretion

$\mathbf{pH_i}$ = highest pH value after administration of test compound

$\boldsymbol{F_s}$ = integral of pH curve over 60 min before administration of test compound

$\boldsymbol{F_i}$ = integral of pH curve over 60 min after administration of test compound.

Moreover, using various doses of the test compound and of a standard, dose-response curves can be established and activity ratios with confidence limits can be calculated.

CRITICAL ASSESSMENT OF THE METHOD

The method of Gosh and Schild being modified by several authors can be used for standardization of secretagogues, like gastrin, and for evaluation of acid secretion inhibiting anti-ulcer drugs.

MODIFICATIONS OF THE METHOD

Burn et al. (1952) described the evaluation of substances which affect gastric secretion using perfusion of the stomach in anesthetized **cats**.

Lawrence and Smith (1974) described the measurement of gastric acid secretion in the **rat** by conductivity. The stomach of an anesthetized rat is continuously perfused with 2 ml/min of an isotonic (0.308 molar) glucose solution at 37°C. The conductance of a solution depends on the total ion concentration and is therefore not specific for hydrogen ions. Since hydrogen ions have an equivalent conductance nearly

5 times greater than any other ion found in gastric juice and since they are secreted in a far greater concentration than other ions, conductivity measurements can be regarded as a relatively specific measure of hydrogen ions. Using Mullard conductivity cells (type E 791/B) and a commercially available meter (Phillips PW 9501) simultaneous measurements in 6 rats were performed.

Gallo-Torres et al. (1979) described in detail a method for the bioassay of antisecretory activity in the conscious rat with acute gastric fistula with additional collection of the biliary and pancreatic secretion by means of a catheter in the common bile duct. The gastric secretions are collected by gravity via a cannula in the most gravity dependent site of the glandular stomach.

Larsson et al. (1983) described studies in the acutely vagotomized rat. Truncal vagotomy is performed under ether anesthesia by cutting the dorsal and ventral branches of nervus vagus just below the diaphragm. The pylorus is then ligated and a polyethylene catheter (PP 200) is inserted into the duodenum, close to the pylorus. Each animal is placed in a modified Bollman cage and is allowed to recover at least 1 h before the experiment. Gastric juice is collected by free drainage in 30 min samples.

Herling and Bickel (1986) showed that gastric acid secretion in stomach-lumen perfused rats can be stimulated *in vivo* on the subreceptor level by IBMX (phosphodiesterase inhibitor) and forskolin (non-receptor activation of the adenylate cyclase). H^+/K^+-ATPase inhibitors and H_2-antagonists show, according to their different modes of action, also a different inhibitory profile in this assay.

Hammer et al. (1992) used anesthetized female Sprague-Dawley rats weighing 200–320 g. After insertion of a tracheal cannula, a 3-mm silicon tubing is placed through the mouth and advanced to the stomach. The tubing is tied to the esophagus at the neck. A 4-mm drainage tube is inserted into the stomach through a laparotomy incision and an incision in the duodenum, and ligated in place at the pylorus. Gastric perfusate (0.9% saline at 37°C) is collected on ice every 5 min for titration to pH 7.0.

J.3.1.2 Isolated Rat Stomach

PURPOSE AND RATIONALE

The isolated whole stomach of the rat was recommended for evaluation of H_2-receptor antagonists (Bunce and Parsons 1976).

PROCEDURE

Fed immature rats of either sex weighing 38–42 g are anesthetized with sodium pentobarbitone i.p. The abdomen is opened and the esophagus ligated close to the stomach. An incision is made in the rumen of the stomach and the contents washed out with warm Krebs-Henseleit solution. A second incision is then made at the pyloric sphincter and polyethylene cannulae are inserted and tied into the stomach via these incisions. The stomach is rapidly dissected out and placed immediately into a 10 ml organ bath containing Krebs-Henseleit solution at 37°C. The lumen of the stomach is perfused at a rate of 1 ml/min with a modified Krebs-Henseleit solution (without Na_2CO_3 and KH_2PO_4) at 37°C. Both solutions are gassed with 95% O_2/5% CO_2. The effluent perfusate from the stomach is passed over a micro dual electrode. The changes in pH are converted to a function of hydrogen ion activity by an an-

tilog function generator and continuously recorded on a potentiometric pen recorder. The drugs are added, in a volume not exceeding 0.5 ml, to the complete Krebs-Henseleit solution bathing the serosal surface of the stomach. After setting up the stomach preparation the basal H^+ output is allowed to stabilize, both under control conditions and in presence of the H_2-antagonist, before the secretory responses to histamine are investigated. The response to a dose of histamine is assessed by measuring the amount of acid secreted at peak response above the preceding basal level.

EVALUATION

The rate of acid secretion is expressed as $[H^+]$ moles $\times$ 10^{-8} per min. The effect of the antagonist is assessed by measuring the potency of the agonist. An estimate of potency is firstly obtained using the agonist alone, and then a second estimate is obtained in the presence of the agonist-antagonist combination. The potency ratio is calculated according to Finney (1964).

MODIFICATIONS OF THE METHOD

A similar method was described by Szelenyi (1981) and Stanovnik et al. (1988) using the isolated stomach of the **mouse**.

Weigert et al. (1995) evaluated the effect of the opiate receptor antagonist naloxone on vagally stimulated secretion of bombesin-like immunoreactivity, somatostatin and gastrin from the isolated rat stomach which was perfused via the celiac artery with Krebs-Ringer buffer. Vagal stimulation was performed with 1 ms, 10 V and 2, 5, 0r 20 Hz, respectively.

J.3.1.3 Chronic Gastric Fistula in Rats

PURPOSE AND RATIONALE

A permanent gastric fistula using an especially designed Pavlov's type of cannula in the rat has been described by Lane et al. (1957) and Komarow et al. (1960, 1963). Moreover, the preparation of chronically denervated gastric pouches in the rat has been reported by Alphin and Lin (1959).

PROCEDURE

For a **permanent gastric fistula** in rats Komarow et al. (1960, 1963) developed a stainless steel cannula of the type extensively used in Pavlov's laboratories. The cannula is 10–12 mm in length with an inner bore of 3 mm diameter and a bevelled flange at each end. The inner bore at one flange is threaded to permit insertion of a removable screw which acts as a stopper between experiments. The lumen of the cannula permits a snug fit with a No. 8 French catheter.

Male Wistar rats weighing 280–300 g are used. Under ether anesthesia, the left upper quadrant of the abdomen is shaved and the animal placed on its right side. An incision of 5–10 mm in length is made about 5 mm below and parallel to the lower left costal margin between the parasternal and mammary lines and the deep abdominal muscles are divided. The area of the rumenal wall is then drawn up through the incision. This area should be close to the greater curvature but far enough away from the glandular portion of the stomach to avoid sacrificing secretory mucosa. A small incision is made in the exposed portion of the rumen and a purse string suture is loosely placed around the margin of the opening. The unthreaded flange of the cannula is inserted into the rumen and the suture is pulled tight around the shaft of the cannula and tied. The incision is then closed by two layers of interrupted sutures. The deep abdominal muscle is closed first by a suture at each side of the cannula, using a bit of rumen to ensure a tight fit. The incision is closed with skin sutures.

During the postoperative period of 2–3 weeks, the animals are conditioned to the experimental procedure by keeping them in a restraining cage for several hours each day. Food is withdrawn 18 h prior to the experiment. The animal is placed in a restraining cage, the stopper screw removed from the cannula and the stomach gently washed twice with 2–3 ml warm saline, and 6 cm length of rubber catheter is inserted through the lumen of the cannula. Hourly collections of gastric fluid in a graduated centrifuge tube are then started.

The animal model can be used for physiological studies as well as for standardization of secretagogues and for measuring the inhibition of gastric secretion by anti-secretory drugs.

For preparation of **chronic denervated gastric pouches** according to Alphin and Lin (1959) male Wistar or Sprague Dawley rats weighing 250–350 g are used. Under ether anesthesia, a mid-line incision is made along the abdominal wall and the stomach is gently pulled to the outside by means of a stainless steel hook. Two small clamps are then gently applied along the stomach between the smaller and greater curvature, care being taken not to injure the blood vessels supplying the glandular and the non-glandular portions of the stomach.

An incision is made between the clamps from one end to the other end of the greater curvature with as little involvement of the mesenteries as possible. The mucosa and the muscular wall are sewed up separately. A new opening is made midway along the greater curvature of the denervated pouch into which one end of a stainless steel cannula is secured by double purse-string sutures. The stainless steel cannula is 3 cm in length with an inside diameter of 3 mm. The other end of the cannula is led through a small puncture 1 cm on the left of the midline of the abdomen. The gastric end of the cannula is firmly anchored to the body wall by silk sutures. After closing the midline incision of the body wall by silk sutures, the animal receives 150 MU procaine penicillin. The animals receive a pasted diet for some days and are kept constantly in an air-conditioned room with constant temperature during the recovery period of 2–3 weeks.

For experiments, the animals are deprived of food, but not of water prior to the test, placed in restraining cages and the gastric juice is collected in graduated centrifugation tubes. The amount of secretion into the pouch and the acidity of the fluid are measured after secretagogues, e. g. 20 mg/kg histamine s.c., alone and then two hours later after administration of potential antisecretory drugs.

EVALUATION

The effect on volume and HCl secretion at 30 min intervals after administration of the test compound is compared with the control values. The decrease is expressed as percentage of control.

MODIFICATIONS OF THE METHOD

Larsson et al. (1983) described a modified technique for the chronic fistula rat. Under methohexital anesthesia a plastic cannula is implanted in the rumen of rats close to the glandular part of the stomach wall. At the same time, a polyethylene tube (PE 50) for compound administration is inserted into the upper part of duodenum and fixed to the cannula. The duodenal tube is subcutaneously guided to the neck, where the free end is guided through the skin. One week recovery is allowed before experiments. For the experiment, the rats are placed in modified Bollman cages and 6 consecutive 1-h samples of gastric juice are collected from the gastric cannulae. After the first two collection periods, the test compounds are given intraduodenally.

Altar (1980) described design and method of implantation of a chronic gastric cannula in adult rats.

Johnson et al. (1990) described a chronic gastric cannula for feeding ethanol liquid diet to rats.

Tsukamoto et al. (1984) reported an improved method for intragastric infusion in conscious rats with simultaneous implantation of a cannula into the jugular vein for blood sampling and drug administration.

Rossowski et al. (1997) measured the inhibition of gastric secretion by adrenomedullin, amylin, calcitonin-gene related peptide and their fragments in rats equipped with chronic gastric fistulas.

Bickel et al. (2004) measured sham-feeding in rats with chronically implanted gastric fistula after treatment with an anorectic compound.

J.3.1.4 Chronic Gastric Fistula in Dogs

PURPOSE AND RATIONALE

A simple technique for preparing chronic gastric fistulas in dogs which does not require placement of cannulae or tubes has been described by Foschi et al. (1984).

PROCEDURE

Male mongrel or Beagle dogs weighing 12–18 kg are used. After thiopental and halothane anesthesia, a round incision (2 cm) is made on the left side of the abdomen below the costal arch. The muscular fascial layers are cut across to either the peritoneum or the abdominal cavity. The stomach is grasped on the greater curvature, as high as possible, and is gently pulled through the abdominal wall. A round excision of the serous-muscular layer (0.5 cm diameter) is made, and then the mucosa is cut and sutured to the serous layer with catgut. A purse string of 3–0 silk is placed 1.5 cm around the gastrostomy hole to invert the opening and to form an antireflux flap. The stomach is also sutured to the peritoneum, the fascial layer, and the skin with catgut. After 5 days, a silver cannula has to be inserted once a week to avoid closure of the gastrostomy.

After 10–14 days, the animals are trained to lie in a cage to their left sides, supported by a 30° angle with the caudal part of the body raised to avoid the passage of gastric juice into the duodenum. For secretion studies, a short plastic tube is inserted through the fistula and gastric juice is collected for periods of 15 min. After 30 min, secretagogues (e. g., pentagastrin 6 µg/kg/min) are given as continuous infusion and samples collected every 15 min.

EVALUATION

The samples are titrated with 0.1 N NaOH to pH 7.0 by a pH meter. The results are expressed as volume (ml), pH, acid concentration (µE/ml), and output (mE/h).

CRITICAL ASSESSMENT OF THE METHOD

The technique described by Foschi et al. (1984) has the advantage of simplicity.

MODIFICATIONS OF THE METHODS

Boldyreff (1925) reported improvements and details of the technique described by Pavlov (1902).

Thomas (1941) described an improved cannula for gastric and intestinal fistulas using a removable flange being inserted separately into the stomach or intestine.

Emås (1960) reported on gastric secretory responses to repeated intravenous infusions of histamine and gastrin in non-anaesthetized and anesthetized cats with gastric fistula. A gastric cannula as well as a duodenal cannula were inserted.

Daly et al. (1980) described an apparatus for intragastric titration in the conscious dog. A titration display unit provides a record of the secretory response both as a digital printout and a bar chart display.

J.3.1.5 Heidenhain Pouch in Dogs

PURPOSE AND RATIONALE

The preparation of a chronic gastric pouch, as described by Heidenhain in 1878, is one of the classic techniques in experimental surgery. This model has much contributed to the understanding of the physiology and pathology of the stomach and to modern techniques of abdominal surgery in man. The surgical technique has been described again in detail by deVito and Harkins (1957). A preparation of chronic denervated pouches in the rat has been described by Alphin and Lin (1959). Both preparations can be used as pharmacological models for testing antisecretory drugs.

PROCEDURE

Short-haired mongrel dogs or Harrier dogs weighing 15–20 kg are fasted 24 h preoperatively. Intravenous pentobarbital sodium, 30 mg/kg, provides satisfactory anesthesia. It can be supplemented, if necessary, during operation. The abdominal part is shaved with electric clippers, then with a razor. The skin is disinfected with Zephiran-70% alcohol. Sterile drapes are applied to cover the whole surgical field. A mid-line linea alba incision from xiphoid to umbilicus provides excellent exposure and ease for closure. As the posterior sheath is divided, the large ventral fat pad present in dogs should be excised completely. A self-retaining retractor is applied and the stomach is palpated for the absence of food. Then the spleen is displaced, wrapped in warm, moist pads and laid on the ventral wall below the incision.

The stomach is pulled into the operative field. The greater curvature is held at multiple points so that the stomach is stretched out and the line of incision for the pouch is selected. The pouch should be made from the corpus of the stomach so that true parietal cell juice can be obtained. A line projected from the incisura angularis perpendicular to the proximal lesser curvature will generally fall across the junction between corpus and antrum. Appropriate division of the gastric branches of the right gastroepiploic artery at the lower end of the proposed line of transsection clears the greater curvature for 1–2 cm. The gastroepiploic artery itself should be sectioned at this site and a long rent formed on the adjacent omentum, else the omentum vessels tend to tear during subsequent manipulations.

An index finger is then inserted through this defect dorsal to the stomach to emerge higher on the greater curvature through the gastrosplenic ligament at the upper end of the proposed line of transsection. This portion of the greater curve is cleared for 1–2 cm. Von Petz clamps with their staplings are used to control bleeding and to avoid leakage of gastric content. The stomach should be kept stretched and flattened while the clamps are applied. After division between the staples, any bleeding is controlled and the cut edges of the main stomach and pouch are then oversewn with continuous sutures of black silk. The suture should be of an inverting type. Surprisingly, leakage or excessive adhesions are not a problem when serosal apposition is neglected.

The pouch so formed is about 30% of the corpus volume and provides adequate secretory volume for further studies. A cannula, made of stainless steel, 3 cm long with a bevelled flange threaded at the other end is placed in the most ventral portion of the pouch through a small incision in the anterior wall. A single purse-string of silk holds it in place. A double sheet of omentum is then wrapped about the pouch and the cannula before being pulled through the abdominal wall, about 3 cm to the left of the mid-line subcostally. It is important that the cannula be held snugly by fascia, otherwise it will readily pull out of the pouch and abdominal wall. The linea alba is closed with a continuous suture of silk and the skin with subcuticular stitches of chromic catgut. On the outside of the cannula a stainless steel jacket is screwed. For further collections, a bag is connected to the cannula by a threaded adapter, facilitating removal for daily drainage of secretions.

At the end of surgery, 300 MU penicillin and 0.5 g of streptomycin are instilled intraperitoneally. Before recovery from anesthesia the dog receives 500 ml 5% glucose in saline intravenously. The same volume is given for 3 days postoperatively together with oral fluid ad libitum. From the 4th day onward, normal food is given. Twenty-four hours secretions are collected every morning and analyzed for free HCl. A period of 7–10 days is required for full recovery from the operation. Special care has to be taken for each animal being kept separately in a suitable cage with mesh bottom.

For pharmacological studies, food is withdrawn 18 h prior to the experiment with water ad libitum. The animals are placed in Pawlow stands and a continuous i.v. infusion of either pentagastrine at a dose of 8 µg/kg/h or histamine at a dose of 0.1 mg/kg/h is administered. Secreted fluid is collected at 15 or 30 min intervals and analyzed for free HCl. As soon as the secretion has reached a plateau, test compounds are given orally or intravenously.

EVALUATION

The effect on volume and HCl secretion at 15 or 30 min intervals after administration of the test compound is compared with the control values. Maximal inhibition is calculated as percentage change against the predrug value. Secretin inhibits gastric secretion volume in a dose-dependent manner. Activity ratios for unknown preparations of secretin can be calculated by 2+2 point assays in comparison with the international standard. Gastric secretion can be stimulated by slow continuous infusion of pentagastrin, e. g., (Gastrodiagnost) 8 µg/kg/h.

The Heidenhain pouch technique can also be used for evaluation and standardization of **gastrin analogues**. Two or more doses of the test compound and the standard are given intravenously. Dose-response

curves are established using gastric juice secretion, acid secretion, or pepsin secretion, within two 15-min collection periods as parameters. Activity ratios with confidence limits can be calculated.

For evaluation of **H_2-antagonists**, a continuous infusion of histamine is given over a period of 45 min, starting with 3×10^{-8} M/kg/h. Then, the dose of histamine is doubled and infused for the next 45 min. This procedure is repeated until secretion has reached a plateau. Secretory response curves are constructed in the presence or the absence of a H_2-antagonist at a concentration between 2×10^{-6} and 5×10^{-7} M/kg/h.

To evaluate the **type of gastric acid secretion inhibition**, e. g., cholinergic, histaminergic, or gastrinergic mechanisms, either carbachol (8 µg/kg/h), or histamine (80 µg/kg/h), or pentagastrin (8 µg/kg/h), are administered as continuous i.v. infusion until a plateau of acid secretion is reached. The experiments are performed at weekly intervals with and without the administration of various doses of test compounds. Regression lines of antisecretory effects of various doses of test drugs are constructed and used for calculation of ID_{50} values. Relative potencies versus a standard, e. g., cimetidine, can be calculated by four- or six-point assays.

MODIFICATIONS OF THE METHOD

Boldyreff (1925) described a simplified method for isolation of a portion of the stomach as compared to the original method of Heidenhain (1878).

Gastric motility can be measured by balloon manometry of the Heidenhain pouch in the conscious dog. The animals are deprived of food for 18 h before the experiment, but water is allowed ad libitum. A latex balloon, connected via a polyethylene catheter to a pressure transducer (Statham P 23 BB), is introduced through the fistula cannula into the accessory stomach. Changes in intragastric pressure are measured on a frequency measurement bridge and are recorded continuously. The number and height of the pressure waves are used as indices of gastric motor activity. Secretin inhibits gastric motility dose-dependent. After injection of gastrin or gastrin analogues, a dose-dependent increase of pressure is noted over a wide dose-range.

Jacobson et al. (1966, 1967) studied gastric secretion in relation to mucosal blood flow by an antipyrine clearance technique in conscious dogs with vagally denervated gastric fundic (Heidenhain) pouches. A vagally denervated fundic pouch was so constructed that the entire arterial blood supply was delivered by the splenic artery. A non-cannulating transducer (electromagnetic flowmeter) and a hydraulic occluder were implanted on the vessel.

The Heidenhain pouch preparation was used by Carter and Grossman (1978), Kauffman et al. (1980) to study the effect of luminal pH on acid secretion evoked by topical and parenteral stimulants and the effect of topical and intravenous 16,16-dimethyl prostaglandin E_2 on gastric bicarbonate secretion.

Baker (1979) and Roszkowski et al. (1986) developed a modified Heidenhain dog pouch preparation for collecting gastric juice exclusively from the pouch during experimental periods but allowed the pouch to be an integral part of the gastrointestinal tract during non-experimental periods. The pouch is prepared using conventional techniques but, instead of being fitted with a simple cannula through the abdominal wall, a three-way cannula is used which provides passage between the exterior orifice, the pouch and the main body of the stomach. By inserting an appropriate adapter, passage is available only to the pouch and not to the main stomach or vice versa.

The Heidenhain pouch technique in dogs has been used for preclinical evaluation of various drugs, such as:

- a histamine H_2 antagonist by Uchida et al. (1993),
- dual histamine H_2 and gastrin receptor antagonists by Kawanishi et al. (1997),
- a 5-HT_4 receptor antagonist by Bingham et al. (1995),
- an other 5-HT_4 receptor antagonist by Wardle et al. (1996),
- inhibition of motilin-induced phase III contractions by pentagastrin by Yamamoto et al. (1994),
- peptide YY by Zai et al. (1996),
- reversible K^+-competitive inhibitors of the gastric H^+/K^+-ATPase by Parsons et al. (1995),
- the antiulcer agent SWR-215 by Kataoka et al. (1997),
- a selective gastrin/CCK-B receptor antagonist by Yuki et al. (1997).

Descroix-Vagne et al. (1993) used Heidenhain pouch preparations in **cats** and **rabbits** to study the effect of perfusion at pH 5.5 on acid and pepsin secretion.

J.3.1.6 Gastrin Activity

PURPOSE AND RATIONALE

Biological activity of gastrin and its analogues can be determined with a bioassay using the acid secretion as determined by pH-metry (Gosh and Schild 1955, 1958; Barrett 1966; Smith et al. 1970) or by measurement of conductivity according to Lawrence and Smith (1974).

Radioimmunoassays for gastrin have been developed (Jaffe and Walsh 1979) and are available as commercial kits.

PROCEDURE

Male Sprague-Dawley or Wistar rats weighing about 250 g are used. They are withheld from food, but not from water, 18 h prior to the experiment. Four animals are used per dose of test drug or standard. Anesthesia is induced by i.p. injection of 5 ml/kg of 25% urethane solution. Body temperature is artificially stabilized by means of a rectal thermometer and a heated pad. The trachea is exposed and cannulated. The jugular veins are then exposed and cannulated with polyethylene tubes bevelled at the tip. The abdomen is opened through a midline incision, the pyloro-duodenal junction exposed and a catheter with two lumina is introduced through a cut in the duodenum up to the cardiac part of the stomach and secured firmly by tying a ligature around the pylorus. Care must be taken not to include blood vessels within the ligature.

Using a peristaltic pump, the stomach is perfused continuously with a phosphate-citrate buffer at 37°C. In the effluent pH is measured with a pH-meter and continuously recorded. At the beginning, gastric secretion is stimulated by an intravenous injection of 0.5 µg/kg pentagastrin. Then, the injections are repeated in 1 h intervals with alternating doses between

0.2, 0.4, 0.8, and 1.6 µg/kg of standard or test compound. Since in this dose range linearity of the response to gastrin can be assumed a 2+2 point parallel assay is allowed. After each injection, pH or conductivity is measured for 45 min. The area under the curve after each dosage is evaluated by planimetry.

EVALUATION

Each of 4 animals receives two doses of standard and test compound in the order of a Latin square. The dose differences have to follow a logarithmic scale. The evaluation is performed with the 4 × 4 assay according to Gosh and Schild (1958).

MODIFICATIONS OF THE METHOD

Wan (1977), Chang and Lotti (1986) used CF_1 female **mice**. The whole stomach was placed in tissue baths and perfused. The effluent of the perfused stomachs was collected at 15 min intervals, and the hydrogen ion concentration was determined by titration with 0.01 M NaOH to pH 7.0, or continuously recording with a pH-meter.

Lotti and Chang (1989) tested the inhibition of gastrin-induced acid secretion by a selective non-peptide gastrin antagonist in mice, rats and **guinea pigs**.

Black and Kalindjian (2002) reviewed gastrin agonists and antagonists.

J.3.1.7 Receptor Binding for Gastrin

PURPOSE AND RATIONALE

The gastrin gene in all mammals consists of three exons and encodes a 101 (human, mouse) or 104 (rat) precursor peptide with an N-terminal signal peptide, which is removed at residues 21 or 25 to generate progastrin. The conversion of progastrin to smaller peptides is regulated by multiple mechanisms (Dockray et al. 2001).

Binding to gastrin receptors can be determined in isolated guinea pig gastric glands (Praissman et al. 1983; Gully et al. 1993).

PROCEDURE

The gastric glands of male guinea pigs weighing between 300 and 400 g are isolated according to Berglindh and Obrink (1976). The animals are anesthetized with 30 mg/kg Nembutal. The abdomen is opened and the aorta is cannulated in a retrograde direction. Heparin solution (250 IU/ml) is injected forcefully through the cannula. After one min, the animal is bled through the cannula and a ligature is placed around the mesenteric vessels. The chest is opened and the thoracic aorta clamped. A warm (37°C) phosphate buffered saline solution is pumped into the aorta, whereupon the portal vein is opened to allow a free outflow of the perfusate. By this procedure, most of the solution is forced through the gastric blood vessels. When the stomach appears totally exsanguinated, it is rapidly removed, opened along the lesser curvature and emptied. The cardial and antral regions are discarded. The corpus is rinsed several times with phosphate buffered saline solution and blotted with filter paper.

The thoroughly washed fundic mucosa from two guinea pigs is minced with fine scissors in a standard buffer consisting of 15 mM HEPES, 130 mM NaCl, 12 mM $NaHCO_3$, 3.0 mM NaH_2PO_4, 2.0 mM $MgSO_4$, 1.0 mM $CaCl_2$, 5.0 mM glucose, 4.0 mM L-glutamine, pH 7.4. The minced tissue is washed and then incubated with 0.1% collagenase in the above mentioned standard buffer containing 0.1% bovine serum albumin in a shaker bath at 37°C. After 40 min, the glands are liberated by a series of resuspensions through a 10 ml plastic pipette, filtered through 200 µ nylon mesh (Nytex), washed and collected by centrifugation. The glands are then resuspended in 40 ml of the standard binding buffer containing 0.1% bovine serum albumin at pH 7.4. Two ml aliquots are transferred into 15 ml plastic centrifuge tubes. The amount of protein

contained in fundic glands is determined according to Lowry et al. (1951).

[^{125}I]Gastrin binding is measured in the presence of 0.4 ml of gland suspension in triplicate tubes that contain 50 µl of either buffer, unlabeled gastrin (1 µM), or displacers at the desired concentration and 50 µl of [^{125}I] gastrin (70 pM final concentration). After 90 min of incubation at 37°C, the mixture is layered over 1 ml ice-cold incubation buffer in microcentrifuge tubes and is centrifuged at 10,000 *g* for 5 min. The supernatant is discarded and the radioactivity is measured in a γ-scintillation counter.

EVALUATION

IC_{50} values and K_i constants are calculated.

J.3.1.8 Gastrin Releasing Peptide/Bombesin/Neuromedin

Bombesin is a tetradecapeptide originally isolated from frog skin by the group of Erspamer (Anastasi et al. 1971). Shortly before, Nakashima et al. (1970) isolated from the skin of *Rana pipiens* a peptide called ranatensin because of its contractile effects on smooth muscle. **Gastrin-releasing peptide**, which shares a C-terminus with amphibian bombesin, has been isolated from a variety of mammalian and non-mammalian species (Spindel et al. 1993). **Neuromedin B**, a decapeptide originally isolated from porcine spinal cord (Minamino et al. 1983), also shows sequence homology to bombesin and gastrin-releasing peptide. **Neuromedin N**, a six amino acid neurotensin-like peptide, shows a high affinity to brain neurotensin receptors and is rapidly inactivated by brain synaptic peptidases (Checler et al. 1990).

The peptides which belong to the bombesin family can be classified in three subgroups according to the sequence of their C-terminal tripeptide: bombesin (-His-Leu-MethNH_2), ranatensin and litorin (-His-Phe-MethNH_2), and phyllitorin (-Ser-Phe MethNH_2).

Bombesin and its homologues are known to affect a wide spectrum of biological processes (Tache et al. 1988; Parkman et al. 1994; Thomas et al. 1994; Konturek et al. 1995; Varga et al. 1994, 1995; Glad et al. 1996).

In the **gastrointestinal tract**, bombesin/gastrin-releasing peptide stimulates hormone and peptide release, stimulates gastric, pancreatic, bile and intestinal secretion, prevents gastric injury, causes smooth muscle contraction and induces epithelial growth (Dietrich et al. 1994; Kortezowa et al. 1994; Liu et al. 1995; Takehara et al. 1995; Wada et al. 1995; Weigert et al. 1995; Roberge et al. 1996; Yegen et al. 1996; Won Kyoo Cho 1997; Azay et al. 1998; Cox et al. 1998; Mercer et al. 1998; Milusheva et al. 1998; Nishino et al. 1998; Alvoro-Alonso et al. 1999; Bozkurt et al. 1999; Ladenheimer et al. 1999; Shahbazian et al. 1999).

Bombesin-related peptides inhibit **food intake** (Kirkham et al. 1994; Ladenheimer et al. 1996; Smith et al. 1997; Plamondon et al. 1998; Rushing and Gibbs 1998; Aalto et al. 1999; Edwards and Power 1999; Horstmann et al. 1999; Merali et al. 1999).

Several **central activities** of neuromedin B and gastrin-releasing peptide are reported, e. g. involvement in the hypothalamic-pituitary system (Pinski et al. 1992; Plamodon and Merali 1997; Garrido et al. 1998, 1999). Moody and Merali (2004) reviewed the behavioral implications of bombesin-like peptides and associated receptors within the brain. Roesler et al. (2004) discussed bombesin receptors as novel therapeutic targets in anxiety disorders. **Autocrine actions** of neuromedin B and gastrin-releasing peptide in small and non-small cell lung carcinomas are described (Gaudino et al. 1988; Siegfried et al. 1999).

J.3.1.9 Bombesin Receptor Binding

PURPOSE AND RATIONALE

Different types receptors have been described for bombesin-like peptides (von Schrenk et al. 1989; Battey et al. 1991; Rouissi et al. 1991; Severi et al. 1991; Fathi et al. 1993). The mammalian bombesin receptor subfamily of G protein coupled receptors consists of the gastrin-releasing peptide receptor (GRP-R), also called BB2, the neuromedin B receptor (NMB-R), also called BB1, and the bombesin receptor subtype 3 (BRS-3), also called bb3 (Fathi et al. 1993; Mantey et al. 1997; Donohue 1999; Jian 1999). A fourth subtype, bombesin receptor subtype 4, has been isolated from a cDNA library from the brain of the frog, *Bombina orientalis* (Katsuno et al. 1999). A ligand with high affinity to all four receptors has been identified (Pradhan et al. 1998).

Moody et al. (1978) studied the binding of the radiolabeled bombesin analogue [^{125}I]bombesin to rat brain membranes. Functional GRP-preferring bombesin receptors were identified in human melanoma cells by Pansky et al. (1997). Benya et al. (1995) expressed and characterized clones of human bombesin receptors.

PROCEDURE

BALB/3T3 fibroblasts devoid of gastrin-releasing peptide receptor (GRP-R) and neuromedin B receptor (NMB-R) are selected by clonal expansion after assaying for GRP-R or NMB-R by RNase protection and binding studies (Benya et al. 1992). These BALB/3T3 cells are stably transfected using a full length human GRP-R clone (huGRP-R transfected cells) or a full length human NMB-R clone (huNMB-R transfected cells) (Corgay et al. 1991). In both cases the receptor is subcloned into a modified version of the pCD2 plasmid and transfected using calcium phosphate precipitation. Stable transfectants are isolated in the presence of 800 µg/ml aminoglycoside G-418 (GIBCO, Waltham MA), identified by binding studies, and then maintained in DMEM containing 10% fetal bovine serum and 270 µg/ml G-418. Cells are passaged every 3–5 days at confluence by splitting 1:4.

[^{125}I-D-Tyr^{0}]NMB (2200 Ci/mmol), ^{125}I-GRP (2200 Ci/mmol), and [^{125}I-Tyr^{4}]Bn (2000 Ci/mmol) are prepared using Iodo-Gen and purified using high pressure liquid chromatography. Binding studies are performed by suspending disaggregated cells in binding buffer containing 75 pM levels of either [^{125}I-D-Tyr^{0}]NMB or [^{125}I-Tyr^{4}]Bn and 3×10^{6} cells/ml for 30 min at 22°C. Nonsaturable binding of either radiolabeled peptide is the amount of radioactivity associated with transfected cells when the incubation mixture contains either 1 µM NMB of 1 µM Bn.

The ability of various bombesin related agonists or antagonists to inhibit the binding of [^{125}I-Tyr^{4}]Bn to huGRP-R transfected cells and of [^{125}I-D-Tyr^{0}]NMB to huNMB-R transfected cells is compared.

EVALUATION

Data are expressed as the percentage of saturably bound reactivity in the absence of nonradioactive peptide. For each experiment each value is determined in duplicate, and the results are expressed as the means ± standard errors of at least 3 separate experiments.

MODIFICATIONS OF THE METHOD

Radulovic et al. (1991) studied biological effects and receptor binding affinities of pseudononapeptide bombesin/CRP receptor antagonists.

Fanger et al. (1993) identified a 63-kDa serum protein that binds somatostatin and gastrin-releasing peptide but not bombesin.

Wada et al. (1997), Ohki-Hamazaki et al. (1999), and Yamada et al. (2000a, 2000b) studied mice lacking the gastrin-releasing peptide receptor, the bombesin subtype-3 receptor or the neuromedin B receptor.

Mantey et al. (2004) and Boyle et al. (2005) described selective ligands for the bombesin receptor subtype 3.

Akeson et al. (1997) identified four amino acids in the gastrin-releasing peptide receptor that are required for high affinity agonist binding.

Ryan et al. (1998) studied the intracellular signaling of the human bombesin orphan receptor BRS-3 by various bombesin receptor agonists and antagonists.

Chave et al. (2000) analyzed the expression of bombesin-like peptides and their receptor subtypes in normal and neoplastic colorectal tissue.

Sun et al. (2000) investigated the presence and characteristics of the functional receptors for bombesin/GRP in human prostate adenocarcinoma specimens by radio-receptor assay and the mRNA expression of the three bombesin receptor subtypes by RT-PCR.

Weber et al. (2000) determined the structure of the mouse gastrin-releasing peptide receptor gene and investigated its basal promotor activity.

Radioligands for the **GRP receptor** are:

- [^{125}I][DTyr^{6}]bombesin-6–13-methylester, [^{125}I]GRP, [^{125}I][Tyr^{4}]bombesin,

for the **neuromedin B receptor:**

- [^{125}I]BH-NMB, [^{125}I][Tyr^{4}]bombesin,

for the **bombesin receptor subtype 3:**

- [^{125}I][Tyr^{6},βAla^{11},Phe^{13},Nle^{14}]bombesin-6–14 (Alexander et al. 2000).

J.3.1.10 Evaluation of Bombesin Receptor Antagonists as Anti-Cancer Drugs

PURPOSE AND RATIONALE

Bombesin and gastrin-releasing peptide affect the growth and differentiation of lung epithelium in the fetus and the adult. Gastrin-releasing peptide is an autocrine growth factor for various small cell carcinoma cell lines. Bombesin/gastrin-releasing peptide receptors were also identified in other human cancer tissue (Halmos et al. 1995). Therefore, bombesin- and gastrin-releasing peptide-antagonists were synthesized and tested as antitumor agents (Heimbrook et al. 1991; Qin et al. 1994a, 1995; Thomas et al. 1994; Azay et al. 1996; Casanueva et al. 1996; Halmos and Schally 1997; Moody and Jensen 1998).

The procedure of Qin et al. (1994a) on the inhibitory effect of an bombesin receptor antagonist on the growth of human pancreatic cells *in vivo* and *in vitro* is described as example of various similar studies.

PROCEDURE

Cancer Cell Line

Cancer cells of the CFPAC-1 human pancreatic cell line, originally established from a well differentiated ductal pancreatic adenocarcinoma of a 26-year-old white male with cystic fibrosis, are routinely maintained in a monolayer culture in Costar T75 culture flasks with IMDM medium containing 10% FCS, 0.5 g/liter L-glutamine, 25 mM HEPES, 3.7 g/liter $NaHCO_3$, 100 units/ml penicillin, 100 µg/ml streptomycin, and 0.25 µg/ml amphotericin B under humidified 5% CO_2 at 37°C. The cells growing exponentially are harvested by an incubation with 0.25% trypsin-EDTA in calcium- and magnesium-free Hank's balanced salt solution for 5 min at 37°C. For tumor cell implantation, a cell suspension is prepared in serum-free IMDM by repeatedly passing the cells through a G-22 needle; then the cells are diluted to a concentration of 5×10^6 cells/ml.

Implantation of Tumors in Nude Mice

Male athymic BALB/c (nu/nu) 6-week-old mice are housed in a laminar airflow cabinet under pathogen-free conditions throughout the experiments. Three nude mice receive s.c. injections in the flanks with 0.2 ml of cell suspension (1×10^6 cells) and serve as tumor donors. After 4 weeks, the implanted tumors grow to a size of about 5 mm in diameter and are removed from the mice. Tumor samples are dissected free of necrotic tissue and blood vessels and are cut into small fragments of about 8 mm^3. Under ether anesthesia, two pieces of tumor fragments are implanted s.c. by trocars on both sides of the flanks for each mouse. The mice bearing the implanted tumors are randomly divided into groups with 10 mice in each group.

The nude mice with implanted tumors start to receive injections of the bombesin antagonist or vehicle 7 days after the tumor cell injection. The treatment is continued for 25 days.

Evaluation of Tumor Growth

During the treatment, the size of the implanted tumors is measured by calipers in each mouse at 3–4 days intervals for 25 days to construct the tumor growth curve *in vivo*. Tumor volume is calculated by the formula: Tumor volume = length × width^2 × 0.5. Tumor volume

doubling time is defined as the time required for the tumors to grow from 50 mm^3 to 100 mm^3 for the control group and from 35 mm^3 to 70 mm^3 for the treatment group, respectively. The tumor growth delay time is estimated as the time difference for the treated tumors and the controls to reach a volume of 70 mm^3. At the end of the experiment, the animals are sacrificed by an overdose of ether. The tumors are removed from the animals, weighed, and immediately frozen in liquid nitrogen for measurement of DNA and protein content in tumor tissues.

Determination of DNA and Protein in Tumor Tissue

DNA in tumor tissue is determined by the method of Labara and Paigen (1979) which is based on the enhancement of fluorescence reaction upon binding bis-benzimidazole Hoechst 33528 to DNA in cell nuclei in a high ionic strength solution. Tumors collected in each group are pooled and homogenized in 10 times their volumes in a buffer consisting of 0.05 M NaH_2PO_4, 2.0 M NaCl, and 2 mM EDTA (pH 7.4). Hoechst 33528 is dissolved in the same buffer at a concentration of 1 µg/ml and filtered before use. An aliquot of tumor homogenate (0.4 ml) is suspended in 4 ml of Hoechst 33528 solution, followed by incubation in a dark room for 30 min. The reaction is measured by a fluorescence spectrophotometer at excitation and emission wavelengths of 356 and 492 nm, respectively. Calf thymus DNA type I is used as a standard.

Measurement of Cell Growth in Vitro

The effects of bombesin and the bombesin antagonist on the growth of CFPAC-1 human pancreatic cells *in vitro* is evaluated by direct cell counting and [^{3}H]thymidine incorporation assay.

Direct Cell Counting

CFPAC-1 cells collected from 60–70% confluent cultures are used for this study and seeded to 24-well culture plates (1×10^4 cells/well). After the cells are cultured in IMDM containing 10% FCS for 48 h, the medium is replaced by IMDM supplemented with 2.5% FCS and various concentrations of bombesin, bombesin antagonist, or a combination of both. The same volume of medium but without peptides is added to control wells. Following another 24 h of incubation, the culture is terminated by aspiration of the medium from the wells and washing with PBS (0.5 ml/well). The cells are trypsinized by a 10-min incubation with (0.5 ml/well) 0.25% Trypsin-EDTA. The detached cells are dispersed by repeated pipetting using a G-22 needle and syringe. The number of cells is counted by an automated electronic cell counter (Coulter Counter Model ZF).

[^{3}H]Thymidine Incorporation Assay

Single cell suspension is prepared in IMDM with 10% FCS and seeded to 24-well culture plates (1×10^4 cells/well). After 46 h of culture, the medium is changed to IMDM (0.5 ml/well) containing 2.5% FCS and various concentrations of bombesin, bombesin antagonist, or a combination of both. The same volume of medium but without peptides is added to control wells. After 24 h of culture [methyl-^{3}H]thymidine (radioactivity 25 Ci/mg) is added to each well (1µCi/well) to pulse the cells. After a 4-h incubation, the medium is removed from the wells, and the cells are fixed by Camoy's solution (1 ml/well; methanol:glacial acetic acid, 3:1, v/v) for 20 min. After washing 3 times with PBS, the cells in each well are dissolved with 0.5 ml of 0.3 N NaOH for 15 min at room temperature. The cell lysate is collected and mixed with 3 ml of Universal scintillation cocktail. The radioactivity is measured for 1 min by a liquid scintillation beta counter.

Receptor Binding Assay

Receptor binding assay is performed using intact CFPAC-1 cells in monolayer cultures. Tyr^4-bombesin is labeled with ^{125}I-Na using a Bio-Rad enzymobead iodination kit. Mono-^{125}I-Tyr^4-bombesin is purified by high performance liquid chromatography resulting in a specific activity of ^{125}I-Tyr^4-bombesin of about 2000 Ci/mmol. CFPAC-1 cells are seeded to 24-well culture plates (1×10^4 cells/well) and cultured with IMDM containing 10% FCS for 48 h. The cells in subconfluent culture are washed once with serum-free IMDM supplemented with 25 mM 4-(2-hydroxyethyl)-1-piperazineethanesulfonic acid, 10 mM $MgCl_2$, 1 mM EGTA, 10 mM monothioglycerol, 0.25 mM phenylmethylsulfonyl fluoride, aprotinin 10000 kallikrein inactivator units/liter, and 0.1% bovine serum albumin (pH 7.5), followed by an incubation for 2 h at 22°C with the same medium containing (0.5 nM) ^{125}I-Tyr^4-bombesin in the presence or absence of various concentrations of bombesin, bombesin antagonists or structurally unrelated peptides. The binding reaction is terminated by adding 0.5 ml of ice-cold medium to each well. After washing four times with ice-cold PBS (pH 7.4) the cells in each well are dissolved with 0.5 ml of 0.3 N NaOH. The resultant cellular lysate is collected from each well for measurement of radioactivity by a gamma counter.

EVALUATION

All data are expressed as the mean ± SEM of duplicate or triplicate observations from at least 2–3 repeated experiments. Mean values between the treatment and control group are analyzed by the Student *t*-test, Mann Whitney *U*-test, or one-way analysis of variance.

Data from receptor binding assays are analyzed by a ligand-PC computerized curve-fitting program created by Munson and Rodbard as modified by McPherson (1985) to determine the types of binding sites, the dissociation constants (K_d) and the maximal binding capacity of receptors (B_{max}).

MODIFICATIONS OF THE METHOD

Similar studies, mostly by Schally's group, as with tissue derived from human pancreatic cancer were performed with nitrosamine-induced pancreatic cancers in hamsters (Szepeshazi et al. 1993, 1994, 1999), with human prostate cancer (Pinski et al. 1993a, b), with rat prostate cancer (Pinski et al. 1994a), with human gastric cancer (Halmos et al. 1994; Qin et al. 1994b), with human small-cell and non-small-cell lung carcinoma (Pinski et al. 1994b; Moody et al. 1996; Koppan et al. 1998; Kiaris et al. 1999a), with human breast cancer (Yano et al. 1994; Miyazaki et al. 1998; Kahan et al. 2000), with mouse mammary cancer (Szepeshazi et al. 1992, 1997), with human colon cancer (Radulovic et al. 1994), with human glioblastoma (Kiaris et al. 1999b), and with human renal adenocarcinoma (Jungwirth et al. 1998).

J.3.2 Mucus Secretion

J.3.2.1 Isolated Gastric Mucosal Preparation

PURPOSE AND RATIONALE

Main and Pearce (1978) described an isolated gastric mucosal preparation from rats for studying the pharmacology of gastric secretion and the synthesis or release of endogenous substances.

PROCEDURE

Rats of either sex weighing 100–120 g or guinea pigs weighing 400–600 g are anesthetized with 60 mg/kg pentobarbitone s.c. The abdomen is opened along the midline and the stomach exteriorized. The nonglandular portion is removed and the stomach rinsed with mucosal solution, containing 136 mM NaCl, 5 mM KCl, 3.6 mM $CaCl_2 \cdot 6H_2O$, 1.2 mM $MgCl_2 \cdot 6H_2O$, and 16.7 mM glucose. The muscular layer overlying the nonantral region is separated from the mucosa by blistering. The tip of a fine needle (27 gauge) is inserted just below the muscle and mucosal solution injected between the layers. The process is repeated as many times as is necessary to blister the whole area. Fine scissors are then used to cut the muscle along the greater curvature and then parallel to the cut edge. The muscle sheet is pulled back to expose the mucosa. The stomach is then removed, opened by cutting along the greater curvature, and rinsed with mucosal solution.

Two pieces are obtained from one stomach and each is placed, mucosal surface inwards, over a 1-cm^2-opening on a polyethylene vessel (titration cup). Both preparations, one each from the ventral and dorsal surfaces, are stretched lightly over the cup and tied in place. Each tissue is placed in an organ bath, at 37°C, containing 35 ml of serosal solution (110 mM NaCl, 5 mM KCl, 3.6 mM $CaCl_2 \cdot 6H_2O$, 1.2 mM $MgCl_2 \cdot 6H_2O$, 26 mM $NaHCO_3$, and 16.7 mM glucose) being gassed with a 95% O_2/5% CO_2 mixture. The mucosal surface is superfused by means of a peristaltic pump at a rate of 0.5 ml/min with an unbuffered solution of similar ionic composition and gassed with 100% O_2. The volume of solution on the mucosal side is kept constant by suction via the same pump using larger diameter tubing, varying between 1.6 and 2.0 ml. This small volume is used in order to follow changes in acid secretion more closely. Secretion is recorded continuously via a dual microelectrode in the mucosal solution connected with a potentiometric pen recorder. The H^+-ion concentration is noted every 15 min and expressed as apparent secretion rate. Drugs are added to the serosal solution in volumes not exceeding 1 ml. Contact times for drugs and hormones (e. g., gastrin or histamine) are between 30 and 60 min. Recovery periods before the next response are between 45 and 60 min. Responses are readily reversible on replacing the solution in the bath with fresh, warmed serosal solution.

EVALUATION

The secretory response is calculated as the increase in secretion rate at the peak of the response over the preceding basal value. Dose-response curves and time-response curves are established for histamine, gastrin,

and methacholine. The effects of drugs which inhibit acid secretion are evaluated by adding them either at the peak of a response, or 15 to 60 min prior to the secretagogue.

MODIFICATIONS OF THE METHOD

Wan et al. (1974) used the fundic glandular portion of the rat stomach mounted onto a glass tube without removing the muscular layer to study the inhibition of *in vitro* stimulated gastric acid secretion by a histamine H_2-receptor antagonist.

J.3.2.2 Primary Culture of Rat Gastric Epithelial Cells

PURPOSE AND RATIONALE

Zheng et al. (1994) described an *in vitro* model for evaluation of antisecretory agents using primary cultures of rat gastric epithelial cells.

PROCEDURE

Gastric mucosal cells from 1- to 2-week-old Sprague-Dawley rats are isolated according to Terano (1982). Gastric mucosal surface is washed thoroughly with sterile cotton and Hank's balanced salt solution (HBSS) and then rinsed with HBSS before being minced into approximately 1-mm^3 pieces. The minced tissues are incubated in HBSS containing 0.1% collagenase and 0.05% hyaluronidase at 37°C in a shaking water bath for 60 min, then pipetted several times and filtered through a sterile nylon mesh. The filtrate is washed twice with HBSS by centrifugation (200 *g* for 5 min) and resuspended in Coon's modified Ham's F-12 culture medium containing 100 µg/ml penicillin, 100 µg/ml streptomycin, 50 µg/ml gentamycine, 15 mM HEPES, 2 µg/ml fibronectin, and 10% fetal bovine serum. Cells are seeded at a density of $1.5–2 \times 10^5$ or $1–2 \times 10^4$ cells/cm^2 directly onto either 96-well plates or 6-well plates, and maintained in a Steri-Cult incubator at 37°C in a humidified atmosphere with 5% CO_2. The medium is changed daily. The confluent monolayers are formed after 4–5 days in 96-well plates.

Drug Treatment

To measure the effects of individual drugs on the viability of gastric mucosal cells, cells are incubated with 0.02–5 mg/ml drugs in culture medium for either 2 or 48 h for the uptake of MTT (3-[4,5-dimethyl-2-thiazolyl]-2,5-diphenyl-2*H*-tetrazolium bromide) or up to 8 days for the colony-forming efficiency assay. To measure the cytotoxicity of drugs, e. g., indomethacin, and acidified medium to gastric mucosal cells, cells are incubated in either serum-free medium containing 0.5–10 mM indomethacin for 1 h, or pH 3.5 at for 10–30 min.

To study the effect of various antacids, e. g., aluminium hydroxide or sucralfate preparations, cells are incubated for 1 h in culture medium containing these drugs. The drug suspensions are then aspirated away, followed by another hour of treatment with 3.5 mM indomethacin. Alternatively, cells are treated with drugs and 3.5 mM indomethacin concurrently for 1 h. The effects of antacids on acid-induced damage are investigated by incubating the cells with the agents for 2 h and then exposing them to pH 3.5 medium for 10 to 30 min.

MTT (3-[4,5-dimethyl-2-thiazolyl]-2,5-diphenyl-2H-Tetrazolium Bromide) Colorimetric Assay

Cells in 96-well plates are treated with the different drugs and then incubated in 100 µl of culture medium containing 10 µl of an MTT stock solution (5 mg/ml) for 4 h at 37°C according to Mosmann (1983). Following the incubation, 100 µl acid-isopropanol (0.04 N HCl in isopropanol) is added to the wells and incubated overnight at room temperature. The color changes are recorded at 540 nm on a microplate reader. To exclude the disturbance of precipitates in some samples, the samples are centrifuged and only the supernatants are read. For each experiment, a standard curve is generated by measuring the relationship of absorbance to a series of viable cell numbers.

Neutral Red Uptake Assay

Neutral red is prepared as a 1% stock solution in distilled water and diluted to 0.035% in HBSS immediately before each experiment. The cells are treated with the drugs and then stained with 0.1 ml of 0.035% neutral red for 30 min (Parish and Müllbacher 1983). The stain is discarded and the cells are washed twice in HBSS before the addition of 200 µl/well of acidified alcohol solution (50%, v/v, ethanol/water, containing 0.5% acetic acid). After a 2 h incubation period at room temperature, the color changes are measured in a microplate reader.

Colony-Forming Efficiency Assay

The cells are seeded into 6-well plates and incubated in culture medium containing 0.02 to 5 mg/ml of individual drugs for 8 days. Cells are then fixed in 10% formalin and stained with 1% aqueous crystal violet (Sundqvist et al. 1989). Colonies formed on each well are counted (crystal violet stains cell nuclei) and compared with those formed on drug-free wells.

EVALUATION

Data are expressed as mean ± standard error. A one-way analysis of variance followed by Scheffe's post hoc test is used to test the significance between control and drug-treated samples. Differences are considered significant at $P < 0.05$.

MODIFICATIONS OF THE METHOD

Buchan et al. (1993) used cultured human antral epithelial cells enriched for D cells to study the effect of cholecystokinin and secretin on somatostatin release.

J.3.3
Gastric Motility

J.3.3.1
Measurement of Intragastric Pressure in Rats

PURPOSE AND RATIONALE

Gastric motor activity can be measured by recording intragastric pressure in anesthetized rats (Holzer 1992).

PROCEDURE

Sprague-Dawley rats of either sex weighing 220–240 g are deprived of food for 20 h prior experimentation but are allowed free access to tap water. After induction of anesthesia by i.p. injection of phenobarbital sodium (0.92 mmol/kg), the trachea is cannulated to facilitate spontaneous breathing. The left carotid artery is cannulated and connected to a pressure transducer to monitor mean arterial blood pressure. The left jugular vein is cannulated for i.v. injection of drugs and for continuous infusion of physiological saline at a rate of 0.6 ml/h to avoid dehydration of the animals. Intragastric pressure is measured by a catheter (outer diameter 1.9 mm) passed down to the stomach via the esophagus. The position of the catheter tip in the corpus region is verified at the end of each experiment. The catheter has two side holes in its tip segment and is continuously perfused with physiological saline at a rate of 0.6 ml/h. To record intragastric pressure, the catheter is connected to a pressure transducer.

EVALUATION

The gastric motor effect is quantitated by calculation of the area under the curve versus baseline intragastric pressure, measured immediately before injection of the stimulant (e. g., neurokinin A). To test inhibitors, the area under the curve after the stimulant is set as 100% and the effect of application of the inhibitor with the stimulant is calculated as percentage.

MODIFICATIONS OF THE METHOD

Lotti et al. (1986) described a simple mouse assay for the *in vivo* evaluation of cholecystokinin antagonists which is based on visual determination of the gastric emptying of a charcoal meal.

J.3.3.2
Isolated Smooth Muscle Preparation of Guinea Pig Stomach

PURPOSE AND RATIONALE

Boyle et al. (1993) described a novel smooth muscle preparation from the guinea pig stomach for characterization of CCK receptors by use of selective antagonists.

PROCEDURE

Adult male guinea pigs weighing 330–400 g are sacrificed and the stomach rapidly removed. The fundus is discarded and the stomach is opened along the

greater curvature, pinned on a Petri-dish with the mucosa pointing up. The mucosal and submucosal layers are removed by dissection to reveal the underlying smooth muscle layer. Strips of circular muscle (2 × 25 mm) from the corpus region of the stomach are obtained by cutting inwards, following the striations of the lesser curvature. Muscle strips are mounted in siliconized 3 ml organ baths containing Krebs-Henseleit solution. The buffer is modified to include 5 µM indomethacin. The solution is maintained at 37°C and continuously gassed with a mixture of 95% O_2/5% CO_2. Isometric contractile responses are measured with force-displacement transducers (e. g., Grass FT.03) and recorded on a polygraph (e. g., Mark VII Graphtec Linearcorder).

Tissues are placed under 1 g tension and allowed to equilibrate for 30 min after which time they are contracted with a submaximal dose of carbamylcholine (10 nM). Using a 12 min dose cycle, concentration-response curves are established for agonists, e. g., gastrin, pentagastrin, CCK and CCK-analogues. For studies with antagonists, the tissues are exposed to antagonists for 15 min before re-exposure to agonists. The addition of 5 µM indomethacin removes the spontaneous activity due to the inherent myogenic tone existing in the tissue, but leaves the responses to the agonists unaffected.

EVALUATION

Contractile responses to exogenously applied agonists are expressed as absolute changes in tension and are transformed as a percentage of the maximal response achieved for that agonist in order to obtain potency values. EC_{50} values are obtained graphically for individual concentration-response curves. Responses to agonists in the presence of antagonists are expressed as a percentage of the control maximum response obtained in the same tissue preparation. Agonist concentration-response curves in the absence and presence of increasing concentrations of antagonists are obtained. The method of Arunlakshana and Schild (1959) is used to provide Schild plots of the data, and to obtain affinity constants for the antagonists.

MODIFICATIONS OF THE METHOD

Riazi-Farzad et al. (1996) described an improved preparation of the **isolated rat stomach fundus strip** based on the finding that the majority of the contractile response to 5-HT and carbachol was present in the left ventral longitudinal quartile of the tissue.

Van Nueten et al. (1978), Reyntjens et al. (1984), Schuurkes et al. (1985), Kishibayashi and Karasawa (1998) used an **isolated gastroduodenal preparation of the guinea pig**. After ligation of the esophagus, the stomach was filled with 20 ml saline and suspended in 200 ml of oxygenated Krebs-Henseleit solution, maintained at 37°C. The duodenum was cannulated and connected with an ultrasonic transit time transducer to record changes in intraluminal volume and with a bottle of saline to ensure constant hydrostatic pressure of 6 cm H_2O. Spontaneous phasic activity was always present on the stomach and recorded as rhythmic changes in gastric volume. Gastric peristaltic waves either stopped at the pylorus or were propagated to the duodenum. Antroduodenal coordination was quantified as the relative number of antral waves that were propagated to the duodenum. After 30 min stabilization, drugs were added in varying concentrations and the effects followed for 30 min. Three parameters were determined: (1) contractile amplitude, expressed as milliliters of expelled volume; (2) frequency, measured as number of contractions per minute; (3) percentage of antroduodenal coordination.

J.3.4 Absorption

J.3.4.1 Measurement of Gastric Absorption of Drugs in Rats

PURPOSE AND RATIONALE

Although the stomach is not the prime absorptive site of drugs, the absorption of some drugs from the gas-

tric mucosa has been established (Doluisio et al. 1969; Welling 1977). Worland et al. (1983) described an *in situ* gastric pouch technique for direct measurement of the gastric absorption of drugs in the rat.

PROCEDURE

Male Wistar rats weighing 220–300 are anesthetized by i.p. injection of 50 mg/kg sodium pentobarbital. A cannula is placed in the jugular vein for administration of heparinized saline (3000 IU/kg) and whole blood replacement during the experiment. The replacement blood is collected from heparinized donor rats immediately prior to the experiment. Another cannula is placed into the carotid artery of the experimental animal for the collection of systemic blood samples. A midline incision is made in the abdominal wall. Double ligatures are placed on the superior epigastric vessels and transverse incisions are made between the ligatures. The branches of the right gastroepiploic veins and arteries are then ligated using surgical silk and the gastrohepatic ligament between the stomach and the posterior surface of the left hepatic lobe and the caudal hepatic lobe is separated. The gastrosplenic mesentery is also severed. A strip of gauze is employed to keep the liver lobes out of the surgical field. Using appropriately sized surgical silk, double ties are placed around the short gastric vessels and the esophagus, which are then severed between the ties. The pylorus and pyloric vessels are then ligated and an incision is made in the forestomach to allow the removal of gastric contents.

The pouch is then rinsed with warm saline until clear and the remaining fluid is removed using an adsorbent tissue. A Luer adapter modified from a three-way tap is tied into the incision to enable drug administration via a syringe. The gastric pouch is then transposed to the right of the animal exposing the left gastric vein. The vein is cannulated above the junction with the lienal (splenic) vein using a 21-gauge needle connected to a 15-cm length of polyethylene tubing (i.d. 0.75 mm, o.d. 1.45 mm). A small Oxford clamp with foam rubber insets is employed to prevent dislocation of the cannula during the changing of the sample vials. The drug is administered into the stomach and blood draining from the gastric pouch is collected over timed intervals. To determine the volume (ml) of blood collected, the venous effluent is weighed and hematocrit (HCT) readings are taken for each sample and converted to units using the formula:

$$\text{Volume (ml)} = \frac{\text{mass blood collected (g)}}{\text{HCT}\times\text{blood celldensity}+(1-\text{HCT})\times\text{plasma density}} .$$

Rat blood cell and plasma density measurements are obtained from five determinations from four rats, blood samples being separated at 3000 *g* for 10 min. Samples from the gastric pouch are kept on ice until the plasma can be separated by centrifugation at 3000 *g* for 10 min and the plasma frozen until assay.

Blood replacement is delivered at a rate of 0.7 ml/min from a gently oscillating reservoir using a peristaltic pump.

The compound to be tested is administered in a volume of 0.5 ml to the gastric pouch. Plasma levels are determined with a method specific for the compound under investigation. Plasma samples are collected at 4 min intervals over a period of 30–60 min. At the end of the experiment, the fluid in the gastric pouch is collected for determination of the dose remaining in the stomach.

EVALUATION

Mean values ± standard deviation of plasma concentration are calculated from 4–6 experiments and plotted versus time to demonstrate the absorption profile.

J.3.5 Antacid Activity

J.3.5.1 Evaluation of Antacids

PURPOSE AND RATIONALE

Antacids have been used for the treatment of gastroduodenal ulcerations since a long time (Konturek 1993). The main action of antacids is to reduce the acidity of the gastric content through neutralization and increasing intragastric pH. Since pepsin is not active at higher pH levels, antacids reduce peptic activity (Goldberg et al. 1968) and may also adsorb pepsin (Sepelyak et al. 1984). Binding of bile salts (Clain et al. 1977) by antacids may also have a beneficial influence on peptic ulcer disease. Most antacids contain magnesium and aluminum hydroxide, in some cases also calcium carbonate and sodium bicarbonate. The acid-neutralizing potency can be measured *in vitro*.

PROCEDURE

0.1 M HCl is added to the antacid to be tested. The acid neutralizing capacity is defined as the amount of 0.1 M HCl that can be added to a liquid antacid without reducing the pH of the mixture below pH 3.0. The determination of the acid neutralizing capacity of antacid tablets is performed *in vitro* by stirring a mixture of crushed tablets and water. The time at which all antacid is consumed is much longer for antacid in tablet as compared with the same amounts of antacid in liquid form. Magnesium hydroxide is very insoluble in water, but is readily soluble in hydrochloric acid. In combined preparations, the magnesium hydroxide reacts first to produce an almost immediate neutralizing effect and an increase of the pH within a few minutes. Aluminum oxide, on the other hand, has a weaker antacid activity, reacting more slow with acid (Fordtran et al. 1973; Richardson et al. 1988).

EVALUATION

In vitro titration curves of 0.1 M HCl with 5 ml liquid antacid or one tablet are measured over 3 h and compared with the standard.

CRITICAL ASSESSMENT OF THE METHOD

Acid neutralizing potency may be not the only factor which contributes to the therapeutic effect of antacids. Damage and protection in the stomach are essentially represented by acid secreted by the parietal cells and by bicarbonate released by the surface epithelial cells and mucous neck cells. Among various neurohumoral factors most important in the bicarbonate-secretion appear the prostaglandins, mainly of the E series. Mucosal bicarbonate secretion may be stimulated through the activation of prostaglandins by aluminum hydroxide containing antacids. Aluminum containing antacids were found to protect against mucosal damage due to topical irritants and against stress or aspirin induced lesions. Gastroprotection of aluminum-containing antacids has been attributed to the biological activity of nitric oxide interacting with mucosal prostanoids on the mucosal microcirculation. Therefore, these antacids were found to be active in various experimental ulcer models and to exert cytoprotective activity against ethanol induced gastric injury in rats (Szylenyi et al. 1983; Domschke et al. 1986; Hollander et al. 1986; Konturek et al. 1989, 1992; DiJoseph et al. 1989; Vergin and Kori-Lindner 1990). Konturek (1993) reported that aluminum hydroxide containing antacids protect growth factors, involved in the healing of ulcers, against acid degradation.

J.3.6 Inhibition of HCl Secretion

J.3.6.1 Anticholinergic Activity

J.3.6.1.1 General Considerations

Gastric motility and tonus, as well as gastric secretion are stimulated by cholinergic impulses. Anticholinergic compounds, such as the *Belladonna* alkaloid atropine, were the first drugs used in treatment of gastric ulcers. The doses that are necessary to reduce acid secretion also decrease mucus secretion and cause side effects, such as dry mouth, increase in heart rate and ocular disturbances. Inhibitors of specific muscarinic

receptors responsible for gastric acid secretion were found. Receptors for acetylcholine which play a major role in central and peripheral transmission have been studied extensively (Karlin et al. 1976; Hulme et al. 1990; Jones et al. 1992; Kebabian and Neumeyer 1994).

J.3.6.1.2 Acetylcholine Receptor Binding

PURPOSE AND RATIONALE

The search of specific muscarinic antagonists for inhibition of gastric acid secretion lead to the discovery of pirenzepine, a tricyclic compound, originally tested as psychotropic agent. This compound has a greater gastrointestinal selectivity than other muscarinic antagonists (Carmine and Brogden 1985; Longdong 1986). The activity of pirenzepine has been localized to M_1 receptors.

This, and the involvement of acetylcholine in many physiological processes, has stimulated the research on the various types of muscarinic receptors. At present, 5 types have been described but further subdivisions can be envisaged (Hulme et al. 1990; Jones et al. 1992; Kebabian and Neumeyer 1994; Caulfield and Birdsall 1998; Alexander et al. 2001; Eglen et al. 2001; Ma et al. 2004). The subtypes of muscarinic receptors have been characterized by the use of organs with a predominant subtype receptor population, e. g., rabbit vas deferens stimulated with electric impulses for M_1, electrically stimulated left atria from guinea pigs for M_2, and longitudinal smooth muscle preparations of guinea pig ileum or salivary gland of the rat for M_3 (Doods et al. 1987; Lambrecht et al. 1993), or by the use of selective antagonists (Pitschner et al. 1989; Richards 1990; Svensson et al. 1992,) or agonists (Lambrecht et al. 1993). Further characterization has been achieved by studies of the transduction mechanisms (Brown and Brown 1984; Brown et al. 1985; Parekh and Brading 1992) and by voltage clamp techniques (Bernheim et al. 1992). The five muscarinic receptor subtypes are referred to as M_1–M_5. The odd-numbered receptors (M_1, M_3, M_5) couple efficiently, through $G_{q/11}$, to activation of phospholipase C, which initiates the phosphatidyl-inositol turnover response. The even-numbered muscarinic receptors (M_2-M_4) inhibit adenylyl cyclase activity via activation of the G_i class of G proteins.

The genes for the muscarinic acetylcholine receptor subtypes have been cloned and expressed in Chinese ovary hamster cells (Buckley et al. 1989; Dörje et al. 1991) or in fibroblasts (Kashihara et al. 1992).

Many organs, e. g., rat brain (Luthin and Wolfe 1984; El-Fakahani et al. 1986) have been used for studies on acetylcholine receptor subtypes. Only the method using Chinese ovary hamster cells is presented here.

PROCEDURE

Preparation of Plasmid DNA

The coding sequences of the m1, m2, m3, m4, and m5 receptors are derived from a human genom library. The cDNAs are inserted into the Okayama/Berg pCD or pCD-PS expression vector (Bonner et al. 1987, 1988; Buckley et al. 1989). Plasmid DNA is isolated by two sequential density gradient centrifugations through CsCl (Maniatis et al. 1982).

Cell Culture

Chinese hamster ovary cells are incubated at 37°C in a humidified atmosphere (5% CO_2) as a monolayer culture in Dulbecco's modified Eagle's medium supplemented with 10% fetal calf serum, 100 units/ml each of penicillin G and streptomycin, and 4 mM glutamine.

Transfection Procedures

Cells are transfected using a modified calcium phosphate procedure (Chen and Okayama 1987) involving the use of cotransfected pcDneo as a selectable marker. Selection with the neomycin analog G 418 (600 µg/ml; Gibco NY) is started 72 h after transfection and continued for 2–3 weeks. Media are changed every 3 days. Clonal cell lines are obtained by single cell cloning and assayed for [^{3}H]NMS (N-methylscopolamine hydrochloride) binding capacity.

Membrane Preparation

Cells are grown to about 80% confluency, scraped into ice-cold binding buffer and homogenized for 30 s using a Brinkman homogenizer (setting 5). Membranes are pelleted at 16,000 *g* for 15 min and rehomogenized. Membrane protein is determined using a Bio-Rad protein assay dye reagent. Membranes are stored frozen at –80°C before use.

Radioligand Binding Studies

All membranes, drugs, and radioligands are made up in binding buffer consisting of 25 mM sodium phosphate (pH 7.4) containing 5 mM magnesium chloride. The assays are performed in 1 ml total volume. Final membrane concentrations are: m1 6 µg/ml; m2 10 µg/ml; m3 5 µg/ml; m4 3 µg/ml; and m5 4 µg/ml. In [^{3}H]NMS saturation experiments, 8–10 different concentrations

of the radioligand (2–1400 pM) are employed. For displacement experiments, [^{3}H]NMS in a concentration of 150 pM and 10 different concentrations of the displacer are used. Specific binding is defined as the difference in [^{3}H]NMS binding in the absence and presence of 1 μM atropine. Alternatively [^{3}H]pirenzepine is used. Incubations are carried out at 22°C for 3 h. Assays are terminated by filtration through a Brandell cell harvester onto Whatman GF/C filters. Membranes are washed three times with 5 ml of ice-cold binding buffer before being dried. They are transferred to 10 ml of scintillant (New England Nuclear Aquasol) and counted in a LKB β-counter.

EVALUATION

Data from direct binding experiments are fitted to the equation:

$$\alpha = (B_{\max} x^n/k)/(1 + x^n/k)$$

to derive the Hill coefficient n and to:

$$\alpha = (B_{\max} x/K_D)/(1 + x/K_D)$$

to obtain the dissociation constant K_D and the total number of binding sites $B_{\max}$ (α = [^{3}H]NMS specifically bound; x = [^{3}H]NMS concentration).

Data from displacement experiments are fitted to the equation:

$$\%[^3\text{H}]\text{NMS bound} = 100 - [100x^n/k/(1 + x^n/k)]$$

to obtain the Hill number n and to:

$$\%[^3\text{H}]\text{NMS bound} = 100 - [100 \times IC_{50}/(1 + x/IC_{50})]$$

to derive the IC_{50} value (x = concentration of the cold inhibitor).

K_i values are calculated by the method of Cheng and Prussoff (1973):

$$K_i = IC_{50}/(1 + L/K_D)$$

where L is the concentration of the radioligand, IC_{50} is the concentration causing 50% inhibition of the specific radioligand binding and K_D the dissociation constant of the radioligand receptor complex. Data are analyzed by a non-linear least-squares curve fitting procedure.

Results are expressed as mean values ± SEM of n experiments. Statistical significance is assessed using Student's t-test or Scheffé's method. $P < 0.05$ is accepted as being significant.

MODIFICATIONS OF THE METHOD

The selectivity towards muscarinic receptor subtypes can be tested by radioligand binding assays using either selective ligands or tissues possessing only one receptor subtype (Giachetti et al. 1986; Pitschner et al. 1989; Bickel et al. 1990). M_1-receptors from bovine cortex which has also M_2-and M_3-receptors are tested with the M_1-selective radioligand ^{3}H-pirenzepine. M_2-receptor from porcine heart possessing only this receptor type can be tested with the unselective ligand ^{3}H-N-methylscopolamine. M_3-receptors from rat submaxillary gland are likewise labelled with the unselective ligand ^{3}H-N-methylscopolamine, because this subtype is present predominantly in this tissue.

Measurement of the contractions of rabbit vas deferens after electrical stimulation was used to study the effects of prejunctional M_1 heteroreceptors and postjunctional M_2 receptors (Eltze et al. 1988; Dörje et al. 1991), of guinea pig atria for M_2-receptors and of guinea-pig ileum for M_3-receptors (Lambrecht et al. 1989, 1995). Cardiac muscarinic $M_{2\alpha}$ receptors have been discussed (Wess et al. 1988).

Coexistence of M_2 and M_3 subtypes of muscarinic receptors in canine colonic circular smooth muscle was reported by Zhang et al. (1991).

Investigations on the nature of muscarinic receptors present on parietal cell membranes using binding studies and polymerase chain reaction amplification or parietal cell messenger RNA revealed the existence of only a M_3 receptor responsible for acid secretion (Kajimura et al. 1992).

Spalding et al. (2002) described a novel muscarinic agonist, AC-42, and demonstrated its selectivity for the M_1 muscarinic subtype.

The phenotypes of knockout mice or the responses lost in these animals were used to characterize the properties of the subtypes of muscarinic receptors (Birdsall et al. 2001). Champtiaux et al. (2003) investigated the subunit composition of functional nicotinic receptors in dopaminergic neurons with knockout mice.

Owicki et al. (1990, 1992), McConnell et al. (1991, 1992) used a special apparatus, the 'cytosensor microphysiometer' which measures the rate of proton excretion from cultured cells. Chinese hamster ovary cells were transfected with the m_1 muscarinic acetylcholine receptor. Sequential addition of increasing doses of carbachol every 2.5 min induced an increasing acidification allowing the determination of an EC_{50} value. The effect was antagonized by atropine.

J.3.6.2 H_2-Antagonism

J.3.6.2.1 General Considerations

Three classes of histamine receptors with subtypes for the H_2 receptor have been identified by selective antagonists (Haaksma et al. 1990; Hill 1990; West et al. 1990; Clapham and Kilpatrick 1992). H_2-antagonists inhibit competitively the interaction of histamine with H_2-receptors responsible for acid secretion in the stomach. Although H_2-receptors are present in many tissues, including vascular and bronchial smooth muscle and the right atrium, H_2-antagonists interfere remarkably little with physiological functions other than gastric secretion.

The H_2 receptor was reported to be spontaneously active in transfected CHO cells (Smit et al. 1996). Based on this concept, the H_2 antagonists were reclassified; cimetidine, ranitidine and famotidine are in fact inverse agonists, whereas burimamide acts in this model system as a neutral agonist.

J.3.6.2.2 Histamine H_2-Receptor Binding

PURPOSE AND RATIONALE

Histamine receptors have been classified on the basis of pharmacological analysis (Hill et al. 1997). Histamine exerts its action via at least four receptor subtypes. The H_1 receptor couples mainly to $G_{q/11}$, thereby stimulating phospholipase C, whereas the H_2 receptor interacts with G_s to activate adenylyl cyclase. The histamine H_3 and H_4 receptors couple to G_i proteins to inhibit adenylyl cyclase, and to stimulate MAPK.

Histamine H_2-receptor binding can be determined using homogenates from guinea pig cerebral cortex and ^{3}H-tiotidine as labeled ligand (Gajtkowski et al. 1983; Norris et al. 1984; Hill 1990). Using the polymerase chain reaction, the gene encoding the histamine H_2 receptor has been cloned (Gantz et al. 1991).

PROCEDURE

Preparation of Membranes

Guinea pigs of either sex weighing 400–600 g are sacrificed by exsanguination and the brains rapidly removed. The cerebral cortex is dissected away from the rest of the brain and homogenized in 50 mM sodium-potassium buffer, pH 7.4, using a Potter homogenizer. The homogenate is then centrifuged at 50,000 *g* for 10 min at 4°C. The resulting pellet is washed three times by being resuspended in phosphate buffer followed by recentrifugation. The pellet is finally resuspended in phosphate buffer, pH 7.4, at a protein concentration of 5 mg/ml.

Assay

An aliquot of 100 µl of the homogenate is incubated with 2 nM ^{3}H-tiotidine and varying concentrations of competing test substance, in triplicate, in a total volume of 250 µl, for 30 min at room temperature. The reaction is stopped by the addition of 2 ml of ice-cold phosphate buffer and immediately filtered under reduced pressure through Whatman GF/B glass-fiber filters, followed by 3 times 3 ml washes with room temperature buffer.

Radioactivity is determined by allowing the filters to remain for at least 18 h in NE 260 scintillator (Nuclear Enterprise), followed by liquid scintillation counting.

EVALUATION

K_i values (µM) are calculated for displacement of specific H_2-binding from the relationship

$$K_i = IC_{50}/(1 + [L]K_d^{-1})$$

where IC_{50} is the concentration of the drug required for 50% inhibition of specific binding, [L] is the concentration of ^{3}H-tiotidine in the assay and K_d is the dissociation constant for ^{3}H-tiotidine.

Data can be analyzed using a computer program as described by McPherson (1985).

MODIFICATIONS OF THE METHOD

Hirschfeld et al. (1992) performed photoaffinity labeling studies of the H_2 receptor using the radioactive probes [^{125}I]iodoaminopotentidine and its photolabile azido analogue [^{125}I]iodoazidopotentidine.

Martinez-Mir et al. (1990) studied the distribution of histamine H_1, H_2, and H_3 receptors in postmortem human and rhesus monkey brain by receptor autoradiography using [^{125}I]iodobolpyramine, [^{125}I]iodoaminopotentine, and [^{3}H](R)α-methylhistamine as ligands to label H_1, H_2, and H_3 receptors, respectively.

Traiffort et al. (1992) used [^{125}I]iodoaminopotentidine for pharmacological characterization and auto-radiographic localization of histamine H_2 receptors in human brain.

J.3.6.2.3 H_2-Antagonism in Isolated Guinea Pig Right Atria

PURPOSE AND RATIONALE

H_2-antagonism can be determined in isolated guinea pig right atria which contain predominantly H_2-receptors. Compounds that inhibit the positive chronotropic effect mediated by histamine H_2-receptors in the isolated right guinea pig atrium (Reinhardt et al. 1974) can be classified as specific histamine H_2-antagonists. The test can be used as screening method for H_2-antagonists.

PROCEDURE

Male guinea pigs, e. g., Hartley strain, are sacrificed by exsanguination. The right atria are dissected and suspended at 0.7 g tension in a 25 ml organ bath with Tyrode's solution bubbled with carbogen (5% CO_2/95% O_2) at 38°C. After a stabilization period of 30 min, the contractions are recorded on a polygraph with a force-displacement transducer through a strain gauge. Cumulative concentration-response curves are obtained after sequential additions of histamine (10^{-7} to 10^{-4} M) in the absence of test drugs and the equilibration of test drugs or the standard (cimetidine).

EVALUATION

pA_2 values and relative potencies are calculated by a Schild plot (Arunlakshana and Schild 1959).

MODIFICATIONS OF THE METHOD

Hattori et al. (1990) studied the inotropic, electrophysiological and biochemical responses to histamine in rabbit papillary muscles and found evidence for coexistence of H_1- and H_2-receptors. Histamine increases force of contraction and decreases action potential duration in rabbit papillary muscles. H_2-antagonists antagonize the histamine-induced decrease in action potential duration, however, are less effective in antagonizing the increase in force of contraction produced by histamine. The positive inotropic response to histamine is abolished by sequential addition of a H_1-antagonist.

J.3.6.2.4 H_2-Antagonism in Isolated Rat Uterus

PURPOSE AND RATIONALE

Histamine inhibits spontaneous and electrically stimulated contractions of rat uterus horns. This effect can be antagonized by H_2-, but not by H_1-antagonists.

PROCEDURE

Adult, virgin Wistar rats weighing 180–200 g are used. By microscopic examination of vaginal smears, the stage of the estrus cycle is determined. Only animals in natural proestrus or metestrus are chosen. After sacrifice, the two uterus horns are removed and placed in modified de Jalon solution at room temperature and cleaned of mesenteric fat and connective tissue. Paired preparations from the same animal are used in parallel experiments. Two segments, about 2 cm in length, are taken from the ovarian end of the uterus horns and mounted separately on Perspex organ holders between two steel electrodes arranged at the end of the muscle. The organs are immediately superfused with modified de Jalon solution at 35°C at a rate of 2–3 ml/min being continuously gassed with air. Basal muscle tension is maintained at 0.5 g. The contractions of the preparations are recorded isometrically with a force-displacement transducer linked to a multipen recorder. The intrinsic rhythm of spontaneous and regular con-

tractions appears within 5–10 min after mounting the tissues in their holders.

Organs showing a frequency of only one contraction every two min or less are electrically stimulated with square wave impulses of 2 ms duration for 1 s every 1 min at 10 V and 80 Hz with a suitable stimulator. The organs are linked via a four-way stopcock to a set of reservoirs of modified de Jalon solution containing different concentrations of agonist and test substance. The preparations are superfused for 20–30 min with nutrient solution until mechanical activity of the uterus horns is stabilized in frequency and contraction height before addition of drugs.

The time interval between application of drugs is 15–20 min, the time of contact of the drugs with the uterus segments is about 4–5 min, being interrupted as soon as the contractions of the muscles reach a minimum. Logarithmic dose-response curves for histamine are constructed from mean effects of single doses, taking the average amplitude of 5 contractions immediately preceding the addition of histamine as 100% control activity. In experiments involving antagonists, a standard dose of histamine is used giving a response within the linear region of the log dose-response curve and is set as 100%. Reduction of histamine-induced inhibition is studied by superfusing increasing concentrations of antagonists in addition to the standard dose of histamine.

EVALUATION

Results are expressed in percentage of the reversal of initial depression of contraction height after histamine and plotted against –log mol/l concentration of the antagonist. pA_2 values are calculated according to Ariëns and van Rossum (1957).

J.3.6.2.5 Activity at Histamine H_1- and H_2-Receptors In Vivo

PURPOSE AND RATIONALE

Owen and Pipkin (1985) described a technique that allows simultaneous and quantitative assay of the action of agonists and antagonists at histamine H_1- and H_2-receptors in anesthetized guinea pigs. The principle of the technique is based on H_1-receptor caused bronchoconstriction and H_2-receptor caused tachycardia.

PROCEDURE

Guinea pigs of either sex weighing about 500 g are anesthetized with 90 m/kg sodium pentobarbitone i.p. The trachea is cannulated to permit artificial respiration. Blood pressure is measured from a catheter tied into one carotid artery. Catheters are tied into one jugular and one femoral vein for the administration of drugs.

Airways resistance is measured using a modification of the Konzett–Rössler technique. By means of a small animal respiration pump, the lungs are inflated at a rate of 40 breaths/min. The inflow arm of the circuit includes a side-arm, the outlet of which is placed below 12 cm of H_2O. The volume of air used in the study has to be that which fills the lungs at a pressure of 12 cm H_2O, selected by adjusting the volume until no air escapes through the H_2O trap each time the lungs are filled. The side-arm is then clamped, and the animal is respired with the selected volume for the duration of the study. Airways resistance to inflow is measured using a pressure transducer connected to a second arm of the inflow circuit. Resistance is proportional to the maximum pressure required to inflate the lungs. Inflow pressure is registered on an electronic recorder.

Heart rate is measured from the blood pressure pulse using an instantaneous rate meter and is registered on an electronic recorder.

Intravenous injection of histamine causes simultaneously bronchoconstriction and tachycardia. The threshold dose needed to cause tachycardia may be less than that for bronchoconstriction, but both responses will be apparent over the dose range 1×10^{-8} to 5×10^{-7} mol/kg.

EVALUATION

Agonists

Dose-response curves for agonists compared to the dose-response curve for histamine for both parameters, bronchoconstriction and tachycardia, allow the calculation of potency ratios. Specific H_1-receptor agonists are more potent to cause bronchoconstriction than tachycardia, whereas H_2-agonists provoke tachycardia but are less active or inactive causing bronchoconstriction.

Antagonists

To evaluate antagonists, various doses of the test compound are injected i.v. and dose-response curves of

histamine are established for both parameters to be compared with the dose-response curve of histamine without pretreatment. From the ratios of shift to the right dose-response curves for both parameters can be established. These are similar for mixed antagonists, but a definitively higher potency is shown for H_1-antagonists in bronchoconstriction and a higher potency for H_2-antagonists in tachycardia.

J.3.6.2.6 Inhibition of Histamine Stimulated Adenylate Cyclase from Gastric Mucosa

PURPOSE AND RATIONALE

The *in vitro* potencies of H_2-antagonists can be evaluated using determinations of adenylate cyclase activity in membrane preparations of guinea pig mucosa after stimulation with histamine.

PROCEDURE

Preparation of Membranes

Guinea pigs of either sex weighing 400–600 g are sacrificed. The fundic portion of the stomach is rapidly removed. Food particles are washed away with ice-cold 50 mM Tris buffer, pH 7.4, containing 4 mM EDTA and 0.25 M sucrose (homogenization buffer). The tissue is stretched, mucosal side up, on a glass Petri dish supported on ice and the mucosal layer is scraped off the muscle layer using a scalpel blade. The mucosal scrapings are transferred to 10 ml ice-cold homogenization buffer in a glass homogenization tube, and homogenized using an Ultra-Turrax homogenizer followed by four strokes using a Potter Teflon homogenizer. The resulting suspension is centrifuged at 700 *g* for 10 min at 4°C. The supernatant is discarded, and the pellet resuspended in 50 mM Tris buffer, pH 7.4, containing 4 mM EDTA followed by a further period of centrifugation. The resulting pellet is finally resuspended in Tris/EDTA buffer at a protein concentration of 2.4 mg/ml as determined by the method of Lowry et al. (1951) using bovine serum albumin as standard.

Stimulation of Adenylate Cyclase

Adenylate cyclase activity is measured according to Hegstrand et al. (1976). Aliquots (120 µg) of fundic mucosal homogenate are incubated in 100 mM Tris buffer, pH 7.8, containing 0.6 mM EGTA (ethylene-glycol-bis-(β-aminoethyl ether)-N,N′-tetra-acetic acid), 1 mM IBMX (isobutyl-methyl xanthine), 2 mM $MgCl_2$, 0.1 mM GPT (guanosine triphosphate), histamine at various concentrations between 0.1 µM and 100 µM and the compound under investigation at varying concentrations between 0.1 µM and 1 mM for 10 min at 0°C. The reaction is initiated by the addition of 1 mM ATP followed by a 10 min incubation at 30°C. The reaction is terminated by placing the assay tubes in a boiling water bath for 3 min. After cooling, 40 mg of Alumina 90 (E. Merck, 70–230 mesh) are added to each tube prior to mixing and centrifugation at 700 *g* for 15 min at 4°C.

Assay of Cyclic AMP

The cyclic AMP content of each sample is determined according to Brown et al. (1971) using ^{3}H-cyclic AMP in a competitive protein binding assay. Fifty µl aliquots from the adenylate cyclase assay are incubated with 50 µl of ^{3}H-cyclic AMP (14 nC at a specific activity of 62 Ci/mmol) and 100 µl of previously prepared cyclic AMP binding protein at 4°C. The bound and free ^{3}H-cyclic AMP are separated by the addition of 100 µl of charcoal reagent (2 g bovine serum albumin, 2.5 g Norit GSX charcoal in 100 ml of 50 mM Tris buffer, pH 7.4, containing 4 mM EDTA), followed by mixing and centrifugation at 1000 *g* for 15 min. Two hundred µl aliquots of the supernatant are decanted into scintillation vials containing 10 ml of NE 260 scintillator. Radioactivity is determined by liquid scintillation counting.

EVALUATION

Results are calculated from a standard curve using cyclic AMP as the standard. From these data IC_{50} values (µM) are derived.

J.3.6.3
H^+/K^+-ATPase (Proton Pump) Inhibition

J.3.6.3.1
General Considerations

The parietal cell of the stomach is activated by three major stimuli: histamine, acetylcholine, and gastrin. In addition to the direct action of gastrin and acetylcholine on the parietal cell, these two agents may release histamine from a histamine storage in the gastric mucosa. In this manner, histamine would act as the final mediator of acid secretion. One of the first events leading to acid secretion is a massive membrane transformation that occurs in the parietal cell. When the cell is stimulated, the tubulovesicles in the cytoplasma of the cell fuse and form an expanded secretory canaliculus in the apical membrane where the enzyme H^+/K^+-ATPase is located.

In this way, the ultimate mediator of acid secretion in the stomach is the proton pump H^+/K^+-ATPase which transports hydrogen in exchange for potassium. The rat stomach H^+/K^+-ATPase has been cloned by Shull and Lingrel (1986). Development of specific inhibitors of this enzyme is an approach to suppress acid secretion and ulcer formation since ulcers only exist in acidic medium.

Alderuccio et al. (1993) described an experimental autoimmune gastritis in BALB/c mice as a $CD4^+$ T cell-mediated organ-specific autoimmune disease induced by neonatal thymectomy. Transgenic expression of the gastric H^+/K^+-ATPase β subunit specifically prevented the onset of this form of autoimmune gastritis.

J.3.6.3.2
H^+/K^+-ATPase Inhibition in Membrane Vesicles of Stomach Mucosa

PURPOSE AND RATIONALE

Several H^+/K^+-ATPase inhibitors contain a sulfhydryl group. At lower pH-values the compounds are protinated and rearrange to a sulphenic acid and a sulphenamide, that react with sulfhydryl groups in the enzyme. Therefore, the *in vitro* assays are performed both at neutral and at acidic pH levels.

PROCEDURE

Membrane vesicles containing H^+/K^+-ATPase are prepared from pig stomachs obtained from the local slaughter house (Ljungstrom et al. 1984). Pigs are fasted overnight before slaughter. The gastric mucosa of four stomachs is rinsed with cold saturated NaCl solution for 3–5 min. The superficial cells, cell debris plus the mucus are wiped off with the edge of a plastic ruler and with paper towels. The mucosa is scraped off. About 100 g scrapings are divided into portions of 10 g and homogenized in 0.25 M sucrose with seven strokes in a Potter-Elvehjem Teflon-glass homogenizer. The total volume is 600 ml which is centrifuged at 20,000 *g* for 40 min. The pellet is discarded. The supernatant is centrifuged at 75,000 *g* for 1 h. The resulting microsomal pellet is homogenized in 30 ml 0.25 M sucrose.

Aliquots of 15 ml are transferred to 100 ml centrifuge tubes and layered on top of step gradients, from the bottom comprising 25 ml 37% sucrose (w/v) and 45 ml 7.5% Ficoll (w/v) in 0.25 M sucrose. The tubes are centrifuged at 75,000 *g* for 1 h in a 6×100 ml ME angle rotor at 4°C. The gradient is then fractionated by pumping Fluoroinert 70 through a narrow tubing in a fractionating cap down to the bottom of the tube. Fractions are collected from top through a center hole in the fractionating cap. The yield of vesicles in a typical preparation is about 50–75 mg protein. In order to maintain a stable vesicular structure for a long period of time, the vesicles are frozen at –70°C under nitrogen. They can then be kept for several months without decrease of H^+/K^+-ATPase activity.

The ATPase activity is measured at 37°C as the release of inorganic phosphate (P_i) from ATP. The test drug and the standard (omeprazole) are pre-incubated in concentrations of 0.01 to 100.0 µM in enzyme containing buffers in parallel at pH 6.0 and 7.4 for 30 min at 37°C. Then, the medium of pH 6.0 is adjusted with

HEPES/Tris buffer to pH 7.4. The enzyme reaction is started by addition of nigericin and Tris/ATP. The total reaction volume is 1 ml, containing 20 µg vesicular protein, 4 mM $MgCl_2$, 10 mM KCl, 20 µM nigericin, 2 mM Tris-ATP, 10 mM HEPES and additionally 2 mM Pipes for the pre-incubation medium at pH 6.0.

After 4 min at 37°C, the reaction is stopped by the addition of 10 ml of 50% trichloroacetic acid. The denaturated protein is spun down and the P_i content is determined according to LeBel et al. (1978) based on the reduction of a phosphomolybdate complex by p-methylaminophenol sulfate in a copper acetate buffer or according to Carter and Karl (1982) based on the reaction of phosphomolybdate with the basic dye malachite green.

EVALUATION

IC_{50} values are calculated by probit analysis, whereby 0% corresponds to 4 mM Mg^{2+}-dependent and 100% to 4 mM Mg^{2+} plus 10 mM K^+-dependent ATP hydrolysis. IC_{50} values of the test compound at different pH values are compared with IC_{50} values of the standard. Statistical differences ($p < 0.05$) are calculated by Student's *t*-test.

MODIFICATIONS OF THE METHOD

Proton transport in gastric vesicles can be measured by acridine orange fluorescence quenching (Lee and Forte 1978; Beil et al. 1990). Membrane protein (0.12 mg) is incubated at 37°C in a volume of 2 ml containing: 10 mM Pipes/Tris buffer, pH 7.0 in the presence of 150 mM KCl, 2 mM $MgCl_2$, 2 mM ATP and 10 µM acridine orange. The pump reaction is started by the addition of valinomycine (ionophore for K^+). The decrease of fluorescence is studied at 530 mm as a measure for the intravesicular proton uptake.

CRITICAL ASSESSMENT OF THE METHOD

The pre-incubation period at the lowest possible pH of about 6 is used to initiate the acidic conversion of the test compound into its active principle. This reflects more the chemical instability of the test compound at neutral pH values than its effect during conditions of much higher acidity within the secretory cannaliculus of the parietal cell during acid secretion. Many chemically labile inhibitors are therefore very active in this test system. However, they do not cause an inhibition in more complex test systems and, therefore, are without any practical usefulness (Lindberg et al. 1990). Proton transport studies in gastric vesicles, using the acridine orange fluorescence quenching technique, where a pH gradient similar to *in vivo* conditions is formed (Lee and Forte 1978; Beil et al. 1990) are more suitable for studying the mechanism of action, acid-conversion, and structure-activity relationship of K^+/H^+-ATPase inhibitors (Herling and Weidmann 1994).

J.3.6.3.3 Effect of H^+/K^+-ATPase Inhibitors on Serum Gastrin Levels

PURPOSE AND RATIONALE

It is known from the H^+/K^+-ATPase inhibitor omeprazole that the total acid blockade initiates a gastric antral feed back mechanism resulting in an excessive hypergastrinaemia (Arnold et al. 1986; Creutzfeldt et al. 1986; Larsson et al. 1986) which is believed to cause diffuse endocrine cell hyperplasia, characterized as carcinoids, in the gastric corpus after 2 years of treatment in the rat (Ekman et al. 1985).

PROCEDURE

Groups of 10–15 female Wistar rats weighing 90–110 g are treated daily for 10 weeks with omeprazole (10 or 30 mg/kg p.o.) or the test compound or serve as controls. The compounds are suspended in potato starch mucilage (20 mg/ml) and administered in a volume of 2 ml/kg. On days 1–3, the rats receive the H^+/K^+-ATPase inhibitors by intraperitoneal injection in order to cause gastric acid inhibition and therefore to reduce the gastric acid degradation of subsequent oral doses. After treatment for 2, 4, 7, and 10 weeks, blood samples are collected under ether anesthesia by retroorbital puncture. Gastrin is determined by radioimmunoassay using a commercially available kit, e. g. Gastrin RIAKit II; Dainabot Co., Ltd. At the end of the study of 10 weeks, the animals are studied for their gastric acid output using the pylorus ligation (Shay technique).

EVALUATION

Serum gastrin levels are determined as pg/ml. Statistical differences ($p < 0.05$) are calculated using Student's *t*-test.

MODIFICATIONS OF THE METHOD

Katz et al. (1987) described a five-day test to predict the long-term effects of gastric antisecretory agents on serum gastrin in rats.

J.3.6.3.4 (^{14}C)-Aminopyrine Uptake and Oxygen Consumption in Isolated Rabbit Gastric Glands

PURPOSE AND RATIONALE

Isolated gastric glands from rabbits and other species can be used in studying the control of mechanism of gastric H^+ secretion (Berglindh and öbrink 1967; Berglindh et al. 1967; Sack and Spenny 1982; Sewing et al. 1983; Herling et al. 1987, 1988, 1990). In isolated gastric glands and parietal cells, H^+ secretion cannot be directly measured by titration; therefore, accumulation of weak bases such as aminopyrine is used as an indirect probe of H^+ secretion. Moreover, glandular oxygen consumption can be measured with the Warburg technique.

PROCEDURE

Preparation of Gastric Glands

Rabbits are anesthetized with 40 mg/kg pentobarbital i.v. The abdomen is opened and the aorta is cannulated in a retrograde direction. Five ml of a heparin solution (250 IU/ml) are injected with force through the cannula. After one min the rabbit is bled through the cannula and a ligature is placed around the mesenteric vessels. The chest is quickly opened and the thoracic aorta clamped. Phosphate buffered saline solution (containing 149.6 mM NaCl, 3 mM K_2HPO_4, 0.64 mM NaH_2PO_4, pH 7.3) at 37°C is pumped through the aorta, whereby the portal vein is opened to allow free outflow of the perfusate. By this procedure most of the solution is forced through the mesenteric vessels. The perfusion pressure, as measured proximal to the cannula, can be up to 600 mm Hg.

The stomach appears totally exsanguinated after perfusion with about 500 ml phosphate buffered saline solution and is then removed, cut open along the lesser curvature, and emptied. The cardial and antral regions are discarded. The corpus is rinsed several times with phosphate buffer solution and finally blotted with filter paper, whereby the remaining gastric content as well as some surface epithelial cells are removed. By blunt dissection the mucosa can easily be separated from the muscular and submuscular layers.

The mucosa is then minced into small pieces with a pair of scissors. The pieces are washed twice in warm oxygenated phosphate buffer solution and transferred to a 200 ml flask with 50 ml of a freshly prepared collagenase-enzyme solution containing 1 mg/ml collagenase (type I, Sigma), 1 mg/ml rabbit albumin (Sigma), 2 mg/ ml glucose in 130 mM NaCl, 10 mM $NaHCO_3$, 3 mM NaH_2PO_4, 3 mM Na_2HPO_4, 3 mM K_2HPO_4, 2 mM $MgSO_4$, 1 mM $CaCl_2$, and 10 mg/L phenol-red at pH 7.4. The flask is gassed with 100% oxygen, sealed, and kept in a 37°C water bath under gently stirring with a magnet for 90 min. The cloudy suspension containing the separated glands and some cells is filtered through a nylon mesh into 15 ml test tubes with conical bottoms. The glands rapidly sediment to the

bottom while the free cells remain in the solution. In this way centrifugation can be avoided and the glands can easily be washed free from isolated cells and collagenase by three washings with phosphate buffer at room temperature.

^{14}C-Aminopyrine Accumulation in Gastric Glands

The ability of gastric glands to form acid is measured based on aminopyrine accumulation. The glands are diluted to a final concentration of 2–4 mg dry weight/ml in a medium containing 100.0 mM NaCl, 5.0 mM KCl, 0.5 mM NaH_2PO_4, 1 mM Na_2HPO_4, 1.0 mM $CaCl_2$, 1.5 mM $MgCl_2$, 20.0 mM $NaHCO_3$, 20.0 mM HEPES, 2 g/ml glucose, 1 mg/ml rabbit albumin, adjusted with 1 M Tris to pH 7.4. Samples of 1 ml gland suspension are equilibrated in 1 ml medium containing 0.1 µCi/ml [^{14}C]aminopyrine at 37°C in a shaking water bath together with the agent to be tested. After 20 min either histamine or dibutyryl-cyclic-AMP is added, followed by a 30 min incubation period for histamine and a 45 min incubation period for dibutyryl-cyclo-AMP.

The glands are then separated from the medium by brief centrifugation. The supernatant is withdrawn, the pellets are dried at 80°C for 50 min, weighed and dissolved in 200 µl 1 M NaOH. Aliquots of the supernatant and the digested gland pellet are examined in a liquid scintillation counter. The ratio of intraglandular to extraglandular radioactivity is calculated. All determinations are made in triplicate.

Respiratory Studies

Glandular oxygen consumption is measured at 37°C using a Warburg respirometer and air as the gas phase. The 15 ml flasks with a central well 20% containing KOH solution on a filter paper as CO_2 adsorber are filled with 1 ml medium containing 100.0 mM NaCl, 5.0 mM KCl, 0.5 mM NaH_2PO_4, 1 mM Na_2HPO_4, 1.0 mM $CaCl_2$, 1.5 mM $MgCl_2$, 20.0 mM $NaHCO_3$, 20.0 mM HEPES, 2 g/ml glucose, 1 mg/ml rabbit albumin, adjusted with 1 M Tris to pH 7.4 and 1 ml gland suspension. After 20 min equilibration, the test compound and dbcAMP are added and the oxygen consumption is measured at 15 min intervals for the following 45 min. The recorded oxygen consumption is corrected according to the following formula:

$$O_2 \text{ consumption} = O_2 \text{ recorded} \times K$$

where

- $K = 273 \times (Pb/t{+}273) \times 760$
- t = ambient temperature in °C around the manometers
- Pb = Atmospheric pressure (mm Hg)

The respiratory activity is expressed in µl O_2 consumed per mg dry weight and time.

EVALUATION

IC_{50} values are calculated by probit analysis. Statistical differences ($P < 0.05$) are assessed by Student's t-test, n = the number of different gland preparations.

CRITICAL ASSESSMENT OF THE METHOD

Studies on (^{14}C)-aminopyrine uptake and oxygen consumption in isolated rabbit gastric glands have become a valuable approach for studying the effect of various H_2-receptor antagonists and proton pump inhibitors. When studying gastric acid production with the^{14}C-AP accumulation technique, the addition of basic drugs can be problematic (Fryklund and Wallmark 1986). The basic nature of a test compound can compete with accumulation of ^{14}C-AP. Nevertheless, it is generally accepted that oxygen consumption of gastric glands correlates well with acid formation (Berglindh et al. 1976).

MODIFICATIONS OF THE METHOD

Soll (1978) studied the actions of secretagogues on oxygen uptake by isolated mammalian parietal cells. Parietal cells were prepared from the stomach of dogs by collagenase digestion and counterflow centrifugation. Oxygen consumption was determined by polarography. Isobutyl methyl xanthine (IMX), carbamylcholine, histamine, and gastrin each independently stimulated oxygen uptake. The specificity of these responses was tested by use of an H_2-histamine receptor antagonist or atropine as anticholinergic agent.

Stoll (1980) investigated the [^{14}C]aminopyrine accumulation in isolated *canine* parietal cells when treated with histamine, gastrin and carbachol and the displacement by cimetidine or atropine.

Sewing et al. (1983, 1986) studied the effect of several benzimidazole derivatives on isolated and enriched guinea pig parietal cells using the ^{14}C-aminopyrine accumulation.

Schepp et al. (1994) determined the effects of exendin-4, a peptide from *Heloderma suspectum venom*, and exendin-(9–39)NH_2 on [^{14}C]aminopyrine accumulation in isolated rat parietal cells and compared these with those of glucagon-like peptide-1-(7–36)NH_2.

J.3.6.3.5 Gastric Mucosal Blood Flow

PURPOSE AND RATIONALE

Hydrogen gas clearance has been used to measure blood flow in the basal portion of gastric mucosa in anesthetized rats (Leung et al. 1984, 1986; Pique et al. 1988).

PROCEDURE

Male Sprague Dawley rats are anesthetized with 1.5 g/kg of urethane subcutaneously. A tracheotomy is performed and a PE-250 tubing is inserted into the trachea to facilitate spontaneous breathing and for administration of 3% hydrogen in air. The right carotid artery is cannulated for blood pressure monitoring. A midline laparotomy is then performed and the stomach exteriorized. Through an incision in the forestomach the gastric contents are gently washed out with physiological saline. A double-lumen cannula (outer: Tygon with a diameter of 7 mm; inner: polyethylene with a diameter of 2 mm) are inserted into the stomach and secured by a ligature at the forestomach. The pylorus is ligated and a 0.9% sodium chloride solution is infused through the inner cannula at a rate of 0.8 ml/min and drained from the outer tubing. The gastric effluent is collected at 15-min intervals. Acid output (in micro-equivalents per min) is determined in the perfusate with 0.2 N NaOH with an automatic titrator.

An incision in the serosa and the muscularis externa is made in the gastric wall of the corpus, exposing 3–4 mm of the submucosa. Through this hole a platinum electrode is placed in contact with the exposed basal portion of the mucosa. The electrode is made with a ring of platinum wire, 125 µm in diameter, wound around a glass capillary tube and held in place inside a Teflon tube by epoxy. A Ag-AgCl reference electrode is placed inside the peritoneal cavity. The laparotomy incision is covered by Parafilm to minimize evaporation.

One femoral vein is cannulated for the infusion of saline or drugs. The rat is kept warm with a heat lamp to maintain rectal temperature at 37°C.

Hydrogen Gas Clearance Technique

Current is generated at the surface of a platinum electrode by oxidation of molecular hydrogen to hydrogen ions and electrons. This current, which is measured using a polarographic and amplifying unit, is proportional to the hydrogen tension gradient at the surface of the platinum electrode. When the experimental animal breathes 3% hydrogen in air, the current tracing, graphed on a recorder, gradually rises and reaches a plateau as the tissue adjacent to the electrode is saturated with hydrogen. After the external hydrogen source is removed, the current tracing gradually falls because of removal of tissue hydrogen by blood flow. The rate of dissipation of hydrogen estimates the tissue blood flow (Aukland et al. 1964).

The exponential decrease of the hydrogen gas clearing curves is evaluated by a computer program (Livingstone et al. 1986). Current from the platinum electrode is passed through an ADALAB analog-to-digital converter and discrete digitized values are sampled every 5 s. Blood flow is determined by an Newtonian-Gaussian nonlinear iterative regression program by

means of a biexponential formula:

$$f(x) = A + B\,e^{-k1t(t-T)} + B\,e^{-k2t(t-T)},$$

where *f(x)* is the electrode current, *A* is the baseline current, *B* is the initial current, e is the base of natural logarithms, k_1 is the rate constant for the fast component, k_2 is the rate constant for the slow component, *t* is the time at which the current is observed, and *T* is the time when hydrogen gas was removed.

Mucosal blood flow is expressed in milliliters per minute per 100 g of tissue.

Inhibition of Acid Secretion

Intravenous saline is infused during the first 45 min of the study. After this period, an infusion of 80 µg/kg· h of pentagastrin is administered for 135 min. During the last 75 min an intravenous infusion of the inhibitor or vehicle is administered simultaneously with pentagastrin. Corpus mucosal blood flow measurements are obtained during the resting period, 45 min after start for the pentagastrin infusion, and during the last 15 min of combined infusion of pentagastrin and inhibitor. Acid output is measured at 15 min intervals throughout the experiments.

EVALUATION

All data are expressed as mean ± standard error. The data are analyzed using a paired *t*-test for comparison of basal versus stimulated condition within the same animal, analysis of variance with contrasts, and linear and polynomial regression analysis for comparison between animals in different groups. A probability level of $P < 0.05$ is considered significant.

MODIFICATION OF THE METHOD

The hydrogen gas clearance technique has been used by many authors in experimental gastroenterology, e. g.: Hirose et al. (1991), Holzer and Guth (1991), Lippe and Holzer (1992), Pique et al. (1992), Tsukamoto et al. (1992), Lazaratos et al. (1993), Petho et al. (1994), Tanaka and Guth (1994), Goldin et al. (1996), Hisanaga et al. (1996), Doi et al. (1998), Heinemann et al. (1999).

J.3.7
Anti-Ulcer Activity

J.3.7.1
Pylorus Ligation in Rats (SHAY Rat)

PURPOSE AND RATIONALE

A simple and reliable method for production of gastric ulceration in the rat based on ligature of the pylorus has

been published by Shay et al. (1945). The ulceration is caused by accumulation of acidic gastric juice in the stomach.

PROCEDURE

Female Wistar rats weighing 150–170 g are starved for 48 h having access to drinking water ad libitum. During this time they are housed single in cages with raised bottoms of wide wire mesh in order to avoid cannibalism and coprophagy. Ten animals are used per dose and as controls. Under ether anesthesia a midline abdominal incision is made. The pylorus is ligated, care being exercised that neither damage to the blood supply nor traction on the pylorus occurs. Grasping the stomach with instruments is to be meticulously avoided, else ulceration will invariably develop at such points. The abdominal wall is closed by sutures. The test compounds are given either orally by gavage or injected subcutaneously.

The animals are placed for 19 h in plastic cylinders with an inner diameter of 45 mm being closed on both ends by wire mesh. Afterwards, the animals are sacrificed in CO_2 anesthesia. The abdomen is opened and a ligature is placed around the esophagus close to the diaphragm. The stomach is removed, and the contents are drained in a centrifuge tube. Along the greater curvature the stomach is opened and pinned on a cork plate. The mucosa is examined with a stereomicroscope. In the rat, the upper two fifths of the stomach form the rumen with squamous epithelium and possess little protective mechanisms against the corrosive action of gastric juice. Below a limiting ridge, in the glandular portion of the stomach, the protective mechanisms are better in the mucosa of the medium two fifths of the stomach than in the lowest part, forming the antrum. Therefore, lesions occur mainly in the rumen and in the antrum. The number of ulcers is noted and the severity recorded with the following scores:

- 0 = no ulcer
- 1 = superficial ulcers
- 2 = deep ulcers
- 3 = perforation.

The volume of the gastric content is measured. After centrifugation, acidity is determined by titration with 0.1 n NaOH.

EVALUATION

An ulcer index U_I is calculated:

$$U_I = U_N + U_S + U_P \times 10^{-1}$$

- U_N = average of number of ulcers per animal
- U_S = average of severity score
- U_P = percentage of animals with ulcers

Ulcer index and acidity of the gastric content of treated animals are compared with controls. Using various doses, dose-response curves can be established for ulcer formation and gastric acid secretion. ID_{50} values can be calculated by probit analysis, whereby 0% corresponds to no and 100% to maximal stimulated gastric acid output.

CRITICAL ASSESSMENT OF THE METHOD

The "Shay-rat" has been proven to be a valuable tool to evaluate anti-ulcer drugs with various mechanisms of action.

J.3.7.2 Indomethacin Induced Ulcers in Rats

PURPOSE AND RATIONALE

Nonsteroidal anti-inflammatory agents, like indomethacin and acetyl-salicylic acid, induce gastric lesions in man and in experimental animals by inhibition of gastric cyclo-oxygenase resulting in less formation of prostacyclin, the predominant prostanoid produced in the gastric mucosa.

PROCEDURE

Groups of 8–10 Wistar rats weighing 150–200 g are used. The test drugs are administered orally in 0.1% Tween 80 solution 10 min prior to oral indomethacin in a dose of 20 mg/kg (4 mg/ml dissolved in 0.1% Tween 80 solution). Six hours later, the rats are sacrificed in CO_2 anesthesia and their stomachs removed. Formol-

saline (2% v/v) is then injected into the totally ligated stomachs for storage overnight. The next day, the stomachs are opened along the greater curvature, then washed in warm water, and examined under a 3-fold magnifier. The lengths of the longest diameters of the lesions are measured and summated to give a total lesion score (in mm) for each animal, the mean count for each group being calculated.

EVALUATION

The mean score in control rats is about 25 (range 20–28). Inhibition of the lesion production is expressed as percentage value.

MODIFICATION OF THE METHOD

Dose- and time dependency of the ulcerogenic action of indomethacin were studied by Djahanguiri (1969).

Instead of indomethacin, gastric lesions can be induced by intravenous or oral doses of aspirin which can be prevented by exogenous PGE_2 or PGI_2 (Konturek et al. 1981). Furthermore, reserpine at a dose of 8 mg/kg i.p., or cysteamine hydrochloride at a dose of 400 mg/kg s.c. was given in order to induce ulcers in rats (Tarutani et al. 1985).

Kitajima et al. (1993) studied the role of endothelin and platelet-activating factor in indomethacin-induced gastric mucosal injury in rats. Four hours after subcutaneous injection of 25 mg/kg indomethacin, the rats were sacrificed after ether anesthesia, and the stomach was removed. The stomach was filled with 1.5 ml of 2% buffered formalin for 10 min and then opened along the greater curvature. The total length of the lesions was measured.

Wallace et al. (1989) studied the ulcerogenic activity of endothelin in indomethacin pretreated rats using an *ex vivo* gastric chamber.

Scarpignato et al. (1995) evaluated NSAID-induced gastric mucosal damage by continuous measurement and recording gastric potential difference in the rat.

CRITICAL ASSESSMENT OF THE METHOD

According to West (1982) the cold stress induced ulcer formation, but not the indomethacin- or aspirin-induced ulcers are inhibited by H_2-receptor antagonists, whereas other authors reported protective effects of H_2-receptor antagonists under these conditions (Tarutani et al. 1985).

J.3.7.3 Ethanol Induced Mucosal Damage in Rats (Cytoprotective Activity)

PURPOSE AND RATIONALE

Intragastric application of absolute ethanol is a reproducible method to produce gastric lesions in experimental animals (Robert et al. 1979; Szabo et al. 1981). These lesions can be at least partially inhibited by various drugs, such as some prostaglandins. The protective effect against various irritants has been called cytoprotective activity (Robert 1979; Robert et al. 1979). The method has been modified by several authors. Witt et al. (1985) described a method to objectively quantify the extent of ethanol-induced gastric lesions utilizing a transmission densitometer to measure the optical density of the photographic negative of the stomach mucosa.

PROCEDURE

Male Wistar rats weighing 250–300 g are deprived of food 18 h prior to the experiment but are allowed free access to water. During this time they are kept in restraining cages to prevent coprophagy. The rats are administered either the appropriate vehicle or the cytoprotective drug, e. g. a prostanoid, intragastrally 30 min prior to administration of 1 ml absolute ethanol. Untreated animals are included as controls. One hour after administration of ethanol, the animals are euthanized with CO_2, the stomachs are excised, cut along

the greater curvature, and gently rinsed under tap water. The stomachs are stretched on a piece of foam core mat, mucosal site up.

The subjective scores of the treated tissues are recorded; the graded response is reflecting the least (0) to most (3) damage. A circular full thickness area, about 13 mm in diameter, is cut with a cork borer from each lobe of the fundus just below the ridge dividing the glandular from the non-glandular portion of the stomach. A Plexiglas template (19 × 14 × 0.3 cm), burnished on one side with emery cloth, and with four rows with six holes 13 mm in diameter is placed on a sheet of clear glass, burnished side up, and bound to the glass with photographic tape along the periphery. The excised pairs of tissue from each stomach are placed into the holes of the template.

Pairs of tissue from each stomach are examined to minimize sampling errors. The template is positioned on a rectangular central open area of an Aristo Model T-16 cold cathode transilluminator (38 × 38 cm) containing a W-45 blue-white lamp. A camera is mounted on a copy stand directly above the template. Photographs are taken, the film processed in a standard manner and a contact sheet is made from the negatives. A light transmission densitometer (e. g. MacBeth model TD-501) is used to evaluate the negatives. The optical density of the test tissues is determined by placing each area of the negative in sequence over the aperture through which the light is transmitted. The optical density is displayed on a digital read out and recorded. Hemorrhagic or damaged areas appear bright on the negative, whereas undamaged tissue appears dark. Hence, lower optical density values are indicative of damage while higher optical densities are associated with little, or, as in the case of control, no damage.

EVALUATION

The significance of differences in optical density between control and ethanol-treated tissue is evaluated by nonpaired single-tail Student's *t*-test.

MODIFICATIONS OF THE METHOD

Cytoprotection by prostaglandins was studied in rats by prevention of gastric necrosis produced by various agents such as alcohol, HCl, NaOH, hypertonic NaCl, and thermal injury (Robert et al. 1979) and against gastric injury produced by nonsteroidal anti-inflammatory compounds (Robert 1979; Franzone et al. 1988). The animals are fasted 48 h prior to the experiment and placed 18 h before the administration of drugs into plastic tubes to prevent coprophagy. Fifteen min after application of the test drug, the animals are given 1 ml of the irritant orally. After an additional hour, the animals are sacrificed, the stomachs removed and immediately opened along the greater curvature. Lesions are counted and scored (0 = no lesion; 1 = mild lesions; 2 = severe lesions; 4 = necrosis).

Starrett et al. (1989) employed 3.0 ml/kg ethyl alcohol (100%) or 3.0 ml/kg 0.75 N HCl as necrotizing agent.

Borella et al. (1989) studied the cytoprotective and anti-ulcer activities of the anorganic antacid Magaldrate in the rat using absolute ethanol as irritant.

Masuda et al. (1993) investigated the role of endogenous endothelin in the pathogenesis of ethanol-induced gastric mucosal injury in rats.

CRITICAL ASSESSMENT OF THE METHOD

Several prostaglandins provide cytoprotection, particularly in rats, in a dose-range which has no anti-secretory activity. However, clinical experience with prostaglandins showed that ulcer healing is only achieved at anti-secretory doses (Lindberg et al. 1990). Therefore, it seems very likely that the cytoprotective property of a compound in rats has very limited relevance to prediction of its ulcer healing potential in humans if cytoprotection is really separated from its antisecretory potential (Herling and Weidmann 1994).

J.3.7.4 Subacute Gastric Ulcer in Rats

PURPOSE AND RATIONALE

Ezer (1988) described a method for producing standard subacute gastric ulcers in rats and for the quantitative evaluation of the healing process.

PROCEDURE

Female Wistar rats weighing 120–150 g are fasted for 24 h having access to water at libitum in cages with wire sieves at the bottom. The rats are anesthetized with ether and a polyethylene catheter including a fine steel wire with a needle tip (1.2 mm diameter) at the lower end is orally inserted into the stomach. After the cannula reaches the gastric wall, the upper end of the steel wire is pressed in a definitive manner, so as to puncture the gastric wall. Each rat is kept in the same position during the intervention in order to localize the puncture at nearly the same region of the glandular part of the stomach. The test substances are administered orally, 30 min or 24 h after puncture. Free access to food and water is provided from 2 h up to the end of the experiment. Each group consists of 8–15 rats.

The animals are sacrificed by overdose of ether at definitive time intervals after puncture. The stomach is dissected and opened along the lesser curvature, extensively rinsed in tap water and fixed to the end of a polyethylene tube of 10 mm diameter (plastic tip of an automatic pipette) in a position with the punched ulcer in the center. The end of the tube with the gastric wall is suspended in a beaker containing physiological saline, and the pressure in the tube is gradually increased with a valved rubber ball connected to the other end of the tube. The third part of the system is a tonometer calibrated up to 1 bar. The value of tension at which bubbles appear at the ulcerous gastric wall is noted. This value is termed as tensile strength and can be expressed in mm Hg.

EVALUATION

The extent of the healing of gastric ulcers can be characterized by the healing rate (*HR*) according the following equation:

$$HR = (A - B)/C \quad \text{(mmHg/h)}$$

with

- A = tensile strength (mm Hg) at C time-point after puncture
- B = tensile strength 30 min after puncture (the average value is 143 mm Hg)
- C = time course (h) of the experiment.

Anti-ulcer drugs, such as H_2 antagonists, significantly increase the healing rate, which is decreased by nonsteroidal anti-inflammatory drugs.

CRITICAL ASSESSMENT OF THE METHOD

Similarly to the method of Takagi et al. (1969) who injected 50 µl of acetic acid into the stomach wall (Szelenyi et al. 1982), the method of Ezer (1988) allows to judge the time course of healing of the ulcers.

MODIFICATIONS OF THE METHOD

Okabe and Pfeiffer (1972) induced chronic gastric ulcer in rats by temporary instillation of acetic acid. In pentobarbital anesthesia, a cylindrical glass tube of 6 mm in diameter was tightly placed upon the anterior serosal surface of the glandular portion of the stomach one cm away from the pyloric end. A dose of 0.06 ml/animal of 50% acetic acid was instilled into the tube and allowed to remain one min on the gastric wall. After removal of the acid solution, the abdomen was closed in two layers and the animals brought back to their cages and fed normally. Test drugs were given orally on day 1 twice daily, 4 h after application of acetic acid and continued up to 10 days after induction of ulcer. The animals were sacrificed after 18 h of the last dose to assess ulcer size and healing. Ulcer index was calculated upon the product of length and width of ulcers.

Karmeli et al. (1996) induced gastric mucosal erosions in rats by addition of 0.1% iodoacetamide to the drinking water. The animals were sacrificed after various time intervals, the stomach was resected, washed, lesion area assessed, and mucosal inflammatory mediators determined. Myeloperoxidase was increased and nitric oxide synthase activity decreased. The damage induced by iodoacetamide was significantly ameliorated by treatment with a free radical scavenger, (4-hydroxy-2,2,6,6-tetramethyl-piperidine-1-oxyl, TEMPOL).

Piqueras et al. (2003) described gastric hypersecretion in **mice** due to mast cell activation associated with

mild gastritis induced by 0.1% iodoacetamide administered intragastrally and added to the drinking water for a 6-day period.

Marchetti et al. (1995) and Konturek et al. (1999) described a mouse model of *Helicobacter pylori* infection. Gastric function and healing of chronic acetic acid-induced ulcers in BALB/c mice were studied after inoculation with CagA and VacA positive (type I) or CagA and VacA negative (type II) *Helicobacter pylori* strains. This infection caused immediate suppression of gastric secretion and delayed the healing of ulcers.

Protell et al. (1976) described a reproducible model of acute bleeding ulcer in **dogs** – the "ulcer maker." An instrument has been developed for endoscopy or laparotomy, which creates gastric ulcers of reproducible diameter and depth.

J.3.7.5 Gastric Ischemia-Reperfusion Injury in Rats

PURPOSE AND RATIONALE

Hassan et al. (1997) described the effect of an endothelin converting enzyme inhibitor on local gastric ischemia-reperfusion injury in rats. Endothelin-1 has potent ulcerogenic effects in the stomach (Wallace et al. 1988). Endogenous endothelin-1 has been implicated for ethanol-, indomethacin- and hemorrhagic shock-induced gastric ischemia-reperfusion injuries (Masuda et al. 1993; Kitajima et al. 1993; Michida et al. 1994; Kitajima et al. 1995).

PROCEDURE

Male Wistar rats weighing 200–250 g are fasted for 24 h with free access to water. The rats are anesthetized with 1.5 g/kg urethane i.p. The stomach is exposed by a medial laparotomy and instilled with 0.15 M HCl (1 ml/100 g) via the forestomach. The left gastric artery is clamped by a small vascular clamp for 5 min to induce ischemia and 30 min of reperfusion is done by releasing the clamp. Pretreatment with test drug or standard is given to groups of 5 rats immediately before the induction of ischemia. At the end of the experiment, the rats are sacrificed by cervical dislocation. The stomach is fixed with 10% buffered formalin and photographed for macroscopic evaluation of injuries. For the assessment of microscopic injuries, a sample of corpus 0.5 cm below the limiting ridge containing the entire width of the anterior wall is taken from each stomach and processed for subsequent histological evaluation.

A planimeter attached to a computer is used to trace the macroscopic mucosal injury from color photographs. The results are expressed as a percentage of the total glandular mucosal area.

Each histological section is stained with hematoxylin/eosin and examined under light microscope. An one cm length of each histological section is assessed for epithelial damage (score = 1), glandular disruption, vasocongestion or edema in the upper mucosa (score = 2), hemorrhagic damage in the mid to lower mucosa (score = 3) and deep necrosis and ulceration (score = 4). Each section is evaluated on a cumulative basis to give the histological index, the maximum score thus being 10.

EVALUATION

Data are expressed as mean ± SEM. Comparisons between different groups are made by one way analysis of variance followed by Fisher's least significant difference test. P-values of < 0.05 are considered as statistically significant.

PURPOSE AND RATIONALE

Laxatives of the sennoside type act mainly by acceleration of large intestine transit and inhibition of fluid absorption in the colon (Leng-Peschlow 1986).

PROCEDURE

For **measurement of large intestinal transit time**, female Wistar rats weighing approximately 200 g are anesthetized with ether. A PVC catheter is implanted into the caecum with the distal end fixed on the animal's neck. The animals are allowed to recover and are placed individually in a wire meshed cage to enable the feces to fall through onto blotting paper. Carmine red (10 mg in 0.4 ml distilled water per animal) is injected through the catheter immediately after administration of the test substance. The time until appearance of the first colored feces is registered.

For **measurement of fluid absorption in the colon**, female Wistar rats weighing approximately 200 g are anesthetized with 50 mg/kg pentobarbitone sodium. The colon is ligated and cannulated distal to the caecocolic junction (PE-tube, i.d. 1 mm) and, after a thorough rinse with 50 ml physiological saline to remove all contents, a second cannula (silicone, i.d. 3 mm) is inserted proximal to the rectum for fluid outflow. Four and 6 h after oral administration of the test compounds an open perfusion with an electrolyte solution (NaCl 6.72 g/l, KCl 0.37 g/l, $NaHCO_3$ 2.1 g/l, polyethylene glycol (PEG, mol wt 4000) 2.0 g/l, [^{14}C]PEG 5 µCi/l; pH 6.5, osmolality 275 milliosmol/kg) is started at a rate of 12 ml/h for two consecutive 2 h periods. [^{14}C]PEG activity is measured by liquid scintillation counting, Na^+ and K^+ by flame photometry, Cl^- by coulometric titration, osmolality by freezing point depression and mucus as protein-bound total hexoses by the orcinol-sulphuric acid method. Net H_2O, Na^+, K^+ and Cl^- transport are calculated and expressed as ml or µmol/h and per 10 cm colon length.

EVALUATION

All values are expressed as mean ± standard deviation. Statistical significance is assessed with Student's *t*-test.

MODIFICATIONS OF THE METHOD

Ogunti and Elujoba (1993) tested the laxative activity of *Cassia alata* in rats. Male Charles River rats were kept in individual cages during one week. Any rat producing wet feces was rejected. After administration of the test compounds to groups of 5 rats per dose, the feces were examined for wetness hourly for 12 h. The results were expressed as the mean percent of total feces that were wet per kg rat.

J.4.1.2 Enteropooling Test

PURPOSE AND RATIONALE

The enteropooling assay in rats has been developed by Robert et al. (1976) to test the diarrheogenic property of prostaglandins for prediction of this clinically relevant side effect of several synthetic prostaglandins.

PROCEDURE

Female Sprague Dawley rats weighing 190–215 g are used. The animals are fasted overnight having free access to water. The test compounds are administered orally, and the animals, 12 per group, are sacrificed one hour later. The fluid accumulation occurs in the small intestine which is cut at the pylorus and the ileocecal junction, and its contents, consisting of a thick fluid (in controls) and a very watery fluid (in prostaglandin-treated animals) are collected into a graduated test tube by milking the whole length of the small intestine with the fingers. The volume of fluid is recorded.

EVALUATION

Using various doses, dose-response curves can be established and potency ratios calculated. 16,16-dimethyl PGE_2 was found to be the most active compound.

CRITICAL ASSESSMENT OF THE METHOD

Some other diarrheogenic agents, like $MgSO_4$, castor oil, bile, taurocholate and taurochenodesoxycholate cause enteropooling, whereas mineral oil and tragacanth are ineffective. The anticholinergic agent methylscopolamine partially counteracted the enteropooling. The assay, therefore, can be used to test the laxative or the antidiarrheal activity of compounds (Shook et al. 1989).

MODIFICATIONS OF THE METHOD

Beubler and Badhri (1990) used the PGE_2-induced net fluid secretion in the jejunum and colon in the rat to evaluate the antisecretory effects of antidiarrheal drugs. Polyethylene catheters were placed into the jejunum and colon and Tyrode solution was instilled into the loops. Net fluid transfer rates were determined gravimetrically 30 min after instillation of Tyrode solution.

J.4.1.3 Inhibition of Chloride Secretion in Rabbit Colon[2]

PURPOSE AND RATIONALE

Epithelia have the ability to reabsorb or to secrete fluids and electrolytes. In 1958, Koefoed-Johnsen and Ussing first published a model of ion transport across frog skin epithelium. Ussing also introduced the measurement of the short-circuit current as a means of defining active ion transport (Koefoed-Johnsen and Ussing 1958). Mammalian colon is an example of epithelium which has the capacity to absorb and to secrete electrolytes.

[2]Contributed in the first edition by M. Hropot

Previous studies have shown that mammalian colon actively secretes chloride when exposed to prostaglandins and vasoactive intestinal peptides, which increase the cellular concentration of cAMP resulting in an electrogenic chloride secretion (Frizzell et al. 1976). The elevation of cAMP causes the opening of chloride channels, whereas the colonic epithelium absorbs sodium and chloride ions by an electroneutral mechanism under control conditions. In general it is assumed that absorption takes place mainly in the surface cells, whereas the crypts are the predominant site of secretion (Greger et al. 1985; Binder and Sandle 1987).

PROCEDURE

Rabbits of either sex (2.0 to 4.0 kg body weight) are killed by cervical dislocation. The distal colon is removed, immediately opened into a flat sheet and washed in the standard electrolyte solution. The epithelium with an area of 1.0 cm^2 is stripped from its underlying musculature and mounted in an Ussing chamber. The tissue is mounted vertically and bathed on both sides by electrolyte solutions, which are circulated and oxygenated by a water-jacketed bubble-lift apparatus maintained at 37°C. The carbogen gas used for bubbling contains O_2 and CO_2 in a mixture of 95% and 5%, respectively. The solutions used on the two sides have the following composition (in mmol/l): NaCl 120, $NaHCO_3$ 21, Na_2HPO_4 0.4, K_2HPO_4 1.6, $MgCl_2$ 1.2, glucose 5.

Tissues are continuously short-circuited by a four-electrode automatic voltage-clamp apparatus (AC-Microclamp, Aachen, Germany) which measures short-circuit current (I_{sc}) and automatically subtracts chamber fluid resistance. Transepithelial electrical potential difference is measured between Ag-AgCl electrodes, which make contact with the bathing solutions via agar bridges (5% agar in glucose-free standard electrolyte solution). I_{sc} is measured by passing sufficient current through Ag-AgCl electrodes to reduce the spontaneous transepithelial electrical potential difference to zero. Transepithelial conductance (G_t) is determined by passing 100-ms bipolar current pulses through the tissue.

The standard protocol consists of an initial equilibration period of 20 min. The I_{sc} measured in the presence of indomethacin (1 µmol/l, serosal and mucosal solution) corresponds mostly to the rheogenic reabsorption of sodium. In the next step, amiloride is added at 0.1 mmol/l to block sodium reabsorption. Then PGE_2 (1 µmol/l) is added to the serosal solution in the presence of amiloride in order to stimulate

chloride secretion. After a further equilibration period of 20 min putative blockers of chloride secretion are added to the mucosal or serosal solution.

EVALUATION

Each compound is examined at least 3 times and at three different concentrations (usually 1, 10 and 100 µmol/l). From the mean values a concentration-response curve is constructed, and from this curve the IC_{50} value is read as the concentration producing 50% inhibition of the stimulated I_{sc}.

Data are presented as means ± SEM. Paired *t*-test with a significance level of $p < 0.05$ may be used.

CRITICAL ASSESSMENT OF THE METHOD

The method can be used to study the antidiarrhoic activity of a test compound, but also generally its influence on active electrolyte transport across the cell membrane.

MODIFICATIONS OF THE METHOD

Warhurst et al. (1996) studied the effects of somatostatin analogues on electrogenic ion secretion in isolated rat colonic mucosa mounted in Ussing chambers.

J.4.2 Antidiarrhea Effect

J.4.2.1 Castor Oil Induced Diarrhea

PURPOSE AND RATIONALE

The induction of diarrhea with castor oil results from the action of ricinoleic acid formed by hydrolysis of the oil (Iwao and Terada 1962; Watson and Gordon 1962). Ricinoleic acid produces changes in the transport of water and electrolytes resulting in a hypersecretory response (Ammon et al. 1974). In addition to hypersecretion, ricinoleic acid sensitizes the intramural neurons of the gut.

PROCEDURE

Female Wistar rats weighing 210–230 g are used after overnight food deprivation. For the experiment, the rats are housed in individual cages with no access to drinking water. The potential antidiarrhoic agents are administered orally by gavage in various doses. Controls receive the solvent only. Each dose is given to 10 animals. One hour after dosage, 1 ml of castor oil is administered orally. Stools are collected on non-wetting paper sheets of uniform weight up to 24 h after administration of the castor oil. Every 15 min during the first 8 h, urine is drained off by gravity, and the net stool weight, termed early diarrheal excretion, is recorded. The diarrhea-free period is defined as the time in minutes between castor oil administration and the occurrence of the first diarrheal output. The acute diarrheal phase is the time between the first and the last diarrheal output of the 8-h observation period. Stools occurring between 8 and 24 h after castor oil administration are called late diarrheal excretion.

EVALUATION

With antidiarrheal agents dose-response curves are obtained for decrease of hypersecretion (stool weight) and for increase of the diarrhea-free period are obtained. Inhibitors of prostaglandin biosynthesis increase the diarrhea free period but do not affect early diarrheal secretion (Niemegeers et al. 1984).

MODIFICATIONS OF THE METHOD

Inhibition of castor oil-induced diarrhea in **mice** was tested by Bianchi and Goi (1977).

Dajani et al. (1977) tested antidiarrheal activity in castor-oil treated **monkeys**.

Mannitol-induced diarrhea was used as model in **calves** (Fioramonti and Buéno 1977) and in **pigs** (Théodorou et al. 1991).

J.4.2.2 Antidiarrheal Effect in Cecectomized Rats

PURPOSE AND RATIONALE

Evaluation of antisecretory antidiarrheal agents in animal models is limited primarily to extrapolations of efficacy from enteropooling studies *in vivo* (DiJoseph et al. 1984), isolated intestinal loops (Nakaki et al. 1982), and Ussing flux chamber preparations *in vitro* (Dharmsathaphorn et al. 1984).These studies do not mimic secretory diarrhea. The method of Magnus (1915) using chronic diarrhea in cats induced by continuous milk diet and thereby proofing the antidiarrheal effect of morphine is of historical interest only.

Fondacaro et al. (1990) developed a model of secretory diarrhea utilizing conscious cecectomized rats by surgical resection of the cecum and by use of potent intestinal secretagogues. The rat has a pronounced cecum as part of its gastrointestinal tract. The rat cecum is not only a reservoir for intestinal contents where high concentrations of various microbial flora assist in the digestion of carbohydrates, cellulose and peptides through microbial fermentation processes (Ambuhl et al. 1979; Williams and Senior 1982) but also plays a role in handling of excess intestinal fluid.

PROCEDURE

Cecectomies are performed in unfasted rats weighing 200–250 g. Under anesthesia with methohexital (60 mg/kg i.p.) cecectomy is initiated with a 2-cm midventral incision. The cecum is lifted from the abdominal cavity and exteriorized onto a gauze drape. The cecal apex is freed by severing the avasclular area of the mesocecum. A ligature of no. 1 silk suture is positioned so as to occlude the cecum and its vasculature without compromising ileo-colonic patency. After the ligature is secured and ileo-colonic patency confirmed, the cecum is resected, and the remaining exposed cecal mucosa is washed with saline and cauterized. The intestinal segment is then returned to the abdominal cavity and the abdominal muscle fascia closed with sutures. The dermal incision is closed with wound clips that are removed about 1 week postsurgery. Immediately following the surgical procedure, the animals are returned to their cages and allowed free access to food and water. The animals are permitted at least a 48-h recovery period before being used in an experiment.

For the diarrhea assay, cecectomized rats are put into individual wire-bottomed cages placed over sheets of clean paper, and deprived of food and water for the duration of the assay. Rats are given a two hour's acclimatization period prior to the start of the assay in order to eliminate sporadic episodes of anxiety-induced defecation. During this period, they are observed also for consistent occurrences of pelleted feces; an animal producing other than pelleted stool is disqualified from the study. Diarrhea is induced with oral administration of secretagogues: either 16,16 dimethyl prostaglandin E_2 (0.3 mg/kg) in 3.5% ethanol, carbachol (15 mg/kg) in water, or cholera toxin (0.5 mg/kg) in an aqueous vehicle of 2% $NaHCO_3$ plus 2% casamino acids. Anti-diarrheal agents are administered by gavage after the onset of diarrheal episodes. The cage papers are removed and examined at 15 min intervals for carbachol-induced diarrhea, 30 min intervals for 16,16 dimethyl prostaglandin E_2 induced diarrhea, and hourly when cholera toxin is used as secretagogue. Fetal output is recorded at each interval and scored as follows:

- 1 = normal pelleted stool
- 2 = soft-formed stools
- 3 = water stool and/or diarrhea

Known antidiarrheal agents, such as chlorpromazine (10 mg/kg p.o.), or the alpha-2 receptor agonist clonidine (1.0 mg/kg p.o.), or morphine (10 mg/kg p.o.) reduce the fecal output and induce a cessation of diarrhea.

EVALUATION

The fecal output index is defined as the summation of the number of defecation periods and their ranked consistency score within an observation period and is expressed as mean ± SEM for each group. Student's *t*-test and analysis of variance are used for statistical comparisons of data points. Significance is accepted at $p < 0.05$ or less.

CRITICAL ASSESSMENT OF THE METHOD

The model of diarrhea induced by secretagogues in cecetomized rats has the advantage to mimic secretory diarrhea in man.

J.4.2.3 Evaluation of Antidiarrheal Effect in Cold-Restrained Rats

PURPOSE AND RATIONALE

Barone et al. (1990) tested the effect of various antidiarrheal and other drugs on increased fecal pellet output in cold-restrained rats resembling clinical observations that stressful situations can produce diarrhea in humans.

PROCEDURE

Male Sprague-Dawley rats weighing 260–310 g are maintained on Purina lab chow and water. Since gastric ulcers are reduced if cold-restrained rats are allowed free access to food and water, for studies on fecal output food was not withdrawn prior to the experiment. The rats are studied in normal living cages at room temperature (control, non-stressed animals) or in wire-mesh restraining cylinders placed in a cold (4°C) environment. Test drugs are administered by appropriate routes over optimal effective dose-ranges for their activities and at optimal pretreatment times to maximize their effects. The number of pellets expelled by each animal is measured at 1 and 3 h (fecal pellet output). Generally, the fecal pellets of stressed animals are less firm. Fecal pellet fluid content is determined by weighing fecal pellets, drying them in an oven at 37°C, and weighing them again.

EVALUATION

The dose in mg/kg that inhibits the cold restrained stress induced increase in fecal pellet output by 50% (ID_{50}) is determined using least-squares fit analysis directly from the regression line. If fecal pellet output is decreased by a drug but no clear dose-related effects occur, the maximum percent decrease is determined.

MODIFICATIONS OF THE METHOD

For colonic transit studies, rats are implanted with indwelling catheters in the proximal colon. Animals are anesthetized with 60 mg/kg pentobarbital i.p., and a chronic colonic catheter is positioned to enter the proximal colon 2 cm from the ileocecal junction. A catheter of about 20 cm of silicone tubing prepared with several drops of silicon rubber adhesive coating a 1-cm length along the catheter is positioned into the colon. The colon end of the tubing also is sealed with a 1-cm plug of petroleum jelly intraluminally. A small incision is made in the proximal colon, and the adhesive-coated portion of the Silastic tubing is tied in place with the use of a purse-string suture. The tubing is brought through the abdominal wall, led subcutaneously through the skin in the midscapular region and secured on the back of the neck with the use of a wound clip. The abdominal incision is closed with sutures and wound clips.

Experiments are performed in conscious animals 48–72 h after surgical preparation. At this time, the

radiolabeled marker (^{51}Cr as sodium chromate) is instilled into the proximal colon via the indwelling catheter. After 35, 60, or 120 min, cold-restrained rats and controls are sacrificed and their colons and large intestines are removed. The cecum and equal segments of the colon are dissected, placed into vials and subjected to gamma counting.

Ikeda et al. (1995) investigated the effect of a neurokinin$_1$ receptor antagonist on stress-induced defecation in rats placed in special restraint cages.

Kishibayashi et al. (1993) studied distal colonic function using wrap-restrained stress-induced defecation as described by Williams et al. (1988). The rats were lightly anesthetized with ether, and the foreshoulders, upper forelimbs and the thoracic trunk were wrapped in paper tape to restrict, but not prevent, movement. The animals recovered from anesthesia within 2–5 min and immediately moved around in cages and ate and drank, but had been restricted from mobility of forelimbs, which prevented them from grooming the face, upper head and the neck. Fecal pellet output induced by wrap-restraint stress was weighed during the 1st h after stress. The test drugs were given p.o. 1 h before stress. The ID_{50} values were calculated as the doses that reduced stress-induced defecation by 50%.

J.4.3 Gut Motility

J.4.3.1 Isolated Ileum (MAGNUS Technique)

PURPOSE AND RATIONALE

The isolated ileum, as first described by Magnus (1904), is probably the most widely used model in experimental pharmacology. Magnus already studied simultaneously the spontaneous contractions of the longitudinal and circular musculature and the inhibiting effect of atropine. The method has been used for many purposes, such as the study on the effects of adrenaline on the lower segments causing contraction and on the segments of the upper end causing relaxation by Munro (1951) or the study on the origin of acetylcholine released from guinea-pig intestine and longitudinal muscle strips by Paton and Zar (1968) either retaining or being denervated from Auerbach's plexus. The model is used as a basic screening procedure for spasmolytic activity, whereby an anti-acetylcholine or anticarbachol effect indicates antimuscarinic activity and an anti-$BaCl_2$-effect indicates a musculotropic, papaverine-like effect. In addition to the isolated ileum, other parts of the gut such as the isolated duodenum and colon, have been used widely.

PROCEDURE

Guinea pigs of either sex weighing 300 to 500 g are used. They are sacrificed by stunning and exsanguination. The abdomen is opened with scissors. Just distal to the pylorus, a cord is tied around the intestine which is then severed above the cord. The intestine is gradually removed, with the mesentery being cut away as necessary. When the colon is reached, the intestine is cut. Below the cord, the intestine is cut halfway through, so that a glass tube can be inserted. Tyrode's solution is passed through the tube and the intestine until the effluent is clear. Mesentery is cut away from the intestine that was joined to the colon. Pieces of 2–3 cm length are cut. Preferable the most distal piece is used being the most sensitive one. This piece is fixed with a tissue clamp and brought into a 15 ml organ bath containing Tyrode's solution at 37°C being oxygenated with 95% O_2/5% CO_2. The other end is fixed to an isometric force transducer (UC 2 Gould-Statham, Oxnard USA). A preload of 1 g is chosen. Responses are recorded on a polygraph. After a pre-incubation time of 30 min, the experiment is started.

The following agonists and antagonists (standards) are used (concentrations in g/ml bath fluid):

Agonist	Antagonist
Acetylcholine 10^{-7} g/ml	Atropine 10^{-8}–19^{-9} g/ml
	Scopolamine 10^{-8}–10^{-9} g/ml
Carbachol 10^{-7} g/ml	Atropine 10^{-8}–10^{-9} g/ml
Histamine 10^{-6} g/ml	Histamine antagonists
$BaCl_2$ 10^{-4} g/ml	Papaverine 10^{-5}–10^{-6} g/ml
Serotonin 10^{-6} g/ml	Serotonin antagonists
PGE_2 2×10^{-7} g/ml	PG-antagonists

EVALUATION

Several methods for the quantitative evaluation of an antagonistic effect are available. One approach is the determination of pD'_2 values according to van Rossum and van den Brink (1963). Acetylcholine or histamine is added in $1/2 \log_{10}$ concentration increments until a maximum response is obtained. Control curves are recorded at 30 min intervals. After uniform control responses are obtained, the potential antagonist or the standard is added 5 min before the concentration-response curve is re-obtained. The potency of the antagonist is obtained by calculating the pD'_2 value which is defined as the negative logarithm of the molar concentration of an antagonist that causes a 50% reduction or the maximal response obtained with an agonist.

MODIFICATIONS OF THE METHOD

Many modifications of the Magnus technique have been described in the literature, mainly with the isolated ileum (e. g., Koelle et al. 1950).

Okwuasaba and Cook (1980) dissected the myenteric plexus and longitudinal muscle free of the underlying circular muscle according to the method of Paton (1957), Paton and Zar (1968) and stimulated the preparation with trains of supramaximal rectangular pulses of 1.0 ms duration at a frequency of 0.2 Hz.

Kilbinger et al. (1995) studied the influence of 5-HT_4 receptors on [^{3}H]-acetylcholine release from guinea pig myenteric plexus.

De Graaf et al. (1983) described a fully automated system for *in vitro* experiments with isolated tissues. The apparatus consists of an organ bath equipped with (a) a gradient pump supplying a logarithmic concentration/time gradient of agonist; (b) pumps and valves for dispensing bath fluid, antagonist solutions, and an oxygenation gas mixture; and (c) a transducer with automatic baseline adjustment. The information coming from the preparation is fed into a mini-computer. The data of various experiments can be accumulated and Schild-plots obtained.

Furukuwa et al. (1980) studied the effects of thyrotropin-releasing hormone on the isolated small intestine and taenia coli of the guinea pig.

Paiva et al. (1988) studied the role of sodium ions in angiotensin tachyphylaxis in the guinea-pig ileum and taenia coli.

Barnette et al. (1990) used electrically stimulated strips of circular smooth muscle from the lower esophageal sphincter of dogs to study the inhibition of neuronally induced relaxation by opioid peptides.

Bradykinin antagonism can be studied in the isolated guinea pig ileum bathed in a solution containing atropine (1.5 mM), diphenhydramine (3.4 mM), indomethacin (2.8 mM), and captopril (0.9 mM) (Rubin et al. 1978; Kachur et al. 1987).

Griesbacher and Lembeck (1992) used the isolated guinea-pig ileum for analysis of bradykinin antagonists.

Hew et al. (1990) used field stimulated (95% of maximum voltage, 0.1 Hz, 0.5 ms) guinea pig ileum, bathed in physiological salt solution at 37°C in the presence of 1 mM mepyramine for determination of histamine H_3 bioresponse. Reduction of contractile response by the test substance (>50% relative to control 0.3 mM R-α-methylhistamine) indicates possible H_3 agonism. At a test concentration where no significant activity is seen, ability to inhibit (>50%) R-α-methylhistamine-induced contractile reduction indicates antagonistic activity.

A similar technique was used by Conner et al. (1987) to study antagonist effects at functional 5-HT_{1A} receptors.

Feniuk et al. (1993) used the guinea-pig isolated ileum, vas deferens and right atrium to characterize somatostatin receptors. Transmural electrical stimulation was applied to guinea pig ileum (0.1 Hz, 0.1 ms continuously) and vas deferens (5 Hz, 0.5 ms for 1.5 s every 30 s) at supramaximal currents (approximately 800 mA) delivered from a Digitimer D330 multistimulator.

Radomirow et al. (1994) investigated opioid effects of short enkephalin fragments containing the Gly-Phe sequence on contractile responses of guinea pig ileum after addition of 10 nM acetylcholine or after electrical stimulation.

Coupar and Liu (1996) described a simple method for measuring the effects of drugs on intestinal longitudinal and circular muscle in **rats**. The preparation consists of a segment of rat ileum set up to measure the tension developed in the longitudinal muscle and intraluminal pressure developed in the circular muscle in response to transmural electrical stimulation.

Vassilev et al. (1993) exposed Wistar rats to subtoxic doses of Co^{2+} or Ni^{2+}, receiving $Co(NO_3)_2$ or $NiSO_4$ with drinking water for 30 days, and measured the changes in the contractile responses to carbachol and in the inhibitory effects of verapamil and nitrendipine on isolated smooth muscle preparations of the ileum and the trachea.

Pencheva and Radomirov (1993), Pencheva et al. (1999) studied the effects of GABA receptor agonists on the spontaneous activity of the circular layer in the terminal ileum of **cats**. Segments of the terminal ileum approximately 0.5 cm long were mounted in an organ

bath along the axis of the circular layer through a cotton thread with a large knot situated at the inner part of the gut wall.

Similar preparations of cat ileum were used by Kortezova et al. (1994) and Chernaeva and Mizhorkova (1995).

Vassilev and Radomirov (1992) used an isolated preparation of **rat rectum**. The rectal region, 1–6 cm proximal to the anal sphincter was removed and a 20 mm long segment suspended in an organ bath. The influence of prostaglandins and antagonists on spontaneous mechanical activity and electrically stimulated responses was investigated.

J.4.3.2 Cascade Superfusion Technique

PURPOSE AND RATIONALE

The technique of isolated organ superfusion was developed by Gaddum (1953) for the assay of biologically active substances. Extension of the technique for multiple tissue superfusion with particular reference to the identification and the assay of prostaglandin-like activity was used by various authors (Vane 1964;

Ferreira and Vane 1967; Ferreira et al. 1976; Gilmore et al. 1968; Hong 1974; Bult et al. 1977; Henman et al. 1978; Elliott and Adolfs 1984; Fournau et al. 1984).

PROCEDURE

The apparatus consists of a double-wall glass container (height 20–25 cm, inner diameter 7–8 cm) with an outlet at the bottom. A constant temperature of 38°C is maintained by circulation of warm water through the outer jacket. Inside the glass container can be suspended up to 5 pieces of tissue of various origins. The multiple preparation tissue holder consists of a vertical rectangular rod and plastic platforms for attachment of the tissues and for accurate deflection of the superfusate on to the lower tissue. The rod is grooved at 10 mm intervals with 1 mm deep slots set at an angle of 20° to the horizontal. To the upper surface of the nonwettable platform a small plastic hook is cemented at such a distance from the rod that when the tissue is in position its attachment thread passes between the V-shaped notch cut into the margin of the upper tissue platform. The individual platforms are inserted on to the vertical rod by slotting into the requisite grooves appropriate to the tissue length.

Thus, the superfusate passes at a uniform flow rate down the tissues of the cascade and the tension recording threads are separated from each other by about a 5-mm gap so that the responses can be conveniently recorded. The threads from the organs are connected over isotonic levers to isometric tension transducers. The lever is used for preloads according to the individual organ. Tension exerted by each tissue is recorded on a polygraph. Various media can be used for superfusion, e. g., Krebs-Henseleit solution gassed with 95% O_2 and 5% CO_2.

Many tissue preparations can be used for the cascade, such as rat fundic strip, rat duodenum, rat colon, rat bladder strip, guinea-pig ileum, guinea-pig proximal colon, rabbit stomach strip, rabbit coeliac/mesenteric artery, or rabbit aorta strip. Moreover, donor tissue can be superfused and its effluent be tested in the organs of the cascade.

EVALUATION

Many agonists and antagonists can be tested by appropriate selection of organs. Threshold doses and ED_{50} or ID_{50} values can be determined.

MODIFICATIONS OF THE METHOD

The superfusion technique has been used for several purposes, e. g., for the assay of catecholamines (Armitage and Vane 1964), for detecting active substances in the circulating blood (Vane 1964). A simple and inexpensive piece of apparatus for cascade superfusion procedures has been described by Naylor (1977).

Mombouli et al. (1996) described a bioassay of endothelium-derived hyperpolarizing factor (EDHF) using a perfusion-superfusion cascade where canine carotid arteries were used as donors of vasoactive substances and rings of coronary arteries without endothelium as detectors.

J.4.3.3 In Vivo Evaluation of Spasmolytic Activity in Rats

PURPOSE AND RATIONALE

Maggi and Meli (1982) described an *in vivo* procedure for estimating spasmolytic activity in the rat by measuring smooth muscle contractions to topically applied acetylcholine.

PROCEDURE

Male albino rats weighing 350–400 g are anesthetized with subcutaneous urethane (1.2 g/kg). The left jugular vein is cannulated for administration of test compounds. After laparotomy occluding silk ligatures are applied at a distance of 2 cm from each other in the gut (colon or rectum). Through a small incision the flanged tip of a polyethylene tubing (1 mm i.d., 1.5 mm o.d.) is inserted into the lumen of this pocket-like space and secured in place by a purse string ligature. The free end of the tubing is connected to a pressure transducer and the whole system filled with saline. The same procedure is performed with the urinary bladder. The organs are filled with warm saline (37°C) to obtain a resting pressure of 4–12 mm Hg. Warm saline soaked cotton wool swabs are laid around the exteriorized organs which are maintained warm and moist with warm (37°C) saline dropping from a reservoir at a rate of 10–15 drops/min.

After 15 min stabilization period, saline flow is stopped and a dose-response curve to acetylcholine determined. A volume of 0.5 ml (an amount sufficient to put the whole outer surface of the organ into contact with the bathing solution) of acetylcholine at the desired concentration is applied within 2–3 s from a syringe to the outer surface of the target organ. To construct a dose-response curve of acetylcholine, increasing concentrations are applied to the target organ until maximal contraction is obtained. After at least 3 or more control curves have been obtained at 10 min intervals, the antagonist is administered.

EVALUATION

The quantitative analysis of the data is carried out by plotting the results of each experiment as log (acetylcholine dose ratio-1) against log dose antagonist (Arunlakshana and Schild 1959). The regression line is calculated according to the method of least squares and ED_{50} values and 95% confidence limits according to Litchfield and Wilcoxon (1949). From ED_{50} values, the dose of the antagonist (mg/kg i.v.) to produce an acetylcholine dose ratio of 10 is calculated according to Daly et al. (1975). Parallel displacement to the right of the agonist dose response curve and a slope of unity for the regression line indicate competitive antagonism. The DR_{10} values from different organs are compared by means of Student's *t*-test for unpaired data.

MODIFICATIONS OF THE METHOD

In vivo registration of gut motility in guinea pigs was already described by Straub and Viaud (1933). A four cm long part of the gut was ligated and filled with Tyrode solution. Gut motility was measured at variable intraluminal pressure.

J.4.3.4 Colon Motility in Anesthetized Rats

PURPOSE AND RATIONALE

The influence of spasmolytic drugs on carbachol induced increase of colonic motility can be measured in anesthetized rats. The method has also be used to study the stimulation of colonic motility by an enkephalin analogue pentapeptide (Bickel 1983).

PROCEDURE

Male Sprague-Dawley rats weighing 350–500 g are anesthetized with pentobarbital i.v. A pressure sensitive tip catheter is inserted into the colon ascendens and the signals of the intraluminal pressure changes are recorded. The colonic contractions are stimulated by i.v. injection of 3 mg/kg carbachol. The height and the duration of the contractions are recorded. Then, the test compound is injected intravenously. The decrease of contractions is measured and the duration of the spasmolytic activity determined by repeated administration of carbachol at 15 min intervals, until the contractions are not significantly different from the response obtained with carbachol alone.

EVALUATION

Significant differences are calculated using Student's unpaired *t*-test.

MODIFICATIONS OF THE METHOD

Maggi and Meli (1984) used eserine-induced hypertonus of **guinea pig** distal colon *in vivo* as a phar-

macological procedure for testing smooth muscle relaxants. Male albino guinea pigs weighing 240–300 g are anesthetized with 1.5 g/kg urethane s.c. Through a midline abdominal incision, the proximal part of the hypogastric loop of the distal colon is exposed and occluding silk ligatures are applied at a distance of 2 cm from each other, taking great care to avoid any lesion to the vascular and nervous supply. Through a small incision, the flanged tip of a polyethylene tube (1 mm i.d., 1.5 mm o.d.) is inserted into the lumen and secured by means of a purse-string ligature. The free end of the tube is connected to a pressure transducer and the whole system is filled with saline. Intraluminal pressure and its variations are recorded on a polygraph. The effect of drugs is assessed as inhibition of eserine induced hypertonus.

Théodorou et al. (1991) studied the absorptive and motor components of the antidiarrheal action of loperamide in **pigs**. Motility was recorded by implantation of intraparietal electrodes into various parts of the gut.

Raffa et al. (1987) used a method utilizing the insertion of a 3 mm glass bead into the distal colon in **mice** to evaluate the activity of intracerebroventricularly administered μ- and δ-opioid agonists on colonic bead expulsion time.

J.4.3.5 Continuous Recording of Electrical and Mechanical Activity in the Gut of the Conscious Rat

PURPOSE AND RATIONALE

Bueno et al. (1981) described a method for continuous electrical and mechanical activity recording in the gut of the conscious rat. In this study two methods for the continuous recording of motor events – microtransducers and the electromyogram – are compared for the rat stomach and intestine.

PROCEDURE

Male Wistar rats weighing 200–300 g are housed singly in wire-bottomed cages and allowed lab chow and water ad libitum during the training period of 30 days. Under halothane anesthesia pairs of electrodes are implanted along the greater curvature of the pyloric antrum 5 and 2 cm from the pylorus, on the antimesenteric border of the duodenum 2 and 5 cm beyond the pylorus, and along the jejunum, 4 cm from the pylorus using a procedure described by Ruckebusch and Fioramonti (1975).

The contractions of the circular muscle layer are recorded with strain gauge microtransducers sutured onto the serosa at less than 1 cm from each set of electrodes (Pascaud et al. 1978). The free ends of the electrodes and strain gauge wires are carried subcutaneously and exteriorized on the back of the neck. The wires are inserted into a glass tube (15 cm and 0.5 cm external diameter) to prevent twisting and any contact with the metallic lids of the cage.

EVALUATION

Both electrical and mechanical activities are continuously recorded starting 5–7 days after surgery on a multichannel recorder (e. g., 8-channel Dynograph, Beckman, USA) using lead selector couplers (type 9856, Beckman) at a constant time of 0.1 s for the electrical spiking activity and strain gauge couplers (type 9863, Beckman) for the contractile force minitransducers. Simultaneously low frequency signals (frequency < 3 Hz) of the electromyogram are eliminated through filters and the spiking activity, integrated for each 20 s, is recorded on a potentiometric recorder. The electrical and mechanical activities are also recorded simultaneously on a magnetic tape recorder.

The index of motility, expressed as mcoul/min is calculated from the integrated records of electrical activity. The index of mechanical motility is calculated as the area under all contraction waves occurring during 1 min, and is expressed as gs/min. Mechanical and electrical activities during a test period of 30 min after administration of stimulant drugs, e. g., the gastrointestinal hormones gastrin and cholecystokinin, or relaxing drugs, like anticholinergic agents, are compared with the values of a 30 min pretest period.

MODIFICATIONS OF THE METHOD

Wright et al. (1981) described a similar method for long-term recording of intestinal mechanical and elec-

trical activity in the unrestrained rat. Mechanical activity is detected using miniaturized half-bridge metal foil strain-gauge force transducers. The electrical activity is monitored by silver/silver chloride bipolar electrodes. The lead wires from the recording units are encased in a metal compression spring and are permanently joint to a ball connector positioned on the top of the cage, such allowing the animal free access to all parts of the cage.

Stam et al. (1995) described computer analysis of the migrating motility complex of the small intestine recorded in freely moving rats. Myoelectric activity of the small intestine was recorded digitally in fasted, freely moving rats with multiple pairs of electrodes in the antimesenterial smooth muscle. A computer program was developed to distinguish the three characteristic phases of the migrating motility complex.

Fändriks (1993) measured duodenal wall motility, mucosal fluid transport and alkaline secretion in anesthetized **cats**. A triple-lumen tube supplied with two small balloons was positioned via the esophagus in the duodenal lumen and its distal end was led through a small incision in the antimesenteric border of the distal duodenum at the level of the ligament of Treitz. The most oral of the balloons was positioned immediately to the pylorus. After filling with air, the balloons occluded the lumen and isolated a 2 cm segment of the proximal duodenum. A double-lumen tube was inserted into the stomach for luminal perfusion.

Martinez et al. (1993), Jimenez et al. (1994) studied gastrointestinal motility and coordination in **chickens**. Animals were chronically implanted with electrodes in stomach, duodenum, ileum, caeca and rectum.

Nakajima et al. (1996) used a telemetric device (supplied by Data Sciences International, Inc., St Paul, MN) which can be implanted in the abdominal cavity of small animals. Gastric motility of freely moving rats could be continuously recorded for up to 60 days.

J.4.3.6 Propulsive Gut Motility in Mice

PURPOSE AND RATIONALE

The passage of a charcoal meal through the gastrointestinal tract in mice is used as parameter for intestinal motility and to study the effect of laxatives.

PROCEDURE

Groups of 10 female mice (e. g., NMRI strain) weighing 15 g are fed an oat diet for 3 days. Eighteen hours prior to the experiment food, but not water, is withdrawn. The animals are treated either subcutaneously 15 min or orally 60 min before administration of the charcoal meal (0.2 ml of a 4% suspension of charcoal in 2% carboxymethylcellulose solution). The mice are sacrificed after various time intervals, 20 min, 40 min, 60 min and 120 min. Ten animals serve as controls for each time interval. The entire intestine is immediately removed and immersed in 5% formalin to halt peristalsis; then washed in running water. The distance the meal has traveled through the intestine as indicated by the charcoal is measured and expressed as percent of the total distance from the pylorus to the caecum.

EVALUATION

Student's *t*-test is used to compare the control and the drug-treated group.

CRITICAL ASSESSMENT OF THE METHOD

The charcoal passage test can be used for evaluation of laxative activity as well as for inhibition of intestinal motility.

MODIFICATIONS OF THE METHOD

Instead of charcoal, unsubstituted Hostapermblau (CuPcB) suspended in gummi arabicum mucilage can be used.

Carmine red (15) suspended in a 1% tragacanth solution was used for measurement of small intestine transit in **rats** (Leng-Peschlow 1986).

Miller et al. (1981) measured the intestinal transit in the rat by the use of radiochromium (^{51}Cr). Female Sprague Dawley rats weighing approximately 200 g were implanted with indwelling silastic cannulae in the proximal duodenum. Following a 3 day recovery period, the animals were fasted for 18 h and then treated with the test compounds. Thirty min later, 0.2 ml of radiochromium (0.5 mCi $Na^{51}CrO_4$) was instilled into the small intestine via the indwelling silastic cannula. Twenty-five min after chromium instillation, the animals were sacrificed. The small intestine was carefully removed and divided into 10 equal segments. The radioactivity was determined with an automatic gamma counting system. The effect of drugs could be quantified by determining the geometric center of the distribution of chromium through the small intestine.

Shook et al. (1989) used radiolabeled chromium to measure gastrointestinal transit in mice.

Megens et al. (1989) used the charcoal test to study the *in vivo* dissociation between the antipropulsive and antidiarrheal properties of opioids in rats.

Lish and Peters (1957) recommended an intestinal antipropulsive test in intact insulin-treated rats providing certain advantages over the commonly used charcoal meal test for screening of synthetic antispasmodic and antipropulsive agents.

J.4.3.7 Nerve-Jejunum Preparation of the Rabbit

PURPOSE AND RATIONALE

Perivascular nerve stimulation induces cessation of peristalsis of rabbit jejunum (Finkelman 1930). Effects of test compounds on this phenomenon can be tested.

PROCEDURE

Albino rabbits are sacrificed and the jejunal part of the gut prepared. The nerve lies in the mesentery along with the arterial blood supply. Nerve-jejunum preparations are suspended in an organ bath. The preparation is stimulated with pulses at a frequency of 20 Hz with 0.5 ms and about 5 volt for 10 s at 3 min intervals. Test compounds are applied to the organ bath in a cumulative manner at 6 min intervals. Peristalsis movements for each period of 3 min between drug application or of the period of cessation of peristalsis induced by nerve stimulation of the rabbit jejunum preparation are recorded. The effect of drugs on spontaneous peristalsis movement and on the cessation of peristalsis movement exerted by perivascular nerve stimulation is tested.

EVALUATION

The areas of peristalsis movement for each period of 3 min are measured using a planimeter. The effects are expressed as percentage of change between controls and test compound treated preparations.

J.4.3.8 Motility of Gastrointestinal Tract in Dogs

PURPOSE AND RATIONALE

Intraluminal pressure and motility of the small intestine can be measured in unanesthetized dogs with balloon catheter systems via a duodenal Mann-Bollman (1931) fistula according to Tasaka and Farrar (1976) or in the loop of a Thiry–Vella fistula (see below).

PROCEDURE

Fistulas of the small intestine are created in male Beagle dogs weighing 15–20 kg. The animals are anesthetized with 40 mg/kg pentobarbital i.v. and fixed on an operation table. After shaving and careful disinfection of the skin a midline incision is made. A 10–15 cm length of ileum, approximately 15 cm proximal to the caecum, is excised. The remaining ileum is anastomosed end-to-end. The excised ileum is anastomosed, end to side, to the proximal or middle jejunum. Radiopaque tantalum markers are sutured to the serosa distal to this anastomosis in order to guide the direction for subsequent intubation. The other end is sutured to the skin. To create a skin ileostomy which does not shrink rapidly, a small amount of muscle, fascia and subcutaneous tissue are excised from the abdominal wall.

For the measurement of the pressure inside the intestine, an air-filled system is employed. Air-filled latex balloons (Cementex), 5 mm in diameter, are attached to air-filled PE 190 polyethylene catheters (ID 1.19 mm) with a length of 120 cm. Three balloon-catheter pressure assemblies are tied together with the balloons 5 cm apart. The catheters are connected to Statham p23 db pressure transducers and to a polygraph. The transducers are rendered airtight by repeated applications of latex to all the connections.

The dogs are withheld from food, but not from water 18 h prior to the experiment. The balloon-catheter assemblies are introduced through the fistula and secured in an appropriate position. The system is filled with air to a pressure of 10 mm Hg. Similarly, balloon-catheter assemblies can be introduced into a Thiry–Vella fistula.

Intraluminal pressure is measured continuously; frequency and amplitude of pressure waves are recorded. After a period of 1 h, the test drug is administered orally or subcutaneously and the above mentioned parameters recorded for 10 min intervals.

EVALUATION

For 10 min intervals amplitude frequency (f_A), average degree and duration of amplitudes (A) and average pressure performance (PL_i) are calculated. Post-drug values are compared with pre-drug readings.

MODIFICATIONS OF THE METHOD

Goldenberg and Burns (1973) reported on a technique using rubber balloon catheters inserted in the duodenum, ileum, or colon of dogs, secured by purse-string sutures and filled with water to record intraluminal pressure monitored by Statham pressure transducers connected to a polygraph. Furthermore, an antispasmodic agent can be tested for relaxation of morphine sulfate (0.3 mg/kg i.v.) induced spasms of the intestinal tract.

Fox et al. (1985) implanted chronically extraluminal strain gage force transducers on the serosal surface of the gastrointestinal tract of dogs.

J.4.3.9 Thiry–Vella Fistula

PURPOSE AND RATIONALE

As described first by Thiry (1864) and improved by Vella (1892), a part of the jejunum is isolated and the ends are exteriorized through the abdominal wall allowing to measure *in vivo* motility and function of the intestines in dogs and other species (Boldyreff 1925).

PROCEDURE

Male Beagle dogs weighing 15–20 kg are used. They are fasted 24 h preoperatively. Intravenous pentobarbital sodium, 30 mg/kg, provides satisfactory anesthesia. It can be supplemented, if necessary, during operation. The abdominal part is shaved with electric clippers, then with a razor. The skin is disinfected with Zephiran –70% alcohol. Sterile drapes are applied to cover the whole operative field. A mid-line linea alba incision is made. A loop of the jejunum, about 70 cm in length, is separated leaving the blood supply through the mesenterium intact. Both distal and proximal ends are exteriorized through the abdominal wall and provided with stomata. An end-to-end jejuno-jejunal anastomosis is performed.

EVALUATION

The preparation can be used to evaluate intestinal motility. A latex balloon connected via a polyethylene catheter to a pressure transducer (Statham P 23 BB) is introduced through the proximal ostium. Changes in

intragastric pressure are measured on a frequency measurement bridge and are recorded continuously. The number and height of the pressure waves are used as indices of intestinal motor activity. Secretin inhibits motility of the small intestine dose-dependent.

MODIFICATIONS OF THE METHOD

Sarr et al. (1981) and Bastidas et al. (1990) used **dogs** with Thiry–Vella loops to study jejunal absorption.

Bilchik et al. (1993) examined the effects of physiological doses of peptide YY in dogs with jejunal and ileal exteriorized, neurovascularly intact Thiry–Vella fistulas.

Ashton et al. (1996) created Thiry–Vella fistulas using a 20 cm segment of distal colon under general anesthesia in dogs. Colonic absorption of water and electrolytes was evaluated in awake, conscious animals.

Liu et al. (1996a) studied the effects of intravenous peptide YY on colonic water and electrolyte transport in awake dogs which had 20 cm neurovascularly intact colon Thiry–Vella fistulas.

In an other study, Liu et al. (1996b) evaluated the effects of cholecystokinin and peptide YY on intestinal absorption of water and electrolytes using colonic, ileal, or jejunal fistulas in dogs.

These authors (Liu et al. 1995) also examined the effects of intraluminal administration of a new substituted peptide YY analog on intestinal absorption of water and electrolytes in dog with jejunal, ileal and colonic Thiry–Vella fistulas.

Barry et al. (1995) investigated the effect of luminally administered dopamine, the D_1-receptor agonist SKF 38393, the α_1-receptor antagonist terazosin, and the α_2-receptor antagonist yohimbine on ileal water and electrolyte transport in dogs with Thiry–Vella fistulas.

Walters et al. (1994) described the effect of a model of canine jejuno-ileal orthotopic autotransplantation on jejunal and ileal transport of water and electrolytes. For neurally intact jejunal loops, myoneural continuity between the loop and the proximal duodenum and jejunum was maintained by preserving a bridge of tunica muscularis devoid of mucosa between the proximal jejunum and the loop. All intrinsic neural and lymphatic continuity to the loop was carefully maintained by not transecting any of the mesentery to the loop.

For the autotransplanted jejunal loop the dogs underwent construction of an identical loop with the muscular bridge after preparation of an jejuno-ileal autotransplantation. For this purpose, all neural, lymphatic, myogenous, and connective tissue connections with the jejuno-ileum were transected except for the fully isolated and stripped superior mesentery artery and vein at the base of the small bowel mesentery. The perivascular and adventitial tissue of these two vessels were carefully dissected away and transected under optical magnification. From here, the mesenteries to the distal duodenum and to the distal ileum were transected in radial fashion and the distal duodenum and distal ileum 5 cm from the ileo-colonic junction were also transected. At this point, the jejuno-ileum was completely isolated from any neural/lymphatic continuity with the dog except for any neural/lymphatic elements travelling within the media of the mesenteric artery and vein.

Neurally intact and autotransplanted ileal loops were prepared in a similar way.

Remie et al. (1990) described in detail the preparation of a Thiry–Vella loop in the **rat**. After laparotomy the segment to be isolated has to be located carefully. The segment should be vascularized by two or more tributary arteries. For ligation of the arcade, two ligatures are placed around the blood vessels 2–3 mm from each other. The two ligatures are tightened, the gut wall is disinfected with iodine solution, and both the vessels of the arcade and the gut wall are cut. The same procedure is performed at the other end of the segment to be isolated. This segment is laid on gauze moistened with warm saline avoiding torsion of the vessels. For end-to-end anastomosis the remaining parts of the gut are approximated and two corner sutures are placed. A continuous suture with transfixing stitches is placed on the anterior and posterior wall. Using a pair of sharp scissors two holes are made in the abdominal wall and the skin. Subsequently, standard end-to-side anastomosis technique is used to sew the gut to the internal abdominal muscle. The two stay sutures are at 180° and the posterior wall is sutured first. Following this, the skin is sutured to the abdominal muscle, using a running suture.

Chu et al. (1995) used Thiry–Vella fistulas of either the jejunum or ileum in rats in order to determine whether the trophic effects of bombesin on the small bowel mucosa are mediated by nonluminal factors or endogenous luminal secretion.

Bárdos and Nagy (1995) prepared double Thiry–Vella fistulas in rats. The first Thiry–Vella loop was created from the lower duodenum. After 1 month or more, a similar fistula was prepared from the upper part of the colon. The two loops were positioned along the midline and formed a line of 4 openings of the abdominal wall providing an easy access for inserting stimulatory devices to either of the loops in the same animal. A rubber balloon made of latex rubber was tied

to a silicon rubber tube, inserted into the isolated loop via one of its orifices and then fixed to the body by a tape. Stimulation was performed by injection of various volumes of water into the balloon from an attached syringe. Behavioral reactions of the animals were recorded as scores during 10 s stimulation periods.

In order to purify the putative luminal cholecystokinin-releasing factor, Spannagel et al. (1996) collected intestinal secretions by perfusing a modified Thiry–Vella fistula of jejunum in conscious rats.

Snoj et al. (1992) found that phosphatidylcholine inhibited postoperative adhesions after small bowel anastomosis in the rat.

Gianotti and Tchervenkov (1992) used a Thiry–Vella loop in **guinea pigs** to study the stimulatory effect of intraluminal nutriment on burned guinea pig intestinal mucosa.

Philpott et (1993) created Thiry–Vella loops in 21 week old **rabbits** in order to study the influence of luminal factors on intestinal repair during refeeding of malnourished infant rabbits.

Silbart et al. (1996) examined the ability of several bacterial endotoxins and their subunits to act as adjuvants or carrier proteins in stimulating an intestinal secretory Ig4 response to 2-acetylaminoflourene using Thiry–Vella loops in rabbits.

J.4.3.10 Continuous Recording of Mechanical and Electrical Activity in the Intestine of Conscious Dogs

PURPOSE AND RATIONALE

Cyclic motor activity occurring in almost all parts of the gastrointestinal tract is due to a migrating electric complex (Szurszewski 1969; Fioramonti et al. 1980;

Sarna and Condon 1984; Sarna et al. 1984; Sarna 1985). Smooth muscle cells of the gut show periodic oscillations of membrane potentials called electrically controlled activity; they are also named slow waves, basic electrical rhythm, or pacesetter potentials. If the membrane potential depolarizes beyond a certain threshold during such an oscillation, the smooth muscle contracts. This is usually associated with a rapid burst of electrical oscillations, called electrical response activities or spikes. Electrical response activity is, therefore, associated with contractions on a 1:1 basis.

Implantation of extraluminal force transducers allows the monitoring of contractile activity in conscious animals (Bass and Wiley 1972; Ormsbee and Bass 1976; Ormsbee et al. 1981). The data can be analyzed by computer (Ehrlein and Hiesinger 1982; Schemann et al. 1985). The effects of opiate agonists, morphine, natural enkephalins, endorphins, and synthetic enkephalins and opiate antagonists, like nalorphine, as well as other gastrointestinal hormones, such as motilin, can be studied (Bickel and Belz 1985, 1988; Bickel et al. 1985).

PROCEDURE

Male Beagle dogs weighing 15–20 kg are anesthetized with thiobarbital and anesthesia is then maintained with halothane and a mixture of N_2O and O_2 (3:1). Under aseptic conditions several miniaturized strain gauge force transducers are sutured onto the muscular layers of the gastrointestinal tract. Before implantation, the transducers are externally calibrated giving linear signals over a range from 10 to 300 mN. Each transducer has its recording axis perpendicular to the longitudinal axis of the intestine to record contractions of the circular smooth muscles. The proximal ends of the strain gauge transducers are fitted to a plug embedded in a stainless-steel cannula implanted into the abdominal wall. The signals are continuously recorded and stored in a HP 9835A Hewlett Packard computer, allowing later analysis of the data.

For measuring electrical activity, bipolar electrodes are implanted at several parts of the intestinal tract. The lead wires from the electrodes are externalized via a stainless-steel cannula. Electromyogram is recorded on an electroencephalograph.

The animals are kept in a standardized environment with one daily feeding at 9:00 A.M. The dogs are trained to stand in a Pawlov stand. Eighteen hours prior to the beginning of the experiment, the animals are fasted with access to water. Motility data and electrical activity are first recorded for fasting dogs without drug treatment. Then the drug is injected intravenously during the period of quiescence of the migrating motor complex.

EVALUATION

Recordings are analyzed for duration of cycles (min) and motor complexes (min), mean height (mN) and frequency (*n*/min). The length of the cycles is measured from the beginning of one complex to the beginning of the next complex. Electromyogram is analyzed for slow waves (cycles/min), maximum amplitude of the spike bursts (mV), duration of the spike bursts (ms) and duration of the effect (min). The data before and after administration of various doses of the test compound are compared by statistical means (Student's *t*-test).

MODIFICATIONS OF THE METHOD

Itoh et al. (1977) and Nagakura et al. (1996) used extraluminal force transducers for recording contractile motility of the gastrointestinal smooth muscle in conscious dogs.

Nakada (1995) recorded gastrointestinal and gallbladder contractions in conscious dogs by chronically implanted strain gauge transducers and gallbladder volume changes by a chronically indwelling gallbladder catheter.

Orihata and Sarna (1994) investigated contractile mechanism of gastroprokinetic agents in conscious dogs. The spatial and temporal parameters of gastric, pyloric and duodenal contractions during the entire period of gastroduodenal emptying, during a 60-min period of drug infusion and during the post-drug-infusion period were analyzed by a computer method.

J.4.4 Absorption

J.4.4.1 Everted Sac Technique

PURPOSE AND RATIONALE

The everted sac technique is used to study the transport of substances from the mucosal to the serosal surface (Wilson and Wiseman 1954).

PROCEDURE

Male Wistar rats weighing 150–220 g are anesthetized with 30 mg/kg pentobarbitone s.c. A midline abdominal incision is made. The rats are sacrificed by cardiac puncture. The small intestine from the ligament of Treitz to the ileocaecal junction with a length of 6–7 cm is rapidly removed and everted with a glass rod. The sac is securely ligated at both ends and filled with Krebs-Henseleit bicarbonate buffer solution (pH 7.4) containing 0.4% glucose and pre-gassed with 95% O_2/5% CO_2. The sac is incubated at 37°C in a glass vessel containing the same buffer solution and gassed with 95% O_2/5% CO_2.

After 5 min, the drug solution is added to the glass vessel and the preparation is further incubated. After given time intervals, the fluid from the everted sac is removed and the volume determined. The concentration of the drug transported from the mucosal to the serosal side is determined by appropriate analytical methods.

EVALUATION

Determinations of the drug in the everted sac at different time intervals allow evaluation of pharmacokinetic parameters.

MODIFICATIONS OF THE METHOD

Madar (1983) used the small intestine everted sac of **chicken** for demonstration of amino acid and glucose transport.

Harnett et al. (1989) used everted segments of distal ileum of **rats** to study taurocholate absorption.

Turner et al. (1990) used everted sacs of ileum in **sheep** to study selenate and selenite absorption.

Goerg et al. (1992) used the stripped descending colon of the **rat** as everted sac to study the inhibition of neuronally mediated secretion in rat colonic mucosa by prostaglandin D_2.

Under ether anesthesia, the descending colon is removed and transferred into ice-cold bathing solution. The colon is placed on a plastic rod. After a circular incision with a blunt scalpel, the serosa and muscularis propria are stripped away, leaving the mucosal-submucosal preparation consisting of the mucosa, the muscularis mucosae, and a part of the submucosa with the completely preserved submucosal plexus. The tube-like mucosal-submucosal preparation is mounted as an everted sac in a holding apparatus (volume of the outer compartment 25 ml). The potential difference between the outer mucosal side and inner serosal side is measured by two agar bridges. The tissue is short-circuited by a voltage clamp after correcting for the offset potential and compensating for the solution resistance.

Moreover, transmural ion fluxes can be determined with the everted sac technique. Net fluxes of sodium, chloride, and potassium are studied by direct measurements of volume changes and changes of electrolyte concentrations in the inner volume of the everted sacs. Unidirectional fluxes can be determined simultaneously with the direct measurement of net fluxes by adding the isotopes $^{22}Na^+$ and $^{36}Cl^-$ to one side of the everted sac.

Schilling and Mitra (1990) used the everted gut technique in rats to study enteral insulin absorption.

Mizuma et al. (1993) studied the active absorption in the intestine and metabolism of the β- and α-anomers of the glucoside and galactoside of p-nitrophenol to find a more suitable prodrug for poorly absorbed drugs. The everted sac technique was used to investigate the intestinal absorption of these glycosides from the mucosal to the serosal side of the rat jejunum.

Kitagawa et al. (1996) investigated the influence of various factors, such as temperature, on the absorption of methochlorpromazine in the small intestinal everted sac of rats.

Tanaka et al. (1996) estimated the transport characteristics of thyrotropin-releasing hormone (TRH) and its chemically modified derivative with lauric acid (Lau-TRH) across the rat small or large intestine by means of an *in vitro* everted sac experiment.

Sasaki et al. (1995) studied the absorption characteristics of azetirelin, a new thyrotropin-releasing hormone analogue in rats by means of *in situ* closed loop and *in vitro* everted sac experiments.

Toskulkao et al. (1995) examined the effects of stevioside (a natural non-nutritive sweetening agent) and of steviol (a product of enzymatic hydrolysis of stevioside) on intestinal glucose absorption in hamster jejunum using the everted sac technique.

Motozono et al. (1994) determined the effect of age on gastrointestinal absorption of tobramycin in suckling, weanling and adult rats by an everted sac method.

J.4.4.2 Stomach Emptying and Intestinal Absorption in Rats

PURPOSE AND RATIONALE

Reynell and Spray (1956) described a method for the simultaneous measurements of gastric emptying, intestinal transit and absorption of test substances in the rat using phenol red as marker.

PROCEDURE

Adult male Wistar rats weighing 200–300 g are allowed water but are deprived of food 24 h before the experiment. They are treated orally or subcutaneously with the test compound 15 min prior to oral administration by gavage of 1.5 ml 0.07% phenol red in 2% carboymethylcellulose solution. Fifteen min later the animal is sacrificed and the stomach is immediately removed. The whole stomach including the stomach content is alkalized with 1 N NaOH and homogenized. The homogenate is filtered, and after precipitation of the protein with 10% trichloroacetic acid, centrifuged for 15 min at 3000 rpm. The concentration of phenol red in the supernatant is measured colorimetrically in a photometer at 546 nm.

EVALUATION

Percentage of stomach emptying (S_e) is calculated according to the following formula:

$$S_e = 100 - P_s \times P_a^{-1} \times 100$$

- P_s = Concentration of phenol red in the stomach (µg/ml)

- P_a = Concentration of phenol red in the initial solution after addition of equal volumes of 1 N NaOH and trichloroacetic acid (μg/ml)

MODIFICATIONS OF THE METHOD

By selective ligations of the different parts of the gastrointestinal tract and analysis for phenol red contents and for drug substance, as well as by sacrificing the animals after various time intervals, the degree and time course of absorption can be studied.

Droppleman et al. (1980) described a simplified method for assessing drug effects on gastric emptying in **rats**. Three ml of a semi-solid test meal, based on methylcellulose, are given to rats fasted 24 h prior to the experiment. At a specified time following the test meal, the rats are sacrificed, laparatomized, and the stomachs removed. The full stomachs are weighed on an analytical balance; they are opened and rinsed. Excess moisture is removed and the empty stomach weighed again. The difference is subtracted from the weight of 3 ml of the test meal, indicating the quantity emptied from the stomach during the test period. Gastric motor stimulants, e. g., metoclopramide increase, and anticholinergic compounds decrease gastric emptying.

Megens et al. (1990) used phenol red as marker to measure gastrointestinal propulsion after castor oil or paraffin oil challenge in **rats**.

Hedge et al. (1995) studied 5-HT_4 receptor mediated stimulation of gastric emptying in rats using a specially prepared semi-solid test meal containing charcoal.

Bonnafous et al. (1995) investigated benzodiazepine-withdrawal-induced gastric emptying disturbances in rats. Male Wistar rats, weighing 200–250 g, fasted for 16 h, received by gavage 2 ml of a test meal containing 1 μCi/ml of ^{51}Cr sodium chromate, 15 min after drug administration. Thirty min later, the animals were sacrificed by cervical dislocation. The stomach, small intestine (10 segments) and the colon were excised and placed into tubes. Radioactivity was determined by placing the tubes in a gamma counter. Gastric emptying was calculated as the percentage of total counts found in the small intestine and the colon.

Varga et al. (1995) determined gastric emptying in rats 5 min after a 3-ml intragastric load of 0.9% NaCl using phenol red as marker in order to define which bombesin receptors are involved in the delay of gastric emptying by bombesin-like peptides.

Lasheras et al. (1996) studied gastric emptying in rats. Sixty min after oral administration of vehicle or test compounds, the rats received by gavage 40 steel spheroids (1 mm diameter) in 2 ml 3% carboxymethylcellulose. Sixty min later, the animals were sacrificed and the spheroids remaining inside the stomach counted.

Yegen et al. (1996) studied the inhibitory effects of gastrin releasing peptide on gastric emptying in rats using methyl cellulose and phenol red as non-absorbable marker.

Haga et al. (1994) studied gastric emptying in **mice**. Male mice, weighing 18–22 g, had free access to food and water before the experiment. The test compounds were administered orally in 10 ml/kg 0.5% methylcellulose solution. The mice were deprived of food an water and sacrificed 4 h later by cervical dislocation. The stomachs were removed and opened. The contents of the stomach were mixed with 10% trichloroacetic acid, and centrifuged at 3000 rpm for 30 min. The weight of the sediment was taken as the food remaining in the stomach.

Ding and Håkanson (1996) examined the effect of drugs on a cholecystokinin-A receptor-mediated response by gastric emptying of a charcoal meal in mice.

Costall et al. (1987) used the **guinea pig** to study the influence of a 5-HT_3 antagonist on gastric emptying.

Brighton et al. (1987) used scintigraphy following indium-111-labeled meals in Beagle **dogs** and **baboons**. Indium-111-labeled polystyrene beads (500 mCi per dog) were mixed into a meal consisting of 50 g of finely crushed commercial dog food and 50 ml of milk. Images of 1 min duration were taken every 5 min for a period of 1 h using a large field of view gamma camera (ON Sigma 410).

Gullikson et al. (1991, 1993) studied gastric emptying of a solid meal in dogs.

J.4.4.3 Intestinal Drug Absorption

PURPOSE AND RATIONALE

Doluisio et al. (1969) described an *in situ* rat gut technique to determine absorption rates of drugs.

PROCEDURE

Male Sprague-Dawley albino rats weighing 220–260 g are fasted 16–24 h prior to surgery allowing, however, drinking water ad libitum. They are kept in cages having wide mesh floors to prevent coprophagia. One hour prior to surgery, the animals are anesthetized with 1 g/kg ethylurethane i.p. The small intestine is exposed by a midline abdominal incision, and two L-shaped glass cannulae are inserted through small slits at the duodenal and ileal ends. Care has to be taken to handle the small intestine gently in order to maintain an intact blood flow. The cannulae are secured by ligation with silk suture, and the intestine is returned to the abdominal cavity. Four cm long segments of tubings are attached to the exposed ends of both cannulae, and a 30-ml hypodermic syringe fitted with a three-way stopcock and containing perfusion fluid warmed to 37°C is attached to the duodenal cannula. As a means of clearing the gut, perfusion fluid is passed slowly through it and out the ileal cannula to be discarded until the effluent is clear. The remaining perfusion solution is carefully expelled from the intestine by means of air pumped through from the syringe.

Immediately afterwards, 10 ml of drug solution are introduced into the intestine by means of a syringe. The stopwatch is started, and the ileal cannula is connected to another 30 ml syringe fitted with a three-way stopcock. This arrangement enables the operator to pump the lumen solution into either the ileal or the duodenal syringe, remove 0.1-ml aliquots, and return the remaining solution to the intestine within 10–15 s. To assure uniform drug solution concentrations throughout the gut segment, aliquots are removed from the syringes alternatively. Samples are collected every 5 min. Depending on the drug to be studied, the concentration is determined by chemical methods.

EVALUATION

The concentrations of the drug are plotted on a logarithmic scale on the ordinate versus time on the abscissa on a linear scale. Half-life values can be calculated.

MODIFICATIONS OF THE METHOD

Ochsenfahrt (1979) described a more sophisticated method to measure the absorption of drugs in the vascularly perfused, isolated intestine of the rat. Male rats weighing about 350 g are anesthetized with urethane. The abdomen is opened by a midline incision. The mesentery of the ascending and transverse colon is gently pulled away from the mesentery of the small intestine. The vessels to the colon are ligated and cut. The superior mesenteric artery is freed from the surrounding mesentery. The duodenal vessels are ligated and cut. A suitable segment of the jejunum of about 7 cm length is selected. The proximal cannula is tied into the lumen of this segment, and the duodenum is cut. The lumen of the segment is washed with 3–4 ml warm Krebs-Henseleit solution. Then, the distal cannula is tied. After the mesenteric vessels distal to the experimental segment are ligated, the rest of the small intestine, ileum, and colon is excised. Temporarily, the intestine is covered with gauze soaked with saline solution.

The preparation of the rat is interrupted for 8–10 min, while a second rat (donor rat), which has been anesthetized with urethane, is prepared. The donor rat supplies the arterial blood; the sponta-

neous respiration is supported with a respiration pump through a tracheal cannula. The right jugular vein of the donor rat is cannulated for the blood infusion and 2 mg heparin dissolved in 0.1 saline solution is administered. A cannula is placed into the left carotid artery of the donor rat; this tube is later connected to the superior mesenteric artery of the test segment. Blood lost by the donor rat is replaced with heparinized blood taken from other rats immediately before the beginning of the experiment.

In the test animal, a thin silicon tube is inserted in the left carotid artery. Two mg heparin, dissolved in 0.1 ml saline, are injected. The superior mesenteric vein is ligated distal to the splenic vein and a plastic cannula is inserted for venous outflow. The cannula is then connected to a drop counter. The luminal cannulae of the segment are connected to a recirculation unit which is filled with Krebs-Henseleit solution at 37°C, and the luminal perfusion of the segment (mucosal solution) is started. The mucosal solution is oxygenated and recirculated. The superior mesenteric artery is ligated with a thread at its origin at the aorta and then cannulated. This cannula is first connected to the carotid artery of the test animal and later to the carotid artery of the donor animal. The isolated vascularly perfused segment is suspended in a serosal bath containing Krebs-Henseleit solution at 37°C. Venous blood outflow is collected in plastic vials at 15 min intervals. Samples are taken from the mucosal and serosal solutions at the beginning and the end of each period. By this way, the mucosal disappearance rate, the venous appearance rate, and the serosal appearance rate can be measured.

Schilling and Mitra (1992) measured insulin absorption from the distal duodenum/proximal jejunum and from the distal jejunum/proximal ileum in anesthetized rats by the closed-loop technique.

Schümann and Hunder (1996) described a modified device for the differentiated study of intestinal transfer in isolated intestinal segments from mice and suckling rats *in vitro*. A luminal perfusion system for small intestinal segments was adapted for the use in mice and rat pups to investigate longitudinal differences in drug and toxin transfer.

J.4.5 Duodenal Ulcer Formation

J.4.5.1 Cysteamine-Induced Duodenal Ulcers in Rats

PURPOSE AND RATIONALE

Duodenal ulcers can be induced in rats by repeated administration of cysteamine or propionitrile in rats (Dzan et al. 1975; Szabo 1978; Szabo et al. 1979).

PROCEDURE

Male Sprague-Dawley rats with an initial weight of 200 g are used. Cysteamine-HCl is administered three times on day 1 in a dose of 280 mg/kg orally. Protective drugs, such as H_2-antagonists, are given 30 min prior cysteamine treatment. The rats are sacrificed on the third day. For histological evaluation, the stomach and duodenum are fixed in 10% aqueous buffered formaldehyde and paraffin-embedded sections are stained with hematoxylin and eosin. Duodenal ulcers develop in the anterior (antimesenteric) and posterior wall of the proximal duodenum, about 2–4 mm from the pylorus. The more severe ulcers, located on the anterior wall, frequently perforate, resulting in focal or generalized peritonitis, or penetrate into the liver. The opposite ulcer invariably penetrates into the pancreas.

EVALUATION

The intensity of the duodenal ulcer is evaluated using scores from 0 to 3.

- 0 = no ulcer
- 1 = superficial mucosal erosion
- 2 = deep ulcer usually with transmural necrosis
- 3 = perforated or penetrated ulcer

CRITICAL ASSESSMENT OF THE METHOD

In view of the development of modern gastric K^+/H^+-ATPase inhibitors the predictive value of methods using experimental ulcers in the rat for clinical healing rates in man has been challenged (Herling and Weidmann 1994).

MODIFICATIONS OF THE METHOD

The cysteamine-induced duodenal ulcer has been used for pharmacological studies by many authors, e. g.:

Evangelista et al. (1992), Krantis et al. (1993), Pascaud et al. (1993), Tanaka et al. (1993), Morimoto et al. (1994), Pendley et al. (1995), Sikiric et al. (1997), Drago et al. (1999).

Okabe et al. (1971), Sato et al. (1989) described a method for experimental, penetrating gastric and duodenal ulcers in rats. Rats were anesthetized with ether and an incision was made in the abdomen. A round metal mold, 6 mm in diameter, was placed in close contact with the serosal surface of the duodenal wall, about 7 mm distal to the pylorus. **Glacial acetic acid** (60 ml) war poured into the mold and was left in place for 20 s. After the acetic acid was removed, the treated surface was rinsed with 50 ml of 0.02 N NaOH and the abdomen was closed. A drug or the vehicle was given p.o. once a day for 14 consecutive days beginning 2 days after the operation. The animals were sacrificed on the 16th day after the operation and the ulcerated area (mm^2) was measured.

Mepirizole-induced duodenal ulcers were described by Okabe et al. (1982), Sato et al. (1989), Tanaka et al. (1989). A drug or the vehicle was given p.o. 30 min before mepirizole (200 mg/kg) was administered s.c. Twenty-four hours later, 1 ml of 0.5% Evan's blue solution was injected via the tail vein of each rat and the rats were sacrificed by CO_2 asphyxiation. The gastroduodenal region was removed and examined for lesions.

J.4.6 Models of Inflammatory Gut Disease

J.4.6.1 Experimental Ileitis

PURPOSE AND RATIONALE

An experimental model of inflammatory bowel disease produced by the intraluminal administration of the cytotoxic plant lectin ricin into the rabbit ileum was developed by Sjogren et al. (1994), Goldhill et al. (1995, 1997). *In vitro*, electric field stimulation results

in larger non-cholinergic excitatory junction potentials in ricin-treated circular muscles than in controls.

PROCEDURE

Inflammation

Acute ileitis is induced with ricin in male New Zealand white rabbits. The animals are anesthetized with intramuscular xylazine (9 mg/kg) and ketamine (50 mg/kg) and maintained with intravenous pentobarbital (15 mg/kg). A midline incision is made, a ligated terminal ileal loop (~10 cm in length) is constructed in each animal and 1 ml of ricin (1 mg/ml) or vehicle is injected into the lumen. The loop is removed after 5 h, a time period that allows development of ileitis, abnormal myoelectric activity and increased response to electric field stimulation. Animals are sacrificed with an overdose of pentobarbital. The loop is opened along its length, gently flushed of luminal contents with cold oxygenated Krebs-bicarbonate-saline and prepared for contractility studies.

Contractility Studies

Muscle strips (~1 × 0.4 cm) with mucosa removed are cut in the axis of the circular muscle and attached to isometric tension transducers in 10-ml organ baths with modified oxygenated Krebs-bicarbonate-saline at 37.5 ± 0.5°C. Tissues are allowed to equilibrate at L_i (the length at which no tension can be measured) for 20 min. The strips are then stretched to L_0, which is determined as the length at which maximum force is generated in response to acetylcholine (0.5–1 mM). Strips are then allowed to equilibrate for an additional 20 min.

Effect of Inflammation on Response to Tachykinins

Concentration-response curves are constructed to substance P and neurokinin agonists (or analogues) on separate muscle strips in vehicle- and ricin-treated tissues. Studies are performed in the presence or absence of tetrodotoxin to distinguish between neural and non-neural effects of ricin treatment.

Effects of Ricin Treatment to Responses to Electrical Field Stimulation

Muscle strips are passed through a pair of ring electrodes (2-mm diameter) and stimulated for 10 s by square-wave pulses (0.5 ms duration, supramaximal voltage) at 1–10 Hz. Stimulation is performed in the presence of atropine (1 mM) and N^G-nitro-L-arginine methyl ester) (L-NAME) (0.1 mM).

EVALUATION

Maximum increases in muscle tone in response to tachykinin addition of electrical field stimulation are obtained through visual analysis of chart recorder outputs. Responses to tachykinins are expressed as absolute tension development. Electrical field stimulation data are expressed as a percentage of the response to 1 μM acetylcholine added at L_0 to reduce the variation of the data. Values are given as mean ± SEM Tachykinin concentration responses are fitted to sigmoid curves and EC_{50} values (with 95% confidence intervals) are determined from these curves. Differences between frequency or concentration-response curves are assessed statistically by multivariate analysis of variance, with adjustments made for multiple comparisons. In cases in which curves are significantly different to one another, maximal responses were compared statistically using Student's *t*-test.

MODIFICATIONS OF THE METHOD

Miller et al. (1991) induced ileitis in **rabbits** by luminal perfusion with histamine monochloramine or with acetic acid.

Rachmilewitz et al. (1997) induced inflammation in the small intestine in **rats** by intrajejunal administration of 0.1 ml 2% iodoacetamide.

Sukumar et al. (1997) induced ileitis in rats by two doses of indomethacin (7.5 mg/kg) administered subcutaneously 24 h apart.

Ileitis in **guinea pigs** was induced by intraluminal trinitrobenzene sulfonic acid (Miller et al. 1993; Izzo et al. 1998; Mazelin et al. 1998).

Likewise, ileitis in **hamsters** was induced by intraluminal injection of trinitrobenzene sulfonic acid (Boyd et al. 1995).

Shibata et al. (1993) induced ileitis in **dogs** by administration of 10 ml 100% ethanol and 1 g trinitrobenzene sulfonic acid dissolved in 10 ml water through a tube inserted into the ileum.

Interleukin-10 (IL-10) is produced by T cells, B cells, and macrophages. It down-regulates the function of T helper (Th) -1 cells, natural killer (NK) cells, and macrophages. In 1993, Kuhn et al. reported that, in IL-$10^{-/-}$ mice, inflammation occurred in the whole intestine. The lesions were observed mainly in the duodenum, proximal jejunum, and ascending colon. Pathological thickening of the intestinal wall, due to hyperplastic changes, was observed in the duodenum and jejunum. In the colon, goblet cell depletion, degeneration of the epithelium, infiltration of IgA-producing plasma cells, and an increase in major histocompatibility complex (MHC) class II expression were detected. As in the IL-$2^{-/-}$ mice, the activation of $CD4^+$ cells and the depletion of their inhibitor, the regulatory T cells, are presumed to be the cause of the inflam-

mation. In 2000, Jijon et al. assessed the mechanism behind a poly (ADP-ribose) polymerase (PARP) induced increase in epithelial permeability that is associated with chronic, non-resolving colitis, which develops spontaneously in the IL-10-gene-deficient mouse. They demonstrated that treatment of IL-10-deficient mice with the PARP inhibitor 3-aminobenzamide reversed the typical signs of Crohn's disease in these mice, namely increased permeability, high levels of mucosal interferon-α (IFN-α) and tumor necrosis factor α (TNF-α), and increased nitric oxide (NO) production. In the same year, Cantorna et al. (2000) used the IL-10-deficient mouse model to investigate the role of vitamin D on the course of inflammatory bowel disease (IBD). The animals were divided into three groups: vitamin D deficient, vitamin D sufficient, and active vitamin D supplemented. In contrast with vitamin D-deficient IL-10 knockout (KO) mice, vitamin-D-sufficient mice did not develop diarrhea, waste, or die prematurely. To the authors' surprise, supplementation with active vitamin D for only 2 weeks blocked the progression and significantly ameliorated the symptoms in the mice that had established spontaneously developed IBD. The importance of animal models for the evaluation of pharmacological strategies was further emphasized in a straightforward mini-study conducted by Gratz et al. (2002), who administered murine monoclonal anti-TNF-α antibodies intraperitoneally into IL-10 KO mice that had established IBD. Demonstration of significant histological improvement of inflammation that correlated well with a resolution of diarrhea and rectal bleeding accentuated the pivotal role that TNF-α appears to play in the pathogenesis of IBD and emphasized the importance of this model. Recently, a pioneer therapeutic approach to IBD was tested in the IL-10 KO model by Watanabe et al. (2003a, 2003b). The group developed poly-DL-lactic acid microspheres containing dichloromethylene diphosphonate that, once administered rectally, were specifically taken up by macrophages, subsequently depleting them. The authors showed reduced numbers of resident macrophages in the intestinal lymphoid follicles in this model, associated with suppression of development of chronic colitis.

J.4.6.2 Experimental Colitis

PURPOSE AND RATIONALE

Inflammatory bowel diseases, ulcerative colitis and Crohn's disease, represent chronic alteration of the

gastrointestinal tract of unknown etiology perhaps involving immunological events. The immunological parameters have been described as secondary but may possibly be attributed to the chronicity of the disease. Several compounds have been described to elicit cell-mediated immune responses in the gut, such as dinitrochlorobenzene (DNCB) (Rosenberg and Fischer 1964; Norris et al. 1982; Norris 1989) or 2,4,6,-trinitrobenzene sulfonic acid (TNBS) (Morris et al. 1989; Selve and Wöhrmann 1992).

PROCEDURE

A three-step concept is realized to mimic the human disease, using 2,4,6-trinitrobenzene sulfonic acid (TNBS) as a defined hapten:

1. specific hypersensitivity by active immunization,
2. local inflammation by local challenge,
3. chronicity by chronic application of the immunogen.

Female Sprague Dawley rats weighing 150–200 g are sensitized by intradermal injection of 0.8% TNBS (Fluka, Neu-Ulm, Germany) solution into a shaved area on the back once daily for three consecutive days. TNBS is dissolved in 0.05 ml Freund's incomplete adjuvant together with 1 mg/ml ovalbumin. After 18 days, the animals receive a further intradermal booster injection. Intradermal challenge of 0.08% TNBS in 0.05 ml 0.9% NaCl solution with or without ovalbumin, or ovalbumin solution without TNBS, is given 14 days later in order to determine the type and specificity of the immunological reaction.

Ten days after the intradermal challenge, a flexible polyethylene tube of 0.5 mm diameter is implanted under ketamine (100 mg/kg i.p.) anesthesia 15 cm proximal to the cecum and emerging at the neck for TNBS or drug administration. After a 10-day recovery phase, the animals are treated daily for 3 weeks with 0.08% TNBS in saline (0.2 mg/rat) given through the catheter. Control groups receive only saline. Drugs are applied either by gavage twice a day. suspended in carboxymethyl cellulose, or intraluminally once a day, suspended in saline. The animals are sacrificed by CO_2 inhalation 24 h after the last intraluminal application of TNBS. The distal 10 cm of small intestine anterior to the ileo-caeco-colic junction (5 cm distance to the open end of the catheter) including Peyer's patches are dissected, cut open longitudinally and rinsed with saline.

Immediately after dissection, the distal small intestine is visually assessed for inflammation according to the following scores:

Enteritis score	*Gross morphology*
0	No visible damage of the whole 10 cm the small intestine
1	Slight inflammation, slight redness (hyperemia), villi visible under 15 fold magnification
2	Intermediate inflammation, discontinuous hyperemia, intermediate redness of villi
3	Intensive inflammation, intensive hyperemia, intensive redness of villi

The dissected gut segments, precisely 10 cm long, are weighed for measurement of edema formation. They are then incubated in Tris buffer for 30 min at 37°C in a shaking water bath (1 ml/100 mg tissue, Tris 50 mM, pH 7.4, 100 mM NaCl, 1 mM $CaCl_2$, 1 mg/ml glucose). Following incubation, aliquots of the solutions are centrifuged (13,000 *g*, 2 min, 20°C) for determination of leucotriene B_4 (TB_4) by a commercial radioimmuno-assay (e. g., Amersham Buchler, Brunswick).

EVALUATION

Results are expressed as means ± SEM of (n) experiments. Differences between control and inflamed tissue, and influence of drug treatment are compared. Statistical significance is calculated by Wilcoxon-Mann-Whitney U-test for unpaired data. The level of significance is taken as $p < 0.05$.

MODIFICATIONS OF THE METHOD

Several authors used the trinitrobenzene sulfonic acid model in *rats* with slight modifications (Hogaboam et al. 1996; Kitano et al. 1996; Yue et al. 1996; Lora et al. 1997; Taniguchi et al. 1997; Cruz et al. 1998; Fries et al. 1998; Goldhill et al. 1998).

Zea-Ariate et al. (1994) studied chronic colitis in Wistar rats after intracolonic instillation of 20 or 42 mg of trinitrobenzene sulfonic acid in 30% and 40% ethanol and compared the effect with the administration of ethanol alone.

Alternatives to the 2,4,6-trinitrobenzene sulfonic acid model in **rats** were proposed:

Wallace et al. (1995), Hawkins et al. (1997) recommended dinitrobenzene sulfonic acid to produce experimental colitis in the rat.

Patterson and Colony (1983) tested sulphasalazine and 5-aminosalicylic acid in experimental colitis induced in **guinea pigs** by topical dinitrochlorobenzene.

Neurath et al. (1996) studied chronic intestinal inflammation induced by 2,4,6-trinitrobenzene sulfonic acid (TNBS) in **mice**.

These authors (Neurath et al. 1997) investigated the role of tumor necrosis factor in this mouse model and showed that no significant TNBS-induced colitis could be induced in mice in which the TNF-alpha gene had been inactivated by homologous recombination.

Cuzzocrea et al. (2004) found that 5-amino-isoquinolinone reduces colon injury in experimental colitis induced by dinitrobenzene sulfonic acid in mice.

Antony et al. (1997), Oyen et al. (1997) used trinitrobenzene sulfonic acid to induce experimental colitis in **rabbits**.

Dams et al. (1998) compared gamma-camera imaging in rabbits with colitis after retrograde instillation of trinitrobenzene sulfonic acid with technetium-99m-labeled liposomes after various time intervals with macroscopically scored severity of inflammation.

A model of diffuse colitis in **rats** induced by intraluminal colonic instillation or serosal application of dilute **acetic acid** was described by MacPharson and Pfeiffer (1976, 1978). Ritzpatrick et al. (1990) tested the anti-inflammatory effects of various drugs on acetic acid induced colitis in the rat.

For instillation into the colon of rats, a 2 cm length of soft polyethylene tubing is fitted to a Luer stub adapter. The open end of the tubing is sealed with glue. The whole length of the tubing is perforated with a needle at 0.5 mm length by four holes, 90° apart. A 1 ml syringe containing 10% acetic acid in saline is fitted to the adapter. The tubing is inserted intrarectally into the colon of rats and 0.2 ml is injected into the lumen. After 10 s contact *in situ*, the remaining acid is withdrawn and the lumen washed with three successive 0.5 ml volumes of isotonic saline. Test drugs are administered daily during the following days. Diffuse colonic lesions appear after 3 days in control animals and the animals experience a bloody diarrhea. An initial mucosal inflammation develops into submucosal edema; petechial hemorrhages become enlarged with subsequent neutrophil invasion, and pseudopolyps become evident.

Terzioglu et al. (1997) studied the effect of prostaglandin E_1 on the experimental colitis induced by rectal instillation of 10% acetic acid in rats.

Fabia et al. (1994) induced colitis in rats in an exteriorized colonic segment by administration of 4% acetic acid for 15 s. Four days later, this colonic segment was examined using a morphological scoring system, and measurements of myeloperoxidase activity and plasma exudation into the colonic segment.

Eliakim et al. (1995) demonstrated that ketotifen ameliorated capsaicin-augmented acetic acid-induced colitis. Rats were pretreated with subcutaneous injections of 20, 30, and 50 mg/kg capsaicin. Colitis was induced 2 weeks later by flushing 2 ml 5% acetic acid into the proximal colon.

Higa et al. (1997) studied the role of neutrophils in the pathogenesis of acetic acid-induced colitis in mice.

Millar et al. (1996) evaluated the antioxidant potential of new treatments for inflammatory bowel disease using acetic acid-induced colitis in rats.

Myers et al. (1997) determined colonic transit in rats by calculating the geometric center of distribution of a radiolabeled marker (^{51}Cr) instilled into the proximal colon after induction of distal colitis by intracolonic administration of 4% acetic acid.

Palmen et al. (1998) studied the effects of local butesonide treatment on cell-mediated immune response in acute and relapsing colitis in rats.

Several **other agents** can induce experimental colitis in animals (Kim and Berstadt 1992), such as

- **phorbol esters** (Fretland et al. 1990),
- **carrageenan** (Marcus and Watt 1969; Benitz et al. 1973; Watt and Marcus 1973; Abraham et al. 1974; Jensen et al. 1984. Kitano et al. 1994; Pricolo et al. 1996),
- **amylopectin-sulfate** (Watt and Marcus 1972),
- **dextran sulfate** (Ohkusa 1985; Okayasu et al. 1990; Axelsson et al. 1966; Shintani et al. 1997; Kanauchi et al. 1998),
- the **chemotactic peptide FMLP** (Magnusson et al. 1985; *von Ritter et al. 1988;* LeDuc and Nast 1990).

Ekstrom (1998) described **oxazolone**-induced colitis in rats. Dark Agouti rats were skin-sensitized with oxazolone and further challenged intra-rectally with oxazolone dissolved in carmellose sodium/peanut oil.

Suzuki et al. (1997) developed a rat model for human ulcerative colitis by using **1-hydroxy-anthraquinone** to cause severe inflammation of colonic mucosa.

Aiko et al. (1997), Satdnicki et al. (1998) induced chronic granulomatous colitis in female Lewis rats via intramural (subserosal) injections of **peptidoglycan-polysaccharide** into the distal colon.

Surfactants being used to enhance drug absorption may cause intestinal damage. Oberle et al. (1995) evaluated mucosal damage by surfactants in a single-pass *in situ* perfusion model in the rat. The release of LDH and mucus into the lumen of jejunum and colon following perfusion of the nonionic surfactants Tween 80 and Triton X-100 was determined.

Axelsson and Ahlstedt (1993) reviewed the actions of sulfasalazine and analogues in various animal models of experimental colitis, in particular in the hapten-, immune complex- and dextran models.

Bach et al. (1985) studied the inhibition of LTC synthetase and of rat liver glutathione *S*-transferases by sulfasalazine.

Stein et al. (1993) determined arachidonic acid oxidation and damage in the colon in rats stressed by the **cold-restraint** method.

Kirsner et al. (1959), Kraft et al. (1963) induced severe colitis in **rabbits** which had previously been sensitized to egg albumin and had mild colonic inflammation induced by intrarectal instillation of a small amount of diluted **formalin**.

Meenan et al. (1996) induced immune-complex colitis in rabbits by using various formalin concentrations (2%, 0.75%, and 0.5%).

Hodgson et al. (1978) induced colitis in rabbits by a modified technique. Preformed immune complex of human serum albumin and anti-HSA with antigen excess was injected to non-sensitized rabbits after provocation of mild inflammation in the colon with diluted formalin.

Kuroe et al. (1996a, b) induced granulomatous enterocolitis in rabbits by repeated submucosal injection of **muramyl dipeptide** emulsion into the rectum and colon with a flexible endoscope. Extraintestinal manifestations, such as pericholangitis, were observed.

Walsh and Zeitlin (1987) studied the effects of salazopyrin, 5-aminosalicylic acid and prednisolone on immune complex-mediated colitis in **mice**.

A survey on various genetic and immune manipulations which lead to inflammatory bowel disease in mice was given by Powrie and Leach (1995).

$CD4^+$ T lymphocytes injected into severe immunodeficient (SCID) mice lead to an inflammatory and lethal bowel disease (Claesson et al. 1996; Leach et al. 1996; Rudolphi et al. 1996; Bregenholt et al. 1998).

Hermiston and Gordon (1995) described an inflammatory bowel disease in mice expressing a dominant negative N-cadherin resembling Crohn's disease.

Watanabe et al. (1998) reported that interleukin7 transgenic mice develop chronic colitis with decreased interleucin7 protein accumulation in the colonic mucosa.

Mitchell and Turk (1990) described a model of **granulomatous bowel disease in guinea pigs**. Epithelioid cell granulomas and primary macrophage granulomas were induced by the inoculation of BCG (Pasteur) and irradiated Mycobacterium leprae, respectively, into the terminal ileum.

Wallace et al. (1998) induced colitis in guinea pigs and in rats by intracolonic administration of trinitrobenzene sulfonic acid.

Some **monkeys**, such as the cotton-top tamarin, *Saguinus oedipus* (Chalifoux and Bronson 1981; Madara et al. 1985; Lushbach et al. 1985; Podolsky et al. 1988; Hesterberg et al. 1996; Warren 1996), and juvenile rhesus monkeys (Adler et al. 1990), develop **spontaneous colitis**.

CRITICAL ASSESSMENT OF THE METHODS

The relevance of animal models for the pathogenesis and treatment of human inflammatory bowel disease was reviewed by Dieleman et al. (1997) and by Sartor (1997).

A critical review of *in vitro* models in inflammatory bowel disease was given by McKay et al. (1997).

J.5 Emetic and Anti-Emetic Activity

J.5.0.1 Assessment of Emetic and Anti-Emetic Activity in Dogs

PURPOSE AND RATIONALE

Emesis comparable to man occurs only in a few animal species. Among laboratory animals, the dog is a suitable species to test anti-emetic drugs. Apomorphine-induced emesis is also used to evaluate neuroleptic drugs (see E.5.3.8). Burkman (1982) described a technique relying upon the use of apomorphine either as a reference standard against which other emetics can be compared, or as a challenging agent against which anti-emetic compounds can be evaluated.

PROCEDURE

Beagle dogs weighing between 15 and 20 kg are used. Each dog is given 200 g food 30 min prior to an assay session. The threshold emetic dose of apomorphine hydrochloride is established for each dog by administering single doses at 5 day intervals in gradually increasing amounts. The starting dose is 0.07 mM/kg (22 mg/kg) body weight, i.m., and is subsequently increased (or decreased) as required. Injection sites alternate between contralateral gluteus muscles. After every third or fourth dose of the emetic, the animals receive an equivalent volume of vehicle under similar conditions in order to detect the presence of a conditioned emetic response.

The threshold dose is defined as the concentration provoking an emetic episode and determined for each individual animal. The threshold emetic dose is relatively stable for a given group of dogs over a period of 2 months. Continued administration to the same dogs for longer periods of time is inadvisable as Pavlovian emetic conditioning becomes evident after 8–10 doses of apomorphine. Establishment of an emetic threshold for a test compound using a similar dosing schedule allows to quantitatively express the test compound's emetic potency as a ratio compared with the reference standard. Usually, 4–6 animals are sufficient to provide a reliable estimate of the test compound's emetic efficacy and potency.

In the anti-emetic assay, dogs whose apomorphine threshold emetic dose has been determined receive various concentrations of the potential anti-emetic drug at a given time interval prior to apomorphine. The dose initially selected for the anti-emetic is a fraction of the acute LD_{50} of this drug in mice. A new threshold dose is estimated in the presence of the test anti-emetic and compared to the threshold dose in the presence of the reference standard chlorpromazine.

EVALUATION

Using the threshold doses, the relative potency of an emetic compared to apomorphine, or the relative potency of an anti-emetic compared to chlorpromazine, is calculated.

MODIFICATIONS OF THE METHOD

Cisplatin-induced emesis in the **dog**, as described by Gylys et al. (1979), was used by Turconi et al. (1991) to test the anti-emetic properties of 5-HT_3 receptor antagonists.

Heaslip and Evans (1995) studied the emetic, central nervous system, and pulmonary activities of rolipram in the dog after i.v. and intragastral application.

Gupta and Sharma (1996) tested the activity of antioxidants against emesis induced by an intravenous dose of 3 mg/kg cisplatin in healthy mongrel dogs.

Szelenyi et al. (1994) described emesis in **domestic pigs** as a new experimental tool for detection of anti-emetic drugs and for evaluation of the emetogenic potential of new anticancer agents. Healthy young, 12–15-week-old domestic pigs of either sex were lightly anesthetized with ketamine (10 mg/kg, i.v.) and xylazine (2 mg/kg, i.v.) and a cannula inserted into a superficial vein of one of the extremities. The challenging agents, e. g., cisplatin, carboplatin, cyclophosphamide, or ifosfamide were infused intravenously at different doses during a total administration time of 15 min. After removing of the cannula the animals

were placed in their boxes for observation of emesis over 24 h. Drugs with anti-emetic potential were given intravenously 15 min prior cisplatin infusion.

Göthert et al. (1995) found a dose-dependent inhibition of cisplatin-induced emesis in pigs by anpirtoline, a mixed 5-HT_1 receptor agonist/5-HT_3 receptor antagonist.

Gardner et al. (1995, 1998) used the **house musk shrew** (*Suncus murinus*) to test antagonism against cisplatin-induced emesis.

Kwiatkowska et al. (2004) performed a comparative analysis of the potential of cannabinoids and ondansetron to suppress cisplatin-induced emesis in *Suncus murinus* (house musk shrew).

J.5.0.2 Anti-Emetic Activity in Ferrets

PURPOSE AND RATIONALE

The ferret is a well established animal model of emesis which responds to cancer chemotherapeutic agents in a manner similar to that observed in man (Florczyk et al. 1982). The animals react with vomiting and retching after challenge with central (loperamide and apomorphine), peripheral ($CuSO_4$), or mixed central and peripheral (ipecacuanha, cisplatin) emetic stimuli. The model has been used to test the anti-emetic properties of 5-HT_3 receptor antagonists and tachykinin NK_1 receptor antagonists.

PROCEDURE

Adult male ferrets weighing 1 to 1.5 kg are randomly assigned to the different treatment groups. Each animal is anesthetized by inhalation with methoxyflurane. A jugular vein is cannulated and exteriorized from the outside of the neck. Following recovery from the anesthesia, the animals are dosed with the test drug or the standard or the vehicle 30 min prior i.v. administration of 10 mg/kg cisplatin. The numbers of retches and vomits occurring following the administration of the emetogen are recorded in each animal for 5 h. Retching is defined as rhythmic inspiratory movements against a closed glottis, and vomiting as forced expulsion of upper gastrointestinal contents.

EVALUATION

Duration of action of the compounds is assessed by determining the period of time for which the inhibitory effects remain significantly different from vehicle controls.

Statistical analysis of the data is performed by a repeated measure analysis of variance (ANOVA) followed by pairwise comparisons against control at each time period using Fisher's LSD multiple comparison test.

MODIFICATIONS OF THE METHOD

Fink-Jensen et al. (1992) reported that the excitatory amino acid receptor antagonists, 2,3-dihydroxy-6-nitro-7-sulphamoylbenzo(f)quinoxaline (NBQX) and 6-cyano-7-nitroqinoxaline-2,3-dione (CNQX), which preferentially block non-NMDA subtypes of excitatory amino acid receptors, effectively inhibit cisplatin-induced emesis in ferrets.

Emesis in ferrets was induced by X-irradiation or oral doses of copper sulfate (Andrews and Bhandari 1993).

Watson et al. (1995) studied the anti-emetic effects of a selective NK_1 receptor antagonist using the gag reflex in ferrets. The gag reflex is mediated by mechanoreceptors in the superior laryngeal nerve, which projects to the nucleus tractus solitarius. (Mifflin 1993). The gag reflex was evoked in conscious ferrets by gentle tactile stimulation of the pharynx and larynx and was recorded as an all or none response before and after drug administration.

Furthermore, the authors induced retching in the ferret by electrical stimulation of the vagal afferents under urethane anesthesia (Andrews et al. 1990). The dorsal or ventral abdominal vagus was isolated and ligated and the central cut-end stimulated before and after drug administration.

Duplantier et al. (1996) studied the emetic behavior in the ferret induced by inhibitors of phosphodiesterase type IV (PDE IV) and by rolipram comparing with the [^{3}H]rolipram binding activity. Robichaud et al. (1999, 2001) compared several PDE IV inhibitors and studied the mode of action inducing emesis in ferrets.

J.5.0.3 Assessment of Emetic and Anti-Emetic Activity in Pigeons

PURPOSE AND RATIONALE

Emesis in pigeons can be induced by various agents. Formerly, the phenomenon has been used for standardization of cardiac glycosides (Hanzlik 1929). More re-

cently, dose response curves of emesis have been determined for various agents and anti-emetic effects were evaluated (Wolff and Leander 1994, 1995).

PROCEDURE

Male White Carneaux pigeons are kept in individual stainless steel cages at constant temperature and humidity. They are maintained at 90% of their free-feeding body weights by once-daily feeding of approximately 20 g Purina Pigeon Checkers.

All testing is conducted during the illuminates phase of the light-dark cycle. On test days, the birds are fed 5 min before the start of an emetic trial. If vomiting occurs, the pigeons are given an additional 20 g of feed before being returned to their home cages at the conclusion of the observation period. Individual subjects are allowed a recovery period of at least 3 days between each drug test.

For the following compounds emetic doses are reported:

- Cisplatin 10 mg/kg, injected into a wing vein.,
- Ipecac syrup, 1 to 3 ml/kg, administered via a feeding needle passed through the crop to the opening of the proventriculus,
- emetine, 1 to 20 mg/kg, injected into the pectoralis muscle,
- m-(chlorphenyl)-biguanide (mCBG), 0.32 to 5 mg/kg, injected intramuscularly,
- ditolyganidine (DTG), 5.6 mg/kg, injected intramuscularly.

Test substances with potential anti-emetic activity are injected at various doses 15 min before the emetic challenge. The animals are observed for vomiting during 2 h.

EVALUATION

ED_{50} values for with 95% confidence limits are calculated for the activity of emetic substances, as well as for the inhibition of emesis by anti-emetic drugs after a high dose of the emetic compound.

J.5.0.4 Activity Against Motion-Induced Emesis

PURPOSE AND RATIONALE

The house musk shrew (*Suncus murinus*) is a small insectivore that has been shown to exhibits emesis when exposed to linear reciprocation motion (Ueno et al. 1988; Okada et al. 1994).

PROCEDURE

Adult male (body weight range 55–90 g) and female (body weight range 35–50 g) are used. The animals receive a dose of the test drug or vehicle in a volume of 4 ml/kg 15 min before motion testing. The animals are placed in a Perspex chamber (11 cm wide × 22 cm long × 11 cm high) that is attached to the platform of a shaker set to execute a linear horizontal movement of 4 cm at a frequency of 1 Hz along the long axis of the chamber. The animals are allowed approximately 3 min to become accustomed to the chamber before exposure to motion for a period of 5 min, during which the number and timing of emetic episodes are recorded. An emetic episode usually consists of a short period of rapid retching followed by a vomit. A cross-over design is used for the experiment, with animals exposed to motion testing following treatment with vehicle control on one occasion, and following treatment with test drug on another. An interval of 12 days is allowed between treatments.

EVALUATION

Group results are expressed as mean ± SEM. Either Student's *t*-test or the Wilcoxon signed rank test is used as a measure of significance.

MODIFICATIONS OF THE METHOD

Gardner and Perren (1998) described a model of post-anesthesia-induced emesis in Suncus murinus.

Parker et al. (2004) tested the effect of cannabinoids on lithium-induced vomiting in the *Suncus murinus* (house musk shrew).

Lucot (1989) used cats to test the activity of HT_3 antagonists against motion-induced sickness.

J.5.0.5 Foot Tapping in Gerbils

PURPOSE AND RATIONALE

Foot tapping in gerbils, a centrally mediated behavior (Graham et al. 1993; Bristow and Young 1994; Rupniak and Williams 1994; Vassout et al. (1994), has been claimed to be highly predictive for NK_1 antagonists to prevent cisplatin-induced retching in ferrets and to be a simple *in vivo* assay for CNS penetration (Rupniak et al. 1997).

PROCEDURE

Mongolian gerbils of either sex weighing 35–70 g are anesthetized by inhalation of an isoflurane/oxygen mixture to permit exposure of the jugular vein through a skin incision in the neck, using blunt dissection to clear surrounding salivary gland and connective tissues. Test compounds or vehicle are administered using an injection volume of 5 ml/kg i.v. The wound is closed and a second incision is made in the midline of the scalp to expose the skull. The highly selective, peptidase-resistant NK_1 receptor agonist GR73632 (D-Ala-[D-Pro^9,Me-Leu^8]substance P-(1–17) (Hagan et al. 1991) is infused directly into the cerebral ventricles (3 pmol in 5 µl i.c.v.) by vertical insertion of a cuffed 27-gauge needle to a depth of 4.5 mm below bregma. The scalp incision is closed and the animal allowed to recover from anesthesia in a clear Perspex observation box (25 × 20 × 20 cm). The duration of hind foot stepping is then recorded continuously for 5 min using a stopclock. The time relapse from induction to recovery from anesthesia, with intervening i.v. and i.c.v. injections is about 3–4 min.

EVALUATION

Data are subjected to one-way analysis of variance (ANOVA), followed by Dunnett's or Newman-Keuls multiple comparison *t*-tests.

CRITICAL ASSESSMENT OF THE METHOD

The specificity of the method to predict anti-emetic activity has to be proven.

J.6 Gall Bladder Functions

J.6.1 Bile Secretion

J.6.1.1 Cholagogic Activity in Mice

PURPOSE AND RATIONALE

A rapid method for standardization of cholagogues in mice by simple weighing the gall bladder filled with bile was published by Litvinchuk (1976).

PROCEDURE

Groups of 10 female mice (e. g., NMRI strain) weighing 15–20 g are used. Food, but not water, is withdrawn 24 h prior to the experiment. The test compound or the control solution is administered subcutaneously or

orally. After 1 h, the animals are sacrificed and bled from the carotid artery. Laparotomy is performed, the liver exposed, and a No. 75 silk ligature is tied around the cystic duct, which is detached from the bile ducts and removed from the peritoneal cavity. If a large volume of bile has been accumulated, the full gall bladder is removed together with the bile ducts. The isolated gall bladder is weighed on a suitable balance, after which the contents are removed, the gall bladder walls are washed with distilled water, dried on filter paper, and the organ is weighed again. The difference in weight of the full and the empty gall bladder indicates the quantity of bile secreted during a measured time. The concentration of cholates, bilirubin, and cholesterol in the bile can be determined.

EVALUATION

The average of secreted bile in groups of 10 treated mice is compared with the average value of the control group using Student's *t*-test.

CRITICAL ASSESSMENT OF THE METHOD

The method has the clear advantage of simplicity but does not measure the true bile excretion since the outflow from the bile bladder during the test period is neglected.

MODIFICATIONS OF THE METHOD

Sterczer et al. (1996) studied the effect of cholagogues on the volume of the gallbladder in healthy dogs fasted for 24 h by two-dimensional ultrasonography. The volume was measured immediately before the administration of each test substance and at 10-min intervals for 120 min thereafter.

J.6.1.2 Choleretic Activity in Rats

PURPOSE AND RATIONALE

In contrast to other animals, rats do not possess a bile bladder. Therefore, cannulation of the bile duct in rats can be used as a suitable model to measure choleresis, i. e. bile production.

PROCEDURE

Male rats (e. g. Sprague-Dawley strain) weighing 300–500 g are used. Food, but not water, is withdrawn 18 h prior to the experiment. The animals are anesthetized with 5 ml/kg 25% urethane solution. The trachea is cannulated and the abdomen opened by a midline incision. The pylorus is ligated and the bile duct cannulated from the duodenum with a thin (0.05 mm diameter) polyethylene catheter which is pushed up to the liver. The secreted bile volume is measured for 30 min intervals and then the bile is returned to the duodenum. After a preperiod of 60 min, the test substances are administered subcutaneously or intraduodenally. The bile volume is registered in 30 min intervals for 2 h.

EVALUATION

The average values of the post-drug periods are compared with the pre-drug readings.

MODIFICATIONS OF THE METHOD

Several authors tested the choleretic activity of plant extracts and essential oils (De la Puerta et al. 1993; Peana et al. 1994; Trabace et al. 1994) and of synthetic compounds (Grella et al. 1992; Paglietti et al. 1994) in rats.

Tripodi et al. (1993) investigated the anticholelithogenic and choleretic activities of taurohyodeoxycholic acid by measurement of biliary flow and biliary solids content in rats.

Bouchard et al. (1993) induced cholestasis in rats by treatment with 17-α-ethinyl estradiol and studied the influence of oral treatment with ursodeoxycholic and tauroursodeoxycholic acids.

Vahlensieck et al. (1995) studied the effect of *Chelidonium majus* herb extract on choleresis in the isolated perfused rat liver.

Miki et al. (1993) investigated the metabolism and the choleretic activity of homochenodeoxycholic acid in **hamsters** with bile fistula.

Pesson et al. (1959) recommended the**guinea pig** as the best choice among the common laboratory animals to study choleretic agents.

Cohen et al. (1992) reported a study in male **black-tailed prairie dogs** (*Cynomys ludovicianus*) weighing 1.0 ± 0.2 kg anesthetized with 20 mg/kg xylazine i.m. and 20 min later with 100 mg/kg ketamine i.m. Through an abdominal incision, the cystic duct is ligated, and gallbladder bile is aspirated. A PE-

50 polyethylene cannula is inserted into the common bile duct and secured with silk sutures, thereby completely diverting bile flow for collection. The bile duct cannula is externalized, the abdominal incision closed, and the prairie dog placed in a restraining cage with access to food and water.

Matsumura et al. (1996) analyzed hypercholeresis in **dogs** with pigment gallstones after cholate infusion.

J.6.1.3 Chronic Bile Fistula in Rats

PURPOSE AND RATIONALE

Most of the techniques for collection of bile in rats use restrained or anesthetized animals. Such factors as well as the surgical intervention itself may profoundly influence the results. Therefore, Remie et al. (1990, 1991) developed a technique for a permanent double bile fistula in rats. The procedure is described in detail.

PROCEDURE

Preparation of Cannulae

Cannulae are made of silicon rubber. The proximal bile cannula, which will be inserted into the common bile duct in the direction to the liver, is 18 cm long (Silastic tubing, Dow Corning, no. 605–135; 0.51 i.d. and 0.94 o.d.) and has one square cut and one bevelled end. Two silicon rings are wrapped around the cannula at 7 mm and 50 mm, respectively, from the bevelled end.

The distal bile cannula, which will be inserted into the common bile duct in the direction of the gut, is made of the same material, is also 18 cm long and has one square cut and one bevelled end. This cannula, however must have a smaller tip-diameter (Silastic tubing, Dow Corning, no. 605–105: 0.31 i.d. and 0.64 o.d.). To serve this purpose, the square cut end of the cannula is immersed in ether, causing the tubing to dilate. When the tubing is wide enough, a 13 mm piece of small diameter Silastic tubing is inserted. Subsequently, two silicon rings are wrapped around the cannula, one at the joint of the two tubes and the other 5 cm from the tip. The tip in then cut at a 45° angle, 7 mm from the first silicon ring.

The duodenal cannula (Silastic tubing, Dow Corning, no. 605–135) is also 18 cm long, and has one square and one bevelled end. An additional ring is placed 30 mm from the tip. Before the cannulae are fixed to the skull, they must be connected to a stainless steel needle bent in a 90° angle.

Anesthesia

The animal is anesthetized with halothane/N_2O/O_2.

Preparation of the Crown of the Head

The head of the animal is shaved and disinfected. An incision of about 1 cm is made and the bregma exposed. Three stainless steel screws (1.0 × 4.2 mm) are mounted in the crown, two in the left and one on the right side of the bregma. The screws are tightened that approximately 2 mm is left between the skull and the head of the screws.

Double Cannulation of the Bile Duct

The abdominal wall is shaved and disinfected and the animal secured on the operation board with adhesive tape. A midline incision is made from the level of the

pubic bones to the xyphoid cartilage. The abdomen is then opened by making an incision over the linea alba towards the sternum up to the distal part of the fourth sternebra, thus exposing the xiphoid cartilage.

Then, the intestines are lifted out and are laid next to the animal on moistened gauze. Using jewelers forceps, the bile duct is stripped off its surrounding tissue and ligated with a 7–0 suture. The duct is placed under tension with an artery forceps for cannulation. With the aid of a microscope, a V-shaped hole is made just cranial of the first ligature with iridectomy scissors. The sterile proximal cannula is inserted into the duct. The second ligature is tied and pulled tight ensuring that the cannula is not obstructed. The bile is now flowing into the cannula. The first ligature is released and the threads are tied behind the silicon ring. The rat is then turned and the ligature reclamped, thereby putting the distal part of the duct under tension. A third ligature is loosely introduced around the duct, distal to the first ligature. Another V-shaped aperture is made between the first and third ligature for insertion of the distal bile cannula. The third ligature is tied and pulled tight. The first ligature is released from the artery forceps and tied around the second cannula behind the silicon ring. All the loose threats are cut close to the knots. The sections of the cannulae which lie between the silicon rings are placed kink-free in the abdominal cavity. The cannulae are fixed using 7–0 silk suture to the abdominal muscle near the xiphoid cartilage.

Cannulation of the Duodenum

After location of the place where the bile duct enters the duodenum (sphincter of Oddi), a four fine-stitch purse-string suture (7–0) is made in the wall of the duodenum at the outer border at about 1 cm proximal to the sphincter. Using a 20G needle, an incision is made inside the purse string. The cannula is inserted into the duodenum until the first, smaller silicon ring has entered the lumen, and the purse string is tightened between the first and the second ring. This cannula together with the bile cannula is placed kink-free in the abdominal cavity and anchored to the internal muscle.

The abdomen is closed of resorbable sutures leaving 1 cm of the skin unclosed.

Subcutaneous Tunneling and Anchoring of the Cannulae

>From the back of the neck, a slender needle holder is pushed subcutaneously through the connective tissue in caudal direction as near as possible to the skin down to the xiphoid cartilage. The cannulae are then grasped and pulled through to emerge at the crown of the head. The abdominal wall is closed completely.

With a 5 cm piece of polyethylene tubing (0.75 × 1.45 mm), the two long ends of the L-shaped stainless steel adapters are connected and the short ends inserted into the respective cannulae. The cannulae together with the tubing are fixed to the skull with acrylic glue flowing under the heads of the screws.

Postoperative Care

The animals are allowed to recover in a warm and quiet place. They reach usually preoperative weight within 2–3 days, and display normal feeding and drinking behavior. Supplementation with saline besides the normal tap water may be necessary.

Collection of Bile

The animals are housed in individual metabolic cages. For bile collection, they are attached to long swiveled PE-cannulae (0.75 × 1.45 mm). A stainless steel coil is used to protect the rats from gnawing on the tubing. For continuous collection of bile, the cannula can be connected to a fraction collector.

CRITICAL ASSESSMENT OF THE METHOD

Among other applications, the method is suited to study the enterohepatic circulation of compounds.

MODIFICATIONS OF THE METHOD

Castilho et al. (1990) studied the intestinal mucosal cholesterol synthesis in rats using a chronic bile duct-ureter fistula model. Male Wistar rats weighing 300–350 g were anesthetized with 50 mg/kg pentobarbital i.p. and submitted to a bile duct-right ureter fistula utilizing a PE-50 catheter after a right-kidney nephrectomy.

J.6.1.4 Chronic Bile Fistula in Dogs

PURPOSE AND RATIONALE

Herrera et al. (1968) described a special cannula which can be used to obtain bile or pancreatic juice from a duodenal pouch after appropriate surgical procedures.

PROCEDURE

Male Beagle dogs weighing 15–20 kg are used. The abdomen is opened through a midline epigastric incision under barbiturate anesthesia. The duodenum is mobilized at the pyloric and jejunal ends, and a 5-cm duodenal segment containing the common bile duct is isolated. The distal stoma of the duodenum is closed and continuity restored by end-to-side duodenojejunostomy. The duodenal pouch is closed at both ends.

The cannula to be inserted is made of stainless steel and consists of 3 parts. The main casement measures 10.5 cm in length, with an external diameter of 1.0 cm. The internal end is flanged, and 1.5 cm from this point there is a short lateral limb, also 1.5 cm in length. The lateral limb is also flanged but, in addition, possesses a small V-shaped defect to facilitate insertion into the pouch. When not in use, the cannula is sealed from the exterior by inserting a threaded plug which allows bile to enter the duodenum in the normal manner. For collection of bile this plug is removed and a long obturator is inserted. The latter effectively isolates the bile secretion from duodenal contents. A similar hollow obturator is reserved for use when duodenal perfusion is studied, the obturator being connected via a plastic tube to the irrigating fluid.

Through a small antimesenteric incision in the duodenal pouch, the lateral limb of the cannula is inserted; the V-shaped defect in the flange facilitates entry into the pouch. A purse string secures the cannula in position. The defunctioned loop of duodenum is then brought anterior to the pancreas, and the remaining limb of the cannula inserted through a small duodenotomy and secured by a further purse-string suture. The whole system is then generously wrapped in omentum and the cannula exteriorized through a stab incision toward the flank. An external collar stabilizes the cannula. The cannula is left open to drain blood and secretions for 24 h postoperatively, after which time the plug is inserted. Physiologic saline is administered subcutaneously for a period of 3 days, after which the animals are permitted to drink water. Daily checks of the cannula are advisable to ensure that the plug remains tight. The animals receive normal kennel food and water ad libitum.

The dogs are allowed at least 4 weeks to recover. Eighteen hours prior to the experiment food is withdrawn but water allowed ad libitum. The long hollow obturator is inserted and bile collected for 15 min periods. After 1 h pretest time, the test compound is given either orally or intravenously.

EVALUATION

Secretion of bile is measured at 15 min intervals and volume and bile contents are determined from 1 ml samples. The values are compared with pretest data. The remaining bile is re-infused into the duodenum via the hollow obturator.

MODIFICATIONS OF THE METHOD

Boldyreff (1925) described several techniques for fistulae of the gall bladder and also for the fistula of the ductus choledochus in dogs.

An abdominal incision about 10 cm is made on the median line. The duodenum is pulled out and the orifice of the large (first) pancreatic duct is found. The orifice of the ductus choledochus with the orifice of the small (second) pancreatic duct is situated on the other side of the intestine some 2 or 3 cm nearer the stomach. The ductus choledochus goes straight from the gallbladder to the duodenum; further it lies parallel to is and at its end it is attached to the wall of the duodenum. The small pancreatic duct goes from the gland straight to the duodenum.

At the very beginning of the operation it is useful to cut the ligamentum that goes from the liver to the duodenum, because this facilitates orientation and operating. It is necessary to cut out a piece of the intestinal wall with the orifice of the ductus choledochus. But before this one must prepare off a little bit the intestine from the pancreas so as to be able to close conveniently and securely the hole in the intestine and divide between double ligatures the second pancreatic duct.

On the duodenum around the orifice of the ductus choledochus an incomplete oval figure is now marked with a knife, so that the duct enters this figure through the incomplete part of the oval and has its orifice in the middle of this figure. The length of the oval is about 1.5 cm and its width 1 cm. A suture is then made on the edge of this oval, which is cut out not completely but

leaving a small bridge about 0.5 cm wide between the intestine and the oval; through the bridge the duct enters the oval. The mucosa of this bridge must be completely destroyed with a knife.

The oval piece of the intestine is now turned with the mucosa up and its serosa is sutured to the serosa of the intestine The hole in the intestine is very carefully closed with two layers of sutures. Two heavy threads are then passed underneath the intestine on either side of the place of operation; they are laid through the abdominal wall and tied after the operation is over. They serve as temporary supporting sutures. The oval piece of the intestine is now sutured with the skin of the abdominal wound and the wound is closed in the usual manner. The supporting sutures must be taken out one day or two days after the operation.

J.6.1.5 Prevention of Experimental Cholelithiasis

PURPOSE AND RATIONALE

Several animal species develop gallstones, either spontaneously or induced by diet, such as **tupaias** (Schwaier 1979; Schwaier et al. 1979), **ground squirrels** (Fridhandler et al. 1983; MacPherson et al. 1987; MacPherson and Pemsingh 1997), **hamsters** (Holzbach 1984; Cohen et al. 1995) and **owl monkeys** (Pekow et al. 1995).

The **prairie dog** (*Cynomys ludovicianus*) is the animal model that has been used most extensively to study diet-induced cholesterol gallstone formation and the inhibition thereof (Holzbach 1984; Conter et al. 1986; Matoba et al. 1989; Cohen et al. 1990; Broughton et al. 1991; Afdhal et al. 1993; Kam et al. 1996).

Davis et al. (2003) and Saunders et al. (1991) studied the use of statins for the prevention of gallstones in cholesterol-fed prairie dogs.

PROCEDURE

Wild-caught male prairie dogs weighing about 1 kg were kept in quarantine for 3 weeks and fed normal rodent chow. Then the diet was changed to a lithogenic diet consisting of a 1.2% cholesterol formulation for the study period of 28 days. Medication (drug or placebo) was applied through a gastric tube under slight sedation twice a day. Blood chemistry analysis for total cholesterol and triglycerides was performed on study days 0, 14, and 28.

At the completion of the study period, all animals were placed under general anesthesia and underwent an open cholecystectomy. A subcostal incision was made in the right upper quadrant, and the gallbladder removed using clips on the cystic duct. The gallbladder was then opened and visually inspected for gallstones. Bile from the gall bladder was the aspirated for microscopic analysis.

A sample of bile of each animal was examined using light microscopy to determine the presence of cholesterol crystals.

EVALUATION

Statistical analysis was performed using Student's *t*-test for cholesterol and triglyceride data. The Fisher exact test was utilized for analysis of gallstone and cholesterol crystal formation data.

MODIFICATIONS OF THE METHOD

Chapman et al. (1998) established and characterized primary gallbladder epithelial cell cultures in the prairie dog.

Chen et al. (1999) studied biliary sludge and pigmented stone formation in bile duct-ligated guinea pigs.

Stone et al. (1987) developed a rat model to explain the ciclosporin-induced cholestasis observed in transplantation patients.

J.6.2 Gall Bladder Motility

J.6.2.1 Activity on Isolated Gall-Bladder Strips from Guinea Pigs

PURPOSE AND RATIONALE

Effects on the smooth musculature of the gall bladder can be studied in isolated strips of gall bladder from guinea pigs or cats (Chowdhury et al. 1975; Fara and Erde 1978; Cabrini et al. 1995).

PROCEDURE

Guinea pigs of either sex weighing approximately 400 g are anesthetized with 3 g/kg urethane i.p. The gall bladder is removed and cut into longitudinal strips 10×3 mm. The strips are suspended in a Krebs solution bath between a stationary hook and an isometric strain gauge. Tension is recorded on a polygraph. The bath is maintained at 37°C and aerated with a gas mixture of 95% O_2 and 5% CO_2. After a half-hour stabilization period, test doses of acetylcholine (1 mg/ml) are added to determine viability of the preparation. Dose-response curves for the muscle strips are obtained by introducing one dose of the stimulating agent and waiting until the maximal response to that dose is reached (usually 5–15 min). The bath is then rinsed three times and 15 min allowed before a new dose is tested.

EVALUATION

Concentrations for the maximal response and ED_{50} values are calculated.

MODIFICATIONS OF THE METHOD

Eltze et al. (1997) found that contractions of the isolated guinea-pig gallbladder elicited by muscarinic stimuli are mediated by functional muscarinic M_3 receptors.

J.6.2.2 Gallbladder Motility in Dogs

PURPOSE AND RATIONALE

Gall bladder motility can be measured in anesthetized dogs with intraluminal manometry.

PROCEDURE

Beagle dogs weighing 15–18 kg are fasted for 16 h prior to the experiment. Median laparotomy is performed under pentobarbital anesthesia (25 mg/kg i.v.). An incision is made in the bile bladder and a 2 mm diameter polyethylene catheter introduced. The catheter is advanced as far as possible to the neck of the gall bladder and tied. The pressure in the interior of the gall

bladder is recorded on a pen recorder via a Statham pressure transducer (P 23 BB) and a frequency measuring bridge.

EVALUATION

Cholecystokinin increases dose-dependent the intraluminal pressure. The preparation can be used for evaluation of cholecystokinin or cholecystokinin-like activity.

MODIFICATIONS OF THE METHOD

Ryan and Cohen (1976) used adult opossums (*Didelphis viginiana*) of either sex, weighing 2.5–3.0 kg.

J.6.2.3 Cholecystokinin Activity (Isolated Gallbladder or Intestine)

PURPOSE AND RATIONALE

A sensitive bioassay for cholecystokinin utilizing strips of rabbit gall bladder has been described by Amer and Becvar (1969). Segments of ileum and colon have been used by Paton and Zar (1968) and by Zetler (1984).

PROCEDURE

Male albino rabbits weighing 1.5–2.5 kg are fasted 18 h prior to the experiment. The animals are sacrificed by cervical dislocation and the liver is quickly dissected out. The gallbladder is teased away from the liver and immediately placed in Locke-Ringer solution. The biliary contents are emptied and the gall bladder is cut spirally (right-handed spiral starting from the bile duct) into a strip of muscle tissue 30–40 mm in length and about 5 mm wide. The muscle strip is placed in an organ bath containing Locke-Ringer solution at 37°C continuously bubbled with carbogen. The initial tension of the muscle is adjusted to 0.5 g. The bath fluid is changed every 30 min. The test compound and the standard (range 5–20 mIDU (Ivy dog units) are added alternatively. The maximum of contractions is usually reached after 5 min. Then, the bath fluid is changed. The next dose is applied when the tension has achieved again the starting value.

EVALUATION

The maximum of contraction is taken as endpoint. Using at least two doses of test compound and standard, parallel line assays can be carried out and potencies ratios can be calculated.

CRITICAL ASSESSMENT OF THE METHOD

This bioassay has the advantage to be sensitive and less time consuming than *in vivo* assays, such as measuring gall bladder motility in the anesthetized dog (see J.6.2.2). However, the assay is not specific for cholecystokinin, since also gastrin and gastrin analogues cause contractions of the isolated bile bladder. This assay allows also to calculate potency ratios of different gastrin analogues.

MODIFICATIONS OF THE METHOD

The whole gallbladder of the mouse or a strip of guinea pig gallbladder is used for evaluation of cholecystokinin-like peptides, ceruletide, ceruletide analogues, and cholecystokinin octapeptide by Zetler (1979, 1984)

Paton and Zar (1968), Zetler (1984), Chang and Lotti (1986), Barthol and Holzer (1987) used isolated segments of ileum and colon from guinea pigs for determination of CCK-like activity.

Makovec et al. (1986), Tachibana et al. (1996) studied the *in vivo* activity of derivatives of CCK in emptying the gallbladder in mice.

Henke et al. (1997) tested CCK-A agonists in the isolated guinea pig gall bladder.

Singh et al. (1995) used gall bladder strips from guinea pigs to evaluate CCK receptor antagonists.

Fukamizu et al. (1998) tested the effect of a cholecystokinin-A receptor antagonist against CCK-8 induced contractions in isolated smooth muscle fibers of gall bladders and longitudinal fibers of ileum from guinea pigs.

J.6.3 Sphincter Oddi Function

J.6.3.1 Relaxation of Sphincter of Oddi In Vitro

PURPOSE AND RATIONALE

The integrity of the relaxation function the sphincter of Oddi is a prerequisite for normal delivery of bile into the duodenum. Sphincter of Oddi relaxation is mainly executed by non-adrenergic, non-cholinergic (NANC) nerves that are essentially nitrergic in several species including guinea pigs (Pauletzki et al. 1993) and rabbits (Lonovics et al. 1994).

PROCEDURE

Biliary sphincter of Oddi muscle rings of approximately 6 mm length from adult male New Zealand white rabbits weighing form 3500–4000 g pretreated with various drugs or diet are prepared. The papilla Vater is eliminated and the ampullary part of the muscle rings of approximately 3 mm length are mounted horizontally on two small L-shaped glass hooks one of which is connected to a force transducer attached to a polygraph for measurement and recording of isometric tension. The experiments are carried out in an organ bath (5 ml) containing Krebs bicarbonate buffer which is maintained at 37°C and aerated continuously with carbogen. The initial tension is set at 10 mN and the rings are allowed to equilibrate over 1 h during which period the sphincters develop characteristic 14–19 per min rhythmic contractions. Atropine (1 μM) and guanethidine (4 μM) are continuously present (NANC solution). Changes in isometric tension in response to two consecutive trains of impulses of electrical field stimulation (40 stimuli, 50 V, 0.1 ms and 20 Hz) are then studied.

EVALUATION

The data representing changes in isometric tension expressed as means ± standard deviation are evaluated by means of analysis of variance (ANOVA) followed by a modified Student's *t*-test for multiple comparisons according to Bonferroni's method. Changes are considered statistically significant at P-values smaller than 0.05.

MODIFICATIONS OF THE METHOD

In addition to studies with the isolated sphincter of Oddi of rabbits (Slivka et al. 1994; Sari et al. 1998; Jia and Stamler 1999) and guinea pigs (Harrington et al. 1992; Gocer et al. 1995; Lu et al. 1997), several pharmacological studies were reported with the isolated sphincter of Oddi of **opossum** (Perodi et al. 1990; Allescher et al. 1993), and of the **Australian brush-tailed possum** (*Trichosurus vulpecula*) (Baker et al. 1992, 1996).

J.6.3.2 Function of Sphincter of Oddi In Vivo

PURPOSE AND RATIONALE

Dogs were used for *in vivo* studies of the function of the sphincter of Oddi (Sarles 1986; Pozo et al. 1990; Matsumara et al. 1991; Kobayashi et al. 1994; Wang et al. 1998). Shima et al. (1998) recorded the spontaneous motility and the response to cerulein on the canine sphincter of Oddi using a constant-perfusion technique.

PROCEDURE

Mongrel dogs weighing 7–9 kg fasted overnight are anesthetized with 25 mg/kg intravenous pentobarbital sodium and are maintained under adequate anesthesia with 12.5 mg/kg intravenous pentobarbital sodium as required. Systemic blood pressure is monitored through a catheter placed into the femoral artery. A femoral vein is cannulated and used for systemic administration of Ringer's solution and drugs.

After an upper median laparotomy, a small longitudinal incision is made in the common bile duct. Two catheters (outer diameter 2.0 mm) are cannulated and tied in the bile duct to avoid any leaks and the occlusion of the orifice of the catheters. One is distally placed at 5 mm proximal to the choledochoduodenal junction and is used to perfuse the sphincter of Oddi with saline at a rate of 0.12 ml/min using an infusion pump. The other is proximally placed and used to siphon off the hepatic bile. Pressure changes are recorded on a polygraph through a pressure transducer which is placed between the infusion pump and the catheter.

EVALUATION

To evaluate the effects of intravenously administered drugs on the sphincter of Oddi, a motility index is calculated by measuring the square between the zero line and the trace of the sphincter of Oddi pressure changes per minute.

Results are expressed as means ± SEM; n is the number of independent observations of different animals. The paired and unpaired t-tests are used for statistical analysis. $P < 0.05$ is considered significant.

MODIFICATIONS OF THE METHOD

Thune et al. (1992, 1995) studied simultaneously the flow resistances in the common bile duct and main pancreatic duct sphincters in anesthetized **cats** using a perfusion technique.

Elbrønd et al. (1994) prepared the sphincter of Oddi and duodenum in anesthetized **rabbits** with perfused catheters and bipolar electrodes. Increasing, successive doses of cholecystokinin were administered intravenously every 15th min. The digitized recordings were scored on a computer in control and stimulatory cholecystokinin sequences.

Further studies in **rabbits** were performed by Nakamura (1996), Chiu et al. (1998).

Opossums were used by Calabuig et al. (1990), Hanyu et al. (1990),Cullen et al. (1996), Herrmann et al. (1999) to study the function of the sphincter of Oddi.

Several authors used the **Australian brush-tailed possum** (*Trichosurus vulpecula*) for studies of the function of the sphincter of Oddi *in vivo* (Baker et al. 1990; Saccone et al. 1992; Cox et al. 1998a, b; Huang et al. 1998).

The **prairie dog** was used by several authors to study the function of the sphincter of Oddi (Ahrend et al. 1992; Kaufman et al. 1993; Thierney et al. 1994).

Pasricha et al. (1995) reported a model in **pigs** for endoscopic biliary manometry, similar in technique to the procedure in humans.

J.7 Pancreatic Function

J.7.0.1 Acute Pancreatic Fistula in Rats

PURPOSE AND RATIONALE

The effect of exogenous hormones, e. g. secretin, or other drugs on pancreas secretion can be measured in rats with acute pancreas fistula.

PROCEDURE

Male Sprague Dawley rats weighing 150–200 g are used. Eighteen hours prior to the experiment food is withdrawn with free access to water. Groups of 4–5 rats are used for each dose of drug evaluation, the control group consists of at least 7 rats. The animals are anesthetized with 5 ml 25% urethane solution i.m. and the is trachea cannulated. The abdomen is opened by a mid-line incision and the pylorus ligated. The proximal part of the bile duct is ligated near the hepatic porta. The bile is drained via a thin polyethylene tube into the duodenum. The distal part of the bile duct with the orifices of pancreatic ducts is cannulated with another thin polyethylene tube. The pancreatic juice is collected in graduated microvessels. After a pre-test period of 60 min, the test compounds are applied intravenously or intraduodenally.

EVALUATION

The secretion after injection of the test compound is compared with the pre-test values. Secretin increases pancreatic secretion volume in a dose-dependent manner. Activity ratios for unknown preparations can be calculated by 2+2 assays in comparison with the international standard.

MODIFICATIONS OF THE METHOD

Guan et al. (1990) inserted two separate cannulae for bile and pancreatic juice to Wistar **rats** under methoxyfluorane anesthesia. Both fluids were returned to the intestine. Placing the rats in modified Bollman-

type restraint cages, experiments could be performed after a few days in conscious animals.

Ito et al. (1994) studied the inhibition of CCK-8-induced pancreatic amylase secretion by a cholecystokinin type-A receptor antagonist in rats.

Niederau et al. (1989) compared the effects of CCK receptor antagonists on rat pancreatic secretion *in vivo*. Output of amylase in pancreatico-biliary secretion was measured after various doses of caerulein. The effects of high caerulein doses were dose-dependent inhibited by CCK-antagonists.

Alvarez and Lopez (1989) studied the effect of alloxan diabetes on exocrine pancreatic secretion in the anesthetized **rabbit**. After a 14–15 h fasting period, but with free access to water, rabbits weighing about 2.0 kg are anesthetized by intravenous injection of 1.0 g/kg urethane. After tracheotomy, a median laparotomy is performed, the main pancreatic duct is exposed and cannulated near its entrance to the duodenum following ligation of the pylorus and cannulation of the bile duct for deviation of bile to the exterior.

Kim et al. (1993) studied the effect of [(CH_2NH) 4,5]secretin on pancreatic exocrine secretion in **guinea pigs** and rats using an acute pancreatic fistula preparation.

Niederau et al. (1990), Tachibana et al. (1996) determined pancreatic exocrine secretion in **mice**. Because the cannulation of mouse pancreatic duct is not possible for technical reasons, the amount of amylase was determined *in vivo*. Five min after i.v. administration of test drugs, mice were sacrificed and a 5 cm-duodenal loop was removed. The duodenal contents were washed out with 1.0 ml ice-cold saline and collected for amylase activity.

J.7.0.2 Exocrine Secretion of Isolated Pancreas

PURPOSE AND RATIONALE

Procedures for isolation and perfusion of rat pancreas in order to record membrane potential and effective membrane resistance during the collection of perfusates and for simultaneous measuring of flow of pancreatic juice were described by Kanno (1972), Kanno and Saito (1976), Kanno et al. (1976), Saito et al. (1980). Similar techniques to measure exocrine secretion of the isolated pancreas have been used by other groups (Penhos et al. 1969; Mann and Norman 1984; Trimble et al. 1985; Norman and Mann 1986, 1987; Norman et al. 1989; Park et al. 1993).

PROCEDURE

Male Sprague Dawley rats weighing about 250 g are fasted for 24 h before the experiments but are allowed to drink water. Under ether anesthesia and after cannulation, the vascular system and the common duct are separately perfused. The rectum and the transverse colon are separated from the pancreas following ligation and sectioning of their vascular supply. Perfusion is performed through the hepatic end of the common duct with the outlet at the duodenal end. The **flushing preparation** is used when continuously recording the transmembrane potential and, in this preparation, the common duct is flushed at a constant pressure of 5 cm H_2O following cannulation of both ends with stainless steel tubes. The **draining preparation** is used during the electrical measurements are made from as many acinar cells as possible in every 10 min. In the draining preparation, the hepatic end of the duct is ligated and the pancreatic juice collected from the duodenal end following cannulation with a stainless steel tube. In both preparations, the inlets of the vascular perfusion are the superior mesenteric artery and the coeliac artery, and the outlet is the portal vein. The rate of vas-

cular flow is kept constant at 1 ml/min with the aid of a roller pump. The animal is then killed by cutting the carotid arteries and the perfusion begins. The spleen is removed after section of its vascular supply close to the hilum, care being taken to avoid interference with the supply from the splenic artery. The blood supplying stomach and liver is stopped by tying the hepatic artery and gastric arteries. The superior mesenteric vein and the descending branch of the superior mesenteric artery are then ligated. The mesentery with its embedded whole pancreas and the attached duodenum is then removed and mounted on a paraffin block in a lucite chamber containing 20 ml of standard Krebs-Henseleit solution. The contents of the duodenum is then drained with a polyethylene tube. The level of the standard Krebs-Henseleit solution in the bath is kept constant with a siphon. The temperature of the preparation and perfusing Krebs-Henseleit solution containing 8 vol% erythrocytes is maintained at 37°C. The perfusion solution in the reservoir is continuously bubbled with 5% CO_2 in O_2.

The rate of flow of pancreatic juice is measured by attaching a calibrated tube made of silicone-rubber to the free end of the pancreatic duct cannula. Every 10th min the tube is replaced and the rate of flow of pancreatic juice is noted. The sample is diluted with Krebs-Henseleit solution up to 100 ml and the amount of amylase assessed.

Intracellular recordings are made from the pancreatic acinar cells by manually advancing KCl-filled microelectrodes under direct visual control. The microelectrode is connected to the probe of a solid state pre-amplifier. Resting potentials are observed at the screen of a cathode ray oscilloscope and simultaneously recorded on a direct visual oscillograph.

Measurements are made every 10 min for half an hour as base level, followed by measurements every 10 min during infusion of drug for one hour.

EVALUATION

All results are expressed as mean ± SEM. Statistical analysis is performed using Student's *t*-test.

J.7.0.3 Chronic Pancreatic Fistula in Rats

PURPOSE AND RATIONALE

Suguiyama et al. (1996) described the preparation of a chronic pancreatic fistula in the WBN/Kob rat, a strain which develops spontaneously chronic pancreatitis (Ohashi et al. 1990; see also J.7.0.14).

PROCEDURE

Male WBN/Kob rats at an age of 2 months are used. Before surgery, the rats have free access to chow and water. After an 18-h fast, laparotomy is performed through a midline incision under general anesthesia with ether. A polyethylene catheter (inside diameter 0.28 mm; outside diameter 0.61 mm, length 30 cm), as an external pancreatic fistula, is inserted into the common biliary pancreatic duct immediately proximal to the ampulla of Vater. The bile duct is ligated proximally to the pancreas. Another catheter is introduced into the bile duct distal to the confluence of the hepatic ducts, and the opposite end of the catheter is inserted into the duodenum near the ampulla through the stomach to drain the bile into the intestine. A third catheter is inserted in the duodenum through the stomach to return pancreatic juice. A fourth catheter is placed in the femoral vein, and 0.15 M sodium chloride is continuously administered at a flow rate of 1 ml/h with a sy-

ringe pump. All catheters are brought into the abdominal cavity or the femoral region through a subcutaneous tunnel starting in the middle portion of the tail. The rat is then placed prone in a cage with the proximal portion of the tail fixed to a side wall of the cage. When awakened, the rat is allowed access to food and water ad libitum. Pancreatic juice is collected and continually re-circulated with a syringe pump every 6 h until the secretion test.

The secretion test is started 3 days after surgery. After a 12-h fast, pancreatic juice is collected every 30 min in a plastic syringe. The juice volume is determined by weighing. A 50-µl sample is taken for the analysis of juice composition, and the remaining juice is returned to the duodenum for the next 30-min collection period.

After a 30-min basal period, the test compound is administered in graded doses, each dose for 30 min.

The bicarbonate concentration of pancreatic juice is measured with a microgasometer (Natelson 1958) in a sample size of 10 µl. Protein concentration is determined by measuring optical density at 280 nm with purified bovine trypsinogen as standard.

EVALUATION

All values are presented as mean ± SEM. Results are analyzed by means of the Wilcoxon test. Differences are considered significant at $p < 0.05$.

J.7.0.4 Acute Pancreatic Fistula in Dogs

PURPOSE AND RATIONALE

The effect of exogenous hormones, e. g. secretin or gastrin, or of vagal stimulation, on pancreatic secretion can be measured in dogs with acute pancreas fistulas.

PROCEDURE

Beagle dogs of either sex weighing 12–20 kg are used. The animals are fasted for a 24-h period and then anesthetized with 25 mg/kg sodium pentobarbital i.v. After opening the abdomen along the mid-line, the pyloric sphincter is ligated and the common bile duct cannulated to prevent the entry of acid chyme and bile into the duodenum. The bile is allowed to drain. The pancreas is gently exposed and the major pancreatic duct ligated. A polyethylene tube of 2 mm diameter is inserted into the minor pancreatic duct for collection of the secretion. The left femoral vein is cannulated for continuous infusion or i.v. injection. The pancreatic juice is collected in an ice-bath in a special tapered tube with fine calibrations for measuring volumes of less than 1 ml.

At the end of each collection period, the volume is recorded, and the bicarbonate content determined titrimetrically. Furthermore, pancreatic enzymes, such as amylase, are determined in the samples. Determination of protein concentrations in the pancreatic juice can be used as end-point since the total protein concentration is proportional to the individual enzymes (Keller et al. 1958). In a pretest period of 10 min, samples are collected every 2 min. Then, the test compound is injected intravenously and the pancreatic juice is collected every 2 min.

EVALUATION

The secretion after injection of the test compound is compared with the pre-test values. Secretin increases pancreatic volume and bicarbonate secretion in a dose-dependent manner. Activity ratios for unknown preparations can be calculated by 2+2 points assays in comparison with the international standard.

Moreover, the model can be used for standardization of gastrin analogues.

MODIFICATIONS OF THE METHOD

Glad et al. (1996) tested the influence of gastrin-releasing peptide on acid-induced secretin release and pancreatobiliary and duodenal bicarbonate secretion in Danish country strain **pigs** weighing between 22 and 30 kg. The animals, starved overnight with free access to water, were premedicated with 4 mg/kg i.m azaperone, and with 5 mg/kg i.p. metomidate. After 20 min a cannula was placed in an ear vein, and 5–10 mg/kg metomidate was given i.v. followed by intubation and artificial respiration with 50% O_2 and 50% N_2O. Anesthesia was maintained with an intravenous bolus infusion of 0.53% α-chloralose.

Both external jugular veins were cannulated for infusion of saline or drugs. A femoral artery was cannulated for withdrawal of blood samples and recording of blood pressure. After laparotomy the cystic duct

was ligated, and the common hepatic duct and the pancreatic duct were catheterized. The duodenal segment was defined as extending from the pylorus to the ligament of Treitz. A Foley catheter was passed through the pylorus into the proximal part of the duodenum and inflated. Distal to the pylorus the pancreaticoduodenal arteries, veins and nerves were dissected, and a double ligature was passed under these structures and tied around the duodenum. At the ligament of Treitz an inflated Foley catheter was placed in the distal part of the duodenum and tied with a suture around the duodenum. A catheter was placed through a splenic branch of the left gastroepiploic vein and advanced through the lienal vein to the portal vein.

The flow of pancreatic juice and bile was tested before and after the experiment by means of an intravenous bolus of 5 pmol/kg secretin. Before the experiment the duodenum was continuously perfused at a rate of 2 ml/min for 435 min with isotonic saline containing phenol red (10 mg/l) as a marker. After drug treatment (intravenous infusion of gastrin-releasing peptide or duodenal HCl perfusion) pancreatic and hepatic secretions were collected in 15-min periods and the volumes determined by weighing. Duodenal effluents were collected in 15-min periods and phenol red concentrations determined spectrophotometrically. Blood sampled were withdrawn for determination of secretin by radioimmunoassay.

J.7.0.5 Chronic Pancreatic Fistula in Dogs

PURPOSE AND RATIONALE

Herrera et al. (1968) described a special cannula which can be used to obtain pancreatic juice or bile from a duodenal pouch after appropriate surgical procedures (Preshaw and Grossman 1965).

PROCEDURE

Male Beagle dogs weighing 15–20 kg are used. The abdomen is opened through a midline epigastric incision under barbiturate anesthesia. The duodenum is mobilized at the pyloric and jejunal ends, and a 5-cm duodenal segment containing the main pancreatic duct is isolated. The proximal level of the duodenal section lies immediately distal to the opening of the common bile duct and the distal level of section lies 2.5 cm distal to the main pancreatic duct. The distal stoma of the duodenum is closed and continuity restored by end-to-side duodeno-jejunostomy. The duodenal pouch is closed at both ends.

The cannula to be inserted is made of stainless steel and consists of 3 parts. The main casement measures 10.5 cm in length, with an external diameter of 1.0 cm. The internal end is flanged, and 1.5 cm from this point there is a short lateral limb, also 1.5 cm in length. The lateral limb is also flanged but, in addition, possesses a small V-shaped defect to facilitate insertion into the pouch.

When not in use, the cannula is sealed from the exterior by inserting a threaded plug which allows pancreatic juice to enter the duodenum in the normal manner. For collection of juice this plug is removed and a long obturator is inserted. The latter effectively isolates the pancreatic secretion from other duodenal contents. A similar hollow obturator is reserved for use when duodenal perfusion is studied, the obturator being connected via a plastic tube to the irrigating fluid.

Through a small antimesenteric incision in the duodenal pouch, the lateral limb of the cannula is inserted; the V-shaped defect in the flange facilitates entry into the pouch. A purse string secures the cannula in position. The defunctioned loop of duodenum is then brought anterior to the pancreas, and the remaining limb of the cannula inserted through a small duodenotomy and secured further by a purse-string suture. The whole system is then generously wrapped in omentum and the cannula exteriorized through a stab incision toward the flank. An external collar stabilizes the cannula.

The cannula is left open to drain blood and secretions for 24 h postoperatively, after which time the plug is inserted. Physiologic saline is administered subcutaneously for a period of 3 days, after which the animals are permitted to drink water. Checking the cannula daily is advisable to ensure that the plug remains tight. The animals receive normal kennel food and water ad libitum.

The dogs are allowed at least 2 weeks to recover. Eighteen hours prior to the experiment food is with-

drawn but water allowed ad libitum. The long obturator is inserted and pancreatic juice collected for 15 min periods. After 1 h pretest time, the test compound is given either orally or intravenously.

EVALUATION

Secretion of pancreas juice is measured at 15 min intervals and volume and enzyme content determined. The values are compared with pretest data.

MODIFICATIONS OF THE METHOD

Boldyreff (1925) described details of the technique as recommended by Pavlov (1902) as well as his own modification.

Konturek et al. (1976, 1984) performed experiments with chronic gastric fistulas in **cats** as well as in **dogs** to compare the species-specific activities of vasoactive intestinal peptide and secretin in stimulation of pancreatic secretion.

Ninomiya et al. (1998) studied the effects of a cholecystokinin A receptor antagonist on pancreatic exocrine secretion stimulated by exogenously administered CCK-8 in conscious dogs with chronic pancreatic fistula.

Garvin et al. (1993) described distal pancreatectomy with autotransplantation and pancreaticocystostomy in dogs.

Kuruda et al. (1995) developed a new technique in dogs for pancreatico-gastrointestinal anastomosis that consists of pancreatectomy using the ultrasonic dissector and implantation of the pancreatic duct into the gastrointestinal tract without suturing the pancreatic parenchyma.

J.7.0.6 Somatostatin Activity

PURPOSE AND RATIONALE

Somatostatin is a neuropeptide, also called somatotrophin release inhibiting factor (SRIF or SRIF-14), which occurs not only in the brain, but also in a variety of peripheral tissues. Two other related peptides somatostatin-28 (SRIF-28) and cortistatin (Vasilaki et al. 1999), also occur naturally (Humphrey 1998). Somatostatin acts via G-protein coupled receptors of which five subtypes are cloned (Hoyer 1998).

Somatostatin analogues and antagonists have been tried for a variety of indications (Bass et al. 1996; Coy and Taylor 1996; Papageorgiou and Borer 1996; Rohrer et al. 1998; Yang et al. 1998; Hocart et al. 1999). The long-acting octapeptide somatostatin analog, octreotide, has been studied thoroughly (Ambler et al. 1996; Danesi and Del Tacca 1996; Hoffmann et al. 1996; Paran et al. 1996) and gained clinical use as gastric antisecretory agent.

Somatostatin inhibits basal pancreatic secretion as well as secretion stimulated by food, cholecystokinin, and secretin. Inhibition of pancreatic secretion can be used as bioassay to compare synthetic analogues with the original somatostatin.

PROCEDURE

Male Wistar rats weighing 300–400 g are anesthetized with methoxyfluorane and prepared with silastic cannulae. Two cannulae drain pancreatic juice and bile separately, one cannula is inserted into the duodenum for return of bile and pancreatic juice to the intestine and for intestinal infusion. Another cannula is located in the abdominal cavity and a fifth cannula into the right jugular vein for drug infusion. After surgery, the rats are placed into modified Bollman-type restrain cages. The rats have free access to food and water. Dur-

ing recovery and between the experiments, pancreatic juice and bile are collected and continuously returned to the intestine by a servo-system consisting of a collection tube in a liquid-level photodetector coupled to a peristaltic pump.

Experiments are performed on the third to eighth days postoperatively. The rats are assigned to treatment groups on a random basis and, treatment days are equally divided among the third to eighth postoperative days. The rats are fasted overnight before each experiment. Bile and pancreatic juice are collected separately every 30 min; the volume of pancreatic juice is measured, and 10 ml is taken for protein assay. Different doses of the test drug and the standard are given as continuous i.v. infusion over a period of 2 h.

EVALUATION

Inhibition of pancreatic fluid and protein output is calculated compared to control infusion and expressed as percentage. From dose-response curves activity ratios can be calculated.

MODIFICATIONS OF THE METHOD

Konturek et al. (1985) and Susini et al. (1980) studied the effect of somatostatin analogues on pancreas secretion in dogs.

Cai et al. (1986) reported on the biological activity of octapeptide analogs of somatostatin assaying GH concentrations in blood samples of anesthetized rats by RIA and studying the inhibition of gastric secretion on dogs.

Biological actions of prosomatostatin have been described by Meyers et al. (1980) using *in vitro* and *in vivo* GH bioassays.

Taylor et al. (1996) employed the technique of cytosensor microphysiometry for real-time evaluation of somatostatin subtype receptor activity in CHO-K_1 cells stably expressing the human sst_2 receptors.

Cytotoxic analogs of somatostatin have been synthesized and evaluated (Nagy et al. 1998).

Gilon et al. (1998) studied a synthetic receptor 5-selective somatostatin analogue *in vivo* in rats. The compound inhibited bombesin- and caerulein-induced amylase and lipase release from the pancreas without inhibiting growth hormone or glucagon release.

Jeandel et al. (1998) described the effects of two somatostatin variants on receptor binding, adenyl cyclase activity and growth hormone release from the frog pituitary.

Hofland et al. (1994) determined relative potencies of somatostatin analogs on the inhibition of growth hormone release by cultured human endocrine tumor cells and normal rat anterior pituitary cells.

Rohrer et al. (1998) and Rohrer and Schaeffer (2000) described rapid identification of subtype-selective agonists of the somatostatin receptor through combinatorial chemistry.

Hoyer et al. (2004) characterized *in vitro* a non-peptide somatostatin sst_1 receptor antagonist.

Reubi et al. (2000) described SST_3-selective potent peptidic somatostatin receptor antagonists.

Nunn et al. (2003a, 2003b) reported properties of putative small-molecule somatostatin sst_2 receptor-selective antagonists.

Using high-throughput parallel synthesis, Moinet (2001) prepared non-peptide ligands for the somatostatin sst_3 receptor.

Gademann et al. (2001) reported that peptide folding induces high and selective affinity of a linear and small β-peptide to the human somatostatin receptor 4.

Nunn (2003c) described β^2/β^3-di- and α/β^3-tetrapeptide derivatives as potent agonists at somatostatin sst_4 receptors.

Somatostatin analogs labeled with ^{99m}technetium, ^{111}indium, and ^{90}yttrium were developed for tumor diagnosis and therapy (O'Byrne and Carney 1996; Pearson et al. 1996; Stolz et al. 1996, 1998; Thakur et al. 1996).

Radioimmunoassays for somatostatin have been developed (Arimura et al. 1975; Gerich et al. 1979; Patel and Reichlin 1979; Patel 1984) and are available as commercial kits.

Siehler et al. (1998) reported that [^{125}I]Tyr^{10}-cortistatin$_{14}$ labels all five somatostatin receptors.

J.7.0.7 Receptor Binding for Somatostatin

GENERAL CONSIDERATIONS

A family of five somatostatin receptor subtypes from various species including man has been described (Yamada et al. 1992; Reisine and Bell 1995; Hoyer et al. 1995; Bruns et al. 1996; Liapakis et al. 1996; Patel and Srikant 1994; Hoyer et al. 1995; Patel et al. 1996; Nilsson and Folkesson 1997; Patel 1997; Pscherer et al. 1996; Shimon et al. 1997; Humphrey et al. 1998; Moller et al. 2003; Olias et al. 2004). There are several endogenous ligands, such as somatostatin-14, somatostatin-28 and the corticostatins (Meyerhoff et al. 1992; De Lecea 1996; Fukusumo 1997). A number of synthetic peptide analogues have been developed and their relative affinities at human recombinant receptors in radioligand receptor studies have been established (Raynor et al. 1992; Bass et al. 1996; Coy and Taylor 1996; Pearson et al. 1996; Piwko et al. 1996, 1997a, b).

Greenmman and Melmed (1994) evaluated the expression of three somatostatin receptor subtypes (SSTR3, SSTR4, and SSTR5) in pituitary tumor specimens. SSTR3 expression was studied by reverse transcription coupled to polymerase chain reaction, whereas SSTR4 and SSTR5 expression was determined by ribonuclease protection assay.

Somatostatin occurs not only in the hypothalamus and in the gut, but also in several other organs. Somatostatin$_1$ receptors in the nucleus accumbens have been found to mediate the stimulatory effect of somatostatin on locomotor activity in rats (Raynor et al. 1993a). Molecular cloning and expression of a pituitary somatostatin receptor with preferential affinity for somatostatin-28 has been described by O'Carroll et al. (1992).

Cloning and expression of a mouse somatostatin receptor (SSTR 2B) has been reported by Vanetti et al. (1992). Pharmacological properties of two cloned somatostatin receptors have been described by Rens-Domiano et al. (1992).

Subtype-selective peptides have been identified by Raynor et al. (1993b). The somatostatin receptor, SSTR3, coupled to adenyl cyclase, has been cloned by Yasuda et al. (1992). Somatostatin receptors SSTR4 and SSTR5 have been cloned and characterized by Raynor et al. (1993c).

The somatostatin receptor SST_1 mediates inhibition of central neurons (Viollet et al. 1997).

The somatostatin receptor SST_2 inhibits growth hormone release (Raynor et al. 1993b), inhibits parietal cell function and ion secretion in rat distal colon (McKeen et al. 1996; Warhurst et al. 1996; Wyatt et al. 1996), and inhibits neurons in the rat locus coeruleus (Chessell et al. 1996). High basal gastric acid secretion has been found in somatostatin receptor subtype 2 knockout mice (Martinez et al. 1998). The cytoplasmatic tail of the somatostatin receptor SST_2 undergoes alternative splicing giving rise to two isoforms, SST_{2A} and SST_{2B} (Schulz et al. 1998).

The somatostatin receptor sst_3 mediates relaxation of isolated gastric smooth muscle cells (Gu et al. 1995).

The fourth human somatostatin receptor has been cloned and characterized by Rohrer et al. (1993).

The somatostatin receptor sst_5 may have a role in inhibition of hormone release from the pituitary (Tallent et al. 1996) and pancreas (Rossowski and Coy (1994) and mediates the antiproliferative effect of somatostatin in vascular smooth muscle (Lauder et al. 1997).

PROCEDURE

Crude membrane preparations are obtained by homogenizing (Polytron, setting 6, 15 s) tumor cell cultures (e. g. human SCLC line NCI-H69, rat pancreatic tumor AR42J) or rat tissues (lung, pancreas, cerebral cortex) in ice-cold 50 mM Tris-HCl and centrifuging twice at 39,000 *g* (10 min), with an intermediate resuspen-

sion in fresh buffer. The final pellets are resuspended in 10 mM Tris-HCl for assay. Aliquots of the membrane preparation are incubated for 25 min at 30°C with [^{125}I-Tyr^{11}]SRIF (2000 Ci/mmol, Amersham) in 50 mM HEPES (pH 7.4) containing bovine serum albumin (10 mg/ml; fraction V, Sigma), $MgCl_2$ (5 mM), Trasylol (200 KIU/ml), bacitracin (0.02 mg/ml), and phenyl-methyl-sulfonyl fluoride (0.02 mg/ml). The final assay volume is 0.3 ml. The incubations are terminated by rapid filtration through Whatman GF/C filters (pre-soaked in 0.3% polyethylenimine) under reduced pressure. Each tube and filter is then washed three times with 5 ml aliquots of ice-cold buffer. Specific binding is defined as the total [^{125}I-Tyr^{11}]SRIF bound minus that bound in the presence of 200 nM unlabeled SRIF.

EVALUATION

The binding parameters are calculated from the experimental data by non-linear least-squares regression analysis using an appropriate computer program.

CRITICAL ASSESSMENT OF THE METHOD

Somatostatin occurs in many organs and has more activities than anticipated at its discovery. Therefore, the occurrence of a family of receptors rather than a single receptor is not surprising.

MODIFICATIONS OF THE METHOD

Receptor scintigraphy with a radioiodinated somatostatin analogue has been described by Bakker et al. (1990).

The tissue-selective binding of somatostatin-14 and somatostatin-28 in rat brain was studied by Srikant et al. (1990).

Feniuk et al. (1993) characterized somatostatin receptors in guinea-pig isolated ileum, vas deferens and right atrium.

Yang et al. (1998) reported synthesis and biological activities of potent peptidomimetics selective for somatostatin receptor subtype 2 by testing inhibition of forskolin-stimulated cAMP accumulation in a mouse cell line that contains a cAMP response element fused to the *E. coli* β-galactosidase gene and by measuring growth hormone release from primary cultures of rat anterior pituitary cells.

J.7.0.8 Secretin Activity

PURPOSE AND RATIONALE

Synthetic derivatives of secretin can be tested for activity against the standard using the bioassay of a chronic pancreatic fistula in dogs. Moreover, stability of secretin preparations has to be checked when using this bioassay.

PROCEDURE

Dogs with a chronic pancreatic fistula prepared according to Preshaw and Grossman (1965), Herrera et al. (1968) (see J.6.1.4) are used. Eighteen hours prior to the experiment food is withdrawn but water allowed ad libitum. Pancreatic juice is collected for 15 min periods. After 1 h pretest time, a test dose of 0.2 KE/kg Karolinska-secretin is given intravenously. In one hour intervals the test preparation or the standard is given alternatively in logarithmic doses between 0.1 and 1.6 KE/kg intravenously. The volume of pancreas juice secreted during 30 min after injection is used as parameter.

EVALUATION

Using at least two doses of test compound and standard, parallel line assays can be carried out and potencies can be calculated. Each of 4 animals receives two doses test compound and two doses standard, the application scheduled according to a Latin square. Potency ratios with confidence limits are calculated.

CRITICAL ASSESSMENT OF THE METHOD

The method is time consuming and needs dogs with chronic fistula. Nevertheless, for final evaluation of a test compound this bioassay can not be avoided.

MODIFICATIONS OF THE METHOD

The standardization of secretin has been described as early as 1952 by Burn et al. using anesthetized **cats**. After laparotomy the pylorus and first duodenal loop are brought outside and turned to the animal's left side. The bile duct is identified by gently squeezing the bile-bladder. The pancreatic duct usually enters the duodenum about 2 mm below the entry of the bile-duct. Starting about 2 cm below the bile duct, the pancreas is separated from the duodenum by blunt dissection, the blood vessels being tied and divided where necessary. When the pancreatic duct is reached, two silk ligatures are placed around and a length of 5 mm is dissected. A dose of secretin is injected intravenously and one of the ligatures is then tied as near the duodenum as possible. The duct is then cut and a flow of juice is usually visible. A small cannula is tied into the duct and attached to a rubber tube and L-piece whose position is adjusted so that the flow of juice continues. The cannula and the L-piece are clamped in position and the abdomen is closed.

The relation between the dose injected and the number of drops of pancreatic juice secreted is almost linear, but the slope differs in different cats. In making a comparison between two preparations, the dose-response relation is first determined for the standard preparation by administration of three or more different doses. A dose of the test preparation is then injected and the effect compared with the curve of the standard. Further doses of the test preparation and comparison of the dose-response curves allow the calculation of the relative potency.

Izzo et al. (1989) studied the internalization of labelled secretin into isolated pancreatic acinar cells of **rats**.

J.7.0.9 Receptor Binding for Secretin

PURPOSE AND RATIONALE

Secretin receptor antagonists, such as reduced peptide bond pseudopeptide analogues of secretin, inhibit the binding of ^{125}I-secretin to secretin receptors in pancreatic acini (Haffar et al. 1991).

Radioimmunoassays for secretin have been developed (Boden and Wilson 1979; Chang and Chey 1980) and are available as commercial kits.

PROCEDURE

Dispersed acini from guinea pig pancreas are prepared according to Peikin et al. (1978) and Jensen et al. (1982). After sacrifice, the pancreas of a guinea pig is immediately removed and trimmed of fat and mesentery. A suspension of dispersed acini is prepared by injecting the pancreas 5 times with 5 ml of digestion solution composed of standard incubation solution plus purified collagenase (0.12 mg/ml). The pancreas is incubated for 4 sequential 10-min periods at 37°C in a Dubnoff incubator at 160 oscillations per min. The gas phase is 100% O_2. The digestion solution is discarded, and the tissue is washed 3 times with 5 ml of standard incubation solution. The tissue is dispersed by passing it 5 times through each of a series of siliconized glass pipettes of decreasing bore (3, 1, and 0.5 mm). Large fragments and the duct system are discarded. The suspension of dispersed acini is layered over standard incubation solution containing 4% albumin and centrifuged at 800 *g*. The supernatant is discarded, and the acini are washed twice with standard incubation solution containing 4% albumin.

^{125}I-Secretin and ^{125}I-labeled analogues are prepared using chloramine T and a method described by Chang and Chey (1980), Jensen et al. (1983), Zhou et al. (1989). They are separated from ^{125}I using a disposable C_{18} cartridge (Sep-Pak) and then separated from unlabeled peptide with reverse phase HPLC using a 4.6-mm × 25-cm column of mBondapak C_{18}. The column is eluated with a linear gradient of acetonitrile in 0.1% trifluoroacetic acid (v/v) from 0 to 54% acetonitrile in 60 min using a flow rate of 1.0 ml/min.

For binding of ^{125}I-secretin incubations are performed containing 0.25 ml of cell suspension of pancreatic acini (one pancreas in 10 ml of standard incubation buffer) and 50 pM ^{125}I-secretin with or without 1 mM secretin. Nonsaturable binding of ^{125}I-secretin is measured as the amount of radioactivity associated with acini when the incubation contains 50 pM ^{125}I-secretin plus 1 mM secretin. Secretin antagonists are added in various concentrations. Saturable binding of ^{125}I-secretin is expressed as percentage of radioactivity bound in the absence of the antagonists.

EVALUATION

K_i values are calculated from percent of controls of bound ^{125}I-secretin using the equation:

$$K_i = [R/(R-1)][S\,B/(S+A)]$$

where R = the observed saturable binding of ^{125}I-secretin in the presence of the antagonist (B) expressed as a fraction of that obtained when B is not present. A is the concentration of ^{125}I-secretin (0.05 nM), S is the k_d determined by Scatchard analysis.

MODIFICATIONS OF THE METHOD

Bawab et al. (1991) characterized the down regulation of the ^{125}I-secretin binding sites and the associated desensitization of the secretion receptor-cAMP system in rat gastric glands.

Molecular cloning and expression of a cDNA encoding the secretin receptor in COS cells was reported by Ishihara et al. (1991).

Steiner et al. (1993) localized secretin receptors mediating rat stomach relaxation by autoradiography of frozen sections of the rat stomach with ^{125}I-labeled porcine secretin.

Ulrich et al. (1993) studied the intrinsic photoaffinity labeling of native and recombinant rat pancreatic secretin receptors.

Vilardaga et al. (1994) investigated the properties and regulation of the coupling to adenylate cyclase of secretin receptors stabile transfected in Chinese hamster ovary cells.

Molecular cloning, expression and functional characterization of a human secretin receptor was reported by Chow (1995), Patel et al. (1995), of the rabbit secretin receptor by Svoboda et al. (1996). The full-length human secretin receptor cDNA was subcloned into the mammalian expression vector pRc/CMV and expressed in cultured CHO cells (Ng et al. 1999). Intracellular cAMP accumulation of the stably transfected cells was measured by a radioimmunoassay, while the extracellular acidification rate was measured by the Cytosensor microphysiometer.

J.7.0.10 Cholecystokinin Activity (Isolated Rat Pancreatic Acini)

PURPOSE AND RATIONALE

Cholecystokinin (CCK) is one of the first discovered gastrointestinal hormones and one of the most abundant neuropeptides in the brain (Crawley and Corwin (1994). CCK is found in high concentrations in the mammalian brain and may be implicated in the neurobiology of anxiety and panic disorder (Bourin et al. 1996). Two types of CCK receptors have been identified (Wank 1995; Noble et al. 1999; Miyasaka and Funakoshi 2003): CCK-A receptors are mainly located in the periphery, but are also found in some areas of the CNS. CCK-B receptors (Noble and Roques 1999) are widely distributed in the brain. Major biological actions of CCK are the reduction of food intake (Moran and Kinzig 2004) and the induction of anxiety-related behavior. Inhibition of feeding is mainly mediated by the A-type receptors, whereas anxiety-like behavior is induced by stimulating B-type receptors (Fink et al. 1998).

Isolated pancreatic acini of rats can be used for evaluation of cholecystokinin activity of synthetic derivatives and for plasma CCK-like activity (Liddle et al. 1984; Höcker et al. 1990; Schmidt et al. 1991).

PROCEDURE

For plasma determinations, CCK or inhibitors are extracted from a plasma sample using PR-18 cartridges (Merck, Darmstadt, Germany). One ml plasma is diluted with 4 ml 0.1% trifluoroacetic acid and applied to a cartridge. After a wash (15 ml), CCK and inhibitor are eluted with acetonitrile/water (80:20, v/v) and lyophilized. Pancreatic acini are prepared from female Sprague-Dawley rats weighing 180–200 g, 1 to 2 weeks post ovarectomy, by enzymatic digestion of pancreas with collagenase (Jensen et al. 1982). Test compounds, or extracted material reconstituted with Krebs-Ringer HEPES buffer, or CCK standard is incubated with acini (final volume 0.25 ml). Lipase is measured with an autoanalyser (e. g., Hitachi type 705 or 805). Release is calculated as percent of the initial content determined in each incubation vial.

EVALUATION

CCK bioactivity is determined by comparison with a CCK-8 standard curve. Results are expressed as CCK-like bioactivity.

MODIFICATIONS OF THE METHOD

Amblard et al. (1998) evaluated cyclic cholecystokinin analogues for their ability to stimulate amylase secretion from isolated pancreatic acini.

Inhibition of CCK-8 induced release of amylase from pancreatic cells was used for measurement of CCK_A antagonism (Yamazaki et al. 1995; Akiyama et al. 1996; Patel et al. 1996; Taniguchi et al. 1996; Ballaz et al. 1997; Martin-Martinez et al. 1997).

Deyer et al. (1993) reported on acetylcholine and cholecystokinin induced acid extrusion in mouse isolated pancreatic acinar cells as measured by the microphysiometer. The microphysiometer continually measures the pH of the medium bathing a cell sample. EC_{50} values for the acidification rate were determined for CCK and CCK analogues. Dunlop et al. (1997) used the Cytosensor microphysiometer to analyze the activity of cholecystokinin antagonists against the CCK-4-mediated response in hCCK-B CHO cells.

J.7.0.11 Receptor Binding of Cholecystokinin

PURPOSE AND RATIONALE

Receptor binding assays for CCK have been described by several authors, such as Innis and Snyder (1980) for rat pancreas; Gaisano et al. (1989), Doi et al. (1990), Blevis et al. (1990), Maletínská et al. (1992) for isolated pancreatic acini; Saito et al. (1981), Chang et al. (1983) for guinea pig cerebral cortex, Praissman et al. (1983) for guinea pig mucosa, Van Dijk et al. (1984) for rat brain and pancreas; Steigerwalt et al. (1984), Chang and Lotti (1986) for gallbladder membranes; Kaufmann et al. (1993) for guinea-pig cerebral cortex and rat pancreas.

Using transfected COS cells, Talkad et al. (1994) identified three different states of the pancreatic CCK receptor, with the very-low-affinity state being the most abundant.

DeTullio et al. (1999) and Herranz (2003) reviewed advances in the chemistry of cholecystokinin receptor agonists and antagonists.

Radioimmunoassays for cholecystokinin have been developed (Harvey 1979) and are available as commercial kits.

PROCEDURE

Membranes of rat (Sprague Dawley) pancreas, guinea pig (Hartley) cerebral cortex, and bovine gallbladder are prepared by homogenization in 50–100 vol of 50 mM Tris-HCl (pH 7.4 at 37°C) using a Polytron (Brinkman, PT 10, setting 4 for 10 s for pancreas or brain and maximal speed for bovine gallbladder). Homogenates are centrifuged at 50,000 *g* for 10 min, and

the pellets are resuspended in the same buffer and centrifuged as described above. The resulting pellets are resuspended in 4000, 80, and 25 ml of binding assay buffer for each g of original tissue wet weight of pancreas, brain, and gallbladder, respectively. ^{125}I-CCK-8 binding assay buffer contains 5 mM dithiothreitol, 50 mM Tris-HCl (pH 7.4 at 37°C), 5 mM $MgCl_2$, 2 mg of bovine serum albumin, and bacitracin at 0.14 mg/ml for pancreas; 10 mM HEPES, 5 mM $MgCl_2$, 1 mM EGTA, bacitracin at 0.25 mg/ml, and 130 mM NaCl (pH adjusted to 6.5 with NaOH) for brain; and 10 mM HEPES, 5 mM $MgCl_2$, 1 mM EGTA, bacitracin at 0.25 mg/ml, soybean trypsin inhibitors at 0.2 mg/ml, and 130 mM NaCl (pH 6.5) for bovine gallbladder.

^{125}I Bolton-Hunter labeled CCK-8 (New England Nuclear) is used. Free and bound ^{125}I-CCK-8 are separated by filtration using Whatman G/F B glass fiber filters that are presoaked with 50 mM Tris-HCl (pH 7.4) containing bovine serum albumin (1 mg/ml). Immediately after the filtration, the filters are washed rapidly three times with 4 ml of Tris-HCl containing bovine serum albumin (0.1 mg/ml). Radioactivity is counted with a gamma counter, e. g. Beckman Instruments. Specific ^{125}I-CCK-8 binding is defined as the difference between total binding and nonspecific binding in the presence of 1 mM CCK.

EVALUATION

IC_{50} values are determined by regression analysis of displacement curves. Inhibitor constants (K_i) are calculated from the formula

$$K_i = I/(K_{d'}/K_{d-1})$$

where I is the concentration of the inhibitor, and K_d and $K_{d'}$ are the dissociation constants of ^{125}I-CCK-8 in the absence and presence of the inhibitor, respectively.

MODIFICATIONS OF THE METHOD

Subtypes of the cholecystokinin receptor, forming a cholecystokinin receptor family, have been described, such as CCK_A from pancreas and other parts of the gastrointestinal tract and in a few discrete brain regions (Kachur et al. 1991; Poirot et al. 1992; Wank et al. 1992a).

According to the IUPHAR Compendium of Receptor Characterization and Classification 1998; CCK_A and CCK_B receptors are designated as CCK_1 and CCK_2, respectively.

A survey on ligands for cholecystokinin receptors was given by Trivedi (1994).

Van der Bent et al. (1994) described molecular modeling of **CCK-A receptors**.

For CCK_A receptor binding assays (Fossa et al. 1997), the pancreas from a male Hartley guinea pig is dissected and placed in saline. Fatty tissue and blood vessels are dissected away and the tissue placed in 20 vol of buffer (50 mM Tris HCl, pH 7.4, 0.35 mg/ml bacitracin and 0.5 mg/ml soybean trypsin inhibitor) at 4°C and minced using scissors. The tissue is homogenized (Polytron, setting no. 9 for two 15-s bursts), strained through gauze and centrifuged at 100,000 *g* for 15 min at 4°C. The supernatant is discarded and the pellet resuspended in 20 vol of buffer and recentrifuged. The final pellet is diluted to a concentration of 1.25 mg/ml (original wet weight) in buffer and kept on ice until used. The incubation reaction is initiated by the addition of 100 µl of tissue to 96-well plates containing 150 µl of incubation buffer (50 mM Tris HCl, pH 7.4, and a final concentration of 5 mM $MgCl_2$, 5 mM dithiothreitol and 1% DMSO) with 60 pM final concentration of ^{125}I-BH-CCK_{8S}, and drug or vehicle. After a 30-min incubation the reaction is terminated by rapid filtration using a Skatron cell harvester (Skatron Instruments, Inc. VA) onto GF/B filters that were soaked for 2 h in 50 mM Tris HCl, 0.1 mg/ml bovine serum albumin. The filters are dried and counted on a Betaplate counter (Wallac Inc. Gaithersburg, MD) for 45 s per sample.

Povoski et al. (1994) reported cholecystokinin receptor characterization and cholecystokinin A receptor messenger RNA expression in transgenic mouse pancreatic carcinomas and dysplastic pancreas.

Yule et al. (1993), Blevins et al. (1994) recorded intracellular Ca^{2+} concentration signaling stimulated by cholecystokinin or by a partial CCK agonist in Chinese hamster ovary-CCK-A cells or in isolated pancreatic acini.

Ghanekar et al. (1997) established a Chinese hamster ovary cell line bearing the mouse type A cholecystokinin receptor.

CCK-A agonists were evaluated as anorectic agents (Pierson et al. 1997; Simmons et al. 1998).

CCK_B receptors occur predominantly in the central nervous system indicating involvement in behavioral functions (Moran et al. 1986; Wank et al. 1992b; Derrien et al. 1994; Schäfer et al. 1994) but also in pancreatic cancer cells (Smith et al. 1993; Zhou et al. 1992) and small lung cell cancer lines (Sethi et al. 1993).

For CCK_B receptor binding assays (Fossa et al. 1997), guinea pig cortex is homogenized with a Teflon homogenizer in 20 vol of 50 mM Tris HCl (pH 7.4) containing 5 mM $MgCl_2$ at 4°C and centrifuged at

100,000 *g* for 30 min. The supernatant is discarded and the pellet resuspended and spun again. The pellet is diluted to a concentration of 10 mg/ml (original wet weight) with assay buffer (10 mM HEPES, 5 mM $MgCl_2$, 1 mM EGTA, 130 mM NaCl, and 0.2 mg/ml bacitracin, pH 6.5) before use. The incubation reaction is initiated by the addition of 50 µl of tissue to 96-well plates containing 150 µl of assay buffer with 1% DMSO final concentration, 50 pM final concentration of ^{125}I-BH-CCK_{8S} and the appropriate concentration of drug or vehicle. Non-specific binding is estimated using 1 µM CCK_{8S}. The reaction is terminated by spinning the plates using a H1000B rotor at 3000 rpm for 5 min at 4°C. The pellet is washed with 200 µl of 50 mM Tris HCl and respun. The supernatant is again discarded, the pellet resuspended and the tissues harvested onto Betaplate filters soaked in 0.2% polyethylenimine for 2 h using a Skatron cell harvester (Skatron Instruments, Inc., VA). The filtermats are dried and counted on a Betaplate counter (Wallac Inc. Gaithersburg, MD) for 45 s per sample.

Lee et al. (1993) described cloning and characterization of the human brain cholecystokinin-B/gastrin receptor.

Kaufmann et al. (1993) studied the binding of a series of succinylated cholecystokinin tetrapeptide derivatives to different tissues and their effects on intracellular calcium mobilization ($[Ca^{2+}]_i$) in the human T-cell line Jurkat and rat pituitary (GH3) cells.

Durieux et al. (1989) described [^{3}H]pBC 264 as the first highly potent and very selective radioligand for CCK_B receptors.

Slaninova et al. (1995) recommended the radioiodinated CCK_8 analogue, SNF 8702, as a selective radioligand for CCK_B receptors.

Knapp et al. (1990) found CCK-B receptor heterogeneity in various brain areas of the guinea pig using a highly selective CCK-B receptor radioligand.

Dunlop et al. (1996) described the functional characterization of a Chinese hamster ovary cell line transfected with the human CCK-B receptor gene. Functional coupling in these cells was demonstrated using agonist stimulated mobilization of intracellular Ca^{2+}, measured with the FURA-2 technique.

Kaufmann et al. (1995) described the effects of guanyl nucleotides on CCK_B receptor binding in brain tissue and continuous cell lines, such as Jurkat T-cells, rat pituitary GH3 cells, rat glioma C6 cells, and small cell lung cancer NCI-H69 cells.

Cuq et al. (1997) reported that mRNAs encoding CCK_B but not CCK_A receptors are expressed in human T lymphocytes and Jurkat lymphoblastoid cells.

CCK_A receptor antagonists have been described (Chang and Lotti 1986; Makovec et al. 1986; Evans 1993; Gully et al. 1993) as well as **CCK_B receptor antagonists** (Hill and Woodruff 1990; Ohtsuka et al. 1993; Pendley et al. 1993).

Selective non-peptide **CCK_B/gastrin receptor antagonists** have been described by Bertrand et al. (1994, Makovec et al. 1999; Takeuchi et al. 1999). Harper et al. (1999) analyzed some of them in radioligand binding assays in mouse and rat cerebral cortex.

Cholecystokinin dipeptoid antagonists with anxiolytic properties which bind preferably to CCK_B receptors have been reported by Boden et al. (1993).

CCK_A receptor antagonists (Ballaz et al. 1997) and **CCK_B receptor antagonists** (Revel et al. 1998) with anxiolytic-like activity in animal models were described.

J.7.0.12 Acute Experimental Pancreatitis

PURPOSE AND RATIONALE

Acute interstitial pancreatitis can be induced in the rat by excessive doses of a pancreatic secretagogue (Lampel and Kern 1987) such as caerulein (Renner et al. 1986; Ito et al. 1991; Yazu et al. 1991).

PROCEDURE

Induction of Pancreatitis

Male Wistar rats weighing 200 g are used. Pancreatitis is induced by caerulein given as 5 intraperitoneal injections of 40 µg/kg each at hourly intervals on day 1. Controls receive saline injections only. Treatment with potential drugs is started at day 1 and continued for 7 or 14 days. The rats are sacrificed after 1 or 2 weeks following caerulein injection.

Preparation of Pancreatic Acini

The rats are decapitated after overnight fasting and the pancreata are quickly removed. The pancreata are injected with digestion medium containing 170 U/ml collagenase and incubated for 15 min at 37°C. The medium is changed for the second incubation for 60 min with 15 ml digestion medium containing 200 U/ml collagenase. Acini are dissociated by sequential passage through 4 pipettes of different diameters in a standard medium containing 0,1% soybean inhibitor. The suspension is filtered through a single layer of gauze and layered over 15 ml of 4% bovine albumin. After centrifugation for 2 min at 400 rpm, the pellet is washed 3 times with 20 ml of incubation medium containing 0.5 mM $CaCl_2$. Finally, the acini are resuspended in 10–20 ml of the incubation medium containing 10 mM HEPES, 145 mM NaCl, 4.7 mM KH_2PO_4, 1.0 mM $CaCl_2$, 1.2 mM $MgCl_2$, 16.5 mM glucose, 0.1% bovine serum albumin, 0.01% soybean trypsin inhibitor, Eagles minimal essential amino acids and vitamins, adjusted to pH 7.4 and bubbled with 100% oxygen.

Measurement of [^{3}H]-Thymidine Uptake Into Pancreatic Acini

Aliquots (5 ml) of the acini suspension are incubated at 37°C for 30 min, and 6-[^{3}H]-thymidine (5 mCi/mmol) is added as a final concentration of 0.8 mCi/mol. After incubation for 60 min, 200 ml aliquots are filtered by vacuum through Whatman GF/B glass fiber filters. Filters which trapped the acini are washed with 15 ml ice-cold buffer. After adding 5 ml of Aquazol II to

each vial, the radioactivity of the filters is counted with a scintillation spectrometer.

Measurement of Amylase Secretion from Pancreatic Acini

Acini are resuspended in 5 ml of the incubation medium and pre-incubated at 37°C for 30 min. Carbachol at concentrations between 10^{-7} and 10^{-4} M or CCK-8 at concentrations between 10^{-11} and 10^{-8} M is added and the acini suspension is incubated at 37°C for an additional 30 min. Triplicate 300 ml aliquots are centrifuged for 5 s at 3000 rpm. The amylase activity in the supernatant is measured by a commercial amylase test. Triplicate 500 ml aliquots are sampled before adding the secretagogue and the amylase contents (total amylase) are measured after sonification.

EVALUATION

Thymidine uptake is compared between control, caerulein treated animals and animals treated with drugs. Dose-response curves of amylase secretion after carbachol and CCK-8 are established for each group. Moreover, amylase concentrations in the acini are compared.

MODIFICATIONS OF THE METHOD

Griesbacher and Lembeck (1992), Griesbacher et al. (1993) studied the prevention of **caerulein-induced** experimental acute pancreatitis in the rat by the bradykinin antagonist HOE 140.

Several authors (Ito et al. 1994; Ogden et al. 1994; Liu et al. 1995; Sledzinski et al. 1995; Weidenbach et al. 1995; Chen et al. 1996; Lembeck and Griesbacher 1996; Asano et al. 1997; Ito et al. 1997) used different dose regimens of caerulein administration to induce acute pancreatitis in rats.

Niederau et al. (1995) used caerulein to induce acute necrotizing pancreatitis in mice and evaluated the protective effects of secretin and of the cholecystokinin-receptor antagonists proglumide and benzotript.

Huch et al. (1995) induced necrotizing pancreatitis by intraductal infusion of low-dose glycodeoxycholic acid (10 mmol/l) followed by intravenous cerulein (6 µg/kg/h) for 6 h.

Several other chemicals and drugs may induced acute pancreatitis (Vogel 1994).

Merkord et al. (1997) studied the pathogenesis and the time course of lesions of acute interstitial pancreatitis in rats induced by intravenous injection of 6 mg/kg **dibutyltin dichloride** (DBTC), an organotin compound used in chemical industry and in veterinary medicine. First, the cytotoxic effects on the biliopancreatic duct epithelium lead to epithelial necrosis with obstruction of the duct, subsequent cholestasis, and interstitial pancreatitis; and second, the hematogenic effects of DBTC cause direct injury of pancreatic cells followed by interstitial edema and inflammation. A chronic course is found when the obstruction of the duct and cholestasis persist.

Destruction of acinar cells has been found after the administration of **ethionine** in rats (Herman and Fitzgerald 1962).

Niederau et al. (1985), Neuschwander-Tetri et al. (1994), Norman et al. (1995), Van Laethem et al. (1995), Taniguchi et al. (1996) described acute necrotizing pancreatitis induced by caerulein in **mice**.

Pancreatitis can be induced in mice by a **choline-deficient diet** (Lombardi et al. 1975; Niederau et al. 1990). Mice weighing 10–14 g are fed regular laboratory chow ad libitum before the experiment. A choline-deficient diet supplemented with 0.5% ethionine is given for a period of 66 h, after which it is replaced by regular chow.

Lake-Bakaar and Lyubsky (1995), Hirano (1997), Niederau et al. (1995) induced acute pancreatitis in female Swiss-Webster mice by feeding a choline- and methionine-deficient diet supplemented with 1% ethionine.

Emanuelli et al. (1994) demonstrated that a single injection of endotoxin (lipopolysaccharides, *E. coli* 0111-B4) into the superior pancreaticoduodenal artery of **rabbits** induced a dose-dependent acute necrotizing pancreatitis.

Watanabe et al. (1993) induced acute hemorrhagic pancreatitis in rats by surgically **closing a 1 cm length of duodenal loop** at points proximal and distal to the orifice of the pancreatic duct for 6 h with bypassing the bile from the liver hilus distal to the closed loop. The effects of Hoe 140, a bradykinin antagonist, were studied.

Ha et al. (1994, 1996) used the closed duodenal loop technique to study the role of endogenous and exogenous cholecystokinin in experimental pancreatitis and the effect of a cholecystokinin receptor antagonist on the early stage of the healing process in acute pancreatitis.

Kimura et al. (1988) found beneficial effects of a cholecystokinin A receptor antagonist in three methods of acute experimental pancreatitis: pancreatitis in mice induced by 6 intraperitoneal injections of 50 µg/kg caerulein, necrotizing pancreatitis in rats induced by injection of sodium taurocholate into the common

bile duct followed by 4 subcutaneous injections of 50 µg/kg caerulein, and in closed duodenal loop induced pancreatitis in rats.

Obermaier et al. (2001, 2004a, 2004b) described **ischemia/reperfusion-induced pancreatitis** in rats. Male Wister rats weighing 290–330 g were anesthetized by intraperitoneal injection of 60 mg/kg pentobarbital. The were placed on a heating pad and ventilated after tracheotomy with normal air (TSE, Bad Homburg, Germany). Polyethylene catheters were placed in the right carotid artery and the left jugular vein. The upper abdomen was opened by transverse laparotomy. The intestine was exteriorized to the right. The stomach was turned up cranially, and fixed on the skin by sutures. All exteriorized segments were moistened and covered with transparent foil to prevent drying. The pancreas was separated from the stomach and the short gastric vessels were ligated. The border to the caudal apart of the pancreas tail segment was the constant branch of the pancreaticoduodenal artery running to the caudal part of the spleen. Pancreatic and connective tissue in the area of the celiac axis were dissected. Thus the complete vascular isolation of the pancreatic tail pedunculated on the splenic vessels was accomplished.

The common hepatic artery was identified in order to allow PO_2 measurements, the pancreas was fixed on an oval plastic pad with sutures to the connective tissue and splenectomy was performed. A PO_2-sensitive Clark-type probe was inserted into the pancreatic tissue. The probe was fixed to connective tissue on its distal end with a suture. For local intra-arterial access, a small polyethylene catheter was inserted in the retrograde direction into the left gastric artery and fixed. The pancreatic tail-segment was covered with foil to prevent access of ambient air and drying. After a stabilization period of 10 min, the pancreatic tail segment was flushed with 1 ml of heparinized saline via the catheter in the left gastric artery, after clamping the celiac axis and the common hepatic artery. Paleness of the pancreatic tail segment indicated successful flushing.

For the induction of isolated pancreatic tail ischemia two clamps were put on the splenic vessels and then the clamps of the celiac axis and the common hepatic artery were removed. Continuously decreasing tissue PO_2 indicated successful ischemia. The clamps on the splenic vessels were removed after an ischemic period of 120 min, and disappearing paleness always indicated successful reperfusion. The animals were observed for a further 2 h. At the end of the experiment, the pancreas was excised for histological examination. Biopsy samples from the non-ischemic head served as control tissue to exclude experimental side-effects on the non-ischemic pancreatic head.

Microcirculatory measurements were done by intravital fluorescence microscopy. Histological examinations of the perfused pancreas tail were performed after staining with hematoxylin and eosin.

J.7.0.13
Taurocholate-Induced Pancreatitis in the Rat

PURPOSE AND RATIONALE

Retrograde infusion of bile salts into the pancreatic duct induces severe necrotizing pancreatitis indicated by reduced amylase output and histological changes.

PROCEDURE

Male Sprague-Dawley or Wistar rats weighing 200–300 g are anesthetized by i.m injection of a mixture of 87 mg/kg ketamine and 13 mg/kg xylazine. After laparotomy, the pancreaticobiliary duct is cannulated through the duodenal papilla with a polyethylene catheter (P10, Clay Adams) which is introduced by means of a puncture in the duodenum. A precision pump is used to infuse 0.6 ml 5% sodium taurocholate into the pancreaticobiliary duct during a 10-min period at an infusion rate of 6 ml/h. The catheter is then withdrawn and the abdominal cavity surgically closed.

After various time intervals (several hours up to 2 weeks), the animals are anesthetized and the pancreaticobiliary duct is cannulated again. The response to various doses of caerulein is measured.

EVALUATION

The degree of amylase output (mg/h) is taken as parameter. Dose response curves after various doses of caerulein are established.

MODIFICATIONS OF THE METHOD

The effects of various agents on experimental pancreatitis induced by retrograde intraductal injection of **taurocholate** solution or bile acid in rats have been studied by various authors (Bielecki et al. (1994), Hietaranta et al. 1995; Nakae et al. 1995; Niederau et al. 1995; Kimura et al. 1996; Mithofer et al. 1996; Paran et al. 1996; Tachibana et al. 1996; Norman et al. 1997; Plusczyk et al. 1997; Manso et al. 1998).

Tanaka et al. (1995), Sakai (1996) induced necrotizing pancreatitis by retrograde injection of **deoxycholate** solution into the biliopancreatic duct of rats.

J.7.0.14 Chronic Pancreatitis

PURPOSE AND RATIONALE

Chronic pancreatitis was induced by various means in rats (Zhou 1990, 1994; Goto et al. 1995; Puig-Diví et al. 1996), golden hamsters (Rutishauser et al. 1991, 1995), cats (Reber et al. 1992, 1999; Zhao et al. 1996), dogs (Hayakawa et al. 1993; Tanaka et al. 1994, 1998), and pigs (Vinter-Jensen et al. 1997).

Puig-Diví et al. (1996) induced chronic pancreatitis in rats by trinitrobenzene sulfonic acid infusion into the pancreatic ducts.

PROCEDURE

Male Sprague Dawley rats weighing 300–350 g are anesthetized with ketamine (100 mg/kg i.p.) after an overnight fast. Access to the pancreas is gained through a ventral midline incision. The duodenum is opened and the biliopancreatic duct cannulated through the papilla using polyethylene tubing (PE 10). The biliopancreatic secretion is allowed to drain freely for 15 min. To prevent liver damage, the duct is tied close to the liver. Retrograde infusion is initiated by means of a controlled pressure device that uses the height of a liquid column (trinitrobenzene sulfonic acid or vehicle) in a vertical pipette connected to the infusion cannula to control the intraductal pressure and infusion volume. Ductal pressure is never allowed to exceed 20 cm H_2O. In the treated group 0.4 ml of 2% trinitrobenzene sulfonic acid in phosphate buffered saline + 10% ethanol (pH 8) is infused. Ethanol is employed as an epithelial "barrier breaker" to facilitate trinitrobenzene sulfonic acid penetration into the tissue. Rats in the control group undergo the same procedure, except that trinitrobenzene sulfonic acid in absent from the infusion medium.

The total exposure time of the gland to the instillate is 60 min, followed by a washout period of 30 min. Ligatures are then released, the duodenum and the abdominal wall are sutured, and the animals are kept under observation for 2 h after surgery. Rats are then

transferred to individual cages, where they are fasted for 24 h. Thereafter they receive standard chow and their weight gain is recorded weekly.

Blood is withdrawn after various time intervals by cardiac puncture under light ether anesthesia for determination of glucose and serum α-amylase (EPS test, Boehringer Mannheim GmbH).

Groups of treated rats and controls are sacrificed at 3, 4, and 6 weeks after the surgical procedure. Pancreata are fixed in 10% neutral buffered formaldehyde and embedded in paraffin. Several sections are cut and stained with haematoxylin-eosin for light microscopy evaluation. The degree of periductal and intralobular fibrosis, patchy acute and chronic inflammatory cell infiltrates, common duct stenosis, and segmentary gland atrophy is evaluated.

EVALUATION

Data are expressed as means ± SEM. A two-tailed Student's *t*-test for unpaired values is used for statistical comparison of mean values of serum amylase, glucose and rat weight.

MODIFICATIONS OF THE METHOD

Chung and Richter (1971), Zhou et al. (1990, 1994) induced chronic pancreatitis in rats by **ligation of the pancreatic duct**.

Injection of oleic acid (Goke et al. 1989; Goldstein et al. 1989; Andersen et al. 1994; Kakugawa 1996; Seymour et al. 1995, 1998) or of a viscous solution of zein – oleic acid – linoleic acid (Kataoka et al. 1998) into the pancreatic duct was used to induce chronic pancreatitis in rats.

Goto et al. (1995) described a chronic pancreatitis model with diabetes induced by intraperitoneal **cerulein** injection plus water immersion stress in rats.

Pancreatic blood flow was measured in **cats** with chronic pancreatitis induced by partial ligation of the pancreatic duct by Austin et al. (1980), Reber et al. (1992, 1999), Widdison et al. (1992).

Zhao et al. (1996, 1998) induced progressing lesions of chronic pancreatitis in cats by intraductal injection of alcohol or by a combination of intraductal and intraparenchymal injection of ethanol together with partial obstruction of the main pancreatic duct to 70% of its original lumen by fixation of a small catheter in the papilla.

Hayakawa et al. (1993) induced pancreatolithiasis in **dogs** by partial obstruction of the major pancreatic duct.

Rats of the diabetic strain WBN/Kob (Tsuchitani et al. 1985; Nakama et al. 1985) develop **spontaneously chronic pancreatitis** (Ohashi et al. 1990; Sato et al. 1993; Sugiyama et al. 1996a, b; Arai et al. 1998; Ito et al. 1998) with pancreatic fibrosis and parenchymal destruction and both endocrine and exocrine pancreatic dysfunction (see also K.2.0.2).

Transgenic mice overexpressing $TGF_{\beta 1}$ (Sanvito et al. 1995) develop tissue changes in the pancreas resembling changes found in chronic pancreatitis.

Shetzline et al. (1998) identified target tissues of pancreatic polypeptide using an *in vivo* radioreceptor assay in order to further elucidate the function of this hormone.

J.8 Liver Function

J.8.1 Hepatocellular Function

J.8.1.1 Hepatitis in Long Evans Cinnamon Rats

PURPOSE AND RATIONALE

The Long Evans Cinnamon strain of rats has been recommended as a useful model to study genetically transmitted fulminant hepatitis and chronic liver disease (Yoshida et al. 1987; Hawkins et al. 1995). The underlying cause is thought to be due to excessive copper accumulation in the liver of Long Evans Cinnamon rats, thus making this animal a model for Wilson's disease in humans (Okayasu et al. 1992). Chelation therapy or feeding a copper-deficient diet can ameliorate the symptoms in Long Evans Cinnamon rats and Wilson's disease (Togashi et al. 1992).

PROCEDURE

Male Long Evans Cinnamon rats obtained from a commercial breeder at an age of 5 weeks are housed in temperature- und humidity-controlled rooms at a 12:12 light/dark cycle. Groups of 6–10 rats are given different diets based on a 15% purified egg protein diet and supplemented with vitamins or drugs. Drugs are applied via minipumps intraperitoneally implanted under ether anesthesia.

The occurrence of jaundice is easily observable as the time when the ears and tail turn yellow and the urine becomes bright orange, staining the fur in the lower abdominal region. Usually, the jaundice progressively worsens, ending in death of the animal within about a week. Incidence of jaundice and mortality vs. time are used as parameters.

EVALUATION

Statistics are performed using StatView II software package for Student's *t*-test, ANOVA, and the Scheffé F-test for comparison between means. All data are expressed as means. A p-value < 0.05 is used as the threshold of significance.

MODIFICATIONS OF THE METHOD

Several drugs which are known to be effective or which are potentially effective in treatment of Wilson's disease were studied in this animal model, such as D-penicillamine (Togashi et al. 1992; Yokoi et al. 1994; Shimizu et al. 1997), trientine (= triethylenetetramine) (Iseki et al. 1992; Sone et al. 1996; Yamamoto et al. 1997), tetrathiomolybdate (Ogra et al. 1995; Suzuki 1997; Sugawara et al. 1999), or the investigative drug TJN-101 (Yokoi et al. 1995).

The interferon-γ transgenic mouse which carries the mouse INF-γ gene develops chronic hepatitis from the age of 6–10 weeks and was recommended by Okamoto et al. (1999) as a model for **chronic hepatitis**.

J.8.1.2 Temporary Hepatic Ischemia

PURPOSE AND RATIONALE

Hepatocellular function is altered by temporary hepatic ischemia as occurring during surgical management of acute hepatic trauma and being essential during hepatic transplantation. To study this, total hepatic ischemia in rats is produced by placing a ligature around the hepatic artery, portal vein, and the common bile duct.

PROCEDURE

Hepatic Ischemia Procedure

Male albino Holtzman rats, weighing 300–350 g are fasted for 16 h prior to the experiment but are allowed water ad libitum. The rats are anesthetized lightly with ether and the abdominal cavity is opened through a midline incision. Splenectomy is performed following which a temporary extracorporal splenofemoral shunt is established between the splenic vein and the right femoral vein using a PE-190 tubing. To insure total hepatic ischemia, the portal vein as the hepatic artery and the bile duct are occluded by placing a tourniquet around the vessels. Blood pressure is measured via a catheter inserted into the right femoral artery. After heparinization (10 mg/kg), hepatic ischemia is produced for 60 min. During the ischemic period, 0.7 ml of saline is given i.v. at 20-min intervals for volume replacement. At the end of the 60-min is-

chemic period, the tourniquet around the portal vein, hepatic artery and the bile duct is removed in order to re-establish blood flow to the liver. The abdominal incision is then closed and the animals receive either saline (nontreated) or the drug. Following administration of saline or the drug the catheters are removed and the animals are returned to their home cages.

Sham-operated animals are prepared exactly in the same manner except that the tourniquet around the portal vein, hepatic artery, and the bile duct are not placed.

Measurement of Indocyanine Green Clearance

Three hours following the end of ischemia, the experimental as well as the sham-operated rats are lightly anesthetized with ether and a femoral artery and vein of each animal cannulated. Sodium heparin (400 units) is given i.v. and the animals are allowed to awake. Indocyananine green is given i.v. at 5 mg/kg (low) or 25 mg/kg (high) to the animals via the femoral vein and 0.2 ml arterial blood samples are taken at 5, 6, 8, 10, 12, 15, 18, and 20 min later. The blood samples are diluted with 0.8 ml of 1% bovine serum albumin in normal saline and centrifuged at 6000 rpm for 20 min at 4°C. The spectrophotometric absorbance of the supernatant is read at 800 nm and the indocyanine green concentration determined from a standard curve.

EVALUATION

The $t_{1/2}$ of indocyanine green clearance is computed for each animal using a computer program which calculates the least square line of log indocyanine green vs. time. Mean and standard errors for each group are compared using the Student *t*-test.

MODIFICATIONS OF THE METHOD

Daemen et al. (1989) compared the electromagnetic versus the microsphere and the clearance method for liver blood flow measurement in the rat.

Kawaguchi et al. (2004) described the protective effect of a Rho kinase inhibitor against hepatic ischemia-reperfusion injury in rats.

J.8.1.3 Model for Direct Transhepatic Studies in Dogs

PURPOSE AND RATIONALE

A chronic conscious dog model for repeated transhepatic studies over a period of 6–8 weeks was developed by O'Brien et al. (1991). This model can be applied to the study of the hepatic effects of pancreatic hormone secretion and glucose metabolism, to studies of the hepatic mechanisms associated with high first-pass metabolism and food interactions of drugs (Semple et al. 1990), and to studies of insulin balance in dogs that have undergone previous pancreatectomy and islet cell auto-transplantation.

PROCEDURE

Four silastic catheters, 0.062 in. ID × 0.125 in. OD (lengths: carotid 70 cm; jugular 70 cm; hepatic 80 cm; and portal 70 cm) and two ultrasonic transit time flow probes suitable for long-term implants (Burton and Gorewit 1984), 4 mm for the hepatic artery and 6 mm for the portal vein, are cleaned with chlorhexidine scrub and rinsed with distilled water. Double velour dacron cuffs are placed 15 cm from the external ends of all the devices.

Male dogs weighing 20–25 kg are sedated and anesthetized with a 2% halothane/L O_2 mixture. Skin interface sites and subcutaneous pockets for placement of catheters are prepared. After skin closure the external ends of the catheters are sealed. Then the catheters and flow probes are placed into the abdomen by retrieving them from the subcutaneous pockets. First, the hepatic artery flow probe is placed, then, the portal venous

flow probe inserted. To eliminate extrahepatic blood flow, the gastroduodenal artery is ligated. Then, the portal vein and the hepatic vein catheters are placed. After ensuring catheter patency, the abdomen is closed. Finally, a carotid artery catheter and a jugular venous catheter are placed.

EVALUATION

Blood samples can be withdrawn from the catheters placed into the carotid artery, the right external jugular vein, the portal vein, and the hepatic vein. Blood flow is measured by flow probes in the hepatic artery and the hepatic portal vein.

The following values are measured:

- Plasma flow in the portal vein and plasma flow in the hepatic artery,
- drug concentration in the portal vein, in the hepatic artery, in the hepatic vein, and in the right external jugular vein.

From these data plasma flux in the portal vein, in the hepatic artery, and in the hepatic vein and the interval areas under the curve for these vessels are calculated.

J.8.2 Liver Cirrhosis and Necrosis

J.8.2.1 General Considerations

Various factors induce liver cirrhosis in man, such as alcoholism, viral hepatitis, intoxications, bile duct disorders, inborn diseases, and others. In the process leading to cirrhosis, accumulation of connective tissue and parenchymal regeneration are competing events. Excessive formation of connective tissue with collagen overproduction in the liver reduces hepatic blood flow, impairs the metabolic functions of the liver, and increases portal vein pressure. These mechanisms result in hepatic failure, esophageal bleeding, portal hypertension and ascites. Therefore, the search for agents to prevent liver cirrhosis is focused on inhibitors of excessive connective tissue formation in the liver (Kervar et al. 1976; Nolan et al. 1978). The main component of connective tissue formed as a response to chronic injury is collagen. The collagenous fibers consist of triple helical molecules. Their formation depends on the presence of hydrogen bonds involving the post-translationally hydroxylated amino acid hydroxyproline. If the number of hydrogen bonds is reduced due to a decrease of hydroxylated amino acids, the resulting collagen can not form the triple helix and is degraded instead of being deposited in the extracellular matrix.

Insoluble collagen is responsible for most of the mechanical functions of connective tissue, e. g., bone, tendon and skin, being influenced by hormones, desmotropic drugs, such as D-penicillamine, and by maturation and age (Vogel 1969, 1972, 1974a, b, 1976, 1978, 1980, 1989; Bickel et al. 1990, 1991). The aim of fibrosuppressive compounds is to reduce only the excessive formation of insoluble collagen in the liver leaving collagen synthesis and turnover in other tissues intact. Fibrosuppressive effects by inhibition of proline hydroxylation can be screened with *in vitro* methods, however, the desired organ specificity has to be tested in models of liver cirrhosis and fibrosis *in vivo* together with functional studies of the connective and supporting tissue. Detailed description of methods for studying collagen metabolism and mechanical function of connective tissue is given in the Sect. M.2.1.3 (hormones).

J.8.2.2 Inhibition of Proline Hydroxylation

PURPOSE AND RATIONALE

The thermal stability of the triple helix of collagenous proteins is crucially dependent upon the intramolecular hydrogen bonds involving the 4-hydroxyproline residues synthesized by the enzyme prolyl 4-hydroxylase. This makes the enzyme a possible target for therapeutic antifibrotic agents.

PROCEDURE

Enzyme activity is assayed in sealed test tubes. The reaction volume of 1 ml contains 50 mM Tris buffer, pH 7.5, 10–100 mM (60000 d.p.m.) 2-oxo[1-^{14}C]glutarate, 1–50 mM $FeSO_4$, 0.1–1 mM ascorbate, 10–100 mg (Pro-Pro-Gly)$_{10}$, 0.1 mg catalase, 2 mg bovine serum albumin, 100 mM dithiotreitol, 0.05–0.2 mg enzyme, and inhibitors in various concentrations. After incubation at 37°C for 30 min, the generated $^{14}CO_2$ is trapped and determined.

EVALUATION

Inhibition modes are determined by plotting 1/v versus 1/concentration of the variable substrate (Lineweaver-Burk plot). The K_i values are derived from a secondary transformation (slopes or intercepts vs. inhibitor concentrations). The lines of best fit for primary plots and secondary transformations are calculated by using the method of least squares. The mean K_i value of 4–6 experiments is calculated.

MODIFICATIONS OF THE METHOD

The collagen hydroxylases lysyl hydroxylase and prolyl 3-hydroxylase have similar reaction mechanisms as prolyl 4-hydroxylase, differing only in the specificity for the amino acid sequence of the substrate (Kivirikko and Myllylä 1982). Instead of (Pro-Pro-Gly)$_{10}$, 50–500 mg Arg-Ala-Gly-Ile-Lys-Gly-Ile-Arg-Gly-Phe-Ser-Gly are used.

The activity of prolyl 3-hydroxylase is assayed in a reaction volume of 1.5 ml containing 50 mM Tris buffer, pH 7.5, 1,000,000 d.p.m. of biologically obtained [2,3-^{3}H]proline-labeled protocollagen substrate in which all proline residues recognized by proline 4-hydroxylase are converted to hydroxyproline, 2 mM ascorbate, 0.2 mg/ml catalase, 2 mg/ml bovine serum albumin, 15 mM 2-oxoglutarate, 50 mM Fe^{2+}, 100 mM dithiothreitol, 0.2–2 mg enzyme, and inhibitors at various concentrations. After incubation at 37°C for 30 min, the reaction is stopped by addition of 0.5 ml 10% trichloroacetic acid (w/v). The reaction mixture is then distilled, and 1.6 ml of ^3H_2O is counted for radioactivity.

J.8.2.3 Influence on Collagen Synthesis in Human Skin Fibroblasts

PURPOSE AND RATIONALE

Secretion of collagen by fibroblasts and other cells capable of synthesizing extracellular matrix is dependent on the hydroxylation of proline residues by prolyl 4-

hydroxylase. This enzyme is located in the cisternae of the endoplasmic reticulum. An agent aimed at inhibition of this enzyme must therefore pass both the external cell membrane and the endoplasmic reticular membrane. Organ specificity of a prolyl 4-hydroxylase inhibitor can be achieved by applying a prodrug which can be converted to the active agent only in cells of specialized tissues, e. g., in the liver, but not generally in fibroblasts.

PROCEDURE

Confluent cultures of human skin fibroblasts are preincubated for 24 h at 37°C without serum in glutamine-free Dulbecco's minimal essential medium supplemented with 50 mg/ml sodium ascorbate, 60 mg/ml 3-aminopropionitrile, and 100 U/ml penicillin G. The cells are then exposed to the potential inhibitor at various concentrations for 20 min, followed by the addition of 2 mCi [U-^{14}C]proline/ml. The incubation is continued for 5 h at 37°C. Then, the cells are separated from the medium. After removal of non-incorporated [^{14}C]proline, the proteins from medium and cells are hydrolyzed, and the hydroxyproline content is determined by amino acid analysis. The total incorporation of radioactivity serves as marker for protein synthesis.

EVALUATION

Two individual samples are taken for each concentration of the inhibitor and 6 samples for the controls. Proline incorporation is expressed as % of control radioactivity. Hydroxyproline synthesis is expressed as relative Hyp/Pro ratio according to the formula:

$$(\mathrm{Hyp/Pro_{sample}}/\mathrm{Hyp/Pro_{control}}) \times 100\,.$$

J.8.2.4 Influence on Collagen Synthesis in Chicken Calvaria

PURPOSE AND RATIONALE

To find fibrosuppressive agents for therapeutic use, it is necessary to have prodrugs which cross cell membranes readily and are converted intracellularly to the active agent. Proinhibitors which are cleaved hydrolytically can suppress collagen synthesis in chicken calvaria.

PROCEDURE

Calvaria are removed from chicken embryos, age 15 days, and washed for 3 min with DMEM at 37°C. They are then transferred into Pyrex tubes (8–10 calvaria/tube) containing 3 ml medium supplemented with 2 mM glutamine, 6 mCi [U-^{14}C-]proline, and various concentrations of the inhibitor. The samples are incubated for 1.5 to 6 h at 37°C. The experiment is terminated by placing the tubes in ice and separation of calvaria from the culture medium. The calvaria are washed once with 3 ml of fresh medium, which is then pooled with the incubation medium. Bovine serum albumin and phenyl methyl sulfonyl fluoride are added (final concentration 1 mg/ml and 6 mg/ml, respectively). The calvaria are extracted for 16 h with 25 ml of 0.5 M acetic acid.

The following procedure is identical for the medium and the calvaria extracts. The samples are extensively dialyzed against 0.5 M acetic acid at 4°C. Aliquots are withdrawn for SDS-PAGE1 and the triple-helix stability assay is performed. The remaining material is lyophilized, resuspended in 2 ml 6 N HCl and hydrolyzed at 105°C for 24 h. After evaporation of the acid, the samples are dissolved in 2 ml H_2O, and the hydroxyproline content is determined according to Juva and Prockop (1967).

In order to study the degree of collagen hydroxylation and proportion of collagen biosynthesis, calvaria are incubated in the presence of 10 mCi [3,4-^{3}H]-proline/ml and 2 mCi [U-^{14}C]-proline/ml for 3 h under the conditions described above. After lyophilization, aliquots of media and calvaria samples are digested with collagenase according to Peterkofsky et al. (1982). The degree of hydroxylation is calculated from the ^{3}H/^{14}C ratio in the digested material; the amount of collagen as a proportion of total protein synthesis is determined by the relation of collagenase degradable vs. collagenase resistant radioactivity. The stability of the extracted collagenous material against digestion by a trypsin/chymotrypsin mixture is tested according to the procedure proposed by Bruckner and Prockop (1981): An aliquot of either culture medium or calvaria extract is incubated for 15 min at a temperature between 25°C and 45°C in a total volume of 800 µl of 0.04 M NaCl/0.1 Tris, pH 7.4. After quenching to 0°C the sample is digested with 200 µl of a mixture of each 1 mg trypsin and chymotrypsin/ml buffer

for 15 min at room temperature. One hundred µl of 1 mg BSA/ml buffer is added, and the protease-resistant radioactivity, consisting of triple-helical collagen, is precipitated with 100 µl 100% trichloroacetic acid (w/v). The sample is transferred in total to a Schleicher and Schüll OE 67 filter paper of 2.5 cm diameter. The digested material is removed by repeated washing with cold 5% trichloroacetic acid and methanol. The filters are then dried and the radioactivity is determined. Unhydrolyzed samples are studied by SDS-polyacrylamide gel electrophoresis, and autofluorography. The morphologic appearance of the control and treated cultures is studied by electron microscopy.

EVALUATION

IC_{50}-values of hydroxyproline synthesis are read graphically from concentration response curves. Total protein synthesis is estimated as the incorporation of proline; the mean ± standard deviation is calculated from four samples.

MODIFICATIONS OF THE METHOD

Canalis et al. (1977) used cultured calvaria from 21 day fetal rats to study the effects of insulin and glucagon on bone collagen synthesis.

J.8.2.5 Allyl Alcohol Induced Liver Necrosis in Rats

PURPOSE AND RATIONALE

Administration of allyl alcohol induces focal liver necrosis in rats which can be partially prevented by treatment with several drugs such as antibiotics.

PROCEDURE

Female Wistar rats weighing 120–150 g are used. At 8:00 A.M. of the first day food but not water is withdrawn. At 3:00 P.M. the compounds to be tested for protective activity are administered i.p. or orally. One hour later, the animals are dosed orally with 0.4 ml/kg of a 1.25% solution of allyl alcohol in water. At 8:00 A.M. of the second day the treatment with the potentially protective drugs is repeated. Food but not water is withheld until the third day. At 8:00 A.M. of the third day the animals are sacrificed and the liver removed. The parietal sides of the liver (left, medium and right lobe and lobus caudatus) are checked using a stereomicroscope with 25 times magnification. Focal necrosis is observed as white-green or yellowish hemorrhagic areas clearly separated from unaffected tissue. The diameter of the necrotic areas is determined using a ocular-micrometer. These values are added for each animal to obtain an index for necrosis.

EVALUATION

Using 10 animals for controls and for each treatment group, the mean of necrosis index is calculated and compared with Student's *t*-test. The protective effect is expressed as percentage decrease of the necrosis index versus controls.

J.8.2.6 Carbontetrachloride Induced Liver Fibrosis in Rats

PURPOSE AND RATIONALE

Chronic administration of tetrachloride to rats induces severe disturbances of hepatic function together with histologically observable liver fibrosis.

PROCEDURE

Groups of 20 female Wistar rats with a starting body weight of 100–150 g are used. The animals are treated orally twice a week with 1 mg/kg carbontetrachloride, dissolved in olive oil 1:1, over a period of 8 weeks. The animals are kept under standard conditions (day/night rhythm 8:00 A.M. to 8:00 P.M., 22°C room temperature, standard diet, e. g. Altromin 1321 pellets, and water ad libitum). Twenty animals serve as controls receiving olive oil only, 40–60 animals receive the carbontetrachloride only, and groups of 20 rats receive in addition the compound under investigation in various doses by gavage twice daily (with the exception of the weekends, when only one dose is given) on the basis

of the actual body weight. The animals are weighed weekly.

At the end of the experiment (8 weeks), the animals are anesthetized and exsanguinated through the caval vein.

In the *serum*, the following parameters are determined:

- Total bilirubin,
- total bile acids,
- 7S fragment of type IV collagen,
- procollagen III N-peptide.

The following organs are prepared for determination of hydroxyproline:

- Liver,
- kidney,
- aortic wall, and
- tail tendons.

The specimens of the organs are weighed and completely hydrolyzed in 6 N HCl. Hydroxyproline is measured by HPLC and expressed as mg/mg wet weight of the organs.

To measure **mechanical properties of connective tissue**, the following organs are prepared: Femur and tibia of both sides, tail tendons, and strips from dorsal skin (Bickel et al. 1990, 1991; detailed description of the methods see N.2.1.3). Furthermore, the influence on the healing process of skin wounds is studied (Method see N.2.1.3.5).

For **histological analysis**, 3–5 pieces of the liver weighing about 1 g are fixed in formalin and Carnoy solution. Three – 5 sections of each liver are embedded, cut and stained with azocarmine aniline blue (AZAN) and evaluated for the development of fibrosis using a score of 0–IV.

Grade 0:	Normal liver histology.
Grade I:	Tiny and short septa of connective tissue without influence on the structure of the hepatic lobules.
Grade II:	Large septa of connective tissue, flowing together and penetrating into the parenchyma. Tendency to develop nodules.
Grade III:	Nodular transformation of the liver architecture with loss of the structure of the hepatic lobules.
Grade IV:	Excessive formation and deposition of connective tissue with subdivision of the regenerating lobules and with development of scars.

EVALUATION

For detection of significant differences ($p < 0.05$), the unpaired *t*-test is used. For comparison of the scores in the histological evaluation, the χ^2-test is used.

MODIFICATIONS OF THE TEST

Instead of chronic intoxication with carbontetrachloride resulting in liver fibrosis, acute hepatocellular damage can be achieved by short term application of carbontetrachloride.

Wistar rats with a starting body weight of 120–150 g are treated daily for 5 days with various oral doses of the compound under investigation. From day 2 to day 5 (4 applications) the rats receive by gavage a dose of 1 mg/kg carbontetrachloride dissolved in olive oil (1:1). Blood is withdrawn every day and the aminotransferases ALAT and ASAT, as well as total bilirubin are determined in the serum.

Niederberger et al. (1995, 1998) induced liver cirrhosis and ascites in rats by treatment with carbon tetrachloride.

Sakamoto et al. (2005) induced liver cirrhosis in rats by intraperitoneal injection of 10 mg/kg dimethylnitrosamine three times a week for 3 weeks.

Kawaura et al. (1993) produced liver cirrhosis with ascites in **dogs** by administration of 2 ml carbontetrachloride per kg body weight once a week for 4 weeks. Eight weeks afterwards, the supradiaphragmatic inferior vena cava was constricted to 50% resulting in ascites formation of 500 to 1000 ml. The dogs could be treated by ligation of the common hepatic artery and hepatocyte inoculation into the spleen.

Wirth et al. (1997) studied the effects of a bradykinin B_1 receptor antagonist in rats with CCl_4-induced liver cirrhosis.

In the model of CCl_4-induced liver fibrosis, the antifibrotic agents HOE077 and safironil decreased collagen accumulation in the liver by inhibition of stellate cell activation, which was more pronounced in female than it was in male rats (Wang et al. 1998). In the same model (Bickel et al. 1998) demonstrated powerful antifibrotic effects of a new prolyl 4-hydroxylase (P4-H) inhibitor, S4682, having a K_i of 155 nM at the purified enzyme P4-H. Inhibition of prolyl hydroxylation in stellate cells was inhibited with an IC_{50} of 39 μM by S4682. In drug-treated rats, ascites was significantly lower compared with controls. Histological examination proved a significantly lesser score of liver fibrosis after drug treatment.

J.8.2.7 Bile Duct Ligation Induced Liver Fibrosis in Rats

PURPOSE AND RATIONALE

Bile duct ligation in rats induces liver fibrosis which can be evaluated by histological means and by determination of serum collagen parameters.

PROCEDURE

Male Sprague Dawley rats weighing approximately 250 g are anesthetized with ketanest (Rompun). Laparotomy is performed under antiseptic conditions. A mid-line incision in the abdomen is made from the xiphosternum to the pubis, exposing the muscle layers and the linea alba, which is then incised over a length corresponding to the skin incision. The edge of the liver is then raised and the duodenum pulled down to expose the common bile duct, which pursues an almost straight course of about 3 cm from the hilum of the liver to its opening into the duodenum. There is no gallbladder, and the duct is embedded for the greater part of its length in the pancreas, which opens into it by numerous small ducts. A blunt aneurysm needle is passed under the part of the duct selected, stripping the pancreas away with care, and the duct is divided between double ligatures of cotton thread. The peritoneum and the muscle layers as well as the skin wound are closed with cotton stitches.

The animals receive normal diet and water ad libitum throughout the experiment. Groups of 5–10 animals receive the test compound in various doses or the vehicle twice daily for 6 weeks. Then, they are sacrificed and blood is harvested for determination of bile acids, 7S fragment of type IV collagen, and procollagen III N-peptide. The liver is used for histological studies and for hydroxyproline determinations. Control animals show excessive bile duct proliferation as well as formation of fibrous septa. The picture is consistent with complete biliary cirrhosis.

EVALUATION

For detection of significant differences ($p < 0.05$), the unpaired *t*-test is used.

MODIFICATIONS OF THE METHOD

Alpini et al. (1994) found an upregulation of secretin receptor gene expression in rat cholangiocytes after bile duct ligation.

Fiorucci et al. (2003) used 4-week bile-duct-ligated cirrhotic rats to study the effects of a nitric oxide-releasing derivative of ursodeoxycholic acid.

J.8.2.8 Galactosamine Induced Liver Necrosis

PURPOSE AND RATIONALE

Single dose or a few repeated doses of D-galactosamine cause acute hepatic necrosis in rats (Decker and Keppler 1972). Prolonged administration leads to cirrhosis (Lesch et al. 1970).

PROCEDURE

For induction of acute experimental hepatotoxicity, divided doses of 100 to 400 mg/kg D-galactosamine are injected to rats i.p. or i.v. during one day.

For induction of liver cirrhosis, male Wistar rats weighing 110–180 g are injected intraperitoneally three times weekly with 500 mg/kg D-galactosamine over a period of one to 3 months. Potential protective substances are administered orally with the food or by gavage every day. The rats are sacrificed at various time intervals and the livers obtained by autopsy.

EVALUATION

The livers are evaluated by light microscopy and immunohistology using antibodies against macrophages, lymphocytes and the extracellular matrix components, e. g., laminin, fibronectin, desmin, collagen type I, III, and IV. The extent of liver cell necrosis and immunoreactivity for macrophages, lymphocytes and the extracellular matrix components is graded semiquantitatively on a 0 to 4+ scale (0 = absent, 1+ = trace, 2+ = weak, 3+ = moderate, and 4+ = strong). Furthermore, serum enzyme activities, such as GOT and GPT, are determined.

MODIFICATIONS OF THE METHOD

Other agents used to induce experimental cirrhosis are ethionine, thioacetamide (Dashti et al. 1996), dialkylnitrosamines, tannic acid, aflatoxins, pyrrolidizine alkaloids, and hepatotoxic components from mushrooms, such as amatoxins and phallotoxins (Zimmerman 1976).

Bruck et al. (1996) found an inhibition of thioacetamide-induced liver cirrhosis in rats by a nonpeptidic mimetic of the extracellular matrix-associated Arg-Gly-Asp epitope.

Intrahepatic cholestasis can be induced by alpha-naphthylisothiocyanate in rats (Krell et al. 1982).

Fulminant liver destruction can be induced with anti-Fas antibody.

Rodriguez et al. (1996) injected inbred female C57BL mice with anti-Fas antibody. The animals died within a few hours due to massive apoptosis of hepatocytes. This was accompanied by the sequential activation of cysteine proteases of the interleukin$_{1\beta}$-converting enzyme (ICE) and CPP32 (caspase-3) types in the cytosol of the hepatocytes. Systemic injection of the tripeptide *N*-benzyloxycarbonyl-Val-Ala-Asp-fluoromethylketone inhibited the intracellular activation of CPP32-like proteases *in vivo* and fully protected mice against Fas-mediated fulminant liver destruction and death.

Suzuki (1998) showed that the CPP32 subfamily, rather than the ICE subfamily, plays the dominant role in Fas antibody-induced hepatitis.

J.8.2.9
Liver Fibrosis Induced by Schistosome Cercariae

CCl_4-induced liver fibrosis is the most commonly used model in liver fibrosis. The major shortcoming of this method is the high relative variability of the amount of collagen produced in the liver by treatment with the toxin. Determination of hydroxyproline, as a parameter of collagen deposition in the liver, showed a large relative variability of 75% after 8 weeks of treatment with twice-weekly administration of CCl_4. To ensure adequate statistical interpretation, 50 rats/group are needed (Bickel et al. 1996).

Exposure of mice tails to *Schistosome cercariae* causes infiltration of the cercariae into the circulation and subsequent deposition of the schistosome eggs in the liver. Thereafter liver fibrosis is produced in the liver in a time-dependent fashion. Hydroxyproline of the liver increases by threefold and sevenfold, 10 and 18 weeks after infection. The relative variabilities of the hydroxyproline content of the liver were 10% to 20%, 10 and 18 weeks after infection, respectively (Phillips et al. 1977, 1987). The advantages of this model are the simplicity of fibrosis induction, the uniform generation of liver fibrosis with a very low variability with regard to the collagen produced in the liver, and, most of all, that it represents a disease model which accurately corresponds to the human disease. One should not forget that at least 200 million people suffer from schistosomiasis, most of them living in developing countries.

In this model the antifibrotic active compound Safironil caused a significant reduction of collagen type I and fibronectin in the liver. The beneficial effects of Safironil were at least in part due to a decrease in stellate cell activation by a mechanism sensitive to tumour growth factor $(TGF)_{\beta 1}$ (Phillips et al. 1997).

J.9
Eviscerated Animals

J.9.1
Evisceration in Rats

PURPOSE AND RATIONALE

Eviscerated animals have been used to study the influence of hormones and other drugs on carbohydrate disposal (Russell 1942; Creutzfeldt et al. 1961; Wick and Drury 1963; Willms et al. 1969; Tanira and Furman 1999).

"Functional" evisceration has been performed by most authors (Russell 1942; Creutzfeldt et al. 1961; Creutzfeldt and Deuticke 1962; Willms et al. 1969; Penhos et al. 1970; Smith 1986; Smith et al. 1990; Tanira and Furman 1999). The abdominal viscera, with the exception of the liver, are removed, and the blood vessels supplying the liver – the coeliac axis and the portal vein – are tied and cut.

PROCEDURE

Male Wistar rats weighing 180 to 280 g are allowed free access to food and water until the experiment. They are anesthetized with 55 mg/kg pentobarbitone sodium i.p. Cannulae are placed in the left femoral vein and in the abdominal aorta via the left femoral artery.

The abdominal cavity is opened and the anterior mesenteric artery, posterior mesenteric artery and the coeliac axis are cut between double ligatures close to the abdominal aorta. The hepatic portal vein is ligated and cut in the same manner. After ligating and cutting the esophagus and the rectum, the abdominal portion of the gastrointestinal tract is removed, together with the pancreas and the spleen. The muscle and the skin incisions are sutured. After completion of the operation the rats are left for 15 min to equilibrate.

Drugs are injected intravenously through the venous cannula. Blood samples are withdrawn from the aortic cannula before and at various intervals after drug ad-

ministration to be assayed for insulin, blood glucose and non-esterified fatty acids.

EVALUATION

All results are expressed as mean ± SEM. Statistical analysis is performed using ANOVA.

CRITICAL ASSESSMENT OF THE METHOD

The described "functional" evisceration can be performed within 2–3 min without any hemorrhage or any signs of shock, even in hypophysectomized or adrenalectomized animals. That the liver remaining *in situ* is effectively cut off from the blood stream is proven by the fact that rats eviscerated in this way will die within 1–2 h without infusion of glucose.

MODIFICATIONS OF THE METHOD

Some authors removed also the kidneys and the adrenals in rats (Creutzfeldt and Deuticke 1962).

Dogs were eviscerated and nephrectomized under sodium pentobarbital anesthesia by Levine et al. (1950).

J.9.2 Evisceration in Rabbits

PURPOSE AND RATIONALE

Evisceration in rabbits was performed by Drury (1935), Wick and Drury (1963), Lippmann and Hommel (1968, 1969), Menzel and Haupt (1972). A detailed description of the technique was given by Lippmann and Hommel (1968).

PROCEDURE

Rabbits of both sexes weighing 2.6–3.2 kg kept on standard diet and tap water ad libitum are used. Food is withdrawn 12 h before surgery and the abdominal skin is shaved. The animals are anesthetized with 50 mg/kg hexobarbital sodium intravenously. After fixation of the animal, the abdominal cavity is opened by electrocautery from the xyphoid process until 3 cm cranial of the symphysis. The rectum is cut between double ligatures as far caudally as possible. Bleeding from the arteria rectalis has to be avoided. The arteria mesenterica inferior, which is a tiny vessel in the rabbit, is ligated close to the aorta. The root of the mesentery is cut up to the superior mesenteric artery which is tightly ligated. Then the arteria coeliaca is ligated in the same manner allowing complete removal of the root of the mesentery. The esophagus is ligated close to the cardia. After double ligature of the portal vein the whole gastrointestinal tract including the pancreas and the spleen is isolated and the liver is functionally cut off. To eliminate the function of the kidneys, the renal arteries are ligated close to the aorta and the ureters close to the hilus. Cannulae are introduced into the caval vein via the renal veins. The right renal vein is ligated close to the hilus and the tip of a polyethylene catheter placed 4–6 cm caudal from the inferior caval vein for blood withdrawal; the left renal vein is also ligated close to the hilus and the tip of a polyethylene catheter placed 6 cm cranial from the inferior caval vein for infusion.

The animal receives via the catheter 750 IU heparin, 0.3 mg/kg lobeline hydrochloride, 3 mg/kg pentylenetetrazole, 0.01 mg/kg ouabain, and 1.3 mg/kg synephrine to stabilize the cardiovascular function.

Drugs are injected intravenously through the infusion cannula. Blood samples are withdrawn from the other cannula before and at various intervals after drug administration to be assayed for insulin and blood glucose.

EVALUATION

All results are expressed as mean ± SEM. Statistical analysis is performed using ANOVA.

MODIFICATIONS OF THE METHOD

Schäfer (1990) measured glucose disappearance rates into peripheral tissues *in vivo* in adult eviscerated, nephrectomized and adrenalectomiced rabbits, Wistar rats and non-diabetic sand rats with physiological insulin concentrations in the blood.

K.1 Methods to Induce Experimental Diabetes Mellitus

K.1.1 Pancreatectomy in Dogs

GENERAL CONSIDERATIONS

Dysfunction of the visceral tract has been considered for a long time to be the cause of diabetes mellitus. Bomskov in 1910 reported severe diabetic symptoms in dogs after cannulation of the ductus lymphaticus. This observation, however, could not be confirmed in later experiments (Vogel 1963). The technique was similar to that described by Gryaznova (1962, 1963) for ligation of the thoracic duct in dogs.

Von Mehring and Minkowski in 1890 noted polyuria, polydipsia, polyphagia, and severe glucosuria following removal of the pancreas in dogs. The final proof for the existence of a hormone in the pancreas was furnished by Banting and Best (1922) who could reduce the elevated blood sugar levels in pancreatectomized dogs by injection of extracts of the pancreatic glands. The role of the pituitary gland in development of diabetes has first been elucidated by Houssay (1930, 1931) in pancreatectomized dogs (Survey by Beyer and Schöffling 1986).

PURPOSE AND RATIONALE

The technique of complete pancreatectomy in the dog as described in detail by Foà (1971) and by Sirek (1986) has been used by many scientists as a relevant animal model for insulin-deficient diabetes mellitus in man. Some remarks of our own experiences are added to an abbreviated version of Sirek's description.

PROCEDURE

Male Beagle dogs weighing 12–16 kg are used. After appropriate premedication the animal is placed on its back intubated with a tracheal tubus and anaesthesia is achived and maintained by an inhalation anaesthetics (e. g. fluroane). After removal of the fur and disinfection of the skin a midline incision is made from the xyphoid process reaching well below the umbilicus. Bleeding vessels are ligated and the abdomen is entered through the linea alba. The falciform ligament is carefully removed and the vessels ligated. A self-retaining retractor is applied. By passing the right hand along the stomach to the pylorus, the duodenum with the head of the pancreas is brought into the operating field. First, the mesentery at the unicate process is cut and the process itself is dissected free. The glandu-

lar tissue is peeled off from the inferior pancreaticoduodenal artery and vein. The vessels themselves are carefully preserved. Along a line of cleavage which exists between the pancreas, the pancreaticoduodenal vessels and the duodenal wall, the pancreas is separated from the duodenum and from the carefully preserved pancreatico-duodenal vessels. The small vessels to the pancreas are ligated. The dissection is carried out from both sides of the duodenum. In the area of the accessory pancreatic duct the glandular tissue being attached very firmly has to be carefully removed in order to leave no residual pancreatic tissue behind.

The pancreatic duct is cleaned, doubly ligated and cut between the ligatures. The dissection proceeds until one encounters a small lobe containing the main pancreatic duct. The glandular tissue adheres here firmly to the duodenum. Blunt dissection and ligation of the vessels is followed by ligation of the pancreatic duct. By pulling on the pylorus and the stomach, the pyloric and the splenic parts of the pancreas are delivered into the wound. The duodenal part is placed back into the abdominal cavity. The mesentery of the body and tail of the pancreas is cut with scissors. The small vessels are doubly ligated and cut. The pancreatic tissue is bluntly dissected from the splenic vessels. The pancreatic branches of the splenic vessels are doubly ligated and cut. Working in direction from the spleen to the pylorus, the pyloric part of the pancreas is the last one to be dissected. Finally, all pancreatic tissue is removed.

The surgical field is checked once more for pancreatic remnants. The concavity of the duodenum and its mesentery is approximated by a few silk stitches and the omentum is wrapped around the duodenum. Retroperitoneal injection of 5 ml 1% procaine solution is given to prevent intussusception of the gut. 250,000 IU penicillin G in saline solution are instilled into the peritoneal cavity. The abdominal wall and the subcutaneous layer are closed by sutures and finally the skin is sutured with continuous everting mattress stitches.

After the operation, the animal receives via a jugular vein catheter for 3–4 days the following treatment: 1000 ml 10% glucose solution with 10 IU human insulin Regular, 3 ml 24% Borgal (sulfadioxin/trimethoprim) solution, 2 ml 50% metamizol and 400 IU secretin. On the third day, the animal is offered milk. After the animal has passed the first milk feces, commercially available dry food together with a preparation of pancreatic enzymes for substitution. Insulin is substituted with a single daily subcutaneous dose of a long-acting insulin (e. g. Lantus) and the insulin dose is individually adjusted according to the blood glucose levels achieved. Vitamin D_3 is given every three months as a intramuscular injection of 1 ml Vigantol forte.

MODIFICATIONS OF THE METHOD

Experiments performed by Houssay (1930, 1931) performing hypophysectomy in pancreatectomized dogs revealed amelioration of the diabetic state. These experiments contributed to the understanding of hormonal control in diabetes mellitus.

Rappaport and coworkers (1966) and Lau and coworkers (1976) used a pedunculated subcutaneous autotransplant of an isolated pancreas remnant for the temporary deprivation of internal secretion in the dog.

Subtotal pancreatectomy in **rats** was described by Scow (1957), Scow and coworkers (1957), Wagner and Cardeza (1957), Bonner-Weir and coworkers (1983), Noguchi and coworkers (1994), Tanigawa and coworkers (1997). The pancreatic tissue between the common bile duct, duodenal loop, and portal vein in the duodenal segment, along the greater curvature in the gastric segment, and along the splenic vein in the splenic segment, was surgically excised in 3- to 4-weeks old rats weighing 80–100 g.

Greeley (1937) proposed a 3-stage procedure with 3–4 weeks intervening between operations for pancreatectomy in **rabbits**.

Itoh and Maki (1996) reported surgical removal of 90% of pancreatic tissue in 7 or 13 weeks old **mice**. Under sodium pentobarbital anesthesia (65 mg/kg i.p.), the pancreas and the spleen were surgically removed with careful conservation of the common bile duct and major vessels surrounding the duodenum. Approximately 10% (by weight and by insulin content) of the pancreas tissue was left intact adjacent to the lower duodenal loop.

K.1.2 Alloxan-Induced Diabetes

PURPOSE AND RATIONALE

Surveys on chemically induced diabetes in animals were given by Frerichs and Creutzfeldt (1968, 1971). This kind of diabetes predominantly based on insulin-deficiency due to chemically (beta cell toxicity) destroyed pancreatic beta-cells.

Hyperglycemia and glucosuria after administration of alloxan has been described in several species, such as in dogs (Brunschwig et al. 1943, Tasaka et al. 1988), in rabbits (Baily and Baily 1943), in rats (Dunn and McLetchie 1943, Goldner and Gomori 1944) and in other species (Frerichs and Creutzfeldt 1968, 1971). Guinea pigs have been found to be resistant (Maske and Weinges 1957). Dosage and treatment regimen have been elaborated for the most frequently used species. In most species a triphasic time course is observed: an initial rise of glucose is followed by a decrease, probably due to depletion of islets from insulin, again followed by a sustained increase of blood glucose.

PROCEDURE

Rabbits weighing 2.0 to 3.5 kg are infused via the ear vein with 150 mg/kg alloxan monohydrate (5.0 g/100 ml, pH 4.5) for 10 min resulting in 70% of the animals to become hyperglycemic and uricosuric. The rest of the animals either die or are only temporarily hyperglycemic (Baily and Baily 1943, Pincus et al. 1954, Bänder et al. 1969).

Rats of Wistar or Sprague-Dawley strain weighing 150–200 g are injected subcutaneously with 100–175 mg/kg alloxan (Blum and Schmid 1954, Katsumata and Katsumata 1990, Katsumata et al. 1993).

Male **Beagle dogs** weighing 15–20 kg are injected intravenously with 60 mg/kg alloxan. Subsequently, the animals receive daily 1000 ml 5% glucose solution with 10 IU Regular insulin for one week and canned food ad libitum. Thereafter, a single daily dose of a long-acting insulin (e. g. Lantus) is administered subcutaneously and the insulin dose is individually adjusted according to the blood glucose levels achieved. (Brunschwig at al 1943, Geisen 1988).

MODIFICATIONS OF THE METHOD

Kodoma and coworkers (1993) described a new diabetes model induced by neonatal alloxan treatment in rats. Male Sprague Dawley rats 2, 4, or 6 days of age were injected intraperitoneally with 200 mg/kg of alloxan monohydrate after a 16 h fast. The most severe diabetic symptoms occurred in rats injected on day 6.

Keikkila and coworkers (1974) reported the prevention of alloxan-induced diabetes by ethanol administration in mice.

K.1.3 Streptozotocin-Induced Diabetes

PURPOSE AND RATIONALE

Rakieten and coworkers (1963) reported the diabetogenic activity of the antibiotic streptozotocin. The compound turned out to be specifically cytotoxic to beta-cells of the pancreas.

PROCEDURE

Male Wistar rats weighing 150–220 g fed with a standard diet are injected with 60 mg/kg streptozotocin (Calbiochem) intravenously. As with alloxan, three phases of blood glucose changes are observed. Initially, blood glucose is increased, reaching values of 150–200 mg% after 3 h. Six–eight h after streptozotocin, the serum insulin values are increased up to 4 times, resulting in a hypoglycemic phase which is followed by persistent hyperglycemia. Severity and onset of diabetic symptoms depend on the dose of streptozotocin. After the dose of 60 mg/kg i.v., symptoms occur already after 24–48 h with hyperglycemia up to 800 mg%, glucosuria and ketonemia. Histologically, the beta-cells are degranulated or even necrotic. A steady state is reached after 10–14 days allowing to use the animals for pharmacological tests.

CRITICAL ASSESSMENT OF THE METHOD

Streptozotocin induced diabetes in laboratory animals, mostly in rats, has become a valuable tool in diabetes research being used by many investigators.

MODIFICATIONS OF THE METHOD

A survey on susceptibility of various species to streptozotocin was given by Frerichs and Creutzfeldt (1971). Multiple low doses of streptozotocin induce immune pancreatic insulitis in rats thereby mimicking immune type 1 diabetes in humans (Like and Rossini 1976, Rossini et al. 1977). Miller (1990) described the effect of streptozotocin on the golden Syrian hamster using a single i.p injection of 50 mg/kg streptozotocin. Enhancement of streptozotocin induced diabetes in CD-1 mice by cyclosporin A was reported by Iwakiri and coworkers (1987). Grussner and coworkers (1993) induced long-lasting diabetes mellitus in Yorkshire Landrace pigs with a dosage of 150 mg/kg streptozotocin.

Stosic-Grujicic and coworkers (1999) described protection of mice from multiple low dose streptozotocin-induced insulitis and diabetes by the immunosuppressive drug leflunomide. Bleich and coworkers (1999) found that elimination of leukocyte 12-lipoxygenase in mice ameliorates low dose streptozotocin-induced diabetes by increasing islet resistance to cytokines and decreasing macrophage production of nitric oxide. Masutani and coworkers (1998) studied the role of poly(ADP-ribose)-polymerase (Parp) in streptozotocin-induced diabetes. Parp-deficient ($Parp^{-/-}$) mice were established by disrupting *Parp* exon 1 using the homologous recombination technique. These mice were almost resistant to streptozotocin-induced diabetes.

K.1.4 Other Diabetogenic Compounds

PURPOSE AND RATIONALE

Several other compounds have been found to induce symptoms of diabetes and/or obesity, such as dithizone (Maske and Weinges 1957, Frerichs and Creutzfeldt 1971, Hansen et al. 1989, Goldberg et al. 1991) or gold-thioglucose (Stauffacher et al. 1967, Caterson et al. 1988, Silva and Hernandez 1989, Heydrick et al. 1995) or monosodium glutamate (Sartin et al. 1985).

PROCEDURE

Goldberg and coworkers (1991) injected various chelators, such as dithizone, 8-(p-toluene-sulfonylamino)-quinoline (8-TSQ), and 8-(benzenesulfanylamino)-quinoline (8-BSQ) in a single i.v. dose of 40–100 mg/kg to cats, rabbits, golden hamsters and mice. Dithizone injection causes a triphasic glycemic reaction in rabbits. A phase of initial hyperglycemia is detected after 2 h, followed by a normoglycemic phase after 8 h and a secondary permanent hyperglycemic phase after 24–72 h. Histologically, complete and partial degranulation of beta cells is observed.

K.1.5 Growth Hormone-Induced Diabetes

Cotes and coworkers (1949) described the diabetogenic action of pure anterior pituitary growth hormone in cats. In intact adult dogs and cats the repeated administration of growth hormone induces an intensively diabetic condition with all symptoms of diabetes including severe ketonuria and ketonemia. Rats of any age subjected to a similar treatment do not become diabetic but grow faster (Young 1945) and show striking hypertrophy of the pancreatic islets.

K.1.6 Corticosteroid-Induced Diabetes

Ingle (1941) described hyperglycemia and glucosuria in forced fed rats treated with cortisone. In the guinea pig and in the rabbit, experimental corticoid diabetes could be obtained without forced feeding (Hausberger and Ramsay 1953, Abelove and Paschkis 1954). In the rat, the adrenal cortex, stimulated by corticotrophin, has the capacity to secrete amounts of steroids which induce steroid diabetes (Ingle et al. 1946).

K.1.7 Insulin Deficiency Due to Insulin Antibodies

PURPOSE AND RATIONALE

A transient diabetic syndrome can be induced by injection of guinea pig anti-insulin serum in various species (Moloney and Coval 1955, Wright 1968).

PROCEDURE

Bovine insulin, dissolved in acidified water (pH 3.0), is incorporated in a water-oil emulsion based on complete Freund's adjuvant or a mixture of paraffin oil and lanolin. A dose of 1 mg insulin is injected in divided doses subcutaneously to male guinea pigs weighing 300–400 g. Injections are given at monthly intervals and the guinea pigs are bled by cardiac puncture two weeks after the second and subsequent doses of antigen. It is possible to get 10 ml blood from every animal once a month.

Intravenous injection of 0.25–1.0 ml guinea pig anti-insulin serum to rats induces a dose-dependent increase of blood glucose reaching values up to 300 mg%. This effect is unique to guinea pig anti-insulin serum and is due to neutralization by insulin antibodies of endogenous insulin secreted by the injected animal. In this way a state of insulin deficiency is induced. It persists as long as antibodies capable of reacting with insulin remain in the circulation. Slow rate intravenous infusion or intraperitoneal injection prolongs the effect for more than a few hours. However, large doses and prolonged administration accompanied by ketonemia, ketonuria, glucosuria, and acidosis are fatal to the animals. After lower doses, the diabetic syndrome is reversible after a few hours.

K.1.8 Virus-Induced Diabetes

Juvenile-onset (type I) diabetes mellitus may be due to virus infections and β-cell specific autoimmunity (Craighead 1978). The D-variant of encephalomyocarditis virus (EMC-D) selectively infects and destroys pancreatic β-cells in susceptible mouse strains similar to human insulin-dependent diabetes (Yoon et al. 1980, Giron and Patterson 1982, Giron et al. 1983, Vialettes et al. 1983). Adult, male ICR Swiss mice are susceptible to the diabetogenic effect of the D-variant of encephalomyocarditis virus in contrast to adult C3H/HeJ male mice which are relatively resistant. Pretreatment with cyclosporin A, a potent immunosuppressive drug, results in increased severity and incidence of diabetes in susceptible ICR Swiss mice and induction of diabetes in resistant C3H/HeJ mice (Gould et al. 1985).

MODIFICATIONS OF THE METHOD

Hirasawa and coworkers (1997) studied the possible role of macrophage-derived soluble mediators in the pathogenesis of encephalomyelitis virus-induced diabetes in mice. The inactivation of macrophages prior to viral infection resulted in the prevention of diabetes. Utsugi and coworkers (1992) demonstrated that intraperitoneal inoculation with NDK25, a variant of encephalomyocarditis virus which has been cloned from

the M variant of encephalomyocarditis virus, caused DBA/2 mice to develop non-insulin-dependent diabetes mellitus. See and Tilles (1995) challenged CD-1 mice with a diabetogenic strain (E2) of coxsackievirus B4. Islet cell destruction was associated with chronic islet cell inflammation, elevation of islet cell antibody, and prolonged presence of viral RNA in the pancreas. Stubbs and coworkers (1994) investigated the effect of Kilham rat virus (KRV) infection on GLUT2 expression in diabetes-resistant BB/Wor rats. Viral antibody-free diabetes resistant rats did not develop spontaneous diabetes, but inoculation with Kilham rat virus induced autoimmune beta cell-destruction and hyperglycemia. Hayashi and coworkers (1995) investigated the role of adhesion molecules in the reovirus type2-induced diabetes-like syndrome in mice. Ellerman and coworkers (1996) studied Kilham rat virus induced autoimmune diabetes in multiple strains of rat.

K.2
Genetically Diabetic Animals

GENERAL CONSIDERATIONS

Several animal species, mostly rodents, were described to exhibit spontaneously diabetes mellitus on a hereditary basis. These findings were highly appreciated with the expectation to get more insight into the pathogenesis of diabetes in humans. During the last few years since the discovery of leptin (Zhang et al. 1994) and its downstream signal transduction cascade (Friedman and Halaas 1998) tremendous new insight of the genetics of diabetic and obese animal disease models derived. Up to now at least 6 genetically diabetic animal models exhibit defects in the leptin pathway: The*ob* mutation in the mouse resulted in leptin deficiency. The*db* mutation in the mouse and the *cp* and*fa* mutations in the rat are different mutations of the leptin receptor gene. The *fat* mutation in the mouse results in a biologically inactive carboxipeptidase E, which processes the prohormone conversion of POMC into α-MSH, which activates the hypothalamic MC4 receptor. Finally the Agouti yellow (*y*) mouse exhibit an ubiquitous expression of the Agouti protein which represents an antagonist of the hypothalamic MC4 receptor.

Symptoms of diabetes and obesity are overlapping in many animal models (see also L.2. Genetically obese animals).

CRITICAL ASSESSMENT

The pathophysiological mechanisms which finally lead to the diabetes phenotype (hyperglycemia, hyperinsulinemia and insulin resistance) exhibited of the various animal disease models for non-insulin dependent diabetes do not necessarily be identical to those in human disease. Therefore, detailed knowledge about the (patho-)physiology of these animal disease models is a prerequisite for interpretation of experimental results and their value for the human disease.

K.2.1 Spontaneously Diabetic Rats

The occurrence of spontaneous diabetes has been reported in several strains of rats.

BB Rat

The BB rat (Bio Breeding (BB) rat) is a model of spontaneous diabetes associated with insulin deficiency and insulitis due to autoimmune destruction of pancreatic beta cells. (Nakhooda et al. 1977 and 1978, Like et al. 1982, Oschilewski et al. 1985, Lee et al. 1988, Solomon et al. 1989, Papaccio and Mezzogiorno 1989, Kolb et al. 1990, Velasquez et al. 1990, Lefkowith et al. 1990, Gottlieb et al. 1990, Ellerman et al. 1993). Diabetes is inherited as an autosomal recessive trait and develops with equal frequency and severity among males and females. The onset of clinical diabetes is sudden, and occurs at about 60–120 days of age. Within several days, diabetic animals are severely hyperglycemic,hypoinsulinemic, and ketotic unless insulin treatment is instituted. Pipeleers and coworkers (1991) described the transplantation of purified islet cells in diabetic BB rats. Hao and coworkers (1993) reported that the immunosuppressive agent mycophenolate mofetil can prevent the development of diabetes in BB rats. Klöting and Vogt (1991) characterized the features of a subline of diabetes-prone BB rats (BB/OK rats). The circadian variations in blood pressure and heart rate of this strain were compared with spontaneously hypertensive rats (Berg et al. 1997).

WBN/Kob RAT

Spontaneous hyperglycemia, glucosuria and glucose intolerance have been observed in aged males of an inbred Wistar strain, named the WBN/Kob rat (Nakama et al. 1985, Tsuchitani et al. 1985, Koizumi 1989, Shimoda et al. 1993).These animals exhibit impaired glucose tolerance and glucosuria at 21 weeks of age. Obvious decreases in the number and size of islets are found already after 12 weeks of age. Fibrinous exudation and degeneration of pancreatic tissue are observed in the exocrine part, mainly around degenerated islets and pancreatic ducts in 16 weeks old males. These rats develop demyelinating, predominantly motor neuropathy, later accompanied by axonal changes (Yagihashi et al. 1993).

Cohen Diabetic Rat

Diabetes in Cohen rats is characterized by hyperglycemia, glucosuria, and hyperinsulinemia, with late development of hypoinsulinemia, insulin resistance, and a decrease in the number and sensitivity of insulin receptors. The rats develop overt diabetes and diabetes related complications when fed a diet rich in sucrose or other refined sugars and poor in copper content, but not when fed a starch or stock diet (Cohen 1972, Velasquez et al. 1990).

Goto–Kakizaki Rat

Non-obese, insulin-resistant Goto–Kakizaki (GK) rats are a highly inbred strain of Wistar rats that spontaneously developed type II diabetes. Defects in glucose-stimulated insulin secretion, peripheral insulin resistance, and hyperinsulinemia are seen as early as 2 to 4 weeks after birth. Impaired skeletal muscle glycogen synthase activation by insulin was observed, accompanied by chronic activation of diacylglycerol-sensitive protein kinase C.

Zucker-Fatty Rat

The Zucker-fatty rat is a classic model of hyperinsulinemic obesity. (Zucker 1965). Obesity is due to a simple autosomal recessive (*fa*) gene and develops at an early age. Obese Zucker rats manifest mild glucose intolerance, hyperinsulinemia, and peripheral insulin resistance similar to human type 2 diabetes. However, their blood sugar level is usually normal throughout life (Bray 1977, Clark et al. 1983, McCaleb and Sredy 1992, Abadie et al. 1993, Alamzadeh et al. 1993, Kasim et al. 1993, Galante et al. 1994).

Zucker Diabetic Fatty Rat (Zdf/Drt-Fa)

The obese Zucker Diabetic Fatty rat originally derived from the Zucker fatty rat (Peterson et al. 1990). and has the identical mutation (fa) in th leptin receptor. In addition a defect in the insulin promoter has been described (Griffen et al. 2001). Insulin promoter activity is reduced 30–50% in homozygous ZDF fetal islets, and insulin mRNA levels are similarly reduced by 45%. Only the males become diabetic at the age of around 10 weeks spontaneously with hyperglycemia of about 20 mmol/l; the females develop diabetes only when feeding a high-fat diet.. Diabetes phenotype develops due to lipotoxicity to the β-cell (Lee et al. 1994). These rats are characterized besides hyperglycemia by insulin resistance, moderate hyperinsulinemia, extreme hyperphagia due to the loss of calories by glucosuria and obesity.

Wdf/Ta-Fa Rat

The WDF/Ta-fa rat, commonly referred to as the Wistar fatty rat, is a genetically obese, hyperglycemic rat established by the transfer of the fatty *(fa)* gene from the Zucker rat to the Wistar Kyoto rat. (Ikeda et al. 1981, Kava et al. 1989, Velasquez et al. 1990). The Wistar fatty rat exhibits obesity, hyperinsulinemia, glucose intolerance, hyperlipidemia, and hyperphagia similar to Zucker rats being, however, more glucose intolerant and insulin resistant than Zucker rats. Hyperglycemia is usually not observed in females but can be induced by addition of sucrose to the diet. Kobayashi and coworkers (1992) found an increase of insulin sensitivity by activation of insulin receptor kinase by Pioglitazone in Wistar fatty rats (*fa/fa*). Sugiyma and coworkers (1992) found a reduction of glucose intolerance and hypersecretion of insulin in Wistar fatty rats after treatment with pioglitazone for 10 days.

OLETF Rat

A spontaneously diabetic rat with polyuria, polydipsia, and mild obesity was discovered in 1984 in an outbred colony of Long-Evans rats. A strain of rats developed from this rat by selective breeding has since been maintained at the Tokushima Research Institute (Otsuka Pharmaceutical, Tokushima, Japan) and named OLETF. The characteristic features of OLETF rats are: (1) late onset of hyperglycemia (after 18 weeks of age), (2) a chronic course of disease, (3) mild obesity, (4) inheritance by males, (5) hyperplastic foci of pancreatic islets, and (6) renal complications (nodular lesions). The clinical and pathological features of disease in OLETF rats resemble those of human NIDDM. Administration of diazoxide (0.2% in diet), an inhibitor of insulin secretion, to OLETF rats from the age of 4 to 12 weeks completely prevented the development of obesity and insulin resistance (Aizawa et al. 1995). Ishida and coworkers (1995) found that insulin resistance preceded impaired insulin secretion in OLETF rats.

ESS-Rat

The occurrence of spontaneous diabetes in a colony of rats (Stilman Saldago), called eSS-rat was reported by Tarrés and coworkers (1981). The animals show abnormal glucose tolerance tests from the age of 2 months onwards. The syndrome consists of a mild type of diabetes that does not diminish the longevity of the animals. Six-months old rats show disruption of the islet architecture and fibrosis of the stroma (Dumm et al. 1990).

Obese SHR Rat

The strain of obese SHR rats was developed by Koletsky (1973, 1975) by mating a spontaneous hypertensive female rat of the Kyoto-Wistar strain with a normotensive Sprague Dawley male. After several generations of selective inbreeding, these obese SHR exhibited obesity, hypertension, and hyperlipidemia. In addition, some rats developed hyperglycemia and glucosuria associated with giant hyperplasia of pancreatic islets. From these rats, several substrains were developed, such as the JCR:LA-corpulent rat which exhibits a syndrome characterized by obesity, hypertriglyceridemia and hyperinsulinemia with impaired glucose tolerance (Russell et al. 1994). Reduced insulin receptor signaling was found in the obese spontaneously hypertensive Koletsky rat (Friedman et al. 1997).

SHR/N-cp Rat

The congenic SHR/N-cp rat strain, developed at the National Institutes of Health, USA, (Hansen 1983, Michaelis et al. 1986, Hansen 1988, Adamo et al. 1989) was derived by mating a male Koletsky rat heterozygous for the corpulent gene (cp/+) to a female rat of the Okamoto strain. After a minimum of 12 backcrosses, homozygous (cp/cp) SHR/N-cp rats exhibit obesity, mild hypertension, hyperinsulinemia, and glucose intolerance.

BHE Rat

The BHE rat colony was originally developed by breeding black and white hooded rats of the Pennsylvania State College strain and albino rats of the Yale (Osborne Mendell) strain. The BHE rat is a model in

which the diabetic state is manifested only at maturity. BHE rats have hyperinsulinemia at 50 days of age associated with glucose intolerance and tissue resistance to insulin. Later on, BHE rats have less hyperinsulinemia with reduced pancreatic insulin stores, and show mild hyperglycemia and hyperlipidemia.

LEW.1AR1/Ztm-iddm RAT

Lenzen et al. (2001), Jörns et al. (2004) described a Type I (insulin-dependent) diabetes mellitus rat model (LEW.1AR1/Ztm-*iddm*), which arose through a spontaneous mutation in a congenic Lewis rat strain with a defined MHC haplotype (RT1.Aa B/Du Cu). Diabetes appeared in the rats with an incidence of 20% without major sex preference at 58+/-2 days. The disease was characterised by hyperglycaemia, glycosuria, ketonuria and polyuria. In peripheral blood, the proportion of T lymphocytes was in the normal range expressing the RT6.1 differentiation antigen. Islets were heavily infiltrated with B and T lymphocytes, macrophages and NK cells with beta cells rapidly destroyed through apoptosis in areas of insulitis.

K.2.2 Spontaneously Diabetic Mice

KK Mouse

Nakamura (1962, 1967) reported on a diabetic strain of the KK-mouse. The animals were moderately obese and showed polyphagia and polyuria. Mice at the age of seven months or older showed glucosuria and blood sugar levels up to 320 mg%. The pancreatic insulin content was increased, but histologically degranulation of the β-cells and hypertrophy of the islets were found. Sections of the liver showed a reduction of glycogen and an increase in lipid content.

KK-A^y Mouse

Iwatsuka and coworkers (1970) reported on yellow KK mice (also named KK-A^y mice), carrying the yellow obese gene (A^y). These mice develop marked adiposity and diabetic symptoms in comparison with their littermates, black KK mice. Blood glucose and circulating insulin levels as well as HbA_{1c} levels were increased progressively from 5 weeks of age. Degranulation and glycogen infiltration of B cells were followed by hypertrophy and central cavitation of islets. Lipogenesis by liver and adipose tissue were increased. Insulin sensitivity of adipose tissue was more remarkably reduced than in black KK mice to its complete loss at 16 weeks of age. Renal involvement is uniquely marked by early onset and rapid development of glomerular basement membrane thickening (Diani et al. 1987).

KK-A^y mice can be used to demonstrate the extrapancreatic action of antidiabetic drugs, such as glimepiride, a novel sulfonylurea (Satoh et al. 1994). Sohda and coworkers (1990) evaluated ciglitazone and a series of 5-[4-(pyridylalkoxy)benzyl]-2,4-thiazolidinediones for hypoglycemic and hypolipemic activities in yellow KK mice. Hofmann and coworkers (1992) evaluated the expression of the liver glucose transporter GLUT2 and the activity and the expression of phosphoenolpyruvate carboxykinase in the liver of obese KKA^Y mice after treatment with the oral antidiabetic agent pioglitazone.

NOD Mouse

The NOD mouse strain was established by inbreeding diabetic CTS mice derived originally from the JCL-ICR strain. Like the BB rat, the NOD mouse is a model of insulin dependent diabetes mellitus and develops hypoinsulinemia secondary to autoimmune destruction of pancreatic β cells in association with insulitis and auto antibody production. Following insulitis, destruction of the insulin-producing pancreatic β cells ensues in many (but not all) mice, with physiologic manifestations of insulin depletion appearing between 3 and 7 months of age. The onset of diabetes can be prevented by an immunmodulating drug (Baeder et al. 1992) or by a soluble interleukin-1 receptor (Nicoletti et al. 1994). Hutchings and Cooke (1995) compared the protective effects afforded by intravenous administration of bovine or ovine insulin to young NOD mice. Bergerot and coworkers (1997) reported that feeding small amounts (2–20 µg) of human insulin conjugated to cholera toxin B subunit can effectively suppress β-cell destruction and clinical diabetes in adult NOD mice. Insulin-dependent diabetes mellitus in NOD Mice is the result of a $CD4^+$ and $CD8^+$ T cell-dependent auto-immune process directed against the pancreatic β-cells (Serreze and Leiter 1994, Verdaguer et al. 1997).

Elias et al. (1990) described induction and therapy of autoimmune diabetes in the non-obese diabetic (NOD/Lt) mouse by a 65-kDa heat shock protein.

Obese Hyperglycemic Mice

Ingalls and coworkers (1950), Mayer and coworkers (1951), Bleisch and coworkers (1952) observed hereditary diabetes in genetically obese mice. The obese hyperglycemic mice were glycosuric, the non-fasting blood sugar levels were about 300 mg%, but neither ketonuria nor coma were observed. One of the most interesting features was insulin-resistance; doses as high as 400 IU/kg had little effect on blood sugar. The serum insulin-like activity was high, the islands of Langerhans were hypertrophic, their insulin content was increased and the liver glycogen stores were decreased. Kidneys and other organs did not show pathological changes. Obviously, the diabetic condition of this and other strains of obese hyperglycemic mice is different from that of the human diabetic patient. The*ob* mutation was identified as a mutation in the leptin gene in adipose tissue (Zhang et al. 1994) and the substitution of leptin reverses the obese and diabetic phenotype completely (Halaas et al. 1995). Other strains or substrains of mice with obesity and hyper-

glycemia have been described by Dickie (1962), Westman (1968), Stein and coworkers (1970), Coleman and Hummel (1973), and Herberg and Coleman (1977). Gill and Yen (1991) studied the effect of ciglitazone on endogenous plasma islet amyloid polypeptide (amylin) and insulin sensitivity in obese-diabetic viable yellow mice (VY/Wfl-A^{vy}/a).

Diabetic db/db Mice

The diabetes *db/db* mouse strain is derived from an autosomal recessive mutation having occurred spontaneously in mice of the C57BL/KsJ strain which was identified as a mutation in the leptin receptor gene (Tartaglia et al. 1995). On this basis, the diabetes mouse (C57BL/6J *db/db*) consistently develops a severe diabetic syndrome similar to that found in the C57BL/KsJ *ob/ob* mouse, characterized by early onset of hyperinsulinemia, and hyperglycemia up to 20 to 25 mmol/l. (Hummel et al. 1966, Coleman and Hummel 1967, Like et al. 1972). The *db/db* mouse, in contrast to the *ob/ob* mouse, develops significant nephropathy (Gardner 1978). Mutations on the leptin receptor result in an obese phenotype identical to that of *ob* mice (Li et al. 1998). C57BL/KsJ *ob/ob* mice are phenotypically the same as other strains of *db* mice. The leptin receptor (Ob-R) gene encodes 5 alternatively spliced forms, Ob-Ra, Ob-Rb, Ob-Rc, Ob-Rd (Lee et al. 1996). In the *db/db* mouse strain, the Ob-Rb transcript contains an insert with a premature stop codon as a result if abnormal splicing (Chen et al. 1996, Friedman and Halaas 1998).

Coleman and Hummel (1969) joined adult diabetic mice (*db/db*) of the C57BL/Ks strain in parabiosis with normal mice of the same sex. Little, if any, amelioration of the disease was observed in parabiont diabetics and no symptoms of diabetes were observed in the normal parabiont. Instead, the normal partners lost weight, became hypoglycemic, and died of apparent starvation 50 days after surgery. In contrast, the diabetic partners gained weight rapidly and remained diabetic. Raizada and coworkers (1980) demonstrated a decrease of insulin receptors and impaired responses to insulin in fibroblastic cultures from the diabetic *db/db* mouse.

Diabetes Obesity Syndrome in CBA/Ca mice

A spontaneous maturity onset diabetes obesity syndrome occurs in a small proportion (10–20%) of male CBA/Ca mice. Inbreeding can increase the incidence to 80%. It occurs at 12–16 weeks of age, and is characterized by hyperphagia, obesity, hyperglycemia, hypertriglyceridemia, hyperinsulinemia, and an impaired glucose tolerance. The mice are also resistant to exogenous insulin. Female mice remain normal except for a slight increase in serum insulin. The male obese diabetic mice have a normal life expectancy.

Wellesley Mouse

The Wellesley mouse, described first by Jones (1964), is a hybrid with predisposition to diabetes mellitus. The diabetic animals have elevated levels of immunoreactive insulin in serum, enlarged pancreatic islets and reduced insulin responsiveness in peripheral tissues (Cahill et al. 1967, Gleason et al. 1967, Like and Jones 1967).

K.2.3 Chinese Hamster

Meier and Yerganian (1959, 1961) described the occurrence of hereditary diabetes mellitus in the Chinese hamster (*Cricetulus griseus*). Blood sugar levels of diabetic hamsters were elevated from a normal of 110 mg% up to 600 mg%. Severe polyuria, glucosuria, ketonuria, and proteinuria were observed. The diabetic condition could be improved by administration of insulin, and oral antidiabetic drugs were effective in mildly diabetic hamsters. Pathological changes were seen in histological sections of pancreas, liver and kidney. The number of pancreatic islets was decreased, and the cells of the remaining islets were abnormal. This animal model has been studied by several authors.

K.2.4 Other Species with Inherited Diabetic Symptoms

SAND Rat

The sand rat (*Psammomys obesus*) lives in the desert regions of North Africa and the Near East. In the laboratory the animals develop diabetic symptoms when fed Purina laboratory chow instead of an all vegetable diet (Hackel et al. 1965 and 1967, Miki et al. 1967, deFronzo et al. 1967, Brodoff et al. 1967, Strasser 1968). The diabetic syndrome in the sand rat usually develops within 2–3 months with variations in severity between the animals. Severely hyperglycemic animals die prematurely from ketosis. Initially, the pancreatic islets appear normal. In the intermediate stage of the disease, degranulation of pancreatic β cells is observed. This is followed by β cell degeneration and necrosis with resultant insulinopenia and ketonuria. Histological studies by Dubault and coworkers (1995) showed insulitis in animals who became insulin-dependent in later stages and recommended *Psammomys obesus* as a model of latent progression to insulin-deficiency in type 2 diabetes patients.

Spiny Mouse

The spiny mouse (*Acomys cahirinus*) is a small rodent living in the semi-desert areas of the Eastern Mediterranean (Pictet et al. 1967). Diabetes occurs in about 15% of the animals under laboratory conditions accompanied by hyperplasia of the endocrine pancreas. Great variations in the appearance and severity of diabetes and obesity occur in this species. Some animals show obesity, mild hyperglycemia, and hyperinsulinemia. Others have frank hyperglycemia with glucosuria that leads to fatal ketosis. Regardless of the stage of the disease, all spiny mice characteristically have massive hyperplasia of pancreatic islets and increased pancreatic insulin content. Despite the large insulin stores, plasma insulin response to glucose is delayed or impaired suggesting an impairment of the insulin release mechanism.

African Hamster (Mystromys albicaudatus)

Spontaneous diabetes mellitus was described in South African hamsters (*Mystromys albicaudatus*) by Packer and coworkers (1970), Stuhlman and coworkers (1972, 1974, 1975), Schmidt and coworkers (1974). Characteristics established as part of the diabetic syndrome in this species include hyperglycemia, glucosuria, ketonuria, polyuria, polyphagia and polydipsia. Pancreatic lesions include β-cell vacuolization, glycogen infiltration, nuclear pycnosis, margination of organelles, and β-cell death.

Tuco-Tuco

The diabetic syndrome in Tuco-tucos (*Ctenomis talarum*) is similar to that in sand rats and spiny mice (Wise et al. 1972). However, Tuco-tucos tend to have less hyperglycemia and are less prone to ketosis. Many animals, mainly males, become hyperphagic and quite obese. Degranulation of β cell is the usual lesion in the pancreas, but amyloid hyalinization of islets has been observed in a few animals.

Macaca Nigra

A high incidence of spontaneous diabetes mellitus was found in *Macaca nigra* (Celebes black apes) with analogies to human diabetes (Howard 1972, 1974a, b, 1975). Abnormal signs include hyperglycemia, decreased clearance of glucose, in intravenous tolerance tests, reduced insulin secretion and increased serum lipids. Insulin secretory capacity is lost concomitant with amyloid infiltration into the islets of Langerhans. Secondary manifestations are atherosclerosis, thickened basement membranes of muscle capillaries, and cataracts. The genetic predisposition in these monkeys is exacerbated by changes in diet and environment.

K.2.5 Transgenic Animals and Knockout Mice

GENERAL CONSIDERATIONS

Insulin exerts its diverse biological effects by binding to and activating the membrane-bound insulin receptor (IR), thereby initiating the insulin signal transduction cascade (see K.6.3 and K.6.3.2). IRs are not only present in the classical insulin target tissues, i. e., adipose tissue, skeletal muscle, and liver, but are also widely expressed throughout the organism in tissues such as pancreas, the central nervous system (CNS), lymphatic cells, and kidney. Signals initiated by the activated IR result in the diverse biological effects of insulin, such as the stimulation of glucose transport, the inhibition of gluconeogenesis, the stimulation of protein and lipid synthesis, and the regulation of gene transcription. Because the roles of many components of the signaling pathway were initially characterized *in vitro*, more recent research has focused on the analysis of insulin action *in vivo* by generating mice with targeted disruption of genes for these components. Since the pattern of inheritance of type II diabetes points to a disease of polygenic nature, not only single gene-deficient mice but also models with combined genetic

disruptions have been created in an attempt to represent the polygenic nature of the disease.

Realization that metabolic diseases do not only involve many genes but also many organs necessitated engineering the mouse genome with spatial and temporal controls. This requires the generation of premutant mice whereby the alleles of interest is flanked by recognition sites for DNA recombinases such as Cre (loxP sites) or Flp (Frt sites; Branda and Dymecki 2004). When such premutant mice are bred with transgenic mice that express the corresponding DNA recombinase in a tissue-specific fashion, the gene of interest is inactivated only in that particular tissue. An added sophistication of spatially controlled mutagenesis is the inclusion of temporal control, which is achieved by using ligand-activated chimeric recombinases composed of fusion of the recombinase with the ligand binding domain of a nuclear receptor (Metzger and Chambon 2001). Employing spatially and temporally controlled mutagenesis revealed that metabolic perturbation in one tissue encroaches on the metabolism of another. This tissue communication and crosstalk allows for metabolic flexibility, with respect to the use or production of metabolic fuel. Understanding this may ultimately reveal the genetic determinants that limit the degree of metabolic flexibility, thus promoting metabolic diseases in humans (Bickel 2004).

The first knockout models of insulin resistance aimed at the disruption of major molecules in IR signaling in each tissue. The successful generation of viable, heterozygous IR knockout mice showed that 50% of IR expression is sufficient for the maintenance of physiological blood glucose concentrations. In contrast, homozygous IR-deficient mice rapidly develop diabetic ketoacidosis and die within 3–7 days after birth (Accili et al. 1996, Joshi et al. 1996), showing the indispensability of IR for the control of glucose metabolism. The new techniques for conditional gene inactivation in mice are particularly helpful if conventional knockout of a gene results in embryonic lethality, preventing the analysis of gene function in the adult. Conditional mutagenesis enables the inactivation of a gene of interest in a specific tissue or in a temporally controlled manner, thereby providing new insights into the contribution of a gene to a complex physiological phenotype such as insulin resistance.

Skeletal Muscle and Insulin Resistance

Because insulin resistance in skeletal muscle is one of the earliest detectable defects in type II diabetic patients, muscle-specific insulin receptor knockout (MIRKO) mice have been generated as a model for muscle-specific insulin resistance. MIRKO mice displayed elevated fat mass, serum triglycerides, and free fatty acids, indicating that insulin resistance in muscle contributes to the altered fat metabolism associated with type II diabetes (Brüning et al. 1998). Additionally, Kim and coworkers (2001) demonstrated that IR deficiency in muscle promotes redistribution of substrates to adipose tissue, thereby contributing to increased adiposity in MIRKO mice. Surprisingly, blood glucose, serum insulin, and glucose tolerance were normal in these mice, initially leading to the interpretation that tissues other than muscle are more essential for insulin-regulated glucose disposal than previously assumed. However, Zisman and coworkers (2000) disrupted the gene for the glucose transporter 4 (GLUT4), which mediates glucose transport in response to insulin, selectively in mouse muscle tissue. They found that Glut4-mediated glucose uptake in muscle was indeed essential for the maintenance of normal glucose homeostasis. Consistently, mice with a combined muscle-specific functional inactivation of IR and the closely related insulin-like growth factor receptor (IGF-1R) also display a complete type II diabetic phenotype, implicating a compensatory role of IGF-1R for mediating insulin's stimulation of glucose transport *via* Glut4 in muscle (Fernandez et al. 2001).

Adipose Tissue and Insulin Resistance

The strong association between the world-wide epidemic of obesity and dramatically increasing prevalence of insulin resistance and type II diabetes has prompted recent research to focus on the mechanisms linking adipose tissue to whole body insulin sensitivity, β-cell function, and overall glucose metabolism. Newborn mice with IR deficiency show a marked reduction in white adipose tissue mass, pointing to a role for IR in the regulation of adipocyte growth and differentiation (Accili et al. 1996). Mice with an adipose tissue-specific knockout of the IR (FIRKO) also display a reduced fat mass, loss of the normal correlation of plasma leptin and body weight, and protection against both obesity and obesity-related glucose intolerance. Interestingly, they also exhibit an 18% extended lifespan (Bluher et al. 2003). Strikingly, whereas adipocytes of control mice exhibit a bell-shaped size distribution, adipocytes of FIRKO mice demerge into groups of small and large cells. Interestingly, these differently sized cells also show different expression of fatty acid synthase and the transcription factors CCAAT enhancer binding protein (C/EBP)-α as well as sterol regulatory element-binding protein 1 (SREBP1). Thus inactivation of the IR revealed a pre-

viously unrecognized heterogeneity of adipose tissue. Consistent with the phenotype of GLUT4-null mice, which display a depletion of fat stores (Katz et al. 1995), the selective disruption of GLUT4 in adipose tissue caused an impaired glucose transport, followed by development of insulin resistance. The role of adipose tissue in muscle-specific IR deficiency was addressed in mice with a targeted inactivation of IR-mediated signaling in both muscle and adipose tissue (Lauro et al. 1998). These mice did not become diabetic despite peripheral insulin resistance and a mild impairment of β-cell function. Together, these data suggest that there may be a critical threshold in whole body insulin resistance that finally leads to a diabetic phenotype. Moreover, this insulin resistance might result in excessive demands on the pancreatic β-cells to secrete insulin, leading to consecutive decompensation of these cells. These data clearly assign adipocytes an important role in lipid storage, development of obesity, and regulation of glucose homeostasis.

Role of the β-Cell in Impaired Glucose Tolerance

Mice with a specific disruption of the IR gene in β-cells show a selective loss of insulin secretion in response to glucose and a progressive impairment of glucose tolerance (Kulkarni et al. 1999), indicating that insulin stimulates its own secretion via IRs on β-cells, thus playing an important functional role in glucose sensing by the pancreatic β-cell. Therefore, defects in insulin signaling at the level of the β-cell may contribute to the observed alterations in insulin secretion in type 2 diabetes. Interestingly, a β-cell-specific IGF-1R knockout model also underscored a role for this receptor in the control of glucose-stimulated insulin secretion and glucose tolerance (Kulkarni et al. 2002). The interplay between insulin resistance and insulin secretory defects has also been addressed by the generation of mice deficient for insulin receptor substrate 1 (IRS-1) and β-cell glucokinase (GK). The heterozygous β-cell GK knockout is characterized by decreased insulin secretion in response to glucose, whereas IRS-1-deficient mice are insulin resistant but do not develop overt diabetes (Abe et al. 1998). In contrast to either individual mutation, the double-knockout mice developed a diabetic phenotype (Terauchi et al. 1997), demonstrating that the combination of individual minor defects in insulin action or insulin secretion can cause overt diabetes.

Insulin Resistance in the Brain

The liver-specific insulin receptor knockout (LIRKO) mouse, as expected, exhibits a dramatic phenotype with severe insulin resistance and progressive liver failure (Michael et al. 2000), mirroring the critical role of insulin signaling in liver for regulating glucose homeostasis and maintaining normal hepatic function. However, IRs and insulin-signaling proteins are not exclusively expressed in classic insulin target tissues; they are also widely distributed throughout the CNS. CNS-specific disruption of the IR gene (NIRKO) revealed an important role of IRs in the regulation of energy disposal, fuel metabolism, and reproduction (Brüning et al. 2000). It has very recently been shown in conventional IR-deficient mice that combined restoration of IR function selectively in brain, liver, and pancreatic β-cells rescues these mice from neonatal death, prevents diabetes in a majority of animals, and restores adipose tissue content, lifespan, and reproductive function. Interestingly, IR substitution either limited to brain or liver and pancreatic β-cells was sufficient to prevent neonatal death but not lipatrophic diabetes, leading to the surprising finding that IR signaling in nontypical insulin target tissues like the brain seems to be crucial to maintain fuel homeostasis and prevent diabetes.

Inactivation of IRS Proteins

Aside from IR knockouts, various molecules of the signal transduction pathway initiated by IR have been disrupted, such as IRS-1, which was believed to be the principal substrate for the IR and IGF-1R. Mice deficient for IRS-1 exhibit impaired glucose tolerance and a decrease in insulin/IGF-1-stimulated glucose uptake *in vivo* and *in vitro*, thereby providing a mouse model of genetically determined insulin resistance (Abe et al. 1998, Jenkins and Storlien 1997). Additionally, elevated blood pressure and plasma triglyceride levels were observed, as well as impaired endothelium-dependent vascular relaxation, indicating that insulin resistance plays an important role in the clustering of coronary risk factors leading to accelerated atherosclerosis. The residual insulin/IGF-1 action in IRS-1-deficient mice correlated with the existence of an alternative tyrosine-phosphorylated protein (IRS-2) (Araki et al. 1994), which is also capable of activating the signaling cascade. Surprisingly, disruption of IRS-2 impaired peripheral insulin signaling and pancreatic β-cell function, resulting in progressive deterioration of glucose homeostasis (Withers et al. 1998). This phenotype results from insulin resistance in liver and skeletal muscle and β-cell dysfunction. Succeeding studies indicated tissue-specific functions for IRS-1 and IRS-2 in mediating the metabolic effects of insulin *in vivo*, IRS-1 having a major role in skeletal

muscle and IRS-2 in liver, muscle, adipose tissue, pancreatic β-cells, and reproductive tissue. Interestingly, mice with a double knockout of IRS-1 and the subsequently identified IRS-3 (Lavan et al. 1997) displayed a phenotype of early-onset severe lipatrophy associated with hyperglycemia, hyperinsulinemia, and decreased plasma levels of the anorexigenic hormone leptin. The IRS-1/IRS-3 double-knockout phenotype in mice (Lausten et al. 2002) might mimic the situation in humans better than the single IRS-1 knockout.

The concept that several subclinical genetic alterations in insulin action can synergize to result in overt diabetes was tested in mice double heterozygous for IR and IRS-1 alleles with a ~50% reduction in expression of either protein (Brüning et al. 1997). In these mice, the combined genetic defects led to aggravation of insulin resistance with 5- to 50-fold elevated plasma insulin levels and respective β-cell hyperplasia, and ~ 40% of the animals developed overt diabetes at the age of 4–6 mo. This mouse model of type II diabetes, in which diabetes arises in an age-dependent manner from the interaction between two genetically determined, subclinical defects in the insulin-signaling cascade, demonstrates the important role of epistatic interactions in the pathogenesis of common diseases with non-Mendelian genetics. Moreover, this model has been used successfully to identify further modifying C57BL/6 loci regulating insulin sensitivity (Almind et al. 2003).

Inactivation of PPARs

It has been shown that the abnormal accumulation of lipids in tissues other than adipose adversely affects insulin sensitivity, indicating a complex system for the comprehensive control of lipid and glucose homeostasis. The key coordinators in this metabolic axis are members of the nuclear hormone receptor superfamily. Among those, PPARs (see K.6.4.4) respond to small lipid agents, e. g., dietary fatty acids, and contribute a key mechanism in the regulation of lipid and glucose metabolism (reviewed by Rangwala and Lazar 2004). The important physiological role of the PPARs, i. e., PPAR-α,-β/δ and -γ, was deduced from findings identifying the PPARs as primary targets of two key classes of synthetic compounds that have been used in the successful treatment of diabetes and dyslipidemia. In particular, thiazolidinedione (TZD) insulin sensitizers are potent and specific PPAR-γ ligands and activators. Fibrates have predominant activity as PPAR-α agonists, favorably affecting serum lipid levels. Diverse knockout models have been created to study the function of the single PPAR isoforms *in vivo*.

Consistent with the concept that PPAR-α is the member of the PPAR family that mediates cellular lipid utilization, pharmacological inhibition of cellular fatty acid flux in mice lacking PPAR-α caused massive hepatic and cardiac lipid accumulation, hypoglycemia, and death in 100% of male and 25% of female animals, demonstrating a pivotal role for PPAR-α in lipid and glucose homeostasis *in vivo*. Nevertheless, there was no major phenotypic defect detectable in PPAR-α knockouts without pharmacological challenge (Djouadi et al. 1998). Muoio and coworkers (2002) showed that skeletal muscle of PPAR-α-deficient mice exhibited only minor changes in fatty acid homeostasis, and even mRNA expression of known PPAR-α target genes in muscle tissue was not significantly affected. They proposed that this finding might be explained by high levels of PPAR-β/δ compensating for the lack of PPAR-α, suggesting redundancy in the functions of PPARs as transcriptional regulators of fatty acid homeostasis.

In contrast to the embryonic lethality of homozygous PPAR-γ knockouts (Barak et al. 1999), mice deficient only for the PPAR-γ2 isoform survived, exhibiting an overall reduction in white adipose tissue, less lipid accumulation, and decreased expression of adipogenic genes in adipose tissue (Zhang et al. 2004). Consistently, embryonic fibroblasts of PPAR-γ2 knockouts showed a dramatically reduced capacity for adipogenesis *in vitro*. In addition, insulin sensitivity was impaired in these mice, with decreased expression of IRS-1 and Glut4 in skeletal muscle, but TZDs were able to normalize this insulin resistance (Zhang et al. 2004). In contrast, heterozygous PPAR-γ knockouts show reduced disposition to insulin resistance. Strikingly, this phenotype is blunted by treatment with a synthetic PPAR-γ ligand of the TSD class, indicating that optimal levels of PPAR-γ activity are crucial for its beneficial effects. To address these obvious incongruities, PPAR-γ has been selectively disrupted in liver, adipose tissue, and muscle. Briefly, although adipose tissue appears to be the main site of TZD action, the conditional knockouts highlight important functions for muscle and liver PPAR-γ in the control of body composition and insulin sensitivity. PPAR-γ deficiency in adipose tissue leads to progressive loss of fat, hyperlipidemia, fatty liver, and accompanying hepatic insulin resistance (He et al. 2003). The mice can maintain normal whole body glucose homeostasis and normal insulin sensitivity only as long as some adipose tissue is present. These studies identify a molecular link between blood glucose homeostasis and lipid metabolism, providing a genetic basis for the observed

phenotypic correlation between obesity and type II diabetes mellitus.

Transgenic Animal Model for Type I Diabetes

Aichele and coworkers (1994) used a synthetic peptide corresponding to an immunodominant epitope of lymphocytic choriomeningitis virus glycoprotein (LCMV GP) to prime or to tolerize $CD8^+$ T cells *in vivo*. Peptide-specific tolerance was then examined in transgenic mice expressing LCMV GP in the β islet cells of the pancreas. These mice developed $CD8^+$ T cell-mediated diabetes within 8–14 days after LCMV infection. Specific peptide-induced tolerance prevented autoimmune destruction of β islet cells and diabetes in this transgenic mouse model.Oldstone and coworkers (1991) showed that virus infection triggers insulin-dependent diabetes mellitus in a transgenic mouse model. Ablation of tolerance and induction of diabetes by virus infection in viral antigen transgenic mice was reported by Ohashi and coworkers (1991). Von Herrath and coworkers (1994) investigated how virus induces a rapid or slow onset insulin-dependent diabetes mellitus in two distinct transgenic mouse models. Von Herrath and coworkers (1995) evaluated the role of the costimulatory molecule B7-1 in overcoming peripheral ignorance in transgenic mice which expressed the glycoprotein or nucleoprotein of lymphocytic choriomeningitis virus as the self-antigen in pancreatic β-cells. Von Herrath and Holz (1997) reported that pathological changes in the islet milieu precede infiltration of islets and destruction in β-cells by autoreactive lymphocytes in a transgenic model of virus-induced IDDM. RIP-LCMV transgenic mice that express the viral glycoprotein or nucleoprotein from lymphocytic choriomeningitis virus (LCMV) under control of the rat insulin promoter (RIP) in pancreatic β-cells develop autoimmune diabetes after infection with LCMV. Upregulation of MHC class II molecules associated with the attraction/activation of antigen presenting cells to the islets occurs as soon as 2 days after LCMV inoculation of transgenic mice, clearly before $CD4^+$ and $CD8^+$ lymphocytes are found entering the cells. Possibilities of treatment of virus-induced autoimmune diabetes were discussed (von Herrath et al. 1997). Moritani and coworkers (1996) reported the prevention of adoptively transferred diabetes in nonobese diabetic mice with IL-10-transduced islet-specific Th1 lymphocytes as a gene therapy model for autoimmune diabetes. Birk and coworkers (1996) generated transgenic NOD mice carrying a murine Hsp60 transgene driven by the $H°2E_\alpha$ class II promoter in order to examine the hypothesis of a pathogenic role for self-reactive cells against the stress protein Hsp60 in autoimmune destruction of pancreatic cells in the diabetes of NOD mice.

Future Developments

The employment of even more sophisticated strategies in conditional gene targeting may overcome these limitations in the future. Conditional inactivation of genes is mainly achieved by the Cre-loxP system (Lewandoski 2001). Moller (1994) and Plum and coworkers (2005) recently summarized our current knowledge about the use of knockout and transgenic animal models in diabetes research. Animal models of insulin resistance has recently been reviewed by Nandi and coworkers (2004).

K.2.6 Metabolic Systems Biology

With the completion of the many genomes, genetics is positioned to meet physiology. Argmann and coworkers (2005) predicted the coming of "systems metabolism" in mammals through the use of the mouse, as a model system to study metabolism. Building on mouse genetics with increasingly sophisticated clinical and molecular phenotyping strategies has enabled scientists to now tackle complex biomedical questions, such as those related to the pathogenesis of the common metabolic disorders. The ultimate goal of such strategies will be to mimic human metabolism with the click of a mouse.

Techniques in mouse genetics and phenomics have rapidly evolved over the past decade, which with the renaissance of integrative physiology positioned scientists well for the emergence of the discipline, systems biology. Such systems biology approaches hold great promise in the area of metabolism. The efficient conversion of metabolic parts to metabolic systems will depend on the integration of discovery-based and hypothesis-driven phenogenomic approaches, which rely on the study of mouse models derived from both reverse- and forward genetic strategies. A stable marriage of *in silico* with wet biology that allows for reiterative testing of the computationally identified networks will be crucial for the success of systems biology approaches. Such integrated approaches will become indispensable future resources for drug target identification as well as drug discovery and evaluation. It is expected that such insight into complex metabolic networks will ultimately translate into better therapeutic strategies for metabolic diseases.

K.3
Measurement of Blood Glucose-Lowering and Antidiabetic Activity

K.3.1
Hypoglycemic Effects

K.3.1.1
Blood Glucose-Lowering Effect in Rabbits

PURPOSE AND RATIONALE

The rabbit has been used since many years for standardization of insulin (see K.4.1). Therefore, it has been chosen as primary screening model for screening of blood glucose lowering compounds as well as for establishing time-response curves and relative activities (Bänder et al. 1969, Geisen 1988).

PROCEDURE

Groups of 4–5 mixed breed rabbits (e. g. Hoe:BASK, SPFWiga) of either sex weighing 3.0–4.5 kg are used. For insulin evaluation, food is withheld overnight. For evaluation of sulfonylureas and other blood glucose lowering agents the animals are on a normal diet (e. g. Era mixed feed 8300) prior to the experiment. The animals are gently placed into special restraining boxes allowing free access to the rabbit's ears.

Oral blood glucose lowering substances are applied by gavage in 1 ml/kg of 0.4% starch suspension or intravenously in solution. Several doses are given to different groups. One control group receives the vehicle only. By puncture of the ear veins, blood is withdrawn immediately before and 1, 2, 3, 4, 5, 24, 48, and 72 h after treatment. For time-response curves values are also measured after 8, 12, 16, and 20 h. Blood glucose is determined in 10 µl blood samples with the hexokinase enzyme method (Glucoquant test kit).

Evaluation

Average blood sugar values are plotted versus time for each dosage. Besides the original values, percentage data related to the value before the experiment are calculated. Mean effects at a time interval are calculated using the trapezoidal rule. The values of the experimental group are compared statistically with the *t*-test or the WILCOXON test for each time interval with those of the control group. Differences between several treated groups and the control group are tested using a simultaneous comparison according to Dunnett or Nemenyi/Dunnett. Dose dependencies and relative activities are determined by means of linear regression analysis after Fieller (1944) and Sidak (1967). All data

for statistical comparisons have to be tested for homogeneity of variances according to Levene (1960) and for normal distribution according to Shapiro and Wilk (1965). In the case of regression analyses, the lines are additionally tested for parallelism according to Tuckey (1966) and for linearity according to Scheffé (1959). The level of significance for all procedures is chosen as 5%.

MODIFICATIONS OF THE METHOD

For special purposes the effect of blood sugar lowering agents is studied in glucose loaded animals. Rabbits of either sex weighing 3.0–4.5 kg are treated either once (0.5 h after test compound) or twice (0.5 and 2.5 h after test compound) orally with 2 g glucose/kg body weight in 50% solution.

A biological assay of insulin preparations in comparison with a stable standard using the blood sugar lowering effect in rabbits has been proposed by Harrison and coworkers (1925).

The biological assay of insulin using the blood sugar lowering effect in rabbits has been until recently the official assay in several pharmacopoeias, such as European Pharmacopoeia, 2nd edn 1980; Deutsches Arzneibuch 1986; British Pharmacopoeia 1988; United States Pharmacopoeia 23 and The National Formulary 18, 1995.

The rabbit blood glucose bioassay as well as the mouse convulsion assay and the mouse glucose assay were used for establishing international standards for highly purified human, porcine and bovine insulins (Bristow et al. 1988).

In several pharmacopoeias, the biological assays have been replaced by chemical methods (British Pharmacopoeia 1999; European Pharmacopoeia, 3rd edn 1997; but the rabbit blood sugar method is still valid in the United States Pharmacopeia USP 24, 2000.

PROCEDURE

Four groups of at least 6 randomly distributed rabbits weighing at least 1.8 kg are kept in the laboratory and maintained on a uniform diet for not less than one week before use in the assay. About 24 h before the test each rabbit is provided with an amount of food that will be consumed within 6 h. The same feeding schedule is followed before each test day. During the test all food and water is withheld until the final blood sample has been taken. The rabbits are placed into comfortable restraining cages to avoid undue excitement.

Immediately before use two solutions of the standard preparation are made, containing 1 unit and 2 units of insulin per ml, respectively, and two dilutions of the preparation being examined which, if the assumption of potency is correct, contain amounts of insulin equivalent to those in the dilutions of the standard preparation. As diluent, a solution is used of 0.1–0.25% w/v of either m-cresol or phenol and 1.4 to 1.8 w/v of glycerol being acidified with hydrochloric acid to a pH between 2.5 and 3.5.

Each of the prepared solutions is injected subcutaneously to one group of rabbits, using the same volume, which should usually be between 0.3 and 0.5 ml for each rabbit, the injections being carried out according to a randomized block design. Preferably on the following day, but in any case not more than 1 week later, each solution is administered to a second group of rabbits following a twin crossover design. One hour and 2.5 h after each injection a suitable blood sample is taken from the ear vein of each rabbit. Blood sugar is determined by a suitable method, preferably using glucose oxidase.

EVALUATION

The results of the assay are calculated by standard analytical methods (e. g., USP 23, 1995).

CRITICAL ASSESSMENT OF THE METHOD

The classical bioassay based on blood-sugar lowering activity in rabbits has been replaced by chemical methods in some pharmacopoeias (Underhill et al. 1994), but is still included in USP 24 (2000) and will be still necessary for evaluation of synthetic insulin derivatives.

MODIFICATIONS OF THE METHOD II

An assay of insulin activity after intraperitoneal injection in rats has been described by Rafaelsen and coworkers (1965) and Young (1967). Shults and coworkers (1994) reported as one of the first on an implantable potentiostat-radiotelemetry system for *in vivo* sensing of glucose, implanted into the paravertebral thoracic subcutaneous tissue of a dog. An enzyme electrode sensor measures the oxidation current of hydrogen peroxide formed by the stoichiometric conversion of the substrate glucose and oxygen as a cofactor in an immobilized glucose oxidase layer. Salehi and coworkers (1996) described the development of a compact, low power, implantable system for *in vivo* monitoring of oxygen and glucose concentrations.

K.3.1.2 Blood Glucose-Lowering Effect in Rats

PURPOSE AND RATIONALE

Rats are used for screening as well as for quantitative evaluation of blood glucose lowering agents.

PROCEDURE

Male Wistar rats (e. g. Hoe:WISKf, SPF 71) weighing 180–240 g are kept on standard diet (e. g. Altromin 1324). Groups of 4–7 non-fasted animals are treated orally or intraperitoneally with various doses of the test compounds suspended in 0.4% starch suspension. One control group receives the vehicle only. Blood is withdrawn from the tip of the tail immediately before, and 1, 2, 3, 5, and 24 h after administration of the test compound. Blood glucose is determined in 10 µl blood samples with the hexokinase enzyme method (Glucoquant test kit).

EVALUATION

Average blood sugar values are plotted versus time for each dosage. Besides the original values, percentage data related to the value before the experiment are calculated. Mean effects over a time period are calculated using the trapezoidal rule. Statistical evaluation is performed as described for tests in rabbits.

MODIFICATIONS OF THE METHOD

Studies in Glucose-Loaded Rats

For special purposes the effect of blood sugar lowering agents is studied in glucose loaded animals. One g glucose/kg body weight is given in a 50% solution either orally 5 min after oral administration or subcutaneously 5 min after intraperitoneal administration of the test compound.

Studies in Streptozotocin-Diabetic Rats

Male Wistar rats (e. g. Hoe:WISKf, SPF 71 strain) weighing 170–220 g are kept on standard diet (e. g. Altromin 1324). Ten–fourteen days prior to the study they are injected with 60 mg/kg streptozotocin (Calbiochem) intravenously. Blood sugar levels rise from 5.5–6.0 mmol/l up to 25.0–28.0 mmol/l and glucosuria occurs. Plasma insulin levels fall below 4 µU/ml. Compounds which release insulin from pancreatic islets as sole hypoglycemic activity are not effective in rats with severe streptozotocin induced diabetes.

K.3.1.3 Blood Glucose-Lowering Effect in Mice

PURPOSE AND RATIONALE

Eneroth and Ahlund (1968, 1970a and b) recommended a twin crossover method for bioassay of insulin using blood glucose levels in mice instead of hypoglycemic seizures giving more precise results. This test was induced into the British Pharmacopoeia 1980 and continued up to 1988. Moreover, the test is included as alternative in the European Pharmacopoeia, 2nd edn 1980; and in Deutsches Arzneibuch, 9. Ausgabe, 1986.

PROCEDURE

Non-fasting mice of the same strain and sex are used having body masses such that the difference between the heaviest and lightest mouse is not more than 2 g. The mice are assigned at random to four equal groups of not less than 10 animals. Two dilutions of a solution of the substance or of the preparation to be examined and 2 dilutions of the reference solution are prepared using as diluent 0.9% NaCl solution adjusted to pH 2.5 with 0.1 N hydrochloric acid and containing a suitable protein carrier. In a preliminary experiment, concentrations of 0.02 IU and 0.10 IU are tested. Each of the prepared solutions (0.1 ml/10 g body weight) is injected subcutaneously to one group of mice according to a randomized block design. Not less than 2.5 h later, each solution is administered to a second group of mice following a twin crossover design. Exactly 30 min after each injection, a sample of 50 µl of blood is taken from the orbital venous sinus of each mouse. Blood glucose concentration is determined by a suitable method, such as described by Hoffman (1937).

EVALUATION

The potency is calculated by the usual statistical methods for the twin-cross-over assay.

K.3.1.4 Blood Glucose-Lowering Effect in Dogs

PURPOSE AND RATIONALE

Besides experiments in rats and rabbits studies in dogs are necessary to predict the effect of a new compound in man due to differences in species related metabolism.

PROCEDURE

Male Beagle dogs weighing 15–20 kg are kept on standard diet (e. g. Erka mixed feed 8500). Food is withdrawn 18 h prior to the administration of the test compound which is given either orally or intravenously in various doses. Control animals receive the vehicle only. Blood is collected at different time intervals up to 48 h. Blood glucose is determined with the hexokinase enzyme method (Glucoquant test kit) and plasma insulin with an immunological method (Riagnost-kit).

EVALUATION

Average blood sugar values are plotted versus time for each dosage. Besides the original values, percentage data related to the value before the experiment are calculated. Mean effects over a time period are calculated using the trapezoidal rule. Similarly, plasma insulin levels are plotted versus time and compared with control values. Statistical evaluation is performed as described for tests in rabbits.

MODIFICATIONS OF THE METHOD

Studies in Pancreatectomized Dogs

The surgical technique of pancreatectomy in dogs is described in Sect. K.1.0.1. The animals are pancreatectomized up to 2–3 years prior to the study. They are kept on dry feed (Vipromix) together with 2–3 g pancreatic enzymes (Viveral). Insulin is substituted with a single daily subcutaneous dose of 32 IU Insulin Ultratard HM. For substitution of vitamin D an intramuscular dose of 1 ml Vigantol is given every 3 months.

On the day before the study, the animals receive 32 IU of the shorter acting Basal-H insulin. This insulin is administered at the same time when food and test compound are given in the morning. The test drug

is applied as oral suspension in tap water. Blood glucose is determined before and up to 6 h after treatment in hourly intervals. Control animals receive tap water only.

Studies in Alloxan-Diabetic Dogs

Chemical diabetes can be induced by a single intravenous dose of 60 mg/kg alloxan. Afterwards, the animals receive infusions of 1000 ml 5% glucose together with 10 IU Regular Insulin via a jugular vein catheter daily during one week and canned food ad libitum. Thereafter, a single dose of 28 IU Insulin Ultratard HM is given daily and the animals are fed commercial diet (Altromin pellets). On the day before the study, the dogs receive 28 IU of the shorter acting Basal-H insulin. This insulin is given at the same time as food and test compound in the morning. The test drug is applied as oral suspension in tap water. Blood glucose is determined before and up to 6 h after treatment in hourly intervals. Control animals receive tap water only.

Continuous Blood Glucose Monitoring

A device for continuous blood glucose monitoring and infusion in freely mobile dogs was described by Geisen and coworkers (1981, 1988) and Bänder and coworkers (1969).

K.3.1.5 Blood Glucose-Lowering Effect in Other Species

Instead of rats male guinea pigs (e. g., Pirbright white, Hoe:DHPK, SPF Lac) weighing 250–380 g can be used. Blood is withdrawn by puncture of ear veins before, and 1, 3, and 5 h after administration of the test compound or the vehicle. Blood sugar determinations and statistical evaluations are performed as described for rabbits and rats.

Genetically obese and diabetic yellow KK mice have been used by Sohda and coworkers (1990) for evaluation of hypoglycemic activity of potential antidiabetic drugs. Gill and Yen (1991) studied the effect of ciglitazone in obese-diabetic viable yellow mice (VY/Wfl-A^{vy}/a).

K.3.2 Euglycemic Clamp Technique

PURPOSE AND RATIONALE

The euglycemic glucose clamp technique has provided a useful method of quantifying *in vivo* insulin sensitivity in humans (DeFronzo et al. 1979). In this technique a variable glucose infusion is delivered to maintain euglycemia during insulin infusion. Whole-body tissue sensitivity to insulin, as determined by net glucose uptake, can be quantitated under conditions of near steady state glucose and insulin levels. Kraegen and coworkers (1983, 1985) developed the euglycemic glucose clamp technique for use in the intact conscious rat.

PROCEDURE

Male Wistar rats weighing 150–200 g are fasted overnight and anesthetized with pentobarbital (40 mg/kg, i.p.). Catheters are inserted into a jugular vein and a femoral vein for blood collections and insulin and glucose infusion, respectively. To evaluate the insulin action under physiological hyperinsulinemia (steady state plasma insulin concentration during the clamp test around 100 µU/dl), and maximal hyperinsulinemia (under which maximal insulin action may appear) two insulin infusion rates, 6 and 30 mU/kg/min, are used. The blood glucose concentrations are determined from samples collected at 5-min intervals during the 90-min clamp test. The glucose infusion rate is adjusted so as to maintain the blood glucose at its basal level during the clamp test. The final glucose infusion rate is calculated from the amount of glucose infused for the last 30 min (from 60 to 90 min after start of the clamp) in which the blood glucose levels are in a steady state. The glucose metabolic clearance rate is obtained by dividing the glucose infusion rate by the steady state blood glucose concentration. The steady state plasma insulin concentration is calculated from the insulin concentrations at 60 and 90 min after the start of the

clamp. At the start and end of the euglycemic clamp test, free fatty acid concentration is also determined and the free fatty acid suppression rate is calculated.

EVALUATION

All values are analyzed by one-way ANOVA. When the steady state plasma insulin is maintained at submaximal concentration by the euglycemic clamp technique, the glucose infusion rate and glucose metabolic clearance rate value are considered to reflect the state of receptor binding levels in the peripheral tissue as an index for insulin sensitivity. Under maximal hyperinsulinemia these values are thought to reflect the state of the enzymes and glucose transport system activated after the binding to receptors, indicating mainly insulin responsiveness.

MODIFICATIONS OF THE METHOD

Burnol and coworkers (1983) used the euglycemic insulin clamp technique coupled with isotopic measurement of glucose turnover to quantify insulin sensitivity in the anesthetized rat.

Bryer-Ash and coworkers (1995) used this technique to demonstrate reduction of insulin sensitivity by amylin corresponding to reduced insulin receptor kinase activity.

The effects of counterregulatory hormones on insulin-induced glucose utilization by individual tissues in rats, using the euglycemic hyperinsulinemic clamp technique combined with an injection of 2-[1-^{3}H]-deoxyglucose, were studied by Marfaing and coworkers (1991).

Lang (1992) determined the insulin-mediated glucose uptake in normal and streptozotocin-diabetic rats using the euglycemic-hyperinsulinemic clamp technique.

Hirshman and Horton (1990) reported increased insulin sensitivity and responsiveness in peripheral tissues of the rat after glyburide as determined by the glucose clamp technique.

Lee and coworkers (1994) studied the metabolic effects of troglitazone on fructose-induced insulin resistance with the euglycemic hyperinsulinemic clamp technique in rats.

Tominaga and coworkers (1992, 1993) studied the influence of insulin antibodies in anesthetized rats and of thiazolidinediones on hepatic insulin resistance in streptozotocin-induced diabetic rats by the glucose clamp technique.

Gelardi and coworkers (1991) used the hyperinsulinemic-euglycemic clamp technique to evaluate the insulin sensitivity in the obese offspring of streptozotocin-induced mildly hyperglycemic rats.

Hulman and coworkers (1993) studied insulin resistance in the conscious spontaneously hypertensive rat with the euglycemic hyperinsulinemic clamp technique.

Cheung and Bryer-Ash (1994) described a modified method for the performance of glucose insulin clamp studies in conscious rats under local anesthesia.

Burvin and coworkers (1994) developed a modification of the euglycemic insulin clamp technique and used it to repeatedly assess *in vivo* insulin effects in awake streptozotocin-induced diabetic rats.

Xie and coworkers (1996) described a modified euglycemic clamp technique in cats.

Finegood and coworkers (1987) estimated endogenous glucose production during hyperinsulinemic-euglycemic glucose clamps using unlabeled and labeled glucose infusates in dogs.

Xie and coworkers (1996) described an insulin sensitivity test using a modified euglycemic clamp in **cats** and rats. This test uses the amount of glucose required to be infused to maintain euglycemia over a 30-min period in rats and 60 min in cats following a bolus administration of insulin as the index of insulin sensitivity. Glucose levels are determined a short intervals and variable glucose infusion is used to hold glucose levels with-in a few percentage points of the basal pre-test glucose level. A new blood sampling technique is described that allows each insulin sensitivity test to be carried out using a total of only 0.5 ml of blood.

K.3.3 Hypoglycemic Seizures in Mice

PURPOSE AND RATIONALE

The biological assay of insulin using hypoglycemic seizures in mice has been suggested already in 1923 by Fraser. The biological standardization of insulin using the mouse convulsion method has been published in detail by the Health Organisation of the League of Nations in 1926 (Trevan and Boock, Hemmingsen and Krogh) and has been until recently the official assay in several pharmacopoeias, such as European Pharmacopeia, 2nd edn 1980; Deutsches Arzneibuch 1986; British Pharmacopoeia 1988. In most pharmacopoeias, the biological assays have been replaced by chemical methods (British Pharmacopoeia 1999; European Pharmacopoeia, 3rd edn 1997).

PROCEDURE

Ninety-six mice of either sex (but not of mixed sexes) weighing 20 ± 5 g are randomly distributed into 4 groups. The mice are deprived of food 2–20 h immediately preceding the test. Solutions of the insulin standard and of the test preparation containing 30 and 60 milliUnits/ml are prepared by diluting the original solution with 0.9% NaCl solution, pH 2.5. 0.5 ml/20 g mouse of these solutions are injected subcutaneously. The mice are kept at a uniform temperature, between 29 and 35°C, in transparent containers within an air incubator with a transparent front. The mice are observed for 1.5 h and the number of mice is recorded that are dead, convulse or lie still for more than 2 or 3 s when placed on their backs.

EVALUATION

The percentage of mice of each group showing the afore mentioned symptoms is calculated and the relative potency of the test solution calculated using a $2 + 2$ point assay.

CRITICAL ASSESSMENT OF THE METHOD

Attempts to replace the tests in mice and rabbits by *in vitro* tests, such as the rat diaphragm test, the rat epididymal fat pad test, or even the radioimmunoassay failed due to several reasons (Trethewey 1989). Nevertheless, for industrial production and for stability studies, the classical bioassays based on hypoglycemic seizures in mice or hypoglycemia in rabbits have been replaced by chemical methods (Stewart 1974, Underhill et al. 1994).

MODIFICATIONS OF THE METHOD

A modification of the mice seizure method using rotating hollow cylinders has been proposed by Young and Lewis (1947). A similar technique which increases the sensitivity of the mice seizure method has been used by Vogel (1964). The equipment consisted of seven perforated metal drums with a diameter of 15 cm. The drums were rotated in oblique position at 10 rotations per minute. Female mice weighing 16 to 20 g were deprived of feed at the afternoon before the test. On the test day, groups of 6 mice received doses of 0.5; 1.0 or 1.5 IU/kg of test preparation or standard subcutaneously and were placed after 20 min into the rotating drums. Controls received saline only. Mice with insulin-induced seizures dropped out from the rotating drum. The number of animals dropping out was counted after 15; 30; 45 and 60 min. Mice dropping out due to hypoglycemic seizures received 0.5 ml of 10% glucose solution intraperitoneally. ED_{50} values and activity ratios were calculated according to Litchfield and Wilcoxon (1949).

K.3.4 Effects of Insulin Sensitizer Drugs

PURPOSE AND RATIONALE

Insulin sensitizer drugs are reported to improve symptoms in patients with established type 2 diabetes (NIDDM = non-insulin dependent diabetes mellitus) (Colca 1995; Kuehnle 1996). In contrast to sulfonylureas, these compounds do not lower blood glucose in normal animals. Various animal models resembling type 2 diabetes are used for evaluation. Details of these models are described in the respective chapters. *In vitro* techniques showed an increased glucose uptake into muscle tissue and into adipocytes.

PROCEDURE

In Vivo Studies

Chang et al. (1983) studied ciglitazone in *ob/ob* and *db/db* mice, diabetic Chinese hamsters, and normal and streptozotocin-diabetic rats.

Fujita et al. (1983) investigated the effects of ciglitazone in obese-diabetic yellow *KK* (*KK-A*^{y}) mice and obese Zucker-fatty rats.

Diani et al. (1984) treated C5BL/6J-*ob/ob* and C57BL/KsJ-*db/db* mice for several weeks with ciglitazone and studied the morphological effects on pancreatic islets.

Fujiwara et al. (1988) performed studies in *KK* and *ob/ob* mice and Zucker fatty rats.

Moreover, Fujiwara et al. (1991) studied the effects of CS-045 on glycemic control and pancreatic islet structure at a late stage of the diabetes syndrome in C57BL/KsJ-*db/db* mice.

Ikeda et al. (1990), Sohda et al. (1990) used insulin resistant animals (yellow *KK* mice, Zucker fatty rats, and obese Beagle dogs with moderate insulin resistance).

Gill and Yen (1991) studied the effects on endogenous plasma islet amyloid polypeptide and insulin sensitivity in obese-diabetic viable yellow mice.

Hofmann et al. (1991, 1992) treated insulin resistant KKA^y mice.

Stevenson et al. (1991) studied the effects of englitazone in nondiabetic rats and found no overt hypoglycemia but an enhancement of insulin action.

Kobayashi et al. (1992) found an increase of insulin sensitivity by activating insulin receptor kinase in genetically obese Wistar fatty rats treated with various doses of pioglitazone.

Sugiyma et al. (1992) found a reduction of glucose intolerance and hypersecretion of insulin in Wistar fatty rats after treatment with pioglitazone for 10 days.

Tominaga et al. (1993) used the glucose clamp-technique in streptozotocin-induced diabetic rats.

Yoshioka et al. (1993) found antihypertensive effects in obese Zucker rats.

Lee et al. (1994) studied the metabolic effects on fructose-induced insulin resistance in rats.

Apweiler et al. (1995) administered BM 13.09143 to lean and obese Zucker rats and performed hyperinsulinemic-euglycemic clamp studies in these animals.

Fujiwara et al. (1995) found a suppression of hepatic gluconeogenesis in long-term troglitazone treated diabetic KK and C57BL/ksJ-*db/db* mice.

Lee and Olefsky (1995) studied the effects of troglitazone in normal rats with the euglycemic glucose clamp technique.

In Vitro Studies

Kirsch et al. (1984) found a reversal of cAMP-induced post-insulin receptor resistance in rat adipocytes *in vitro*.

Ciaraldi et al. (1990) performed *in vitro* studies using cultured hepatoma cells (Hep G2) and muscle cells (BC3H-1) and found an increased glycogen synthase I activity in both cell types.

Murano et al. (1994) found a stimulation of fructose-2,6-bisphosphate production in rat hepatocytes.

Kellerer et al. (1994) reported the prevention of glucose-induced insulin resistance of insulin receptor in rat-1 fibroblasts.

Bader et al. (1993) found an increased [^{32}P]incorporation in the 95 kD β-subunit of the insulin receptor and an increased phosphorylation of the synthetic substrate Poly[GluNa4:1Tyr] in receptors isolated from skeletal muscle of obese Zucker rats treated with CS 045.

Teboul et al. (1995) found that thiazolidinediones convert myogenic cells (C_2C_{12}N myoblasts, a subclone of the C_2C_{12} cell line) into adipose-like cells. Thiazolidinediones or fatty acids prevented the expression of myogenin, α-actin, and creatine kinase and abolished the formation of multinucleated myotubes. In parallel, these treatments induced the expression of a typical adipose differentiation program including acquisition of adipocyte morphology and activation of adipose-related genes.

Tafuri (1996) reported that troglitazone enhanced the rate and percent differentiation of fibroblasts to adipocytes. Basal glucose transport and synthesis of GLUT1 transporter messenger RNA were increased.

Stevenson et al. (1990) examined the effects of racemic englitazone (CP 68722) in adipocytes and soleus muscles from *ob/ob* mice and in 3T3-L1 adipocytes. Administration of the drug in various doses lowered plasma glucose and insulin dose-dependently without producing frank hypoglycemia in either diabetic or nondiabetic animals. Basal and insulin-stimulated lipogenesis were enhanced in adipocytes from *ob/ob* mice. Glycogenesis and basal glucose oxidation in isolated soleus muscles were stimulated.

Kreutter et al. (1990) used 3T3-L1 adipocytes and found a stimulation of 2-deoxyglucose uptake.

Masuda et al. (1995) found an insulinotropic mechanism distinct from glibenclamide in isolated rat pancreatic islets and HIT cells.

K.3.5 Effects of Thiazolidinediones on Peroxisome Proliferator-Activated Receptor-γ

PURPOSE AND RATIONALE

Peroxisome proliferator-activated receptors (PPARs) compose a subfamily of the nuclear hormone receptors. Three distinct PPARs, termed α, δ, and γ, each encoded by a separate gene and showing a distinct tissue distribution pattern, have been described (Keller and Wahli 1993; Green 1995; Devchand et al. 1996; Lemberger et al. 1996; Schoonjans et al. 1996a, b, 1997, Willson et al. 2000), Walczak and Tontomoz 2002). Ligands that induce the transcriptional activity of PPARα and γ have been identified (Forman et al. 1995; Devchand et al. 1996; Lehmann 1995). Fatty acids and eicosanoids regulate gene expression through direct interactions with peroxisome proliferator-activated receptors α and γ (Kliewer et al. 1997). PPARγ is a central regulator of adipocyte gene expression and differentiation (Tortonoz et al. 1995; Brun et al. 1996; Wu 1998, Lowell 1999). Thiazolidinedione derivatives which are antidiabetic agents are potent and selective activators of PPARγ (Young et al. 1997; Henke et al. 1998, Murakami et al. 1998; Reginato et al. 1998; Ribon et al. 1998, Vázquez et al. 2002).. Berger et al. (1996) found a correlation of antidiabetic actions of thiazolidinediones in *db/db* mice with the conformational change in peroxisomal proliferator-activated receptor-γ: Murphy and Holder (2000) suggested a therapeutic potential of PPARγ agonists in the treatment of inflammatory diseases and certain cancers.

Steppan et al. (2001), Berger (2001) showed that adipocytes secrete a signaling molecule which they called resistin (for resistance to insulin). Circulating resistin levels in mice are decreased by thiazolidindiones and are increased in diet-induced and genetic forms of obesity. On the other hand adipocytes secrete another adipocytokine called adiponectin. Serum levels of adiponectin correlate with insulin sensitivity and are increased by the treatment with thiazolidindiones (Choi et al. 2005, Do et al. 2006).

PROCEDURE

Plasmids

The pSG5-haPPARγ1 expression construct is generated by inserting the hamster PPARγ complementary DNA into the EcoRI site of the pSG5 expression vector (Strategene, La Jolla, CA). As reporter construct, pPPRE-chloramphenicol acetyltransferase (CAT) is used containing two copies of the peroxisomal proliferator response element from the enhancer region of the murine acyl coenzyme A-oxidase gene adjacent to the glutathione-S-transferase minimal promotor and the CAT gene.

Cell Culture and Transfections

COS-1 cells are seeded at 2.1×10^5 cells per dish in 35-mm dishes (for transactivation assays) and 3×10^6 cells/dish in 150-mm dishes (for binding assays) in DMEM (high glucose) containing 10% charcoal-stripped fetal calf serum, nonessential amino acids, 100 U/ml penicillin G, and 100 µg/ml streptomycin sulfate at 37°C in a humidified atmosphere of 10% CO_2. After 24 h, transfections are performed with Lipofectamine (Life Technologies, Gaithersburg, MD). For transactivation experiments, transfection mixes are used containing 1 µg receptor expression vector, and 1 µg pCH110 (Pharmacia, Piscataway, NJ)

as an internal control and, for binding studies 20 µg receptor expression vector.

Binding Assay

Transfected cells are grown for 48 h after transfection with the receptor expression vector. Receptor preparation is performed according to Tilley et al. (1989). Cell lysates containing receptor are prepared in TEGM (10 mM Tris-HCl, pH 7.2; 1 mM EDTA; 10% glycerol; 7 µl/100 ml β-mercaptoethanol; 10 mM Na molybdate; 1 mM dithiothreitol; 5 µg/ml aprotinin; 2 µg/ml leupeptin; 2 mg/ml benzamide; and 0.5 mM phenylmethylsulfonylfluoride). Plates are placed on ice, rinsed with TEG (10 mM Tris-HCl, pH 7.2; 50 mM EDTA; and 10% glycerol), and scraped into 0.5 ml TEGM. The material is pooled, frozen in liquid nitrogen to lyse the cells, and thawed on ice. The lysate is centrifuged at 22,000 *g* for 20 min at 4°C to remove the debris and stored frozen (–80°C) until use. For each assay, an aliquot of receptor-containing lysate (0.1–0.25 mg protein) is incubated with 10 nM ditritiated AD-5075 (21 Ci/mmol) with or without test compound for ~16 h at 4°C in TEGM (300 µl final volume). Unbound ligand is removed by incubation on ice for ~10 min after the addition of 200 µl dextran/gelatin-coated charcoal. After centrifugation at 3000 rpm for 10 min at 4°C, 200-µl aliquots of supernate are counted in an liquid scintillation counter.

PPAR binding assays using gel filtration to separate the bound radioactivity ligand from the free ligand (Kliewer et al. 1997) have been replaced by the scintillation proximity assay (SPA) which increases the throughput of PPAR competition assays (Nichols et al. 1998, Elbrecht et al. 1999). In this technique the ligand binding domain is labeled with biotin and immobilized on streptavidin-modified scintillation proximity beads. When a potential radioligand of PPARγ, binds to the PPARγ ligand binding domain, light, which leads to a detectable signal, is emitted. Competition with a nonlabeled ligand avoids the binding of the radioligand to the PPARγ ligand binding domain and no signal is emitted. With this binding assay, there is no need to separate free radioligands from bound ligands, thus simplifying the process.

Su et al. (1999) described the use of a PPARγ-specific monoclonal antibody to demonstrate thiazolidinediones induced PPARγ receptor expression *in vitro.*

Transactivation Assay

After transfection, cells are incubated for 48 h in culture medium with or without increasing concentrations of test compounds. Cell lysates are produced using reporter lysis buffer (Promega Corp., Madison, WI). CAT activity is determined using radiolabeled butyryl CoA as substrate in a diffusion based assay. β-Galactosidase activity is determined according to Hollons and Yoshimura (1989).

Lipogenesis Assay

PPARγ plays an important role in the regulation of cell differentiation (Lowell 1999). Adipogenesis requires combined high levels of PPARγ and other transcription factors such as CAAT/enhancer binding protein (C/EBP) and adipocyte determination and differentiation-dependent factor 1/sterol regulatory binding protein (ADD-1/SREBP-1). PPARγ plays an essential role in the molecular control of adipogenesis. Ectopic expression of PPARγ induces adipocyte differentiation (Tontonoz et al. 1994), whereas in the absence of PPARγ adipocytes fail to develop (Lowell 1999). Adipocyte differentiation leads to expression of adipocyte-specific genes, such as aP2 (Tontonoz et al. 1994) or lipoproteinlipase (Schoonjans et al. 1996c) which are under the control of PPARγ. The lipogenesis assay, based on preadipocytes differentiation to adipocytes, where PPARγ plays an important role, has been used to select PPARγ agonists for *in vivo* studies. Henke et al. (1998) tested compounds for their ability to promote differentiation of C3H10T1/2 stem cells via measurement of glucose incorporation into total lipid of the cells.

Protease Digestion Assay

The protease digestion assay is performed according to the method of Allan at al (1992) with minor modifications. The plasmid pSG5-haPPARγ1 is used to synthesize ^{35}S-radiolabeled PPARγ1 in a coupled transcription/translation system. The transcription/translation reactions are subsequently aliquoted into 22.5-µl volumes, and 2.5 µl PBS with or without a thiazolidinethione are added. The mixtures are incubated for 20 min at 25°C, separated into 4.5-µl aliquots, and 0.5 µl distilled water or distilled water-solubilized trypsin are added. The protein digestions are allowed to proceed for 10 min at 25°C, then terminated by the addition of 20 µl denaturing gel loading buffer and boiling for 5 min. The products of the digestion are separated by electrophoresis through a 1.5-mm 12% polyacrylamide-SDS gel. After electrophoresis, the gels are fixed in 10% acetic acid-40% methanol for 30 min, treated in EN^{3}HANCE for an additional 30 min. and dried under vacuum for 2 h at 80°C. Autoradiography is then performed to visualize the radiolabeled digestion products.

EVALUATION

Binding Assays

For binding assays, competition curves are generated by incubation of 10 nM [^{3}H]AD-5075 with hamster PPARg1 produced by transient transfection of COS-1. The percentage of ligand bound after incubation in the presence of the indicated concentration of each unlabeled compound for 16 h is plotted.

Activation Assays

For activation assays of PPARg in COS-1 cells transiently cotransfected with pSG5-haPPARg1 and pPPRE-CAT, normalized CAT activity is plotted after incubation in the presence of the indicated concentration of each compound for 48 h.

Lipogenesis Assays

The lipogenic activity of PPAR agonists can be assessed by determining radioactive glucose uptake into the total lipids of cells. The amount of glucose incorporation into lipids in these cells provides a measure of cell differentiation. Moreover, the expression of adipocyte marker genes (aP2, lipoprotein lipase, leptin) and the accumulation of triglycerides in the cytoplasm confirmed by oil red O staining are other methods to evaluate the lipogenic activity of PPARγ agonists.

Protease Digestion Assay

For evaluation of the protease digestion assay, the partially protease-resistant conformation product of PPARγ is visualized by autoradiography on SDS-PAGE after incubation with the thiazolidinedione and increasing concentrations of trypsin.

MODIFICATIONS OF THE METHOD

Berger et al. (1999) reported distinct biological effects of PPARγ and PPARδ ligands.

Desvergne and Wahli (1999) reviewed nuclear control of metabolism by peroxisome proliferator-activated receptors.

Lin et al. (1999) reported a fluorescence-based method for investigating the interactions of PPAR with ligands.

Brown et al. (2001) described identification of a subtype selective human PPARα agonist through parallel-array synthesis.

Xu et al. (2001) investigated the structural determinants of ligand binding selectivity between the peroxisome proliferator-activated receptors.

Lee et al. (2003) reviewed metabolic disorders and peroxisome proliferator-activated receptors.

Ram (2003) underlined the therapeutic significance of peroxisome proliferator-activated receptor modulators in diabetes.

Norris et al. (2003) found that muscle-specific PPARγ-deficient mice develop increased adiposity and insulin resistance but respond to thiazolidines.

Vikramadithyan et al. (2003) studied a peroxixome proliferators-activated receptor alpha (PPARα) and PPARγ agonist as body weight lowering, hypolipidemic and euglycemic agent. HEK 293 cells were used to conduct the reporter-based transactivation of PPARα and PPARγ.

Matsusue et al. (2003) found that liver-specific disruption of PPARγ in leptin-deficient mice improves fatty liver but aggravates diabetic phenotypes.

Stanley et al. (2003) studied subtype-specific effects of peroxisome proliferator-activated receptor ligands on co-repressor activity.

Wurch et al. (2002) described pharmacological analysis of wild-type α, γ and δ subtypes of the human peroxisome proliferator-activated receptor.

K.3.6 Antidiabetic Effects of Liver X Receptor Agonists

PURPOSE AND RATIONALE

The nuclear receptors liver X receptor (LXR)α and LXRβ which are sensors of cholesterol metabolism and lipid biosynthesis are also regulators of inflammatory cytokines, suppressors of hepatic glucose production, and involved in different cell-signaling pathways. LXRα is a target gene of the peroxisome proliferators-activated receptor-γ, a target of drugs used in treating elevated levels of glucose seen in diabetes (Steffensen and Gustafsson 2004). Furthermore, insulin induces LXRα in hepatocytes, resulting in increased expression of lipogenic enzymes and suppression of key enzymes in gluconeogenesis, including phosphoenolpyruvate carboxykinase (PEPCK). Mukherjee et al. (1997) observed sensitization of diabetic and obese mice to insulin by retinoid X receptor agonists. Treatment of diabetic rodents with a LXRα agonist resulted in dramatic reduction of plasma glucose (Cao et al. 2003).

PROCEDURE

Oral Glucose Tolerance Study in fa/fa Rats

Obese insulin-resistant female Zucker (*fa/fa*) rats, 10 weeks of age, are orally gavaged for 9 days with either vehicle of the LXRα agonist. Eight h after the last dose, animals are fasted overnight and on the following morning subjected to an oral glucose tolerance test. Blood was obtained from the animals via the tail vein at time 0 and times 15, 30, 60, and 120 min after an oral glucose challenge (2.5 g of glucose/kg body weight). Plasma glucose and insulin levels are analyzed on all samples, and the results are expressed as the product of glucose AUC and insulin AUC.

Glucose Output with ZDF Rat Liver Slices

Precision-cut liver slices are generated from control, treated for 7 days with the LXRα agonist after an overnight fast. After preincubation and wash phases, the slices are incubated for 2 h at 29° C in Krebs-Henseleit bicarbonate buffer containing 40 mM mannitol in either the presence or absence of 10 mM lactate. Incubation media glucose levels are assessed at the 2-h time by subtracting the basal rate of glucose output per gram liver tissue from the substrate-stimulated rate of glucose output per gram of liver tissue.

Nuclear Run-On Experiment

A nuclear run-on experiment (Cao et al. 2002) is performed in the livers of diabetic *db/db* mice treated for 7 days with the LXRα agonist. Mouse liver nuclei are isolated (Schibler et al. 1983) and *in vivo* elongation reaction is performed (Goldman et al. 1985). The radiolabeled RNA is then subjected to slot blot (Mauvieux et al. 1998) in probes.

mRNA Measurement

Total RNAs are prepared from frozen tissue samples or cells with TRIzol reagent (Invitrogen) or Qiagen RNA prep kit. Mouse phosphoenolpyruvate carboxykinase and G6P mRNA are measured by RNase protection assay and quantified with a Molecular Dynamics Phaosphorimager Model 51. Rat mRNA is subjected to reverse transcription reactions using the Omniscript reverse transcriptase kit (Qiagen). The resulting cDNA is amplified using TaqMan 2 × PCR master mix (Applied Biosystems). The PCR products are detected in real time using an ABI-7900HT sequence detection system (Applied Biosystems). The rat PEPCK branched cDNA is analyzed according to Burris et al. (1999).

CRITICAL ASSESSMENT OF THE METHOD

Chisholm et al. (2003) reported that a LXR ligand induces severe lipogenesis in db/db diabetic mice.

MODIFICATIONS OF THE METHOD

Stulnig et al. (2002a, 2002b) concluded that LXR ligands mediate beneficial metabolic effects in insulin resistance syndromes including type 2 diabetes by interfering with peripheral glucocorticoid activation.

K.4
Measurement of Insulin and Other Glucose-Regulating Peptide Hormones

K.4.1
Radioimmunoassays for Insulin, Glucagon and Somatostatin

PURPOSE AND RATIONALE

Insulin activity is an important laboratory parameter in the clinical evaluation of several diseases such as diabetes mellitus types I and II, states of impaired glucose tolerance, and insulin-producing tumors (insulinomas), where the insulin secretion released from pancreas β-cells is altered.

The first description of an immunoassay of endogenous plasma insulin in man has been given by Yalow and Berson (1959, 1960). Yalow and coworkers (1960) provided evidence that the bioassays hitherto being used (isolated rat diaphragm, epididymal fat pad tissue) measure insulin-like activity but not true insulin levels in blood. Since that time, the method has been used and modified by many investigators, e. g., Grodsky and Forsham (1960), Morgan and Lazarow (1963), Hales and Randle (1963), Melani and coworkers (1965, 1967), Wright and coworkers 1968. Survey on the radioimmunoassay of insulin have been given by Ditschuneit and Faulhaber (1975), Freedlender and coworkers (1984).The introduction of radioimmunoassay (RIA) by Berson and Yalow (1959) provided a novel method for measuring insulin in plasma and serum. In order to improve reliability and practicability, various technologies have appeared in the field of immunoassays. Variety is seen in the choice of labels (radioactive, enzymatic, fluorescent, etc.), separation methods (precipitation of antigen-antibody complexes, coated solid-phase antibody technology, etc.), detection methods (spectrophotometry, fluorimetry, amperometry, potentiometry, and calorimetry), and principles such as the competitive or noncompetitive immunoassay. These immunoassay techniques have become important analytical methods in clinical chemistry laboratories for the selective detection of drugs or proteins as well as hormones such as insulin at trace levels.

PROCEDURES

Immunization

Semisynthetic or biosynthetic human insulin is used as immunogen and as standard. Formerly, porcine insulin has been used since Yalow and Berson (1960) and subsequently many other authors have shown that

antisera raised against porcine insulin react identically with human and porcine insulin. Guinea pigs weighing 350–450 g are injected subcutaneously with 0.4 ml of an emulsion of 5 mg human insulin dissolved in 1.0 ml 0.01 N HCl and 3.0 ml complete Freund's adjuvant (Difco Laboratories). For boostering, 0.2 ml of an identically prepared emulsion is injected in monthly intervals. Fourteen days after the third booster injection, the animals are slightly anesthetized and 8–10 ml blood are withdrawn by cardiac puncture. Boosting is continued at monthly intervals and the animals are bled 2 weeks following each booster injection.

The optimal antiserum titer for use in the radioimmunoassay is determined using conditions identical to those employed in routine immunoassays. The percentage binding of 1 µU ^{125}I insulin is determined for dilutions of antisera ranging from 10^3 to 10^6 fold. The steepness of the antisera dilution curve is a measure of the affinity of the antiserum and therefore the potential sensitivity of the radioimmunoassay. Antisera with the steepest slopes, but not necessarily the highest titer, are selected for further study. The selected antisera dilutions are then run in an immunoassay using a full range of standards. A reduction in the percent ^{125}I-insulin bound to antibody from 50% (in the absence of unlabeled insulin) to 45% (in the presence of unlabeled insulin) (B/Bo = 0.9) is a reasonable measure of assay sensitivity.

Assay

The antibody-bound ^{125}I-insulin prepared as described above can be separated from free ^{125}I-insulin in various ways, such as by paper electrophoresis, as originally described by Yalow and Berson (1960), or by a two-antibody system, as described by Morgan and Lazarow (1963), Starr and coworkers (1979). In this method, the soluble insulin-anti-insulin complex is precipitated by an anti-guinea pig serum antibody. The following procedure is recommended (Freedlender et al. 1984):

- A buffer is prepared from a solution of 8.25 g boric acid and 2.70 g NaOH dissolved in 1 l water. After dissolving 5.0 g of purified bovine serum albumin (BSA), pH is adjusted with concentrated HCl to 8.0.
- In disposable plastic tubes, 10 × 75 mm, the following volumes are added:
  - 100 µl serum or standard
  - 900 µl buffer
  - 100 µl 1 mU ^{125}I-insulin in assay buffer
  - 100 µl guinea pig anti-insulin antiserum diluted in assay buffer (at a concentration to bind 50% of the ^{125}I-insulin in the absence of unlabeled hormone)
- The mixture is incubated at 4°C for 72 h. Then, the following solutions are added:
  - 100 µl normal guinea pig serum diluted 1:400 in the assay buffer
  - 100 µl rabbit anti-guinea pig globulin serum diluted in assay buffer
- The mixture is again incubated at 4°C for 72 h and then centrifuged (2,000 × *g*, 20 min, 4°C). The supernatant is decanted and radioactivity counted in the precipitate for 5 min.

EVALUATION

Counts in the nonspecific binding tubes are subtracted from counts in all other tubes. Data are linearized using an unweighted logit-log transformation (Rodbard and Frazier 1975). Micro-units insulin in a logarithmic scale are plotted against the ratio B/Bo ^{125}I-insulin on a logit scale. The range of B/Bo between 0.4 and 0.9 is the most suitable for determination of insulin concentration in plasma.

CRITICAL ASSESSMENT OF THE METHOD

The immunoassay of insulin as described by Yalow and Berson (1960) has been a break-through for many immunological assays of peptide hormones and other drugs. At present, not only guinea pig anti-insulin antisera, but also complete RIA kits are available from a number of commercial firms.

MODIFICATIONS OF THE METHOD

Cam and McNeill (1996) published a sensitive radioimmunoassay optimized for reproducible measurement of rat plasma insulin. Relatively small volumes (25 µl) of plasma from control, diabetic, and fasted rats can be assayed reproducibly with charcoal in the final separation step.

The hormones, insulin, glucagon and somatostatin are determined radioimmunologically: insulin with the RIAgnost-kit and rat insulin as standard; glucagon with a rabbit antibody, ^{125}I-glucagon as tracer, and polyethylene glycol as precipitant; somatostatin with a rabbit antibody, ^{125}I-tyrosyl-somatostatin as tracer and charcoal dextran for separation of free and bound hormone. At least 3 experiments per concentration are performed. The values of each collection period of 1 min are averaged and plotted *vs* time. The effects of the test compound (increase or decrease of the secreted hormones) are compared with the control periods and the effect of elevated glucose.

K.4.2 Bioassay for Glucagon

PURPOSE AND RATIONALE

Glucagon is a 29-amino-acid, single-chain polypeptide which is secreted by the α-cells in the islets of Langerhans. It is synthesized from preproglucagon, a 180-amino-acid precursor (Bell et al. 1983). Proglucagon is processed in islet and intestinal cell lines (Tucker et al. 1996). Glucagon interacts with a 60-kDa glycoprotein receptor on the plasma membrane of target cells (Sheetz and Tager 1988).

A biological assay of glucagon is described in the British Pharmacopoeia 1988. The potency of glucagon is estimated by comparing its hyperglycemic activity with that of the standard preparation of glucagon using the rabbit blood sugar assay as performed for insulin determinations.

PROCEDURE

Rabbits of either sex, weighing 1.8 to 2.8 kg are maintained under uniform conditions and an adequate uniform diet for at least one week. Forty-eight hours before the beginning of the test, each rabbit is injected with 1 ml of cortisone acetate injection. The animals are deprived of food, but not water, from 16 h before each test day until the withdrawal of the last blood sample on that day. The rabbits are randomly distributed into 4 groups of at least 6 animals.

The standard preparation to be used is the 1st International Standard for Glucagon, porcine, established in 1973, consisting of freeze-dried porcine glucagon with lactose and sodium chloride (supplied in ampoules containing 1.49 Units), or another suitable preparation the potency of which has been determined in relation to the International Standard.

The entire contents of one ampoule of the standard preparation are reconstituted with 2 ml of saline solution, acidified to pH 3.0 with hydrochloric acid and diluted with the same solvent to a convenient concentration, for example 100 milliUnits per ml. Two dilutions are made containing 24 and 6 milliUnits per ml, respectively, and at the same time two dilutions are made of the preparation being examined. The rabbits are injected subcutaneously with doses of 1 ml of each of the four solutions, giving the doses in random order following a twin cross-over design on two consecutive days at the same time each day. At 20 and 60 min after injection, a blood sample is taken from a marginal ear vein of each rabbit. Blood glucose concentrations are determined using a suitable method, such as the glucose-oxidase procedure.

EVALUATION

The result of the assay is calculated by standard statistical methods using the means of the two blood glucose levels found for each rabbit.

MODIFICATIONS OF THE METHOD

Glucagon can be determined by radioimmunoassay (Unger 1959, Harris et al. 1978, von Schenk 1984). Commercial kits are available.

K.4.3 Receptor Binding and In Vitro Activity of Glucagon

PURPOSE AND RATIONALE

The binding of glucagon to its receptor is assayed with rat liver plasma membranes (Neville 1968, Pohl et al. 1971, Goldstein and Blecher 1976). Displacement of ^{125}I-labeled glucagon is measured for synthetic glucagon analogs in comparison to natural glucagon. Cyclic AMP formation as the first step in glucagon action on liver is measured as a bioassay in liver plasma membranes.

PROCEDURE

Preparation of Membranes

Male Sprague-Dawley rats weighing 160–200 g are decapitated and the livers rapidly removed and trimmed of fat and connective tissue. The pooled livers are placed on a pre-chilled glass plate and chopped finely with a stainless steel blade. Ten-gram portions of the mincate are suspended in 35 ml of ice-cold 1 mM $NaHCO_3$ and homogenized in a loose fitting Dounce homogenizer. Two homogenates are combined, brought to 500 ml with ice-cold medium, stirred magnetically for 5 min, and finally filtered once through two layers of cheesecloth. The filtrate is centrifuged ($1{,}500 \times g$, 10 min). Supernatant fluid is aspirated to waste using a serum pipette attached to a water pump. Homogenizations and centrifugations are continued until all of the tissue has been processed. The pooled pellets are again homogenized. The suspension is adjusted to $44 \pm 0.1\%$ (wt/wt) sucrose solution by the addition of 70% sucrose solution. Sucrose gradients are prepared in 1×3.5-in. tubes by pipetting 26 ml of the tissue suspension followed by an overlay of 13 ml of $42.3 \pm 0.1\%$ sucrose. Centrifugation is carried out ($95{,}100 \times g$, 2 h). The float containing the plasma membranes can be removed by pinching the tube slightly above the float, then lifting off the float with a spoon-shaped Teflon-coated spatula. These floats are transferred to a pre-weighed plastic centrifuge tube (50 ml), and the well-mixed suspension centrifuged at ($40{,}000 \times g$, 30 min). Following aspiration of the supernatant to waste, the tubes are reweighed in order to estimate the yield of plasma membranes. After addition of an equal volume of medium, the pellet is aspirated repeatedly through a 20-gauge needle fitted to a syringe. The plasma membrane suspension is distributed in 0.2 or 1.0 ml aliquots to screwcap plastic vessels for storage in liquid nitrogen.

Radioiodination of Glucagon

Three nmol glucagon are allowed to react with a 1.0 nmol sample of carrier-free $Na^{125}I$ (2.0 mC) in the presence of 1.5 nmol chloramine-T, added at a regular interval of 30 s (0.5 nmol each time). Reaction is terminated by addition of 0.5% sodium metabisulfite solution (Hagopian and Tager 1983). By chromatographic purification (Jørgensen and Larsen 1972), fractions of 2 ml are collected, and the monoiodinated glucagon as determined by reverse phase HPLC is stored at –20°C for receptor binding assays.

Receptor Binding

Membrane suspensions adjusted to 50 µg protein in 400 µl of Tris-HCl buffer (25 mM, pH 7.5, with 1% BSA) are incubated for 10 min with 50 µl peptide solution (Tris-HCl buffer) and 50 µl of [^{125}I]glucagon (10^6 cpm, 25 fmol). The samples are then filtered through Oxoid filters and washed three times with 1 ml of Tris-HCl buffer. The radioactivity retained in the filters is counted by a γ-counter.

Adenylate Cyclase Assay

The assay is carried out with a membrane suspension containing 25–30 µg protein in a volume of 0.1 ml of 25 mM Tris/HCl (pH 7.5) containing 1% BSA, 1 mM ATP with 4×10^6 cpm [α^{32}P]ATP, 5 mM $MgCl_2$, 1 nM cAMP containing 10,000 cpm of [^{3}H]cAMP, 10 mM GTP, 20 mM phosphocreatine and 0.72 mg/ml creatinine phosphokinase (100 U/ml). Assays are run in triplicate.

EVALUATION

Results are expressed as the percentage inhibition of [^{125}I]glucagon specific binding for receptor binding assays. For adenylate cyclase assays the results are expressed as percent potency relative to the maximal stimulation by glucagon which is defined as 100%.

MODIFICATIONS OF THE METHOD

Azizeh and coworkers (1995, 1997) synthesized and tested a glucagon antagonist and multiple replacement

analogs of glucagon by adenylate cyclase assay according to Lin and coworkers (1975) and receptor binding assay according to Wright and Rodbell (1979).

K.4.4 Glucagon-Like Peptide I

PURPOSE AND RATIONALE

Several intestinal peptides have been described to have insulinotropic or incretin activity, e. g. GIP (gastric inhibitory peptide, glucose-dependent insulin releasing peptide) (Creutzfeldt 1985, Baer and Dupré 1989, Volz et al. 1995). More recently, glucagon-like peptide-1 (7–37) or the (7–36)amide is described as a new incretin (Kreymann et al. 1987, Fehmann et al. 1989, 1990, 1991a, 1992, 1995, Holz et al. 1993). The insulinotropic activity has been confirmed in diabetic and non diabetic subjects (Gutniak 1992, Nathan et al. 1992, Nauck et al. 1993, Ørskov 1993). The insulin stimulatory effect of glucagon-like peptide-1(7–36)amide is glucose-dependent (Göke et al. 1993a). The peptide does not only stimulate insulin release but also inhibits glucagon secretion (Komatsu et al. 1989). Cloning and functional expression of the rat (Thorens 1992) and human (Dillon et al. 1993) glucagon-like peptide1 (GLP-1) receptor has been achieved. The sequence of glucagon-like peptide-1 (7–36)amide is completely conserved in all mammalian species studied, implying that it plays a critical physiological role. Intracerebroventricular administration of GLP-1 powerfully inhibits feeding in fasted rats, which is blocked by the GLP-1-receptor antagonist exendin(9–39) (Turton et al. 1996; Meurer et al. 1999).

Peptides isolated from reptile venoms, such as exendin-4, were found to have similar activity as glucagon-like peptide-1(7–36)amide (Göke et al. 1993b; Adelhorst et al. 1994; Schepp et al. 1994). Gedulin et al. (2005) found that exendin-4 improves insulin sensitivity and β-cell mass in insulin-resistant obese *fa/fa* Zucker rats independent of glycemia and body weight. Shechter et al. (2003) described [2-sulfo-9-fluorenylmethoxycarbony]$_3$-exendin-4 as a long-acting glucose-lowering prodrug. Analogs and antagonists of glucagon-like peptide-1(7–36)-amide have been synthesized and evaluated in pharmacological experiments (Watanabe et al. 1994, Hjorth and Schwartz 1996, Montrose-Rafizadeh et al. 1997).

Besides insulin release from perfused pancreas (see K.6.6), the receptor binding according to Göke and Conlon (1988) on rat insulinoma-derived cells (RINm5F cells), the cAMP formation and the insulin release were studied (Göke et al. 1989a, b).

PROCEDURE

Binding Studies with RINm5F Cells

The RINm5F cell line is derived from a radiation-induced insulin-producing rat tumor (Gazdar et al. 1980). The RINm5F cells are grown in plastic culture bottles (Praz et al. 1983). They are detached from the surface of the bottles before the experiment using phosphate-buffered saline (PBS, 136 mM NaCl, 2.7 mM KCl, 8.1 mM Na_2HPO_4, 1.5 mM KH_2PO_4, pH 7.3) containing 0.7 mM EDTA, and centrifuged ($100 \times g$, 5 min). The pelleted cells are resuspended in an incubation buffer (2.5 mM Tris-HCl, 120 mM NaCl, 1.2 mM $MgSO_4$, 1.5 mM KCl, and 15 mM CH_3COONa, pH 7.4) containing 1% human serum albumin, 0.1% bacitracin and 1 mM EDTA. Approximately 3×10^6 cells/tube are incubated for 5 min at 37°C, followed by the addition of unlabeled peptide (final concentration range from 10 pmol to 1 mmol) and radiolabeled tracer (approximately 40,000 c.p.m.). Iodination of the glucagon-like peptide-1(7–36)amide is carried out using the lactoperoxidase method. The total volume of incubation is 0.3 ml. After incubation for 60 min, aliquots (200 µl) of the cell sus-

pensions are centrifuged (11,500 × *g*, 2 min) through an oil layer (dibutylphthalate/dinonylphthalate, 10/4, v/v). Cell-surface associated radioactivity in the pellet is counted using a γ-counter (e. g. Gamma 5500, Beckman).

Determination of cAMP Production in RINm5F Cells

Approximately 1×10^6 cells in 0.45 ml buffer (113 mM NaCl, 4.7 mM KCl, 1.2 mM KH_2PO_4, 10 mM HEPES, 2.5 mM $CaCl_2$ and 1.2 mM $MgSO_4$, pH 7.4) containing 1% human serum albumin are pre-incubated for 10 min at 37°C, and then incubated for 10 min after the addition of 2 µl 3-isobutyl-1-methylxanthine (IBMX, 50 mM) in order to prevent the breakdown of cAMP. The reaction is then started by the addition of 50 µl of a peptide solution dissolved in the above buffer (final concentration range from 10 pM to 1 µM). After incubation for 10 min at 37°C, the reaction is stopped by the addition of 200 µl 12% trichloroacetic acid (TCA). The reaction mixture is sonicated for 30 s at 25 W (e. g., Heat system, Ultrasonics) and centrifuged (11,500 × *g*, 2 min). 25 µl of 1 M HCl is added to 0.5 ml supernatant. TCA dissolved in the supernatant is removed by diethyl ether (3 × 1 ml) and the resulting supernatant is stored at –40°C until cAMP assays being performed by use of a RIA kit.

K.4.5 Insulin-Like Growth Factors

PURPOSE AND RATIONALE

Three different lines of research have led to the discovery of insulin-like growth factors (Froesch et al. 1985): Growth hormone does not stimulate growth processes by itself but induces factors, named sulfation factors or somatomedins, that mediate the message of growth hormone (Salmon and Daughaday 1957, Nevo 1982, Laron 1999). Pierson and Temin (1972) extracted factors from serum with multiplication-stimulating activity (MSA) for chicken fibroblasts in the cell culture and with non-suppressible insulin-like activity. Serum exerts insulin-like effects on insulin target tissues such as muscle and adipose tissues to a much greater extent than it can be expected on the basis of the insulin content in serum. The activity of factors other than insulin in the epididymal fat pad assay was proven by the persistence of serum insulin-like activity after pancreatectomy (Steinke et al. 1962). Since this activity could not be suppressed by insulin antibodies, the factors were called 'non-suppressible insulin-like activity' or NSILA.

They were finally identified as insulin-like growth factors I and II (Rinderknecht and Humbel 1978a, b) structurally related to insulin. These polypeptide hormones are present in serum in high concentrations but are bound to specific carrier proteins (Zapf et al. 1975). Most of IGF and also the IGF-binding protein are synthesized and secreted, but apparently not stored by the liver (Schwander et al. 1983, Sara and Hall 1990).

Insulin-like growth factor 1 (IGF-1) is a polypeptide of 70 amino acids, whose function of is more or less clarified (Cascieri et al. 1988, Moxley et al. 1990, Salamon et al. 1991, Schmitz et al. 1991, Vikman et al. 1989, Laron 1999). The metabolic activity of IGF-1 is regulated by at least 6 IGF-binding proteins, the most important being IGFBP-3. The effects of growth hormone on protein metabolism are mediated by IGF-1,

whereas these 2 hormones are antagonistic in their effects on insulin and some aspects of lipid metabolism. IGF-1 has been shown to improve glycemic control and to reduce insulin requirements in both IDDM and NIDDM (Simpson et al. 1998). One important clinical use is replacement therapy in primary IGF-1 deficiency, such as Laron syndrome, which is characterized by dwarfism due to primary GH resistance or insensitivity (Laron 1999). IGF-1 improves bone healing *in vivo* (Kobayashi et al. 1996). A truncated variant of human IGF-1 with the tripeptide Gly-Pro-Glu absent from the N-terminus, has been isolated from bovine colostrum, human brain and porcine uterus which is about 10-fold more potent than IGF-1 at stimulating hypertrophy and proliferation of cultured cells (Ballard et al. 1999).

The function of insulin-like growth factor II is less defined (Roth 1988). IGF-II has an insulin-like effect *in vitro* and *in vivo* (Shizume et al. 1996, Burvin et al. 1998). IGF-II, administered acutely, affects glucose homeostasis in a manner very similar to insulin, probably via the insulin receptors, although with significantly lower potency.

Two subtypes of IGF receptors exist which are different from the insulin receptor and different in their affinity for IGF I and IGF II (Rechler 1985; Verspohl et al. 1988). They belong to the insulin receptor family of receptor tyrosine kinases (Ullrich and Schlessinger 1990, Schlessinger and Ullrich 1992, Fantl et al. 1993). Although insulin and IGF bind with high affinity to their own specific receptors, each can also bind to the heterologous receptor with reduced binding affinity (DeMeyts 1994).

With recombinant DNA technology insulin analogs with modified amino acid sequence can be produced which may bind differently to the insulin and IGF receptor resulting in different biological activities (Drejer 1992, Schäffer 1993). It has been speculated whether the unexpected carcinogenic effect of an insulin analog (Dideriksen et al. 1992) is related to the mitogenic effect in mouse NIH 3T3 fibroblasts which express IGF receptors but not insulin receptors (Gammeltoft and Drejer 1991). Biosynthesis of 10 kDa and 7.5 kDa insulin-like growth factor II in a human rhabdomyosarcoma cell line has been described by Nielsen et al. (1993).

For new insulin analogs the kinetics of association and dissociation to the receptors should be studied and *in vivo* metabolic activity should be compared with insulin and IGF I.

The *in vivo* metabolic action of insulin-like growth factor I can be compared with insulin in adult rats using the following methods (Schmitz et al. 1991): Dose-dependence and time-dependence of blood sugar decrease after intravenous injection, antilipolytic effect (decrease of non-esterified fatty acids) after i.v. injection, stimulation of glucose disposal during euglycemic clamping after intravenous infusion. Furthermore, all other assays described for insulin can be applied. Gazzano-Santoro and coworkers (1998) described a cell-based potency assay for insulin-like growth factor-1.

PROCEDURE

Cells from the human cell line HU-3, established from the bone marrow of a patient with acute megakaryoblastic leukemia, are adapted to grow in the presence of human thrombopoietin. Removal of thrombopoietin results in decreased proliferation and rapid loss of viability. Cells are cultured in RPMI-1640 medium with 2% heat-inactivated human serum, 2 mM glutamine, 10 mM HEPES (pH 7.2) and 5 ng/ml thrombopoietin in culture flasks. They are grown in suspension at 37°C in a humidified 5% CO_2 incubator and are routinely subcultured every two or three days when densities reach $0.8–1.5 \times 10^6$ cells/ml.

The cell growth assay is performed under serum-free conditions in assay medium consisting of RPMI-1640 supplemented with 0.1% BSA, 10 mM HEPES (pH 7.2) and 50 µg/ml gentamycin. Cells are washed twice in the assay medium and resuspended at a density of 0.25×10^6 cells/ml. In a typical assay, 100 µl of a cell suspension (25,000 cells/well) and 100 µl of IGF-1 at varying concentrations are added to flat bottomed 96-well tissue culture plates at 37°C and 5% CO_2 and cultured for 2 days. 40 µl of Alamar Blue™ (undiluted) are then added and the incubation continued for 7–24 h. The plates are allowed to cool to room temperature for 10 min on a shaker and the fluorescence is read using a 96-well fluorometer with excitation at 530 nm and emission at 590 nm.

EVALUATION

Results, expressed as relative fluorescence units, are plotted against IGF-1 concentrations using a 4-parameter curve-fitting program. Test compounds are compared with the standard.

MODIFICATIONS OF THE METHOD

Boge and coworkers (1994) described an enzyme immunoreceptor assay for the quantitation of insulin-like growth factor-1 and insulin receptors in bovine muscle tissue.

Hodgson and coworkers (1995) tested mutations at positions 11 and 60 of insulin-like growth factor-1 using (a) quantification of affinities for the human insulin receptor overexpressed on NIH 3T3 cells, (b) quantification of affinities for the type 1 IGF receptor via competition for binding to a monolayer of MDA-MB-231 cells, (c) promotion of the *in vitro* mitogenesis of growth-arrested MCF-7 cells in the presence of 17-β-oestradiol, and (d) a competition assay for binding to IGF-binding proteins secreted by MCF-7 cells.

In order to investigate the influence of insulin-like growth factor-1 and IGF-binding protein-1 on wound healing, Lee and coworkers (1996) measured the contraction of collagen gels with embedded fibroblasts.

Ernst and White (1996) studied the hormonal regulation of IGF-binding protein-2 expression in C_2C_{12} myoblasts.

Frystyk and Baxter (1998) described a competitive assay for rat insulin-like growth factor (IGF)-binding protein-3 (rIGFBP-3) based on the ability of IGFBP-3 to form a ternary complex with the acid labile subunit (ALS) in the presence of IGF. Human ALS was bound to test tubes pre-coated with anti-human ALS antibody. The assay depends on a competition between a covalent complex of ^{125}I-hIGF-I and hIGFBP-3, added as tracer, and hIGFBP-3 or rIGFBP-3 in standards or test samples, for binding to the immobilized hALS. Purified natural hIGFBP-3 served as standard.

Damon and coworkers (1997) used the C_2 skeletal myogenic cell line to characterize an insulin-like growth factor-binding protein, named Mac25/IGFBP-7.

To explore the possible relationship between insulin-like growth factor I and diabetic retinopathy, Naruse and coworkers (1996) examined the effects of glucose on IGF-I stimulated thymidine incorporation into DNA and IGF-I binding in cultured bovine retinal pericytes.

Jonsson and coworkers (1997) used a fluorometric proliferation assay with AlamarBlue to study the proliferative capacity of isolated human osteoblasts which were dose-dependently stimulated by IGF-I.

K.4.6 Amylin

GENERAL CONSIDERATIONS

Amylin, also named islet amyloid polypeptide, is a pancreatic islet peptide consisting of 37 amino acids with a role in the maintenance of glucose homeostasis. The peptide is predominantly present in the β-cells of the pancreas and to a lesser extent in the gastrointestinal tract and in the nervous system, where amylin mRNA is also present along with specific binding sites.

Amylin has structural and functional relationships to two other messenger proteins, calcitonin and calcitonin gene-related peptide (Rink et al. 1993, Pittner et al. 1994, van Rossum et al. 1997, Wimalawansa 1996).

Amylin inhibits food intake in rodents when given centrally as well as peripherally (Morley et al. 1997, Lutz et al. 1998). Bhavsar and coworkers (1998) found a synergy between amylin and cholecystokinin for inhibition of food intake in mice.

Amylin reduces insulin-stimulated incorporation of glucose into glycogen in skeletal muscle. Young and coworkers (1992) found that increasing concentrations of amylin progressively depressed the maximal insulin-stimulated radioglucose incorporation into soleus muscle glycogen.

Castle and coworkers (1998) reported an inhibition of 3-O-methyl-D-glucose transport in perfused rat hindlimb muscle under hyperinsulinemic conditions.

Bryer-Ash and coworkers (1995) found that amylin-mediated reduction in insulin sensitivity corresponds to reduced insulin receptor kinase activity in the rat *in vivo*.

Transgenic mice expressing human islet amyloid polypeptide develop diabetes mellitus by 8 weeks of age, which is associated with selective β-cell death and impaired insulin secretion (Janson et al. 1996).

Mulder and coworkers (2000) showed that amylin-deficient mice develop a more severe form of alloxan-induced diabetes.

In single β-cells exhibiting normal glucose sensing, amylin causes membrane hyperpolarization, increases net outward current and reductions in insulin secretion. In contrast, in cells with abnormal glucose sensing (e. g., from *db/db* diabetic mice) amylin has no effect on electrical activity or secretion (Wagoner et al. 1993).

Amylin suppressed the cAMP generation induced by glucagon-like peptide 1 (GLP-1) in RINm5F cells dose-dependently (Göke et al. 1993).

Amylin, also named human islet amyloid polypeptide (hIAPP) according to van Hulst and coworkers (1997), may be implicated in the pathogenesis of pancreatic islet amyloid formation and type 2 diabetes mellitus (Wimalawansa 1997). Van Hulst and coworkers (1997) used transgenic mice for the study of (patho)physiological roles of hIAPP *in vivo*. Leckstrom and coworkers (1997) studied plasma levels and immunoreactivity of insulin and islet amyloid polypeptide in *Psammomys obesus* (sand rat) under low-energy and high-energy diet.

Amylin given peripherally or centrally inhibits acid gastric secretion in a dose dependent manner and has a protective effect against indomethacin- or ethanol-induced ulcers only when injected centrally. Subcutaneous or central injection of amylin produces a dose-dependent inhibition of gastric emptying, which may contribute to the activity of amylin in the regulation of carbohydrate absorption. In addition, amylin inhibits food intake both when injected peripherally or centrally. Amylin is considered to take part in the rapid endocrine response during digestion to maintain euglycemia (Guidobono 1998).

Amylin slows the rate of gastric emptying in spontaneously diabetic BB/Wistar rats (Macdonald 1997) and inhibits gastric acid secretion in rats (Rossowski et al. 1997).

Guidobono and coworkers (1997) reported a cytoprotective effect of amylin against indomethacin- and ethanol-induced ulcers when given intracerebroventricularly, but not when given subcutaneously.

Clementi and coworkers (1997) found a protective, dose-dependent effect of amylin against reserpine- and serotonin-induced gastric damage in rats, however, no anti-ulcer effect after pylorus ligation.

The search for a superior compound with the biological actions of human amylin resulted in the identification of [$Pro^{25,28,29}$]human amylin, assigned the USAN name pramlintide. Young and coworkers (1996) compared this compound with human and rat amylin in various pharmacological tests, such as receptor assays (binding to rat nucleus membranes, amylin receptors; binding to membranes from SK-N-MC cells, CGRP receptors; binding to membranes from T46D cells, calcitonin receptors), gastric emptying in rats, plasma glucose after oral glucose gavage. When studying glycogen metabolism in the isolated soleus muscle of rats, pramlintide was slightly more potent than human amylin, but not different from rat amylin in inhibiting insulin-stimulated incorporation of [U-^{14}C]glucose into muscle glycogen. After intravenous infusion of amylin or pramlintide, a dose-dependent increase of plasma glucose, plasma lactate and ionized calcium was found. Mean arterial blood pressure decreased with higher doses.

Clementi and coworkers (1995) found an anti-inflammatory activity of amylin in mouse ear edema induced by Croton oil and acetic acid-induced peritonitis in the rat, but not in serotonin-induced rat paw edema and plasma protein extravasation induced by dextran in rat skin.

Bell and coworkers (1995), Bell and McDermont (1995) reported that amylin has an hypertrophic effect in rat ventricular cardiomyocytes and exerts the contractile response via $CGRP_1$-preferring receptors.

In anesthetized rats, amylin increased after intravenous infusion urine flow, sodium excretion, glomerular filtration rate and renal plasma flow (Vine et al. 1998).

Clementi and coworkers (1996) reported that intracerebroventricularly injected amylin induced in rats a dose-dependent decrease of locomotor activity without affecting grooming and sniffing.

Amylin dose-dependently stimulated cell proliferation of human osteoblast like (hOB) cells and increased osteocalcin production (Villa et al. 1997). Cornish and coworkers (1998) found in adult male mice after daily subcutaneous injection of amylin for 4 weeks an increase of histomorphometric indices of bone formation and a reduction of bone resorption. Muff and coworkers (1995) and Poyner (1997) identified, characterized and cloned the receptors for calcitonin, calcitonin-gene-related peptide and amylin.

PURPOSE AND RATIONALE

Binding sites with high affinity for amylin are present in several brain regions, with the nucleus accumbens and surrounding tissue containing more than twice as many banding sites as any other regions (Beaumont et al. 1993).

PROCEDURE

Membrane Preparation

Membranes are prepared from male Sprague-Dawley rats (150–200 g). Following decapitation, the basal forebrain regions (nucleus accumbens) are removed to PBS (pH 7.4) at 4°C. The tissues are weighted, then placed in 10 ml/g tissue of ice-cold 20 mM HEPES/KOH (pH 7.4) and homogenized with a Polytron (10 s at setting 4). An additional 30 ml of cold HEPES/KOH is added, and the homogenate centrifuged (48,000 × *g*, 15 min). After discarding the supernatant fluid, membrane pellets are resuspended by homogenization in 40 ml of fresh HEPES/KOH and

centrifuged as before. Membranes are washed again by homogenization in buffer and centrifugation. The final membrane pellet is resuspended in a volume of 20 mM HEPES/KOH containing 0.2 mM PMSF added immediately before use from a stock 0.2 M solution in ethanol. A volume of buffer is used to yield a concentration of about 80 mg original tissue/ml. Membranes are kept frozen at –80°C until use.

Binding Assay

Membranes from 4 mg of original wet weight of tissue are incubated with ^{125}I-BH-amylin (rat amylin, BH-labeled at the amino-terminal lysine, (Amersham Corp.) in 20 mM HEPES/KOH (pH 7.4), containing 0.5 mg/ml bacitracin, 0.5 mg/ml BSA and 0.2 mM phenylmethylsulfonyl fluoride (PMSF), for 60 min at 23°C. Incubations are carried out in duplicate tubes and are started by addition of membranes. Incubations are terminated by filtration through glass fiber filters that have been presoaked in 0.3% polyethylene-imine, followed by washing with 15 ml of cold PBS.

EVALUATION

Competition curves are generated by measuring binding of 13 pM ^{125}I-BH-amylin in the presence of 10^{-11} to 10^{-6} unlabeled peptide. Data are fitted to a four-parameter logistic equation to derive half-maximal inhibitory concentrations (IC_{50} values) and slope factors (Hill coefficients).

MODIFICATIONS OF THE METHOD

Sheriff and coworkers (1992) characterized amylin binding sites in the human hepatoblastoma cell line, HepG2. Perry and coworkers (1997) studied amylin and calcitonin receptor binding in the mouse α-thyroid-stimulating hormone thyrotroph cell line.

K.5 Insulin Target Tissues and Cells

K.5.1 Adipose Tissue and Adipocytes

GENERAL CONSIDERATIONS

Rodent adipose tissue and cells represent the targets exhibiting the most prominent insulin sensitivity (i. e. lowest EC/IC_{50}) and responsiveness (i. e. highest fold stimulation/inhibition above basal) of the relevant insulin signaling cascades (e. g. insulin receptor activation) and metabolic end effector systems (e. g. lipolysis) in comparison to liver (e. g. gluconeogenesis) and muscle cells (e. g. glucose transport). This might be based in part on technical advantages of the adipose tissue/adipocyte preparation in comparison to that of muscle/myocytes. But more likely it reflects the exquisite physiological role of the adipose tissue in the regulation and coordination of glucose and lipid metabolism, i. e. insulin stimulation of lipid synthesis (lipogenesis) and insulin inhibition of lipolysis. On basis of their relatively easy technical preparation, functional adipose tissue fragments (epididymal fat pads) and primary adipocytes (isolated epididymal adipocytes) from rats as well as adipocyte cell lines derived from mice (3T3-L1, F442A) are the first choice for the development of robust and reliable cell/tissue-based assay systems for insulin-like activity.

K.5.1.1 Epididymal Fat Pads of Rats

GENERAL CONSIDERATIONS

Insulin-like activity can be measured by the uptake of glucose into fat cells, which at low extracellular glucose concentrations (see K.6.1.6) represents the rate-limiting step for the conversion of glucose in and its storage as lipids, or for the oxidative (glycolysis plus citric acid cycle) and non-oxidative (glycogen synthesis) metabolism of glucose. Adipose tissue from the epididymal fat pads from rodents has been found to be very suitable for the analysis of non-oxidative and oxidative glucose metabolism. Early studies (Beigelman 1959, Steelman et al. 1961) determined the difference of glucose concentration in the medium after incubation of pieces of epididymal rat adipose tissue for the direct determination of glucose uptake (encompassing non-oxidative and oxidative glucose metabolism) or measured oxygen consumption in Warburg vessels (Ball and Merill 1961, Froesch et al. 1963) or the release of radiolabeled $^{14}CO_2$ from [^{14}C]glucose after its trapping and counting (Martin et al. 1958, Slater et al. 1961, Gliemann 1965a and 1967b, 1972) monitoring glucose oxidation, exclusively. The latter principle was used by Martin and coworkers (1958) using epididymal fat pads from the rat. This method has been used by various authors (Humbel 1959, Ditschuneit et al. 1959) and described in detail by Renold and coworkers (1960) and Siess and coworkers (1965). Sönksen and coworkers (1965) found a close correlation between "suppressible" insulin-like activity measured by the fad pad method and insulin concentration determined by immunoassay. Ball and Merrill (1961) used the manometric measurement of the net gas exchange of rat adipose tissue to quantitate small amounts of insulin. A survey of the biological assays of insulin-like serum activity was given by Faulhaber and Ditschuneit (1975).

The use of serum from pancreatectomized animals revealed the presence of factors apparently exerting insulin-like activity other than insulin (Steinke et al. 1962, 1965). Subsequently, the nature of these insulin-

like activities has been characterized (see K.6.3.6.4), but so far they escaped their unequivocal characterization and molecular identification, presumably due to their structural heterogeneity and low abundance.

PURPOSE AND RATIONALE

The epididymal fat pad assay, originally developed as bioassay of insulin-like activity in serum samples, can also be used for measuring activity of synthetic insulin derivatives and analogs as well as for the evaluation of peripheral insulin-like effects of antidiabetic compounds, such as sulfonylureas and biguanides, which have long been assumed to exert their blood glucose decreasing activity exclusively *via* stimulation of insulin release and improvement of peripheral insulin sensitivity, respectively. However, in the subsequent decades this tissue-based system has been replaced by cell-based assays (see below) which for most applications offer the advantages of higher sensitivity, accuracy, reproducibility and test capacity (throughput) despite lower expenditure in the number of animals (*per* data point) required.

K.5.1.2 Primary Rat Adipocytes

PURPOSE AND RATIONALE

The worldwide dramatic increase in obesity with its associated health problems and the identification of adipocyte-secreted proteins that apparently have major impact on the regulation of whole-body glucose, lipid and energy metabolism have generated major interest in adipocyte biology. Adipocytes are the primary storage site for energy in vertebrate animals. During fasting, adipocytes release energy-rich molecules that provide metabolic fuels to other tissues. Adipocytes also secrete hormones that orchestrate the storage, release, and oxidation of energy-rich molecules throughout the body and that control behavior, including feeding and appetite. Primary adipocytes maintain a large dynamic pool of triacylglycerol (TAG) and express a specific set of proteins to maintain circulating metabolic fuel levels. Primary adipocytes and adipose tissue have been used to study basic adipocyte biology.

Rodbell (1964) and Gliemann (1965, 1967a and b) used primary adipocytes isolated by digestion of epididymal fat pads from rats with collagenase. The conversion of (3- ^{3}H) glucose into total adipocyte TAG has been used as a very sensitive parameter in an improved assay for insulin-like activity by Moody and coworkers (1974) which during the subsequent decades turned out to represent the golden standard for assays for insulin-like activity. Alternatively to primary rat adipocytes, Etherton and Chung (1981) and Etherton and Walker (1982) characterized the insulin sensitivity of isolated swine adipocytes.

Preparation of Rat Adipocytes

Male Wistar or Sprague-Dawley rats weighing 140–200 g are sacrificed and both epididymal fat pads are removed under sterile conditions. The fat pads are cut into pieces and incubated for 20 min at 37°C with 1 mg/ml collagenase (e. g. type CLS II, Worthington, NJ) in Krebs-Ringer HEPES bicarbonate buffer, KRHB, (25 mM HEPES/KOH, pH 7.4, 0.1 mM glucose, 1% wt/vol BSA). The cell suspension is filtered through a 100-µm nylon screen and washed 3 times by flotation (accumulation of a thin cell layer on top of the medium after centrifugation ($1{,}000 \times g$, 1 min, swing-out rotor) with KRHB lacking glucose and finally suspended in the same solution. The suspension is adjusted to a final titer of 3.5×10^5 cells/ml.

Stimulation of Rat Adipocytes with Insulin

Adipocytes are suspended in buffer S (Dulbecco's minimal essential medium ([DMEM] for primary culture to induce insulin resistance, see K.6.3.5) or KRHB (for short-term measurement of insulin-like activity) both containing 5 mM glucose, 0.5 M mM sodium pyruvate, 4 mM L-glutamine, 200 nM 1-methyl-2-phenylethyl)adenosine, 100 µg/ml gentamycine, 1% BSA and 25 mM HEPES/KOH, pH 7.4) at 5% cytocrit (corresponding to about 7×10^5cells/ml). For determination of the packed cell volume, small aliquots of the cell suspension are aspirated into capillary hematocrit tubes and centrifuged for 90 s in a micro-hematocrit centrifuge in order to measure the fractional occupation of the suspension by the adipocytes (= cytocrit). A 20-ml portion of the adipocyte suspension (5% cytocrit) is added to 20 ml of buffer S containing human insulin as indicated. Incubations (20 min, 37°C) are performed under 5% CO_2 in 200-ml polyethylene vials during shaking at 110 cycles/min with a stroke length of 3.5 cm.

Permeabilization of Rat Adipocytes

Studies of intermediary metabolism and its regulation by insulin often require the use of agents that do not readily penetrate the plasma membrane of intact cells due to the size and charge of substrates (e. g. sugar phosphates, nucleotides, hydrophilic inhibitors, antibodies). Such studies would greatly benefit if the permeability of the plasma membrane to these compounds or the release of freely diffusible cytoplas-

mic molecules (e. g. metabolites, proteins) across the plasma membrane could be increased. Thus, permeabilized cells can be useful for the analysis of complicated metabolic processes as well as for the study of the insulin-like activity of agents which do not readily pass the plasma membrane of adipocytes including the elucidation of the molecular mechanism(s) of the insulin(-like) action induced or inhibited by a certain compound/drug. For this, it may be useful to block known signal transduction or metabolic pathways in adipocytes by introducing specific inhibitory antibodies (against key signaling proteins/metabolic enzymes) or peptide substrates (competing for the endogenous protein substrate; e. g. synthetic peptide as kinase substrate) prior to stimulation of the adipocytes with the compound/drug. In conclusion, permeabilized cells should be looked upon as a method that rapidly makes the interior of the cells accessible (for a review see Declercq and Baes 2000).

In general, the widely used methods of short incubation under hypoxic conditions (Gordon et al. 1985) and electroporation (i. e. subjecting cells to a short series of high-voltage electrical discharges permeabilize cells transiently. These cells are characterized by the formation of small protuberances (blebs) indicative of localized cell surface damage. It is conceivable that the stretched plasma membrane of such blebs act as a high-permeability region. Disappearance of blebs and restoration of normal plasma membrane impermeability is achieved again by short (15-min) incubation at 37°C. During the period of enhanced permeability small compounds can be introduced. Upon alternative physical treatment, such as osmotic shock and brief freezing/thawing, the cells are also temporarily permeabilized. Such cells reseal under appropriate conditions (Lepers et al. 1990). These physical methods are probably not selective for the plasma membrane necessitating other permeabilization techniques if intact intracellular membranes are required.

In addition, intactness of intracellular organelles will also benefit from the use of permeabilizing media that are isotonic with the cell content (Bijleveld and Geelen 1987). The cholesterol-sequestering approach produces very fast holes of about 8 nm (Schulz 1990) and is most suited to rapidly measuring cellular enzyme activities as the lesions are sufficiently large to allow entry of large molecular substrates or proteins and to allow cytosolic proteins of at least 285 kDa to leave the cell (Bijleveld and Geelen 1987). Apart from transient permeabilization, all the other techniques for permeabilizing cells have severe limitations due to the fact that cellular integrity is destroyed. The degree of loss of integrity determines the application of a particular permeabilizing procedure. The use of digitonin-permeabilized mammalian cells for measuring enzyme activities in the course of studies on lipid metabolism has been reviewed by Geelen (2005).

Electroporation of Rat Adipocytes

For the introduction of antibodies and peptides as well as compounds/drugs into isolated rat adipocytes without significant loss of cell viability and insulin sensitivity, the method of electroporation has been used successfully. For this, 0.4 ml of buffer E (4.74 mM NaCl, 118 mM KCl, 0.38 mM $CaCl_2$, 1 mM EGTA, 1.19 mM $MgS0_4$, 1.19 mM KH_2PO_4, 25 mg/ml BSA, 3 mM sodium pyruvate and 25 mM HEPES/KOH, pH 7.4) is placed in a 0.4-cm gap-width electroporation cuvette (Bio-Rad, Munich, Germany) together with the antibodies or peptides or compounds/drugs. 0.4 ml of adipocyte suspension (50% cytocrit in buffer E) is added to each cuvette and gently mixed. Electroporation is performed using a Gene Pulser Transfection Apparatus (Bio-Rad, Munich, Germany) which is set at a capacitance of 25 µF and voltage of 800 V (2 kV/cm), at 25°C for six shocks (Shibata et al. 1991, Quon et al. 1993). After the third treatment, the adipocyte suspension is gently stirred with a plastic stick and the electric polarity is reversed. The time constant of electroporation is typically 0.6 ms during the final shock. Routinely, 4 ml of adipocyte suspension (25% cytocrit) is electroporated in five cuvettes. The time required for treatment of the five cuvettes is about 3 min. After electroporation, the cells from five electroporations are pooled and transferred to 50-ml polystyrene tubes. After incubation (30 min, 37°C) in 5% CO_2/95% O_2, the cells are centrifuged ($200 \times g$, 1 min, swing-out-rotor) and the infranatant is aspirated. Thereafter the cells are washed once with 40 ml of buffer E containing 5 mM glucose and 4% BSA, suspended in 20 ml of the same buffer and then incubated (1 h, 37°C) under 5% CO_2 prior to challenge with the appropriate stimulus. Using this electroporation technology Müller and coworkers (2000) introduced into rat adipocytes inhibitory antibodies against tyrosine kinases mediating insulin-like signaling in response to stimuli different from insulin (see K.6.3.6.4).

K.5.1.3 Insulin-Resistant Primary Rat Adipocytes

PURPOSE AND RATIONALE

Primary rat adipocytes can be maintained in culture for long-term treatment with compounds/drug candidates to study their insulin-like activity upon chronic challenge or for the induction of insulin resistance to study the insulin-sensitizing activity of compounds/drugs for up to 24 h without significant loss of viability by incubation in buffer S (see K.6.3.5) containing 5 mM glucose and 0.5 mM sodium pyruvate under 95% O_2/5% CO_2 and continuous gentle shaking with moderate loss of insulin sensitivity and responsiveness, only (Müller and Wied, 1993). The conditions can be modified for the (subsequent) induction of insulin resistance *in vitro*, which might reflect the hyperglycemic and hyperinsulinemic state promoting insulin resistance *in vivo*.

PROCEDURE

For induction of insulin resistance, primary rat adipocytes are incubated in buffer S in the presence of 25 mM glucose, 0.5 mM sodium pyruvate and 10 nM insulin for 4 to 20 h at 37°C under slow shaking. When assayed for insulin-stimulated glucose transport following a 15- to 30-min incubation period in buffer S

containing 0.5 mM glucose and sodium pyruvate but lacking insulin (which enables downregulation of the glucose transport system from the chronically insulin-stimulated to basal levels).

EVALUATION

The adipocytes made insulin-resistant *in vitro* show a right-ward shift of the concentration-response curve (decreased insulin sensitivity) and a reduced maximal glucose transport velocity at constant or only slightly elevated basal glucose transport (decreased insulin responsiveness) (see Müller and Wied 1993). During prolonged incubation in suspension culture, the adipocytes tend to increase their basal glucose uptake which might reflect elevated energy demands due to stress conditions or loss of plasma membrane integrity. It is therefore most critical to choose culture conditions which preserve the energy status of the rat adipocytes and are compatible with 5- to 6-fold stimulations of glucose transport, at least, at low glucose concentrations corresponding to the normal insulin-sensitive state. This allows monitoring of the induction of insulin resistance by culturing of the adipocytes at high glucose and insulin and its blockade by the concomitant presence of compounds/drugs which may act as insulin senitizers. The use of 25 mM glucosamine instead of high glucose/insulin as initially proposed by Marshall and coworkers (1984; see K.6.3.5) on basis of the apparent activation of the hexosamine pathway during glucose/insulin-induced desensitization of rat adipocytes in culture is not recommended. It has meanwhile been demonstrated that intracellular accumulation of glucosamine results in depletion of cytosolic ATP and accompanying induction of the stress response (Hresko et al. 1998) causing apparent loss of insulin responsiveness which is based on massive increment of the basal glucose transport rate rather than on impairment of insulin signaling to the glucose transport system.

K.5.1.4 Cultured Mouse Adipocytes

GENERAL CONSIDERATIONS

Primary adipocytes have several limitations. They do not propagate in culture, they are difficult to transfect with DNA, they usually have a single huge TAG lipid droplet (LD) that interferes with biochemistry and microscopy, their properties vary as a result of the genetics and conditions of the animals from which they have been isolated, and the isolation procedure is tedious and introduces variation. In addition, harvesting primary adipocytes or adipose tissue from animals generally requires the euthanasia of a vertebrate animal and the expense of specialized facilities and protocols. For these reasons and likely others, cell lines have been developed that can be induced to store TAG, to express proteins that are hallmarks of primary adipocytes, exert many of the functional and physiological features of primary adipocytes and presumably to recapitulate key events in adipocyte ontogeny.

K.5.1.4.1 3T3-L1 Adipocytes

PURPOSE AND RATIONALE

Three decades ago, Kehinde and Green (1974) reported that a clonal subline of mouse 3T3 cells had a propensity to differentiate into adipocytes when in a "resting state". This 3T3-L1 cell culture model of adipogenesis has been exploited extensively to investigate the molecular mechanisms of adipocyte differentiation, lipid metabolism, insulin signaling, and glucose transport as well as to identify physiologically important adipocyte-secreted proteins (adipokines or adipocytokines), such as adiponectin, visfatin and resistin (for reviews see Banerjee and Lazar 2003, Stefan and Stumvoll 2002, McGillis 2005).

Green and Kehinde (1974) isolated from the established mouse fibroblast line 3T3 two subclonal lines that accumulate large amounts of TAG after they had undergone stimulus-induced differentiation from confluent fibroblasts *via* the state of preadipocytes to mature adipocytes. The cell line 3T3-L1 has been used extensively by many authors (Spooner et al. 1979, Frost and Lane 1985, Zuber et al. 1985, Chan et al. 1988, Clancy and Czech 1990, Wieland et al. 1990, Müller et al. 1993). For some purposes (e. g. analysis of the endogenous leptin production), the F442A mouse fibroblastic cell line has been used successfully (Zhang et al. 2002, Teta et al. 2005). Kletzien and coworkers (1992) studied the effect of pioglitazone, an insulin-sensitizing agent, on the expression of the adipocyte fatty acid-binding protein in *ob/ob* mice and 3T3 L1 cells.

PROCEDURES

Culture and Differentiation

3T3-L1 fibroblasts (American Type Culture Collection, Rockville, MD) are seeded in 12-well (60,000 cells/well) or 96-well (15,000 cells/well) plates and maintained in DMEM (high glucose), 10% fetal bovine serum (FBS), 5 mM L-glutamine and 2% BSA. Following three days at 90–100% conflu-

ence, differentiation is initiated by the addition of DMEM containing 10% FBS, 400 nM human insulin, 1 µM dexamethasone and 1 mM IBMX. Three days later, the medium is replaced with DMEM, 10% FBS and 100 nM insulin. After additional two days, the medium is changed to DMEM (low glucose) and 10% FBS. The presence of putative insulin-sensitizing compounds, such as glitazones (e. g. 1–10 µM pioglitazone) in the various differentiation media considerably may improve the degree of differentiation as has been shown in numerous studies since the introduction of these drugs into the anti-diabetic therapy. The differentiated adipocytes are used 5 to 12 d after completion of the differentiation protocol, when more than 85% of the cells expressed the adipocyte phenotype (LD accumulation as observed with "Oil Red" staining). Prior to experimentation, the cells are rinsed two times with low serum medium (DMEM containing 5 mM glucose, 0.5% BSA, 0.1% FBS, 25 mM HEPES/KOH, pH 7.4, 10 mM glutamine, 100 units/ml streptomycin/penicillin), then incubated (12 to 14 h) in this medium lacking FBS (for down-regulation of the insulin signal transduction cascade) and finally washed twice with PBS containing 2 mM sodium pyruvate prior to incubation (30 min, 37°C) with insulin or compounds/drug candidates.

K.5.1.4.2 OP9 Adipocytes

PURPOSE AND RATIONALE

The 3T3-L1 adipocyte model has significant limitations. First, from the time of initial plating, the generation of 3T3-L1 adipocytes from preadipocytes requires at least two weeks (Student et al. 1980). Second, if 3T3-L1 cells become confluent and are further propagated or if they are passaged extensively, they no longer differentiate robustly into adipocytes. These issues make culturing of 3T3-L1 cells demanding and limit their utility in the generation of stable cell lines. Third, it is difficult to efficiently detect RNAs and proteins encoded by transiently transfected DNA in 3T3-L1 adipocytes. This limitation derives from the facts that most plasmid transfection protocols require subconfluent cells and that levels of RNAs and proteins expressed from such transfections dramatically decline before 3T3-L1 cells become adipocytes. Finally, because the 3T3-L1 cell line originated from a single clone and thus has clone-specific traits, it fails to recapitulate the primary cells it models. Thus, an alternative, tractable adipocyte model system would be desirable. A new adipocyte cell culture model, OP9 mouse stromal cells, has been characterized recently that provides a tractable alternative system for studies of adipocyte biology (Wolins et al. 2006). The OP9 cell line was established from the calvaria of newborn mice genetically deficient in functional macrophage colony-stimulating factor (M-CSF) (Nakano et al. 1994).

PROCEDURE

Propagation and Differentiation

OP9 cells are available from the American Type Culture Collection (ATCC, catalog no. CRL-2749), however, have to be tested and selected for those capable of consistent differentiation into adipocytes. OP9 cells are grown in OP9 propagation medium (α-MEM, 20% FBS, 2 mM L-glutamine, 100 U/ml penicillin, and 100 µg/ml streptomycin). The optimal differentiation potential of OP9 cells is achieved when cells are replated every three days at a density of at least 7,000 cells/cm^2. OP9 cells grown in this manner are flat with broad cell processes. In contrast, OP9 cells maintained at low cell density adopt a spindly morphology and differentiate into adipocytes poorly. Three methods can be used to differentiate OP9 preadipocytes into adipocytes.

Serum Replacement Method (SR)

OP9 cells are grown to confluence and then cultured for two additional days in either OP9 or 3T3-L1 propagation medium as described above. The cells are then cultured up to 4 more days in serum replacement medium (α-MEM, 15% KnockOut™ SR [Invitrogen], 100 U/ml penicillin, and 100 µg/ml streptomycin). For the purpose of studying effects of insulin/compounds/drugs, it is important to change the SR medium to OP9 propagation medium after day 2 of differentiation, because KnockOut™ SR contains very high concentrations of insulin (final concentration of 1.7 µM) and 5 ng/ml bone morphogenic protein 4 (BMP-4; R&D Systems). However, BMP-4 makes no significant difference in adipocyte differentiation, so all experiments can be performed without BMP-4 with the exception of the assay for insulin-stimulated glucose uptake.

Insulin/Oleate Method (IO)

OP9 cells are plated at 5,000 cells/cm^2. When cells adhered to the plate, the OP9 propagation medium is replaced with insulin/oleate medium (α-MEM, 0.2% FBS, 175 nM insulin, 900 µM oleate bound to BSA [5.5/1 molar ratio] prepared according to Wolins and coworkers (2005); 100 U/ml penicillin, and 100 µg/ml streptomycin).

Adipogenic Cocktail Method (AC)

This method is very similar to that used for 3T3-L1 cells (see K.5.1.4.1 and Student et al. 1980). Cells are grown to confluence and then cultured for two additional days in 3T3-L1 adipocyte medium (DMEM, 10% FBS, 2 mM L-glutamine, 100 U/ml penicillin, and 100 µg/ml streptomycin). Cells are then cultured for two days in DM1 (DMEM, 10% FBS, 175 nM insulin, 0.25 µM dexamethasone, 0.5 mM IBMX, 2 mM L-glutamine, 100 U/ml penicillin, and 100 µg/ml streptomycin). The cells are cultured for two additional days in DM2 (DMEM, 10% FBS, 175 nM insulin, 2 mM L-glutamine, 100 U/ml penicillin, and 100 µg/ml streptomycin). Differentiated OP9 cells are maintained in OP9 propagation medium.

EVALUATION

OP9 mouse stromal cells represent a new model of rodent adipocytes that will be useful for further studies of the mechanisms of adipocyte differentiation and of mature adipocyte function (Wolins et al. 2006). When OP9 cells are given any one of three adipogenic stimuli, they rapidly accumulate TAG to form numerous, large LD, exert adipocyte morphology, express adipocyte late marker proteins, including glucose transporter 4 (GLUT4), adiponectin, perilipin, and S3–12 and exhibit robust insulin-stimulated glucose transport. OP9 cells can differentiate into adipocytes within two days. This rapid rate of differentiation allows for the detection of transiently expressed proteins in mature OP9 adipocytes. Adipogenesis in OP9 cells involves the master transcriptional regulator of adipocyte differentiation, peroxisome proliferator-activated receptor (PPAR-γ). OP9 cells are late preadipocytes in that, before the addition of adipogenic stimuli, they express the adipocyte proteins CCAAT/enhancer binding proteins α and β, PPAR-γ, sterol-regulatory element binding protein-1, S3–12, and perilipin. OP9 differentiation is not diminished by maintenance in culture at high cell density or by long periods in continuous culture, thereby facilitating the generation of stable cell lines that retain adipogenic potential.

Several practical features of OP9 cells make this cell line a particularly convenient model for adipocyte studies. First, OP9 adipocytes can be rapidly produced from either preconfluent cells (IO method) or confluent cells (SR and AC methods). Second, in contrast to 3T3-L1 cells, OP9 cells can be maintained at high density without loss of potential to differentiate into adipocytes. Third, OP9 cells continue to differentiate well even at high passage number. These features permit large numbers of OP9 cells to be conveniently maintained in culture and OP9 adipocytes to be produced for experiments within a few days.

K.5.1.5 Cultured Human Adipocytes

Murine cell models, most notably the 3T3-L1 cell line, have been the basis for the majority of studies of lipogenesis and lipolysis including their regulation as well as of adipogenesis at the transcriptional and post-transcriptional levels. However, there is a growing concern that the regulation of lipid metabolism may differ between human and murine adipocytes. For example, the resistin gene and its secreted protein product as well as its putative role in the regulation of lipid synthesis and degradation were first identified in the 3T3-L1 cells. Subsequent *in vivo* analysis in mice demonstrated an association between resistin levels, obesity, and type II diabetes. In contrast, clinical studies do not demonstrate a comparable association between serum resistin levels, obesity, and insulin resistance in non-obese and obese human subjects. Likewise the expression of the agouti gene in adipose tissue and its involvement in lipolysis regulation differs between man and mouse. These discrepancies argue for the increased use of human preadipocyte cell models in exploratory research and drug discovery relating to obesity and type II diabetes. Recently, the culturing of human adipocytes has been introduced successfully. The dramatically increasing incidence of diabetes and obesity in the industrialized countries immediately argues for the need of *in vitro* studies with human adipocytes, which justifies a more detailed evaluation of their generation and characterization. Two different sources for differentiated human adipocytes are available so far which differ in their accessibility for daily use and reflection of the primary adipocyte phenotype.

K.5.1.5.1 Adipocytes Derived from Human Adipose-Derived Adult Stem (ADAS) Cells

PURPOSE AND RATIONALE

ADAS cells can be reproducibly isolated from liposuction aspirates through a procedure involving collagenase digestion, differential centrifugation, and expansion in culture. A single milliliter of tissue yields over 400,000 cells (Aust et al. 2004). The undifferentiated human ADAS cells express a distinct immunophenotype based on flow cytometric analyses and, following

induction, produce additional adipocyte-specific proteins (Aust et al. 2004, Gronthos et al. 2001, Halvorsen et al. 2001, Sen et al. 2001, Zuk et al. 2002). The human ADAS cells display multipotentiality with the capability of differentiating along the adipocyte, chondrocyte, myogenic, neuronal, and osteoblast lineages (Aust et al. 2004, Zuk et al. 2002). In the presence of dexamethasone, insulin, IBMX, and a thiazolidinedione, the undifferentiated human ADAS cells undergo adipogenesis. Between 30 and 80% of the cells, based on flow cytometric methods, accumulate LD, which can be stained for neutral lipids with the "Oil Red" dye.

PROCEDURE

LD proteomicsProteomic procedures for the analysis of human (ADAS) and rodent fat cells have been used by DeLany and coworkers (2005), Lee and coworkers (2006), Chen and coworkers (2005) and Brasaemle and coworkers (2004). For the evaluation of ADAS cells (DeLany et al. 2005), liposuction aspirates from subcutaneous adipose tissue sites can be obtained from male and female subjects (30–40 years, 25–30 BMI) undergoing elective procedures in local plastic surgical offices. Tissues are washed three to four times with PBS and suspended in an equal volume of PBS supplemented with 1% bovine serum and 0.1% collagenase type I prewarmed to 37°C. The tissue is placed in a shaking water bath at 37°C with continuous agitation for 60 min and centrifuged ($300 \times g$, 5 min, room temperature). The supernatant is removed, and the pelleted stromal vascular fraction (SVF) is resuspended in Stromal Medium (DMEM/F-12 Ham's, 10% FBS, antibiotics/antimycotics) and plated at a density of 0.156 ml of tissue digest/cm^2 of surface area in T225 flasks using Stromal Medium for expansion and culture according to the procedure of Hauner and coworkers (1989). This initial passage of the primary cell culture is referred to as "Passage 0." Following the first 48 h of incubation at 37°C at 5% CO_2, the cultures are washed with PBS and maintained in Stromal Medium until they achieve 100% confluence (mean cell density of ~30,000 cells/cm^2 after 4 d in culture). The cells are passaged by trypsin/EDTA digestion and seeded at a density of 30,000 cells/cm^2 ("Passage 1") on 10-cm plates.

One day after seeding, plates are either harvested for protein (day 0), or the medium is replaced with an adipogenic differentiation (AD) medium composed of DMEM/F-12 with 3% FBS, 33 µM biotin, 17 µM pantothenate, 1 µM bovine insulin, 1 µM dexamethasone, 0.25 mM IBMX, 5 µM rosiglitazone, and 100 units of penicillin, 100 µg of streptomycin, 0.25 µg of Fungizone. After three days, AD medium is changed to adipocyte maintenance medium, which is identical to the AD medium except for the removal of both IBMX and rosiglitazone. Cells are fed every 3rd day and usually maintained in culture for 9 d prior to harvest.

EVALUATION

The studies published so far provide a composite profile of the proteome of undifferentiated human ADAS cells obtained from multiple donors. Overall, the results confirm the adipocyte-specific protein expression. However, not all of the proteins identified derive from ADAS cells and may be qualified as contaminants. The most striking examples are hemoglobins A and B, reported in the undifferentiated cell lysates. The presence of hemoglobin apparently reflects the cell isolation procedure. The SVF population prepared by collagenase digestion of the adipose tissue and subsequent centrifugation routinely contains erythrocytes that are washed away after a 48-h period during which the ADAS cells adhere to the plastic surface. Typically, nucleated hematopoietic cells, expressing the marker CD45, account for less than 1% of the ADAS cell population by Passage 1 according to previous flow cytometric studies (Aust et al. 2004, Gronthos et al. 2001). Nevertheless it is feasible that some hemoglobin remains bound to the adherent ADAS cell population either as intact erythrocytes or as membrane-bound protein.

Proteomic analyses of total cell lysates from murine 3T3-L1 adipocytes have identified between eight and 100 protein features by one- and two-dimensional gel electrophoresis/mass spectroscopy (Welsh et al. 2004, Wilson et al. 2003, Brasaemle et al. 2004, Choi et al. 2004). The ADAS cell proteome includes a high percentage of identical or similar proteins (DeLany et al. 2005).

K.5.1.5.2 Adipocytes Derived from Commercially Available Human Preadipocytes

PROCEDURE

Frozen human preadipocytes (PromoCell) are thawed and cultured in preadipocyte expansion medium (DMEM/F12 supplemented with 10% FBS, human epidermal growth factor (2.5 ng/ml), hTGF-β (0.25 ng/ml), bovine fibroblast growth factor (bFGF, 0.5 ng/ml), and antibiotics until the cells are confluent. For adipocyte terminal differentiation, preadipocytes are induced with differentiation medium contain-

ing DMEM/F12, 3% rabbit serum, biotin (33 µM), pantothenate (17 µM), human recombinant insulin (0.1 µM), dexamethasone (1 µM), IBMX (0.5 mM), and a peroxisome proliferator-activated receptor (PPAR) γ-ligand, such as troglitazone (3 µM) or F-moc-L-leucine (30 µM). After a 6-d induction period, with fresh medium added every 3rd day, the cells are fed with the same medium without IBMX or a PPAR γ-ligand (adipocyte medium) every 3–4 d for 6 additional days. Cells at passages 3–4 are routinely used for adipocyte differentiation. TAG accumulation is confirmed by staining formaldehyde-fixed cells with the neutral lipid-specific dye, Bodipy, at 1 µg/ml. Microscopic images are obtained using an inverted microscope with iluminator and image acquisition system (Carl Zeiss, Inc., Germany).

EVALUATION

Differentiated adipocytes are fixed in formaldehyde (5%), and TAG is stained with Bodipy. After the fluorescence of each well has been read at 530 nm, the Bodipy-stained lipid is removed, and cells are permeabilized using isopropanol. Isopropanol is subsequently removed, and cellular DNA is stained with EthD-1 (2 µM) for 30 min before measuring EthD-1 fluorescence at 620 nm. The EthD-1 readout is directly correlated with cell density between 2,000 and 40,000 cells/cm^2. Fluorescence units of Bodipy and EthD-1 per well are used to determine the lipid/DNA ratio.

K.5.1.6 Adipocyte–Myocyte Co-Culture

PURPOSE AND RATIONALE

There is growing evidence that paracrine/endocrine communication between adipose and muscle cells may be involved in the induction of insulin resistance during the pathogenesis of type II diabetes. This negative cross-talk, which may be mediated by soluble factors secreted by the adipocytes (e. g. adipokines) can be mimicked *in vitro* by using a co-culture based on human primary skeletal muscle and human primary adipose cells as has been recently introduced by Eckel and coworkers (Dietze et al. 2002).

PROCEDURE

Culture of Human Skeletal Muscle Cells

Satellite cells are isolated from M. rectus abdominis by enzymatic digestion with trypsin followed by a purification step with fibroblast-specific magnetic beads to prevent contamination with fibroblasts. After two passages, the myoblasts are characterized by the manufacturer (PromoCell) using immunohistochemical detection of sarcomeric myosin in differentiated cultures at 100% confluence (8 d). Primary human skeletal muscle cells of four healthy donors are usually supplied as proliferating myoblasts (5×10^5 cells). These cells are grown up to confluence in 25 cm^2 flasks, trypsinized, and subsequently seeded in 175 cm^2 flasks at a density of 1×10^6 cells. After two passages 5–7.5 $\times 10^7$ cells are harvested and stored until further use as frozen aliquots containing 2×10^6 myoblasts. For an individual experiment, myoblasts are seeded in 6-well culture dishes (9.6 cm^2/well) at a density of 10^5 cells per well and are cultured in α-MEM/Hams F-12 medium containing "Skeletal Muscle Cell Growth Medium Supplement Pack" to up to near confluence. The cells are then differentiated and fused by culture in α-MEM for 4 days.

Isolation and Culture of Human Adipocytes

Adipose tissue samples are obtained from the mammary fat of normal or moderate overweight women (BMI 20–30 kg/m^2, 20 and 50 years) undergoing surgical mammary reduction. All subjects should be healthy and have no evidence of diabetes according to routine laboratory tests. Adipose tissue samples are dissected from other tissues and minced into pieces of about 10 mg in weight. Preadipocytes are isolated by collagenase digestion as described (K.5.1.2). Isolated cell pellets are resuspended in DMEM/Hams F12 medium supplemented with 10% FCS, seeded on membrane inserts (3.5×10^5/4.3 cm^2) or in a 6-well culture dish, and kept in culture for 16 h. After washing, culture is continued in an adipocyte differentiation medium. After a period of 15 days, 60–80% of seeded preadipocytes develop into differentiated adipose cells as defined by cytoplasm completely filled with small or large LD.

Co-Culture

Co-culture of human fat and muscle cells is conducted according to a recently published protocol (Dietze et al. 2002, Dietze-Schroeder et al. 2005). Briefly, after *in vitro* differentiation of preadipocytes on membrane inserts, the adipocytes are washed once with PBS and then incubated for 24 h in skeletal muscle cell differentiation medium containing 1 pM insulin. Thereafter, adipocytes are washed twice with PBS and individual membrane inserts are subsequently transferred to the culture plates containing differentiated (4 d) myocytes in α-MEM containing 1 pM insulin. This results in

an assembly of the two cell types sharing the culture medium but being separated by the membrane of the insert. The typical distance from the bottom of the culture dish to the membrane is 0.9 mm. Co-culture is conducted for 48 h.

EVALUATION

Integrity of both cell types is routinely checked by light microscopy at the end of the co-culture period. Following co-culture, the effect of insulin or compounds/drugs are studied as described below for normal myocytes and adipocytes.

K.5.1.7 Adipocytes Derived from Mouse Embryonic Fibroblasts (MEF)

It is often useful to study the effects of insulin/compounds/drugs in adipocytes derived from knockout (KO) mice deficient for one (or several) gene(s) relevant for adipocyte differentiation or function. This may lead to the confirmation/exclusion of the affected gene (product) in the molecular mechanism of insulin/compound/drug action on the regulation of lipid metabolism or differentiation in adipocytes. For this, MEF from the KO mice are isolated and differentiated to adipocytes *in vitro*. Stable lines of MEF adipocytes are generated from 12.5–14.5 d embryos of wildtype or homozygous KO mice as described. Selected MEF cells are cultured in DMEM with 10% FBS. At confluence cells are exposed to a pro-differentiation regimen 1 µM dexamethasone, 5 µg/ml insulin, 0.5 mM IBMX and 5 µM rosiglitazone. After two days cells are maintained in medium containing insulin for 4 d, then in medium without insulin for an additional 3–4 d before use.

K.5.1.8 Brown Adipocytes

Brown fat precursor cells are isolated from the interscapular brown adipose tissue of 5–6 week old C57BL/6 wildtype, KO or transgenic mice. Cells are cultured in maintenance medium (DMEM, 10% FBS, 10 mM HEPES, 100 nM sodium selenite, 3 nM insulin, 15 mM ascorbic acid, 50 µg/ml tetracycline, 50 µg/ml streptomycin, 50 µg/ml ampicillin 1 µg/ml Fungizone [Invitrogen]). Precursors are seeded at 15–20,000 cells/cm^2 in 12-well plates or in 35-mm coverslip-bottom dishes for biochemical and cell biological assays. After they attained confluence (d 0), cells are cultured for two days in differentiation medium (DMEM, 0.5 mM IBMX, 0.5 mM dexamethasone, 125 µM indomethacin after which they are maintained in maintenance medium for an additional three days before use.

K.5.1.9 Conditionally Immortalized Cell Strains

PURPOSE AND RATIONALE

Cell lines provide the cell count and homogenous populations for throughput applications, but do not behave as a primary cell can. It is well accepted that primary cells behave more normally than cell lines. Yet, key limitations exist that preclude one from using primary cells during initial phases of drug discovery. The limitations include cost, homogeneity of cell population and total cell count achievable, donor-to-donor variability, and loss of key cellular behaviours when the cell is outside its home organ.

Conditionally immortalized cell strains are primary cells that behave normally in cell culture, can be expanded beyond 40 population doublings, yet maintain normal behaviours throughout the culture time. This is achieved by combining the telomerase rejuvenating effect of telomerase with a specifically modified temperature-sensitive large-T (ts LT) antigen in the same cell. The ts LT mutant codes for a gene product that is functional at 33°C but non-functional at 37°C. Though the construct overcomes the cells' natural senescence behaviour at low passage and provides a strong proliferative signal, the cells are not able to exhibit a full range of differentiated functions. By switching the culture conditions to 37°C one stops cell proliferation and the cells are responsive to media growth factors that drive differentiation. If the line is carried at 37°C for sufficient time, the strain permanently looses its ability to proliferate. A second mutation in the construct controls SV40's ability to auto-excise. Consequently, this mutant conveys a higher level of karyotype stability to the host genomic background over multiple population doublings. Telomerase, also called telomere terminal transferase, elongates chromosomes by adding TTAGGG sequences to the end of existing chromosomes thereby preventing chromosomes from losing base pair sequences at their ends and from fusing to each other. However, each time a cell divides, some of the telomere is lost (25–200 bp per division). When the telomere becomes too short, the chromosome reaches a critical length and can no longer replicate. At this point cells senescence and may be removed by apoptosis. In somatic and aging cells telomerase activity is usually very low. If telomerase is activated in cell, the cell will continue to grow and divide. Consequently,

the conditionally immortalized cell strain with active telomerase acts like a primary cell but provides homogenous cell populations at the high cell counts of cell lines.

EXPERIMENTAL PROCEDURES

Sequential retroviral (MMLV-based vector possessing the Neomycin selection marker) transfection at low passage using ts LT (u197sA58), followed by the telomerase construct hTERT, leads to highly proliferative strains which are highly responsive to differentiation. The conditional immortalization allows at a permissive temperature production of large uniform cell populations while active telomerase is reversing telomere shortening. Concurrently, at the permissive temperature ts LT is actively driving cell proliferation while maintaining karyotype stability over >40 population doublings. By increasing the culture temperature the cells stop dividing. One then converts to a differentiation medium so that the cells can express normal differentiated function and phenotype once again.

Conditionally Immortalized Human Skeletal Muscle Cells

The XM13A1 cell line introduced from Cambrex, Clonetics Bio Science Walkersville Inc. contains a mixed cell population derived from human skeletal muscle of normal 30–40 year old female subjects. These cells can finally be differentiated from myoblasts into well-developed myotubes (e. g. in 96-well plates) that have morphological and phenotypic characteristics of differentiated muscle. These include creatine kinase activity and stimulation (2- to 2.5-fold above basal) of glycogen synthesis by 0.1–1 μM insulin up to passage 21. Other markers of differentiation found include myogenin, GLUT4, uncoupling protein-3 and GS. Functional activities include stimulation of glycogen synthesis by LiCl and IGF-1, stimulation of glucose transport by AICAR and induction of insulin resistance by glucosamine (see K.5.1.3) or fatty acids.

Conditionally Immortalized Human Preadipocytes

The XA15A1 and XM18B1 cell lines introduced from Cambrex, Clonetics Bio Science Walkersville Inc. represent mixed cell populations derived from subcutaneous adipose tissue of normal 31–40/60 year old male subjects. Both strains are highly responsive, given the correct media conditions (even in the absence of PPARγ ligands glitazones), to differentiate from the primary normal human preadipocytes into functional mature adipocytes after more than 40 population doublings in culture. Markers of differentiation found include glycerol-3-phosphate dehydrogenase and aP2. The differentiated cells secrete leptin and adiponectin into the culture medium and exhibit insulin stimulation of glycogen synthesis (up to 2-fold with EC_{50} of 10–50 nM) and of glucose transport (up to 2.5-fold at 1 μM).

K.5.2 Liver and Hepatocytes

GENERAL CONSIDERATIONS

In type II diabetic patients with moderate fasting hyperglycemia, the liver production of glucose is increased by about 50 g/d above normal (DeFronzo et al. 1992). This modest increase is the consequence of reduced suppression of hepatic glucose production by insulin (Firth et al. 1987) and could be nullified by reducing dietary carbohydrate by 50 g/d. The increased hepatic glucose production in type II diabetes is probably caused by a combination of lack of an insulin-mediated reduction in glucagon secretion (Müller et al. 1970) and hepatic resistance to insulin action at the level of both the insulin signaling transduction cascade and its coupling to the metabolic end effector enzymes of gluconeogenesis. The importance of increased hepatic glucose production is underlined by the fact that when phosphoenolpyruvate carboxykinase (PEPCK), the key rate-limiting regulatory enzyme of gluconeogenesis, is overexpressed in mice carrying a transgene expressing the protein hyperglycemia results (Valera et al. 1994). Independent of whether increased hepatic glucose production plays a primary or only secondary role in the pathogenesis of human type II diabetes, analysis of insulin signaling and metabolic action in liver is important for gaining a complete picture of the pathophysiology of type II diabetes. The model of the isolated perfused rat liver offers advantages in determining insulin action, which, compared to primary and cultured liver cells, are the intact tissue, the near physiological function of the liver, and, compared to the *in vivo* situation, the separation from other effects which may also affect hepatic metabolism, like basal glucagon secretion from α-cells, increased sympathetic activity and/or hypothalamic effects (Nonogaki 2000). Taken together, liver cells harbor a number of important targets for compounds/drugs with insulin-like and anti-diabetic activity, which can be assayed using the intact liver and primary or cultured hepatocytes of human and rodent origin.

K.5.2.1 Perfused Rat Liver

Male Wistar rats weighing 200–250 g are anesthetized with 150 mg/kg hexobarbital intraperitoneally. After opening the abdomen, two ligatures are tied around

the stomach, one around the esophageal end to include the adjacent blood vessels and the other around the pylorus. The stomach is removed between these ligatures, a procedure that facilitates the remaining dissection and the subsequent removal of the liver from the animal. A ligature is placed around the bile duct. The portal vein is tied and cannulated with PP10 tubing. The thorax is opened and the vena cava is cannulated via the right atrium. The lower vena inferior cava is tied and the liver is removed from the animal. From the portal vein the liver is washed with 100 ml heparinized (5 IU/ml) physiological saline solution at 37°C for 3 min whilst the outflow occurs via the vena cava. The preparation is then transferred to a perfusion apparatus, where the portal vein cannula is attached to tubing containing the oxygenated medium.

KRBH with 25% bovine erythrocytes, 1.6% BSA, and 22.5 mM Na-L-lactate is used as perfusion medium. The perfusion rate is 30 ml/min. 70 ml of this solution are used for recirculation over 2 h. The test compounds/drug candidates are added in a concentration of 40–100 µM to the perfusate medium. The central element of the perfusion apparatus is a gas-tight, thermostatized, double-walled suction filter with an insertable sieve base as support of the organ. The discharge tube is elongated with a Plexiglas tube of 18 cm length and 10 mm inside diameter. The lower end of this tube is connected to a peristaltic pump by means of a Luer safety joint. The suction filter for perfusion of the liver has an internal diameter of 95 mm. On the return of the perfusate to the organ, it passes through a heat exchanger (glass spiral) and a filter holder with a sieve membrane of stainless steel (diameter 25 mm, mesh size 50 µm). A variable carbogen/oxygen mixture, the ratio of which is depending on the pH value of the perfusate, is used for gassing. The perfusate in the Plexiglas tube is bubbled with 70 ml gas mixture/min. To avoid foam formation, a detergent (14 µl/ml 0.1% Genapol PF-10) has to be added to the perfusate. Samples for analyses are withdrawn by catheter immediately in front of the Luer joint in the Plexiglas tube.

K.5.2.2 Primary Rat Hepatocytes

Sprague-Dawley rats (100–200 g) are fed *ad libitum* prior to the hepatocyte isolation. Hepatocytes are isolated from rat livers thoroughly perfused with buffer containing collagenase, hyaluronidase and trypsin inhibitor as described by Van den Berghe and coworkers (1980). The rat livers are perfused for 4 min at 25 ml/min flow rate with perfusion buffer and then with collagenase buffer until the digestion is complete (~6 min). At the end of the perfusion, connective tissue and large blood vessels are removed. The hepatocytes are then passed through a 100-µm nylon mesh sieve. The cells are washed twice with 125 ml of wash buffer and collected by centrifugation ($50 \times g$, 2 min). The hepatocytes are suspended in plating medium (DMEM, 10% FBS, 100 nM insulin, 25 nM dexamethasone, 6.3 µg/ml transferrin, 22 µg/l gentamycin) and passed through a 100-µm nylon mesh sieve. Cells (1.6×10^5) are plated in 48-well cell culture plates for the various metabolic assays.

K.5.2.3 Cultured Human Hepatocytes

HepG2/C3A (ATCC) human hepatoma cells are cultured in minimal essential medium (α-MEM, GIBCO) supplemented with 10% FBS), 100 µM non-essential amino acid mix, 1 mM sodium pyruvate, and 1 mM L-glutamine and are seeded in 48-well plates at 1.4×10^5 cells per well three days prior to the experiment.

K.5.3 Muscle Tissue and Myocytes

GENERAL CONSIDERATIONS

Muscle cell lines have been used to study skeletal muscle glucose metabolism in response to acute insulin stimulation. Subcellular fractionation followed by immunoblotting as well as photoaffinity labeling followed by immunoprecipitation has demonstrated that in cultured muscle cells insulin causes rapid translocation of the glucose transporter isoform, GLUT4, to the plasma membrane as has been well established for primary and cultured adipocytes. Over decades,

numerous studies have demonstrated that insulin affects many signalling events (e. g. IR and insulin receptor substrate tyrosine phosphorylation) as well as metabolic end effector systems (e. g. glucose transport and glycogen synthesis) in similar fashion. Despite the considerably higher complexity in gaining access to insulin-responsive cells/tissues from muscle compared to adipose tissue, the eminent physiological role of the human skeletal muscle as the predominant acute and short-term storage site for the daily carbohydrate intake necessitates the use of adequate cell- and tissue-based muscle model systems for assaying the insulin-like activity of compounds/candidate drugs. Moreover, these systems may be helpful for analysis of the molecular mechanisms of muscle insulin resistance and of its abrogation by putative insulin-sensitizing compounds/drugs. According to recent findings culminating in the "lipotoxicity hypothesis" (see K.6.3.4), peripheral insulin resistance seems to be correlated to the deposition or loss, respectively, of TAG or its precursors/degradation products in the cytoplasm of skeletal muscle cells, the so-called intramyocellular lipids. Thus, cell- and tissue-based muscle assay systems are also prerequisite for the analysis of myocellular lipid metabolism.

K.5.3.1 Perfused Rat Hindlimb

Female Wistar rats weighing 170–230 g are starved 48 h before the experiment. They are anesthetized by i.p. injection of 50 mg/kg pentobarbital. After an midline incision, the skin is reflected and the superficial epigastric vessels are ligated. The abdominal wall is then incised from the pubic symphysis to the xyphoid process using electrocautery. After ligation of the uterine, ovarian and inferior mesenteric arteries, the upper half of the uterus, the ovaries and part of the descending colon are excised, together with adhering adipose tissue. Next, branches of the hypogastric and pudoepigastric trunks supplying pelvic viscera are ligated. Ligatures are also placed around the neck of the bladder and the residual portions of the uterus and descending colon. Adipose tissue in the perineal and retroperitoneal regions is removed.

Two pairs of ligatures are placed around the aorta and the vena cava, one just above the origin of the iliolumbar vessels and the other above the origin of the renal vessels. The inferior epigastric, iliolumbar and renal vessels are then ligated as are the coeliac axis and the portal vein. A ligature is also placed around the tail. The ligatures previously placed around the vena cava and aorta above the origin of the renal vessels are then tied. The aorta is incised between the left renal and iliolumbar vessels and a no. 18 polyethylene catheter filled with 0.85% NaCl containing 200 units of heparin/ml is introduced, passed to a point midway between the iliolumbar vessels and the aortic bifurcation, and after flushing with heparin-NaCl solution finally tied in place. The vena cava is cannulated with a no. 16 needle which is secured in a position so that its tip is at the same level as the aortic catheter. The needle is connected with a transparent vinyl tubing. The preparation is then transferred to a perfusion apparatus, where the aorta cannula is attached to tubing containing the oxygenated medium.

KRBH with 25% bovine erythrocytes, 4% BSA, and 10 mM D-glucose is used as perfusion medium. The perfusion rate is 8 ml/min. 70 ml are used for recirculation over 2 h. The test compounds/drug candidate are added in a concentration of 40–100 µM to the perfusate medium. The central element of the perfusion apparatus is a gas-tight, thermostatized, double-walled suction filter with an insertable sieve base as support of the organ. The discharge tube is elongated with a Plexiglas tube of 18 cm length and 10 mm inside diameter. The lower end of this tube is connected to a peristaltic pump by means of a Luer safety joint. The suction filter for perfusion of the hind limb has an internal diameter of 145 mm. On the return of the perfusate to the organ, it passes through a heat exchanger (glass spiral) and a filter holder with a sieve membrane of stainless steel (diameter 25 mm, mesh size 50 µm). A variable carbogen/oxygen mixture, the ratio of which is depending on the pH value of the perfusate, is used for gassing. The perfusate in the Plexiglas tube is bubbled with 70 ml gas mixture/min. To avoid foam formation, a detergent (14 µl/ml 0.1% Genapol PF-10) has to be added to the perfusate. Samples for analyses are withdrawn by catheter immediately in front of the Luer joint in the Plexiglas tube.

K.5.3.2 Rat Diaphragms

Sprague Dawley rats weighing 70–100 g are used. The animals are sacrificed during anesthesia and the diaphragms still attached to the rib cages are carefully removed, released from the rib cages and adhering connective and fat tissues, washed in PBS, spread out and divided into two equal pieces as described by Müller and coworkers (1994). For assaying the effects of insulin/compounds/drugs, the hemidiaphragms are incubated in KRH buffer gassed with

carbogen (95% O_2/5% CO_2) in the presence of 5 mM glucose or other ingredients as indicated for the specific assays. In some cases, diaphragms attached to the rib cage instead of hemidiaphragms are used to prevent spontaneous contraction to less than physiological length.

K.5.3.3 Rat Soleus and Extensor Digitorum Longus

In studies of soleus muscle and extensor digitorum longus (EDL), the hindquarters are perfused for 3 min (25 ml/min) to wash out the blood. The two soleus or EDL muscles from each rat are removed with tendons intact, placed in perforated baskets and incubated in separate test tubes. Muscles from three rats are incubated together with insulin/compounds/drug candidates. The perfusing and incubation medium is KRB (pH 7.4) containing 8 mM glucose, 1 mM pyruvate and 0.2% (w/v) BSA. The incubation medium was gassed continuously with 95% O_2/5% CO_2. At the end of the incubation, muscles are freeze-clamped with aluminium tongs cooled in liquid nitrogen, and then trimmed of connective tissue and visible fat while kept in liquid nitrogen. In order to further ensure that findings reflected the biology of muscle cells, these are before analysis in most experiments isolated from other tissue components by microdissection using a stereomicroscope after freeze-drying.

K.5.3.4 Human Muscle Strips

A human muscle preparation has been introduced successfully by Dohm and coworkers (1988). For this, immediately after the surgical incision, muscle strips (abdominal rectus muscle) are mounted at *in vivo* length by using one set of clamps, which is 2.5-cm wide and constructed from two pairs of hemostats. The clamp is placed by the surgeon on the muscle, and a 0.5–1 g muscle piece is clamped, excised, and immediately transferred to oxygenated (KRBH) for immediate transfer to the laboratory. Muscle fiber strips, weighing between 20 and 50 mg, are dissected free from the mounted specimen, secured with a small Plexiglas support, and cut free. Particular care has to be taken to remove all visible fat. From one muscle piece, it is possible to obtain 5–10 muscle strips. After preparation, the muscle strips are washed for 30 min in KRBH supplemented with 38 mM mannitol, 2 mM pyruvate, and 10 mg/l BSA. The viability of muscle is usually investigated by analysis of 3–0-methylglucose transport (see below). Typically, insulin-stimulated glucose transport follows concentration-dependent fashion with the maximum effect of about 2-fold above the basal glucose transport rate ($\sim$1 µmol/ml · h).

K.5.3.5 Cultured Human Skeletal Muscle Cells

Human skeletal muscle cell cultures are handled as described by Aas and coworkers (2004). A cell bank of satellite cells is established from muscle biopsy samples of the vastus lateralis muscle from four healthy volunteers (age 25–30 years, BMI 22–25, fasting glucose and insulin within the normal range and no family history of diabetes). The biopsies have to obtained with informed consent and approval by the National Committee for Research Ethics. Muscle cell cultures free of fibroblasts were established as previously described (Henry et al. 1995) with minor modifications. Briefly, muscle tissue is dissected in Ham's F-10 media at 4°C, dissociated by three successive treatments with 0.05% trypsin/EDTA, and then satellite cells were resuspended in skeletal cell growth medium with 2% FCS and no added insulin. The cells are grown on culture wells coated with extracellular matrix gel (Gaster et al. 2001). After 2 to 3 weeks at about 80% confluence, fusion of myoblasts into multinucleated myotubes is achieved by growth for 8 d in α-MEM with 2% FCS. Hyperglycaemic medium can be made by the addition of glucose (to a concentration of 10 or 20 mM) to α-MEM with 2% FCS. All cells used in the experiments should be at passage 3 to 6.

K.5.3.6 L6 Myotubes

Stock cultures of L6 rat skeletal muscle cells from the ATCC are grown in α-MEM containing 10% (v/v) FBS, 100 U/ml penicillin, 100 µg/ml streptomycin, and antimycotics (growth medium) in a humidified atmosphere of 95% air and 5% CO_2 at 37°C. For the experiments, stocks are trypsinized and the myocytes reseeded on 6-well cell culture plates or 60 × 15 mm Petri dishes at a density of 4,000 cells/cm^2. After 24 h ($\sim$80% confluence), the medium is changed to α-MEM containing 2% (v/v) FBS and antibiotics/antimycotics as described above (differentiation medium) that is replaced after 2, 4, and 6 d of culture. After 7 d, myotube differentiation is complete, and experimental procedures are initiated. In all experiments, L6 myotubes are serum-starved for 4 h before expo-

sure to insulin/compounds/drugs. All controls are incubated with equal concentrations of the vehicle (e. g. DMSO) and the respective concentrations of fat-free albumin (e. g. BSA) as present in the treated cells.

K.5.3.7 L6 Myotubes Transfected with GLUT4

L6 myotubes express a detectable but rather moderate amount of the insulin-regulated GLUT4 which may account, in part, for the limited insulin stimulation of their glucose transport system. To increase the insulin responsiveness of glucose transport, L6 myocytes are transfected with myc-tagged GLUT4 (L6 GLUT4-myc cells) (Dr. Amira Klip, Davison of Cell Biology, The Hospital for Sick Children, Toronto, Canada). After growth in 96-well tissue culture plates using 200 µl of α-MEM containing 2% FBS, 100 units/ml penicillin G, and 100 mg/ml streptomycin sulfate at 37°C in a humidified atmosphere of 8.5% CO_2, myoblasts are seeded in medium containing 2% (v/v) FBS at a density of $\sim 2 \times 10^4$ cells/ml and used 6–8 d postseeding. Cells are fed fresh medium every 48 h and used at the stage of myocytes or after the differentiation to myotubes.

K.5.3.8 BC_3H_1 Myocytes

GENERAL CONSIDERATIONS

The BC_3H_1 cell line is a non-fusing spontaneously and reversibly differentiating mouse muscle cell line derived from a mouse neoplasm (Schubert et al. 1974). As for other cultured cell lines, the BC_3H^1 myocytes demonstrate intermediate characteristics, possessing electron-microscopic features of both smooth and skeletal muscle but with a nicotinic acetylcholine receptor and an action potential more characteristic of skeletal muscle (Standaert et al. 1984). Unfortunately, BC_3H_1 myocytes do not express GLUT4 and therefore the limited insulin stimulation of glucose transport relies on the glucose transporter isoform 1, GLUT1, exclusively.

PROCEDURE

BC_3H_1 myocytes are cultured to confluence in 100-mm dishes over 10–14 d in DMEM supplemented with 15% "Process Serum Replacement-I" (Sigma) and 25 mM glucose are added 18 h before the experiment. Cells are rinsed and pre-incubated at 37°C for 20 min in Dulbecco's PBS with 0.1 mM $CaCl_2$ and 1 mg/ml BSA, then treated with vehicle or compounds/drug candidates in vehicle for 30 min or overnight.

K.5.3.9 C_2C_{12} Myotubes

PURPOSE AND RATIONALE

C_2C_{12} cells, a mouse skeletal muscle cell line, has been isolated from dystrophic mouse muscle by Yaffe and Saxel (1977), McMahon and coworkers (1994), Ernst and White (1996). Subsequently, the myocytes have been shown to express a limited amount of GLUT4 and to be suitable for stable transfection experiments of exogenous cDNA, making this cell line a candidate for stable transfections of cDNAs that encode mutant skeletal muscle and cardiac protein isoforms.

PROCEDURE

Monolayers of mouse C_2C1_2 myoblasts (ATCC CRL-1772) are grown in Dulbecco's modified high-glucose Eagle's medium (DMEMH; 90%/10% (v/v) FBS/4.0 mM glutamine/50 µg/ml gentamycin, in a humidified incubator at 37°C, 5% CO_2 as has been described by Muoio and coworkers (1999) Cells are grown in 100-mm dishes, sub-cultured at 60–80% confluence, and split at a ratio of 1:10 using trypsin (0.25% (w/v) in MEM with 1.0 mM EDTA). Cells grown to 60% confluence are sub-cultured at a ratio of 1:15 into 6-well dishes that had been coated with 0.01% (w/v) collagen. When cells are 80% confluent, myoblasts are induced to differentiate into myotubes by changing to low-serum differentiation medium (98% DMEMH/2% (v/v) horse serum/4.0 mM glutamine/25 mM HEPES/50 µg/ml gentamycin). Differentiation medium is changed daily. By day 5, cells are typically fully confluent and had differentiated into multinucleated, contracting myotubes.

K.5.3.10 Cardiomyocytes

Cardiomyocytes are isolated by perfusion of hearts from adult rats with collagenase according to established protocols (Eckel et al. 1983 and 1991, Bähr et al. 1995).

K.5.4
Pancreas and Pancreatic β-Cells

GENERAL CONSIDERATIONS

Concurrent with the obesity epidemic, the incidence of type II diabetes is increasing at an alarming rate. Type II diabetes arises when the endocrine pancreas fails to secrete sufficient insulin to cope with the metabolic demand, because of aquired β-cell secretory dysfunction and/or decreased β-cell mass. Insulin secretory dysfunction is well documented. Whether insulin secretory dysfunction is a cause or consequence of the disease (in response to chronic challenge for compensation of the peripheral insulin resistance) is still debated, but there is mounting evidence that it may be symptomatic of changes in β-cell mass. Although proposed 50 years ago, the hypothesis that β-cell loss plays an important role in the pathogenesis of type II diabetes has only recently come to the fore. β-cell mass in the adult is plastic, and adjustments in β-cell growth and survival maintain a balance between insulin supply and metabolic demand. For example, obese individuals who do not develop diabetes exhibit an increase in β-cell mass that appears to compensate for the increased metabolic load and obesity-associated insulin resistance. However, this β-cell adaptation eventually fails in the subset of obese individuals who develop type II diabetes. Indeed, most individuals with type II diabetes whether obese or lean, show a net decrease in β-cell mass. Thus, type II diabetes is a disease of relative insulin deficiency. Given the pivotal role of β-cell mass in determining whether an individual will progress to type II diabetes, there is growing interest in understanding the mechanism that controls the life and death of β-cells. The molecular mechanisms involved in the decision between β-cell life and death have been reviewed by Rhodes (2005). Furthermore, assay systems based on the isolated perfused pancreas, perifused islets, insulinoma cells and cultured β-cells are required to study the effects of compounds/drugs on insulin secretion, β-cell growth and β-cell survival.

K.5.4.1
Perfused Rat Pancreas

PROCEDURE

Male Wistar rats (e. g. Hoe:WISKf, SPF 71-strain) weighing 200–250 g serve as donors. Prior to the experiment, the animals have free access to food and water. The pancreas is removed under pentobarbital (50 mg/kg i.p.) anesthesia. The mesenteric artery is doubly ligated and cut, and the entire intestine below the duodenum is separated and removed from the rat to simplify the exposure. The esophagus is ligated as high as possible and cut above the ligature. A loose ligature is placed, but not tied, around the entire gastrohepatic ligament. The aorta is cautiously exposed through the crura of the diaphragm well above the point of origin of the celiac axis. The ligature around the gastrohepatic ligament is then tied as tightly as possible, and the ligament cut above the ligature. The aorta is cut between the double clamps and below the lower clamp, and the preparation is lifted out from the abdomen. The clamps are removed from the aorta which is slit open on the side opposite to the origin of the celiac axis, revealing the opening of the latter. The arterial cannula

is inserted and tied in place. An opening is made close to the ligature, as near as the end of the portal vein as possible.

EVALUATION

Circulation through the preparation is initiated and fluid is observed to flow from the slit in the portal vein. After a minute or two, the flow is stopped and a cannula is inserted into the portal vein and tied in place. Flow is then resumed at a perfusion pressure of about 100 mm Hg. Carbogenated Krebs-Ringer bicarbonate buffer with 2% BSA and 5.5 mM glucose is used as perfusion medium at a temperature of 37.5°C with a perfusion rate of 1.75 ml/min. The perfusate is collected every minute for 30 min. After 5 min perfusion with 5.5 mM glucose, the test compound is added until the 15th min (concentrations between 0.05 and 0.5 mM for highly active substances), followed by perfusion with 5.5 mM glucose and finally with 16.6 mM glucose. The perfusate medium samples are stored at –20°C until further processing.

K.5.4.2 Perifused Islets

Male Wistar rats weighing 200–250 g serve as donors. Before the study, the animals have free access to food and water. Two donor rats are used for each test. The pancreas is removed under pentobarbital anesthesia. The islets are obtained by the collagenase (e. g. collagenase type IV, Worthington) method and collected under a stereomicroscope. In each test, up to 10 chambers each with 15 islets are perifused. Cut-off Microfuge tubes, sealed with Tuohy-Borst adapters, serve as perfusion chambers. Two thick-walled, small-diameter Teflon catheters are passed through the adapter into the chamber. One of the catheters extends to the bottom of the chamber and acts as the perifusate inlet, the other extends to the lower edge of the adapter cone and acts as outlet. The latter is connected to a multi-channel peristaltic pump which delivers the perifusate to a fraction collector. The chamber volume is 0.15 ml. The perifusate flow rate is 0.1 ml/min. The perifusate consists of a carbogenated Krebs-Ringer bicarbonate buffer with 1.0 mM glucose, 0.25% BSA, and 5 mM theophylline. The storage vessels for the perifusate, the chambers, and the inlet catheters are immersed in a water bath of 37°C.

EVALUATION

After a pre-perifusion phase of one hour, the perifusate is collected every min for 46 min. From the 2nd until the 18th min, the test compound is added at concentrations between 0.1 and 2.5 μM, and from the 34th to the 46th min, the glucose concentration is raised to 20.0 mM. The hormones: insulin, glucagon and somatostatin are determined by using a commercially available RIA-kit or ELISA-kit.

K.5.4.3 Insulinoma Cells

PURPOSE AND RATIONALE

Chick and coworkers (1977) described a transplantable insulinoma in the rat which was originally observed as primary tumor in the pancreas of an old male NEDH albino rat being previously irradiated during a parabiosis experiment. Fragments of this tumor were transplanted to young NEDH rats in many passages inducing severe hypoglycemia in host rats. Gazdar and coworkers (1980) reported the establishment of a continuous cell line of a rat islet cell tumor which secretes primarily insulin and some somatostatin. Bhatena and coworkers (1982) studied insulin, glucagon, and somatostatin receptors on cultured cells and clones from rat islet cell tumor.

PROCEDURE

The insulinoma is transplanted when the tumor has reached a diameter of about 2 cm and the carrier animal exhibits distinct manifestations of insulin excess. The tumor is removed, cut open, mixed briefly in a mortar and one tenth to one twentieth is injected between the shoulder blades of another animal. No metastases are observed. The histological examination also shows a nonmalignant adenoma. The tumors grow only in rats of the strain NEDH (New England Deaconess Hospital).

K.5.4.4 Cultured β-Cells

GENERAL CONSIDERATIONS

Reliable β-cell models are of paramount importance for diabetes research (see above). It is generally accepted that the use of primary cells is preferable. However, this requires large quantities of isolated pancreatic islets, which is work-intensive and has the inherent inconvenience of representing a mixed population of β-, α-, δ-, and F cells. Consequently, rodent β-cell lines have proven their usefulness, and their continuous development is still essential until clonal human β-cells become available. The intrinsic challenge when establishing a β-cell line is the maintenance of

tissue-specific differentiation combined with adequate cell proliferation. As a result, only a limited number of β-cell lines are available to date, all of rodent origin. Several insulin-secreting cell lines are reported in the literature (review by Poitout et al. 1996). The most widely used are RINm5F, βHC9, βTC6-F7 and, more recently, MIN6. Among the mouse-derived β-cell lines (Miyazaki et al. 1990, Knaack et al. 1994), MIN6 cells (Miyazaki et al. 1990, Ishihara et al. 1993) represent a valuable model, which was further improved by isolation of the clonal subline MIN6m9 (Minami et al. 2000). However, MIN6 cells exhibit secretory responses to pyruvate, which is not a secretagogue for normal islets (Skelly et al. 1998). Mouse βHC9 grow very slowly and are thus difficult to study. Of rat origin, RINm5F cells are poorly differentiated, have low insulin content and do not respond to glucose in the physiological concentration range (Halban et al. 1983, Praz et al. 1983, McClenaghan et al. 1998), and BRIN-BD11 cells are poorly differentiated, exhibiting low insulin content and weak secretory responses to glucose (McClenaghan and Flatt, 1999). Finally, loss of differentiated features as a function of time in tissue culture has been reported for several rodent cell lines, including RIN1046–38 and βTC6 (Clark et al. 1990, Ferber et al. 1994). Genetic engineering of RIN1046–38 cells results in clones with stable glucose responsiveness but with maximal insulin secretion occurring at subphysiological glucose concentrations because of a high level of low K_m hexokinase activity in these cells (Ferber et al. 1994, Hohmeier et al. 1997). Stable glucose responsiveness has also been reported for βTC cells after clonal selection in soft agar (Knaack et al. 1994), but even these cloned cell lines (e. g. βTC6-F7) appear to lose glucose responsiveness after prolonged tissue culture (Zhou et al. 1998). Currently, clonal INS-1 cells (e. g. INS1–832/13 or 1E; Hohmeier et al. 2000) appear to represent the most attractive vehicles for studying β-cell function.

PROCEDURE

RINm5F

Insulin-producing cells from the RINm5F cell line are grown in RPMI medium containing 10% (v/v) heat inactivated FCS, 50 IU/ml penicillin, 0.25 µg/ml amphotericin B, and 50 µg/ml streptomycin at 37°C in an atmosphere of humidified air/CO_2 (19:1) (Praz et al. 1983). The cells are seeded at a density of 3.5×10^4 cells/ml in 20 ml of medium (75 cm^2 culture flasks). The medium is replaced 4 times a week (one passage). Thereafter, the cells are treated with trypsin (0.02% trypsin in 0.9% NaCl/0.2 mM EDTA) for 2–5 min at 37°C. The trypsin-treated cells are diluted, re-seeded at a density of 2×10^6 cells per 75 cm^2 culture flask and grown to 70% confluency.

For single-cell patch clamp studies, RINm5F cells are maintained in RPMI 1640 tissue culture media, containing 11 mM glucose, supplemented with 10% FCS, 2 mM glutamine and 50 µg/ml gentamycine. Cells are seeded out every 2–3 d onto Petri dishes and kept in a humidified atmosphere of 95% O_2 and 5% CO_2 at a temperature of 37°C. The cells are isolated by incubation in a Ca^{2+}-free medium containing 0.25% trypsin for about 3 min. Single cells and clusters of 2–3 cells are obtained after centrifugation with 800 rpm and are stored on ice until use. The tight-seal whole-cell patch-clamp technique can be applied to single cells.

MIN6

The MIN6 cell has been derived from transgenic mice expressing a comparable transgene (Miyazaki et al. 1990). MIN6 cells cultured on a gelatine layer have been shown to form spherical cell clusters (pseudo-islets) similar to those in islets. (Hauge-Evans et al. 1999). Two rodent insulin genes have been identified in MIN6 cell pseudo-islets (Roderigo-Milne et al. 2002). The glucose-induced biphasic insulin secretion pattern observed in isolated mouse islets was also demonstrated in MIN6 pseudo-islets. Differences between pancreatic islets representing a complete endocrine organ and the artificial MIN6-pseudo-islets containing only β-cells were observed cautioning the use of the pseudo-islets for evaluation of compounds/drugs (Brenner and Mest 2003).

For culture, MIN6 cells (starting passage 40) are maintained in DMEM containing 25 mM glucose and supplemented with 15% heat-inactivated FBS in humidified 5% CO_2/95% air at 37°C. Cells are exposed to glucose-free extracellular solution for 30 min prior to measurement of insulin secretion or intracellular calcium.

Palmitate-Treated MIN6

Busch and coworkers (2005) studied the effect of fatty acids on the viability and functionality of pancreatic β-cells. For this, palmitate-treated MIN6 cell pools are selected and routinely passaged in 75-cm^2 flasks with 20 ml DMEM containing 25 mM glucose, 24 mM $NaHO_3$, 10 mM HEPES, 10% (by vol.) FCS, 50 IU/ml penicillin, 50 mg/ml streptomycin, and 1 mM palmitate coupled to 2.3% BSA (wt/vol). This selection procedure is carried out twice, giving rise to two independent pools of palmitate-treated cells. Both pools

are used for transcript profiling experiments and functional studies. Control MIN6 cells are taken through the same selection process but using BSA-medium without palmitate. Cells are seeded in DMEM as follows. For [^{14}C]palmitate-labeling and protein measurement, 2×10^5 cells per well in 24-well dishes (0.5 ml) are used, for microarray experiments, 5×10^6 cells per 25-cm^2 flask (5 ml) are used, for analysis of lipid composition, 6×10^6 cell per 10-cm dish (15 ml) are used. At 48 h before the experiments (24 h after seeding), the medium is replaced with DMEM (as above but with 5 mM glucose) supplemented with either BSA alone or BSA coupled to palmitate. Couplings are prepared in DMEM (25 or 5 mM glucose) as desribed by Busch and coworkers (2002). The couplings are diluted 1:8 (for culture and for experiments), giving a final concentration of 1 mM palmitate to 2.3% BSA (wt/vol), corresponding to a molar ratio of 3:1.

HIT-T15

The insulin secreting HIT cell line has been developed by Santerre and coworkers (1981) by isolating pancreatic islets from the hamster, dispersing the islets into single cells, transforming the cell isolates with the simian virus 40 (SV40), and cloning out the insulin-secreting cell lines. These clonal cells retain a differentiated function and respond to secretagogues and inhibitors of insulin secretion (Boyd et al. 1991).

INS-1/2

Asfari and coworkers (1992) derived INS-1 cells and INS-2 cells from parental radiation-induced RINm5F cells. In the course of a co-culture of lymphocytes and RINm5F cells in the presence of 2-mercaptoethanol, the authors observed the formation of free-floating cell aggregates which appeared to be morphologically different from the parental cells. These clusters were isolated and gave rise to the INS-cell lines, whose viability is dependent on the presence of 2-mercaptoethanol in the media and whose secretory characteristics are similar to those of native islets with its modulation by free radicals upon challenge of the cells by alloxan has been reported by Janjic and coworkers (1995). Due to the nonclonal nature of these cells, limited stability over passages probably explains some of the discrepancies observed among the numerous laboratories using parental INS-1 cells worldwide. To circumvent this problem, Hohmeier and coworkers (2000) stably transfected INS-1 cells with the human proinsulin gene, followed by selection of clones based on robust glucose-stimulated insulin secretion. The resulting INS-1–832/13 cells are highly glucose responsive. However, these cells overexpress human insulin driven by the ubiquitous cytomegalovirus promoter in addition to the endogenous rat insulin, rendering it impossible to judge the differentiated state based on insulin content. An alternative approach would be the cloning of well differentiated INS-1 cells without genetic manipulation. Hence, the clonal INS-1E cells has been isolated from the parental cells based on both their insulin content and their secretory response to glucose as well as adequate proliferation (Hohmeier et al. 2002).

INS-1E

Clonal INS-1E cells, derived from parental INS-1 cells (Asfari et al. 1992) on basis of selection for insulin content and adequate proliferation (Janjic et al. 1999), are cultured in a humidified atmosphere containing 5% CO_2 in complete medium composed of RPMI 1640 supplemented with 5% heat-inactivated FCS, 1 mM sodium pyruvate, 50 µM 2-mercaptoethanol, 2 mM glutamine, 10 mM HEPES, 100 U/ml penicillin, and 100 µg/ml streptomycin. The maintenance culture is passaged once a week by gentle trypsinization, and cells are seeded at a density of 4×10^4 cells/cm^2, i. e. 3×10^6 cells, in 75-cm^2 Falcon bottles with 20 ml complete medium. The potential presence of mycoplasma is regularly checked using a photometric enzyme immunoassay for the detection of PCR-amplified mycoplasma DNA (Roche, Diagnostics). INS-1E are seeded at 2×10^5 cells/ml in Falcon 24-well plates and used 4–5 days thereafter, with one medium change on d 3 or 4. For generation of INS-1E cell clusters, cells are seeded in nonadherent bacterial 10-cm petri dishes and cultured in complete medium for 5–6 d before use. The stable differentiated INS-1E β-cell phenotype was reported for over more than 100 passages corresponding to a 2-year continuous follow-up. INS-1E cells can be safely cultured and used within passages 40–100 with high insulin contents. Glucose-induced insulin secretion is concentration-dependent and similar to rat islet responses as are the secretion responses to amino acids and sulfonylureas. Moreover, INS-1E cells retained the amplifying pathway, as judged by glucose-induced augmentation of insulin release in a depolarized state. Finally, spheroid clusters, sometimes referred to as pseudoislets (Hauge-Evans et al. 1999), composed of reaggregated INS-1E cells, can be prepared and tested for their ability to respond to secretagogues. Thus, INS-1E cells represent a stable and valuable β-cell model for the analysis of insulin secretion induced by compounds/drug/candidates.

β-TC

Hanahan (1985) applied gene transfer technology to the establishment of β-cell lines. In order to target the expression of viral DNA to the β-cell, recombinant oncogenes have been designed by fusion of the 5′-regulatory region of the rat insulin II gene with the early coding region of SV40. The transgenes have been microinjected into fertilized mice embryos, which were then implanted in the oviduct of pseudopregnant females. The offspring specifically expressed SV40 in their β-cells and spontaneously developed β-cell tumors at 10–20 weeks of age. Tumors were subsequently excised, isolated and propagated in culture, giving rise to β-tumor cell (***β*-TC**) lines (Erfrat et al. 1988). Because these cells do not grow in culture at low density, the have not been cloned, and several subpopulations have been derived. Hamaguchi and coworkers (1991) applied this technique to the development of the NIT1 cell line from transgenic NOD mice in order to establish an immortalized source of NOD β-cells.

Betacyt

The betacyte, also called the HepG2Ins/β-cell, is a genetically engineered insulin-secreting human liver cell line that is glucose responsive (Simpson et al. 1995 and 1996, Tuch et al. 1997). The clone was constructed by doubly transfecting the HepG2 cell line with insulin cDNA under the control of the constitutive CMV promoter and the cDNA for the glucose transporter isoform 2 (GLUT2), which is specific to β-cells and hepatocytes. Interestingly, this cell is capable not only of synthesizing, storing and secreting insulin in a regulated fashion when challenged with physiological concentrations of glucose, but also of acting as a liver cell and secreting albumin.

K.6
Assays for Insulin and Insulin-Like Metabolic Activity

EVALUATION

Data from the metabolic assays (and signaling assays, see below) are calculated as stimulation factor above basal activity (absence of insulin/compound/drug candidate) for processes stimulated (e. g. lipogenesis, glucose transport and GLUT4 translocation) or as difference between the basal and insulin/compound/drug candidate-induced values for processes down-regulated (e. g. lipolysis). In each case, these data, which reflect the responsiveness of the metabolic effector system studied toward the respective stimulus (insulin/compound/drug candidate), are normalized to the basal (set at 0%) and maximal insulin action (set at 100%; elicited by maximally effective concentration of insulin). For characterization of the sensitivity of the metabolic effector system toward the respective stimulus, effective concentrations for the induction of 150% (or higher) of the basal activity (set at 100%) can be given. These so-called EC_{150}-values facilitate the insulin-independent comparison of the relative potency of the insulin-like activity between compounds/drug candidates, in general, and in particular for those frequently observed stimuli, which do not elicit the same maximal response in % stimulation or inhibition and/or fail to approach the maximal insulin response.

Typically, at least three different cell/tissue preparations with two to four independent incubations with insulin/compound/drug candidate and two to four independent activity measurements (i. e. assays) should be performed. Concentration/response curves can be fitted to the equation

$$y = a + b[x/(x + k)]$$

using a Marquardt-Levenberg non-linear least squares algorithm. When plotted on linear-log axes, this equation gives a sigmoidal curve where the parameters are associated with the following properties:

$$\begin{aligned} a &= \text{basal response;} \\ a + b &= \text{maximal response;} \\ k &= \text{half-maximal concentration}(EC_{50}); \\ x &= \text{concentration of insulin.} \end{aligned}$$

The term “insulin-like activity” is used in a wide range of definitions varying in the type and number of parameters evaluated by the respective assays which

have to be fullfilled by a given compound/drug candidate. An appropriate criterium for a compound/drug candidate with insulin-like activity may represent that it exerts at least 20% of the maximal insulin response in at least three major metabolic insulin actions (e. g. glucose transport, lipogenesis, anti-lipolysis) in at least one insulin target cell/tissue. However, the final judgement of a compound/drug candidate as being appropriate for further evaluation and development has to rely on the complete data set of its profiling in many metabolic and signaling assays rather than to stick to the fullfillment of fixed criteria for one or a few parameters.

K.6.1 Assays for Insulin and Insulin-Like Activity Based on Adipocytes

K.6.1.1 Differentiation

PURPOSE AND RATIONALE

The increase in obesity and the identification of adipocyte-secreted proteins that regulate energy metabolism (Drevon 2005) have generated huge interest in adipocyte biology. Adipocytes are the primary storage site for energy in vertebrate animals. During fasting, adipocytes release energy-rich molecules that provide metabolic fuels to other tissues. Adipocytes also secrete hormones that orchestrate the storage, release, and oxidation of energy-rich molecules throughout the body and that control behavior, including feeding (Rajala and Scherer 2003). Insulin as anabolic hormone is of critical importance for the differentiation of adipocytes in humans. Consequently, assays that monitor the quantitative analysis of adipocyte differentiation may be helpful for studying the effects of insulin/compounds/drugs on pathways which are engaged both directly in the regulation of the differentiation and in the molecular mechanisms of metabolic insulin action.

PROCEDURE

Understanding the molecular mechanism underlying adipocyte differentiation has been one of the major focuses of many researchers in the field of metabolic disorders. Methods in use for the assessment of fat cell development and maturation after initiation of adipogenesis in cell culture include microscopic examination of cellular LD formation and cellular lipid staining by Oil Red O (von Goor et al. 1986). These methods, although excellent in detecting the presence of intracellular lipid, are ineffective in objectively quantifying the degree of fat accumulation if not used in conjunction with other extraction and analytic systems. Particularly, during the process of adipogenesis of preadipocytes, it is observable that cells are heterogeneous in their response to adipogenic agents in terms of speed of adipogenic conversion and degree of fat accumulation (Shigematsu et al. 2001). This heterogeneity of response may cause difficulties when evaluating and comparing the effects of several treatments that target only fat cells of certain status due to the masking influence of those non-targeted cells. Thus, an effective method to detect and classify cells with similar fat content will certainly increase analytical precision in monitoring fat cell development and the ability to quantify the effects of therapeutic agents. Currently, flow cytometry and fluorescence-activated cell sorters (FACSs) are extensively used in the analysis of adipocyte differentiation and lipid accumulation as well as their modulation by compounds/drugs as is exemplified best by the study from Lee and coworkers (2004).

EVALUATION

A simple and sensitive method to detect and quantify lipid accumulation inside cells by flow cytometry has been introduced (Lee et al. 2004). Using this method, elevated levels of cytoplasmic granularity can be detected that correlate well with an increased level of lipid accumulated inside cells after adipogenic conversion. Furthermore, this method is appropriate to monitor and quantify adipose cell maturation within a complex population of cells and to identify and collect the adipose cells with similar lipid storage for further analysis. Flow cytometry offers distinct advantages over existing detection systems for cytoplasmic lipid staining and lipid extraction and can represent a powerful analytical tool to monitor the effect of chemicals and biological molecules, including compounds and putative anti-obesity drugs on adipose cell conversion and maturation. Moreover, in combination with a cell sorting facility, this method offers a simple and efficient means of collecting adipose cells of specific status for further analysis. In conclusion, flow cytometry enables the direct measurement of the lipid content of specific cells in a complex population of adipose cells. Not only is the system simple, sensitive, and quantitative, but it also offers an advantage over the existing methodology, with its capability of monitoring the degree of intracellular lipid accumulation in a precise, fast, and selective manner. These results provide a basis for developing a variety of applications in com-

pound and drug screening procedures to monitor adipose cell development.

K.6.1.2 Lipogenesis

GENERAL CONSIDERATIONS

Lipogenesis encompasses the complete biosynthetic pathways for TAG stored in cytoplasmic LD and phospholipids building up the internal and plasma membranes (including their lipidic intermediary and degradation products). The type as well as the concentration of the labeled precursor (e. g. glucose, fatty acids) whose conversion or incorporation into TAG and phospholipids is followed determines which step(s) of the lipogenic pathway is monitored by the lipogenesis assay (e. g. glucose transport, acylation). Thus, simple variations of the assay conditions allow the selective analysis of individual rate-limiting steps of lipogenesis and their modulation by compounds/drug candidates.

K.6.1.2.1 Method Based on the Incorporation of Radiolabeled Glucose

PURPOSE AND RATIONALE

This assay measures the complete pathway of lipid synthesis (lipogenesis) encompassing the transport of the radiolabelelled glucose across the plasma membrane of the adipocytes, its conversion into glycerol and/or fatty acids and their subsequent esterification into predominantly neutral TAG and phospholipids and finally the deposition of TAG in LD in the cytoplasm of the adipocytes. Since in adipocytes each of these steps is stimulated by insulin, albeit to varying degrees, the lipogenesis assay is perfectly suited for the analysis of effects of compounds/drugs on the complex insulin signaling cascade regulating lipogenesis. Dependent on the experimental conditions chosen (i. e. low or high glucose), the assay monitors predominantly the effect of insulin/compound/drug on glucose transport or on the subsequent esterification. At low glucose concentrations (up to 0.1 mM glucose), when according to TLC-analysis of the total TAG after enzymatic digestion the majority of the radiolabel is incorporated into the glycerol backbone, the glucose transport step is rate-limiting and monitored. In contrast, at higher glucose concentrations (above 2 mM), when two thirds of the radiolabel are recovered with the fatty acid moieties of TAG, the rate-limiting and monitored step is the esterification rather than glucose transport, which is driven by mass action. Since in adipocytes the insulin stimulation of glucose transport is significantly more pronounced than that of esterification, the lipogenesis assay performed at low glucose concentration (< 0.1 mM glucose) exhibits the highest insulin responsiveness whereas at intermediary glucose concentrations (0.1–2 mM), it represents a compromise for the measurement of both transport and esterification with intermediary insulin responsiveness and at high glucose concentrations (> 2 mM glucose) it predominantly monitores the esterification with lowest insulin responsiveness.

PROCEDURE

For measurement of lipogenesis monitoring effects on both glucose transport and esterification, isolated rat adipocytes are incubated with D-[^{3}H]glucose (0.55 mM final concentration, 0.1–1 μCi). The cells are lysed and the total lipids separated from water-soluble products and the incubation medium including the unincorporated [^{3}H]glucose by addition of toluene-based scintillation cocktail. After phase separation, radioactivity incorporated into total lipids/phospholipids is determined by liquid scintillation counting directly without removal of the lipid phase based on determination of the radiolabel of the lipidic products partitioned into the toluene phase containing the scintillator rather than of the [^{3}H]glucose left in the aqueous phase lacking scintillator (Moody et al. 1974).

The reaction is started by the transfer of 0.2 ml of adipocyte suspension (3.5×10^5 cells/ml) in KRHB to scintillation vials containing 0.1 ml of [3-^{3}H]glucose (2 μCi/ml, 4.4 mM), 0.4 ml of 2-fold KRHB and 0.3 ml of insulin or compound/drug with insulin-mimetic activity dissolved in vehicle (e. g. DMSO) and diluted with KRHB to the appropriate concentration of compound and vehicle (e. g. 3% DMSO). The scintillation vials are placed under a stream of carbogen for 10 s, then closed and placed in a very slowly shaking water bath (37°C). After incubation for 90 min, the reaction is terminated by the addition of 10 ml of toluene-based scintillation cocktail. The vials are mixed rigorously using a vortexer and subsequently left standing for 2–4 h to allow phase separation. The ^{3}H-radioactivity is determined with a liquid scintillation counter.

EVALUATION

Blank values obtained from a typical reaction mixture containing buffer and [3-^{3}H]glucose but lacking either adipocytes or compound/drug/insulin have to be included in each experiment. Since the quality of the cells decreases with time (resulting in increased lipogenesis in the basal state), it is recommended to

set up 2 basal incubations for every 20–25 test mixtures. In addition, for direct comparisons (e. g. of insulin analogs) incubations with identical (insulin) concentrations should be performed immediately for one agent (insulin) after the other rather than with the complete concentration series for one agent (insulin) after the other. This procedure allows the resolution of potency differences of less than 10% between two insulin analogs as reflected in corresponding shifts of the apparent EC_{50}-values with identical maximal responses. The blank values lacking adipocytes (usually 500–600 dpm) are subtracted from the values measured for the corresponding set of test mixtures containing adipocytes to correct for ^{3}H-radiation originating from the aqueous phase (i. e. [^{3}H]glucose left in the incubation medium). Fold stimulations reflecting the responsiveness of the glucose transport and/or esterification systems of the adipocytes toward insulin/compound/drug are calculated as ratio between the corrected test values (presence of insulin/compound/drug) and basal values (absence of insulin/compound/drug). Typically, insulin induces 15- to 20-fold, 8- to 12-fold and 2.5- to 4-fold stimulations in lipogenesis at 50 µM, 0.55 mM and 2 mM glucose, respectively. Due to the very limited number of pipetting steps (with the most critical one being the transfer of an equal number of cells to each assay mixture), the standard deviations are rather low. Usually, 2–4 measurements per data point are sufficient.

An insulin-concentration/response curve should be performed for each experiment to test the insulin sensitivity and responsiveness (and thus the quality) of the adipocytes prepared. Appropriate insulin concentrations are 0.01, 0.02, 0.04, 0.06, 0.08, 0.1, 0,12, 0.15, 0.2, 0.5, 1, 5 nM (final concentration in the assay). Typically, the EC_{50} for human insulin is 0.06–0.10 nM. The insulin-like activity of compounds/drugs can be expressed as % of the maximal insulin stimulation (that is as the ratio between the fold stimulation provoked by the compounds/drugs with insulin-like activity at the maximally effective concentration and that induced by 5 nM insulin) to correct for the varying quality (i. e. insulin responsiveness) of the cells from different preparations.

K.6.1.2.2 Method Based on the Incorporation of a Fluorescent Fatty Acid Analog

PURPOSE AND RATIONALE

Usually lipogenesis is studied by the incorporation of radiolabeled glucose into toluene-extractable acylglycerols in the presence of glucose at concentrations below 2 mM (see above). Under these conditions glucose transport and, in consequence, supply of glycerol-3-phosphate is rate-limiting. For uncoupling of glucose transport/glycerol-3-phosphate synthesis from (re)esterification, lipogenesis has to be performed in the presence of high glucose. To circumvent analysis of lipogenesis at high glucose (> 2 mM) by (radio)labeling the glycerol moiety of TAG, which necessitates the application of glucose of high specific radioactivity, a fluorescent fatty acid analog can be used for its insulin-sensitive incorporation into TAG in isolated rat adipocytes.

Several recent reports suggest that the fluorescent fatty acid derivative, NBD-stearate, behaves like naturally occurring fatty acids, since it has been shown to enter rat hepatocytes by the same uptake mechanism as that described for unmodified fatty acids (Elsing et al. 1995, Storch et al. 1995). Furthermore, measurement of the uptake of a fluorescent long-chain fatty acid derivative into COS7 cells transfected with a 3T3-L1 adipocyte cDNA library led to the identification of fatty acyl-CoA synthetase and a putative fatty acid transport protein (Schaffer and Lodish 1994). Recently the efficient incorporation of NBD-FA, 12-((7-nitrobenz-2-oxa-1,3-diazol-4-yl)amino)dodecanoic acid, into mono- and diacylglycerol(-3-phosphate) in isolated rat adipocytes and its significant stimulation by insulin has been reported by Müller and coworkers (1997).

PROCEDURE

Incubation of the Adipocytes

200 µl of adipocyte suspension is supplemented with 190 µl of KRHB containing 0.1/2 mM glucose (= KRHBlow/KRHBhigh) and 10 µl of an insulin solution (routinely 200 nM) or compound/drug candidate (routinely 200 µM in 20% DMSO) and incubated for 15 min at 37°C in a slowly shaking water bath. The assay is started by the addition of 50 µl of 0.9 mM NBD-FA (prepared daily from a 100 mM stock solution in ethanol by dilution with KRHBlow/KRHBhigh under mild heating). After incubation at 37°C under mild shaking (stage 11, thermomixer, Eppendorff) for 90 min, lipogenesis is terminated by filtration of the total mixtures over GF/C-filters under vacuum. The filters are rapidly washed three times with 1 ml of KRHBlow/KRHBhigh each, placed in 20-ml plastic scintillation vials and extracted with 400 µl THF for 15 min under rigorous shaking. 300 µl of the extract is transferred into new tubes and centrifuged (15,000 × *g*, 5 min). The supernatant is dried (SpeedVac) and sus-

pended in 50 µl THF. 5-µl samples are analysed by TLC on silica gel Si-60 plates using 78 ml diethyl ether, 22 ml petrol ether, 1 ml acetic acid as solvent system. Fluorescent lipid products on the dried plates are visualized under UV (312 nM) and photographed (Polaroid CU5). The amount of acylglycerols (AG) is determined by fluorescence scanning with excitation at 342 nm and emission at 505 nm or fluorescence imaging with excitation at 460 nm and emission at 540–560 nm. The relative peak area of each lipid product minus a background value (derived from an equal-sized region of the TLC plate which does not contain any lipid product) is calculated as arb. units.

Characterization of the Fluorescent Lipids

For elucidation of the type of lipid(s), the synthesis of which is stimulated by insulin/compound/drug, the fluorescently labeled lipids are analyzed. This enables the characterization of the signaling and enzymatic steps preferentially activated during stimulus-induced lipogenesis. For this, adipocytes are labeled with 0.5 mM NBD-FA for 4 h at 37°C. Total lipids are extracted from the washed cells with chloroform/methanol (3/1 by vol.), dried and suspended in THF. NBD-fatty acylglycerol-3-phosphate, NBD-fatty acyl-palmitoylglycerol-3-phosphate and NBD-fatty acyl-palmitoylglycerol and NBD-fatty acyl-dipalmitoylglycerol are separated by TLC (Silica Gel Si-60 F_{254}) using toluene/ethylacetate (9/1 by vol.) as solvent system and subsequently eluted from the plate using the line elution method with ethylacetate as eluent. Larger amounts are separated by flash column chromatography (Still et al. 1978) on YMC-spherical silica (60 A, 40 µM, YMC Europe GmbH, Schermbeck).

EVALUATION

The nitrobenzyldiazolyl (NBD) moiety of NBD-FA is a strong fluorophore and is located far away from the carboxyl terminus. Furthermore, the apparent overall length of NBD-FA (carbon backbone including NBD moiety) is comparable to palmitic acid. It has been shown that insulin stimulation of the synthesis of the three lipid species harboring one NBD-fatty acyl residue each, in isolated rat adipocytes, closely resembles that of radioactive labeling of total lipids by [3-^{3}H]glucose with regard to both insulin responsiveness and sensitivity. The data available suggest that incorporation of one residue of NBD-FA into glycerol-3-phosphate blocks further acylation, resulting in the accumulation of mono-NBD-fatty-acylglycerol-3-phosphate, NBD-fatty-acylpalmitoylglycerol-3-phosphate and NBD-fatty-acylpalmitoylglycerol rather than of NBD-fatty acyl-dipalmitoylglycerol. One possibility is a stringent substrate specificity of diacylglycerol transferase (DGAT), for both the acceptor, diacylglycerol, and the donor acyl-CoA.

Stimulation of the rate-limiting enzyme of the esterification steps, GPAT, by insulin has been well established (Sooranna and Saggerson 1976, Vila and Farese 1991, Farese et al. 1994). It is generally accepted that in rat adipocytes the glucose transport step is rate-limiting for insulin-stimulated lipogenesis in the presence of 0.1 mM glucose in the incubation medium (see above). Thus under these conditions, the stimulation of synthesis of these AG by insulin may mainly reflect the effect of insulin on glucose transport. At 2 mM glucose, however, processes subsequent to glucose transport and glycerol-3-phosphate production will become rate-limiting. Both transport and esterification may be studied more conveniently using incorporation of NBD-FA rather than of [3-^{3}H]glucose into lipids (see K.6.1.2.1), in particular under conditions of screening for compounds/drug candidates. Thus, assaying lipogenesis with NBD-FA can be used as a sensitive and reliable (non-radioactive) method for analyzing insulin signaling and lipid synthesis in rat adipocytes, in particular, if there is interest on the impact of high glucose concentrations in the incubation medium (and thus of conditions of insulin resistance; see K.6.3.5) on these processes.

K.6.1.3 Glucose Transport

GENERAL CONSIDERATIONS

Glucose transport is generally assumed to represent the rate-limiting step for lipogenesis in adipose tissue *in vivo* and in adipocytes *in vitro*, at least under conditions of low to moderate concentrations of glucose in the plasma and incubation medium, respectively (see above). Its stimulation by insulin is of exquisite sensitivity and responsiveness. Insulin resistance is defined as the reduced ability of cells or tissues to respond to physiological levels of insulin and is characteristic of non-insulin-dependent diabetes mellitus (type II diabetes). Skeletal muscle is the primary tissue responsible for the postprandial uptake of glucose from the blood in humans. The two major transporters expressed in adipose tissue/skeletal muscle are the muscle/fat-specific glucose transporter GLUT4 and the ubiquitous transporter GLUT1. The insulin-stimulated acute activation of glucose transport mainly occurs by one of two mechanisms: translocation of GLUT4 and GLUT1 from intracellular vesicles to the

plasma membrane and augmentation of the intrinsic catalytic activities of the transporters. The molecular mechanisms underlying the glucose transport and its regulation are similar for adipose and muscle cells. Consequently, adipocytes are more widely used for transport studies than myocytes due to their more convenient accessibility and more pronounced insulin responsiveness. However, studies for clarification of the mechanism by which compounds/drugs with insulin-ike and/or insulin-sensitizing activity stimulate glucose uptake in skeletal muscle for the treatment of type II diabetes have to be performed with assay systems based on muscle cells or tissues. When differentiated into myotubes, cultured L6 muscle cells possess many of the properties of mature skeletal muscle tissue. They express both GLUT4 and GLUT1 and are capable of increasing glucose transport *via* insulin stimulation.

PURPOSE AND RATIONALE

Uptake of glucose in cultured cells is commonly determined by using non-metabolizable radioactive hexoses, such as 3-*O*-methylglucose (3MG) or 2-deoxyglucose (2DG), labeled with a high specific activity of tritium. [^{3}H]3MG necessitates a very short incubation time due to fast equilibration of the analog across plasma membranes and requires either rapid separation of the cells from the aqueous incubation medium of the reaction mixture, usually by centrifugation through a suitable oil cushion with a buoyant density of less than 1, or the prevention of 3MG efflux by washing with a mercuric chloride solution. Uptake assays based on [^{3}H]2DG are more convenient because 2DG is phosphorylated to a stable and membrane-impermeable derivative, 2-deoxyglucose-6-phosphate (2DG6P), by hexokinase or glucokinase, which may accumulate at a specific intracellular compartment, ensuring less rapid equilibration, slower kinetics and more convenient measurement of 2DG transport compared to 3MG (Frost and Lane 1985). However, routine use of these radiolabeled analogs is costly and requires a specialized institution where isotopes can be handled. Consequently, considerable efforts have been spent during the last decade in the development of assays using non-radioactive tracers, which are compatible with the analysis of glucose transport with sufficient insulin responsiveness.

K.6.1.3.1 Method Based on Radiolabeled 2-Deoxyglucose

Isolated Tissues

[2-^{3}H]2DG (12 mCi/mouse) is injected i.p. into mice fasted for 6 h. After 40 min, mice are sacrificed and tissues are excised and rinsed in ice-cold PBS, 1 mM EDTA. Tissue samples are homogenized in 0.5% perchloric acid and centrifuged. The protein pellet is solubilized in 0.3 N NaOH, 0.1% SDS for protein determination. The supernatant is neutralized with KOH and an aliquot is counted to yield total tissue counts (2DG and 2DGP). A second aliquot is treated with $Ba(OH)_2$ and $ZnSO_4$ to remove 2DGP and counted to yield [2-^{3}H]2DG. Specific [2-^{3}H]2DGP accumulation in itssues is calculated as difference between total tissue counts and [2-^{3}H]2DG counts.

Primary and Cultured Adipocytes

50-µl portions of adipocyte cell suspension (1×10^6 cells/ml) are pipetted into minisorp tubes (Nunc, Denmark) and equilibrated at 25°C for 30 min. Insulin (80 nM stock in KRH/5% BSA) and compounds/drugs (lyophilized, 2 mg/ml or 2% DMSO, 30 µM) are added in 50 µl KRHB and incubated for 30 min at 25°C. Thereafter, 50 µl of 2-deoxy-D-[1-^{3}H]glucose (2 µCi per ml of KRHB containing 10 µl/ml of ^{3}H-stock, 0.2 mCi/ml specific activity 20–30 Ci/mmol, 0.3 mM) are added (total volume of the final incubation mixture = 150 µl). After further incubation for 20 min at 25°C in a shaking water bath, the assay is terminated by transfer of 100 µl samples on top of 250 µl dinonylphthalate (density < 0.93–0.96 g/ml, Merck, Darmstadt, FRG) in 500-µl plastic tubes (Beckman) and centrifugation in a microfuge (10,000 × *g*, 1 min, room temperature). The adipocytes remain on top of the oil layer, while the buffer is below the oil layer. The tube is cut with a special knife at the position of the oil layer below the adipocyte layer, then transferred into scintillation vials containing 5 ml aqueous scintillation cocktail (Zinsser Nr. 312 or Beckman Ready Safe) and counted for radioactivity. To correct for 2DG unspecifically associated with the adipocyte plasma membrane or entrapped in extracellular spaces or penetrated into the adipocytes by diffusion, 2 µl of cytochalasin B (20 µM final conc.) from a 1 mM stock solution (in 10% ethanol, diluted with H_2O from a 10 mM stock in ethanol at the day of use) and, as a control, 2 µl of 10% ethanol are added prior to addition of radiolabeled 2DG and incubated under identical conditions (Gliemann et al. 1972, Foley and Gliemann 1981, Müller and Wied 1993).

EVALUATION

Specific transport is calculated as the difference between total cell-associated radioactivity (absence of cytochalasin B) and unspecifically associated/

entrapped radioactivity (presence of cytochalasin B). Under the conditions used, 2DG transport is linear with time up to 20 min. The fold stimulation for glucose transport is calculated as ratio between stimulated specific transport (presence of insulin/compound/drug) and basal specific transport (absence of insulin/compound/drug). For insulin (2 nM), this stimulation factor usually lies in the range between 15 and 25. To compensate for the varying insulin responsiveness of different adipocyte preparations, the insulin-like activity of compounds/drugs can be calculated as percentage of the maximal effect as described above for lipogenesis.

This assay measures the total glucose uptake encompassing the transport of the non-metabolizable glucose analog, 2DG, *via* the specific glucose transporters, GLUT1 and GLUT4, and the molecular mechanism of their movement from intracellular vesicles to the plasma membrane (GLUT translocation) including the underlying signaling cascade through which insulin stimulates glucose transport in adipocytes. Since 2DG taken up the cell is immediately phosphorylated by hexokinase, the assay actually monitors the accumulation of 2DG6P (presumably in specialized intracellular compartments). However, the rate-limiting step of glucose uptake at low glucose concentrations is the transport *via* GLUT1/4 rather than the phosphorylation. This results in apparently longer linear periods of glucose uptake in comparison to the use of non-phosphorylatable glucose analogs, such as 3MG (see K.6.1.3.3) and thereby considerably facilitates the experimental procedure and kinetic analysis. Subsequent conversion of the 2DG6P into lipids and glycogen or its oxidation does not occur. Thus, the use of 2DG is a reliable measure for glucose transport into adipocytes.

K.6.1.3.2 Method Based on Unlabeled 2-Deoxyglucose

PURPOSE AND RATIONALE

A non-radioisotope, enzymatic assay based on the methods of Manchester and coworkers (1990) and Sasson and coworkers (1993) for measuring of 2-deoxyglucose-6-phosphate (2DG6P) in tissues and cultured cells has been developed by Yamamoto and coworkers (2006). These methods enable the detection of 2DG6P accumulating in cells by measurement of the fluorescence of NADPH produced from $NADP^+$, which is coupled to the oxidation of 2DG to 2DG6P by glucose-6-phosphate dehydrogenase (G6PDH). This approach, however, requires the cultivation of many cells on large plates and the preparation of cell extracts because the fluorescence of NADPH is rather weak. Consequently and more recently, a diaphorase–resazurin system that produces a potent fluorescent substance in the presence of NADPH has been linked. Uptake of 2DG into the cells can be measured by the addition of a single assay solution to the cell culture, followed by a simple incubation.

PROCEDURE

The differentiated 3T3-L1 adipocytes or L6 myotubes are incubated with 170 µl/well of α-MEM with 2% FBS in the presence of compounds/drugs/insulin for 10–30 min. After incubation, the cells are washed twice with Krebs–Ringer–phosphate–Hepes (KRPH) buffer (pH 7.4, 20 mM HEPES, 5 mM KH_2PO_4, 1 mM $MgSO_4$, 1 mM $CaCl_2$, 136 mM NaCl, 4.7 mM KCl) containing 0.1% BSA. The washed cells are then incubated with KRPH buffer containing 1 mM 2DG and 0.1% BSA for 1–2 h (termed the 2DG-uptake period) at 37°C in 95% O_2/5% CO_2. After incubation, the cells are washed twice with KRPH buffer containing 0.1% BSA and then 25 µl of 0.1 N NaOH was added. To degrade NAD(P)H, $NAD(P)^+$ and any enzymes in the cells, the culture plate is subjected to one freeze–thaw cycle and incubated at 85°C for 40 min on a temperature-controlled bath. The components in the wells are then neutralized by the addition of 25 µl of 0.1 N HCl and then 25 µl of 150 mM triethanolamine (pH 8.1) is added.

To determine the low concentrations of 2DG and/or 2DG6P present in a 96-well microplate, a diaphorase–NADPH amplifying system is combined with previous methods (Sasson et al. 1993, Manchester et al. 1990) for measuring 2DG6P in tissues and cultured cells. 50 µl of 2DG solution at various concentrations is dispensed into each well of a 96-well plate and incubated for 90 min at 37°C after the addition of 150 µl of an assay cocktail of 50 mM triethanolamine (pH 8.1), 50 mM KCl, 0.5 mM $MgCl_2$, 0.02% BSA, 670 µM ATP, 0.12 µM $NADP^+$, 25 µM resazurin sodium salt, 5.5 units/ml hexokinase, 16 units/ml G6PDH, and 1 unit/ml diaphorase. The assay cocktail is prepared before each assay from stock solutions of enzyme, coenzyme, and substrate that are maintained in the freezer or refrigerator. At the end of the incubation, fluorescence at 590 nm with excitation at 530 nm is measured by a microplate reader to detect the resorufin derived from reduced resazurin. A standard curve is generated by placing 2DG standard solutions in wells of the culture plate that had been prepared without cells.

EVALUATION

Glucose uptake in cultured cells is routinely determined by using non-metabolizable radioactive hexoses, such as 3MG or 2DG, labeled with a high specific activity of tritium. Assaying the uptake of [^{3}H]2DG is more convenient than assaying the uptake of [^{3}H]3MG because 2DG is converted to a stable and impermeable derivative 2DG6P through phosphorylation by hexokinase or glucokinase (see above). Because both methods rely on the use of substantial amounts of radioactive material, the concentration of the unlabeled analog is usually kept low (50–500 µM) in the uptake mixture to maintain a high specific activity. Measuring the uptake of these analogs at concentrations comparable to normal or pathological blood glucose levels (5–10 mM) is not practical because of the excessive amount of radioactive analog that would be required to maintain a specific activity high enough to obtain reliable data. Furthermore, the high concentration of analog needed is very expensive and a specialized institution registered for using radioactive isotopes is required. Although new fluorescently labeled glucose analogs for use as tracers of glucose uptake have been synthesized, none of these molecules has been found to show the same biological behavior as 2DG (Perret et al. 2004). Therefore, 2DG is often considered to be the gold standard in reference tracers of glucose transport and phosphorylation.

The resazurin–diaphorase-amplifying system facilitates the measurement of NADPH in the 2DG uptake assay, because the resorufin fluorophore produced is water-soluble and has high fluorescence intensity. In addition, there will be little background interference from other biochemical entities in the cell or from chemical compounds/drugs added during the assay because the emission wavelength of resorufin is longer and its fluorescence wavelength is much longer than those of NADPH. Furthermore, analysis of resorufin can be measured on standard, clear tissue-culture plates because the material comprising the culture plate, such as polystyrene, does not interfere with the fluorescence signal of resorufin.

K.6.1.3.3 Method Based on 3-*O*-Methylglucose

The rate of 3MG transport is determined according to Whitesell and Gliemann (1979), Karnieli and coworkers (1981), Basi and coworkers (1992) by a modification of the L-arabinose uptake method described by Foley and coworkers (1978).

PROCEDURE

5-ml polyethylene miniscintillation vials are prepared with 50 µl of incubation medium containing L-[1-^{3}H]glucose and 3-*O*-[methyl-^{14}C]glucose such that their concentration is 0.5 mM (58.2 and 11.6 µCi/µmol, respectively). L-Glucose is included as a marker for the extracellular space. Sugar uptake is initiated by the rapid addition of 200 µl of adipose cell suspension (2×10^8 cell/ml) and then rapidly stopped by the addition of 10 µl of a 10 mM solution of cytochalasin B in 25% ethyl alcohol. The duration of this 'pulse' incubation is adjusted from 3 to 25 s so that the uptake achieved will be approximately one third of the equilibrium level. The equilibrium level of uptake is determined by incubating cells for 5 to 6 min in the presence of 3MG only and then for one additional min following the addition of L-glucose. Experimental blanks are obtained by adding cytochalasin B to the labeled sugar solution prior to the addition of cells. Following incubation, two 100-µl portions of each incubation mixture are separated from the incubation medium by centrifugation through dinonylphthalate, and the separated cells are counted for radioactivity (see above for 2DG transport). The net uptake of 3MG is then counted, and the initial uptake velocity or rate of transport is determined.

EVALUATION

3MG is a non-phosphorylatable glucose analog which can be used for the accurate measurement of the true initial glucose transport rate without interference with the subsequent glucose-metabolizing steps (e. g. phosphorylation to glucose-6-phosphate). Since the volume of the adipocyte cytosol is rather small, the time period required for equilibration of the extracellular and intracellular glucose concentration is rather short. This necessitates sophisticated experimental procedures enabling start and termination of the transport reaction within a few seconds. Therefore, for routine purposes 2DG rather than 3MG is commonly preferred.

K.6.1.3.4 Method Based on a Fluorescent Glucose Analog

Zou and coworkers (2005) described a sensitive and non-radioactive assay for direct and rapid measuring glucose transport in single living cells. The assay is based on direct incubation of mammalian cells with a fluorescent D-glucose analog, 2-[*N*-(7-nitrobenz-2-oxa-1,3-diazol-4-yl)amino]-2-deoxy-D-glucose (2-NBDG) followed by flow cytometric detection of total fluorescence produced by the cells due to accumu-

lation of 2-NBDG-6-phosphate with time. However, despite a series of experiments has been conducted to define the optimal conditions for this assay, Zou and coworkers (2005) failed to demonstrate a clear-cut stimulation of 2-NBDG transport into these cells by insulin.

K.6.1.4 Glucose Transporter Translocation

PURPOSE AND RATIONALE

The transport of glucose across the plasma membrane of mammalian cells represents one of the most important nutrient transport events, since glucose plays a central role in cellular energy homeostasis and intermediary metabolism. Apparently, rather than mediated by a single transporter molecule, glucose transport is mediated by a family of highly related transporters characterized by 12 transmembrane regions and amino-/carboxy-termini facing the cytoplasm (Assimacopoulos-Jeannet et al. 1991, Gould and Holman 1993, Mueckler 1994), the most important ones with regard to carbohydrate metabolism and regulation by insulin are:

GLUT1: the erythrocyte-type glucose transporter,

GLUT2: the liver-type glucose transporter,

GLUT3: the brain-type glucose transporter,

GLUT4: the insulin-responsive glucose transporter

GLUT5: the small intestine sugar/fructose transporter

GLUT8: a small intestine/hypothalamic glucose sensor and ion channel lacking a transport function

Among these isoforms, the insulin-responsive GLUT4 is the only one, which is expressed in mammalian muscle and adipose tissue, exclusively, and localized in cytoplasmic vesicles (GLUT4 vesicles) derived from the tubulo-vesicular structures of the trans-Golgi network in the unstimulated state. In animal and human adipose and muscle tissues insulin induces several-fold increases in glucose transport by causing the movement and fusion of GLUT4 vesicles to and with the plasma membrane, respectively. This so-called GLUT4 translocation leads to increase in the number of GLUT4 molecules exposed at the plasma membrane which results in elevated glucose transport velocity (i. e. increase in v_{max}). Numerous cellular, animal and human studies have revealed significant impairment of GLUT4 translocation in the insulin-resistant and diabetic state. The molecular basis remains unclear so far but may include alterations in the complex machinery regulating the targeting, docking and fusion of the GLUT4 vesicles as well as in the phosphorylation of protein (SNARE) components involved (see below). This is suggested by the findings that GLUT4 is inactivated by phosphorylation in the insulin-resistant state and activated by dephosphorylation (Reusch et al. 1993) and that the phosphorylation state of GLUT4 is increased in primary rat adipocytes made insulin-resistant *in vitro* by incubation with high glucose and insulin (Müller and Wied 1993, see K.5.1.3).

K.6.1.4.1 Methods Based on the Determination of GLUT Molecules in Isolated Plasma Membranes

GENERAL CONSIDERATIONS

The insulin-stimulated GLUT4 translocation in adipocytes can be assayed by a number of different procedures either dependent on or independent of subcellular fractionation, i. e. the preparation of plasma membranes of high purity. This admittedly tedious and time-consuming procedure is prerequisite for the majority of techniques appropriate for the analysis of cell surface expression of GLUT4 (and thus reflecting GLUT4 translocation) in primary rat adipocytes, which had been challenged with insulin/compounds/drugs. These techniques rely on the determination of the amount of immunoreactive GLUT4 by immunoblotting with the recently introduced specific anti-GLUT4 antibodies in isolated and sufficiently pure plasma membrane vesicles. Alternatively, radioactively or fluorescently labeled glucose analogs which are recognized but not transported by GLUT4 can be used for determination of the number of GLUT4 at the plasma membrane of intact rat adipocytes upon covalent crosslinking (see K.6.1.4.2.3). In contrast, in cultured murine or human adipocytes GLUT4 translocation can be followed upon transfection with a recombinant GLUT4 which is tagged with an extracellular epitope recognized by a specific antibody thereby circumventing the necessity for subcellular fractionation or covalent crosslinking (see K.6.1.4.1.2 and K.6.1.4.2).

Preparation of Rat Adipocyte Plasma Membrane Vesicles

Adipocytes are isolated from epididymal fat pads of 160–180 g male Wistar rats by collagenase digestion under sterile conditions and incubated with insulin or compounds/drugs as described (see K.5.1.2). The subcellular fractionation is performed according to McKeel and Jarett (1970) and Simpson and coworkers (1983) with the following modifications: The postnuclear supernatant is centrifuged (12,000 × *g*, 15 min). The washed pellet is suspended in 35 ml of buffer and recentrifuged (1000 × *g*, 10 min). The washed pellet (12,000 × *g*, 20 min) is suspended in 5 ml of buffer, layered onto a 20 ml cushion of 38% (w/v) sucrose, 20 mM Tris/HCl (pH 7.4), 1 mM EDTA and centrifuged (110,000 × *g*, 60 min, 4°C). The membranes at the interface between the two layers (1 ml) are removed by suction, diluted with three volumes of buffer and layered on top of a 8 ml cushion of 24% Percoll, 250 mM sucrose, 20 mM Tris/HCl (pH 7.4), 1 mM EDTA. After centrifugation (45,000 × *g*, 30 min) the plasma membranes are withdrawn with a Pasteur pipette from the lower fourth of the gradient (1 ml), diluted with 10 volumes of buffer and recentrifuged (150,000 × *g*, 90 min, 4°C). The pellet is suspended, recentrifuged, finally dissolved in buffer at 2–5 mg protein/ml and stored at –80°C. The majority of plasma membranes are recovered as outside-out vesicles as revealed by the low cryptic activity of exofacial 5′-nucleotidase which is detected after detergent solubilization of the vesicles.

K.6.1.4.1.1 Determination by Immunoblotting

The methods described above lost their importance with the introduction of antibodies specific for GLUT4 representing the major (insulin-)regulated GLUT isoform which accounts for more than 90% of the max-

imal insulin-stimulated glucose transport activity in primary rat adipocytes and is localized in the basal state almost exclusively (95%) at intracellular vesicles and in the maximally stimulated state with 50% at the plasma membrane. Consequently, the amount of GLUT4 in plasma membrane vesicles derived from basal and stimulated (by insulin/compound/drug) rat adipocytes is now usually determined by immunoblotting for GLUT4. In case of weak expression of GLUT4 (e. g. cultured human adipocytes) or limited availability of starting materials (e. g. human adipose tissue), the sensitivity of the immunological detection can be considerably improved by immunoprecipitation of GLUT4 from the solubilized plasma membrane vesicles prior to immunoblotting.

Polyclonal affinity-purified rabbit antibodies have bee successfully raised against a synthetic peptide corresponding to the COOH-terminal domain of rat GLUT4 (residues 495–509) (James et al. 1989). The plasma membrane vesicles are subjected to SDS-PAGE (25 µg protein/lane) and electrophoretically transferred onto nitrocellulose filters (Towbin et al. 1979). Incubations of the filters with primary and secondary antibodies (^{125}I-labeled or peroxidase-labeled anti-rabbit IgG from goat) and quantitative evaluation of the immunoreactive material by autoradiography and densitometry or enhanced chemiluminescence and luminescence imaging, respectively, are carried out as described previously (Müller and Wied 1993) for the demonstration of the sulfonylurea-induced GLUT4 translocation in isolated rat adipocytes, which may be based on phosphorylation of GLUT4. Evidence has been presented suggested that insulin promotes serine phosphorylation of GLUT4 at the carboxyl terminus (Lawrence et al. 1990a, b) arguing for a causal relationship between GLUT4 translocation and phosphorylation in response to insulin and insulin-like acting sulfonylureas, such as glimepiride.

K.6.1.4.1.2 Determination of GLUT Molecules in Plasma Membrane "Sheets"

PURPOSE AND RATIONALE

In non-recombinant adherent murine and human adipocytes as well as non-adherent primary adipocytes which express endogenous GLUT4, only, its translocation can be monitored by the plasma membrane "sheet" assay. This is based on placing glass coverslips onto the adherent cells (6- or 12-well culture plates) following incubation with insulin/compounds/drugs. Upon removal of the coverslips the adherent cells are sheared and their plasma membranes attached to the coverslip become disrupted, leaving the cytosolic components and the intracellular particulate materials (including the intracellular GLUT4 vesicles) with the medium of the plate. Subsequent immunofluorescent detection of GLUT4 remaining attached to the coverslips enables the semi-quantitative determination of GLUT4 located at the plasma membrane and apparently deprived from intracellular GLUT4.

PROCEDURE

The protocol for the preparation of plasma membrane sheets is derived from that of Moore and coworkers (1987) with modifications adapted from Robinson and coworkers (1992) and Fingar and coworkers (1993). 3T3-L1 adipocytes or human cultured adipocytes are plated on poly-D-lysine-coated coverslips the day before an experiment. Adipocytes are incubated for 1.5 h at 37°C in Leibovitz's L-15 medium containing 0.2% BSA and treated in the absence or presence of insulin/compounds/drug candidatess. The cells are washed twice in ice-cold buffer A (100 mM NaCl, 50 mM HEPES/KOH, pH 7.3) and once in buffer B (100 mM KCl, 2 mM $CaCl_2$, 1 mM $MgCl_2$, 10 µM leupeptin, 2 µg/ml trypsin inhibitor, 0.5 mM benzamidine, 20 mM HEPES/KOH, pH 7.2) and then sonified in buffer B for 3 sec using a Branson 250 sonifier with a microtip placed 1 cm above the coverslip (output control = 4, duty cycle = 30). Adherent plasma membrane sheets are washed twice in ice-cold buffer B, fixed in 3% paraformaldehyde for 10 min, and processed for indirect immunofluorescence using affinity-purified anti-GLUT4 antisera and rhodamine-conjugated secondary antibodies as described (Garcia de Herreros and Birnbaum 1989).

K.6.1.4.2 Methods Based on the Determination of GLUT Molecules at the Plasma Membranes of Intact Cells

GENERAL CONSIDERATIONS

For recombinant cultured murine and human adipocytes, the need for subcellular fractionation (i. e. preparation of plasma membrane vesicles of sufficient purity) can be circumvented by heterologous expression of GLUT4 tagged at the extracellular loop with an epitope for which specific antibodies are available (e. g. c-myc) and subsequent immunological detection of GLUT4 in the intact and appropriately fixed cells. Alternatively, GLUT exposed at the plasma membrane of intact adipocytes can be photoaffinity-labeled with membrane-impermeable specific and radioactive probes which enable the subsequent

detection upon immunoprecipitation of GLUT4/1 from total membranes. Moreover, the methods of "in-cell" immunoblotting or colorimetry enable accurate and straightforward detection of plasma membrane GLUT4 of cultured and subsequent to the treatment fixed adipocytes without the need for cell fractionation or plasma membrane sheet generation.

K.6.1.4.2.1 In-cell Immunoblotting

PURPOSE AND RATIONALE

The "in-cell immunoblot" is an immunocytochemical assay performed in microtiter plate formate. Target-specific primary antibodies and infrared-labeled secondary antibodies are used to detect target proteins in fixed cells, and fluorescent signal from each well is quantified. Two targets at 700 and 800 nm using two spectrally distinct dyes are monitored. Separate lasers and fluorescence detectors are used for each dye and offer a wide linear detection range. With two detection channels two separate targets can be probed or the quantification accuracy is increased by using the second channel for normalization against a second target or DNA stain. Quantification accuracy is maximized by normalization because adjustments can be made for differences in cell number from well to well. Two-color normalization also helps to prevent false negatives and provides more accurate evaluation of the treatment of cells with compounds/drug candidates. The use of near-infrared probes yields high sensitivity for measuring small changes in the protein amount. The direct detection of proteins (e. g. GLUT4) in their cellular context eliminates variabilities and artifacts caused by cell lysis, gel loading, electrophoresis, and membrane transfer.

This method enables the analysis of cell surface expression of proteins (e. g. GLUT4) in adherent cells without the need for cumbersome and labor-intensive cell fractionation procedures. Upon incubation of the adherent adipocytes with insulin/compounds/drug candidates, GLUT4 expression at the plasma membrane is detected by "in-cell" immunoblotting using conditions for fixation and permeabilization of the adipocytes, which enable access of the anti-epitope antibodies to plasma membrane GLUT4, only, rather than to intracellular GLUT4 vesicles.

PROCEDURE

3T3-L1 fibroblasts or human adipocytes are seeded in 96-well clear round bottom plates (BD Bioscience cat# 353077) at 200,000 cells/well, grown to confluency and then differentiated into mature adipocytes as described above. After serum deprivement overnight by replacement of the differentiation medium with serum-free DMEM, the adipocytes are incubated with insulin/compound/drug in 200 µl of the same medium for 15 min at 37°C. For fixation, 25 µl of 36% formaldehyde is added gently to each well using side of the wells (to avoid detaching of the cells from the well bottom). After incubation for 20 min at room temperature with very gentle rotation, the fixation solution is removed. For permeabilization, the cells are washed three times with 100 µl of PBS containing 0.1% TX-100 for 5 min each by carefully pipetting the permeabilization solution down the sides of the wells to avoid detaching the cells from the well bottom. Thereafter, the permeabilization solution is removed and the washing step is repeated two more times. After addition of 100 µl of blocking buffer (Odyssey, LICOR Biosciences) to each well and incubation for 1 h at room temperature with very gentle shaking on a rotator, 50 µl of anti-GLUT4 antibody (1:200–1:500, Calbiochem) is added and the incubation continued overnight at 4°C. Thereafter, the primary antibody solution is removed and the plates are washed five times with 200 µl of PBS containing 0.1% Tween-20 for 5 min each. 50 µl of fluorescently labeled secondary antibody solution (goat anti-rabbit IRDye 800CW, Rockland Immunochemicals, 1:800 diluted in Odyssey blocking buffer with 0.2% Tween-20) is added to each well. After incubation for 1 h at room temperature on a rotator under protection from light, the secondary antibody solution is removed and the plates are washed five times with 200 µl of PBS containing 0.1% Tween-20 at room temperature for 5 min each. After the final wash, the washing solution is completely removed from the wells. The plates are immediately scanned by placing on the Odyssey scan surface with detection in the 800 nm channel and at 169 µm resolution at 3.0 to 3.5 mm focus offset and an intensity setting of 5 or less.

K.6.1.4.2.2 In-cell Colorimetry

PURPOSE AND RATIONALE

Understanding the molecular mechanisms of insulin action has been of major interest since the discovery, several decades ago, that insulin stimulates glucose transport *in vivo*. Subcellular fractionation (see K.6.1.4.1 and K.6.3.6.1), cell photolabeling coupled to immunoprecipitation and immunofluorescence (see below) or immunoelectron microscopy have been used to detect translocation of GLUT4 to the cell surface (Wilson and Cushman 1994, Kozka et al. 1991, Smith

et al. 1991). All of these methods are laborious and suffer from methodological inaccuracies. Subcellular fractionation is cumbersome and produces membranes that are rarely pure. Moreover, quantitative recovery of all membrane compartments is difficult or impossible. Affinity labeling of surface glucose transporters followed by immunoprecipitation depends on the ability to obtain quantitative immunoprecipitation and recovery upon SDS-PAGE. This technique results in the incorporation of about 1/10.000 of the label added, thus the signal to noise ratio is low. Moreover, the reactivity of the photolabel can depend on the level of activity of the transporter (Vannucci et al. 1992) in addition to the amount of transporter exposed at the cell surface. Immunofluorescence detection does not distinguish the native GLUT4 molecules incorporated into the cell membrane from molecules in subplasmalemmal vesicles, and is not a quantitative technique. Immunogold electron microscopy detects antigens at the plasma membrane accurately, but has not been successfully used in a quantitative fashion. None of the above techniques is suitable for large numbers of experiments, as would be required for screening of antidiabetic drugs stimulating insulin signaling or GLUT4 translocation. Therefore, Wang and coworkers (1998) intended to develop a fast and quantitative approach to measure GLUT4 translocation in intact cells. The method described uses cells in culture and does not require subsequent immunoprecipitation, SDS-PAGE or use of radioactivity, as required by the photolabeling technique. It does not require large amounts of cells nor laborious subcellular fractionation and is rapid, sensitive and quantitative.

PROCEDURE

Construction of L6 Cells Expressing c-myc Epitope-Tagged GLUT4 (GLUT4myc)

GLUT4myc cDNA is constructed by inserting the human c-myc epitope (14 amino acids) into the first ectodomain of GLUT4 as described by Kanai and coworkers (1993). The epitope does not affect GLUT4 activity. GLUT4myc cDNA is subcloned into the mammalian expression vector pCXN (pCXN-GLUT4myc) as described by Niwa and coworkers (1991). L6 myoblasts are transfected with pCXN-GLUT4myc and pSV2-bsr, a blasticidin S deaminase expression plasmid, and selected with blasticidin S hydrochloride.

Cell Culture

L6-GLUT4myc myoblasts in cell monolayers are maintained in α-MEM supplemented with 10% FBS in a humidified atmosphere containing 10% CO_2 and 90% air at 37°C. Cells are grown in 12- or 24-well plates and, prior to experiments, incubated with serum-free α-MEM supplemented with 25 mM glucose for 5 h.

Colorimetric Assay of Surface GLUT4myc

Quiescent L6-GLUT4myc cells are incubated with compounds/drug candidates, then washed once with PBS, fixed in 3% paraformaldehyde in PBS for 3 min at room temperature. The fixative is immediately neutralized by incubation with 1% glycine in PBS at 4°C for 10 min. The cells are blocked with 10% goat serum and 3% BSA in PBS at 4°C for at least 30 min. Primary monoclonal antibody (anti-c-myc, 9E10) is then added into the cultures at a dilution of 1:100 and maintained for 30 min at 4°C. The cells are extensively washed with PBS before introducing peroxidase-conjugated rabbit anti-mouse IgG (1:1,000). After 30 min at 4°C, the cells are extensively washed and 1 ml *o*-phenylenediamine dihydrochloride reagent is added to each well. The colorimetric reaction is stopped by addition of 0.25 ml of 3 N HCl for 10 min at room temperature. The supernatant is collected and the optical absorbance is measured at 492 nm.

EVALUATION

Standard curves can be generated using either peroxidase conjugated anti-mouse IgG alone or myc-tag peptide. For this, myc-tag peptide at various concentrations is coated onto 24-well plates by incubation at 4°C for 24 h and then allowed to dry. The plates are rinsed with PBS to move excess salt and the uncoated spaces are blocked with 10% goat serum and 3% BSA.

K.6.1.4.2.3 Exofacial Labeling

PURPOSE AND RATIONALE

Alternatively, in non-recombinant primary and cultured adipocytes GLUT translocation can be analyzed by exofacial labeling of the GLUT molecules. For this, the membrane-impermeable photoreactive substrate analogs, radiolabeled bismannose propylamine (ATB-BMPA; Ryder et al. 2000) and biotinylated and spacer-equipped glucose compound (GP15; Hashimoto et al. 2001), which are all recognized but not transported by GLUT1 and GLUT4. In addition, a series of photoaffinity probes based on a dihexose structure, in which the hexose moieties (d-mannose or d-glucose) are linked through their 4-OH positions to a 2-aminopropyl spacer, to probe the cell-surface exposure of GLUT4 has been generated. Comparisons

of aryl azide, benzophenone and aryl diazirinetrifluoroethane photoaffinity labelling derivatives of hexoses (Holman et al. 1986, 1988, 1990) have suggested that the latter are most suitable as they are highly efficient cross-linkers with good specificity. A (diazirinetrifluoroethyl)benzoyl moiety has been attached through an amide link to the central amine group. More recently a biotinylated version of this compound has been developed in which a linker to biotin is attached through the hydroxy group of the 2-hydroxy-4-(1-diazirine-2,2,2-trifluoroethyl)benzoyl moiety (Koumanov et al. 1998). This compound has been used to assess the cell-surface exposure of GLUT4 in the human muscle of control and type II diabetic patients and marked impairments in the insulin-stimulated translocation of GLUT4 have been identified using this technique (Ryder et al. 2000). All these substrate analogs can be covalently crosslinked to the GLUT isoforms by photoaffinity-labeling *via* the attached diazirinetrifluorobenzoyl moiety upon UV-irradiation following incubation of the cells with insulin/compounds/drugs. After removal of free substrate analog by washing of the adipocytes, total membranes are prepared from the lysed cells and counted for radioactivity (ATB-BMPA) or detected by immunoblotting for interaction with streptavidin (GP15). Both measures reflect the amount of total GLUT1/4 located at the plasma membranes at the time point of cell lysis, exclusively. For specific analysis of GLUT4 or GLUT1 translocation, the isoforms have to be immunoprecipitated with specific antibodies since the substrate analogs do not discriminate between GLUT4 and 1 (Holman et al. 1990).

PROCEDURE

For the use of photoaffinity labeling with GP15, (Hashimoto et al. 2001), primary rat adipocytes, which have been incubated with insulin/compounds/drugs are maintained at 18 C in the presence of 300–500 µM photoreactive probe for 1 min either in the presence or absence of 0.5 M glucose. The samples are then irradiated for 1 min in a Rayonet photochemical reactor using 300 nm bulbs. Excess reagent is removed by extensive washing in physiological buffers and then 0.3 µM avidin is added to block the cell-surface tagged transporters. Excess avidin is then removed by washing the cells. For detection of biotinylated GLUT4 by blotting, adipocyte samples are homogenised in HEPES/EDTA/sucrose (HES) buffer (255 mm sucrose, 1 mM EDTA, 20 mM HEPES (pH 7.2), 1 µg/ml antipain, aprotinin, pepstatin and leupeptin, each, and 100 µM 4-(2-aminoethyl)benzenesulfonyl fluoride hydrochloride (AEBSF). Homogenates are washed once with HES buffer and subjected to centrifugation (554,000 × *g*, 30 min, 4 C) to obtain a total membrane fraction. This pellet is solubilized in PBS, pH 7.2, with 2% of Thesit ($C_{12}E_9$) and 1 µg/ml each of antipain, aprotinin, pepstatin and leupeptin, and 100 µM AEBSF. The samples are solubilized for 50 min at 4 C with rotation and then subjected to centrifugation (20,000 × *g*, 20 min, 4 C). Biotinylated proteins in the supernatants are either immunoprecipitated using a GLUT4 antiserum as described above or precipitated with streptavidin beads (Pierce, Rockford). Following GLUT4 immunoprecipitation, complexes are released into electophoresis-sample buffer (62.5 mM Tris/HCl, pH 6.8, 2% SDS, 10% glycerol) at room temperature. The steptavidin precipitates are washed four times with PBS buffer containing 1% Thesit with protease inhibitors, four times with PBS containing 0.1% Thesit *plus* protease inhibitors and once in PBS. Electrophoresis-sample buffer is added to each pellet. The sample is then heated to 95 C for 30 min and subjected to centrifugation (2,300 × *g*, 1 min). After removal of the supernatants, the pellets are washed with additional electrophoresis-sample buffer, heated to 95 C for 30 min and resubjected to centrifugation. Mercaptoethanol is added (10% final concentration) to the above samples in electrophoresis-sample buffer and these samples are then subjected to SDS-PAGE (10% gel). Proteins are transferred to nitrocellulose membranes. Membranes are blocked with 5% non-fat milk in Tris-buffered saline containing 0.1% Tween (TBS-T) and washed six times with TBS-T. Membranes are either incubated with streptavidin-HRP (Amersham) or with affinity-purified anti-GLUT4 C-terminal antibody in TBS-T containing 1% BSA (2 h, room temperature), followed by washing (six times in TBS-T) and detection using secondary antibody linked to horseradish peroxidase. GLUT4 protein is visualized with enhanced chemiluminescence (ECL).

K.6.1.4.3 Method Based on the Reconstitution of GLUT4 Translocation

PURPOSE AND RATIONALE

Insulin action on peripheral tissues including fat, heart, and skeletal muscle leads to increased glucose transport. The basis for this action lies in the increased translocation of GLUT4-containing vesicles from an intracellular reservoir compartment and ultimately exposure of the GLUT4 at the cell surface where it facilitates transport (see K.6.1.3 and K.6.1.4). Kinetic

studies have identified that GLUT4 traffics through multiple intracellular compartments involving endosomes, the trans-Golgi network (TGN), and a specialized compartment in which GLUT4 is enriched and it is the exocytosis process that is stimulated by insulin (Satoh et al. 1993, Yang and Holman 1993). However, the site of insulin action along the exocytic pathway is unknown and potentially could involve increased release or budding of GLUT4 vesicles from tubular-vesicular structures, increased movements of vesicles along microtubules, increased transit through cortical actin near the cell surface, increased docking and then fusion of GLUT4 vesicles at the plasma membrane, and then possibly stimulation of catalytic activity of plasma-membrane-inserted GLUT transporters. For further resolution of the key-regulated step, an *in vitro* fusion reaction has been developed in which GLUT4 vesicles are immunoisolated and fused with reconstituted plasma membrane in the presence of cell cytoplasm. The separate analysis of this partial reaction in the exocytic limb of the translocation sequence allows direct analysis of the extent to which fusion is stimulated by insulin or insulin-like compounds/drug candidates. Remarkably, the magnitude and time course for insulin's action on glucose transport is fully recapitulated in the vesicle fusion reaction.

Cell-free reconstitution of vesicle fusion reactions have many advantages for studying cell biology processes, as the separate components of the fusion reaction can be separately manipulated and combined. The cell-free approach is particularly powerful in studying insulin-regulated fusion as separate mixing of vesicles containing insulin-activated and non-activated components is feasible. With this approach, it can be studied whether the action of insulin/compounds/drugs leads to activation of GLUT4 vesicles, activation of components of the cytoplasm fraction, or activation of components of the plasma-membrane fraction. For insulin, recent data reveal that it is the activation of that plasma-membrane fraction that is the key-regulated step in the stimulation of fusion (Koumanov et al. 2005).

However, the exact nature of insulin signals that regulate GLUT4 translocation and how they affect the donor membrane, plasma membranes, or some other components in the translocation machinery remain unclear. In attempts to further characterize the translocation machinery and to study its modulation by insulin/compounds/drugs, two distinct *in vitro* reconstitution assays for GLUT4 translocation have been developed (Inoue et al. 1999, Koumanov et al. 2005).

K.6.1.4.3.1 Analysis by Immunoblotting

Preparation of Plasma Membranes and Donor Membranes

In an attempt to define the mechanism of insulin-regulated GLUT4 translocation, Inoue and coworkers (1999) developed an *in vitro* reconstitution assay based on immunoblotting detection of the membrane fusion reaction. For this, differentiated 3T3-L1 adipocytes (stably transfected with mycGLUT4 cDNA by using a retroviral expression plasmid for the preparation of donor membranes) in 10-cm dishes are serum-starved for 18 h and then incubated in the presence or absence of insulin/compounds/drugs. After washing twice with ice-cold PBS, the cells are homogenized immediately by using 20 strokes of a 1-ml Teflon-in-glass homogenizer in a buffer containing 10 mM HEPES/KOH (pH 7.4), 1 mM EDTA, 250 mM sucrose, 1 mM DTT, 1 mM Na_3VO_4, 50 nM okadaic acid, 1 mM PMSF, and 0.1 mg/ml aprotinin. For preparing the donor membranes containing mycGLUT4, the homogenization buffer is supplemented with 0.5 mM $ZnCl_2$. The homogenate is centrifuged ($500 \times g$, 1 min). For collection of plasma membranes, the supernatant is centrifuged ($1{,}500 \times g$, 5 min). The supernatant is centrifuged ($12{,}000 \times g$, 15 min). For collection of donor membranes (consisting of both low- and high-density microsomes), the supernatant is centrifuged ($100{,}000 \times g$, 1 h). The resulting pellets of plasma membranes and donor membranes are suspended in the homogenization buffer without $ZnCl_2$, adjusted to a protein concentration of 2–4 mg/ml using the Bradford method and immediately used for the *in vitro* association assay.

In Vitro Association Assay

Donor membranes and plasma membranes (15–30 µg each) are mixed at 4°C in 75 µl of assay buffer (20 mM HEPES/KOH, pH 7.0, 250 mM sucrose, 0.5 mM EDTA, 1.5 mM $MgCl_2$, 0.5 mM $CaCl_2$, 1 mM DTT, 50 µg/ml BSA, 50 mM KCl), supplemented with an ATP-regenerating system (1 mM ATP, 8 mM creatine phosphate, 25 units/ml creatine phosphokinase). The amount of protein for plasma membranes and donor membranes in the assay is equal. The reactions are initiated by incubation at 37°C. After 2–10 min, the reactions are returned to 4°C and subjected to one of two procedures to separate the plasma membranes or plasma membrane-associated donor membrane vesicle structures from the donor membranes. Two different methods for the demonstration of the fusion of donor membranes and plasma membranes have been used successfully by Inoue and coworkers (1999).

Method I

The mixture is applied to the top of a discontinuous 28–44% sucrose gradient with 2% steps and subjected to centrifugation (100,000 × *g*, 18 h). Each 4-ml step layer is diluted with ice-cold water and centrifuged (200,000 × *g*, 1 h). The final pellets are dissolved in SDS-sample buffer.

Method II

The mixture is centrifuged (15,000 × *g*, 15 min) after dilution with 1 ml of the ice-cold homogenization buffer supplemented with 0.5 M KCl. The final pellet is dissolved in SDS-sample buffer. For detection of mycGLUT4 translocated from the donor membranes into the re-isolated plasma membranes during the *in vitro* association reaction, plasma membrane proteins are tested for the myc epitope by immunoblotting with appropriate primary antibodies and secondary anti-IgG antibodies coupled to peroxidase. The chemiluminescent signals for mycGLUT4 on the blot, which are quantitated by densitometric scanning have to be proportional to the load over the range used.

K.6.1.4.3.2 Analysis by Fluorescent Resonance Energy Transfer (FRET)

Isolation of Tagged GLUT4 Vesicles

For demonstration of GLUT4 translocation in the reconstitution system introduced by Koumanov and coworkers (2005), rat adipocytes at 40% cytocrit are stimulated with 5 nM insulin for 20 min at 37°C. In a typical experiment 10 ml of cells are used. After cooling the cells to 18°C, the surface GLUT4 is labeled with 500 µM biotinylated photolabel GP15 (see K.6.1.4.2.3) and incubated with 10 µg/ml of cells DyLight647 streptavidin for a further 15 min. Insulin/compound/drug is removed and GLUT4 is internalized. The cells are then homogenized and processed as described by Simpson and coworkers (Simpson et al. 1983) to obtain a post-high-density-microsome supernatant, containing the fluorescently tagged GLUT4 vesicles. The GLUT4 vesicles are purified by immunoisolation using an anti-GLUT4 antibody (Satoh et al. 1993) prebound to the MBP-pa construct attached to a 0.7 ml amylose resin column. After 2 h incubation, the column is washed with intracellular buffer (IC buffer, 20 mM HEPES/KOH, pH 7.4, 140 mM potassium glutamate, 5 mM NaCl, 1 mM EGTA) and the GLUT4 vesicles are eluted in 500 µl fractions with 20 mM maltose in IC buffer. The presence of GLUT4 in each fraction is monitored by measuring the DyLight 647 fluorescence. Usually, fractions 1–3 are pooled together and used as a source of purified GLUT4 vesicles. GLUT4 in the fractions is analyzed using a sheep anti-GLUT4 antibody.

Preparation of Cytosol and Plasma Membrane-Liposomes

Concentrated cytosol is prepared from rat adipocytes in the basal state or following treatment with insulin/compounds/drugs for 20 min. Cells are washed once with buffer without BSA and once with IC buffer. As much buffer as possible is removed and the cells are vortexed and then spun (265,000 × *g*, 70 min). The cytosol is recovered between the pellet of crude membranes at the bottom and the fat layer at the top and kept frozen at −70°C until further use. Basal and insulin/compound/drug-treated plasma membranes are prepared (Simpson et al. 1983) and reconstituted in phospholipid-liposomes using an adaptation of previously described methods (Kono 1983, Schurmann et al. 1989). Purified plasma membrane is solubilized in 1.25% octyl glucoside and applied to Sephadex G50 column. 200-µl aliquots of solubilized eluted protein (300 µg/ml) are gently vortex mixed with 40 µl of 150 mg/ml Soya bean phosphatidylcholine (Type IV-S, Sigma) in 20 mM HEPES (pH 7.4). A biotin-Europium (TMT) ligand is added at 55 nM final concentration and the mixture is sonicated for 15 s and frozen to −70°C for at least 2 h. The samples are then thawed, resonicated and purified on flotation Histodenz gradients. The liposomes are mixed 1:1 with 80% Histodenz in reconstitution buffer (25 mM HEPES, pH 7.4, 100 mM KCl, 1 mM DTT) containing 10% glycerol. This is overlayed with 30% Histodenz in reconstitution buffer containing glycerol, and then with buffer only. After centrifugation (35,000 rpm, 12 h, SW41Ti rotor), liposomes are collected at the 0/30% Histodenz interface. The amount of encapsulated biotin-Eu(TMT) is monitored by measuring the fluorescence against a standard curve. Typically 1–2 nM of Biotin-Eu(TMT) is encapsulated in 1 ml of isolated liposomes.

Fusion Assays

Fusion assays are performed in duplicate. 50 µl of GLUT4 vesicles, liposomes and cytosol are mixed with 25 µl of IC buffer containing 1 µM biocytin on ice. Fusion is initiated by adding 50 µl of ATP regenerating system (final concentrations: 1 mM ATP, 5 mM $MgCl_2$, 8 mM phosphocreatine, and 31 U/ml creatine phosphokinase Type 1) at 37°C. In some cases GLUT4 vesicles and plasma membrane liposomes are mixed with the ATP regenerating system on ice and the reac-

tion is initiated by adding cytosol. Fusion is stopped by returning the samples on ice and addition of 1% TX-100 containing excess biocytin.

EVALUATION

The extent to which fusion had occurred prior to this endpoint is detected by TR-FRET between Europium (TMT) and DyLight 647 in a FARCyte microplate reader. The TR-FRET signal is calculated from the ratio of the emission at 670 nm/612 nm with excitation at 340 nm. The zero time point is used as a measure of the background and is subtracted from each value. Generally the extent of fusion at 5 min is compared with the maximal fusion obtained by incubation at 37°C for 30 min.

The*in vitro* reconstitution approach for GLUT4 translocation provides an unequivocal evaluation of the role of compounds/drug candidates in the fusion step as it represents a partial reaction in the GLUT4 vesicle translocation process. Although several recent microscopy studies on GLUT4 movement in cells have suggested that a regulated fusion step is likely (van Dam et al. 2005, Kanda et al. 2005, Lizunov et al. 2005), it is difficult to interpret such studies as many factors before and after the fusion step can influence the appearance of tagged-GLUT4 at the cell surface. Although the use of TIRF microscopy (Lizunov et al. 2005) has narrowed down the number of partial reactions involved in the insulin stimulation of exocytosis, the interpretation of these microscopy images is equivocal because the net incorporation of GLUT4 into the plasma membrane can be interpreted as indicating an involvement of the cytoskeleton, docking and fusion and endocytosis. In addition, fusion and endocytosis may be tightly coupled and the location of the membrane site at which these partial reactions occur may not be distinct. The *in vitro* analysis of the fusion reaction allows the fusion step to be studied in isolation from any involvement of the cytoskeleton or the endocytosis steps.

Applications

Li and McNeill (1997) reviewed various quantitation methods for the insulin-regulatable glucose transporter GLUT4 including reconstituted glucose transport, cytochalasin B binding assays, immunocytochemistry, immunoblots, ELISA, and exofacial labels. The effect of streptozotocin-induced diabetes on GLUT4 phosphorylation in rat adipocytes has been studied by Begum and Draznin (1992). The effect on glucose transporters by sulfonylureas was studied by Jacobs and Jung (1985), Jacobs and coworkers (1989), that of metformin by Matthei and coworkers (1991). Cusin and coworkers (1990) found that hyperinsulinemia increases the amount of GLUT4 mRNA in white adipose tissue and decreases that of muscles. Hofmann and coworkers (1991) determined GLUT4 content by Western immunoblot protein analysis and by Northern blot analysis of GLUT4 mRNA in epididymal fat or soleus muscle tissue of streptozotocin-treated rats and of obese male KKA^Y mice after treatment with pioglitazone. The effect of *in vivo* thyroid hormone status on insulin signaling and GLUT1 and GLUT4 glucose transport systems in rat adipocytes was studied by Matthei and coworkers (1995). Galante and coworkers (1994) studied insulin-induced translocation of GLUT4 in skeletal muscle of insulin-resistant Zucker rats. Recycling of GLUT4 was studied by Laurie and coworkers (1993), Rampal and coworkers (1995). Bähr and coworkers (1995) studied the stimulation of myocardial glucose transport and glucose transporter-1 (GLUT1) and GLUT4 protein expression in cultured cardiomyocytes from rats. Teresaki and coworkers (1998) studied the influence of an insulin sensitizer on GLUT4 translocation in adipocytes of rats fed a high fat diet. Ren and coworkers (1995) evaluated the effect of increased GLUT4 protein expression in muscle and fat on the whole body glucose metabolism by the euglycemic hyperinsulinemic clamp technique in conscious mice. Uphues and coworkers (1995) used cardiac ventricular tissue of lean and genetically obese (fa/fa) Zucker rats to study the expression, subcellular distribution and insulin-induced recruitment of the glucose transporter GLUT4. Zeller and coworkers (1995) studied the GLUT1 distribution in adult rat brains using a newly developed immuno-autoradiographic method. Abe and coworkers (1997) reported molecular cloning of bovine GLUT4. Dalen and coworkers (2003) reported that the expression of the insulin-responsive glucose transporter GLUT4 in adipocytes is dependent in liver X receptor α.

K.6.1.5 Fatty Acid Transport

PURPOSE AND RATIONALE

To gain knowledge of the biochemical pathways of fat metabolism in human physiology is central to understanding the derangements and pathology in the adipocyte handling of fatty acids associated with obesity and type II diabetes. The adipocyte stores large amounts of TAG, which continually turn over during lipolytic hydrolysis and reacylation of exogenous fatty acids. Human adipocytes do not have the capacity to synthesize significant amounts of fatty acids *de novo*. The large part of TAG synthesis comes from fatty acids provided by lipoprotein lipase hydrolysis of chylomicron or very low density lipoprotein TAG in the capillary blood vessels provided by the intestinum and the liver, respectively. Fatty acids act as detergents that rapidly dissolve the plasma membrane, causing cell lysis if allowed to accumulate. More conflicting, the abnormal storage of TAG in the LD of cells from non-adipose tissues (muscle, liver, pancreatic β-cells) may interfere with the insulin regulation of lipid and carbohydrate metabolism as well as with glucose-induced insulin secretion *via* ill-defined molecular mechanisms which are collectively termed the lipotoxicity hypothesis for the pathogenesis of type II diabetes. The flow of fatty acids into the adipocyte can be high and these fatty acids have to be efficiently and rapidly converted to TAG and stored away in the cytoplasmic LD. The synthesis of lipids, in particular of TAG, including the biogenesis of LD by adipocytes depends on the uptake of free fatty acids (FFA) from the blood stream. FFA transport across the adipocyte plasma membrane involves both passive diffusion (at high FFA concentrations) and facilitated diffusion *via* specific transport proteins (at low concentrations). Current evidence indicates that several classes of fatty acid transport proteins, long-chain fatty acyl-CoA synthetases (ACS) and cytosolic fatty binding-proteins participate in fatty acid transport and activation. In eukaryotic systems, both fatty acid transport proteins (FATPs), fatty acid-binding proteins (FABPs), ACS and fatty acyl-CoA binding proteins are suggested to function in concert to facilitate long chain fatty acid uptake. There is considerable evidence that insulin stimulates fatty acid transport up to 3-fold in adipocytes by inducing the translocation of specific FATPs (CD36) from intra-

cellular vesicles to the plasma membranes, a molecular mechanism resembling GLUT4 translocation (see above). Potential drugs targeting these proteinaceous components of the transport pathway are promising. They may specifically block fatty acid uptake, cytoplasmic trafficking and/or activation in adipocytes for the pharmacotherapy of obesity, diabetes and the metabolic syndrome in humans. Conversely, stimulation of fatty acid uptake into adipocytes by potential drugs with insulin-like activity may be beneficial for the anti-diabetic therapy on basis of storage of excess of FFA in adipose tissue, the site specifically designed for the deposition of carbons taken in by daily food. The removal of FFA from the circulation would thereby circumvent the putative lipotoxic effects of FFA in other non-adipose tissues. It is hypothesized that high circulating levels of FFA occur when uptake and activation of fatty acids exceed the adipocyte's capacity for storage or β-oxidation. This leads to excess fatty acid internalization and resultant lipotoxicity of non-adipose cells and tissues (muscle, liver, pancreas). However, so far no drugs are available, which either increase or decrease the storage of TAG (by stimulation/inhibition of fatty acid transport and esterification or inhibition/stimulation of lipolysis in adipose tissue or non-adipose tissues, respectively. Their identification requires the development of assay systems for monitoring fatty acid transport, esterification and lipolysis appropriate for throughput screening.

K.6.1.5.1 Method Based on Radiolabeled Fatty Acids

Adipocytes

The [^{3}H]oleic acid uptake assays are performed with confluent 3T3-L1 adipocyte cell monolayers according to the procedure developed by Stremmel and coworkers (1986) and Pohl and coworkers (2005). [^{3}H]Oleic acid (173 µM, 0.05–0.20 µCi) is dissolved in a defatted BSA solution (173 µM) at a ratio of 1:1.2 ml of the oleate/BSA solution is incubated with the cell monolayer of each well of a 6-well culture dish at 37°C. The uptake is terminated after 5 min by removal of the solution followed by addition of 5 ml of an ice-cold stop solution (PBS containing 0.5% BSA and 200 µM phloretin). The stop solution is discharged after 2 min, and the culture dishes are washed by dipping them six times in ice-cold oleate/BSA solution (173 µM). NaOH (2 M) is added to lyse the cells. After neutralization, aliquots of the lysates are used for protein and radioactivity determination (in a liquid scintillation counter after addition of 10 ml of scintillation cocktail Ultima-Gold).

Hepatocytes

For measurement of fatty acid uptake into hepatocytes according to the procedure described by Chang and coworkers (2006), 200 µl of a suspension of freshly isolated hepatocytes (5×10^5 cells in PBS with > 95% viability according to trypan blue exclusion) are added to 200 µl of oleate-BSA buffer solution containing 40 µM of oleic acid, 10 µM BSA and 5 µCi/ml [^{3}H]oleate in PBS. At increasing periods of time (0–120 s) afterwards, 5 ml of buffer containing 0.1% BSA and 500 µM phloretin in BSA are added to the mixture to stop the uptake. The entire mixture is immediately run through a glass fiber filter under low vacuum (< 10 mm Hg) to collect the cells. The glass fiber is placed in a vial with scintillation fluid to count radioactivity. A blank vial and a vial with an aliquot of oleate-BSA buffer solution is used as negative and positive controls, respectively. The assays done at the time point zero are used as the background uptake activity and subtracted from the activity measured at each time point. The final values are corrected for cell viability, determined after isolation of the hepatocytes by trypan blue exclusion or MTT.

Viability of Cultured Cells – MTT Assay

To evaluate the cytotoxic effect of the drugs, an MTT [3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide] assay is performed. Cells are seeded in 12-well plates and incubated with compounds/drug candidates. Subsequently, 200 µl of 0.25% (w/v) MTT is added to each well, and cells are further incubated for 2 h. The resulting formazan crystals are then solubilized by adding 1 ml of MTT lysis solution (10% SDS and 1 mM acetic acid in DMSO). Absorbance at 570 nm is measured. The results are expressed as the percentage of absorbance related to control cells.

Viability of Cultured Cells – Trypan Blue Assay

After incubation of the cells in the absence (control group) or presence of compound/drug candidate, the cells are exposed to the membrane-impermeant dye, trypan blue (0.1%, w/v) for 15 min at 37°C. The presence of dye is determined by light microscopy and the numbers of unstained and stained cells in the field are counted to obtain an estimate of the percentage of the cells taking up the dye.

Viability of Cultured Cells – Lactate Dehydrogenase (LDH) Release

After incubation of the cells with compound/drug candidate, LDH release into the medium is measured by

determining LDH activity (cytotoxicity detection kit-LDH, Roche Applied Science). The amount of color formed in the assay is proportional to the number of lysed cells. The LDH activity in the total of dead islet cells (high control) is measured after solubilization of the cells with 5% (by vol.) Triton X-100.

EVALUATION

To determine the percentage cytotoxicity, the absorbance at 490 nm is measured in multiple samples with subtraction of values obtained in control incubation (low control with cells but without compound) using the following equation:

$$Cytotoxicity(\%) = \frac{\text{compound value} - \text{low control}}{\text{high control} - \text{low control}} \times 100$$

K.6.1.5.2 Method Based on Fluorescent Fatty Acids

GENERAL CONSIDERATIONS

Fatty acid transport can be more easily studied in yeast compared to mammalian cells, which makes a yeast-based assay system attractive for throughput screening in drug discovery. Fatty acid uptake has been demonstrated to be essential for growth of yeast under conditions of blocked *de novo* synthesis. This occurs in the natural state when cells are grown under hypoxic conditions due to the requirement of the acyl-CoA desaturase for oxygen. During hypoxia, cells specifically require an exogenous source of long-chain unsaturated fatty acids. Fatty acid uptake is dependent upon two proteins, Fat1p, the orthologue of the mammalian FATPs and an ASCL, either Faa1p or Faa4p. Yeast with deletions in the structural gene encoding Fat1p (FAT1) or Faa1p and Faa4p (FAA1 and FAA4) cannot grow anaerobically whether or not unsaturated fatty acids are added to the growth media due to a defect in fatty acid activation (Faergeman et al. 1997 and 2001 , Dirusso et al. 2000). These deficiencies in transport and growth can be alleviated by expression of a selected group of FATPs (mmFATP1, mmFATP2 and mmFATP4 ; Johnson et al. 2000). The yeast system was recently successfully exploited as a method for screening fatty acid uptake inhibitors, which function by specific interaction with a mammalian FATP conditionally expressed in yeast (Li et al. 2005).

PURPOSE AND RATIONALE

This method (Li et al. 2005) is based on the use of the fluorescent fatty acid analog, 4,4-difluoro-5-methyl-4-bora-3*a*,4a-diaza-*s*-indacene-3-dodecanoic acid (C_1-Bodipy-C_{12}). The length of C_1-Bodipy-C_{12} is approximately equivalent to that of an 18-carbon fatty acid. The Bodipy fluorophore is 11 carbons away from the carboxylate group. Both a non-homogenous and homogenous assay designs have been developed. Cellular uptake of C_1-Bodipy-C_{12} can be monitored using fluorescence microscopy. For this, cells are first incubated with C_1-Bodipy-C_{12} to allow uptake and then unincorporated ligand is removed using repeated washes with the fatty acid-binding protein BSA. For detection of fatty acid uptake, the cells are attached to microscope slides by coating with polylysine and then visualized using confocal microscopy. For high-throughput screening, this is not practical, however, due to the requirement of several washing cycles and centrifugations or of microscopy as detection method. The homogenous assay avoids multiple washing steps and relies on a standard microtiter plate fluorescence reader. In this method, extracellular fluorescence is quenched by the addition of trypan blue which does not penetrate into intact 3T3-L1 adipocytes. The assay has been validated with the non-fluorescent natural fatty acid, oleic acid, in addition to sodium azide and Triacsin C, compounds that interfere with fatty acid uptake by blockade of the fatty acid activation step.

PROCEDURE

Yeast cells with the genes for Fat1p and Faa1p deleted and transformed with the expression vector encoding murine FATP2 (mmFATP2) under the control of the GAL10 promoter are grown to 0.1 A_{600} (mid-log phase) in yeast-supplemented minimal media containing 2% galactose and 2% raffinose (without leucine and histidine) at 30°C to induce expression of the mmFATP2. Cells are harvested by centrifugation (5,000 × *g*, 5 min) and then resuspended in PBS at a cell density of 6×10^7/ml prior to use. In a standard uptake assay, 50 µl of yeast cells (3×10^6) is dispensed into each well and incubated with 5 µM C_1-Bodipy-C_{12} in the dark for 3 min in 100 µl total volume. C_1-Bodipy-C_{12} is prepared in PBS containing BSA (7.5 µM final concentration in the assay). Then, 50 µl of trypan blue (0.33 mM final concentration) is added to the reaction to quench the extracellular fluorescence of C_1-Bodipy-C_{12}. Fluorescence intensity is measured on a fluorescence microtiter plate reader (e. g. Molecular Devices) with filter set at 485 nm excitation and 528 nm emission. Fluorescence intensity is recorded after adding trypan blue at room temperature for various times (0, 30, 60 min). The ratio of measured fluorescence intensity of yeast cells expressing

and lacking mmFATP2 is calculated and used to assess the C_1-Bodipy-C_{12} uptake activity of the corresponding mammalian FATP. Cells are incubated with compounds/drugs on an orbital shaker (250 rpm, 30°C) for 2 h prior to assaying C_1-Bodipy-C_{12} uptake.

EVALUATION

This yeast-based assay system introduced by Li and coworkers (2005) for the identification of compounds/drug candidates that target the mammalian FATPs is critically dependent on the bypass of the time-consuming repeated washing steps with BSA required to limit the fluorescent signal from unincorporated ligand. For this, a quenching reagent was chosen, that decreases the signal of non-cell-associated C_1-Bodipy-C_{12}, which obscures the cell-associated fluorescence. Consequently, the quenching dye must have an absorbance spectrum that significantly overlaps the fluorescence emission of the Bodipy fluorophor, such as Trypan blue, with a peak absorbance at 607 nm. This dye has been shown to quench the extracellular fluorescent probes used in phagocytosis assays but does not quench internal fluorescence since it is effectively excluded from living cells due to impermeability of the cell membrane to this compound. BSA is added to the assay mixture to solubilize the hydrophobic fatty acid analog. It has been found that the apparent fluorescence measured in the presence of BSA is much more consistent compared to that measured in the absence of BSA. The signal difference between the positive and the negative controls (ratio of cells expressing and lacking the mammalian FATP) is usually in the range of 4- to 5-fold. Therefore, utilizing trypan blue to quench the non-cell associated C_1-Bodipy-C_{12} it is possible to omit the washing cycles for monitoring fatty acid uptake.

One advantage of the yeast cell-based assay to target the mammalian FATPs is that it relies on a phenotype (i. e. fluorescence signal) specific to the target protein. Thus, it mimics the biological context of the protein more closely than the cell-free system (Fernandes 1998). A draw-back of the cell-based assay, however, is the lack of knowledge about the mechanism of interaction with and specificity toward the target protein. Therefore, secondary screens must be performed, which are required to eliminate toxic compounds. Compounds which kill the cells allow the nonspecific entry of trypan blue leading to quench of the internalized ligand. Additionally, some selected compounds might work by non-FATP-mediated mechanisms, including those that increase the permeability of the cell membrane and facilitate trypan blue entry into the cells. In conclusion, the data presented so far demonstrate that the yeast cell-based fatty acid uptake assay employing a *S. cerevisiae* strain deficient in fatty acid uptake, that expresses mmFATP2 and tests the mmFATP2-dependent C_1-Bodipy-C_{12} transport activity can be used for high-throughput screening of inhibitors or activators of the fatty acid transport and may be successfully applied to other members of the FATP and ACS families.

K.6.1.6 Cellular Esterification

PURPOSE AND RATIONALE

The following assay monitors the complete pathway of esterification of glycerol-3-phosphate synthesized *via* glycolysis from glucose, which is transported into the adipocytes upon insulin-dependent GLUT4 translocation with fatty acids taken up by the adipocytes *via* the fatty acid transport proteins (in insulin-dependent fashion) (see K.6.1.2 and K.6.1.5).

PROCEDURE

For this assay described by Sooranna and Saggerson (1976), adipocytes are treated with low concentrations of saponin to permeabilize the plasma membrane (without disrupting internal membranes) and subsequently incubated with L-[U-^{14}C]glycerol-3-phosphate for 10 min at 25°C. Toluene-based scintillation cocktail is added and the lipid and aqueous phases are separated by centrifugation. The lipid phase is removed and counted for radioactivity.

EVALUATION

This assay measures the complete esterification pathway of glycerol-3-phosphate into lipid-soluble products (TAG, phospholipids, lipidic intermediates such as [lyso]phosphatidic acid) including the regulatory cascade which is stimulated by insulin. One or the other of the activation or acylation steps may be affected by compounds/drug candidates. Glucose transport does not interfere due to the use of the permeabilized adipocytes as is revealed by lack of inhibition of basal esterification by cytochalasin B.

K.6.1.7 Lipid-Synthesizing Enzymes

PURPOSE AND RATIONALE

The effects of insulin/compounds/drugs on the three acylating enzymes involved in the esterification pathway, glycerol-3-phosphate-acyltransferase (GPAT), monoacylglycerol-3-phosphate-acyltrans-ferase (AGPAT) and 1,2-diacylglycerol-acyltrans-ferase (DGAT) (for a review see Coleman and Lee 2004) can be assayed individually using microsomes (GPAT, AGPAT, DGAT) and mitochondria (GPAT, AGPAT) prepared from adipocytes which have been pretreated correspondingly. Care must be taken to preserve the activation state of the acylating enzymes during preparation of the microsomes after challenge of the adipocytes with insulin/compounds/drugs by the inclusion of mixtures of phosphatase and protease inhibitors. For the analysis of putative direct effects of compounds/drugs on the acylation enzymes, they are added to the cell-free incubation mixtures containing microsomes/mitochondria from untreated adipocytes.

Preparation of Microsomes/Mitochondria

Isolated rat adipocytes, which have been incubated with insulin/compounds/drugs, are homogenized by 10 strokes in a motor-driven Teflon-in-glass homogenizer in TES buffer (20 mM Tris/HCl, pH 7.4, 250 mM sucrose, 1 mM EDTA) supplemented with 10 µM okadaic acid, 10 mM sodium pyrophosphate, 100 mM NaF, 10 mM glycerol-3-phosphate, 1 mM sodium orthovanadate, 0.1 mM PMSF, 10 µg/ml each of antipain, leupeptin, pepstatin and E-64. After differential centrifugation steps for the removal of cell debris (500 × *g*, 5 min), plasma membranes (2,000 × *g*, 15 min) and mitochondria (10,000 × *g*, 20 min), the supernatant is centrifuged (100,000 × *g*, 60 min, 4°C). The pellet is resuspended in TES buffer and centrifuged (16,000 × *g*, 10 min). The microsomes are recovered from the supernatant by centrifugation (100,000 × *g*, 60 min, 4°C). Microsomes and mitochondria are resuspended in TES buffer (at 4 mg protein/ml) and finally stored at −80°C and used only once after thawing. According to the distribution of the marker enzymes (NADPH-cytochrome-c reductase, GRP-78 and BiP for microsomes, succinate dehydrogenase and porin for mitochondria, adenylate cyclase and Na^+/K^+-ATPase for plasma membranes), the microsomes are contaminated to varying degree with mitochondria and are significantly deprived of plasma membranes.

K.6.1.7.1 Glycerol-3-Phosphate Acyltransferase (GPAT)

PROCEDURE

Radioactive Assay

The incubation mixture contains 50 mM Tris/HCl (pH 7.4), 200 mM KCl, 1 mM DTT, 150 µM palmitoyl-CoA, 4 mM $MgCl_2$, 10 mM NaF, 2 mg/ml BSA, 0.2 mM [^{3}H]glycerol-3-phosphate (2 µCi) and microsomes from primary rat adipocytes (25–100 µg) in a final volume of 0.5 ml. The reaction is started by addition of the microsomes in the absence or presence of 2 mM *N*-ethylmaleimide (NEM). After incubation (3 min, 37°C), the reaction is stopped with 2 ml of water-saturated butanol, followed by 1.5 ml of butanol-saturated water. The butanol phase is separated and washed twice. An aliquot is counted for radioactivity. Under these conditions the rate of product formation is linear for up to 15 min.

Fluorescent Assay

Up to 100 µl of microsomes/mitochondria are incubated with 100 µl of reaction mixture containing 40 mM Tris/HCl (pH 7.4), 8 mM $MgCl_2$, 4 mg/ml BSA, 10 mM NaF, 1 mM NDC, 0.3 mM glycerol-3-phosphate in a total volume of 200 µl. After incubation (60–180 min, 25–30°C) in the absence or presence of 2 mM NEM, the reaction is terminated by the addition of 300 µl of chloroform/methanol (2/1, by vol.) containing 0.1 M HCl and thoroughly mix-

ing. After phase separation (5000 × *g*, 10 min), 180 µl of the lower organic phase are removed and dried. The resin is solubilized in 50 µl of dichloromethane by thorough mixing. Portions (5 µl) are analyzed by thin layer chromatography (Merck, silicagel Si-60) using acetic acid methylester/toluol (2/1 or 1/1, by vol.) with synthetic NBD-labeled mono-, di- and tridodecanoylglycerol run in parallel as markers.

EVALUATION

In case of using of microsomes which are equipped with the complete lipid-synthesizing machinery, the predominant radiolabeled/fluorescent product formed is TAG with accumulation of only minor amounts of its precursors, phosphatidic acid (3–8%) and lysophosphatidic acid (1–4%) as determined by thin layer chromatography and fluorography. However, under the conditions used GPAT activity is rate-limiting for the formation of radiolabeled or fluorescent TAG and consequently, the rate of TAG formation is a direct reflection of the activity of GPAT. In case of using mitochondria, which are typically contaminated by microsomes, their total GPAT activity is determined in the absence of NEM. mtGPAT1 activity, which is resistant to inhibition of NEM (Bell and Coleman 1980), is determined in the presence of 2 mM NEM and subtracted from the total activity to yield the NEM-sensitive GPAT activity, representing the activity from the microsomal GPAT and mtGPAT2 (Bell and Coleman 1980, Lewin et al. 2004). Typically, 2 mM NEM is sufficient to inhibit all of the microsomal GPAT and mtGPAT2 activity.

Time- and concentration dependence of sulfonylurea-stimulated GPAT was tested by Müller and coworkers (1994). Insulin has been reported to stimulate microsomal GPAT by 2- to 3-fold in primary rat adipocytes. The molecular mechanism of this regulation remains to be elucidated. Phosphorylation (by casein kinase II and allosteric activators (polar head groups derived from glycosyl-phosphatidylinositol lipids) have been discussed (Vila et al. 1990; see K.6.3.6.4).

K.6.1.7.2 Acylglycerol-3-Phosphate Acyltransferase (AGPAT)

PROCEDURE

Radioactive Assay

1-ml incubation mixtures are prepared by sonication of monoacyl-glycerol-3-phosphate (MAGP) (up to 100 µM), TX-100 (0.5%), phosphatidylcholine (0.2 mg/ml), [^{14}C]palmitoyl-CoA (40 µM), NaF (50 mM), $MgCl_2$ (1.5 mM) in 150 mM Tris/HCl (pH 8.0). The reaction is started by addition of up to 20 µg of microsomes. After incubation (10 min, 37°C, constant shaking), the reaction is terminated by the addition of 4.5 ml of chloroform/methanol (1/2, by vol.), then of 1.5 ml of chloroform and 1.5 ml of 2 M KCl/0.2 M H_3PO_4. Diacylglycerol-3-phosphate contained in the chloroform layer is dried, redissolved in chloroform/methanol (2/1, by vol.) and then analyzed by TLC using chloroform/methanol/acetic acid/water (25/10/3/1, by vol.). Dried TLC plates are subjected to fluorography (ENHANCE spray, NEN/DuPont; Kodak X-Omat AR films).

Spectrophotometric Assay

AGPAT can be assayed by measuring the reaction of released CoA-SH with 5,5′-dithiobis(2-nitrobenzoic acid) (DTNB = Ellman's reagent) spectrophotometrically. The reaction mixture consists of 100 mM Tris/HCl (pH 7.4), 20 µM oleoyl-CoA, 50 µM 1-acylglycerol-3-phosphate, 1 mM DTNB (10 mM stock in 1 M Tris/HCl, pH 8.0) and up to 50 µl of sample (~200 µg microsomal protein) in the presence of compounds/drug candidates in the wells of a 96-well microtiter plate (200 µl total vol.). The reaction is initiated by the addition of oleoyl-CoA after preincubation of the microsomes with all other components for 2–4 min. The increase in absorbance at 405 nm is followed at 37°C with a microtiterplate spectrophotometer. Control incubations are performed in the absence of 1-acylglycerol-3-phosphate, and the observed rates are subtracted from the rates measured in the presence of acyl acceptor.

K.6.1.7.3 Diacylglycerol Acyltransferase (DGAT)

PROCEDURE

The incubation mixture (250 µl) contains 150 mM Tris/HCl (pH 8.0), 10 mM $MgCl_2$, 1 mg/ml BSA, 50 µM [^{14}C]palmitoyl-CoA (3 µCi, 25,000 cpm/nmol). The reaction is started by the addition of up to 50 µl of a mixture containing 1.5 mM 1,2-diacylglycerol and phosphatidylcholine (0.2 mg/ml) in absolute ethanol and up to 100 µg of microsomal protein. After incubation (15 min, 37°C), the reaction is terminated by the addition of 1 ml of 2-propanol/heptane/water (80/20/2, by vol.). TAG contained in the heptane layer is further purified. The dried samples are redissolved in chloroform/methanol (2/1, by vol.) and analyzed by TLC using petroleum ether/diethyl ether/acetic acid (80/20/1,

by vol.) or hexan/diethylether/acetic acid (70/291/1, by vol.) and fluorography or radioactivity scanning.

K.6.1.8 Formation of Lipid Droplets (LD)

GENERAL CONSIDERATIONS

In vertebrate animals the most abundant energy reserve is stored as TAG in the LD of adipocytes. These LD can be as large as 100 µm and are composed of a core of TAG surrounded by a phospholipid and cholesterol monolayer into which numerous proteins are embedded (DeLany et al. 2005, Brasaemle et al. 2004, Wolins et al. 2005, Robenek et al. 2004, 2005a, 2005b). Most other types of cells contain tiny LD that store primarily cholesterol esters and serve as a reservoir of cholesterol for the synthesis and maintenance of membranes. Steroidogenic cells of the adrenal cortex, testes, and ovaries use stored cholesterol additionally as a source of substrate for steroid hormone synthesis. Little is known about the mechanisms that control the flux of neutral lipids into and out of LD in any type of cell, but it is clear that the processes that control lipid traffic in adipocytes are central to the regulation of whole body energy metabolism. Moreover, the biogenesis of these structures, in general, and in adipocytes, in particular, remains to be elucidated. Several proteins have been identified on their surface, including adipocyte differentiation-related protein (ADRP or adipophilin), perilipins, and caveolin, but their roles in LD assembly are unknown.

ADRP and perilipins are abundant on LD. ADRP is found mostly on smaller LD. Caveolin is a 21-kDa membrane protein with a hairpin structure whose N and C termini face the cytosol. This is in agreement with the model proposed for the assembly of LD. According to this model the TAG will during the biosynthesis "oil-out" between the leaflets of the bilayers, forming lens-shaped structures in the membrane. The LD, covered by a monolayer, will be formed by the budding of such a lens from the membrane. The structure will be stabilized by proteins bound to both the luminal and cytosolic surface of the membrane.

PURPOSE AND RATIONALE

Cell-free systems are extremely useful for studies of sorting processes, such as the budding of transport vesicles and are the only method for determining the mechanism by which such complex structures are formed. A microsome-based, cell-free system has been developed by Marchesan and coworkers (2003) to study the transport of TAG from microsomes to the cytosol. This system assembles TAG-containing LD similar to the small LD isolated from 3T3-L1 cells. Caveolin, ADRP, vimentin, and the GRP-78 are present on these LD and the release of the LD from microsomes is dependent on PLD and the formation of PA. This cell-free system may be helpful for the screening and characterization of compounds/drug candidates activating or inhibiting LD biogenesis by interference downstream of TAG synthesis (e. g. DGAT activity, assembly of LD-associated proteins at the ER, LD release from the ER) as well as for the elucidation of the mode of action of compounds/drug candidates identified in cell-based assays for lipogenesis (see K.6.1.2).

K.6.1.8.1 Preparation of Microsomes

3T3-L1 cells are cultured and differentiated for 2 days (unless stated otherwise) as described above. The cells (2×10^6 cells/incubation) are homogenized (30 strokes in a Dounce glass homogenizer in 10 mM Tris/HCl (pH 7.5) containing 250 mM sucrose, 1 mM EDTA, 100 KIU/ml Trasylol, 0.1 mM leupeptin, 0.1 µM pepstatin, and 1 mM PMSF, and the microsomes are isolated by two distinct gradient ultracentrifugation methods as described (see K.6.1.8.2). To remove loosely bound (non-integral) proteins from the microsomes, the pellet is resuspended in 500 mM Tris/HCl (pH 7.5) containing 1.2 M KCl (high salt wash) and incubated (30 min, 4°C) with head-over-tail mixing. The microsomes are then recovered by ultracentrifugation (160,000 × *g*, 70 min, 12°C). The washed microsomes are resuspended in 10 mM Tris/HCl (pH 7.5) containing 250 mM sucrose.

K.6.1.8.2 Cell-Free System

Incubation

The *in vitro* system used to investigate the formation of LD and introduced by Marchesan and coworkers (2003) is based on microsomes that had been subjected to a high salt wash, an activator from the 160,000 × *g*-supernatant from homogenized rat adipocytes, and a substrate for DGAT. To prepare the DGAT substrate, 0.25 mg of 1,2-diacylglycerol is dissolved in 40 µl of 10 mM Tris/HCl (pH 7.5) with 1.0 mM palmitoyl-CoA by gentle vortexing: 1.25 µl of [^{14}C]palmitoyl-CoA (55 mCi/mmol; total 0.06 µCi) and 360 µl of 10 mM Tris/HCl (pH 7.5) are added, and the mixture is vortexed again. To start the reaction, 600 µl of the partially purified cytosolic activator in 10 mM Tris/HCl

(pH 7.5) containing 250 mM sucrose, 150 µl of 1.4 M $MgCl_2$ (in the same buffer), and 50 µl of the microsome solution (0.5–1 mg of microsomes) are added to the DGAT substrate. Incubation is carried out (37°C, 60 min) (the production of LD plateaued between 30 and 60 min). After the incubation, the total production of radioactive TAG is measured, and the incubation mixture is subjected to gradient ultracentrifugation as described below. Before centrifugation, the mixture is supplemented with (final concentrations) Trasylol (100 KIU/ml), leupeptin (0.1 mM), PMSF (1 mM), pepstatin A (1 µM), N-acetyl-Leu-Leu-norleucinal (5 µM), and EDTA (0.5 mM).

Gradient Ultracentrifugation

For gradient I, the samples are adjusted to 25% sucrose, and 1 ml is layered under 2 ml of 50 mM Tris/HCl (pH 7.5) with 10% sucrose and 10 mM EDTA, which in turn is overlaid with 2 ml of 50 mM Tris/HCl (pH 7.5), 10 mM EDTA, and centrifuged (160,000 × *g*, 17 h, 4°C, Beckman SW55 Ti rotor). Homogenates of 3T3-L1 cells (differentiated for 10 days) are used to establish the gradient. The gradient is divided into four fractions with mean densities of < 1.018 (2 ml), 1.034 (1 ml), 1.055 (1 ml), and 1.098 (1 ml) g/ml, respectively. The major amount of TAG (∼60%) is recovered in the d < 1.018 g/ml fraction. The pellet (microsomes and cell debris) contains only ∼3% of the total amount of TAG recovered from the gradient. Caveolin is present in all fractions and in the pellet.

For gradient II, the samples are adjusted to 40% sucrose, and 1.2 ml is layered under 3 ml of 50 mM Tris/HCl (pH 7.5) with 25% sucrose and 10 mM EDTA, which is in turn overlaid with 1 ml of 50 mM Tris/HCl (pH 7.5) and 10 mM EDTA. After centrifugation (160,000 × *g*, 17 h, 4°C Beckman SW55 Ti rotor) the gradient is arbitrarily divided into 5 fractions with mean densities of 1.055 (1.2 ml), 1.099 (1 ml), 1.112 (1 ml), 1.141 (1 ml), and 1.161 (1 ml) g/ml, respectively. Most (75%) of the TAG is present in the top fraction (d < 1.055 g/ml). Caveolin is present in the top fraction and in the two bottom fractions.

K.6.1.8.3 Characterization of Lipid Droplets

SDS-PAGE

LD fractions in microcentrifuge tubes are delipidated with 1.5 ml of cold acetone overnight at –20°C followed by centrifugation (14,000 × *g*, 30 min, 4°C) and removal of solvent from the protein pellet. The pellet is further extracted with acetone (20°C) followed by acetone/ether (1/1, by vol.) and ether. Residual solvents are evaporated under nitrogen, and proteins are solubilized in 2 × Laemmli sample buffer by incubation in a bath sonicator at 65°C for 4–5 h with frequent mixing using a vortex mixer. Additional 2-mercaptoethanol is added to samples before loading onto SDS-PAGE gels. Typically, LD proteins from 28 dishes of adipocytes are loaded onto 30-cm-long SDS-PAGE gels for staining and further identification. Typically, proteins from two dishes of cells are loaded onto gels for transfer to nitrocellulose membranes and immunoblotting. Gels containing greater protein loads are stained for 2 h in 0.25% Coomassie Blue G250 in 10% acetic acid, 50% methanol and then destained in 7% acetic acid, 5% methanol for 4–6 h. To confirm the identification of known LD-associated proteins, nitrocellulose membranes containing LD proteins are probed with antisera raised against the amino terminus of rat perilipin A, mouse adipophilin (Research Diagnostics Inc., NJ), mouse TIP47 (Research Diagnostics), mouse S3–12), and caveolin-1 (Signal Transduction Inc.).

In-Gel Tryptic Digestion of LD-Associated Proteins

Coomassie-stained protein bands are excised from the gels and destained with 45% acetonitrile in 100 mM ammonium bicarbonate. The resulting gel slices are incubated with 10 mM Tris(2-carboxyethyl)phosphine hydrochloride, alkylated by the addition of 50 mM iodoacetamide, and then digested in situ with trypsin (100 ng per band in 50 mM ammonium bicarbonate). The tryptic peptides are extracted using POROS 20 R2 beads (Applied Biosystems) in 0.2% trifluoroacetic acid in 5% formic acid. The extracted peptides are concentrated using C_{18} zip-tips and eluted with 0.1% trifluoroacetic acid in 30% acetonitrile followed by 0.1% trifluoroacetic acid in 75% acetonitrile. The eluates are dried under vacuum using a SpeedVac concentrator.

Mass Spectrometry

The resulting peptides are dissolved in 2–25 µl of HPLC sample solvents containing water/methanol/acetic acid/trifluoroacetic acid (70/30/0.5/0.01, by vol.). The volume used is proportional to the staining intensity of the given band. Micro-HPLC-MS/MS analysis is conducted on an LCQ electrospray ionization ion trap mass spectrometer coupled with an online MicroPro-HPLC system. Two microliters of tryptic peptide solution is injected into a Magic C18 column (0.2 × 50 mm, 5 µm, 200 Å, Michrom BioResources) which had been equilibrated with 70% solvent A (0.5% acetic acid and 0.01% trifluoroacetic

acid in water/methanol (95/5, by vol.) and 30% solvent B (0.5% acetic acid and 0.01% trifluoroacetic acid in methanol:water (95/5, by vol.). Peptides are separated and eluted from the HPLC column with a linear gradient from 30 to 95% solvent B in 15 min at a flow rate of 2.0 µl/min. The eluted peptides are sprayed directly into the LCQ mass spectrometer (2.8 kV). The LCQ mass spectrometer is operated in a data-dependent mode for measuring the molecular masses of peptides (parent peptides) and collecting MS/MS peptide fragmentation spectra.

Database Search and Protein Identification

The measured molecular masses of parent peptides and their MS/MS data are used to search for information of non-redundant DNA/protein sequence database using the program KNEXUS (Genomic Solutions). The mass error tolerance used in the database search is usually ± 3 Da for the parent ions and ± 0.5 Da for the fragment ions, respectively. Protein identifications are made based on expectation values $< 1 \times 10^{-2}$ or the quality of MS/MS spectra of peptides identified. BLAST searches are performed for hypothetical and unknown proteins.

K.6.1.9 Re-Esterification

PURPOSE AND RATIONALE

In adipose tissue under conditions of enhanced lipolysis, i. e. during fasting or β-adrenergic stimulation, synthesis of TAG from endogenous fatty acids released from the LD during lipolysis is usually not completely repressed. This apparently vicious cycle of the so-called re-esterification is regulated in complex fashion and critically depends on the concentration of the exogenous fatty acids, which in combination with the lipolytically released fatty acids form a common pool for re-esterification. Thus, the supply from/removal by the circulation of fatty acids ultimately determines the rate of re-esterification which thereby ensures rapid and hormone-independent delivery of fatty acids into the circulation in case of immediate demand for nutrients. Previous studies of the regulation of FFA re-esterification *in vitro* have used the balance technique (Vaughan 1962), in which re-esterification is calculated from the difference between glycerol and FFA release (Gilbert et al. 1974, Hammond and Johnston 1987). This method does not distinguish between FFA re-esterification and TAG synthesis. Other studies that measured both processes simultaneously did not provide exogenous FFA in the incubation medium (Brooks 1982), and so do not accurately mimic the situation *in vivo*, in which FFA substrate may be derived from the plasma, either from hydrolysis of circulating lipoproteins or from albumin-bound FFA.

Whether FFA re-esterification may be regulated independently from TAG synthesis can be addressed by the recently developed dual-isotopic technique for measuring FFA re-esterification in adipose tissue Leibel and Hirsch 1985). This method allows TAG synthesis and re-esterification to be measured independently and simultaneously. Studies using this technique hace suggested that the rate of FFA re-esterification is not regulated at the cellular level, but rather by changes in the extracellular environment (Leibel et al. 1989, Edens et al. 1990).

PROCEDURE

Pre-incubation medium consistes of Krebs-Henseleit bicarbonate buffer containing 5 g/100 ml BSA and 4.17 mM glucose. Dual isotope incubation medium is a composition identical to pre-incubation medium, except that it also contains 0.5 mM palmitic acid and both [U-^{14}C]glucose and [9,10-^{3}H]palmitic acid. Palmitic acid is complexed to BSA as described by Leibel and coworkers (1984) with minor modifications. Briefly, a film of mixed unlabeled and [^{3}H]palmitic acid is dissolved with ethanol and a small (12%) molar excess of NaOH. This solution is heated at 60°C for 30 min with gentle shaking. It is then dried under a stream of N_2. Pre-warmed (60°C) 10% BSA in distilled, deionized water is added. The 10% BSA is heated and gently shaken until clear. The 10% BSA (now containing 1 mM palmitic acid) is combined with an equal volume of double-strength KHB bicarbonate buffer with glucose to make the incubation medium. The final medium specific activity of [^{14}C]glucose ranges from 0.4 µCi/ µmol to 0.9 µCi/ µmol, that of [^{3}H]palmitate is 2.0 µCi/µmol. The final concentration of glucose in the incubation medium is 5 mM. The gas phase above both pre-incubation and incubation media is 5% CO_2/95% O_2. All incubations are carried out 2 h at a shaking speed of 80 cycles/min and temperature of 37°C. Zero time samples are run and all other values are corrected accordingly. The isolated rat adipocytes are suspended at a 50% concentration and aliquoted (200 µl) into 2 ml of incubation medium. Incubations are done in 20-ml polypropylene, screw-top vials at 37°C, with shaking at 80 cycles/min. Incubations in medium containing either no added FFA or 0.5 mM palmitic acid are done in the basal state (no additions) and either with adenosine deaminase to prevent inhibition of lipoly-

sis or with isoproterenol (1 µM) to stimulate lipolysis. At the end of the incubations (2 h), the adipocytes and medium are poured into iced Falcon tubes containing PE90 catheters. The tubes are spun gently for 1–2 min at 0°C to float the adipocytes. Incubation medium is withdrawn from beneath the adipocytes through the catheter and frozen for subsequent glycerol assay by the method of Laurell and Tibbling (1966). The cells remaining in the tube are extracted by the method of Dole and Meinertz (1960). The extracted lipids are subjected to TLC to isolate TAG. The TAG is recovered and counted simultaneously for both ^{3}H and ^{14}C. The incorporation of [^{14}C]glucose into TAG calculate the rate of re-esterification as described (Leibel and Hirsch, 1985).

EVALUATION

Under these experimental conditions, ^{14}C is not incorporated into the fatty acid moiety of AG and ^{3}H is not incorporated into the glycerol moiety. FFA re-esterifcation can be measured because both unlabeled FFA arising from lipolysis and medium-derived [^{3}H]palmitate are esterified in newly synthesized [^{14}C]AG. The degree of dilution of [^{3}H]palmitate by unlabeled, endogenous FFA in [^{14}C]TAG is an index of the rate of re-esterification. Re-esterification is calculated as the difference between the total theoretical moles of FFA in TAG (µmol[^{14}C]TAG × 3) minus the actual total µmoles of [^{3}H]palmitate esterified into TAG. Therefore, FA re-esterification, or the esterification of unlabeled FFA in TAG equals [(3 × µmol[^{14}C]TAG)-µmol[^{3}H]TAG], where µmoles of [^{3}H]TAG represents the amount of [^{3}H]palmitate esterified into [^{14}C]TAG. The data are expressed as µmol FFA re-esterified per µmol newly synthesized TAG (3 × µmol[^{14}C]TAG - µmol[^{3}H]TAG/µmol[^{14}C]TAG), a value that theoretically can vary between zero (no re-esterification) and three (all newly esterified fatty acids derived from lipolysis). Adipocyte size is measured in aliquots of isolated adipocytes by microscopy. The lipid content of aliquots of isolated adipocytes is determined gravimetrically in Dole extracts. Adipocyte concentration in the incubation mixture is calculated by dividing lipid content by cell size (assumed to be 100% lipid).

K.6.1.10 Cellular Lipolysis

GENERAL CONSIDERATIONS

Deregulation of lipid metabolism has long been recognized as essential in the development of obesity and the metabolic syndrome. White adipose tissue (WAT) lipolysis plays a pivotal role in controlling the quantity of TAG stored in fat depots and in determining plasma free fatty acid levels (Frayn 2002). Hence, targeting critical steps of this catabolic process constitutes one of the strategies to combat obesity and the metabolic syndrome (Nisoli and Carruba 2004).

Activators of lipolysis represent a pharmacological interest only if the same molecule or another compound stimulates oxidation of fatty acid and energy expenditure. The lipolytic and thermogenic β3-adrenergic agonists highly efficient in rodents to decrease fat mass and insulin resistance have so far not been effective in humans. There are several potential explanations. Unlike rodents, adult humans have very little brown adipose tissue, the tissue specialized in thermogenesis in rodents, which possesses a lot of β3-adrenoceptors. The receptors are expressed at low levels in human white adipocytes, again a major difference with rodents. Finally, the first generation of β3-adrenergic agonists may have low efficacies and potencies for the human β3-adrenergic receptor. Nevertheless, the approach is interesting conceptually. Ideally, a strategy could be to stimulate lipolysis and use of the fatty acids by newly formed brown fat cells (Tiraby and Langin 2003, Langin 2006). Concomitant stimulation of fat oxidation in skeletal muscle is an alternative strategy. The recently characterized lipolytic receptors (e. g., natriuretic peptide and pituitary adenylate cyclase-activating polypeptide receptors) and pathways (e. g., residual lipolytic effect of catecholamines in mice with no β-adrenoceptors) may constitute novel drug targets.

Since the launching of nicotinic acid (niacin) as a lipid-lowering drug a long time ago, suppression of lipolysis to decrease free fatty acid level has attracted much interest (Karpe and Frayn 2004). However, most known antilipolytic receptors are expressed in several organs raising the risk for side-effects. The recent cloning of the receptor for nicotinic acid which is mainly expressed in WAT has undoubtedly led to important screening efforts for the identification of agonists with less side-effects than niacin and its long-lasting form, acipimox (Tunaru et al. 2003, Wise et al. 2003). Inhibition of HSL is also attractive as the enzyme has little homology with other mammalian lipases and show a rather limited tissue distribution. Indeed, several series of agonists have been synthesized (Slee et al. 2003, Ebdrup et al. 2004) with an apparent high specificity for some of them (Langin et al. 2005). The effect of chronic treatment in rodent models of obesity and dyslipidaemia is now awaited.

PURPOSE AND RATIONALE

The inhibition of lipolysis induced by starvation or β-adrenergic stimulation in response to insulin is of exquisite sensitivity ($IC_{50} < 0.1$ nM) and responsiveness (lipolysis rate less than 5% of that in the basal state) toward the hormone. This reflects the enormous physiological importance of a tight regulation of fatty acid release from adipose tissue to ensure both adequate nutrient supply and prevention from the detrimental so-called lipotoxic effects of FFA in the circulation. The complex molecular mechanism of the signal transduction in the adipocytes from the insulin receptor downstream to the lipolytic end effector systems, i. e. the TAG-degrading lipases (see K.6.1.13) has been characterized in detail (for a review see Müller and Petry 2005). It encompasses the translocation of lipases (HSL) and LD surface proteins (perilipins) from the cytosol to the LD and *vice versa*, respectively, which is stimulated in the fastened/β-adrenergic state and blocked in response to insulin. These translocation processes are regulated by (PKA-dependent) phosphorylation of both the lipases and LD surface proteins and presumably additional regulatory proteins. These phosphorylations are down-regulated by insulin through stimulation of cAMP degradation by phosphodiesterase 3B which is linked directly to distal elements of the insulin signaling cascade in adipocytes. Basal and stimulated lipolysis as well as its inhibition is monitored *in vitro* with cultured and primary rodent and human adipocytes and can be used to study insulin-like effects on the negative regulation (i. e. activation of the insulin signaling) or direct inhibition of lipolysis (i. e. of the lipases involved) by compounds/drug candidates. Several procedures are available based on the determination of glycerol and fatty acids released from unlabeled, fluorescently labeled or radiolabeled TAG.

K.6.1.10.1 Method Based on Isolated Fat Pads

Gonadal fat pads are removed from male rats and washed several times with PBS. Tissue pieces (~20 mg) are incubated in DMEM containing 2% fatty acid-free BSA with or without 10 µM isoproterenol at 37°C. Portions are collected after 30, 60, 120, 180 and 240 min and analyzed for the FFA and glycerol content by using commercial kits (Wako Chemicals).

K.6.1.10.2 Method Based on the Release of Fluorescent Fatty Acids from Isolated Adipocytes

PROCEDURE

This method which avoids the use of radioactivity but nevertheless enables the visualization and quantitative evaluation of the released fatty acids has been introduced by Müller and coworkers (2003). For fluorescent labeling of adipocyte TAG, 250-µl portions of adipocyte suspension in 1.5-ml plastic cups are incubated (15 min, 37°C) with 200 µl of KRH containing 1% BSA in the presence of 0.55 nM insulin prior to addition of 50 µl of NBD-FA (500 µM, prepared daily by dissolving 39.8 mg NBD-FA in 1 ml ethanol under moderate heating and subsequent 1:200 dilution with KRH containing 1% BSA) and further incubation (1 h, 37°C) under mild shaking (thermomixer 5436, setting 10, Eppendorf, Hamburg, Germany). For removal of free NBD-FA left in the incubation medium, the adipocyte suspensions are combined in 50-ml plastic vials and centrifuged ($500 \times g$, 1 min, swing-out rotor). The infranatant below the cell surface layer is aspirated. The adipocytes are suspended in 30 ml of medium L (Medium 199 containing 25 mM HEPES, 4 mM L-glutamine, 5.5 mM glucose, 3% BSA). After two further cycles of centrifugation and resuspension, the washed adipocytes are finally adjusted to 2.5×10^6 cells/ml in medium L. For treatment with compounds/drug candidates directly inhibiting relevant lipases which may bind to proteins, the adipocytes are washed with medium L lacking BSA and then incubated (15 min, 37°C) with the inhibitors in the same medium. For initiation of lipolysis, 400-µl portions of adipocyte suspension are supplemented with 500 µl of medium L containing 2 or 4% BSA (in case of preincubation with inhibitors) and 5.5 mM glucose and incubated (37°C) for 30–180 min in the presence or absence of combinations of isoproterenol and ADA in plastic scintillation vials (total vol. 1 ml) under mild shaking in a water bath. 150-µl Portions of the suspension are transferred into pre-cooled Eppendorf cups containing 750 µl chloroform/heptane/methanol (3/3/2 by vol.), mixed vigorously and centrifuged ($12{,}000 \times g$, 1 min). The lower organic phase is removed, dried (SpeedVac) and then suspended in 20 µl of THF. 5- to 10-µl portions are analyzed by TLC using Si-60 F_{254} plates (Merck, Darmstadt, Germany) and diethylether/petrolether/acetic acid (78/22/1, by vol.) as solvent system.

EVALUATION

Quantitative evaluation of the amount of NBD-FA is performed by fluorescence imaging (Storm 860, Molecular Dynamics, Germany) using imaging software (Molecular Dynamics, ImageQuant). Alternatively, 20-µl aliquots of the lower phase are supplemented with 325 µl of methanol/chloroform/ heptane (10/9/7, by vol.) and 1.05 ml of 0.1 M potassium carbonate, 0.1 M boric acid (pH 10.5), vortexed and then centrifuged (12,000 × *g*, 1 min). 150-µl Portions of the upper phase are removed and measured for fluorescence (automatic fluorometric analyzer, Cobas Bio, Roche Diagnostics, Germany).

K.6.1.10.3 Method Based on the Release of Glycerol from Isolated Adipocytes

PROCEDURE

The determination of glycerol released from unlabeled adipocytes is the most common and convenient method and can be performed according to published procedures (Petry et al. 2005) with the following modifications. 300-µl aliquots of the incubation mixtures are rapidly transferred into 1.5-ml Eppendorf cups precooled to 4°C and containing 300 µl of 10% (w/v) $HClO_4$. After incubation (1 h, 4°C), the precipitates are removed by centrifugation (12,000 × *g*, 2 min). The infranatants recovered are neutralized with 20% KOH, followed by addition of 60 µl of 1 M Tris/HCl (pH 7.4). 150-µl samples are removed for glycerol determination, frozen in liquid N_2 and stored at –20°C. Glycerol is measured fluorometrically by a modified version of the enzymatic method (Wieland 1974). The reaction mixture contains 0.1 M Tris/HCl (pH 9.3), 0.9 mM ATP, 1.25 mM NAD, 0.1 M $MgCl_2$, 0.25% (v/v) hydrazine hydrate, 5–50 µl sample or glycerol standard, and a mixture of glycerol kinase (0.2 U/ml final conc.) and glycerol 3-phosphate dehydrogenase (0.7 U/ml final conc.) in a total volume of 240 µl. Fluorescence is determined using an automatic fluorometric analyzer.

K.6.1.10.4 Method Based on the Release of [^{3}H]Oleic Acid from Isolated Adipocytes

PROCEDURE

Adipocytes are washed with KRPH buffer (128 mM NaCl, 4.7 mM KCl, 1 mM $MgCl_2$, 1.25 mM $CaCl_2$, 25 mM sodium phosphate, 1 mM sodium pyruvate, 5.5 mM glucose, 50 mM HEPES/KOH, pH 7.4) and then incubated (2 h, 37°C) in fresh KRPH containing [^{3}H]oleic acid (50 µCi *per* 2×10^6 cells and ml) and 1% BSA in the presence of 0.55 nM human insulin. The adipocytes are washed with KRPH (10°C) containing 5.5 mM glucose and 2% BSA or lacking BSA (for subsequent treatment with direct lipase inhibitors for 15 min at 37°C) three times by centrifugation and then incubated (2 h, 37°C) under mild shaking in KRPH containing 5.5 mM glucose, 2% BSA and 400 µM phloretin (for reduction of fatty acid uptake by 85%) at 1×10^6 cells/ml in the presence of lipolytic stimuli. Thereafter, 150-µl portions of the adipocyte suspension are transferred into narrow centrifugation tubes (Beckman) and then overlayed with 100 µl of dinonylphtalate (Merck, Darmstadt, Germany). After centrifugation (2,000 × *g*, 30 sec, 25°C), the tubes are cut through the oil layer and the lower parts of the tubes containing the incubation medium transferred into 5-ml scintillation vials and mixed with 3 ml of chloroform/heptane (1/1, by vol.) containing 2% methanol. After centrifugation (2,000 × *g*, 5 min), the upper aqueous phase is removed by suction. Following addition of 5 ml of liquid scintillation cocktail to the lower organic phase, radioactivity is measured.

EVALUATION

Control values of the 0-min incubation with the corresponding lipolytic stimulus are subtracted in each case to correct for [^{3}H]oleic acid left from the labeling period and accounting for 2–7% of the total radioactivity recovered with the medium. TLC and phosphorimaging analysis revealed that both under basal and lipolytic conditions, [^{3}H]oleic acid accounts for more than 70% of the total radioactivity measured, radiolabeled degradation products (recovered mainly with the aqueous phase) for 15–20% and TAG for up to 6%.

K.6.1.10.5 Method Based on the Release of Unlabeled Fatty Acids from Isolated Adipocytes

PURPOSE AND RATIONALE

Studying lipolysis with human adipocytes and adipose tissues is hampered by methodological problems. The amount of human adipose tissue that is available is usually limited and the rate of lipid mobilization from human adipocytes is low compared to that of rat adipocytes. Both chemical and enzymatic methods for determination of FFA in human blood and serum have been developed (e. g. Matsubara et al. 1983, Shimizu et al. 1980, Duncombe and Rising 1973, Miles et al. 1983, Okabe et al. 1980). However, incomplete recovery of FFA from plasma (Duncombe and Rising 1973)

and interference of BSA with the FFA assays (Matsubara et al. 1983, Shimizu et al. 1980, Okabe et al. 1980) have been reported, which results in an underestimation of FFA values in serum and plasma samples. To overcome this, the extraction method has been modified (Duncombe and Rising 1973), BSA has been included in the standard curve (Miles et al. 1983) or p-toluenesulfonic acid has been used (Matsubara et al. 1983).

These methods are unsuited for FFA determination for human *in vitro* studies since the detection limit is too high using small amounts of human adipose cells with usually low lipolytic activity. Näslund and coworkers (1989) have established a chemiluminometric method for the determination of low levels of FFA based on H_2O_2 determination in a peroxidase luminescence reaction. Since albumin (which must be added to the incubation medium as FFA carrier) inferes with this assay resulting in non-linear FFA standard curves, Näslund and coworkers (1993) modified the chemiluminometric assay for compatibility with biological samples containing albumin.

PROCEDURE

A semiautomatic luminometric method for determination of small amounts of FFA released from human adipocytes *in vitro* has been introduced by Näslund and coworkers (1993). BSA is used as acceptor of FFA in the incubation medium of isolated fat cells. The assay involves pretreatment with the detergent SDS to liberate the FFA from the BSA before activation by acyl-CoA synthetase (ACS). This is followed by oxidation of the resulting thioesters by acyl-CoA oxidase (ACO). The H_2O_2 formed is subsequently measured in a horseradish peroxidase (HRP)-catalyzed luminol reaction. The assay is linear in the interval of 0.01–1 nmol in the cuvette corresponding to 2–200 µmoles in the sample, and 25 samples can be automatically assayed in the luminometer within 75 min. FFA release can easily be studied in a small incubation volume (200 µl) of very diluted (10^4 cells/ml) human adipocyte suspensions. Samples (25 µl) containing 0.25% BSA from incubates of adipose tissue cells do not interfere with the standard curve. This method (Näslund et al. 1993) is sensitive, simple and inexpensive luminometric assay for FFA release. It is many 100-fold more sensitive than standard spectrophotometric methods and can be used for serial studies of lipid metabolism (lipolysis, FFA re-esterification) in small amounts of human adipose tissue or for investigations of FFA release from very diluted human adipose cell samples.

K.6.1.11 Cell-Free Lipolysis

PURPOSE AND RATIONALE

For analysis of effects of compounds/drug candidates on the translocation to the LD and direct activation of HSL including the increase in accessibility of the TAG of LD for degradation by HSL (or other/additional lipases), these individual steps of lipolysis can be reconstituted in a cell-free system consisting of purified LD and crude HSL (and other lipases) prepared from primary rat adipocytes.

PROCEDURE

Preparation of LD from Adipocytes

LD are prepared according to Egan and coworkers (1992) and adaptions from Wolins and coworkers (2005) with the following modifications: After the incubation, the adipocytes are washed two times with KHH by flotation and removal of the infranatant by suction and then homogenized in 25 mM Tris/HCl (pH 7.4), 250 mM sucrose, 5 mM NaF, 10 mM $NaPP_i$, 1 mM Na_3VO_4, 1 mM EDTA, 20 µg/ml leupeptin, 1 mM benzamidine, 0.5 mM PMSF at 15°C. After centrifugation (1,000 × *g*, 5 min, 15°C), 1 ml of the supernatant is combined with 1.5 ml of 65% sucrose (w/v) and poured into a 5-ml centrifuge tube. 1.5 ml of 10% sucrose (w/v) is then layered on top of the sucrose cushion. The tube is filled to capacity with buffer A. The gradient is centrifuged (172,000 × *g*, 60 min, 15°C) and then allowed to coast to rest. The floating fraction of LD is visualized as the upper white layer of the gradient, and is isolated by suction with a syringe (0.8 ml). After one washing cycle with buffer A, the LD are suspended in an equal volume of 4-fold sample buffer containing 10% SDS by incubation (10 min, 65°C) and treatment in a bath sonicator (10 min, 25°C, max. power) for extraction of proteins. After centrifugation (10,000 × *g*, 5 min, 25°C), proteins contained in the infranatant are separated by SDS-PAGE. Alternatively, the gradient is fractionated from bottom to top by suction with a syringe (0.8 ml each). Proteins of fractions 1–5 are precipitated with 5% TCA (15 min, 2°C, 15,000 × *g*, 10 min), washed three times with ice-cold acetone, dried and finally suspended in sample buffer. Fraction 6 is extracted for protein (see above). All samples are analysed by SDS-PAGE and immunoblotting.

Cell-Free System

Adipocytes labeled with NBD-FA (see K.6.1.2.2) are washed with KRH containing 0.5% BSA, suspended

in the same medium at 3.5×10^5 cells/ml and incubated (5 min, 37°C) in plastic scintillation vials under mild shaking in a water bath in the presence or absence of isoproterenol, insulin or compound/drug candidate. Adipocytes (3.5×10^6 cells) are washed twice with BSA-free KRH by flotation ($500 \times g$, 1 min) and then suspended in 2.5 ml of homogenization medium (50 mM Tris/HCl, pH 7.4, 1 mM EDTA, 0.25 M sucrose, 2 mM DTT, 50 mM glycerol-3-phosphate, 10 mM sodium pyrophosphate, 25 mM NaF, 1 µM microcystin, 2 µM cantharidin, 1 mM benzamidine, 5 µg/ml leupeptin, 10 µg/ml pepstatin, 2 µg/ml antipain, 25 µg/ml soy bean trypsin inhibitor, 5 µg/ml PKA inhibitor). The mixture is vortexed, homogenized in a teflon-in-glass homogenizer (10 strokes using a rotating teflon pestle) at 15°C, transferred into plastic vials (under rinsing of the homogenization vessel with homogenization medium) and then centrifuged ($12{,}000 \times g$, 30 min, 4°C, swing-out rotor). The infranatant (cytosol) is separated from the (fluorescent) TAG-containing LD by aspiration with a syringe. To eliminate entrapped unbroken cells, the LD are resuspended in 8 ml of homogenization medium (15°C) containing 120 mM sucrose and 140 mM KCl, vortexed vigorously, and subsequently subjected to centrifugation ($200{,}000 \times g$, 1 h). The infranatant (washing medium) is removed by suction. For initiation of NBD-FA release, 1 ml of ice-cold homogenization medium containing 2% BSA is added to the plastic vial while the LD adhering to the vessel wall are removed by repeated pipetting. A teflon-coated magnetic stirring disc is placed into the vial. The mixture is warmed up to 30°C and incubated under stirring (250 rpm) for 1 to 4 h. The digestion is terminated by addition of 2 ml of chloroform/methanol (3/1; by vol.). The extracts are dried (SpeedVac), suspended in 50 µl of THF and then analyzed by TLC as described below.

Cell-free lipolysis is performed in glass tubes as described by Okuda and coworkers (1994) and Morimoto and coworkers (2000, 2001) with the following modifications: 40 µl of packed NBD-FA-labeled LD are incubated (90 min, 30°C, constant shaking) with 80 µl of a solution enriched for HSL (100–200 µg protein) and 120 µl of buffer C containing 2% BSA, 2 mM DTT with or without 4.2 mg gum arabic. For incubation of the cell-free lipolysis system, compounds are added directly from the 10-mM stock solutions in DMSO to the reaction mixture containing the LD without prior dilution. The final DMSO concentration during all incubations is kept constant at 0.1%. Portions of the lipolysis reaction are terminated by extraction of the total incubation mixture with 720 µl of chloroform/methanol/0.1 N HCl (3/1/1, by vol.). After vortexing and centrifugation ($2{,}000 \times g$, 2 min) of the mixture, the organic phase is collected, dried under a stream of N_2 and resuspended in 40 µl of tetrahydrofurane. 10-µl portions are analyzed by TLC (Silica Gel G plates, Merck Darmstadt, Germany; diethylether/petrolether/acetic acid, 78/22/1 by vol.). NBD-FA released from the total NBD-FA-labeled AG is quantitatively evaluated by phosphorimaging (e. g. Storm 860, Molecular Dynamics, Germany) using imaging software (ImageQuant, Molecular Dynamics), as described previously (Müller et al. 2003).

EVALUATION

A blank value of a control reaction terminated immediately after addition of HSL-solution to the LD is subtracted in each case. Other portions of the lipolysis reaction are supplemented with 760 µl of buffer C containing protease inhibitors and centrifuged through sucrose cushions for the recovery of LD which are then analyzed for protein composition, in particular for the amount of HSL (HSL translocation, see K.6.1.12).

K.6.1.12 Translocation of Hormone-Sensitive Lipase (HSL)

PURPOSE AND RATIONALE

The molecular mechanism of the regulation of lipolysis in adipocytes by starvation, β-adrenergic stimuli and insulin as well as compounds/drugs (e. g. nicotinic acid relies on the movement of HSL from the cytosol, its predominant location in the basal state, to the LD (Egan et al. 1992, Brasaemle et al. 2000, Clifford 2000, for reviews see Holm 1999 and 2003, Londos 2005, Müller et al. 2005). Candidate components involved in this HSL translocation initiated by β-adrenergic stimuli and inhibited by insulin and lipid-lowering durgs are elements of the cytoskeleton and LD-associated proteins, such as perilipin. Interestingly, perilipin has been observed to undergo reverse translocation from the LD to the cytosol upon challenge of adipocytes with insulin. The relative contribution of HSL and perilipin translocation to lipolysis stimulation seems, however, to depend on size, age and origin of the adipocytes. HSL translocation blocked by insulin or compounds can be easily monitored by immunoblotting of isolated LD for HSL

PROCEDURE

For the identification of HSL associated with LD in the induced compared to the basal state of the adipocytes, LD are prepared, purified, suspended in 20% SDS,

vortexed vigorously, then incubated (10 min, 95°C) and finally centrifuged (12,000 × *g*, 5 min). Solubilized LD-associated proteins recovered from the infranatant by suction are analyzed by SDS-PAGE (7.5% separating gel). The proteins are then transferred onto polyvinylidine difluoride (PVDF) membranes for 4 h at 200 mA using 20 mM 3-(cyclohexylamino)-1-propanesulphonic acid (pH 11.0) in 10% methanol. Transfer efficiency is evaluated by Amido black staining in control lanes. The membrane is washed with PBS containing 0.1% Tween-20, then incubated (1 h, 25°C) with PBS containing 0.5 M NaCl and 0.75% BSA and subsequently incubated (18 h, 4°C) in the same buffer with anti-HSL antibody (1:1,000 dilution, 0.5–2 µg/ml). This antibody was raised in white New Zealand rabbits against recombinant full-length His-tagged human HSL. This 84-kD polypeptide was encoded by a pET-derived expression vector under the control of the T7 promoter, expressed in *E.coli*, then partially purified from inclusion bodies by SDS-PAGE and subsequent elution from the gel band and finally homogenized in PBS prior to emulsification in Ribi Adjuvant System (RIBI Immunochem Research Inc., USA) and subsequent intraperitoneal injection into rabbits. The antibody was purified by chromatography on protein A-Sepharose. Subsequently, the blotting membrane is washed two times with PBS containing 0.1% SDS, 0.2% Nonidet P-40, and 0.25% sodium deoxycholate and then once with PBS. Thereafter the filters are incubated (2 h, 25°C) with horseradish peroxidase conjugated anti-rabbit-IgG (1:5,000 dilution) in PBS containing 0.75% BSA.

EVALUATION

Following three washing cycles (see K.6.1.4.3.1, K.6.3.1.3.2.1 and K.6.3.4.3), the amount of HSL is determined by ECL Western blotting detection reagents (Amersham-Pharmacia, Germany) according to the manufacturer's instructions. Quantitative evaluation is performed by luminometric scanning (Roche Diagnostics, Germany) using ImageQuant software.

K.6.1.12.1 Protein Composition of LD

PURPOSE AND RATIONALE

Stimulation as well as inhibition of lipolysis in adipocytes by hormones, nutritional signals or compounds/drug candidates exerts marked effects on the protein composition of LD favoring TAG/LD degradation or TAG/LD synthesis, respectively. These alterations can be monitored by modern proteomic analysis as has already been performed by Brasaemle and coworkers (2004) for 3T3-L1 adipocytes, Liu and coworkers (2004) for CHO fibroblasts, Fujimoto and coworkers (2004) for cultured human HuH7 hepatoma cells, Umlauf and coworkers (2004) for cultured human A431 epithelial cells and Wu and coworkers (2000) for mouse mammary glands. The unexpected identification of caveolin as LD-associated protein in adipocytes (for a review see Liu et al. 2002) demonstrates the power of modern proteomic analysis. These data may be useful to characterize and differentiate the molecular mechanisms of compounds which interfere with the lipid metabolism of physiologically relevant cells, such as adipocytes, at unknown site(s).

PROCEDURE

For proteomic analysis of adipocyte LD, six days after the initiation of differentiation, 40 dishes of 3T3-L1 adipocytes are incubated either under lipolytically stimulated conditions (e. g. 10 µM isoproterenol and 0.5 mM IBMX for 15 min at 37°C) or without the additions for basal conditions and subsequently in the absence or presence of anti-lipolytic stimuli (e. g. insulin or compounds/drug candidates for 2 h) before harvest. Culture medium is removed, and cells are rinsed twice with ice-cold PBS before scraping of the cells into PBS using typical cell scrapers. Cells from sets of 10 dishes of cells are pooled into 15-ml conical screw-capped tubes (Falcon) and centrifuged (500 × *g*, 5 min). Cell pellets are resuspended in a hypotonic medium containing 10 mM Tris (pH 7.4), 1 mM EDTA, 10 mM sodium fluoride, 20 µg/ml leupeptin, 1 mM benzamidine, and 100 µM 4-(2-aminoethyl)benzenesulfonylfluoride hydrochloride by pipetting and incubated on ice for 10 min before homogenization by 10 strokes in a Teflon-glass homogenizer. Cell lysates are centrifuged (26,000 × *g*, 30 min, 4°C, SW41 Ti-rotor Beckman), and the rotor is allowed to coast to a stop. The floating LD layers are harvested using a tube slicer, and the harvested fractions are adjusted to 25% sucrose and 100 mM sodium carbonate (pH 11.5) using a 60% sucrose stock solution and a 1 M sodium carbonate stock solution with protease inhibitors followed by gentle mixing by pipetting. The density-adjusted fractions (~4 ml) are layered into centrifuge tubes containing 1-ml cushions of 60% sucrose and then overlaid with ~5 ml of 100 mM sodium carbonate (pH 11.5) with protease inhibitors followed by ~3.5 ml of the hypotonic lysis medium with protease inhibitors. Tubes are centrifuged (26,000 × *g*, 30 min, 4°C, SW41 Ti-rotor Beckman) and the rotor is allowed to coast to a stop.

Floating LD are harvested using a tube slicer into 1.5-ml microcentrifuge tubes. Residual carbonate solution is removed by centrifuging tubes (14,000 × *g*, 20 min, 4°C, Eppendorf microcentrifuge). The infranatant is removed with an 18-gauge needle from below the floating LD fraction, and the LD fraction is rinsed once with hypotonic lysis solution containing protease inhibitors.

EVALUATION

Typically, LD are isolated from 8 separate sets of 40 dishes of adipocytes grown and differentiated at different times. 4 sets of dishes are used for basal conditions, and 4 sets of dishes are used for lipolytically stimulated conditions. Proteins from LD preparations from 3 sets of 28 dishes of basal adipocytes are separated in 3 lanes of a single SDS-PAGE gel. Coomassie-stained bands are compared and found to be equivalent for all lanes. Bands from one lane are excised for analysis by mass spectrometry. Proteins from LD preparations from 3 sets of 28 dishes of lipolytically stimulated adipocytes are separated in 3 lanes of a single SDS-PAGE gel and compared with a single lane containing proteins from 28 dishes of basal adipocytes on the same gel. Coomassie-stained bands are compared and found to vary slightly between the three preparations from the lipolytically stimulated adipocytes and significantly between basal and stimulated preparations. Bands are excised for all stained proteins from two lanes of stimulated preparations and analyzed by mass spectrometry.

The LD of adipocytes are unique among LD of many types of cells with respect to size, the perilipin-enriched protein composition, and the dynamic rearrangements in structure that occur in response to stimulation of the β-adrenergic signaling pathway. Although perilipin A is the most abundant protein associated with the large LD of basal adipocytes, when lipolysis is stimulated, these LD fragment into myriad micro-LD. Interestingly, the total mass of perilipin does not increase in proportion to the greatly increased surface area of the micro-LD. Some of the excess surface becomes coated with other PAT family members, adipophilin, TIP47, and S3–12 (Wolins et al. 2005). Additionally, the association of numerous unrelated proteins with the LD increases.

Adipophilin was found by proteomic analysis of proteins on LD isolated from lipolytically stimulated 3T3-L1 adipocytes but not basal adipocytes. This finding was confirmed by immunofluorescence microscopy experiments. The appearance of adipophilin on the LD of lipolytically stimulated adipocytes may be a consequence of increased availability of binding sites on micro-LD to stabilize nascent adipophilin. The results strongly suggest that adipophilin plays a role in lipolysis. The identification of caveolin-1 on LD isolated from lipolytically stimulated but not basal adipocytes is consistent with previous observations (Cohen et al. 2004). Caveolin-1, perilipin, and the catalytic subunit of PKA can be co-immunoprecipitated from lysates of adipocytes preincubated with β-adrenergic receptor agonists but not from basal adipocytes (Cohen et al. 2004). Thus, the three proteins form a complex in stimulated cells with caveolin-1 thereby bridging between perilipin and the catalytic subunit of PKA to facilitate the phosphorylation of perilipin. The identifications of lipid metabolic enzymes on the LD of adipocytes and several other types of cells shows that these structures are not passive repositories for neutral TAG but, instead, comprise a dynamic pool of lipids.

The identifications of several proteins in the adipocyte LD preparations carry implications regarding the immediate subcellular neighborhood of LD. The intermediate filament protein, vimentin, is identified in the basal and stimulated state. Previous studies show that fibrous vimentin intermediate filaments collapse into a cage structure around developing LD in differentiating adipocytes (Franke et al. 1987). The disruption of vimentin cage formation halts LD formation (Lieber et al. 1996). Identification of the Eps-15 homology domain protein EHD2, a protein that binds to actin filaments in differentiated 3T3-L1 adipocytes (Guilherme et al. 2004), provides additional evidence of a close link between LD and the cytoskeleton. The identification of calnexin in basal and lipolytically stimulated LD preparations, as confirmed by immunofluorescence microscopy, suggests that segments of endoplasmic reticulum come into close contact with LD. Finally, several mitochondrial proteins can be identified in both preparations, including a subunit of ATP synthase, prohibitin, and pyruvate carboxylase, indicating that mitochondria are closely associated with and difficult to separate from LD. Several studies have illustrated the tight packing of mitochondria around LD in adipocytes (Cohen et al. 2004, Blanchette-Mackie et al. 1995).

In conclusion, surface proteins on adipocyte LD include enzymes involved in many aspects of lipid metabolism, as found on LD in other types of cells. However, unlike other types of LD, perilipins are a major protein component that controls lipid traffic and the association of adipophilin (Brasaemle et al. 1997, Tansey et al. 2001, 2003), HSL (Sztalryd et al. 2003),

CGI-58 (Yamaguchi et al. 2004, Subramanian et al. 2004), and likely of other proteins with the LD. The stimulation of lipolysis is accompanied by the fragmentation of large LD into numerous dispersed micro-LD accompanied by major changes in the overall protein composition. Although most of the changes appear to affect the relative mass of various proteins that also associate with basal LD, adipophilin and caveolin-1 selectively associate with LD in stimulated cells. It is expected that this type of analysis will be useful for the future characterization including elucidation of the mode of action of compounds/candidate drugs which affect lipid metabolism by either stimulating or inhibiting TAG synthesis or degradation and in consequence LD biogenesis in adipose as well as in non-adipose tissues.

K.6.1.12.2 Interaction of HSL and Perilipin

PURPOSE AND RATIONALE

Recently, the differential effects of blocking perilipin phosphorylation on HSL translocation and lipolysis have been dissected (Miyoshi et al. 2006). Employing adenoviral and transgenic expression of a perilipin construct deficient in all 6 PKA sites (Peri A Δ1–6), PKA-dependent phosphorylation of perilipin has been demonstrated not to be required for HSL translocation to the LD, but is essential for the lipolytic actions of LD-associated HSL in adipocytes. Crosslinking and immunoprecipitation studies suggest that PKA-dependent phosphorylation of perilipin promotes close-range interaction with LD-associated HSL. It is conceivable that compounds/drug candidates promoting or abrogating TAG synthesis/LD biogenesis or their degradation modify the HSL-perilipin in negative or positive fashion, which can be monitored with the following assay systems.

PROCEDURE

Construction of Perilipin KO Mice Expressing the Perilipin Mutant Transgene Lacking the 6 PKA Consensus Phosphorylation Sites in BAT

A targeted disruption of the perilipin gene is performed by replacing exon 3 with a neomycin cassette, thereby disrupting coding of all known perilipin mRNAs. The perilipin KO mice are viable and exhibit predicted reductions in adipocyte size and adipose mass (Martinez-Botas et al. 2000). Perilipin KO mice are backcrossed for 10 generations to C57BL/6 mice. For generation of mice expressing a peri Δ1–6 transgene in adipose tissue, a mouse peri Δ1–6 cDNA, FLAG-tagged at the carboxy-terminal using PCR is generated and then ligated into a SmaI site of pBluescript SK vector containing the aP2 enhancer/promoter region, the SV40 small tumor antigen splice site and polyadenylation signal sequence. A fragment containing the entire aP2-perilipin A-FLAG transgene is microinjected into fertilized eggs of C57BL/6 mice using well-described procedures (Brinster et al. 1981). Transgenic mice expressing the peri Δ1–6 transgene almost exclusively in BAT are obtained. These mice are fully viable, exhibit no apparent adipose phenotype and are mated with backcrossed perilipin KO mice to generate perilipin A Δ1–6 mice (Miyoshi et al. 2006).

HSL-Perilipin Crosslinking and Coimmunoprecipitation

Differentiated adipocytes expressing GFP and wild-type or mutant (e. g. deletion of the 6 PKA consensus phosphorylation sites) FLAG-tagged perilipin A are incubated in differentiation medium containing palmitic and oleic acid (240 µM each) for 48 h. After overnight serum depletion, adipocytes are treated for 15 min with 200 nM phenylisopropyl adenosine (PIA, basal state) or 20 µM forskolin *plus* 0.5 mM IBMX (stimulated state), washed with PBS and then maintained for 10 min in hypotonic lysis buffer (20 mM HEPES/KOH, pH 7.5, 2 mM EDTA, 50 mM sodium fluoride, 100 µM sodium orthovanadate, protease inhibitor cocktail) and either PIA or forskolin *plus* IBMX. Cells are then harvested and homogenized (10 strokes with a teflon-in-glass homogenizer on ice). 3,3′-Dithiobis sulfosuccinimidylpropionate (DTSSP), a cross-linker with 12A spacer arm length (Pierce, Rockford) is added to the homogenates and incubated with rotation at 22°C for 30 min. The crosslinking reaction is terminated by addition of Tris/HCl (50 mM final). After addition of Triton X-100 (2% final) and NaCl (75 mM final), samples are drawn through a 23-gauge needle and then centrifuged (10,000 × *g*, 20 min, 4°C) to separate the LD (upper layer), infranatant (lower layer) and a membrane pellet. The LD are isolated with a tube cutter and placed in a fresh tube. The infranatant is subjected to multiple rounds of centrifugation and removal of the residual LD, until almost no LD are visible. The pooled LD fractions are washed with 1 ml of fresh lysis buffer, collected after centrifugation and resuspended in fresh lysis buffer. Half of this LD suspension is used for TAG measurement. The other half is incubated with SDS lysis buffer (10% final) at 37°C for 30 min with vortexing and then centrifuged for 10 min, after which the final LD fraction is harvested. Portions of each fraction are loaded on SDS-PAGE gels and

then immunoblotted for perilipin and HSL. This confirmed that more than 95% of perilipin is removed from the LD and present in the infranatant fraction. The infranatant fraction is immunoprecipitated using the FLAG-Tagged protein immunoprecipitation kit (Sigma) at 4°C for 24 h with rotation. Immunoprecipitates are eluted from the pelleted anti-FLAG agarose beads by boiling in SDS-PAGE sample buffer containing 2-mercaptoethanol. The reducing conditions are sufficient to break the DTSSP-induced protein crosslinks. Eluted samples are electrophoresed and immunoblotted for the LD-associated proteins, perilipin and HSL. To assess potential non-specific crosslinking of perilipin with membrane or cytosolic proteins, immunoblots are also probed with corresponding antibodies (e. g. toward clathrin, adiponectin).

EVALUATION

With respect to the phosphorylation-dependent mechanism by which perilipin promotes lipolysis, the assay monitoring the interaction of HSL and perilipin reveals that the lipolytic action(s) of LD-associated HSL require a novel event(s) mediated by PKA-dependent perilipin phosphorylation. The prpecise nature of this event(s) remains to be elucidated. However, it is likely to involve conformational changes in perilipin that bring LD-associated HSL into proximity with stored neutral TAG. The effected LD-associated HSL presumably includes the pool of HSL that is prepositioned at the LD in the basal state (Moore et al. 2005, Morimoto el al. 2001, Brasaemle et al. 2004). The crosslinking studies suggest that PKA-dependent phosphorylation of perilipin alters the spatial relationship between perilipin and LD-associated HSL in such a way as to facilitate close-range interaction between the two (or between HSL and a perilipin-associated moiety). This interaction may facilitate access of LD-associated HSL to stored neutral TAG, thereby initiating lipolysis. Recently, chronic PKA-dependent phosphorylation of perilipin A has been shown to induce LD remodeling (i. e. fragmentation and dispersion) independently of lipase action (Marcinkiewicz et al. 2006). This suggests that this remodeling promotes lipolysis and supports the concept that PKA-dependent phosphorylation induces dramatic conformational changes in perilipin.

Thus, perilipin seems to act as the critical component of a scaffold that stabilizes LD structure and composition for optimal TAG storage and regulated lipolysis (Moore et al. 2005, Brasaemle et al. 2004). Compounds/drug candidates interfering with lipolysis may directly modify the perilipin-HSL interaction without affecting perilipin phosphorylation. Those compounds could be identified using the crosslinking assay.

K.6.1.13 Triacylglycerol (TAG) Lipases (HSL, ATGL) Activity

GENERAL CONSIDERATIONS

A direct effect of a compound on the activity of HSL rather than its translocation can be assayed in a cell-free system consisting of emulsified TAG rather than intact LD (see K.6.1.12.1). Lipases play a key role in human lipid metabolism as they degrade dietary nutritional as well as intracellular stored lipids and thereby initiate and regulate the release of FFA into the serum. Therefore, they represent potential targets for the development of drugs aimed at obesity, diabetes and atherosclerosis (for a review see Petry et al. 2004). Pancreatic lipase (PL), gastric lipase (GL) and HSL are responsible for the cleavage of dietary and stored lipids, respectively, to fatty acids and glycerol (and MAG) in the stomach and duodenum (GP; for a review see Lengsfeld et al. 2004), enterocytes (PL; for a review see Tiss et al. 2004) and adipocytes (HSL), which finally will appear in the blood stream directly or as lipoproteins after passage across and esterification/assembly into lipoproteins (chylomicrons) in enterocytes. In addition, lipases are responsible for the degradation of lipoproteins (TAG in chylomicrons) in the liver by hepatic lipase or of lipoproteins (VLDL, LDL from the liver, chylomicrons from enterocytes) in muscle and adipose tissue endothelium by lipoprotein lipase (LPL) and endothelial lipase (EL; for a review see Badellino et al. 2004). The activities of LPL and HSL are under tight hormonal control by a complex interplay of transcriptional and post-transcriptional mechanisms.

The rate-limiting role of HSL in the breakdown of adipose tissue TAG, postulated for decades (Fredrikson et al. 1981, Holm 2003, Kraemer and Shen 2002, Yeaman 2004, Osterlund 2001) has been challenged by the data from HSL knockout mice (Hämmerle et al. 2002, Osuga et al. 2000, Wang et al. 2001, for a review see Raben and Baldassare 2005). Catecholamine-induced lipolysis is abrogated, but residual basal lipolysis is observed in adipocytes from HSL-null mice, which surprisingly display a non-obese phenotype and the accumulation of DAG in their adipose tissues. These data suggest the existence of non-HSL lipases in adipose tissue (of rodents, at least), that preferentially hydrolyze the first ester bond of the TAG molecules. To search for such TAG lipases, gene and protein databases for murine and human pro-

teins with structural homologies to known lipases, i. e. the GXSXG motif for serine esterases and the α/β-hydrolase folds, have been screened. Candidates have been analyzed for TAG-hydrolase activity and expression in mouse adipose tissues and during differentiation of 3T3-L1 adipocytes. Only one previously undescribed enzyme fulfilled these requirements and has been named adipocyte TAG lipase (ATGL), desnutrin, or iPLA2ζ (Zimmermann et al. 2004, Jenkins et al. 2004, Villena et al. 2004). The 260 amino-terminal amino acids of this 54-kD protein contains a predicted esterase domain in the α/β-hydrolase fold as well as a GXSXG site with a putative active serine (amino acid 47). Moreover, a "patatin" domain is present in the same domain. Patatin domain-containing proteins have been shown to exert acyl-hydrolase activity on phospholipid, MAG and DAG substrates and is thought to be involved in the ATP and acyl-CoA-independent transacylation reaction. Consistent with this, ATGL catalyze the CoA-independent transfer of oleate from a mono-olein donor to a mono- or diolein acceptor, which generates DAG and TAG, respectively. Using antibodies directed against ATGL, it has been suggested that ATGL is responsible for 75% of the cytosolic acylhydrolase activity in white adipose tissue of HSL-deficient mice. ATGL could therefore participate together with HSL in adipose tissue lipolysis. Although HSL catalyzes the rate-limiting step in TAG hydrolysis, the major physiological substrate for this enzyme is DAG, not TAG. Hämmerle and coworkers generated ATGL-deficient mice (Haemmerle et al. 2006) and thereby confirmed that ATGL is the rate-limiting lipase for the initiation of TAG catabolism in adipose and many non-adipose tissues. The association of ATGL deficiency with increased glucose tolerance, increased insulin sensitivity, and increased respiratory quotient during fasting provides compelling evidence that the decreased availability of FFAs promotes the use of glucose as metabolic fuel despite the presence of massive amounts of fat in adipose tissue and muscle. The inability to mobilize these fat stores leads to energy starvation, resulting in reduced energy expenditure, a decline in body temperature and premature death when ATGL knockout mice are stressed by cold temperature or food deprivation. Thus, ATGL plays a crucial role in energy homeostasis in mice. The observations that ATGL contributes to adipocyte lipolysis in human adipose tissue (Kershaw et al. 2006) and that genetic variation in the human ATGL gene is associated with plasma FFA, TAG and type II diabetes suggest that ATGL may be of similar relevance in humans. However, by comparing human adipose tissue gene expression of HSL and ATGL as well as total triolein lipase activity and lipolytic capacity in adipocytes from lean *vs.* obese human subjects and in addition the tri- and diglyceride hydrolase activities of Cos-7 cell transfected with HSL and ATGL cDNAs, Mairal and coworkers (2006) found evidence for a down-regulation by body fat and for association with *in vitro* hydrolysis of triolein by HSL rather than ATGL. Moreover, their data argue for a predominant role of HSL as both tri- and diglyceride-hydrolysing lipase in human adipocytes. The findings reinforce the necessity for the use of appropriate human cellular assay systems for the identification and characterization of compounds/drug candidates interfering with lipid metabolism, in general, and lipolysis, in particular.

PURPOSE AND RATIONALE

Since neutral lipases are water-soluble enzymes hydrolysing insoluble long-chain TAG substrates and sometimes, in addition, phospholipids to a varying degree (LPL, EL), the cleavage reaction has to occur at the lipid-water interface (Petry et al. 2005, Hide et al. 1992, Verger 1997, Schmid and Verger 1998). This distinguishes lipases from other hydrolytic enzymes and makes them unique target proteins with regard to selectivity and mode of inhibition. The insolubility of neutral TAG has several striking consequences. Both in the serum compartment and in the cytoplasm of cells neutral lipids are never in direct contact with the aqueous milieu. They are organized as high-molecular-mass aggregates in emulsified droplets consisting of an interior TAG core and surrounded by a monolayer shell of phospholipids and embedded proteins (cytoplasmic LD and serum lipoproteins). Alternatively, lipids are organized in smaller complexes bound to serum or intracellular fatty acid/lipid-binding proteins, such as albumin and caveolin. Lipases interact with these special substrate complexes or "super-substrates" using hydrophobic domains which are exposed/unmasked upon contact as a consequence of substrate-induced conformational change, which sometimes has been called "interfacial activation" (Petry et al. 2005, Hide et al. 1992, Verger 1997, Schmid and Verger 1998). The apparently "two-dimensional" reaction of lipases does not simply follow Michaelis-Menten kinetics of enzyme reactions in aqueous milieu and critically depends on the quality of the interface. In PL the free access of lipidic substrates to the catalytic site is hampered by a so-called lid domain. This blockade is released upon interaction of lipase with the water-lipid interface inducing a conformational change. However, there is considerable evidence that HSL lacks a sim-

ilar lid domain (Ben Ali et al. 2004). The authentic, i. e. substrate-specific, measurement of lipase activity as well as the development of reliable lipase assay systems has to take these unique features into account.

Beisson and co-workers (2000) critically reviewed the lipase assay systems used most widely so far. The most sensitive and reliable assays are discontinuous "time-stop" assays using radiolabeled emulsified TAG or phosphoglycerides as substrates. The substrate has to be separated from the product by chromatographic methods or partitioning. Enzymatic fluorescence- or bioluminescence-based or chromatographic methods for determination of the unlabeled products of lipolysis are highly sensitive but are discontinuous, which is also true for even more sensitive radioactive methods. Titrimetric and potentiometric assays are continuous, but are relative insensitive and may interact with acidic or basic assay constituents, such as test compounds. To overcome these handicaps, Beisson and coworkers (1999) have developed an elegant continuous lipase assay using naturally occurring fluorescent TAG isolated from *parinari glaberrimum.* Synthetic octadeca-9,11,13,15-tetronic-3hydroxy-octadecyloxypropylester, a 1 acyl-2 alky glyceride from *parinaric acid*, represents as DAG analog an efficient substrate for HSL, but it is too sensitive toward oxidation to be used under routine conditions. An alternative ultraviolet spectrophotometric assay has been introduced by the same group which is less sensitive to oxidation using TAG from *aleutris fordii* seeds (Pencreac'h et al. 2002).

Whereas continuous assays based on soluble fluorescent substrates are frequently and successfully being used for esterases, they have rarely been described for lipases. Some of these soluble substrates have been proposed for the measurement of lipolytic activity (Hendrickson 1994, Meshulam et al. 1992). These assay systems turned out to be simple, easy-to-handle and of sufficient sensitivity. But one has to keep in mind, that they do not account for the special features of the lipase-substrate interaction and therefore do not discriminate lipases from esterases. In consequence, lipase activity may be underestimated or even remain undetected, in particular in case of assays being performed with crude enzyme sources, such as body fluids or tissue samples. Moreover, the use of water-soluble substrates may lead to gross misinterpretations of the inhibitory profiles of compounds. Consequently, lipidic substrates resembling the native substrate with regard to chain length and amphiphilic nature, equipped with appropriate fluorophores, should be applied whenever feasible.

Importantly, even huge fluorophores, such as BODIPY (Meshulam et al. 1992), rhodamine (Agmon et al. 1993) or pyrene (Scholze et al. 1999) coupled to lipase substrates apparently do not interfere with their cleavage by lipolytic enzymes. Thus, the nature of the fluorescence label does not seem to be very critical. In general, it should be as small and of hydrophobic character as possible to guarantee optimal interaction with the lipase, should not interact with coloured compounds and should be insensitive toward oxidation. For these reasons, the *p*-nitrobenzodifurazan (NBD) moiety has often been chosen as fluorescence label. NBD is a relative small fluorophore and is well accepted by various lipid-handling enzymes/proteins without grossly influencing their recognition and catalytic mechanisms. For instance, NBD-labelling has been used previously for determination of phospholipase A_2 activity in a time-stop assay design (Dagan and Yedgar 1987, Wittenauer et al. 1984). Müller and coworkers (1997) have shown, that 12-(7-nitrobenzo[1,2,3]oxadiazol-4-ylamino)dodecanoic acid (NBD-FA) is taken up by adipocytes and incorporated into TAG in insulin-sensitive fashion. This demonstrates acceptance of NBD-modified fatty acid and lipid precursors as substrates by lipid-handling enzymes, in general.

Starting from NBD-FA a non-soluble lipase substrate, NBD-MAG, has been introduced which upon presentation in mixed phospholipid-NBD-MAG micelles represents a "super-substrate" and is well accepted by a number of neutral lipases. Incorporation of NBD-MAG into mixed micelles and subsequent release of NBD-FA from the micelles in course of lipase action can easily be followed by a change in extinction thereby enabling the design of an assay system for a variety of neutral lipases in crude tissue samples on a routine basis.

PROCEDURE

Preparation of Rat Adipocyte Extract

Adipocytes are isolated from epididymal fat pads of Wistar rats by digestion with collagenase and subsequent separation from undigested tissue using a nylon web as described (see K.5.1.2). Cells obtained from 10 rats are washed three times with 50 ml each of homogenization buffer (25 mM Tris/HCl (pH 7.4), 0.25 M sucrose, 1 mM EDTA, 1 mM DTT, 10 µg/ml each of leupeptin, antipain and pepstatin) by flotation ($500 \times g$, 2 min, 25°C, swing-out rotor), suspended in 10 ml of homogenization buffer and then homogenized by 10 strokes at 1500 rpm in a loosely fitting Teflon-in-glass homogenizer (15°C). The homogenate is centrifuged ($3{,}000 \times g$, 10 min, 4°C). The infranatant be-

low the fat layer is aspirated and recentrifuged. This procedure is repeated three times for complete removal of residual lipid left at the top after the centrifugations. The final infranatant is centrifuged (48,000 × *g*, 45 min, 4°C). The resulting fat-free supernatant is mixed with 1 g of heparin-Sepharose (washed five times with 25 mM Tris/HCl (pH 7.4), 150 mM NaCl), incubated at 4°C for 1 h (under head-to-end rotation of the vial) and then centrifuged (1,000 × *g*, 10 min, 4°C). The supernatant is adjusted to pH 5.2 and incubated (30 min, 4°C). The precipitates are collected by centrifugation (25,000 × *g*, 10 min, 4°C), suspended in 2.5 ml of 20 mM Tris/HCl (pH 7.0), 1 mM EDTA, 1 mM DTT, 70 mM NaCl, 13% sucrose, 10 µg/ml each of leupeptin, antipain and pepstatin and finaly dialyzed (20 h, 4°C) against 3 × 500 ml of 25 mM Tris/HCl (pH 7.4), 50% glycerol, 1 mM EDTA, 1 mM DTT and 10 µg/ml each of leupeptin, antipain and pepstatin. Adipocyte extract is frozen in liquid N_2 and stored at –70°C for up to four weeks.

Preparation of Tissue Extracts

The tissues are surgically removed and washed in PBS containing 1 mM EDTA. Homogenization is performed on ice in lysis buffer A (0.25 M sucrose, 1 mM EDTA, 1 mM dithiothreitol, 20 µg/ml leupeptin, 2 µg/ml antipain, 1 µg/ml pepstatin) using a ultraturax. The infranatants are obtained after centrifugation (20,000 × *g*, 90 min, 4°C). The reaction is performed in a water bath at 37°C for 60 min with 0.1 ml of substrate and 0.1 ml of infranatant.

K.6.1.13.1 Method Based on Fluorescently Labeled Monoacylglycerol (NBD-MAG)

PROCEDURE

Preparation and Immunoprecipitation of HEK293 Cell Lysates Ectopically Expressing Lipases

Expression constructs encoding only the open reading frame of the relevant lipase with or without epitope tags are constructed by subcloning PCR amplification products into a mammalian expression with CMV promoter or into the Gateway entry vector followed by recombination into the Gateway destination vector. Each expression vector is used to transiently transfect HEK293 cells. HEK293 cells are grown in DMEM supplemented with 10% FCS at 37°C in an atmosphere of 5% CO_2. 10-cm tissue culture dishes with 90% confluent HEK293 cells are transfected using Lipofectamine2000 (Invitrogen). 72 h after transfection, cells are washed with ice-cold TBS and harvested. Cells are pelleted by centrifugation (1,000 × *g*, 5 min) and stored at –80°C until lysate preparation. For this, frozen cells are suspended in 1 ml of lipase reaction buffer (20 mM Tris/HCl, pH 8.0, 150 mM NaCl, 0.53% sodium taurodeoxycholate, 1.33 mM $CaCl_2$) containing the complete proteinase inhibitor mix. The resulting suspensions are then sonicated on ice with 4 bursts of 10 s from a probe sonicator. Homogenized lysate is centrifuged (1,000 × *g*, 10 min) for removal of cell debris. 50-µl portions of the resulting cleared lysates are used for direct activity measurements. For immunoprecipitation, portions are supplemented with anti-V5 mouse monoclonal antibody (7.2 µg) and incubated at 4°C overnight with tumbling. Next, 20 µl of protein A-bead suspension is added and tumbled at 4°C for 2 h. Beads are then pelleted with gentle centrifugation, washed four times with 900 µl of lipase reaction buffer followed by resuspension in 100 µl of lipase reaction buffer.

Activity Measurement

Since HSL cleaves MAG in addition to DAG and TAG albeit a rather low rate, Petry and coworkers (2005) introduced the use of NBD-MAG as substrate for a convenient, non-radioactive and homogeneous activity assay for HSL. For preparation of the NBD-MAG substrate, 41.5 µl of a PC solution (6 mg/ml in chloroform), 83.5 µl of a PI solution (6 mg/ml in chloroform) and 100 µl of a NBD-MAG solution (10 mg/ml in chloroform) are added to plastic scintillation vials are dried over a stream of N_2 and stored until use at 4°C for up to three days. The dried lipids are then re-suspended in 20 ml of 25 mM Tris/HCl buffer (pH 7.4), 150 mM NaCl and then subjected to an ultrasonic treatment in a ice bath using a Branson Sonifier (type II, standard microtip; 2 × 1 min at a setting 2 followed by 2 × 1 min at a setting 4 with 1-min intervals). During the ultrasonic treatment, the color of the substrate suspension shifts from yellow (maximum absorbance at 481 nm) to pink (maximum absorbance at 550 nm). It is used after a period of 15 min (minimum) to up to 2 h (maximum). To start the assay procedure, 180 µl of NBD-MAG substrate solution are warmed up to 30°C, supplemented with either 30 µl of an adipocyte extract (appropriately diluted with, 25 mM Tris/HCl buffer, pH 7.4, 150 mM NaCl, 0.2 mM EDTA, 0.5 mM DTT containing 0.1% BSA) or 20 µl of recombinant human HSL in the wells of 96-well microtiter plates.

EVALUATION

The optical density (OD) at 481 nm is recorded continuously at regular time intervals (from 1 to 30

min) using a microplate scanning spectrophotometer. Buffer alone is used as a control experiment. Alternatively, the products generated in the reaction mixture are analyzed by TLC. For this purpose 200 µl of the reaction mixture are transferred into 2-ml reaction vials and supplemented with 1.3 ml of a methanol/chloroform/heptane (10/9/7, by vol.) and then with 0.4 ml of 0.1 M HCl. After intense vortexing, phase separation is initiated by centrifugation (800 × *g*, 20 min, 25°C), 200-µl aliquots of the lower organic phase are removed, then dried under vacuum (SpeedVac evaporator) and finally suspended in 50 µl of tetrahydrofuran (THF). Samples of 5- to 10-µl are separated by TLC on silica gel Si-60 plates using diethylether/petrol ether/acetic acid (78/22/1, by vol.) as elution solvent system. The amount of NBD-FA acid released is evaluated by fluorescence imaging using a phosphorimager (Molecular Dynamics, storm 860 and ImageQuant software) with an excitation wavelength of at 460 nm and emission wavelength of at 540–550 nm.

K.6.1.13.2 Method Based on Fluorescently Labeled TAG

For substrate preparation, NBD-TAG (total mixture of NBD-MAG/DAG/TAG) are extracted with chloroform/heptane from adipocytes, which had been incubated with NBD-FA in the presence of insulin, and purified as described (Müller et al. 1997). For 4 ml of substrate emulsion, 2 mg of dried NBD-TAG is emulsified with 0.2 mg of phosphatidylcholine/phosphatidylinositol, 3/1, w/w) in chloroform. After evaporation of the solvent (SpeedVac), 2 ml of 0.1 M potassium phosphate (pH 7.0) is added and the substrate is sonicated (4 × 1 min, Branson Sonifier 250, setting 2–3, 22°C). Subsequently, 1.6 ml of potassium phosphate is added and the sonication is repeated on ice. After the second sonication, 0.4 ml of potassium phosphate containing 10% BSA is added. 100 µl of substrate emulsion is mixed with 100 µl of rat adipocyte extract as a source for crude HSL (prepared as above) in homogenization medium and incubated (1 h, 30°C). The digestion is terminated by addition of 400 µl of chloroform/methanol (3/1; by vol.) and analyzed as described above for cell-free lipolysis (see K.6.1.11).

K.6.1.13.3 Method Based on Radiolabeled Trioleoylglycerol (TOG)

For assaying trioleoylglycerol (TOG = triolein) cleavage, the TOG droplet emulsion (final conc. 1.7 mM) is prepared by mixing 25–50 µCi glycerol-tri[^{3}H]oleate (in toluene/ethanol, 1/1), 6.8 µmol TOG (in chloroform), 0.6 mg PC and 0.2 mg PI, subsequent drying over a stream of N_2 and final suspending in 2 ml of 0.1 M KP_i (pH 7.0) under ultrasonic treatment (Branson sonifier B-12, standard microtip, setting 2, 2 × 1 min with 1-min intervalls on ice). After addition of 1 ml of 0.1 M KP_i (pH 7.0) and ultrasonic treatment (see above, 4 × 30 sec with 1-min intervalls on ice), the TOG substrate suspension is supplemented with 1 ml of 20% BSA (in 0.1 M KP_i) and stored until use at 4°C (for up to two weeks). The reaction is started by addition of 10 µl of rat adipocyte extract (appropriately diluted with 20 mM M KP_i, pH 7.0, 1 mM EDTA, 1 mM DTT, 0.02% BSA, 10 µg/ml of each leupeptin, pepstatin and antipain) to 10 µl of TOG suspension. After incubation (30 min, 37°C), the reaction is terminated by addition of 325 µl of methanol/chloroform/heptane (10/9/7, by vol.). Phase separation is initiated by addition of 105 µl of 0.1 M K_2CO_3, 0.1 M boric acid (pH 10.5), intense vortexing and centrifugation (8,000 × *g*, 15 min). 150 µl of the upper aqueous phase is transferred into scintillation vials and supplemented with 5 ml of scintillation cocktail (Beckman Ready Safe) for measurement of radioactivity by liquid scintillation counting. This method has been used by Vertesy and coworkers (2002) for the identification of novel inhibitors of HSL with putative anti-diabetic activity from natural sources, such as funghi.

K.6.1.13.4 Method Based on Radiolabeled Tributyrin

For assaying tributyrin cleavage, 10 µl of [^{14}C]tributyrin (20 mM, 0.1 µCi, in ethanol) are dried, then suspended in 25 µl of 0.1 M KP_i (pH 7.25), 140 mM NaCl, 1 mM DTT, 0.2 mM EDTA and finally incubated (30 min, 37°C) with 25 µl of rat adipocyte extract (appropriately diluted with the same buffer). The reaction is terminated by the addition of 325 µl of methanol/chloroform/heptane (10/9/7, by vol.) and 125 µl of 0.1 M NaOH and subsequently processed and described as above (see K.6.1.13.3).

K.6.1.13.5 Method Based on Resorufin Ester

The assay uses 1,2-dilauryl-rac-glycero-3-glutaric acid (6′-methylresorufin) ester (DGGR) as a substrate (Lehner and Verger 1997). DGGR is cleaved by lipase, resulting in an unstable dicarbonic acid ester that is spontaneously hydrolyzed to yield glutaric acid and

methylresorufin, a bluish-purple chromophore with peak absorption at 581 nm. The rate of methylresorufin formation is directly proportional to the lipase activity in the sample. Hydrolysis of DGGR (final conc. 100 µM) is determined at 37°C in a final volume of 1 ml. For this, substrate solution is prepared by mixing 40 µl of the ester (2 mg/ml dioxane) with 160 µl of 20 mM Tris/HCl (pH 8.0), 150 mM NaCl, and 0.05% TX-100. 790 µl of 20 mM Tris/HCl (pH 8.0), 150 mM NaCl, 0.53% sodium taurocholate and 1.33 mM $CaCl_2$ is added, and the reaction is started by addition of 10 µl of rat adipocyte extract. The release of resorufin is monitored at 572 nm. For high-throughput screening of compounds/drug candidates activating or inhibiting lipases, 10 µl of whole-cell lysate or immunoprecipitation beads is added to the wells of a 96-well plate. After adjustment of the samples to 125 µl in lipase reaction buffer, 125 µl of reaction buffer containing DGGR is added (final conc. of 36 µg/ml in a final assay volume of 250 µl per volume). After mixing, OD 581 is monitored at 5 min-intervals for 2 h to assess lipase activity. This procedure has been used by Lake and coworkers (2005) for the analysis of the expression, regulation, and triglyceride hydrolase activity of the adiponutrin family members.

K.6.1.13.6 Method Based on p-Nitrophenylbutyrate

For assaying *p*-nitrophenylbutyrate (PNPB) cleavage according to the procedure described by Holm and Osterlund (1999) with modifications from Soni and coworkers (2004), 10 µl of 2 mM PNPB (in acetonitrile) are added to 890 µl of 0.1 M KP_i (pH 7.25), 140 mM NaCl, 1 mM DTT, 0.2 mM EDTA and then incubated (10 min, 37°C) in the presence of 100 µl of rat adipocyte extract (appropriately diluted with the same buffer) in the absence or presence of 0.01% TX-100. The reaction is terminated by adding 3.25 ml of methanol/chloroform/heptane (10/9/7), vigorously vortexed for 10 s, and then centrifuged ($800 \times g$, 20 min, 21°C). The upper phase is collected and thereafter subjected to incubation at 42°C for 2 min. The absorbance of the released *p*-nitrophenol (extinction coefficient of 12,000) is measured at 405 nm.

K.6.1.13.7 Method Based on Potentiometry

For a potentiometric assay, the hydrolysis of short- and medium-chain TAG is determined at pH 8.0 and 37°C with a pH-stat (TTT 80 Radiometer) by titrating liberated fatty acids with 0.1 N NaOH. The standard mixture using tributyrin contains 14.9 ml of 150 mM NaCl and 100 µl of tributyrin (final vol. 15 ml). With TOG, the assay mix is composed of 14.5 ml of 150 ml NaCl, 2 mM sodium taurodeoxycholate, 0.1 mg/ml BSA and 0.5 ml of TOG.

K.6.1.14 Neutral Cholesterylester Hydrolase Activity

HSL possesses pronounced neutral cholesterylester hydrolase activity in addition to its neutral TAG hydrolase activity in contrast to ATGL, which exhibits the latter, exclusively (Zimmermann et al. 2004, Jenkins et al. 2004). Consequently, assaying cholesterylester hydrolase activity can be used to discriminate between HSL and ATGL activity in crude cell lysates. Cholesterylester hydrolase is measured according to the procedure described by Holm and Osterlund (1999) with modifications from Soni and coworkers (2004) and Ben Ali and coworkers (2005). 1.17 mg of cholesteryl oleate, including 2×10^7 dpm of [^{14}C]cholesteryl oleate, plus a phospholipid mixture (71.4 µl, including phosphatidylcholine [15 mg/ml] and phosphatidylinositol [5 mg/ml], dissolved in chloroform) are placed in a 4-ml glass vial. Solvents are evaporated under a gentle stream of N_2. 2 ml of 0.1 M potassium phosphate (pH 7.5) is added. After incubation (10 min, 37°C), the mixtures are sonicated (twice for 1 min each, separated by a 1-min interval). An additional 1 ml of 0.1 M potassium phosphate (pH 7.5) is added and incubated (10 min, 37°C). The mixtures are sonicated again (four times for 30 s each on ice, separated by 30-s intervals). After sonication, 1 ml of 20% fatty acid-free BSA prepared in 0.1 M potassium phosphate (pH 7.5) is added. For each assay, 100 µl of substrate is mixed with 100 µl of sample and incubated (30 min, 37°C). The reactions are terminated, extracted and counted for radioactivity as described above for the method based on radiolabeled TOG.

K.6.1.15 Lipoprotein Lipase (LPL) Activity

For assaying LPLaccording to Dichek and coworkers (1993) and Iverius and coworkers (1985) with modifications, substrate is prepared by evaporation of 5 mg of unlabeled TOG together with 50 µCi glycerol-tri[^{3}H]oleate and 0.24 mg PC from the solvent, toluene, under a stream of N_2. The dried lipids are emulsified in 1 ml of 1 M Tris/HCl (pH 8.5), 0.1 M NaCl and 2.5% BSA in the absence or presence of 1 M

NaCl and in the presence of 8% heated rat serum under sonication (Branson Sonifier B-12, standard microtip, setting 2, 10 s on, 10 s off, for 10 cycles on ice). Affinity-purified LPL from bovine milk in 15 µl of 10 mM Tris/HCl (pH 7.4), 0.5 mM DTT are incubated (60 min, 37°C) with 5 µl of substrate emulsion. Reactions are terminated by addition of 325 µl of methanol/chloroform/heptane (10/9/7, by vol.) and subsequently of 105 µl of 0.1 M K_2CO_3, 0.1 M boric acid (pH 10.5). After vortexing, the phases are separated and 100-µl portions of the upper aqueous phase are mixed with 5 ml of scintillation cocktail (Beckman, Ready Safe) and counted for radioactivity. LPL activity is determined by subtracting the non-LPL-dependent lipolytic activity (presence of 1 M NaCl) from the total activity (absence of 1 M NaCl).

K.6.1.16 Analysis of Lipolysis Products

TAG Hydrolysis Rate

For the quantitation of DAG and MAG formed by the TAG lipase actions, the reaction is terminated by adding 1 ml of chloroform/methanol (2/1, by vol.) containing 1% acetic acid, oleic acid (10 µg/ml) and standards for monooleoylglycerol (MOG) and dioleoylglycerol DOG (10 µg/ml, sn-1,2 and sn-1,3). The mixture is vortexed vigorously three times over 15 min. After centrifugation (4,000 × *g*, 10 min), 0.5 ml of the lower phase is collected and evaporated under nitrogen. The lipid pellet is dissolved in chloroform and applied onto TLC (Merck, silica gel 60) with chloroform/acetone/acetic acid (96/4/1, by vol.) as solvent. Lipids are visualized with iodine vapor and the bands corresponding to MOG, DOG and TOG and oleic acid are cut out. The comigrating radioactivity is determined by liquid scintillation counting.

Alternatively, for determination of the rate of DAG formation, the lipolysis reaction is terminated by adding 25 µl of 1 M HCl and 1 ml of hexane/isopropyl alcohol (3/2, by vol.) containing oleic acid (10 µg/ml) and standards for MOG, DOG (*sn*-1.2 and *sn*-1.3, Sigma) and TOG (10 µg/ml each). The mixture is vortexed vigorously three times over a period of 15 min. After centrifugation (4,000 × *g*, 10 min), 0.4 ml of the upper phase is collected and evaporated under nitrogen. The lipid pellet is dissolved in chloroform and loaded onto a TLC plate (Merck, silica gel 60). The TLC is developed with chloroform/acetone/acetic acid (96/4/1) as solvent. The lipids and FFA are visualized with iodine vapor, and the bands corresponding to MOG, DOG and TOG and oleic acid are cut out. The comigrating radioactivity is determined by liquid scintillation counting, and the molar concentrations of the products are calculated.

EVALUATION

The specific TAG hydrolase activity (TAG to DAG conversion) is calculated from the total AG lipolytic activity and the DAG formed during the reaction (considering that MAG does not accumulate) by the equation given by Hämmerle and coworkers (2002).

K.6.1.17 Affinity Labeling of TAG Lipases

PURPOSE AND RATIONALE

Compounds which interfere with lipolysis by direct blockade of TAG cleavage can be directed to various lipases in differential fashion. So far, in addition to HSL, ATGL, GS-2 and adiponutrin have been identified as putative TAG degrading lipases in rodent adipocytes. Their differential targeting by compounds/drug candidates can be analyzed by activity tagging (for a review see Petry et al. 2004).A fluorescence technology for selectively screening for lipolytic enzymes developed by Schmidinger and coworkers (2005) is based on the so-called click chemistry utilizing the copper(I)-catalyzed azide-alkyne [3+2] cycloaddition reaction (Speers and Cravatt 2004a and b, Wang et al. 2003). Lipase- and esterase-mediated hydrolysis of acyl esters is based on a mechanism involving a nucleophilic serine, which in most cases is part of a catalytic triad with histidine and asparate. In the first reaction step, the active serine attacks the carbonyl group of the scissile fatty acid to give a tetrahedral transition state. This intermediate state is cleaved to yield the free fatty acid, the alcohol component and the nucleophilic serine. Although many lipases show strong structural and sequential similarities (Pleiss et al. 1998, Arpigny and Jaeger 1999), their substrate and stereospecificities can

vary significantly (Martinelle et al. 1995). It is known that *p*-nitrophenylesters of alkylphosphonic acids irreversible and stoichiometrically react with the nucleophilic serine of lipases and esterases, freezing the reaction at the point of the tetrahedral transition state. In the past, they have been applied to the determination of serine hydrolase activity by using different approaches (Oskolkova et al. 2003, Rotticci et al. 2000). If fluorescent inhibitors are used, the tagged enzyme becomes visible (Mannesse et al. 1995). Thus, it can be detected and quantified on the basis of its fluorescent signal (Scholze et al. 1999). Fluorescently labeled alkyl phosphonates detect active enzymes in electrophoretically pure proteins and in complex proteosome samples (Speers and Cravatt 2004a, Adam et al. 2002, Greenbaum et al. 2002).

PROCEDURE

Activity tagging of lipases contained in adipocyte tissue can be performed according to the protocol of Birner-Grünberger and coworkers (2005). For this, gonadal fat pads (white adipose tissue) of fed and fasted mice are surgically removed and washed in PBS. Homogenization is performed on ice in lysis buffer (0.25 M sucrose, 1 mM EDTA, 1 mM DTT, 20 µg/ml leupeptin, 2 µg/ml antipain, 1 µg/ml pepstatin) using a motor-driven Teflon-in-glass homogenizer (8 strokes, 1,500 rpm). Cell debris is removed by centrifugation (1,000 × *g*, 15 min) to obtain cytoplasmic extracts. Protein concentrations is determined using the BIORAD protein assay based on the method of Bradford. 50 µg of protein sample dissolved in lysis buffer, 10 µl of 10 mM Triton X-100 in methanol (final conc. 1 mM) and 20 µl of activity tag (NBD-labeled single-chain phosphonic acid ester, TAG phosphonates and cholesteryl phosphonates which react with the nucleophilic serine in the active site of lipolytic enzymes due to the active phosphonate moiety with the good leaving PNPB group and then remain covalently attached leading to irreversible inactivation of the lipases) dissolved in methanol (1 nmol/10 µl, final conc. 20 µM) are mixed and the organic solvent is evaporated under a stream of argon. 100 µl of protein sample (0.5 mg protein/ml) is added and the resultant mixture is incubated (2 h, 37°C) under light protection. Proteins are precipitated in 10% ice-cold TCA (1 h, on ice) and collected by centrifugation (10,000 × *g*, 15 min, 4°C). The pellet is washed once with ice-cold acetone and resuspended in 1D sample buffer (20 mM KH_2PO_4, 6 mM EDTA, 60 mg/ml SDS, 100 mg/ml glycerol, 0.5 mg/ml bromophenol blue, 20 µl/ml mercaptoethanol, pH 6.8) or 2D sample buffer (7 M urea, 2 M thiourea, 4% CHAPS, 60 mM DTT, 2% Pharmalyte pH 3–10, 0.002% bromophenol blue). SDS-PAGE is performed in a Tris/glycine buffer system by aligning proteins (50 or 100 µg protein/lane) in a 5% stacking gel and separating them in a 10% resolving gel at 20–50 mA constant current. 2D-gel electrophoresis is performed in the first dimension by isoelectric focusing of 50–500 µg protein in 7 or 18 cm immobilized non-linear pH 3–10 gradients at 6.5/12 kVh and in the second dimension by SDS-PAGE on 7 or 20 cm gels as described by Gorg and coworkers (1985, 1988). Gels are fixed in 7.5% acetic acid and 10% ethanol and scanned at a resolution of 100 µm. NBD fluorescence is detected at 530 nm and an excitation wavelength of 488 nm. For visualization of the whole protein pattern, gels are stained with SYPRO Ruby following the manufacturer's instructions (Molecular Probes) and scanned at 605 nm and an excitation wavelength of 488 nm. For LC-MS/MS-analysis, the fluorescent protein spots are excised and tryptically digested according to the method by Shevchenko and coworkers (1996). Peptide extracts are dissolved in 0.1% formic acid and separated on a nano-HPLC-system. 20-µl samples are injected and concentrated on the loading column (LC packings PepMap™ C-18, 5 µm, 100 A, 300 µm ID × 1 mm) for 5 min using 0.1% formic acid as isocratic solvent at a flow rate of 20 µ l/min. The column is then switched into the nano-flow-circuit and the sample is loaded on the nano-column at a flow rate of 300 nl/min and separated using a gradient from 0.3% formic acid and 5% acetonitrile to 0.3% formic acid and 50% acetonitrile over 60 min. The sample is ionized in a Finnigan nano-ESI source equipped with NanoSpray tips and analyzed in a Thermo-Finnigan LCQ Deca XPplus iontrap mass-spectrometer. Acceptance parameters are two or more identified distinct peptides (Carr et al. 2004). Identified protein sequences are subjected to BLAST and motif search for identification of potential serine hydrolases.

EVALUATION

In pilot experiments, 50 µg of cleared cell lysate (see above) is incubated with 1 nmol of fluorescently labeled lipase inhibitor O-((6-(7-nitrobenz-2-oxa-1,3-dia-zol-4-yl)amino)hexanoyl)-aminoethyl-O-(n-hexyl)phosphonic acid *p*-nitrophenyl ester () and 1 mM TX-100 at 37°C for 2 h under shaking. Total protein is then precipitated with 10% TCA for 1 h on ice, washed once with acetone and subjected to 10% SDS-PAGE. After treatment of the gels with 10% ethanol and 7% acetic acid, the fluorescent signals are detected with laser scanner (excitation 488 nm, emission 530 nm).

K.6.1.18 Interaction of ATGL and CGI-58

PURPOSE AND RATIONALE

In contrast to HSL, which undergoes PKA-dependent phosphorylation and translocation from the cytoplasm to LD upon β-adrenergic stimulation of adipocytes, the regulation of ATGL may rely on protein-protein interaction. It has been demonstrated by Lass and coworkers (2006) that efficient enzymic activity of ATGL depends on interaction with and activation by CGI-58. Mutations in the human *CGI-58* gene are associated with Chanarin-Dorfman Syndrome (CDS), a rare genetic disease where TG accumulates excessively in multiple tissues (Chanarin et al. 1975, Dorfman et al. 1974, Lefevre et al. 2001). CGI-58 interacts with ATGL, stimulating its TAG hydrolase activity up to 20-fold. Alleles of *CGI-58* carrying point mutations associated with CDS fail to activate ATGL. Moreover, CGI-58/ATGL coexpression attenuates lipid accumulation in COS-7 cells. Antisense RNA-mediated reduction of CGI-58 expression in 3T3-L1 adipocytes inhibits TAG mobilization. These data establish an important biochemical function for CGI-58 in the lipolytic degradation of TAG and raise the question whether defects in CGI-58 may contribute to the pathogenesis of type II diabetes and obesity. The following assays allow the analysis of the functional interaction of ATGL with CGI-58 and its modulation by compounds/drug candidates.

PROCEDURE

Preparation of ATGL

Monkey embryonic kidney cells (COS-7, ATCC CRL-1651) are transfected using Metafectene (Biontex, Germany) as described (Zimmermann et al. 2004). For the preparation of cell extracts, cells are collected by trypsin treatment, washed three times with PBS and disrupted in buffer A (0.25 M sucrose, 1 mM EDTA, 1 mM dithiothreitol, 20 µg/ml leupetine, 2 µg/ml antipain, 1 µg/ml pepstatin, 20 mM Tris/HCl, pH 7.0) by sonication. Nuclei and unbroken cells are removed by centrifugation (1,000 × *g*, 4°C, 5 min). The expression of the His-tagged proteins is detected using immunoblotting as described (Zimmermann et al. 2004). COS-7 cells expressing His-tagged mouse ATGL are lysed in buffer C (25 mM NaPO4, pH 7.0, 20% glycerol, 2 mM β-mercaptoethanol, 0,01% NP-40) and incubated with TALON Co^{2+} resin (BD Biosciences). The resin-cell extract suspension is then poured into a micro bio-spin column (Bio-Rad) and washed with 10 column volumes of buffer C containing 500 mM NaCl. Recombinant His-tagged ATGL is eluted by a step-gradient of imidazole (200 mM final concentration) in buffer C. For determination of the purity of the protein, fractions are subjected to SDS-PAGE gel electrophoresis and immunoblotting.

Preparation of GST-Tagged CGI-58

The coding sequence of mouse CGI-58 is cloned into pYex4T-1 vector and transformed into the *S. cerevisiae* BY4742 (Matα; his3; leu2; lys2; ura3) strain. Large-scale overexpression of GST-CGI is achieved by maintaining transformed *S. cerevisiae* carrying in YNB-urea containing 0.5 mM $CuSO_4$ to induce copper promoter-driven expression of the fusion cassette. After induction, cells are harvested and protoplasts are generated with zymolyase and disrupted by sonication in the presence of 0.2% NP-40. The supernatant containing the GST-fusion protein is purified using glutathione-Sepharose beads. Purified GST-CGI is dialyzed overnight with 150 mM KCl, 10 mM potassium phosphate buffer (pH 7.4), and 0.01% NP-40.

Interaction Assay

For the detection of interacting proteins, ELISA plates are coated with 3 µg GST-CGI or GST in buffer D (50 mM Tris, pH 8.0, 150 mM NaCl, 5 mM $CaCl_2$). The wells are blocked with 5% BSA in buffer D and incubated with 50 µg protein/well of COS-7 cell extracts containing His-tagged ATGL in 50 mM potassium phosphate buffer (pH 7.0) in the absence or presence of compounds/drug candidates. After washing with buffer D containing 0.05% Tween 20, the mouse anti-His antibody is added in the same buffer containing 0.5% BSA. Subsequent to three further washes, horseradish peroxidase-conjugated anti-mouse antibody is added. After washing three times with buffer D containing 0.05% Tween 20, the absorbance of tetramethyl-benzidine is determined at 450 nm using 620 nm as reference wavelength. The absorbance of GST coated wells is subtracted from that coated with GST-CGI.

K.6.1.19 Measurement of cAMP Levels

PURPOSE AND RATIONALE

Activation of lipolysis in adipocytes by β-adrenergic stimuli and its inhibition by insulin critically depends on the generation by adenylate cyclase and degradation by phosphodiesterase 3B (PDE3B), respectively (for a review see Müller and Petry 2004). The intracellular cAMP levels can be determined in adipocytes which have been exposed to isoproterenol prior to incubation with insulin/compounds/drug candidates.

PROCEDURE

400 µl of adipocyte suspension (lipocrit 10%) are suspended in 600 µl KRH containing 0.75% BSA, 1.5 mM glucose, and incubated in the absence or presence of lipolytic stimuli (isoproterenol, adenosine deaminase) in combination with insulin or compounds/drug candidates at 37°C in a mildly shaking water bath. 200-µl aliquots are transferred into Eppendorf cups containing 20 µl $HClO_4$ (70%), vortexed vigorously and centrifuged (12,000 × *g*, 15 min, room temperature). 110 µl of the infranatant is removed, taking care not to aspirate any of the precipitate, supplemented with 60 µl of 1 M Tris/HCl (pH 7.5), incubated for 15 min on ice and then centrifuged (13,000 × *g*, 15 min, 4°C). 150 µl of the infranatant is removed for glycerol determination, frozen in liquid N_2 and stored at –20°C prior to determination of glycerol and cAMP levels. cAMP is determined by a modification of the protein kinase binding procedure. Samples and standards are incubated with 8 µg of R-subunit of PKA and 175 nCi [8-^{3}H]cAMP in a buffer composed of 50 mM Tris/HCl (pH 7.4), 4 mM EDTA in a final volume of 200 µl for 4 h at 4°C to reach equilibrium. Charcoal suspension (30 g/l) is added and after vortexing, the mixture is centrifuged at 16,000 × *g*, 2 min, 4°C). The supernatant is transferred into scintillation vials, supplemented with 5 ml water-compatible scintillation fluid

and counted for radioactivity using a liquid scintillation counter.

EVALUATION

The concentration of endogenous unlabeled cAMP in the samples is determined from a linear standard curve.

K.6.1.20 cAMP-Specific Phosphodiesterase (PDE) Activity

PURPOSE AND RATIONALE

Membrane-bound phosphodiesterase of rat epididymal adipose cells is stimulated when intact cells are exposed to insulin. The localization at the endoplasmic reticulum (corresponding to the low density microsomal fraction) and properties of the insulin-sensitive particulate cGMP-inhibitable cAMP phosphodiesterase have been described by Kono and coworkers (1975), Osegawa and coworkers (1982), Saltiel and Steigerwalt (1985), Solomon and coworkers (1986). Recently, the phosphodiesterase isoform, PDE3B, has been identified as target for phosphorylation and activation by protein kinase PKB/Akt, which is a key element of the downstream insulin signaling cascade.

PROCEDURE

The low density microsomal fraction (LDM) of primary or cultured adipocytes (pellet of a 100,000 × *g*/60 min-centrifugation of the post-mitochondrial supernatant prepared from the homogenate of adipocytes exposed to lipolytic stimuli in the absence or presence of compounds; see above) is incubated in the absence or presence of compounds at various concentrations for 20 min. For the assay of cAMP-specific PDE up to 50 µg of LDM protein are incubated (5 min, 30°C) with 500 nM [2,8-^{3}H]cAMP (100 nCi) in 50 mM Tris/HCl (pH 7.4), 0.5 mM DTT, 5 mM $MgCl_2$, 50 µM PMSF in a total volume of 0.25 ml. The incubation is terminated by the sequential addition of 30 µl of 10 mM IBMX and 120 µl of 0.1 N HCl and heating (5 min, 95°C). After neutralization (120 µl of 0.1 N KOH, 80 ml of 250 mM Tris/HCl (pH 7.4), 10 µl of crude 5′-nucleotidase (5 mg/ml) (*Crotalus atrox*) is added to the mixture. The reaction (30 min, 37°C) is terminated by the addition of 60 µl of 200 mM EDTA, 5 mM adenosine. Unreacted cAMP is removed by the addition of 1 ml of a 1:3 slurry of Dowex AG-1X8 (Bio-rad). Solutions are shaken (5 min, 4°C) and centrifuged (1,000 × *g*, 5 min).

EVALUATION

Radiolabeled adenosine left in the supernatant after enzymic degradation of 5′-AMP and chromatographic removal of cAMP is determined by liquid scintillation counting. The assay is proportional to up to 100 µg of protein and linear throughout 20 min. It monitores the putative insulin-like effects of compounds on the regulation of cAMP degradation *via* the insulin signaling cascade (or alternative pathways) as well as directly on the activity state of PDE3B depending on whether or not the compound is present during the incubation of the adipocytes or LDM.

K.6.1.21 Activity State of Protein Kinase A (PKA)

PURPOSE AND RATIONALE

The cAMP levels generated in response to β-adrenergic stimulation in the absence or presence of insulin or compounds in adipocytes determine the activity of PKA phosphorylating both HSL and perilipin which which play key roles in the regulation of lipolysis in adipocytes (see K.6.1.10 and K.6.1.12.2). Thus, the PKA activity ultimately determines the lipolytic state of the adipocytes in response to insulin/compounds/drug candidates. The assay monitors the activity state of PKA in adipocytes in response to β-adrenergic stimuli in the absence or presence of insulin/compounds/drug candidates at the time point of homogenization. This activity ratio is a parameter for the portion of PKA active *in vivo* toward total cellular PKA at the time point of homogenization.

K.6.1.21.1 Radioactive Method

For determination of the activity state of PKA, 500-µl adipocyte suspension (5×10^6 cells/ml) are transferred to 2-ml microfuge tubes, pre-cooled to 4°C, containing at final concentrations: 20 mM Tris/HCl (pH 7.4), 10 mM EDTA and the cAMP PDE inhibitor, Ro 20–1724 (100 µM). The mixture is vortexed briefly, decanted into a 5-ml Teflon-in-glass homogenizer and homogenized with 10 strokes of the rotating (1,500 rpm) Teflon pestle. The homogenate is transferred to pre-cooled microfuge tubes and centrifuged (16,000 × *g*, 10 min, 4°C). The infranatant is removed and immediately assayed for PKA activity. 25 µl of assay medium (20 mM MOPS/KOH, pH 7.0, 10 mM $MgCl_2$, 0.1 mM ATP, 0.5 mg/ml histone H1, 5 mM DTT, 50 µCi/ml [γ-^{32}P]ATP) is added to 25 µl infranatant. After vortexing and incubation for 20 min

at 30°C, the reaction is terminated by addition of 1 ml of ice-cold 20% TCA containing 5 mM sodium pyrophosphate and incubation (1 h, 4°C). The precipitates are sedimented by centrifugation (16,000 × *g*, 5 min, 4°C) and, after removal of the supernatant, dissolved in 100 µl of cold 1 N NaOH and re-precipitated with 20% TCA and 5 mM sodium pyrophosphate. The precipitate is then filtered under vacuum over GF/C-glass microfiber filter that had been pre-wetted with 5% TCA, 5 mM sodium pyrophosphate. The filters are washed with 4 ml of the same medium, dried and counted for radioactivity.

EVALUATION

Each adipocyte infranatant is assayed in quadruplicate under four separate conditions: (I) with no further additions; (II) in the presence of 15 µM cAMP; (III) in the presence of 2 µM PKA inhibitor synthetic peptide and (IV) in the presence of 15 µM cAMP and 2 µM PKA inhibitor synthetic peptide. The results are expressed as corrected PKA activity ratios (I)–(III)/(II)–(IV) according to Honnor and coworkers (1985a and b) and Londos and coworkers (1985).

K.6.1.21.2 Fluorescent Method

PROCEDURE

The method based on fluorescently labeled kemptide has been introduced by Müller and coworkers (2000) and Schölch and coworkers (2004) and can be used for determination of the activity ratio in cells or tissues from rats treated with compounds/drug candidates. For the *ex vivo* experimental design, frozen tissue samples are minced under liquid N_2 in 2 ml of 25 mM MES (pH 6.0), 140 mM NaCl, 2 mmol/l EDTA, 0.5 mM EGTA, 0.25 M sucrose, 50 mM NaF, 10 mM sodium pyrophosphate, 20 mM glycerol-3-phosphate, 1 mM sodium orthovanadate, 2 µM microcystin, 1 µM okadaic acid, and protease inhibitors per gram of wet weight and then homogenized by sequential use of an Ultraturrax homogenizer (30 s, maximum speed) and a Teflon-in-glass homogenizer (tightly fitting, five strokes, 3,000 rpm, on ice). After centrifugation (500 × *g*, 5 min, 4°C), the infranatant below the fat layer is carefully removed, adjusted to 0.5% Triton X-100, and after incubation (30 min, 4°C) and homogenization (Teflon-in-glass, 10 strokes, 500 rpm, 4°C) centrifuged (10,000 × *g*, 15 min, 4°C). The supernatant is re-centrifuged (100,000 × *g*, 1 h, 4°C). Twenty-five microliters of the supernatant (cytosol) are incubated (30 min, 30°C) with 12.5 µl of assay buffer (200 mM Tris/HCl, pH 7.5, 40 mM $MgCl_2$, 4 mM ATP, 400 µM rhodamine-labeled kemptide [PepTag A1 peptide obtained from Serva/Promega Heidelberg, Germany]) in the absence or presence of 10 µM mono-butyryl-cAMP and 50 µM heat-stable PKA inhibitor peptide (Sigma, Germany) in a total volume of 50 µl. The reaction is terminated by placing the tube into a boiling water bath for 2 min, and the mixture is stored at –20°C for further analysis. Portions of this mixture (10 µl) supplemented with 1 µl of 80% glycerol are separated by agarose gel electrophoresis (0.8% in 50 mM Tris/HCl, pH 8.0, 15 min at 100 V). Phosphorylated kemptide (net charge –1) migrating toward the anode and separated from the nonphosphorylated species (net charge +1) moving toward the cathode is visualized under UV light. For quantitative evaluation, the gel material that contained the phosphorylated band is excised (125 µl), heated (95°C), and supplemented with 75 µl of gel solubilization solution and 50 µl of glacial acetic acid, and finally its absorbance is determined at 570 nm using a 96-well plate reader (normalized for liquefied agarose containing no kemptide).

EVALUATION

The PKA activity ratio is calculated as the ratio between the absorbance in the absence and presence of cAMP corrected in each case for unspecific phosphorylation in the presence of the PKA inhibitor (which typically is < 15% of total) and reflects the portion of PKA activity (i. e., cAMP concentration) present at the time point of removal of the tissue or cell samples. Control experiments demonstrated that the activity ratio is independent of dilution of the tissue or cell homogenates (and protein concentration) from 2 g wet wt/ml to 0.03 g/ml (limit of detection) corresponding to 20–0.02 mg protein/ml and of incubation period (up to 2 h), thereby excluding formation of inactive PKA dephosphorylated holoenzyme during homogenization and subsequent assay.

K.6.1.22 PKA Catalytic Activity

PURPOSE AND RATIONALE

In addition to the regulation of the PKA activity by modulation of the cytosolic cAMP levels, insulin and insulin-like compounds/drug candidates may affect PKA by modulating its regulation *via* signaling mechanisms as provoked by insulin or by its direct allosteric activation or blockade by small molecule inhibitors.

PROCEDURE

PKA activity is assayed according to Roskoski and coworkers (1983) and Honnor and coworkers (1985a). The reaction mixture contains 25 µl of rat adipocyte cytosol, 0.4 µM kemptide (consensus substrate peptide), 40 mM Tris/HCl (pH 7.2), 2 mM DTT, 12.5 mM $MgCl_2$, 0.1 mM PMSF, 1 mM IBMX, 100 µM [γ-^{32}P]ATP (1 µCi) with or without 1 µM cAMP in a total volume of 100 µl. After incubation (10 min, 30°C), the reaction mixture is chilled on ice, then supplemented with 3 ml of 75 mM phosphoric acid, 100 mM NaF, 10 mM ATP and immediately spotted on phosphocellulose filters (Whatman P18). After extensive washing with 75 mM phosphoric acid, the filters are dried and counted for radioactivity.

MODIFICATIONS OF THE METHOD

The inhibition of isoproterenol-stimulated PKA by sulfonylureas in rat adipocytes was tested by Müller and coworkers (1994). The direct effect of tolbutamide and glyburide on the activity of PKA in rat liver cytosol was investigated by Okuno and coworkers (1988).

K.6.1.23 Protein Phosphatase (PP) Activity

PURPOSE AND RATIONALE

Insulin inhibits lipolysis by decreasing the phosphorylation and thus the activation state of HSL in adipose tissue *via* both the inhibition of PKA and the stimulation of protein phosphatase 2A (PP2A) *via* ill-defined mechanisms. They may involve the phosphoinositol-3′-kinase (PI3K) signaling pathway, the mitogen-activated protein kinase (MAPK) signaling pathway or soluble mediators of the phosphoinositolglycan (PIG) class (Vila et al. 1990; see K.6.3.6.4).

PROCEDURE

For measurement of PP2A activity, the adipocytes (3×10^7 cells) are washed once with 25 ml of ice-cold 100 mM Tris/HCl (pH 8.5), 10 mM EDTA, 25 mM DTT and immediately resuspended in 0.5 ml of 100 mM Tris/HCl (pH 7.0), 2 mM EDTA, 10 mM DTT, 0.5 mM benzamidine, 0.2 mM PMSF, 2 µg/ml leupeptin, 5 µg/ml pepstatin. After addition of the same volume of ice-cold glass beads, cell extracts are prepared by vigorous vortexing (5 times 5 s each with cooling intervals on ice) and centrifuged (13,000 × *g*, 5 min, 4°C). The supernatant (S13) is diluted with 3 volumes of the same buffer containing 1% BSA. Protein phosphatase activity is assayed as the ability to dephosphorylate ^{32}P-labeled myelin basic protein (MBP). 10 µl of S13 is added to an assay mixture (total volume 50 µl) containing 50 mM Tris/HCl (pH 7.5), 1 mM EDTA, 0.5 mM EGTA, and 0.2 nmol ^{32}P-labeled myelin basic protein (900 dpm/pmol) for 20 min at 30°C in the absence or presence of 2 nM okadaic acid. The reaction is terminated by the addition of 50 µl of ice-cold 10% TCA. After incubation for 15 min on ice and centrifugation (12,000 × *g*, 5 min, 4°C), the supernatant is neutralized with NaOH and measured for radioactivity by liquid scintillation counting (10 ml Aquasol).

EVALUATION

PP2A activity is determined as the difference between ^{32}P-radiolabeled MBP measured in the presence of okadaic acid (10 nM) corresponding to the PP2A independent phosphatase portion and radiolabeled MBP determined after uninhibited incubation corresponding to the total phosphatase activity. Under these conditions, release of $^{32}P_i$ is linear for up to 10 min. One unit of activity is defined as the amount of enzyme that catalyzes the release of 1 µmol of $^{32}P_i$-radiolabel from labeled myelin basic protein in one min under conditions of the standard assay (Müller et al. 2000).

K.6.2 Assays for Insulin and Insulin-Like Metabolic Activity Based on Hepatocytes, Myocytes and Diaphragms

GENERAL CONSIDERATIONS

Despite the eminent importance of studies with primary and cultures adipocytes or adipose tissues on basis of their physiological role in the regulation of lipid and carbohydrate metabolism in humans in combination with the relative low expenditure in preparing adipocytes of high quality and number, compounds and drug candidates for future anti-diabetic and anti-obesity therapy have to be analyzed for their effects in primary and cultured hepatocytes and myocytes or liver and muscle tissues, too. In principle, the majority of the assays described above for adipocytes can be adapted for the use with hepatocytes and myocytes. However, the following selection takes into account the relative contribution of each process monitored to its role in the whole-body regulation of intermediary metabolism in the normal and disease state. Moreover, technical aspects, such as requirement for a special equipment and applicability in throughput screening assays for drug discovery were additional criteria.

K.6.2.1 Glucose Oxidation

PROCEDURE

Cultured Myocytes and Hepatocytes

For the measurement of glucose oxidation on basis of $^{14}CO_2$ release, varying amounts of [^{14}C]glucose (0.1 mCi/ml) are used. Alternatively, glucose oxidation is determined as the formation of [^{3}H]water from [5-^{3}H]glucose. After culture in DMEM medium in 24-well culture dishes, cells are incubated at 37°C for 2 h in 10 µl of KRB solution containing [5-^{3}H]glucose at various concentrations of glucose as described by Wang and coworkers (2004). Control wells containing no cells are included to allow for correction of the conversion of [^{3}H]water into [^{3}H]glucose.

Diaphragm

Glucose utilization by isolated diaphragms can be monitored according to the procedure described by Jeoung and coworkers (2006). For this, diaphragms are removed from 48-h starved mice, rinsed in KHB buffer, blotted, weighed, and placed in 10-ml Erlenmeyer flasks containing 1.5 ml of KHB buffer (pH 7.4), 5 mM glucose, and 0.2% BSA. The flasks are flushed with 95% O_2/5% CO_2 sealed with rubber stoppers, placed in a shaking (60 cycles/min) water bath at 37°C, and pre-incubated for 30 min. Diaphragms are removed from the flasks, blotted, and transferred to new flasks containing 1.5 ml of KHB buffer supplemented with 5 mM glucose containing 20–500 µCi/mmol [U-^{14}C]glucose and 80 µCi/mmol [5-^{3}H]glucose and 1 mU/ml insulin as described by Clark and coworkers (1987). Flasks are flushed with 95% O_2/5% CO_2, sealed with rubber serum caps fitted with hanging center wells and incubated for 1 h with shaking at 37°C. Reactions are terminated by the injection of 0.25 ml of phenethylamine/methanol (1/1, by vol.) into the center wells and 0.1 ml of 60% (w/v) perchloric acid into the incubation medium.

EVALUATION

The rate of glucose oxidation is determined from the production of $^{14}CO_2$, the rate of glycolysis from the difference between the rate of ^3H_2O formed (Ashcroft et al. 1975) and the rate of substrate cycling, and the rate of substrate cycling from the difference between the rates of glycogen synthesis from [U-^{14}C]glucose and [5-^{3}H]glucose. Glucose utilization rates are calculated as pmol of glucose utilized/hour/cell or mg tissue as: Glucose utilized (pmol) = [^{3}H]water formed (cpm)/specific radioactivity of [5-^{3}H]glucose (cpm/pmol).

K.6.2.2 Pyruvate Oxidation

PURPOSE AND RATIONALE

Pyruvate oxidation can be monitored in isolated rat adipocytes as the incorporation of the acetyl-CoA generated into lipophilic products along the fatty acid syn-

thesis and esterification (into TAG) pathways. Under conditions of glucose deprivation pruvate dehydrogenase (PDH) is rate-limiting for the overall conversion of 3-[^{14}C]pyruvate into radiolabeled products (e. g. fatty acids, TAG) which are separated from the unincorporated ^{14}C-labeled pyruvate, acetyl-CoA and hydrophilic intermediates by partitioning into the toluene phase.

PROCEDURE

Isolated rat adipocytes are prepared by collagenase digestion as described above (K.5.1.2), however, in KRHB lacking glucose. 3.5×10^4 cells are incubated (2 h, 37°C) with 0.1 mM [3-^{14}C]sodium pyruvate (0.5 µCi) in 1 ml of KRHB lacking glucose. After addition of 5 ml toluene, the samples are vortexed and incubated overnight at 4°C. 1 ml of the upper toluene phase is removed, supplemented with 10 ml toluene-based scintillation cocktail (e. g. Beckman Quickszint 501) and counted for radioactivity.

EVALUATION

Dichloroacetate (DCA), which acts as unspecific inhibitor of PDH kinase leading to activation of PDH and thereby stimulation of pyruvate oxidation, should be used as control (0.2–5 mM final conc.). Data each corrected for a blank value lacking cells are calculated as fold-stimulation of ^{14}C-incorporation into toluene-soluble products in response to DCA *vs.* basal. In isolated rat adipocytes 5 mM DCA stimulates pyruvate oxidation by 3- to 4-fold. The assay may be useful for the identification of compounds/drug candidates which stimulate pyruvate oxidation by inhibition of PDK (PDK2 in adipocytes) or different modes of action.

K.6.2.3 Pyruvate Dehydrogenase Complex (PDC) Activity

PDC activity is determined according to the method of Jeoung and coworkers (2006). For this, deep-frozen and pulverized diaphragms are homogenized in 5 volumes of extraction buffer containing 30 mM HEPES/KOH (pH 7.5), 0.5 mM thiamine pyrophosphate, 3% Triton X-100, 5 mM EDTA, 2% BSA, 5 mM DTT, 10 µM tosyl-phenylalanyl-chloromethyl ketone, 10 µg/ml trypsin inhibitor, 1 µM leupeptin, 2 mM dichloroacetate (DCA), and 50 mM KF. The supernatant obtained by centrifugation (10,000 × *g*, 10 min, 4°C) is made 9% (w/v) in PEG6000 to precipitate PDC. Pellet produced by centrifugation (12,000 × *g*, 10 min) is suspended in a suspension buffer containing 30 mM HEPES/KOH (pH 7.5), 1% Triton X-100, 0.2 mM EDTA, 2% BSA, 1 µM leupeptin, 5 mM DTT. For determination of total PDC activity, diaphragms are homogenized in 5 volumes of the extraction buffer lacking DCA and KF. The supernatant (200 µl) obtained by centrifugation of the homogenate (10,000 × *g*, 10 min, 4°C) is added to 100 µl of an activation buffer (suspension buffer containing 25 mM $MgCl_2$, 1.5 mM $CaCl_2$, and 1 µg of recombinant pyruvate dehydrogenase phosphatase 1 protein. After incubation (20 min, 30°C) to dephosphorylate and activate PDC, samples are treated with PEG6000 (final 9%, w/v) to precipitate PDC. An aliquot of an extract of the pellet is used to assay of total PDC activity. PDC activity is measured spectrophotometrically in a 96-well plate reader with a coupled assay based on the reaction catalyzed by arylamine acetyltransferase (Nakai et al. 1999, Coore et al. 1971). One unit of PDC activity corresponds to the acetylation of 1 µmol of *p*-(*p*-aminophenylazo)-benzenesulphonate per min at 30°C.

K.6.2.4 Pyruvate Dehydrogenase Kinase (PDK) Activity

GENERAL CONSIDERATIONS

The PDC multienzyme complex (5–10 million Da) catalyzes a key regulatory step in oxidative glycolysis, the irreversible decarboxylation of pyruvate. Its activity is reduced under conditions of increased fatty acid oxidation, i. e. when tissue [acetyl-CoA]/[CoA] and [NADH]/[NAD^+] ratios are elevated. Thus, PDC activity is down-regulated during fasting and in pathological conditions associated with insulin resistance, such as diabetes and obesity (Fuller and Randle 1984, Orfali et al. 1993, Kelley et al. 1992).

The mammalian PDC is composed of multiple copies of three enzymes: pyruvate decarboxylase (E1 subunit), dihydrolipoyl acetyltransferase (E2 subunit, a modular protein which contains a transacetylase and so-called outer and inner lipoyl domains, $E2_c$, $E2_{L1}$ and $E2_{L2}$, respectively), and dihydrolipoyl dehydrogenase (E3 subunit). It is regulated by reversible phosphorylation (Linn et al. 1969, Yeaman 1978). Four pyruvate dehydrogenase kinase (PDK) and two pyruvate dehydrogenase phosphatase (PDP) isozymes have been identified to date (Gudi et al. 1995). PDKs inactivate PDC by catalyzing the ATP-dependent phosphorylation of three serine residues on the PDC E1 subunits.

PURPOSE AND RATIONALE

The blood glucose lowering effect of dichloroacetate (DCA) in diabetic rodents (Lorini and Ciman 1962) and type II diabetic patients (Stacpoole et al. 1978)

has been ascribed to its ability to inhibit PDKs and thereby activate PDC *in vivo*. The primary structures of PDK isozymes 1–4 share little sequence homology with other eukaryotic protein kinases and are more homologous to prokaryotic histidine kinases (Popov et al. 1993). These findings increased the attractiveness for drug discovery projects to identify novel inhibitors of PDK activity as possible therapeutic agents for diabetes and other pathological conditions in which PDC activity is reduced (e. g. lactic acidosis, ischemia) (Bersin and Stacpoole 1997). Until recently, the only known small molecule inhibitors of PDK activity were pyruvate, DCA, halogenated acetophenones and analogs of ATP (e. g. adenosine 5′-[β,γ-imido]triphosphate (p[NH]ppA). The following assays may be useful for the identification of structurally novel PDK inhibitors.

PROCEDURE

Functional PDK Assay

Compounds are assessed for their ability to inhibit the ATP-dependent inactivation of porcine heart PDC. The assay essentially consisted of three steps. First, a BSA-stabilized PDC preparation is acetylated to enhance its intrinsic PDK activity. Second, the PDK reaction is initiated by the addition of ATP. Third, after 7 min the PDK reaction is terminated and the residual PDC activity is assessed by monitoring the formation of NADH at 340 nm. In some experiments, the PDC is either supplemented with rPDK and/or ATP is omitted during the second step.

E1 Subunit Phosphorylation Assay

For phosphorylation of the PDC E1 subunit by endogenous PDK (Jackson et al. 1998), the reaction is initiated by the addition of [γ-^{33}P]ATP (80 mCi/mmol) to intact porcine PDC. The reaction is terminated after 45 s by the addition of TCA. Precipitated protein is recovered by centrifugation, dissolved in 1 M NaOH and the radioactivity of the entire sample is determined by liquid scintillation counting.

PDK Peptide Phosphorylation Assay

PDK activity is determined by measuring the PDK-catalyzed phosphorylation of an acetylated tetradecapeptide substrate, Ac-YHGHSMSDPGVSYR, as previously described (Jackson et al. 1998), except that the reaction volume is 25 µl. Effects of compounds/drug candidates on PDK activity are usually determined in the presence of 0.2 mM [γ-^{33}P]ATP (0.05 µCi/nmol ATP) and 0.5 mM peptide substrate. In experiments where the [γ-^{33}P]ATP (0.05–0.85 µCi/nmol ATP) concentration is varied, the final peptide concentration is 0.5 mM. When the peptide concentration is varied, the final [γ-^{33}P]ATP concentration is adjusted to 0.2 mM. Results are expressed as specific activity (nmol of phosphate transferred per mg of PDK protein per 30 min).

Kinase Autophosphorylation Assay

PDK1 or PDK2 (50 µg/ml) is incubated in a 25-µl reaction mixture containing MOPS (40 mM, pH 7.2), KH_2PO_4 (20 mM), EDTA (0.5 mM), $MgCl_2$ (1.8 mM), KCl (30 mM), DTT (2 mM), NaF (10 mM), [γ-^{32}P]ATP (0.2 mM, 0.01 mCi/mmol) and compounds/drug candidates at 37°C for up to 5 min. The reaction is terminated by the addition of 0.1 volume of a mixture of 425 mM H_3PO_4 and 5 mM p[NH]ppA. The sample is then adjusted to pH 7.4 by the addition of 125 µl of a mixture of 60 mM Tris (pH 8.7) and NaCl (500 mM). The entire sample is then applied to a nitrocellulose membrane and rinsed with TBS (20 mM Tris, 500 mM NaCl, pH 7.5) using a Dot-slot blotting apparatus. Phosphorylated proteins are visualized using a phosphor screen and a phosphorimager (e. g. Storm 840).

Phosphorylation of E1 Protein by PDKs

PDK1 or PDK2 (7.5 µg) is incubated in the presence or absence of 95 µg of acetylated PDC without BSA (Jackson et al. 1998) in a 75-µl reaction mixture containing MOPS (40 mM, pH 7.2), KH_2PO_4 (20 mM), EDTA (0.5 mM), $MgCl_2$ (1.8 mM), KCl (30 mM), DTT (2 mM), NaF (10 mM) and [γ-^{32}P]ATP (0.2 mM, 0.01 mCi/mmol). Following a 45-min incubation at 37°C, the reaction is terminated by the addition of an equal amount of Laemmli sample buffer. 40-µl portions are subjected to SDS/PAGE.

Assay for Direct Inhibition by Supplemental PDKs

PDK2 is added to the functional PDK assay described above, which is performed in the absence and presence of ATP. Alternatively, a PDC preparation which is neither stabilized with BSA nor pre-acetylated is incubated (14 µg/ml) in 180 µl of 40 mM MOPS (pH 7.4), 0.36 mM EDTA, 30 mM KCl, 1.5 mM $MgCl_2$, 120 mM ADP, 2 mM DTT, 10 mM NaF and the additions indicated, at 37°C for up to 10 min. During this step, ADP is omitted in some experiments. The PDC reaction is initiated by the addition of 20 µl of 40 mM MOPS (pH 7.4), 0.36 mM EDTA, 1.5 mM $MgCl_2$, 1 mM DTT, 1.1 mM CoASH, 2.2 mM NAD^+, 2.2 mM pyruvate and 2.2 mM thiamine pyrophosphate. NADH formation over 5 min is monitored at 340 nm.

EVALUATION

The functional PDK assay has a spectrophotometric read-out and measures the effect of PDK activity on PDC function. However the PDK isozyme composition and the stoichiometry of PDK relative to PDC are unknown. Obviously this assay is more difficult to optimize and validate than a traditional kinase assay based upon a model fluorescent peptide substrate. However, the functional PDK assay should identify not only compounds acting at known or presumed sites on the kinase (ATP, lipoamide, or pyruvate binding sites) but also those interfering with interactions between PDK and other PDC protein components (e. g. E1 subunit or the inner lipoyl domain (E2L2) of the E2 subunit of PDC). Although inhibitors of protein–protein interactions are rare, it is desirable that an initial screening assay allows for this possibility.

In contrast to the functional PDK assay, the E1 phosphorylation assay enables PDK activity to be measured directly by testing the compounds/drug candidates for a more specific effect. The ability to inhibit phosphorylation of the E1 subunit by PDK activity intrinsic to the PDC preparation. This assay was used to confirm PDK inhibition in the functional assay. At least one of the concentrations selected for each compound approximated its IC_{50} value determined in the functional assay. The recombinant inner lipoyl domain of the PDC dihydrolipoyl acetyltransferase ($rE2_{L2}$) is a known inhibitor of PDK activity in this assay and is included as a control (Jackson et al. 1998).

The E1 phosphorylation assay is able confirm that apparent PDK inhibition in the functional assay is due to inhibition of E1 phosphorylation. However, this assay suffers from the drawback that the PDK isozyme composition and stoichiometry are undefined. Therefore, a much simpler assay with defined stoichiometry of a synthesized tetradecapeptide (a fragment of the E1 subunit which contains all three of the serines which are phosphorylated by PDK [Yeaman et al. 1978]) can be used. This assay has been modified by Mullinax and coworkers (1985) who demonstrated that this tetradecapeptide is a specific substrate for PDK and the PDH phosphatase. Therefore, this assay is in principle the most amenable to kinetic characterization of inhibitors acting at the active site of PDKs.

K.6.2.5 Fatty Acid Oxidation

GENERAL CONSIDERATIONS

The development of obesity and the associated insulin resistance results from increases in the ratio of food in-

take to energy expenditure. Loss of body weight can be achieved through a reduction in food intake, a stimulation of energy expenditure, or a combination of both. At the same time, a reduction of fatty acid oxidation has been described in obese and diabetic patients, and the resulting accumulation of fatty acid oxidation has been described in obese and diabetic patients and the resulting accumulation of fatty acids or metabolites of fatty acids in tissues such as skeletal muscle and liver seems to play a direct role in the development of insulin resistance. Recent observations in animal models suggest that a stimulation of fatty acid oxidation reduces the accumulation of fatty acids in tissues and increases overall energy expenditure, leading to lean, insulin-sensitive phenotypes. The modulation of fatty acid oxidation is therefore an attractive new therapeutic strategy for the treatment of obesity and insulin resistance.

Fatty acid oxidation modulated by compounds/drug candidates can be measured with myocytes and hepatocytes by indirect (generation of $^3H_20$) or direct (generation of $^{14}CO_2$) procedures with the advantages of lower expenditure in equipment and handling inherent to the former and higher accuracy and physiological relevance associated with the latter. In any case current assays using cultured cells are cumbersome and of low-throughput. Most published procedures utilizing ^{14}C-labeled lon-chain fatty acid substrates (e. g. palmitate or oleate) are performed in tissue culture flasks, in which a center well captures the radioactive CO_2 product (Angelini et al. 1980, Alam and Saggerson 1998, Kaushik et al. 2001). Alternatively, ^{3}H-labeled fatty acids can be used, but a labor-intensive extraction of ^3H_2O is needed (Ibrahimi et al. 1999). These low-throughput assay methods are not suitable for rapid screening of potential drug candidates. More recently, a variant of the $^{14}CO_2$-capturing method has been introduced by Collins and coworkers (1998) which facilitates the accurate, reproducible and safe throughput measurement of the released of $^{14}CO_2$.

K.6.2.5.1 CO_2 Release

PURPOSE AND RATIONALE

The measurement of fatty acid oxidation using a self-contained 48-well assay has been described by Wang and coworkers (2004). Palmitate is conjugated with essentially fatty acid-free BSA to generate a stock solution of 25% (w/v) BSA and 6 mM fatty acid in serum-free medium. After conjugation with albumin, the concentration of fatty acids in the solution is measured using a NEFA kit (Wako Chemicals, Inc.). The stock solution is diluted into the final culture medium to obtain concentrations of 1 to 1000 µM fatty acid. Palmitate oxidation is measured by the production of $^{14}CO_2$ from [1-^{14}C]palmitic acid.

PROCEDURE

For throughput analysis, the cells are incubated for 1 to 3 h at 37°C in 6- to 24-well culture dishes with medium containing 0.2–1 µCi/ml [1-^{14}C]palmitic acid and nonlabeled palmitate (1–1000 µM), 2.5 mM glucose and 0.8 mM carnitine in the presence or absence of compounds/drug candidates. Each culture dish is sealed using a special technique, for instance by covering with Parafilm, which had a piece of Whatman paper taped facing the inside of the Petri dish. Alternatively and for low-throughput application, the cells can be handled according to the protocol published by Fediuc and coworkers (2006). For this, the L6 myotubes are serum-starved for 4 h before exposure to fatty acids [i]and then incubated for 1 h in 60 × 15 mm culture dishes with medium containing 0.2 µCi/ml [1-^{14}C]palmitic acid (1–10 mM) in the absence or presence of compounds/drug candidates. Each culture dish is sealed with Parafilm, which has a piece of Whatman paper taped facing the inside of the Petri dish. After the incubation, CO_2 generated during this period has to be trapped using a special technique, for instance by wetting the Whatman paper with 100 µl of phenylethylamine/methanol (1/1) and subsequent addition of 200 µl of H_2SO_4 (4 M) to the cells. After additional incubation (1 h, 37°C), the amount of $^{14}CO_2$ is determined by careful removal of the Whatman paper and transfer to scintillation vials for radioactivity counting as described by Ceddia and coworkers (2000, 2004).

Alternatively, cultured hepatocytes or myocytes are grown to confluence in the odd-numbered rows of 48-well plates. For standard assays, the cells are washed with PBS twice and then incubated with 125 µl of KRB buffer supplemented with 5 mM glucose at 37°C for 1 h. After removal of this buffer, 125 µl of reaction mixture in KRB buffer containing 0.2 µCi [1-^{14}C]palmitate (~500,000 cpm) and 0.5% BSA is added to the wells. Palmitate is conjugated with essentially fatty acid-free BSA to generate a stock solution of 25% (w/v) BSA and 6 mM fatty acid in serum-free medium. After conjugation with BSA, the concentration of fatty acids in the solution is measured using a NEFA kit (Wako Chemicals). The reactions are performed in the sealed environment of the device at room temperature for 3 h. The reactions are termi-

nated by injection of 250 µl of 1 M HCl into the cell-containing wells to release CO_2. This injection is performed through the pierceable septum using a syringe. The CO_2 is captured in 250 µl of 1 M NaOH in the adjacent connected well as room temperature overnight. The NaOH solution is removed into a scintillation vial and mixed with 4 ml of OptiPhase (HiSafe 3) scintillation cocktail and counted.

For measurement of fatty acid in isolated hepatocytes in suspension according to the procedure of Chang and coworkers (2006), cells (5×10^5) are incubated for 1 h in buffer containing carnitine, NAD, ATP, cytochrome c, $MgCl_2$, coenzyme A, and [^{14}C]palmitic acid complexed with fatty acid-free BSA. The reaction is stopped with 60% perchloric acid. The released CO_2 is trapped by hyamine hydroxide at the top of a hanging center well and counted for radioactivity in a β-scintillation counter. Fatty acid oxidation is calculated as percentage of the maximal value obtained by stimulation of the cells with epinephrine (1 µg/ml).

For measurement of fatty oxidation in native liver tissues according to the procedure introduced by Wu and coworkers (2006), liver slices (0.5 mm thick) are prepared using a tissue slicer and placed in 25-ml Erlenmeyer center-well flasks with 2 ml KRP buffer. [^{14}C]oleic acid bound to fatty acid-free BSA in KRP buffer is added to a final concentration of 0.5 mM and equilibrated for 30 s with a humidified 95% O_2/5% CO_2 gas mix. Flasks are then capped with a rubber stopper containing a centered well enclosing a loosely folded filter paper moistened with 0.2 ml of 1 N NaOH solution. After incubation for 4 h at 37°C, the reaction is stopped by injecting 0.2 ml of H_2SO_4 (1 M). The radioactivity trapped in the filter paper is determined by scintillation counting.

To improve the throughput, a device that accommodates four 48-well culture dishes in a single unit has been designed (Collins et al. 1998). Two adjacent wells form a single experimental unit by means of a coneting chamber, which is sealed from other experimental units and from the outside environment to prevent the release of radioactive material. In this design, obne well of the experimental unit contains the cells and ^{14}C-labeled fatt acid. The [^{14}C]CO_2 produced by β-oxidation of the fatty acids is then released from the culture medium upon addition of HCl and is subsequently captured in the adjacent NaOH-containing well. The data published demonstrate that the use of this device, which has a simple desing and is easy to use, allows highly reproducible evaluation of long-chain fatty acid oxidation in cultured cells with low variability, can be used with a variety of substrates, such as long- and medium-chain fatty acids, and cell lines, such as HepG2, primary rat hepatocytes and HEK293, and unlike previously reported center-well capture methods for β-oxidation assays, can be run in medium-throughput making it suitable for compound characterization and drug discovery. The ability to use primary hepatocytes opens the possibility to evaluate cells after exposure to drugs *in vivo*.

K.6.2.5.2 Release of Acid-Soluble Metabolites (ASM)

PROCEDURE

Determination of fatty acid oxidation as the release of ASM, which predominantly consist of tritiated water and ketone bodies, follows the proccdure described by Moon and Rhead (1987) with modifications introduced by Minnich and coworkers (2001). The reaction mixture is prepared by complete evaporation of the solvent from [9,10-^{3}H]palmitic acid with a 5% CO_2/95% air stream. The [^{3}H]palmitate is resuspended in Hanks' basic salt solution (HBSS) containing 10 mg/ml BSA and brought to a final concentration of 22 µM [^{3}H]palmitate and 0.5 mg/ml BSA with HBSS. 0.2 ml of this mixture is applied to the wells of 24-well culture dishes containing HepG2 cells or L6 myotubes rinsed twice with 1.5 ml of Dulbecco's PBS. Blanks are prepared by applying 0.1 ml methanol for 30 s. After incubation (2 h, 37°C) in humidified 5% CO_2/95% air, the reaction mixture is removed and added to a centrifuge tube containing 0.2 ml of 10% TCA. Each well is rinsed with 0.1 ml of Dulbecco's PBS, which is added to the tube. After 2 min at room temperature, the reaction mixture is centrifuged ($8{,}500 \times g$, 5 min). The supernatants are immediately removed, then supplemented with 70 µl of 6 N NaOH and loaded onto a 1-ml Dowex-1 column in a pasteur pipette. Columns are rinsed with 1 ml of distilled water. The eluate is collected in a scintillation vial containing 10 ml of scintillation cocktail and then counted for radioactivity.

Alternatively, for bypassing the removal of non-oxidized fatty acids by column adsorption, the ASM can be measured directly by transfer of the cells to plastic tubes according to the protocol introduced by Aas and coworkers (2004). The flasks are rinsed with 1.5 ml of perchloric acid (1 M) that is subsequently added to the same plastic tube. The tubes are then centrifuged ($1{,}800 \times g$, 10 min) and 1.0 ml of the supernatant is counted by liquid scintillation. ASM are also measured in the growth media of cells grown on 6-well plates that had been incubated with [1-^{14}C]oleic

acid and [1-^{14}C]palmitic acid. A 250-µl aliquot of the cell medium is precipitated with 100 µl of 6% BSA and 1.0 ml of 1 M perchloric acid. After centrifugation (1,800 × *g*, 2 min), 500 µl of the supernatant is counted by liquid scintillation. No-cell controls have to be included.

EVALUATION

The sensitivity of this assay critically depends on the substrate concentration, cell density, BSA concentration and incubation time. Though the concentration of [^{3}H]palmitate employed routinely (22 µM) is not fully saturating, less than 2% of the substrate is converted to ^3H_2O by L6 myotubes. The [^{3}H]palmitate concentration is thus virtually constant throughout the incubation period. ^3H_2O formation is linear to up to ~60 µg of cell protein per well, at which point the response levels off, and to up to 4 h of incubation. Optimal activity is typically observed in HBSS containing 0.5 mg/ml fatty acid-free BSA in comparison to other media (e. g. MEM). In conclusion, the ^3H_2O release assay combines the advantages of relatively low requirements of cells, radiolabeled substrate and assay time.

ASM, a measure of ketone bodies in the liver and of tricarboxylic-acid-cycle intermediates and acetyl esters in muscle, are assayed in supernatants of the acid precipitate. In myocytes, ASM routinely accounts for over 90% of total oxidation products. Minimal increases in ^{14}C-radioactivity over background levels occur in media in which myocytes have been incubated, indicating that insignificant amounts (< 15% of the counts recovered as CO_2) of ASM are released into the medium.

K.6.2.6 Carnitine Palmitoyltransferase I (CPTI) Activity

PURPOSE AND RATIONALE

Carnitine palmitoyltransferase I (CPT I) which mediates the uptake of long-chain fatty acids into mitochondria, is the rate-limiting enzyme for mitochondrial fatty acid oxidation in mammalian cells. Pharmacological inhibition of CPT I in course of an increase in its physiological negative regulator, malonyl-CoA, as consequence of the inhibition of fatty acid synthase by a natural small molecule (C75) has been demonstrated to lead to appetite suppression. This apparent anti-obesity therapeutic action is presumably based on an alteration in the metabolism of neurons in the hypothalamus, where an increase in malonyl-CoA serves as a secondary messenger of the nutrient status, thereby mediating satiety (Loftus et al. 2000, Hu et al. 2003). In addition, in peripheral tissues (Thupari et al. 2002), C75 has been postulated not only to increase the level of malonyl-CoA but also to act as a malonyl-CoA analog that antagonizes the inhibitory effect on CPT I (McGarry and Brown 1997). Both its central and the peripheral actions could reduce weight in lean and fat mice. Furthermore, both direct activation and direct inhibition of CPT I and the resulting increased

and decreased fatty acid oxidation, respectively, have been implicated as putative target for the improvement of impaired insulin signaling and glucose metabolism in muscle and liver cells in course of reduced lipid accumulation (i. e. reduced lipotoxicity, see K.6.3.2) and of enhanced glucose oxidation according to the inverse relationship between glucose and fatty acid oxidation (i. e. Randle cycle), respectively.

Mammalian tissues express three isoforms of CPT I, liver (L-CPT I), muscle (M-CPT I) (McGarry and Brown, 1997), and brain (CPT I-C) (Price et al. 2002). The liver and muscle isoforms are tightly regulated by their physiological inhibitor malonyl-CoA, which allows CPT I to signal the availability of lipid and carbohydrate fuels to the cell. The malonyl-CoA sensitivity of L-CPT I in the adult rat depends on the physiological state. It is increased by renewed feeding of carbohydrates to fasted rats, by obesity, or following administration of insulin to diabetic rats, whereas it is decreased by starvation and diabetes (Grantham and Zammit 1986, 1988). CPT I activity can be measured with mitochondria from cultured cells and tissues.

PROCEDURE

Preparation of Mitochondrial Fractions

Mitochondria-enriched cell fractions from various cell types (INS, L6 myotubes, HEK293 cells) cultured in 15-cm dishes are obtained with a glass homogenizer as described by Rubi and coworkers (2002). The pellet, in which the mitochondria remain largely intact, is used directly for CPT I activity assays. Mitochondria-enriched fractions are obtained from rat and mouse muscle according to published procedures (Saggerson and Carpenter 1981) with minor modifications. Two soleus muscle samples of each animal are homogenized separately in 250 mM sucrose buffer using an omni-mixer and then centrifuged (1,000 × *g*, 15 min). The pellet is homogenized and centrifuged (600 × *g*, 10 min). The resulting supernatant is centrifuged (15,000 × *g*, 15 min) and the pellet is resuspended in 100 µl of a buffer containing 250 mM sucrose and 150 mM KCl. Mitochondria-enriched fractions from rat and mouse liver are obtained by homogenization in a buffer containing 250 mM sucrose, 1 mM EDTA, and 10 mM Tris-HCl (pH 7.4). The liver suspension is centrifuged (560 × *g*, 15 min), and the supernatant is further centrifuged (12,000 × *g*, 20 min). The pellet is resuspended in 2 mL of homogenization buffer, centrifuged (7,000 × *g*, 10 min), washed and resuspended in 1 ml of the homogenization buffer. To obtain mitochondria-enriched fractions from mice pancreas, tissue is homogenized in a buffer containing 250 mM sucrose, 20 mM Tris-HCl (pH 7.4), 0.5 mM EDTA, 0.5 mM EGTA, 1 mM DTT, 10 µg/ml leupeptin, 4 µg/ml aprotinin, 2 µg/ml pepstatin, and 100 µM PMSF. The homogenate is subjected to differential centrifugation (900 × *g*, 10 min and 5,500 × *g*, 10 min). The pellet is resuspended with a Dounce homogenizer and centrifuged (2,000 × *g*, 2 min and 4,000 × *g*, 8 min). Finally, the pellet is resuspended in 250 µl of 250 mM sucrose (Li et al. 1996). All the processes are performed at 4°C, and fractions are assayed immediately for CPT I activity.

Determination of CPT I Activity

CPT I activity is measured in mitochondria-enriched fractions obtained from cultured cells or tissues. CPT I activity in 10–15 µg of mitochondria-enriched cell fractions, or 20 µg of mitochondrial fractions from tissues is determined by the radiometric method as described by Morillas and coworkers (2001). Extracts are pre-incubated at 30°C for different times in the presence or absence of compounds/drug candidates. Enzyme activity is assayed for 4 min at 30°C in a total volume of 200 µl. The substrates are 50 µM palmitoyl-CoA and 400 or 1000 µM L-[*methyl*-^{3}H]carnitine for L- and M-CPT I isoforms, respectively. In tissues and cell culture extracts, both CPT I (malonyl-CoA-sensitive) and CPT II (insensitive to malonyl-CoA) are present. Thus, in these fractions, CPT I activity is determined as the malonyl-CoA/etomoxiryl-CoA-sensitive CPT activity. CPT II activity, which is also present in mammalian mitochondrial extracts, is always subtracted from the total activity to calculate specific CPT I activity. The presence of CPT activity insensitive to malonyl-CoA (CPT II activity) in mitochondria obtained from cell cultures is typically less than 5% and thus is not taken into consideration. Compounds/drug candidates are pre-incubated with the enzyme for 1–5 min depending on the assay. Compound/drug candidate concentrations ranging from 0.01 to 50 µM are used to estimate the IC_{50} value. Malonyl-CoA (50 µM) is used for malonyl-CoA inhibition assays. In all cases, the molar ratio of palmitoyl-CoA to BSA is kept at 5:1 to avoid the presence of free acyl-CoA and its deleterious detergent effects and to prevent the formation of micelles. Kinetic constants (K_m and V_{max}) are determined by Lineweaver-Burk analysis. Inhibition constants (K_I and k_{inact}) are determined at 20 µM palmitoyl-CoA by nonlinear parameter estimation (Maurer and Fung 2000) using SigmaPlot version 8.0. All protein concentrations are determined using the Bio-Rad protein assay with BSA as a standard.

Binding of Compounds/Drugs to CPT I

The binding of compounds/drugs to CPT I is assessed as described by Tutwiler and Ryzlak (1980) with some modifications. Mitochondria-enriched fractions are pre-incubated for 5 min at 30°C with compounds/drugs at 50 µM. One aliquot is used directly for the CPT I activity assay (unwashed), and the other aliquot is centrifuged (13,000 × *g*, 5 min, 4°C) and resuspended (washed) in 5 mM Tris-HCl (pH 7.2), 150 mM KCl, 2 µg/ml leupeptine, 0.5 µM benzamidine, 1 µg/ml pepstatin, and 1 mM PMSF before the activity assay.

To verify the reversibility of the interaction of compounds/drug candidates with CPT I, dialysis assays are performed. Mitochondria-enriched fractions (160 µg) are pre-incubated at 30°C for 5 min (without the compound/drug) or with a final concentration of 50 µM compound and then dialyzed in buffer containing 10 mM HEPES (pH 7.4), 1 mM EDTA, and 10% glycerol at 4°C. Aliquots are taken before dialysis (0 h), and 24 and 36 h thereafter, and assayed for CPT I activity. This method has been used by Bentebibel and coworkers (2006) to demonstrate novel effects of C75 on CPI I activity and palmitate oxidation.

K.6.2.7 Respiratory Quotient (RQ)

Respiratory quotient changes during variable periods of fasting of rodents are monitored at 24°C ambient temperature in an open respirometric system. Individual O_2-consumption and CO_2-production are recorded every 5 min at a flow rate of ~40 l/h. RQ equals volumes of CO_2 released/volumes of O_2 consumed. During the 18-h measurement period mice are maintained in metabolic cuvettes (5 l9, which contained bedding material (~50 g) and provided access to water *ad libitum*. In each trial, typically 4 mice are investigated. Before and after the experiment, mice are weighed and body temperature are recorded by inserting a rectal probe.

K.6.2.8 Phosphoryation of Acetyl-CoA Carboxylase (ACC) and AMP-Dependent Protein Kinase (AMPK)

PURPOSE AND RATIONALE

In recent years, a large body of evidence has been published showing that in mammals AMP-activated protein kinase (AMPK) responds to hormonal and nutrient signals in the central nervous system and peripheral tissues, modulating food intake and whole-body energy homeostasis (for a review see Carling 2005). AMPK is a heterotrimeric enzyme that has been proposed to function as a "fuel gauge" that monitors changes in the energy status of cells. When activated, AMPK shuts down anabolic pathways and promotes catabolism in response to an increase in the AMP/ATP ratio by downregulating the activity of key enzymes of intermediary metabolism. In its activated state, AMPK phosphorylates serine residues 79, 1,200, and 1,215 of acetyl-coenzyme A carboxylase (ACC), producing an 80–90% decrease in the V_{max} of the enzyme, suggesting that AMPK is the physiological ACC kinase. There is also evidence that long-chain fatty acids (LCFAs) act as potent feedback suppressors of lipogenesis by inhibiting ACC activity. ACC is a multifunctional enzyme that, when active (dephosphorylated form), catalyzes the conversion of acetyl-CoA to malonyl-CoA in the *de novo* lipid synthesis pathway. Malonyl-CoA is a potent inhibitor of CPT I) a rate-limiting step for the entry of LCFAs into mitochondria for oxidation (see above). When ACC is inactive (phosphorylated form), a decrease in malonyl-CoA occurs and disinhibits CPT I, thereby increasing the mitochondrial import and oxidation of LCFAs (for reviews see McGarry and Brown 1997, Carling 2005). Therefore, the AMPK/ACC system is thought to play a central role in the regulation of cellular lipid homeostasis (Spiegelman and Flier 2001). In certain metabolic disorders, such as obesity and type II diabetes, lipid metabolism is dysfunctional, causing fatty acids to increase in the circulation and also in intracellular compartments. High levels of fatty acids are toxic to the cells and may cause deleterious metabolic abnormalities (lipotoxicity). By increasing fatty acid oxidation in peripheral tissues, the AMPK/ACC system may play an important role by protecting the cells from these metabolic abnormalities. Of special interest are the mechanisms that regulate the AMPK/ACC system in skeletal muscle, because this tissue plays a major role in determining whole-body energy expenditure, accounts for 70% of total-body glucose disposal, and may modify substrate utilization toward substantially increasing fatty acid oxidation.

The classical view is that AMPK is activated allosterically by an increase in the intracellular AMP/ATP ratio, by phosphorylation of threonine 172 (Thr-172) within the α-subunit, catalyzed by the upstream kinase LKB1 (the upstream kinase of AMPK), and by inhibition of the dephosphorylation of Thr-172 by protein phosphatases. To date, a wide range of physiological stressors, pharmacological agents, and hormones associated with increases in the intracellular

AMP/ATP ratio have been demonstrated to activate AMPK (Corton et al. 1994, for a review see Carling 2005). Fatty acids, another major cellular energy source, may also regulate AMPK activity in skeletal muscle. It has been reported that in perfused rat cardiac muscle, palmitate and oleate significantly increases AMPK activity without causing any significant alteration in AMP/ATP ratio. Another study has reported that exposure to acetate, octanoate, or palmitate causes a significant reduction in AMP/ATP ratio followed by a significant increase in AMPK activity in primary rat hepatocytes (for reviews see Kemp et al. 1999, Ruderman et al. 1999). In contrast to these observations are reports that the AMPK activity of rat liver purified LKB1/STRAD/MOM25 (the upstream kinase complex of AMPK) was inhibited by long-chain acyl-CoA esters *in vitro* (Lizano et al. 2004, Hawley et al. 2003, Boudeau et al. 2003). Consequently, AMPK and ACC represent important targets for future anti-diabetic and anti-obesity therapy *via* activation of fatty acid oxidation in course of activation of the former and inhibition of the latter. The identification of activators of AMPK or inhibitors of ACC, which act directly at the enzyme level or affect the regulation of the enzymes (i. e. induce their phosphorylation) requires reliable cell-based assay systems for measurement of the activity and phosphorylation state of AMPK and ACC in cultured muscle and liver cells and tissues.

Procedure

Cells are grown on six-well plates and incubated for 60 min in the presence or absence of palmitic acid (1–10 µM). AICAR, a synthetic nucleotide precursor taken up by the cells and phosphorylated to the monophosphate form ZMP, which can accumulate in the cell, mimicks the effect of AMP on AMPK phosphorylation and activation. Therefore, incubation with AICAR (2 mM, 60 min) is used as a positive control for AMPK and ACC phosphorylation in L6 myotubes. Because ACC is a substrate for AMPK, the determination of ACC phosphorylation also serves as an indicator of AMPK activity. Immediately after all treatments, cells are lysed in buffer containing 135 mM NaCl, 1 mM $MgCl_2$, 2.7 mM KCl, 20 mM Tris/HCl (pH 8.0), 1% Triton X-100, 10% glycerol, and protease and phosphatase inhibitors (0.5 mM Na_3VO_4, 10 mM NaF, 1 µM leupeptin, 1 µM pepstatin, 1 µM okadaic acid, and 0.2 mM PMSF), heated (65°C, 5 min), and passed five times through a 25 gauge syringe. An aliquot of the cell lysates is used to determine the protein concentration in each sample by the Bradford method. Before loading onto SDS-PAGE gels, the samples are diluted 1:1 with 2 × Laemmli sample buffer (62.5 mM Tris/HCl, pH 6.8, 2% SDS, 50 mM DTT, and 0.01% bromophenol blue). Aliquots of cell lysates containing 30 µg of protein are subjected to SDS-PAGE (12% and 7.5% resolving gels for P-AMPK and P-ACC, respectively) and then transferred to polyvinylidene difluoride membranes (Bio-Rad Laboratories). The phosphorylation of AMPK is determined using phospho-AMPK(Thr172) antibody (1:1,000 dilution), which detects AMPK-α only when activated by phosphorylation at Thr-172 (Cell Signaling Technology). ACC phosphorylation is detected using phospho-ACC-specific antibody (1:500 dilution; Upstate Biotechnology), which recognizes ACC when phosphorylated at serine 79 (Ser-79). Equal loading of samples is also confirmed by Coomassie blue staining of all gels.

K.6.2.9 AMPK Activity

Regulating energy levels is a fundamental process in every living organism. At a cellular level ATP must be maintained at relatively high levels (normally about 10-fold above the concentration of ADP) in order to drive essential metabolic processes. At a whole body level, maintaining a balance between energy supply and energy demand is also crucial. Within the Western world the consequences of failing to regulate energy metabolism is ever more obvious as demonstrated by the huge increase in the prevalence of metabolic disorders, such as obesity and type II diabetes (Jonsson 2002). One system that is emerging as a key player in the overall regulation of energy balance is the AMP-activated protein kinase (AMPK) cascade. AMPK is activated in response to ATP depletion (Hardie et al. 1998, Hardie et al. 2003, Carling 2004 and 2005), which causes a concomitant increase in the AMP:ATP ratio (Corton et al. 1994). Once activated AMPK phosphorylates a number of downstream substrates, the overall effect of which is to switch-off ATP utilising pathways, e. g. fatty acid synthesis, and switch-on ATP-generating pathways e. g. fatty acid oxidation (Hardie et al. 1998, Kemp et al. 1999). In addition to the acute effects of AMPK, activation of AMPK has longer-term effects, altering both gene expression (Foretz et al. 1998) and protein expression (Winder et al. 2000). Although the physiological consequence of these longer-term effects of AMPK are not fully understood, it seems likely that they are involved in the overall regulation of energy metabolism.

AMPK is activated allosterically by AMP and by phosphorylation. AMPK is phosphorylated on T172 which lies within the activation loop of the kinase catalytic domain, a region where many protein kinases require phosphorylation for their activation (Johnson et al. 1996). Phosphorylation of T172 is catalysed by an upstream kinase, the molecular identity of which remained elusive until very recently. Through advances made in the investigation of the regulation by upstream kinases of SNF1, the yeast counterpart of AMPK, the identity of the upstream kinase appears finally to have been revealed. Three closely related yeast kinases, Elm1, Pak1 and Tos3 have been identified that phosphorylate and activate SNF1 *in vitro* (Hong et al. 2003, Sutherland et al. 2003). The amino acid sequences of the catalytic domains of Elm1, Pak1 and Tos3 are most closely related to members of the mammalian Ca^{2+}/calmodulin dependent protein kinase kinase (CAMKK) subgroup. Another kinase sharing significant amino acid sequence identity with the three yeast kinases was LKB1 (also known as STK11). Recent studies have shown that LKB1 phosphorylates and activates a number of AMPK-related kinases (Lizcano et al. 2004), and although the physiological role of these kinases is largely unknown, it is possible that some of the tumor suppressor functions of LKB1 are mediated via these kinases rather than AMPK itself. The finding that LKB1 lies upstream of AMPK, however, does provides the intriguing possibility that there may be a link between metabolic regulation and cell proliferation, mediated by AMPK (Carling 2005). The following assays enable the measurement of AMPK activity as a consequence of appropriate phosphorylation/dephosphorylation by upstream kinases or by direct activation/inhibition by compounds/drug candidates which may be helpful for future anti-diabetic and anti-obesity therapy, respectively.

K.6.2.9.1 Measurement with Recombinant AMPK

PURPOSE AND RATIONALE

For analysis of direct effects of compounds/drug candidates on the activity of AMPK, the enzyme has to be purified (e. g. from rat liver, isoform mixture) or heterogeneously expressed (e. g. in E. coli or insect cells, specific isoforms) and subjected to kinase assay in the presence of the agents. These test systems may be used for the identification and characterization of activators or inhibitors for AMPK, which both might helpful for future therapy of diabetes and obesity, respectively.

PROCEDURE

Expression of Recombinant AMPK

A new polycistronic bacterial expression system has been introduced by Neumann and coworkers (2003), which yields milligram amounts of heterotrimeric and functional AMPK. For this, the cDNA sequences encoding the subunits of AMPK (GenBank Accession Nos. X95578, X95577, and U40819) are subcloned by PCR and inserted into individual pET-plasmids (*Nde*I/*Spe*I sites of pET3-ax, γ1-subunit, resulting in pγ1; *Nco*I/*Spe*I sites of pET-3dx, β1-subunit, resulting in pβ1; *Nco*I/*Spe*I sites of pET14dx, α1-subunit, resulting in pHis-α1r), harboring an ampicillin resistance gene (ampR). Successive restriction and ligation of individual cistrons to the acceptor vector pγ1 lead to a polycistronic gene consisting of a promoter, ribosome-binding sites (RBS), the sequences of γ-, β-, and His-tagged α-subunits of AMPK, as well as a transcriptional terminator.

Purification of Recombinant AMPK

The tricistronic plasmid pγ1β1His-α1 is transformed into competent host cells (*E. coli* BL21-CodonPlus (DE3)-RIL) and incubated overnight at 37°C on LB agar containing 150 µg/ml ampicillin and 25 µg/ml chloramphenicol. Resuspended cells are used to inoculate LB medium containing appropriate antibiotics. Cultures are grown in a shaker incubator at 37°C. Protein expression is induced with 0.4 mM isopropyl β-D-thiogalactopyranoside final concentration at an O.D. (600 nm) of 0.6 and cultures were grown for additional 4 h. Cells are harvested, washed twice with 0.9% NaCl, resuspended in lysis buffer (15% sucrose, 50 mM sodium phosphate, pH 8.0, 50 mM NaCl, 10 mM imidazole and 1 mM β-mercaptoethanol), and sonicated on ice in a Branson 250 sonifier (50% duty, output 5, 2 min, three times). Insoluble material is removed by centrifugation and the supernatant is loaded onto Ni–NTA agarose (Qiagen). After washing (three column volumes with lysis buffer, 20 mM imidazole) and elution (lysis buffer, containing 250 mM imidazole), the protein is stored at −20°C until use.

Gel filtration Chromatography

For confirmation of complex formation of AMPK holoenzyme, the size of purified AMPK in solution is determined by gel filtration chromatography with a Superose 12 HR 10/30 column (Amersham-Pharmacia) connected to HPLC. Minor non-protein contaminants in Ni^{2+}-purified AMPK are removed by batch affinity purification with Blue Sepharose (Amersham-Pharmacia), using elution with 50 mM sodium phos-

phate (pH 8.5), 1 M NaCl, 50 mM AMP, and 1 mM β-mercaptoethanol. One hundred micrograms of protein is then separated in 25 mM sodium phosphate (pH 7.0), 200 mM NaCl, and 1 mM β-mercaptoethanol at a flow rate of 0.75 ml/min and a temperature of 22°C. The column is calibrated for Stokes radii with the following marker proteins: carbonic anhydrase (24.0 Å, 29 kDa), albumin (35.5 Å, 67 kDa), aldolase (48.1 Å, 158 kDa), catalase (52.2 Å, 232 kDa), ferritin (61 Å, 440 kDa), and thyroglobulin (70.0 Å, 669 kDa).

Alternatively, partially purified AMPK holoenzyme from rat liver (up to the blue-Sepharose step according to the protocol of Carling and coworkers [1989] can be used instead of the recombinant version. It is usually obtained in a partially phosphorylated state and therefore does not require the activation step by exogenous upstream kinases, such as LKB1.

Phosphorylation/Activation In Vitro

Ni^{2+}-purified recombinant AMPK is activated with a partially purified preparation of AMPKK (purified up to the Q-Sepharose step (Hawley et al. 1996), with the exception that NaF and sodium pyrophosphate are omitted from the buffers) in the presence of 100 µM ATP, 5 mM $MgCl_2$, and 1 mM DTT in 50 mM HEPES (pH 7.4), for 30 min at 37°C in a thermostated shaker. Samples are then diluted in HEPES assay buffer (50 mM HEPES, pH 7.4, 1 mM EDTA, 10% glycerol, 50 mM NaF, 5 mM sodium pyrophosphate, and 1 mM DTT) and assayed for AMPK activity. For labelling of AMPK with [^{32}P]ATP, Ni^{2+}-purified recombinant AMPK is incubated in the presence or absence of AMPKK (Q-Sepharose pure) in the presence of 100 µM [γ-^{32}P]ATP (approx. 400 cpm/pmol), 100 µM AMP, 5 mM $MgCl_2$, and 1 mM DTT for 30 min at 37°C in a thermostated shaker. After dilution, AMPK is repurified on NTA–Nickel magnetic agarose beads (Qiagen, Basel) before adding SDS sample buffer and running on 12% acrylamide SDS gels. Radiolabeled AMPK is visualized by autoradiography or phosphorimaging.

Alternatively, for phospho-AMPK (Thr172) detection, the 35%-ammonium sulfate precipitate from treated myotubes or hepatocytes can be used for immunoblotting with polyclonal antibodies to AMPK phosphorylated at Thr172 (Cell Signaling Technology, USA) according to the protocoll of Zhou and coworkers (2001).

Radioactive Assay Method

The radioactive AMPK filter assay with [γ-^{33}P]ATP and a consensus substrate, the so-called SAMS peptide (HMRSAMSGLHLVKRR) (Dale et al. 1995) is conducted as described by Zhou and coworkers (2001) and Davies and coworkers (1989). The 100-µl reaction mixture contained 100 µM AMP, 100 µM ATP (0.5 µCi ^{33}P-ATP per reaction), and 50 µM SAMS in a buffer (40 mM HEPES, pH 7.0, 80 mM NaCl, 0.8 mM EDTA, 5 mM $MgCl_2$, 0.025% BSA, and 0.8 mM DTT). The reaction is initiated with addition of the enzyme. After 30-minute incubation at 30°C, the reaction is stopped by addition of 80 µl 1% H_3PO_4. Aliquots (100 µl) are transferred to 96-well MultiScreen plates (MAPHNOB50; Millipore Corp., USA). The plate is washed three times with 1% H_3PO_4 followed by radioactivity detection in a microtiter plate TopCount apparatus.

AlphaScreenAssay Method

The enzymatic reactions for the Alphascreen are carried out according to Li and coworkers (2003) in white round-bottomed 96-well plates (Packard). Each reaction mixture contained (in a total volume of 0.015 ml) ACC-CREBp (100 nM), ATP (200 µM), buffer A (50 mM HEPES, pH 7.0, 100 mM NaCl, 0.01% BSA (w/v), 5 mM $MgCl_2$, 0.8 mM DTTl), and AMPK (0.74 mU, 1 mU = 1 pmol phosphate incorporated into 200 µM SAMS per min at 30°C in the radioactive filter assay). The reaction is initiated by the addition of the enzyme. Incubation is at 30°C for 30 min. The reaction is terminated by the addition of the detection mixture which contained donor and acceptor beads (40 µg/ml each), Anti-pS^{133}-CREB antibody (4 nM), and EDTA (16 mM) in buffer A (0.015 ml) without $MgCl_2$. The plate is read on an ALPHAQuest instrument (Packard Biosignal) after incubation at room temperature in the dark for 2–24 h.

HTRF Assay Method

The enzymatic reactions for HTRF are identical to those for the Alphascreen but are carried out in black round-bottomed 96-well Optiplates (Packard) as described by Li and coworkers (2003). The reaction is terminated by the addition of detection mixture (0.035 ml) which contained SA-XL665 (14 nM), LANCE Eu-W1024-labeled Anti-pS^{133}-CREB antibody (140 pM), and EDTA (3 mM) in buffer A without $MgCl_2$. The plate is incubated for 1 h at room temperature followed by determination of fluorescence with a Discovery instrument (Packard). The 620- and 665-nm fluorescence signals are counted simultaneously and the ratio (665 nm/620 nm × 10,000) is recorded for each well.

EVALUATION

Inhibition

The *in vitro* AMPK inhibition data are fit to the following equation for competitive inhibition by non-linear regression using a least-squares Marquardt algorithm in a computer program: $V_i/V_o = (K_m + S)/[S + K_m \times (1 + I/K_i)]$, where V_i is the inhibited velocity, V_o is the initial velocity, S is the substrate (ATP) concentration, K_m is the Michaelis constant for ATP, I is the inhibitor concentration, and K_i is the dissociation constant for the inhibitor. For determination of K_m, AMPK is assayed at varying concentrations of SAMS peptide in the presence of 200 µM AMP. Kinetic analysis is performed using Graphpad Prism software as has been introduced for AMPK analysis by Stein and coworkers (2000).

Activation

The availability of ultrafast, ultrasensitive, and robust assays suited to high-throughput screening is key to obtaining small-molecule AMPK activators. In the absence of high-affinity and selective anti-phospho Ser/Thr antibodies for AMPK substrates, two homogeneous AMPK assays have been developed with the commercially available antibody Anti-pS^{133}-CREB and an engineered peptide ACC-CREBp. Anti-pS^{133}-CREB antibody was raised against the phospho-CREB peptide derived from cAMP response element binding protein (CREB). ACC-CREBp is a variant (Arg to Pro) of ACC-CREB, a hybrid peptide consisting of a 9-amino-acid peptide from rat ACC, CREB peptide, and the addition of two hydrophobic Leu residues. ACC-CREBp shows increased suitability as a substrate for AMPK, eliminates phosphorylation by PKA, and preserves antibody binding. The homogeneous time-resolved fluorescence and AlphaScreen AMPK assays are developed using both Anti-pS^{133}-CREB antibody and ACC-CREBp that are either labeled with a fluorescent probe or linked to a photoactivated bead, respectively. Very similar biphasic ATP titration curves are generated by both the filter assay and the AlphaScreen. The inhibitory effect observed at higher ATP concentrations most likely results from ATP competing with AMP binding at the allosteric site. Consistent with this hypothesis, an increase in the AMP concentration (from 30 to 200 µM) shifted the curves to the right, suggesting that more ATP is required to compete with AMP. Nearly identical AMP titration curves are generated by the filter assay and the AlphaScreen.

A small molecule AMPK activator of the thienopyridone class has been identified in a high-throughput screening effort (Anderson et al. 2004, Cool et al. 2006), which directly stimulates partially purified rat liver and recombinant human AMPK ($EC_{50} \sim 1$ µM) and inhibits fatty acid synthesis in primary rat hepatocytes ($IC_{50} \sim 3$ µM) and is lower plasma glucose in ob/ob mice. These results demonstrate that small molecule-mediated activation of AMPK *in vivo* is feasible and represents a promising approach for the treatment of type II diabetes.

K.6.2.9.2 Immunecomplex Kinase Assay

PURPOSE AND RATIONALE

For analysis of the AMPK activity and its regulation *ex vivo* in (muscle and liver) tissues or cells upon treatment of rodents or cultured cells with putative AMPK modulators, AMPK is immunoprecipitated from total cell or tissue homogenates and then subjected to immunecomplex kinase assay using a consensus substrate peptide.

PROCEDURE

Cultured myotubes or hepatocytes, incubated with AICAR or compounds/drug candidates in KRH containing 20 mM glucose for 15 min at 37°C, or alternatively, muscle and liver tissues from rodents, treated with compounds/drug candidates, are homogenized by direct addition of an equivalent volume of ice-cold homogenization buffer (50 mM Tris/HCl, pH 7.4, 250 mM mannitol, 1 mM EDTA, 1 mM EGTA, 50 mM NaF, 5 mM $Na_4P_2O_7$, 1 mM PMSF, 1 DTT and 10% glycerol, 0.1% Triton X-100, 1 µl/ml protease inhibitor cocktail [Sigma]) before snap-freezing in liquid nitrogen. The crude homogenate is sonicated with 4 pulses of 3 s each before centrifugation (18,000 × *g*, 3 min). Alternatively, Witters and Kemp (1992) lysed treated hepatocytes directly in digitonin-containing and phosphatase-containing buffer, followed by precipitation with ammonium sulfate at 35% saturation.

To 200 µl of the sample, 2 µl of α-AMPK antibody (Cell Signaling Technologies) are added, and the immunoprecipitation is incubated overnight at 4°C with gentle mixing. After 12 h immunoprecipitation, 30 µl of protein-A beads (50% slurry) is added to each sample and incubated for 2 h at 4°C with gentle mixing. The assay is started by the addition of the immunecomplexes to assay buffer (80 mM HEPES, pH 7.4, 160 mM NaCl, 1.6 mM EDTA, 200 µM SAMS peptide, 200 µM AMP, 200 µM ATP, 16% glycerol, 0.1% Triton X-100) containing [γ-^{32}P]ATP (0.5 µCi per sample). After the addition of enzyme to the reaction tube, samples are vortex-mixed for 5 s and in-

cubated for 10 min at 30°C. Following the incubation, the reaction mixture is vortex-mixed and spotted on P81 Whatman filter paper, briefly allowed to dry, and washed three times in 1% $HClO_4$ before a single wash in acetone. After sufficient time to allow the filter papers to air dry, they are immersed in a scintillant-fluor cocktail and the activity of each sample is measured in a scintillation counter.

K.6.2.9.3 Selectivity vs. Glycogen Phosphorylase (GP) and Fructose 1,6-bis-Phosphatase (FBP)

RATIONALE AND PURPOSE

The enzymes, glycogen phosphorylase (GP) and fructose 1,6-bis-phosphatase (FBP) are allosterically modulated by AMP and ZMP (Longus et al. 2003, Vincent et al. 1991). AMP activates GP, whereas it inhibits FBP. To assess the specificity of small molecules directly activating AMPK, it may be useful to study the effects of the compounds on the activity of GP and FBP. Lack of increase or decrease, respectively, in their activity indicates that unlike AICAR/ZMP these compounds do not act as general AMP mimetics, but selectively activates AMPK. The possibilities of direct interaction with the AMP-binding site of AMPK (but apparently not with those of GP and FBP) or with a distinct allosteric site of AMPK can then be tackled by investigating the putative additive, subadditive or potentiating effects on AMPK activity of combinations of maximally efficacious concentrations of compounds and increasing concentrations of AMP (and *vice versa*). On basis of additive effects obtained by following this strategy between AMP and a newly identified small molecule AMPK activator, which inhibited fatty acid synthesis in primary rat hepatocytes and increases whole-body fatty acid oxidation in normal rats, Cool and coworkers (2006) suggested its binding to a unique site that differs from that of AMP binding.

GP Activity Assay

To assay GP activity according to Kaiser and coworkers (2001), 1.5 µg/ml of rabbit muscle GPb (Sigma) is added to a reaction mix containing 20 mM Na_2HPO_4 (pH 7.2), 2 mM $MgSO_4$, 1 mM β-NADP (β-nicotinamide adenine dinucleotide phosphate), 1.4 U/ml G-6-PDH (glucose-6-phosphate-dehydrogenase) and 3 U/ml PGM (phosphoglucomutase). AMP or compounds/drug candidates are added to the assay medium followed by the addition of glycogen (final concentration 1 mg/ml) to initiate the reaction. After incubating 10 min at 25°C, GPb activity is assessed by measuring absorbance at 340 nm.

FBPase Activity Assay

FBPase (0.01 U/ml final concentration) in 2 × assay buffer (100 mM Tris/HCl, pH 7, 4 mM $MgCl_2$, 300 mM NaCl, 0.2 mg/ml BSA and 6 mM DTT) is added to the compounds/drug candidates to result in the final desired concentrations. Substrate, D-fructose-1,6-diphosphate, at a final concentration of 0.1 mM is added to the reaction. The reaction mix is incubated at 30°C for 20 min. Following the incubation, 2 volumes of Malachite Green solution (Upstate, USA) containing 0.001% Tween 20 is added and absorbance at 640 nm read immediately.

K.6.2.9.4 AMP:ATP Levels

PURPOSE AND RATIONALE

To confirm that effects elicited by small molecule AMPK activators (e. g. inhibition of fatty acid synthesis, stimulation of fatty acid oxidation) are mediated by direct upregulation of AMPK activity rather than by cytotoxic effects (e. g. uncoupling of mitochondria, blockade of mitochondrial respiration) ultimately leading to decreased levels of ATP and increased levels of AMP, the AMP:ATP ratio of cells can be measured upon challenge with the putative AMPK activator. Lack of effect on AMP:ATP is compatible with the compound exerting its cellular effects by direct activation of AMPK and not as a consequence of cellular stress, toxicity or other means of increasing the AMP:ATP.

PROCEDURE

Primary rat hepatocytes are plated and treated as described above. Following the 4-h incubation with compounds/drug candidates, cells are washed with ice-cold PBS and the adenine nucleotides are extracted by Corton and coworkers (1994) with 500 µl/well $HClO_3$. The acid is extracted with three treatments of 1.1 volumes of 1/1 tri-n-octylamine:1,1,2-trichlorotriflouroethane. 50–100 µl of the aqueous sample is injected in a Whatman Partisil 10 SAX column preequilibrated in buffer A (10 mM K_2PO_4, pH 6.75) according to the procedure of Cool and coworkers (2006). For elution, sample columns are run for 5 min in buffer A, then for 15 min in a linear gradient to buffer B (500 mM K_2HPO_4, pH 5) and finally for 35 min in buffer B at a flow rate of 2 ml/min. To measure nucleotide concentration absorbance is read at 254 nm.

K.6.2.9.5 Malonyl-CoA Levels

PURPOSE AND RATIONALE

Since AMPK activation inhibits ACC activity, one expected *in vivo* consequence is a decrease in cellular malonyl CoA levels, leading to reduced lipid synthesis and elevated fatty acid oxidation (see K.6.2.5). Thus, in conjunction with increased ACC phosphorylation in primary rat hepatocytes, a reduction in malonyl CoA levels may be anticipated in the liver of rats following treatment with compounds/drug candidates.

PROCEDURE

Malonyl CoA levels in rat tissues from animals treated with the appropriate feeding paradigm and sacrificed 1.5 h after treatment with compounds/drug candidates are measured according to the procedure of Cool and coworkers (2006). Tissues are harvested, immediately frozen in liquid nitrogen and then homogenized in a 1:10 volume (w/v) of ice-cold 5% sulfosalicylic acid containing 50 µM dithioerythritol. Homogenates are centrifuged (15,000 × *g*, 60 min, 2°C) and the supernatants filtered through a 0.22-µm filter (Ultrafree-MC, Millipore USA). Samples are stored at −80°C prior to liquid chromatography mass spectrometry analysis. HPLC is run at binary mode (A: 5 mM dimethylbutylamine and 6 mM HOAc; B: 0.1% formic acid in CH_3CN) at 200 µl/min with the third pump to deliver post column mixing solvent CH_3CN. The data are acquired on a TOF mass spectrometer using positive ion TOF-MS mode.

K.6.2.10 Acetyl-CoA Carboxylase (ACC) Activity

GENERAL CONSIDERATIONS

Activation of AMPK increases phosphorylation of various downstream target proteins including ACC, a key component in the regulation and coordination of fatty acid metabolism and catabolism (Carling 2004). ACC, the rate-limiting enzyme for fatty acid biosynthesis, produces malonyl-CoA *via* the catalysis of the carboxylation of acetyl-CoA which acts as inhibitor of CPT1 (Ruderman et al. 2003). Thereby, ACC controls mitochondrial β-oxidation in negative fashion coordinating fatty acid synthesis and degradation in reciprocal fashion. Inhibition of ACC may lead to stimulation of fatty acid oxidation in both muscle and liver with beneficial effects for the therapy of type II diabetes and obesity.

In theory, any component of ACC could be a potential target for drug discovery. In fact, a high-throughput screening assay that screens for inhibitors of the holoenzyme has been described by Soriano and coworkers(2006). However, a more robust assay could increase the potential for finding inhibitors. One assay commonly used to measure CT activity is an enzyme-coupled assay that relies on the absorbance of NADH (Guchhait et al. 1974). High-throughput assay formats based on the UV detection of NADH are problematic because the screening libraries often contain many compounds that absorb strongly at 340 nm, thereby generating false negatives.

K.6.2.10.1 DTNB Method

PURPOSE AND RATIONALE

A modification of the coupled enzyme assay for carboxyltransferase, that avoids the use of NADH de-

tection and therefore offers a potential advantage in a typical HTS environment, has been introduced by Santoro and coworkers (2006). The CT reaction is assayed in the reverse direction in which malonyl-CoA reacts with biocytin (an analog of the biotin carboxyl carrier protein) to form acetyl-CoA and carboxybiotin. The production of acetyl-CoA is coupled to citrate synthase, which produced citrate and coenzyme A. The amount of coenzyme A formed is detected using 5,5′-dithiobis-2-nitrobenzoic acid (DTNB = Ellman's reagent). The assay has been developed for use in both 96- and 384-well microplate formats and validated using a known bisubstrate analog inhibitor of CT. The spectrophotometric readout in the visible absorbance range used in this assay does not generate the number of false negatives associated with frequently used NAD/NADH assay systems that rely on detection of NADH using UV absorbance.

PROCEDURE

The assay buffer consists of 100 mM potassium phosphate (pH 7.6) with 0.1% Tween 20. In preparing the reagent stock solutions, 10 mM malonyl-CoA is dissolved in water, 100 mM OAA is dissolved in assay buffer, 1.2 mM DTNB is dissolved in assay buffer, 100 mM biocytin is sonicated in assay buffer, and ACC is dissolved in assay buffer. Commercially obtained citrate synthase solution is diluted 1:10 in assay buffer. Using the above stock solutions, assay solutions are prepared. "CT solution" contains 30 ml of OAA stock, 3 ml of ACC, and 67 ml of assay buffer, and "CS solution" contains 6 ml of malonyl-CoA stock solution, 36 ml of biocytin stock solution, 6 ml of citrate synthase solution, and 52 ml of assay buffer. Final concentrations of reagents in the assay are as follows: 200 µM malonyl-CoA, 12 mM biocytin, 10 mM OAA, 200 µM DTNB, 21.9 nM ACC, and 104 nM citrate synthase.

Automated screening is performed on an integrated core system (e. g. Beckman SAGIAN). The assay plates used are prespotted with 1 µl of each test compound/drug candidate per well. Using an automated liquid dispenser, 30 µl of CT solution is added to each assay well. The plates are incubated at room temperature for 5 min 40 s to allow for association of potential slow-binding inhibitors with ACC. An automated liquid handler with 384-tip pod (e. g. Beckman Biomek FX) is used to add 9 µl of DTNB to each well. The reaction is then initiated by the addition of 20 µl of CS solution using the liquid handler (with gentle aspiration mixing). The plate is promptly transferred (40 s after the beginning of the CS addition step) to an automated 384-detector (e. g. Molecular Devices SPECTRAmax Plus), and the absorbance at 412 nm is recorded. A second reading is taken 5 min 40 s later. The HTS assay is carried out at room temperature.

EVALUATION

The quality of this assay for throughput assay for inhibitors to the CT subunit of ACC is demonstrated by a large assay signal window, low data variation among controls, and strong Z' factors. The assay is reliable for many hours and reproducible from day to day. The screening assay described here will be a useful tool in the discovery of potential anti-diabetic and anti-obesity drugs targeting human ACC.

K.6.2.10.2 Phosphate Measurement

Colorimetric Method

All assays are performed using clear 96-well plates (e. g. Costar). The order of addition of assay components depended on the type of experiment performed. For initial velocity measurements, all assay components except the substrate with variable concentration are premixed in 200 mM HEPES/KOH (pH 8). The reaction is initiated by adding an equal volume of the missing substrate. Solutions of varying ATP and acetyl-CoA concentrations are prepared in doubly distilled/deionized water; holo biotin carboxyl carrier protein solutions are prepared in 50 mM HEPES (pH 7.3) and 10% glycerol. Aliquots (50 µl) are removed from the reaction mix at fixed time points and placed in a 96-well plate preloaded with 100 µl BioMol Green reagent (BIOMOL) to quench the reaction. Incubation time for color development, typically 30 min, is the same for all mixtures. Absorbance is read at 620 nm using a microplate spectrophotometer. Initial rates are measured within a 10% turnover range of the limiting substrate. Phosphate concentration is determined using a standard curve.

Charcoal Adsorption-Scintillation Counting Method

Alternatively, phosphate can be measured using the charcoal adsorption–scintillation counting method adapted from Stitt and Xu (1988). All assay solutions included a trace of [γ-^{33}P]-labeled ATP. Initial velocity measurements are as described for the colorimetric method. At various time points, a 30-µl aliquot is transferred to an Eppendorf tube, fitted with a 0.45-µm filter, containing 120 µl of 5% TCA and 50 µl of 80 mg/ml activated charcoal. After vigorous mixing, the tube is spun in a microcentrifuge (11,000 × g, 30 s) to filter out the charcoal. A 50-µl aliquot of the fil-

trate is added to 7 ml of aqueous scintillation fluid and counted for 1 min in a scintillation counter. To obtain the 100% turnover count (*plus* background), a 30-µl reaction mix is placed in 170 µl of 5% TCA without charcoal and a 50-µl aliquot is counted as above. Background counts, measured by repeating the assay adding water instead of enzyme, are subtracted from all measurements to determine percentage turnover.

Scintillation Proximity Assay (SPA) Method

Assay solutions (33 µl) containing 5 (or 10) µM ATP, 1 (or 2) nCi/µl [γ-^{33}P]-labeled ATP, 20 µM acetyl-CoA, 40 nM AccC, 40 nM AccA/D, and 80 nM BCCP in buffer A (100 mM HEPES/KOH, pH 8, 150 mM NaCl, 10% glycerol, and 1 mM DTT) are incubated for 1 h. The reaction is quenched by the addition of 10 µl of freshly made solution A (two volumes of solution B [30 mg/ml wheat germ agglutinin-coated polystyrene imaging beads or 30 mg/ml streptavidin-coated SPA scintillation beads, Amersham-Pharmacia Biosciences, in 50 mM HEPES/KOH, pH 7.3] mixed with one volume of 16 mM ammonium heptamolybdate in 2.4 N HCl solution). Shortly thereafter (but no longer than 40 min after), 10 µl of 256 mM citrate solution is added. The beads are spun down (2,000–3,000 rpm, 5 min). For experiments using SPA imaging beads, the plate is kept in the dark for at least 2 h before reading the signal using the Leadseeker instrument (Amersham-Pharmacia Biosciences). For experiments using SPA scintillation beads, radioactivity is determined in a TopCount instrument (e. g. Packard) after the plate has been centrifuged.

EVALUATION

Initial velocity measurements as a function of substrate concentration are carried out using either the charcoal adsorption–scintillation counting method, the colorimetric method, or the SPA method. Data are fitted to the Michaelis–Menten equation (using e. g. the GraphPad Prism software).

In general, phosphate determination is a simple and robust method for the measurement of the overall activity of ACC. The monitoring of phosphate production, at low (nanomolar) protein concentrations, is demonstrated to represent the overall activity of ACC due to the coupled activities of biotin carboxylase and CT and the cycling of biotin cofactor attached to BCCP between the two half-reactions. The method has been adapted for a 384-well screening assay format and validated to monitor competitive inhibitors of either biotin carboxylase or CT. The use of holo-BCCP instead of free biotin, as well as the use of physiologically relevant concentrations of the protein components, makes this assay a good model for the *in vivo* ACC system and will facilitate the identification of physiologically relevant inhibitors.

K.6.2.11 Gluconeogenesis, Ketone Body Formation and TCA Cycle

PURPOSE AND RATIONALE

De novo synthesis of glucose in the liver from precursors such as fructose, pyruvate, lactate, gluconeogenic amino acids, and glycerol is a central mechanism to provide the organism with glucose in times of starvation (Cherrington 1997, Nordlie et al. 1999). On the other hand, when glucose is directly available from external resources, gluconeogenesis is dispensable and consequently needs to be shut off. Integration of these events is complex and occurs through various hormonal and nutritional factors (Barthel et al. 2005). The principal parameters affecting hepatic glucose output are the concentrations of the available glucogenic substrates and the activity of a few regulatory enzymes. The activity of the key gluconeogenic enzymes phosphoenolpyruvate carboxykinase (PEPCK) and glucose-6-phosphatase (G-6-Pase) is regulated by transcriptional and non-transcriptional mechanisms, whereas the third key enzyme, fructose-1,6-bisphosphatase (FBPase), is also regulated through competitive inhibition by fructose 2,6-bisphosphate. Insulin is the most important hormone that inhibits gluconeogenesis. It acts predominantly by suppressing the expression of the genes for the key gluconeogenic enzymes, PEPCK and G-6-Pase (Barthel and Schmoll 2003).

Over the recent years, considerable progress has been made in understanding the mechanisms and molecular details involved in the regulation of hepatic glucose production and its impairment in diabetes. A spectrum of different experimental approaches, ranging from genetic manipulations like knockout models and use of gain or loss of function-mutated constructs in cellular models to the development and application of selective pharmacological compounds, has provided evidence for the convergence of multiple signaling pathways in particular on the level of the transcriptional regulation of PEPCK and G-6-Pase gene expression, the key gluconeogenic genes in liver cells. Analogous to multiple braking systems in cars or motorbikes, the redundancy in the regulation of hepatic glucose production emphasizes the critical importance of this process in the glucose homeostasis of the organism. On the other hand, our increasing knowledge in this field has made it possible to identify a group of promising pharmacological targets, therefore providing a solid basis for the development of new and more potent anti-diabetic drugs.

K.6.2.11.1 Hepatocytes

PURPOSE AND RATIONALE

Isolated hepatocytes can be used to study the effect of drugs on hepatic gluconeogenesis and other hepatic metabolic reactions such as ketone body formation and the tricarboxylic acid cycle.

PROCEDURE

Male Wistar rats weighing 200–300 g are used. The hepatocytes are isolated by perfusion of the liver with collagenase (Berry and Friend 1969, Seglen 1976,Alvarez et al. 1987). The viability of the isolated hepatocytes can be evaluated by the Trypan blue test. Usually 90–95% of the cells exclude the stain and can therefore be regarded as intact. The isolated hepatocytes (20×10^6 cells/vial) are suspended in 3.0 ml of KRB containing 4% BSA. The cell suspension is pre-incubated for 15 min at 37°C in a Dubnoff metabolic shaking incubator gassed with carbogen. The following substrates are added in various combinations, and each sample is incubated for 60 min with 1 mM each of alanine, fructose, glycerol and lactate, and 10 mM pyruvate, or 2 mM sodium palmitate bound to albumin. Compounds/drug candidates are added in concentrations between 0.05 and 5.0 mM. At the end of the 60-min incubation period, 0.2 ml of 70% $HClO_4$ is added into the medium to stop the reaction. The reaction mixture is then centrifuged, and the supernatant obtained is used to determine the intermediate metabolites. Glucose is assayed by the glucose-oxidase method, lactate (Gutmann and Wahlefeld 1974), pyruvate (Czok and Lamprecht 1974), acetoacetate (Mellanby and Williamson 1974), and β-hydroxybutyrate (Williamson and Melanby 1974) by appropriate enzymatic methods.

In order to measure the influence on the tricarboxylic acid cycle, (U-^{14}C) alanine, (1-^{14}C) glutamate, (1-^{14}C) pyruvate, (1-^{14}C) palmitate, or (1-^{14}C) glucose is added after pre-incubation together with various combinations of compounds and substrates, and incubated for 60 min. The radioactivity is measured by the $^{14}CO_2$-capturing method (Gliemann 1965).

K.6.2.11.2 Perfused Isolated Rat Liver

PURPOSE AND RATIONALE

The technique of liver perfusion has been described extensively by Ross (1972), mentioning in his introductory remarks that the isolated liver was first used by Claude Bernard in 1885. Derived from several modifications, the perfusion of rat liver from the portal vein is the most widely used technique.

EVALUATION

Several parameters can be determined in the effluate, such as net glucose production from lactate and net lactate utilization. The values are plotted against time before and after addition of the compounds and drug candidates, such as insulin or sulfonylureas.

MODIFICATIONS OF THE METHOD

This method has been widely used for studying carbohydrate and lipid intermediary metabolism (Herling et al. 1998) as well as drug metabolism (Milne et al. 1997; 2000; Vuppugalla, 2004). Many variations have been reported predominantly with respect to the animal species used. Chaib et al. (2004) compared isolated perfused livers of rats with those of guinea pigs. Den Butter (1994) used livers from rabbits. Further modifications are related to the direction of perfusion via hepatic artery or portal vein or both simultaneously or in connection with the isolated jointly perfused small intestine (Stumpel et al. (1997 and 2000) as well as the continuous perfusion in a recirculated (see above) or open (non-recirculated) manner (Lopez et al. 1998).

Alexander and coworkers (1992) studied hepatic blood flow regulation in an isolated dual-perfused

rabbit liver preparation. Alexander and coworkers (1995) described a miniaturized perfusion circuit using a novel design of organ bath, to maintain a buoyant preparation, and a high-efficiency miniaturized membrane tubing oxygenator for testing hepatic function during prolonged isolated rat liver perfusion. Kobayashi and coworkers (1991) found inhibition of gluconeogenesis in isolated hepatocytes from normal, fasted rats by the sulfonylurea, glimepiride.

K.6.2.11.3 Phosphoenolpyruvate Carboxykinase (PEPCK) Activity

PEPCK is measured using the $NaH^{14}CO_3$ fixation assay as described by Noce and Utter (1975) and Burcelin and coworkers (1995) with some modifications. 490 µl of rat liver cytosol is added to 500 µl of reaction buffer containing 150 µmol Tris/acetate (pH 7.2), 5 µmol sodium IDP, 10 µmol $MnCl_2$, 250 µmol KCl, 10 mM DTT, 2 mM GSH, 400/150 µmol $KHCO_3$ and 15 µCi $NaH[^{14}C]O_3^-$ (10 µmol, Amersham-Pharmacia). The reaction is started by the addition of 10 µl of 0.4 M phosphoenolpyruvate and terminated after 10 min incubation at 25°C by addition of 1 ml of 6 N HCl and placing the

tube on ice. After dilution with 1 ml of deionized water, unreacted CO_2 ($H[^{14}C]O_3^-$) is removed by bubbling with N_2 and CO_2 for 30 min each. The reaction mixture is supplemented with 10 ml of aqueous scintillation cocktail (Beckman ReadySafe) and measured for radioactivity by liquid scintillation counting. From each value appropriate blanks are subtracted containing the same ingredients but lacking either cytosol or IDP. Under these conditions and up to the maximal amount of cytosol used, the incorporation rates are linear with both cytosol concentration and time during the first 15 min at least.

K.6.2.12 Glucose Transport

GENERAL CONSIDERATIONS

Skeletal muscle contains several glucose transporters. Evidence indicates that GLUT4 translocation to the cell surface is the major mechanism responsible for regulated glucose uptake in this tissue. Insulin and muscle contractions are the most important stimuli for GLUT4 mobilization from the intracellular storage compartment to the plasma membrane. Nevertheless, other factors like hypoxia, catecholamines and glucocorticoids can alter this mobilization. Contraction and insulin cause increases in the maximal velocity of glucose transport (Nesher et al. 1985) through three mechanisms: (1) a conformational alteration in cell surface glucose transporter leading to increased transport activity, (2) increase in the number of GLUT4 in the plasma membrane, and (3) rapid synthesis of new transporters (Hayashi et al. 1997, Rea and James 1997). The current knowledge on the differential effects of insulin and contraction on glucose transport in skeletal muscle has recently been reviewed by Pereira and Lancha (2004).

PURPOSE AND RATIONALE

Some studies have been developed with the purpose of explaining the two different mechanisms that stimulate glucose transport due to the action of insulin and muscle contraction. One hypothesis is that there are two separate pools of GLUT4 in the skeletal muscle. GLUT4 from one pool is thus translocated by the action of insulin but not of contraction, whereas GLUT4 from another pool is translocated by contraction stimulation, but not by insulin. In any case, on basis of the major contribution of the skeletal muscle in the insulin-stimulated whole-body glucose disposal in humans, compounds/drug candidates which activate the muscle glucose transport by engagement of either the insulin- or contraction-induced signaling pathway may be helpful for the future anti-diabetic therapy. The following tissue- and cell-based assays can be used for their identification and characterization.

K.6.2.12.1 Method Based on Diaphragms

PROCEDURE

Intact washed rat diaphragms are incubated (30 min, 37°C) in HEPES-buffered saline (25 mM HEPES, 120 mM NaCl, 5 mM KCl, 1.5 mM $CaCl_2$, 1 mM $MgCl_2$, 5 mM glucose, 0.5 mM sodium pyruvate, 1.5 mM KH_2PO_4, pH 7.4) under constant bubbling with 95% O_2/5% CO_2. The diaphragms are then washed two times with the same buffer lacking glucose and further incubated (30 min) in 5 ml of glucose-free buffer in the presence of insulin/compounds/drug candidates. Glucose transport is initiated by addition of 50 µl of 10 µM 2-[1-^{3}H]deoxyglucose (10 µCi/ml) in the absence or presence of 25 µM cytochalasin B (control). After 15 min, the diaphragms are rinsed four times with ice-cold buffer containing 10 mM glucose, 25 µM cytochalasin B, blotted with filter paper and homogenized. Portions of the homogenate are used for protein determination (BCA method).

EVALUATION

1-ml portions of the supernatant of a centrifugation ($10{,}000 \times g$, 15 min) are mixed with 10 ml scintillation cocktail and counted for radioactivity.

K.6.2.12.2 Method Based on Myocytes

PROCEDURE

Transport studies are carried out using six-well Falcon plates. Cells are routinely plated at a density of 1.5×10^5 cells/well. Medium is aspirated and each well is washed with 10 ml of PBS. Nine hundred microlitres of uptake buffer (PBS containing 1 mg/ml BSA) are added to each well. Transport studies are carried out at 23°C and are initiated by adding 100 µl of 2-[1-^{3}H]deoxyglucose (10 µCi/ml) to the desired final concentration (up to 500 µM). At appropriate times, uptake is terminated by rapidly washing the cells twice (less than 15 s) with 10 ml of ice-cold PBS. In the case of 3MG uptake, cells are washed with cold PBS containing 1 mM mercuric chloride. Samples are taken at 15, 30, 45 and 60 s after the addition of radioactive substrate. Cells are solubilized with 1 ml of 0.1% Triton X-100, and 0.8 ml aliquots are counted in 10 ml of

scintillation fluid. Under these conditions, the uptake of 3MG and 2DG is linear with time, and over 95% of the internalized 2DG are phosphorylated. Cells in two wells from each plate are detached with 0.1% trypsin, and counted using a Coulter counter. Studies are carried out in duplicate and each experiment is repeated at least twice. Results are consistent in all cases. Data are analysed by a linear least squares regression fit program (e. g. SlideWrite Plus, version 4.0, Advanced Graphics Software, CA), and by a non-linear regression data analysis program (e. g. Enzfitter program, Biosoft, UK).

EVALUATION

Specific glucose transport (dpm/mg of protein) is calculated as the difference between diaphragm-associated radioactivity measured in the absence (total uptake) and presence of cytochalasin B (non-specific uptake). Under these experimental conditions, transport of 2DG is linear for up to 30 min.

K.6.2.12.3 GLUT4 Translocation in Myocytes

GENERAL CONSIDERATIONS

Understanding the molecular mechanisms of insulin action has been of major interest since the discovery, several decades ago, that insulin stimulates glucose transport *in vivo* by inducing GLUT4 translocation (see aove). GLUT4 translocation is a complex vesicular traffic process which includes fusion and docking steps. Herbst and coworkers (1995) showed previously that introduction of a peptide corresponding to tyrosine-phosphorylated IRS-1 motifs into 3T3-L1 adipocytes resulted in a significant increase in the translocation of GLUT4 to the plasma membrane by immunofluorescence staining which mimicked the response to insulin. However, no relative increase in the rate of glucose uptake was observed in those cells. This led to the speculation that some stimulus may bring GLUT4 vesicles to the plasma membrane (docking) but is not sufficient to trigger fusion with the membrane. A converse phenomenon was observed by others upon introducing isoproterenol to rat adipocytes whereby the insulin-dependent gain in glucose transporter detected in isolated plasma membrane was not changed while glucose transport was decreased. It is therefore conceivable that immunostaining of isolated membranes or of permeabilized cells cannot distinguish GLUT4 proteins docked on the plasma membrane from those which are fully fused with it. It is well conceivable that compounds/drug candidates provoke GLUT4 translocation without concomitant glucose transport activation and, *vice versa*, transport activation in the absence of translocation.

PURPOSE AND RATIONALE

Subcellular fractionation, cell photolabeling coupled to immunoprecipitation and immunofluorescence or immunoelectron microscopy have been used to detect translocation of GLUT4 to the cell surface. All of these methods are laborious and suffer from methodological inaccuracies. Subcellular fractionation is cumbersome and produces membranes that are rarely pure. Moreover, quantitative recovery of all membrane compartments is difficult or impossible. Affinity labeling of surface GLUT4/1 followed by immunoprecipitation depends on the ability to obtain quantitative immunoprecipitation and recovery upon SDS-PAGE. This technique results in the incorporation of about 1/10 000 of the label added, thus the signal to noise ratio is low. Moreover, the reactivity of the photolabel can depend on the level of activity of the GLUT in addition to the amount of GLUT exposed at the cell surface. Immunofluorescence detection does not distinguish the native GLUT4 molecules incorporated into the cell membrane from molecules in subplasmalemmal vesicles, and is not a quantitative technique. Immunogold electron microscopy detects antigens at the plasma membrane accurately, but has not been successfully used in a quantitative fashion. None of the above techniques is suitable for large numbers of experiments, as would be required for throughput screening and even characterization of anti-diabetic drugs or of agents interfering with insulin signaling or intracellular trafficking. Therefore, a fast, sensitive and quantitative technique is needed to measure GLUT4 translocation in intact cultured myocytes, which does not rely on immunoprecipitation, SDS-PAGE or use of radioactivity, as required by the photolabeling technique and does not require large amounts of cells or laborious subcellular fractionation.

Previous studies have shown that in CHO cells or other fibroblasts stably expressing heterologous GLUT4, insulin-stimulated translocation of the transfected GLUT4 is not detectable by immunoblot analysis of subcellular fractions, nor by immunofluorescence microscopy (Kanai et al. 1993). However, transfection of GLUT4myc allowed for detection of the exofacial epitope by ^{125}I-labeled secondary antibody. By this approach, insulin-induced GLUT4myc translocation was observed in CHO cells (Wang et al. 2000). For study of GLUT4 translocation in L6 myocytes, GLUT4myc has to be introduced into L6 in-

sulin-sensitive muscle cells which express endogenous GLUT4 as well as GLUT1 and GLUT3. The amount of GLUT4myc expressed at the surface of basal cells (5 fmol/mg protein) is usually in the range of that of native GLUT4 (about 12 fmol/mg). This discrete level of expression of GLUT4myc likely allows for its correct localization without saturation of the proteins determining its intracellular sorting.

PROCEDURE

Construction and Culture of GLUT4 Ectopically Expressing L6 Myocytes

For the construction of GLUT4myc-expressing L6 myocytes, the human c-myc epitope (14 amino acids) is inserted into the first ectodomain of GLUT4 as described by Kanai and coworkers (1993). The epitope does not affect GLUT4 activity. GLUT4myc cDNA is subcloned into the mammalian expression vector pCXN (pCXN-GLUT4myc). L6 myocytes are transfected with pCXN-GLUT4myc and pSV2-bsr, a blasticidin S deaminase expression plasmid, and selected with blasticidin S hydrochloride. L6-GLUT4myc myocytes in cell monolayers are maintained in α-MEM supplemented with 10% FBS in a humidified atmosphere containing 10% CO_2/90% air at 37°C. Cells are grown in 12- or 24-well plates for immunofluorescence and on glass coverslips for fixation. Prior to experiments, cells are incubated with serum-free α-MEM supplemented with 25 mM glucose for 5 h.

K.6.2.12.3.1
Method Based on Indirect Immunofluorescence

Quiescent L6-GLUT4myc cells grown on glass coverslips are treated with insulin/compounds/drugs, then rinsed once with PBS, fixed with 3% paraformaldehyde in PBS for 3 min at room temperature, and neutralized with 1% glycine in PBS at 4°C for 10 min. The cells are incubated with PBS containing 10% goat serum and 3% BSA at 4°C for at least 30 min. Primary antibody (anti-c-myc 9E10) is added at a dilution of 1:100 and maintained at 4°C for 30 min. The cells are extensively washed with cold PBS before introducing the secondary antibody (Cy3-IgG, 1:1,000) for 30 min at 4°C. The cells are washed, then mounted and immediately examined by immunofluorescence microscopy.

K.6.2.12.3.2
Method Based on Cell Fixation

PROCEDURE

Quiescent L6-GLUT4myc cells treated with insulin/compounds/drugs are washed once with PBS, fixed in 3% paraformaldehyde in PBS for 3 min at room temperature. Thereafter, the fixative is immediately neutralized by incubation with 1% glycine in PBS at 4°C for 10 min. The cells are blocked with 10% goat serum and 3% BSA in PBS at 4°C for at least 30 min. Primary antibody (anti-c-myc, 9E10) is then added into the cultures at a dilution of 1:100 and maintained for 30 min at 4°C. The cells are extensively washed with PBS before introducing peroxidase-conjugated rabbit anti-mouse IgG (1:1,000). After 30 min at 4°C, the cells are extensively washed and 1 ml OPD reagent is added to each well. The colorimetric reaction is stopped by addition of 0.25 ml of 3 N HCl for 10 min at room temperature. The supernatant is collected and the optical absorbance is measured at 492 nm. Standard curves are generated using either peroxidase conjugated anti-mouse IgG alone or myc-tag peptide. Myc-tag peptide at various concentrations is coated onto 24-well plates by incubation at 4°C for 24 h then allowed to dry. The plates are rinsed with PBS to remove excess salt and the uncoated spaces are blocked with 10% goat serum and 3% BSA.

EVALUATION

Introduction of a tag c-myc epitope (14 amino acids) into the first exofacial loop of GLUT4 cDNA allows for the direct detection of GLUT4myc molecules translocated to the plasma membrane upon fixation of the intact myocytes under conditions which do not allow access of the anti-myc antibodies to intracellular structures, such as the GLUT4 vesicles. The efficacy of this method has been compared with that of the conventionally used subcellular fractionation and immunofluorescence approaches. Virtually similar effects of insulin on GLUT4 translocation are detected by all three approaches.

K.6.2.13 Glycogen Synthesis

GENERAL CONSIDERATIONS

Insulin and contractile activity are major regulators of glycogen metabolism in skeletal muscle (Pederson et al. 2005). Insulin stimulates glycogen synthesis, and postprandially, ~80% of ingested glucose is taken up by skeletal muscle and converted to glycogen (Jue et al. 1989a and b, Shulman et al. 1990). Under these conditions, insulin activates glycogen synthase (GS), as well as glucose transport, *via* translocation of the GLUT4 transporter. Glycogen is a major fuel for the contractile activity of skeletal muscle. During contraction, glycogen is utilized as a source of energy, and it has been demonstrated that, perhaps paradoxically, glycogen resynthesis occurs while glycogen is being broken down (Price et al. 1991, 1994). Presumably, this represents a mechanism for the rapid replenishment of glycogen stores when exercise ceases (Bloch et al. 1994, Ivy and Kuo 1998). The period following exercise is characterized by increased glucose uptake and net glycogen synthesis in skeletal muscle, a scenario similar to insulin stimulation of muscle. Despite the fact that the mechanism of GS activation in response to insulin has been extensively studied, the molecular details of both insulin and contraction-induced activation remain mostly unknown. The following assays enable the demonstration of stimulatory effects on glycogen synthesis in muscle cells of compounds with insulin-like activity which may contribute significantly to their blood glucose-decreasing potency.

K.6.2.13.1 Method Based on Diaphragms

PROCEDURE

Male Sprague Dawley rats weighing 70–100 g are used. The animals are sacrificed during anesthesia and the diaphragms are carefully removed, spread out and divided into two equal pieces. The hemidiaphragms are incubated in Krebs-Henseleit buffer gassed with carbogen (95% O_2/5% CO_2) with 5 mM [U-^{14}C]glucose (0.5 µCi/ml) in the presence of insulin/compounds/drugs. After 30 min incubation at 37°C, the hemidiaphragms are blotted on tissue, frozen in liquid nitrogen, and ground in a porcelain mortar and pestle chilled with liquid nitrogen. Samples of the powdered tissue are weighed and dissolved by heating for 45 min at 100°C in 30% KOH (1 ml/100 mg tissue) before ethanol is added to a final concentration of 70%. After 4 h at –20°C, the samples are centrifuged (2,000 × *g*, 10 min). The glycogen pellets are washed 3 times with 70% ethanol before the amount of ^{14}C-labeled glycogen is determined by liquid scintillation counting. Total glycogen is determined according to Lowry and Passoneau (1972) after hydrolysis to glucose (1 N HCl at 100°C for 3 h). The incorporation of [^{14}C]glucose into radiolabeled glycogen is normalized for the total amount of glycogen.

EVALUATION

The concentration dependence of [U-^{14}C]glucose uptake and conversion into glycogen by insulin/compounds/drug candidates is determined. The isolated diaphragm of rats or mice is the preferable organ to study the effect of insulin and substances with insulin-like effects, such as sulfonylureas, on muscle tissue or the influence of denervation (Standing and Foy 1970, Smith and Lawrence 1984, Ishizuka et al. 1990, Hothersall et al. 1990).

K.6.2.13.2 Method Based on Myotubes

L6 myotubes are washed three times with Krebs-Ringer phosphate HEPES (KRPH) buffer (150 mM NaCl, 5 mM KCl, 2.9 mM Na_2HPO_4, 1.25 mM $MgSO_4$, 1.2 mM $CaCl_2$, 10 mM HEPES, pH 7.4) supplemented with 0.1% BSA. The cells are then incubated for 30 min to up to 2 h with 25 µl of reaction medium (glucose-free α-MEM containing 20 mM HEPES, pH 7.4, 0.1% BSA, 100–500 µM [^{14}C]glucose [0.1–0.5 µCi]) in the presence of increasing concentrations of insulin/compounds/drug candidates at 37°C in a humified atmosphere of 8.5% CO_2. Subsequently, the reaction medium is removed by aspiration and the cells are washed with 100 µl of ice-cold PBS. The cells are then disrupted by incubation in 50 µl of 1 N NaOH for 10 min at 60°C. The cell homogenates are cooled to room temperature and trans-

ferred to 96-well FC/DV filter plates (Millipore) containing 100 µl of ice-cold ethanol. The plates are then incubated for 2–3 h at 4°C. The precipitate is filtered under vacuum and washed three times with 250 ml of ice-cold 66% ethanol. The filters are dried under a 100-W incandescent lamp. 50 µl of scintillation cocktail (e. g. Microscint 20, Packard) are added and the wells are sealed. The [^{14}C]glucose incorporated into cellular glycogen is quantified in a TopCount 96-well liquid scintillation counter.

EVALUATION

In order to identify hypoglycemic drugs with insulin-like or insulin-sensitizing activity, Berger and Hayes (1998) developed an assay for activators of glucose incorporation into glycogen utilizing differentiating L6 muscle cells in 96-well plates. In general, *in vitro* assays of glucose incorporation into glycogen in insulin-sensitive tissue have been used culture media containing the normal physiological concentration, ~5.5 mM, of unlabeled glucose and tracer levels of radiolabeled glucose (e. g. Chou et al. 1987, Robinson et al. 1993). Similarily, using this assay design and L6 myotubes, Berger and Hayes (1998) observed that such conditions do not produce glycogen of a high enough specific activity to be accurately quantified in single-well extracts from a 96-well plate. In contrast, use of glucose-free α-MEM as the reaction media increases the signal by more than one order of magitude, thereby allowing quantification of single wells in the 96-well format. Consequently, addition of exogenous (non-radioactive) glucose is omitted, which apparently does not lead to physiological alterations in course of the brief incubation with compounds/drug candidates and the subsequent assay period. Glucose incorporation follows in a time and concentration-dependent fashion and is blocked by typical inhibitors of glucose transport. Both insulin and pervanadate exerting insulin-like activity increase glycogen synthesis in concentration-dependent manner. This assay may serve as a high-capacity screen to identify novel compounds that upregulate glucose anabolic metabolism in skeletal muscle.

K.6.2.14 Glycogen Synthase (GS) Activity

GENERAL CONSIDERATIONS

Glycogen metabolism is controlled largely by the coordinated action of the two enzymes glycogen synthase (GS) and glycogen phosphorylase (GP). Both enzymes are controlled by covalent phosphorylation and by allosteric effectors (Cohen 1986, Roach 1991, Roach et al. 2001). GS undergoes a complex multisite phosphorylation at nine sites by several protein kinases (Roach et al. 2001), most notably PKA, casein kinase I, casein kinase II, GSK-3, and AMPK (Carling and Hardie 1989) which generally lead to inactivation.Important regulatory phosphorylation sites are distributed between the amino- (sites 2 and 2a) and the carboxyl-termini (sites 3a and 3b) of the GS molecule (Lawrence et al. 1983, Skurat et al. 1994, 2000). Full activity can be restored to phosphorylated enzyme by the presence of the allosteric activator glucose-6-phosphate (G-6P). GP is activated by phosphorylation of a single site (GP *a*) by phosphorylase kinase (Cohen 1987). The less active, dephosphorylated form (GP *b*) acquires full activity in the presence of the allosteric effector AMP. Dephosphorylation of all three of these key regulatory proteins, GS, GP, and phosphorylase kinase, is believed to be catalyzed primarily by glycogen-associated phosphatases (PP1G) (Hubbard and Cohen 1989a, b).

K.6.2.14.1 Method Based on Diaphragms

PROCEDURE

GS is assayed according to Oron and Larner (1979), Guinovart and coworkers (1979), Altan and coworkers (1985) with the following modifications: Intact hemidiaphragms are dissected from male Wistar rats and incubated in DMEM (10 ml/hemidiaphragm) with constant bubbling of 95% O_2/5% CO_2. For treatment with insulin/compounds/drug candidates, the hemidiaphragms are incubated (37°C) in the same medium containing 5 mM glucose. For preparation of homogenates, the diaphragms are blotted and frozen in liquid nitrogen. The frozen diaphragms (pool of four) are manually ground in a porcelain mortar and then homogenized at 0°C in 10 vol. of 25 mM Tris/HCl (pH 7.4), 100 mM NaF, 5 mM EDTA, 0.1 mM PMSF. The homogenate is centrifuged (10,000 × *g*, 20 min). The supernatant is used for the GS assay. After addition of 10 µl of diaphragm homogenate to 200 µl of 25 mM Tris/HCl (pH 7.4), 50 mM NaF, 10 mM EDTA (pre-incubated at 30°C) containing either 0.1 or 10 mM G6P, the reaction is initiated by supplementing 0.2 mM [U-^{14}C]UDP-glucose (10 µCi) and terminated after 15 min by the addition of 2.5 ml of ice-cold 66% ethanol and filtration over pre-wetted Whatman GF/C glass fiber disks. The filters are washed, dried and counted for radioactivity. Blanks are assayed by

adding the homogenate to tubes containing the complete reaction mixture plus ice-cold ethanol.

EVALUATION

The fractional velocity as parameter for the portion of GS active *in vivo* (l-form) toward the total enzyme contents (l-+d-forms) at the time point of homogenization is calculated as ratio between the activities measured at 0.1 (l-form) and 10 mM G-6P (l-+d-forms).

The concentration-dependence of sulfonylurea stimulated GS and its potentiation by insulin in the isolated rat diaphragm were studied by Müller and coworkers (1994).

K.6.2.14.2 Method Based on Myotubes/Hepatocytes

PROCEDURE

GS activity is assayed by measuring the incorporation of D-[^{14}C]glucose from UDP-[^{14}C]glucose into glycogen. L6 myotubes or HepG2 cells cultured in 6- or 12-well plates and serum-deprived overnight are incubated with insulin/compounds/drugs in serum-free α-MEM under an atmosphere of 5% CO_2 for 30 min at 37°C. After removal of the incubation medium and washing, the cells are scraped into 0.2–0.5 ml of 10 mM Tris/HCl (pH 7.5) containing 10 mM EDTA, 150 mM KF, 5 mM DTT. The cell lysates are centrifuged (5,500 × *g*, 2 min, 10°C). The infranatant below the lipid layer is cleared from residual lipids by two additional centrifugations (defatted homogenate) and served as source for GS. The reaction is started by adding 30 µl of the homogenate to 60 µl of a reaction mixture (prewarmed at 30°C) containing 33 mM Tris/HCl (pH 7.8), 0.2 mM UDP-[U-^{14}C]glucose (4 µCi), 6.7 mg glycogen, 150 mM KF and 0.1 mM/10 mM G-6P. After incubation for 20 min at 30°C, the reaction is terminated by addition of 2 ml of 66% ethanol, 10 mM LiBr (–20°C), rapid mixing and filtration over pre-wetted Whatman GF/C glass-fiber discs. The filters are washed 5 times with 5 ml of 66% ethanol each at 25°C, dried and measured for radioactivity. Blank values determined by adding the homogenate to tubes containing the complete reaction mixture plus ice-cold ethanol are subtracted from the total values each.

EVALUATION

The fractional velocity is calculated as the ratio of GS activity in the presence of 0.1 mM and 10 mM G6P. Measurements of GS activity in defatted homogenates from myotubes/hepatocytes which had been incubated in the presence of 0.1 mM glucose instead of 5 mM glucose (the concentration routinely used) did not reveal significant differences with respect to both the activity ratio and the effect of insulin. Presumably, the dilution of the limited amount of G6P, which accumulates during incubation with 5 mM extracellular glucose, during the subsequent preparation of the homogenate and the GS assay is high enough to prevent allosteric activation of GS. According to our experience incubation of the isolated rat adipocytes in the presence of 5 mM glucose has a positive impact on their viability, in general, and insulin sensitivity (glucose transport, glycogen synthesis), in particular.

K.6.2.15 Phosphorylation State of GS

PURPOSE AND RATIONALE

A large body of evidence suggests that insulin activation of GS proceeds via the PI-3K/Akt pathway that leads to phosphorylation and inhibition of GSK-3 (Shepherd et al. 1995, Cross et al. 1995). However, GSK-3 alone is not sufficient to account for GS dephosphorylation and activation by insulin (Lawrence and Roach 1997, Skurat et al. 2000). The mTOR, mammalian target for the immunosuppressant drug rapamycin, pathway is also activated by insulin. Rapamycin has been shown to block insulin-mediated activation of GS in muscle and 3T3-L1 adipocytes (Azpiazu et al. 1996, Shepherd et al. 1995) without affecting insulin-induced inactivation of GSK-3 (Cross et al. 1997), opening the possibility that mTOR could control GS phosphorylation *via* a phosphatase. Therefore, insulin may promote glycogen synthesis both *via* inhibition of GSK-3 *and* stimulation of a glycogen-associated type 1 serine/threonine protein phosphatase, PP1G. Studies with mice deficient in the regulatory subunit of PP1G indicate that although PP1G is not necessary for activation of GS by insulin, it is essential for regulation of glycogen metabolism under basal conditions and in response to contractile activity, and may explain the reduced muscle glycogen content in the KO mice, despite the normal activation of GS (Aschenbach et al. 2001). Contractions may utilize a separate signaling pathway from insulin to activate GS in response to contractions. Changes in GS activity in human muscle biopsy samples obtained during isometric contractions are associated with changes in protein phosphatase activity (Katz and Raz 1995), but the identity of this enzyme has not been determined. The phosphorylation state of GS in muscle and liver cells and the impact of compounds/drug candidates can be

monitored by ^{32}P- labeling and subsequent immunoprecipitation of GS.

PROCEDURE

Myotubes/hepatocytes are washed twice by flotation in low phosphate medium composed of KRP-HEPES modified to contain 50 µM KH_2PO_4, 2 mM glucose, 2% BSA and then suspended in the same medium (7.5×10^5 cells/ml). 5-ml portions are incubated with [^{32}P]phosphate (0.2 mCi/ml) for 2 h prior to addition of insulin/compounds/drug candidates and of 0.5 ml of 50 mM glucose. After incubation (20 min, 37°C), the cells are floated by centrifugation (1,000 × *g*, 1 min) and the infranatant is aspirated. The cells are suspended in 1.5 ml of cold 50 mM Tris/HCl (pH 7.6), 100 mM KF, 20 mM glycerol-3-phosphate, 10 mM $K_4P_2O_7$, 10 mM EDTA, 1 mM benzamidine, 0.2 mM PMSF and homogenized by 10 strokes using a tight-fitting Teflon-in-glass homogenizer in the same Eppendorf cup. The homogenate is centrifuged (18,000 × *g*, 30 min, 4°C). 1 ml of the post-mitochondrial supernatant is incubated with 10 µl of GS antiserum raised in guinea pigs by immunization with purified GS from rabbit skeletal muscle. After incubation for 2 h at 4°C, 50 µl of protein A-Sepharose (10% w/v in TES, see below) is added and the incubation continued overnight. The immunoprecipitates are collected by centrifugation (12,000 × *g*, 2 min, 4°C) and washed twice with 1 ml each of TES (50 mM Tris/HCl, pH 7.4, 1 mM EDTA, 150 mM NaCl) containing 1% TX-100, twice with TES and finally once with 50 mM Tris/HCl (pH 7.4). The beads are suspended in 25 µl of 2xLaemmli sample buffer, heated (95°C, 5 min) and centrifuged. The supernatant is subjected to SDS-PAGE (8% resolving gel). The amount of [^{32}P] contained in GS is determined by excising the corresponding gel pieces and measuring their radioactivity by liquid scintillation counting.

K.6.2.16 Protein Phosphatase 1G (PP1G) Activity and Phosphorylation

PP-1 Activity

Muscle PP1 activity is measured according to a protocol from Begum and Ragolia (1996). L6 myotubes treated with insulin/compounds/drug candidates are scraped off the 24-well dishes with 0.3 ml of phosphatase extraction buffer containing 20 mM Tris/HCl (pH 7.2), 2 mM EDTA, 2 mM EGTA with 10 µg/ml each of aprotinin, leupeptin, antipain, soy bean trypsin inhibitor, 1 mM benzamidine, 1 mM PMSF. The cells are sonicated for 10 sec, centrifuged (2,000 × *g*, 5 min) and the supernatants are used for the assay of PP1G activity in the presence and absence of 2 nM okadaic acid to inhibit PP2A activity. The conditions of the assay allow measurement of PP1 and PP2A activities and not PP2B and PP2C enzymes, which require divalent ions. Okadaic acid at 2 nM inhibits PP2A, only, and the PP-1 activity remaining in the assay is comparable with the activity inhibited by inhibitor 2 (Srinivasan an Begum 1994). Purified [^{32}P]-labeled GP *b* is used as a substrate. [^{32}P]-labeled GP *b* is prepared by reacting γ[^{32}P]ATP with purified phosphorylase kinase and GP *a* (Cohen 1983).

In Vivo Phosphorylation and Immunoprecipitation of PP1

Differentiated L6 myotubes are serum-starved overnight. The next day, the medium is removed and replaced by 1 ml of phosphate-free DMEM and incubation is continued for 1 h. [^{32}P]-orthophosphate is added (0.5 mCi/ml), and the cells are incubated for 4 h followed by incubation with compound/drug candidate for up to 1 h. Subsequently, the cells were rinsed four times with 1 ml of ice-cold PBS containing phosphatase and protease inhibitors and harvested in 0.5 ml of lysis buffer (20 mM triethanolamine, pH 7.2, 0.5 mM EGTA, 1 mM EDTA, 2 mM sodium vanadate, 100 mM sodium pyrophosphate, 100 mM sodium fluoride, 40 mM glycerol-3-phosphate, 1 mM benzamidine, 0.1 mM PMSF, 10 µg/ml each of leupeptin, aprotinin, antipain, trypsin inhibitor, and pepstatin A, 140 mM NaCl, and 1% Triton X-100. The cell lysates are centrifuged (16,000 rpm, 10 min) to remove cell debris. 100 µg of cell lysate protein are diluted to 1 ml with lysis buffer and precleared by incubation with rat IgG (5 µg/ml, coupled to protein A sepharose) at 4°C for 1 h. The supernatants are immunoprecipitated with PP1G subunit antibody (10 µg/ml) for 1 h at 4°C followed by treatment with 50 µl protein A sepharose CL6B (50%, by vol.). The pellets are washed four times with 1 ml of lysis buffer and resuspended in 40 ml of 2-fold SDS-sample buffer. The samples are incubated (37°C, 10 min) followed by centrifugation (10,000 × *g*, 1 min) to pellet the sepharose beads. Electrophoresis of the immunoprecipitates is performed in 7.5% SDS-polyacrylamide gels followed by autoradiography. The protein contents of PP1G regulatory subunit are determined by immunoprecipitating unlabeled cell lysates with anti-G subunit antibody, followed by separation of immunoprecipitated proteins on SDS-PAGE. The proteins are transferred to polyvinylidene difluoride membrane and probed with PP1G subunit antibody. The regulatory subunit

of PP1 is identified by incubating with [^{125}I]protein A (0.2 µCi/ml) followed by autoradiography. The intensity of the signal is evaluated by densitometric analysis of the autoradiograms as well as by radioactivity scanning.

K.6.2.17 Lipid Metabolism in Muscle and Liver Cells

GENERAL CONSIDERATIONS

Type II diabetes is characterized by hyperglycemia, hyperinsulinemia, reduced ability to oxidize fat, and TAG accumulation in skeletal muscle fibers. Impaired glucose transport and glycogen synthesis are well documented in insulin-resistant subjects (Richter et al. 1988, Hansen et al. 1992, Boden et al. 1996, Kawanaka et al. 2001), but lipid metabolism is less clearly understood (Goodpaster and Kelley 1998). Especially, focus has been put on the increased intramyocellular TAG content, since an inverse correlation between insulin resistance and intramyocellular TAG has been demonstrated (Pan et al. 1997, Koyama et al. 1997, Simoneau et al. 1995, Phillips et al. 1996, Boesch et al. 1997, Szczepaniak et al. 1999). The mechanism responsible for TAG accumulation remains unclear, but it may depend on either an increased lipid uptake or a decreased lipid oxidation as *de novo* lipogenesis within skeletal muscle is low. Increased plasma-free fatty acid (FFA) availability induces insulin resistance within hours by lipid infusion or within weeks by feeding rats a high-fat diet or in massively obese humans accompanied with intramyocellular TAG accumulation (Storlien et al. 1991, Oakes et al. 1997, Griffin et al. 1999, Boden et al. 2001, Perseghin et al. 1999, Chalkley et al. 1998). Weight loss and lowering of plasma free fatty acids reduced insulin resistance and the TAG content (Roden et al. 1996, Boden et al. 2001). Several studies have shown an association between obesity, insulin resistance, and reduced oxidative capacity in skeletal muscle (Bachmann et al. 2001, for reviews see Guo 2001, Saloranta and Groop 1996, Boden 1997), as demonstrated by the finding of decreased mitochondrial number, altered mitochondrial morphology and decreased expression of mitochondrial genes of the oxidative metabolism (Morino et al. 2005, Petersen et al. 2004, Mootha et al. 2003, Pati et al. 2003). Deficiency of CPT leads to pathological TAG accumulation in muscle tissue further emphasizing the role of mitochondria for lipid homeostasis. Our current knowledge on TAG accumulation in relation to insulin resistance and type II diabetes originates mainly from *in vivo* studies rendering it difficult to determine the contribution of genetic and environmental factors to TAG accumulation in type II diabetes and obesity. Cultured myotubes offer a unique model for separating the genetic influence on insulin resistance and type II diabetes from environmental factors. The following assays can be used for the analysis of lipid metabolism in cultured muscle cells and its modulation by compounds and drug candidates.

K.6.2.17.1 Incubation with Fatty Acids

Solutions containing fatty acids are prepared according to the procedure described by Montell and coworkers (2002). Sodium salt of oleic acid is prepared immediately prior to utilization by dissolving the fatty acid in deionized water containing 1.2 eq of NaOH at 70°C with stirring until an optically clear dispersion is obtained. The fatty acid-salt solution is immediately added to DMEM containing fatty acid-free BSA with continuous agitation to avoid precipitation. Typically, the fatty acid:BSA molar ratio is 5:1. Myocyte cultures are grown in a DMEM/M199 medium (3/1) supplemented with 10% fetal bovine serum, 10 µg/ml insulin, 2 mM glutamine, 25 ng/ml fibroblast growth factor, 10 ng/ml epidermal growth factor. Immediately after myotube differentiation, cells are rinsed in Hanks' balanced salt solution, and a medium devoid of fibroblast growth factor, epidermal growth factor, and glutamine is added. Myotube cultures are maintained in this medium for up to 2 weeks.

K.6.2.17.2 Lipid Synthesis

Incorporation of [^{14}C]Glycerol into Lipids

For qualitative analysis of esterification of glycerol into AG, cells are incubated with 5 mM [U-^{14}C]glycerol (100 µCi/mmol), 5 mM glucose, and 1 mM sodium oleate (BSA:oleate molar ratio of 1:5) for 15 h (Montell et al. 2002). The cell monolayers are then washed three times in Hanks' balanced salt solution, and the lipids are extracted twice with hexane/isopropanol (3/2). After drying under nitrogen, the residual lipid extract is redissolved in chloroform/methanol (2/1) as described (Folch et al. 1957) and separated by TLC by use of hexane/diethyl ether/acetic acid (70/30/1). The lipid spots are identified by iodine vapor and counted in a phosphorimager.

Incorporation of [^{14}C]Glucose into Lipids

The synthesis of neutral lipids starting from glucose can be followed according to the protocol of Aas and coworkers (2004). Myotubes are incubated with either [1-^{14}C]oleic acid (18.5 kBq/ml, 0.6 mM) or [1-^{14}C]palmitic acid (18.5 kBq/ml, 0.6 mM) in the absence or presence of insulin/compound/drug candidate for 4 h before they are harvested into ice-cold PBS, centrifuged (1,000 × *g*, 5 min), resuspended in distilled water and sonicated. Cell-associated lipids are extracted with chloroform/methanol as described (Folch et al. 1957). Briefly, 400 µl of cell homogenate is mixed with 8 ml of chloroform/methanol (2/1, by vol.), and FCS (30 µl) was added as a carrier. After 30 min, 1.6 ml of 0.9% NaCl (pH 2) is added and the mixture is centrifuged (1,000*xg*, 5 min). The organic phase is evaporated under a steam of nitrogen at 40°C. The residual lipid extract is re-dissolved in 200 µl of n-hexane and separated by TLC using hexane/diethylether/acetic acid (65/35/1) as the mobile phase. The bands are visualised with iodine, excised and counted by liquid scintillation. Lipids are also extracted after incubation of myotubes with D-[^{14}C(U)]glucose (74 and 111 kBq/ml, 5.5 mM or 20 mM) for 24 h.

EVALUATION

Extraction of lipids is carried out after incubation of myotubes with D-[^{14}C(U)]glucose for 4 h. Myotubes are exposed to DMEM supplemented with 0.24 mM fatty acid-free BSA, 0.5 mM L-carnitine, 20 mM HEPES, 5.5 or 20 mM [D-^{14}C(U)]glucose [(2.0 µCi/ml), and insulin/compound/drug candidate. On the basis of the typically very low incorporation, the overall glucose incorporation into lipids is determined by counting the total lipid extract washed with a water phase that contained 0.5 M glucose to displace all glucose labeled.

Incorporation of [^{14}C]Palmitate into Lipids

For analysis of lipid synthesis starting with fatty acids accrding to the protocol of Busch and coworkers (2005), cells are treated for 48 h with insulin/compounds/drug candidates. Two hours before the end of the treatment 2.5 µCi [^{14}C]palmitate in ethanol is added to each well (24-well dish, 0.5 ml culture medium). The labeled cells are put on ice, washed in 3 × 0.5 ml ice-cold PBS, scraped off the dish in 1 ml cold PBS, and spun (3,000 × *g*, 10 min). The supernatant is discarded, and lipids in the cell pellet are extracted overnight in 1 ml chloroform/methanol (2/1, by vol.). The extractions are washed in 250 µl H_2O, followed by an additional wash in 125 µl H_2O, and the resulting lipid-containing, organic phase is dried under a stream of nitrogen. The lipids are redissolved in 50 µl chloroform/methanol (2/1, by vol.), and a small fraction is used to determine the total amount of counts in the extracted lipids. The rest of the sample is spotted onto silica plates. The lipids are separated by TLCD-^{14}C(U) in petroleum ether/diethyl ether/methanol/acetic acid (180/14/4/1, by vol.). Spots comigrating with TAG and cholesterol ester standards are individually scraped and counted by liquid scintillation spectrometry. Protein is measured in parallel using a bicinchoninic acid protein assay.

Incorporation of [^{14}C]Acetate into Lipids

This protocol has been adapted from methods previously described (Foretz et al. 1998, Garcia-Villafranca et al. 2003, Cool et al. 2006). Primary rat hepatocytes are isolated as described (see K.5.2.2) and plated at 5×10^4 cells per well on collagen-coated, black-walled 96-well plates in DMEM supplemented with 10% FBS, 5 mM glucose, 1 mM sodium pyruvate, 2 mM L-glutamine, 25 mM HEPES/KOH (pH 7.4), 0.1 mM non-essential amino acids, 5 µg/ml transferrin, 100 nM dexamethasone, 100 nM insulin and 25 µg/ml gentamycin. After 4 h incubation, medium is replaced with medium as described above but lacking FBS and containing 100 nM triiodothyronine. Following a 16 h incubation at 37°C, the medium is removed and replaced with medium containing [^{14}C]acetate (2 µCi/ml) and as a control, AICAR or compounds/drug candidates. Cells are incubated (4 h, 37°C). Subsequently, the plates are rinsed with PBS three times. The final wash is replaced with scintillation cocktail (e. g. Mi-

croscint20, Perkin Elmer) and radioactivity incorporated into fatty acid monitored on a microplate β-reader.

K.6.2.17.3 Lipolysis

GENERAL CONSIDERATIONS

TAG is accumulated in LD in the cytoplasm of skeletal muscle cells (Schick et al. 1993, Oscai et al. 1990). The energy content of this TAG store is higher than the energy content of the muscle glycogen pool. The

muscle TAG concentration is increased by a high-fat diet (Van der Vusse et al. 1996) and in poorly controlled diabetes (Standl et al. 1980, Stearns et al. 1979), and is inversely related to whole-body insulin action (Pan et al. 1997). On the other hand, although existing studies are not unambiguous, the general view is that the intramuscular TAG stores can be mobilized by catecholamines (Froberg et al. 1975, Abumrad et al. 1980) and by exercise (Oscai et al. 1990, Van der Vusse et al. 1996). The exercise-induced decrease in muscle TAG concentration can be reduced by β-adrenergic blockade, and must accordingly be due to some extent to sympathetic stimulation (Stankiewicz-Choroszucha and Gorski 1978). While it seems that the intramuscular TAG constitute a dynamic energy store, the enzymic regulation of TAG breakdown in muscle is poorly understood (Van der Vusse et al. 1996, Martin 1996, Hagstrom-Toft et al. 1997, Kerckhoffs et al. 1998). The expression of HSL and its regulation by adrenaline has been investigated by Langfort and coworkers (1999).

It is thought that HSL is the major enzyme responsible for the hydrolysis of stored TAG in skeletal muscle similar to in adipose tissue. HSL protein or mRNA has been detected in rodent (Holm et al. 1987, Langfort et al. 1999) and in human (Roepstorff et al. 2004) skeletal muscle but with a considerable lower expression than in adipose tissue. The HSL protein expression also varies between fiber types, being higher in oxidative than glycolytic fibers (Langfort et al. 1999). Furthermore, it was recently shown (Hämmerle et al. 2002) that HSL-deficient mice accumulated DAG in adipose tissue and skeletal muscle, indicating that when HSL is missing this leads to an incomplete hydrolysis of TAG with an interruption of the lipolytic cascade at the stage of diacylglycerol hydrolysis. This observation was supported by the findings of a marked reduction in the formation of fatty acids in skeletal muscle as in several other tissues (Hämmerle et al. 2002). Interestingly, when the specific TAG hydrolase activity (the enzymatic conversion of TAG to DAG) was calculated, the specific TAG hydrolase activity was reduced 50% in adipose tissue, whereas no reduction was found in skeletal muscle when comparing HSL-deficient mice with wild type (Hämmerle et al. 2002). These data suggest that HSL is rate-limiting in the catabolism of DAG but not of TAG hydrolysis in skeletal muscle and furthermore points to the existence of one or more lipases with considerable activity, specifically to TAG hydrolysis in skeletal muscle. Further support for the existence of lipases other than HSL involved in basal TAG hydrolysis in skeletal muscle appears from recent studies, where neutral lipase activity in human skeletal muscle only decreased by ~25% when antiserum against HSL was added to the assay medium (Roepstorff et al. 2004, Watt et al. 2004). When a similar approach was taken in basal, resting rat soleus muscle (Langfort et al. 2000, Langfort et al. 1999), HSL activity was decreased by ~60%, indicating that HSL may be less dominating in human skeletal muscle than in rat skeletal muscle and that more lipases than HSL are involved in TAG hydrolysis in the resting state. It has been shown that electrically induced muscle contractions increase the neutral lipase activity of soleus muscle of rats (Langfort et al. 2000). It is surprising from the point of view that exercise is accompanied by increases in circulating catecholamine concentrations, and there is evidence for activation of HSL by epinephrine. Thus, in incubated rat soleus muscle, HSL was activated by epinephrine (Langfort et al. 1999). The impact of skeletal muscle lipid metabolism on exercise and insulin resistance has been reviewed by Kiens (2006). The following assays can be used for investigation of the effects of compounds/drug candidates on the regulation and activity of muscle lipases.

K.6.2.17.3.1 Lipolysis in Isolated Muscle Strips

PROCEDURE

In studies of glycerol release, muscle strips are incubated for indicated periods of time (usually 90 min) in 2 ml of KRB buffer supplemented with 20 mg/ml BSA (pH 7.4), 1 mg/ml glucose, and 0.1 mg/ml ascorbic acid in a shaking water bath (37°C), with air as gas phase according to the protocol of Enoksson and coworkers (2005). After incubation, an aliquot of the medium is removed for analysis of glycerol using an ultrasensitive bioluminescent method (Hellmer et al. 1989). Strips are incubated in duplicate or triplicate in the absence (basal) or presence of various concentrations of isoproterenol, which is a non-selective β-adrenoceptor agonist. The muscle strip is removed from the medium and frozen in liquid nitrogen. It is then removed from the clamps and weighed. Lipolysis is expressed as millimole of glycerol per total incubation medium per time unit per milligram of muscle strip. In studies of FFA release, muscle strips are incubated and analyzed as described for glycerol release, except that 20 mg/ml of fatty acid-free BSA is used as the protein component in the incubation buffer, the number of strips in each type of incubation should range between five and ten, and FFA is analyzed by an ultrasensitive chemiluminescence method as described for adipocytes (Näslund et al. 1993; see K.6.1.10.5).

K.6.2.17.3.2 TAG Lipase Activity in Soleus Muscle

Incubation and Electrical Stimulation

For electrical stimulation of the isolated soleus muscle after 1 h pre-incubation with compound/drug, the isolated soleus muscle with is transferred to fresh incubation medium and fixed in the vertical position and at resting length by small clips attached to the tendons according to the procedure introduced by Langfort and coworkers (2000). The upper tendon is connected to a force transducer. If subsequent electrical stimulation required, the muscles either remain resting or are stimulated electrically through electrodes in both ends to perform repeated ($1 \cdot s^{-1}$) maximal tetanic contractions (200-ms trains of 100 Hz, impulse duration 0.2 ms, 25 V) for 1, 5, 10 or 60 min while tension is recorded.

At the end of the incubation, muscles are freeze-clamped with aluminium tongs cooled in liquid nitrogen, and then trimmed of connective tissue and visible fat while kept in liquid nitrogen. In order to further ensure that findings reflected the biology of muscle cells, these are isolated before analysis from other tissue components by microdissection using a stereomicroscope after freeze-drying. Sometimes single fibres are isolated from fresh, non-frozen muscle by microdissection after collagenase digestion (one muscle being incubated for 3 h at 37°C in 5 ml of DMEM containing 2% (w/v) collagenase).

Preparation of Homogenates

Generally, muscles are homogenized (e. g. Polytron PT 3100, maximum speed) on ice in 10 vol. of 0.25 M sucrose, 1 mM DTT, 40 mM β-glycerophosphate, 10 mM sodium pyrophosphate, 20 mM HEPES/KOH (pH 7.0), 0.31 µM okadaic acid, 20 µg/ml leupeptin, 10 µg/ml antipain and 1 µ/ml pepstatin. The crude homogenate is centrifuged (15,800 × g, 1 min, 4°C). The supernatant is recovered and stored at −80°C until analysis within 1 week. In experiments evaluating the effect of phosphatase treatment on muscle homogenate, the homogenization buffer contained 20 mM Pipes (pH 7.0) instead of sodium pyrophosphate and glycerophosphate.

HSL Assay

HSL assays are based on measurement of release of [^{3}H]oleic acid from 1(3)-mono[^{3}H]oleoyl-2-oleylglycerol, a DAG analog not hydrolysable at position 2 (referred to as MOME activity), and from tri[^{3}H]olein (referred to as TOG activity). Upon phosphorylation by PKA, the TOG activity of adipose tissue HSL increases markedly (Fredrikson et al. 1981, Cook et al. 1982), whereas the MOME activity does not change significantly (Cook et al. 1982, Cook et al. 1983, Greenberg et al. 2001, for a review see Yeaman 2004). Accordingly, MOME activity is a measure of the total enzyme concentration, whereas TOG activity is a measure of the activated form of HSL, and represents the assay of choice for monitoring changes in the activation state of HSL. The TOG and MOME substrates are emulsified with phospholipids by sonication, and BSA is used as fatty acid acceptor. Samples of 14 µl (for TOG activity measurements) or 7 µl (for MOME activity measurement) of muscle supernatant (protein concentration ∼3 mg/ml) or pellet (resuspended to initial volume in homogenization buffer; protein concentration ∼4.4 mg/ml) are incubated for 30 min at 37°C with 100 µl of 5 mM TOG (1.25×10^6 cpm) or MOME (0.4×10^6 cpm) substrate and enzyme dilution buffer (to a total volume of 200 µl). Hydrolysis is stopped by the addition of 3.25 ml of methanol/chloroform/heptane (10/9/7, by vol.), followed by 1.1 ml of 0.1 M potassium carbonate/0.1 M boric acid (pH 10.5). The mixture is vortexed vigorously for 10 s and centrifuged (1,100 × g, 20 min). A 1-ml portion of the upper phase containing the released fatty acids is mixed with 10 ml of scintillation liquid. Radioactivity is determined in a scintillation counter.

K.6.2.17.3.3 Magnetic Resonance Spectroscopy Study of Intramyocellular Lipid Content

Kuhlmann et al. (2003) performed a longitudinal *in vivo* ^{1}H-spectroscopic study of intramyocellular lipid content in Zucker diabetic fatty (ZDF) rats. Magnetic resonance spectroscopy (MRS) has been established as a dependable method for selective detection and quantification of intramyocellular lipid (IMCL) in humans. To validate the interrelation between insulin sensitivity and IMCL in an animal model of type 2 diabetes, volume-selective ^{1}H-MRS at 7 Tesla to non-invasively assess IMCL in the rat was established. In male obese ZDF rats and their lean littermates, IMCL levels were determined repeatedly over 4 months, and insulin sensitivity was measured by the euglycemic-hyperinsulinemic clamp method at 6–7 and at 22–24 weeks of age.

In vivo MRS studies were performed using a 7-T Biospec system (Bruker BioSpin, Ettlingen, Germany), a resonator for excitation and an actively decoupled surface coil for signal detection. Rats were anesthetized with 2–3 vol% isoflurane and 1:2

O_2:N_2O, and their temperature was kept at 37.5°C. The animals were fixed in a non-magnetic device allowing for accurate alignment of their hindleg on top of the surface coil. Voxels of ≈8 mm^3 size were located in M. soleus and in M. tibialis anterior, avoiding vascular structures and gross adipose tissue deposits. Volume-localized ^{1}H-MR spectra [PRESS sequence, echo time (TE) = 17 ms, repetition time (TR) = 1 s, CHESS water suppression, 1024 averages] were obtained with Bruker's ParaVision acquisition software. The integral of the IMCL signal (1.3 ppm) was related to that of total creatine (tCr; 3.05 ppm; program MRUI 97.2, cf. http://www.mrui.uab.es). The IMCL/tCr ratio corresponded to the total muscle IMCL value. In all cases, a clear distinction between EMCL and IMCL was possible. As the IMCL/tCr ratio did not change on using a relaxation delay TR of 2 s instead of 1 s ($n = 4$), the influence of relaxation time changes on observed IMCL values could be excluded. The tCr values for the M. soleus and M. tibialis anterior were determined in obese ZDF rats at 8 weeks and 15 months of age ($n = 8$ each). In both muscles, tCr concentrations proved to be constant (soleus 89 ± 1.1 and 81 ± 1.7 µmol/g dry wt.; tibialis 136 ± 2.2 and 132 ± 1.0 µmol/g dry wt., respectively) and therefore to be a good reference for quantification of IMCL.

For assessing hepatic fat content, the rats were placed prone with their upper abdomen on top of the detecting surface coil. Volume-localized, respiration-triggered ^{1}H-MR spectra were obtained without water suppression (TE = 28 ms, TR = 1 s, 8 mm^3). Fat content was expressed as the ratio of the fat-to-water signal (in percentage).

K.6.2.18 Determination of Other Metabolites in Muscle

Muscle non-lipidic metabolites are determined according to the procedure of Watt and coworkers (2004). For this, muscle samples are divided into aliquots under liquid nitrogen. One piece of muscle (~80 mg wet muscle) is freeze-dried, dissected free of non-muscle contaminants under magnification, and divided into four aliquots. Muscle for glycogen analysis (3 mg) is extracted in 2 M HCl and neutralized with 0.67 M NaOH, and glycogen content is determined as described above and adapted from Passoneau and Lauderdale (1974). A second aliquot of muscle (2 mg) is extracted according to Harris and coworkers (1974), and ATP, phosphocreatine, creatine, and lactate are determined by enzymatic fluorometric techniques according to well-established procedures (Passoneau and Lowry 1993). Intramyocellular TAG content is determined by extraction of the TAG from ~6 mg of tissue in chloroform/methanol (2/1), saponification of the TAG in an ethanol-KOH solution at 60°C, and fluorometric determination of glycerol (Froberg and Mossfeldt 1971, 1975).

K.6.3 Assays for Insulin and Insulin-Like Signal Transduction Based on Adipocytes, Hepatocytes and Myocytes

GENERAL CONSIDERATION

After having established insulin-like activity of compounds/drug candidates in primary or cultured adipose, muscle, and liver cells or tissues with one or several of the metabolic assays described above (see K.6.1 and K.6.2), it is often useful to elucidate the molecular mode of action of these compounds/drug candidates for further characterization and optimization, in particular regarding selectivity and potency. For this, detailed knowledge in the molecular mechanisms of the insulin signal transduction cascade as well as of cross-talking insulin-like signaling pathways as well as the availability of appropriate reliable and robust cell-free and cell-based assays reflecting these events are required. The following view results from the current experimental findings but due to limitations in space and rapid progress still made in this area has to be considered as simplified and temporary, only.

Upon binding of insulin to the IR (insulin receptor) in the major insulin-responsive target cells (adipocytes, myocytes, hepatocytes), the insulin signal transduction machinery, a complex network of protein-protein interactions and protein (serine/threonine/tyrosine) phosphorylation and dephosphorylation cascades between a multitude of cellular signaling components (e. g. enzymes, adaptor proteins, structural proteins), is activated and transmits the insulin signal to a variety of metabolic (predominantly) and mitogenic (to a minor degree) effector systems (e. g. glucose transport, GLUT4 translocation, glycogen synthesis, gene expression, cell differentiation, DNA synthesis) (Biddinger and Kahn 2006, Myers and White 1995, Saltiel 1996, Yenush and White 1997, White 1998, Watson and Pessin 2006). For compounds/drug candidates with insulin-like/sensitizing activity, it is important to differentiate between metabolic and mitogenic signaling in cells of both high (e. g. adipocytes) and low insulin responsiveness (e. g. fibroblasts).

Two major pathways within the insulin signaling cascade have been dissected and are thought to mediate the different biological functions of the hormone: (I) Activation of phosphatidylinositol-3′-kinase (PI3-K) plays a pivotal role for regulation of glucose transport and cellular trafficking as well as glycogen synthesis and lipolysis by insulin. (II) Formation of

the Shc-Grb2 complex leads to activation of the Ras-pathway which has been linked to insulin regulation of both cell growth and gene expression, although this has been questioned recently. Many of the proteins involved in these two cascades have been identified at the molecular level (White 1997, Holman and Kasuga 1997, White 2002). The most upstream located one, the insulin receptor (IR) is a transmembrane tyrosine kinase which when activated by insulin binding, undergoes rapid autophosphorylation and phosphorylates a number of intracellular substrates, among them one or more 50- to 60-kDa proteins, including Shc, a 15-kDa fatty acid binding protein and several so-called insulin receptor substrate proteins, IRS-1/2/3/4, and Gab, which act as adaptor proteins lacking any enzymatic activity. Following tyrosine phosphorylation, the phosphotyrosine residues of the IRS polypeptides act as docking sites for several Src homology 2 (SH2) domain-containing adaptor molecules and enzymes, including PI3-K, Grb2, SHP2, Nck, and Fyn. The interaction between the IRS proteins and PI3-K occurs through the p85 regulatory subunit of the enzyme and results in an increase in catalytic activity of the p110 subunit.

PI3-K is essential and may even be sufficient for many of the insulin-regulated metabolic processes, including stimulation of glucose transport and glycogen synthesis and inhibition of lipolysis (Yeh el al 1997, Alessi and Downes 1998, Shepherd et al. 1998, Shepherd 2005, Cheatham et al. 1994, Herbst et al. 1995, Yeh et al. 1997). PI3-K activation results in the production of phosphatidylinositol (3,4,5)-trisphosphate and phosphatidylinositol (3,4)-bisphosphate which leads to binding and concomitant activation of the membrane-associated serine/threonine protein kinases, PDK1/2 (the nature of PDK2 remaining unclear so far). The binding of the pleckstrin-homology domain of PKB to the PI3-K-generated phosphoinositides both recruits PKB to the plasma membrane and *via* phosphorylation by PDK1/2 stimulates its kinase activity. Activation of Akt requires that it undergoes phosphorylation at two sites (Welsh et al. 2005). PDK1 phosphorylates Akt at Thr308, a residue located in its kinase-domain activation loop. In addition, Ser473 in the C-terminal hydrophobic motif of Akt has long been known to undergo phosphorylation but the identity of the kinase responsible has been controversial. Recently, however, an enzyme complex consisting of mTOR (mammalian target of rapamycin) and RICTOR (rapamycin insensitive companion of mTOR) has been shown to phosphorylate Akt at Ser473 in response to insulin (Hresko and Mueckler 2006, Sarabassov et al. 2005).

Thus the current knowledge favors the view that most metabolic insulin signals emerge from insulin-dependent tyrosine phosphorylation of the IRS proteins (and additional adaptor proteins located in lipid rafts, see K.6.3.6), whereas the mitogenic insulin action is apparently coupled to tyrosine phosphorylation of the Shc proteins. The latter serve as docking sites for the Grb-SOS complex which possesses GDP-GTP exchange activity for the small G-protein Ras and is activated by binding to Shc. In turn GTP-loaded Ras interacts with and activates the Raf serine kinase which phosphorylates the dual specificity kinase, mitogen/extracellular signal-activated kinase MEK (= MAPKK). Activated MEK phosphorylates the mitogen-activated protein kinases MAPK, ERK1 (p44) and ERK2 (p42), which in turn phosphorylate and activate a number of transcription factors (e. g. c-jun, c-fos) and structural proteins ultimately leading to increased gene and protein expression as well as DNA synthesis in insulin-like fashion (Gustafson et al. 1998).

In addition to the identification of the signal transduction pathways directly leading from the IR to downstream targets, several cross talks have been delineated between signal transmission by insulin and other hormones/growth factors (e. g. EGF, angiotensin) or diverse exogenous stimuli (e. g. H_2O_2, phosphoinositolglycans, see K.6.3.6.4) which either mimic to a certain degree (insulin-like activity) or modulate in a positive or negative fashion (insulin-sensitizing or desensitizing activity) metabolic and/or mitogenic insulin action in various cellular systems. Since none of these ligands activates the IR kinase directly, their signalling pathways may converge with that of insulin at a more distal signalling step (Argetsinger et al. 1995, Huppertz et al. 1996, Kowalski-Chauvel et al. 1996, Velloso et al. 1996, Verdier et al. 1997, Baron et al. 1998). Soluble phosphoinositolglycan molecules (PIG) which have been shown to exert partial insulin-like effects in diverse cellular and subcellular systems (Müller et al. 1997, Kessler et al. 1998, Frick et al. 1998, Leon and Varela-Nieto 2004, Müller et al. 2005) can also be classified into the latter category. Interestingly, the second-generation sulfonylureas, glibenclamide and, in particular, glimepiride have been demonstrated to stimulate glucose transport and non-oxidative metabolism in adipose and muscle cells *in vitro* by causing IR-independent tyrosine phosphorylation of IRS-1/2 and stimulating the downstream located insulin signaling events (Müller et al. 1994, Müller and Geisen 1996, Müller 2005). This insulin-like signaling in cells of peripheral tissues

may explain the insulin-independent blood glucose-lowering activity of glimepiride/glibenclamide as has been reported in a number of animal studies (Geisen 1988, Müller et al. 1995, Müller 2000, 2005), which supplements the potent blood glucose decrease *via* insulin release provoked by these widely used antidiabetics.

K.6.3.1 Insulin Receptor (IR) Activation

GENERAL CONSIDERATIONS

Insulin exerts its biological effects through a plasma membrane receptor that possesses a tyrosine kinase activity. Binding of insulin to the α-subunits of the IR induces autophosphorylation *in trans* on tyrosine residues of its β-subunits and thereby stimulates the intrinsic tyrosine kinase activity toward intracellular substrates (such as IRS proteins and Shc) that play crucial roles in the transmission of the signal (see K.6.3). Alterations in tyrosine phosphorylation of the IR have been described in insulin resistant states, such as diabetes and obesity (Combettes-Souverain and Issad 1998). The discovery of pharmacological agents that specifically activate the tyrosine kinase activity of the IR in cell-free and cell-based assay systems has recently been reported (Zhang et al. 1999) and apparently formed the starting point for a number of drug discovery efforts for future insulin-like or sensitizing drugs for the treatment of insulin-resistant patients.

The first critical node in the insulin-signaling network is, by definition, IR and the associated IRS. The IR is a tetrameric protein that consists of two extracellular α-subunits and two intracellular β-subunits. It belongs to a subfamily of receptor tyrosine kinases (RTKs) which also includes the insulin-like growth factor-1 receptor (IGF1R) and an orphan receptor, known as the IR-related receptor (IRR). Each of these receptors is the product of a separate gene, in which the two subunits are derived from a single-chain precursor or proreceptor that is processed by a furin-like enzyme to give a single α-β dimers linked with disulfide bonds to form the tetrameric $\alpha 2 \beta 2$ holoreceptor. This configuration allows for the creation of a hybrid IR-IGF1R complex, which serves as an additional receptor isoform modulated by insulin-like/sensitizing stimuli in differential fashion. The activity of the IR is tightly regulated, as unchecked activation or inactivity would lead to profound metabolic (and presumably proliferative) consequences. There are two splice isoforms of the IR, and each has a different affinity for insulin and IGF-1 (DeMeyts 1976).

Functionally, the IR behaves like a classical allosteric enzyme in which the α-subunit inhibits the tyrosine-kinase activity that is intrinsic to the β-subunit. Insulin binding to the α-subunit, or removal of the α-subunit by proteolysis or genetic deletion, leads to partial derepression, i. e. activation of the kinase activity in the β-subunit by stabilizing the open/relaxed rather than the closed/tense conformation of the activation loops of the two receptor halves. Following this initial activation, transphosphorylation of the β-subunits at tyrosines 1158, 1162, and 1163, leads to an additional stabilization of this conformational change even in the absence of ongoing insulin binding (Ellis et al. 1986,). The determination of the crystal structure of the tyrosine kinase domain of the human IR has provided a better understanding of the molecular mechanism involved in the stimulation of its kinase activity. In the unphosphorylated state, Tyr-1162 is located in the active site of the enzyme and plays an autoinhibitory role by competing with the binding of protein substrates. This tyrosine remains in the unphosphorylated form in the basal state, because other residues in the activation loop also impair ATP binding. The crystallization of the tris-phosphorylated form of the kinase domain has shown that autophosphorylation of these three tyrosines results in a dramatic change in the conformation of the activation loop (Hubbard 1997). This conformation change permits unrestricted access to the binding sites for ATP and protein substrates. It has been postulated that conformational changes induced by ligand binding move the kinase domain of the two β-subunits of the IR nearer to each other, thereby allowing *trans*-phosphorylation of tyrosine 1162 and adjacent tyrosines in the activation loop.

It is important to note that unlike other RTK that bind directly to the cytoplasmic tails of downstream effectors, the IR and IGF-1R engage specific proteins that are known as the IRS proteins and mediate the binding of intracellular effectors (see above). In addition, the IR and the IRS proteins share common mechanisms of regulation: They are negatively regulated by dephosphorylation by protein tyrosine phosphatases (PTPs), phosphorylation by serine/threonine kinases which interfere with IR/IRS function by sterically blocking interaction of IR and IRS or modifying IR kinase activity or downstream signaling of IRS, binding of inhibitory adaptor and signaling proteins (e. g. suppressor of cytokine signalling SOCS1/3, plasma membrane glycoprotein PC-1) and ligand-induced down-regulation of IRS at the translational and transcriptional level. Furthermore, the IR is also down-regulated at the protein level by ligand-induced inter-

nalization and degradation. Some of these regulatory processes may be dysregulated during the pathogenesis of insulin-resistant, hyperinsulinemic states, including obesity, type II diabetes and metabolic syndrome. The following methods may be helpful for the identification and characterization of insulin-like and sensitizing compounds/drug candidates as well as of insulin analogs with favorable kinetic (short- or long-lasting) action profiles using cell-free and cell-based assay systems.

K.6.3.1.1 Insulin Binding

PURPOSE AND RATIONALE

IR binding studies have been performed with various animal tissues and primary and cultured cells of rodent and human origin. Human adipocytes can be used to study simultaneously IR binding and metabolic effects of insulin (Hjøllund 1991). The binding tests are of value to characterize newly synthesized insulin analogs (Schwartz et al. 1987, Ribel et al. 1990, Vølund et al. 1991, Robertson et al. 1992).

K.6.3.1.1.1 Preparation of ^{125}I-Insulin

Most investigators use the "chloramine-T procedure" to iodinate insulin. The reaction is carried out in a 20 ml glass vial in an ice-bath with continuous magnetic stirring. To 2.5 ml 0.05 M phosphate buffer (pH 7.5), 2.0 mCi $Na^{125}I$, and 15 µl of a 1 mg/ml insulin solution are added. Then, 0.5 ml of a chloramine T (50 mg/ml) solution is added dropwise over the course of 1 min. After 10 min, 0.7 ml of a freshly prepared sodium metabisulfite solution (50 mg/ml in 0.05 M phosphate buffer, pH 7.5) is added. One ml of this reaction mixture is transferred to 10 ml 2% BSA for determination of specific activity. In order to absorb unreacted ^{125}I and damaged products, 2.0 g 20–50 mesh AG 1X-8 resin (BioRad) are added (equilibrated in 1 ml 0.05 M phosphate buffer, pH 7.5, containing 0.1 mg/ml thiomerosal and 20 mg/ml crystalline BSA). The reaction mixture is stirred for 10 min, decanted from the resin and diluted to a concentration of less than 25 µC/ml in a solution of 0.8 M glycine, 0.2 M NaCl, 0.05 M phosphate (pH 7.5), and 2.5 mg/ml crystalline BSA. The final solution is stored in multiple aliquots at –70°C.

K.6.3.1.1.2 Binding to Purified Insulin Receptor

IR are partially purified by affinity chromatography on WGA-Sepharose according to the procedure introduced by Ellis and coworkers (1986). Confluent flasks of cells are solubilized with 50 mM HEPES/KOH (pH 7.6), 1 mM PMSF, 1 mg/ml bacitracin. The lysate is then centrifuged (100,000 × *g*, 1 h, 4°C) and loaded on a 2-ml WGA-Sepharose column for 2 h at 4°C. After washing of the column with buffer C (50 mM HEPES/KOH, pH 7.6, 150 mM NaCl, 0.1% TX-100), bound proteins are eluted with 0.3 M N-acetyl-D-glucosamine in buffer C. The IR is further affinity-purified batch-wise by adsorption to monoclonal anti-hIR antibodies which are subsequently bound to anti-mouse IgG coupled to Sepharose beads. After several washing cycles with buffer C (10,000 × *g*, 2 min, 4°C), portions of the hIR-mAb-anti-IgG-beads are suspended in 50 µl of 20 mM HEPES/KOH (pH 7.4), 150 mM NaCl, 20 mg/ml BSA, 0.05% TX-100 and then incubated with ^{125}I-labeled insulin (300 mCi/mg, 0.2 µCi, 5 pM) in the presence of increasing concentrations of unlabeled insulin for 1 h at 4°C. Subsequently, the hIR-mAb-anti-IgG-beads are collected by centrifugation (10,000 × *g*, 2 min, 4°C), rapidly washed with 500 µl of buffer C containing 20 mg/ml BSA and finally counted in a gamma-counter.

K.6.3.1.1.3 Binding to Cultured Cells

Chinese hamster ovary (CHO) cells expressing the wild-type human IR (CHO-hIR) are maintained in Ham's F12 medium supplemented with 10% FCS, penicillin (100 U/ml) and streptomycin (100 µg/ml) (F12 medium). Cells (~ 10^6 cells/100-mm plate) are cotransfected with plasmid DNA (10 µg of expression plasmid *plus* 2 µg of pSV2NEO) in the form of a calcium phosphate precipitate with the addition of a glycerol shock (20% glycerol in F12 medium) after 4 h. After 36 h, the cells are split 1:20 and allowed to grow for 24 h prior to addition of G418 (400 µg/ml). 10–14 d later, colonies from 5 plates (~250–500 colonies) are harvested with trypsin/EDTA (0.05% trypsin, 0.02% EDTA in Ca^{2+}-free and Mg^{2+}-free Hank's basic salt solution and are replated in 24-well culture plates in F12 medium. 2 d later, semi-confluent cells (~4×10^4 cells/well) are washed twice with buffer B (100 mM HEPES/KOH, pH 7.8, 120 mM NaCl, 1.2 mM $MgSO_4$, 1 mM EDTA, 15 mM sodium acetate, 10 mM glucose, 1% BSA) and are then incubated with 16 h at 4°C with 0.5 ml of buffer B containing ^{125}I-labeled insulin (30,000 cpm, 120 Ci/g) *plus* increasing concentrations of unlabeled insulin. Cells are washed twice, solubilized with 0.5 ml of 0.03% SDS and counted in a γ-counter.

K.6.3.1.1.4 Binding to Human Primary Adipocytes

PROCEDURE

Subcutaneous adipose tissue (~4–5 g) is obtained from the abdomen of patients undergoing gastroenterological surgery. Patients suffering from any endocrine or metabolic disorder or taking drugs known to affect metabolism should be excluded. Other exclusion criteria are impaired glucose tolerance measured by determination of fasting blood glucose and the 2 h value after a 75-g oral glucose load. The adipose tissue is finely chopped and incubated for 90 min at 37°C in 25 mM HEPES/KOH (pH 7.4), containing HSA (25 g/l) and collagenase (0.5 g/l). The isolated adipocytes are subsequently washed five times in HEPES/KOH (see above) containing 50 g/l HSA.

IR binding studies with isolated human adipocytes are performed in a 300 µl cell suspension containing about 1×10^5 cells/ml in 10 mM HEPES (pH 7.4), 50 g/l HSA at 37°C. The iodine labeled ligand ([^{125}I]Tyr^{A14}-monoiodinated insulin, specific activity about 350 mCi/mg) in a final concentration of 20 pM is incubated with increasing amounts of unlabeled human insulin and the insulin analog/compound/drug candidate to be tested. The reaction is stopped by adding 10 ml of chilled 0.150 M NaCl and subsequent centrifugation through silicone oil (Pedersen et al. 1981 and 1982, Zeuzem et al. 1984). Non-specific binding is measured by incubating tracer in the presence of a large excess of unlabeled insulin.

For kinetic analysis of binding, the association is studied by incubation of the ([^{125}I]Tyr^{A14}-monoiodinated insulin for various times (1 to 240 min) and the reaction is terminated as described above. At each time point, the non-specific binding is measured and subsequently subtracted from the corresponding data for total binding. Dissociation rates are determined by first incubating isolated human adipocytes at 37°C with either [^{125}I]Tyr^{A14}-insulin or the test compound labeled in the same position for 90 min to achieve steady-state binding conditions. Each incubation mixture is then centrifuged for 60 s The adipocytes are rapidly washed twice by diluting with buffer to the original volume at 4°C and the centrifugations and aspirations are repeated. After the third aspiration, the cells are diluted to the original volume with buffer alone or native insulin or the insulin analog or compound to be tested at a final concentration of 0.2 µM at 22°C. At this hormone concentration a maximal effect of ^{125}I-insulin dissociation is reported (Podlecki et al. 1984, DeMeyts et al. 1976). The reaction is stopped at various times between 10 and 180 min and cell-associated radioactivity is determined.

K.6.3.1.2 IR Conformational Change Using BRET and FRET

PURPOSE AND RATIONALE

BRET is a natural phenomenon in which resonance energy transfer occurs between luminescent donor and fluorescent acceptor proteins (Xu et al. 1999, Angers et al. 2000). Resonance energy transfer occurs when part of the energy of an excited donor is transferred to an acceptor fluorophore, which re-emits light at another wavelength. Resonance energy transfer only takes place if the emission spectrum of the donor molecule and the absorption spectrum of the acceptor molecule overlap sufficiently and if the donor and the acceptor are in proper distance (10–100 Å) and relative orientation (Tsien et al. 1993, Wu and Brand 1994). In the BRET methodology, the first protein partner is fused to *Renilla* luciferase (Rluc), whereas the second protein partner is fused to a fluorescent protein (e. g. yellow fluorescent protein YFP). If the two partners do not interact, only one signal, emitted by the luciferase, can be detected after addition of its substrate cœlenterazine. If the two partners interact, resonance energy transfer occurs between Rluc and the YFP, and an additional signal, emitted by the YFP, can be detected. The strict dependence of BRET on the molecular proximity between energy donors and acceptors makes it a system of choice to study changes in the interaction between two proteins, which usually (in the unstimulated state of the target cell) exist as separate entities or are already assemblied in a preformed complex susceptible to changes in their relative neighborhood or orientation in response to appropriate stimuli.

Binding of insulin to the IR induces a conformational change that brings the two β-subunits of the IR into close proximity, allowing trans-phosphorylation of one IR β-subunit by the other subunit (Hubbard 1997, Combettes-Souverain and Isaad 1998). This autophosphorylation stimulates the tyrosine kinase activity of the IR towards intracellular substrates, such as IRS-1 and initiated downstream signaling to the terminal metabolic insulin effector systems, such as GLUT4 translocation, which are impaired in insulin-resistant and diabetic states. Therefore, methods that allow monitoring of the activity of the IR constitute important tools for the search for insulin-like compounds and putative anti-diabetic drugs.

Biazzo-Ashnault and coworkers (2001) developed a FRET-based assay for monitoring IR kinase activ-

ity. In this assay, the IR has to be immobilized on a microtiter plate with anti-IR antibody. A kinase reaction is then performed using a phosphorylation cocktail containing a biotinylated substrate. After incubation with a fluorescent donor, a strpetavidin-labeled fluorescent acceptor that to the biotinylated substrate is added. Energy transfer only occurs if the fluorescent donor coupled to anti-phosphotyrosine antibody is in close proximity to the streptavidin-labeled fluorescnet acceptor, i. e. if the peptide substrate is phosphorylated on tyrosine residues. Obviously, this is still a heterogeneous assay involving time-consuming incubations and washing steps.

By contrast, Boute and coworkers (2001) developed a completely homogeneous test, based on the BRET methodology, to follow IR kinase activity. A chimeric human IR, in which one IR β-subunit is fused to *Renilla* luciferase (Rluc) and the other IR β-subunit is fused to yellow fluorescent protein (YFP) is produced in HEK cells and partially purified by wheat germ lectin chromatography. Insulin-induced conformational change could be detected as an increase in energy transfer (BRET signal) between Rluc and YFP. This BRET signal corresponds to the ligand-induced conformational changes of the IR before any phosphorylation event, and faithfully reflects the activation state of the IR (Boute et al. 2001).

PROCEDURE

Cell-Based Assay

HEK-293 cells maintained in DMEM supplemented with 4.5 g/l glucose and 10% FBS (Invitrogen) are seeded at a density of 1.2×10^6 cells per 100-mm dish. Transient transfection is performed 1 day later using FuGene 6 (Roche Diagnostics) with either 0.3 µg of IR-Rluc cDNA and 0.3 µg of empty vector or with 0.3 µg of IR-Rluc and 0.3 µg of IR-YFP cDNAs per 100-mm dish. BRET measurements on intact cells are performed essentially as described by Angers and coworkers (2000). 2 days after transfection, HEK-293 cells are detached with Trypsin-EDTA and resuspended in PBS. Approximately 60,000 cells per well are distributed in a 96-well microplate. Cells are incubated for 2 to 10 min in absence or presence of 100 nM insulin. Coelenterazine is added at a final concentration of 5 µM, and light-emission acquisition is started immediately. For use of adherent cells, cells are transfected exactly as described above, but 1 day after transfection, cells are transferred into 96-well microplates (white CulturPlate-96, Packard) at a density of 30,000 cells per well.

In Vitro Assay on Partially Purified Fusion IR

BRET measurements are performed using partially purified fusion IR. Two days after transfection, cells are extracted in buffer containing 1% Triton X-100, 20 mM MOPS, 2.5 mM-benzamidine, 1 mM-EDTA, 1 mM-4-(2aminoethyl) benzenesulfonyl fluoride hydrochloride, and 1 µg/ml each of aprotinin, pepstatin, antipain, and leupeptin. Fusion receptors are partially purified by chromatography on wheat-germ lectin Sepharose by Tavare and Denton (1988). Partially purified fusion IR are aliquoted and stored at −80°C for subsequent use. *In vitro* measurement of BRET signal is performed using 4.5 µl of wheat-germ lectin (WGL) eluate (approximately 2 µg of proteins) preincubated in 96-well microplates for 45 min at 20°C in a total volume of 60 µl containing 30 mM MOPS, 1 mM Na_3VO_4, and different concentrations of ligands. Coelenterazine (7 µl, 2.6 µM final concentration, Molecular Probes, USA) is added to the preparation and light emission acquisition at 485 nm (filter window 20 nm) and 530 nm (filter window 25 nm) is started immediately using a microplate analyser (e. g. Fusion, Packard).

EVALUATION

The BRET ratio has been defined previously (Angers et al. 2000) as [(emission at 530 nm) – (emission at 485 nm) × Cf]/(emission at 485 nm), where Cf corresponds to (emission at 530 nm)/(emission at 485 nm) for the Rluc fusion protein expressed alone in the same experimental conditions (i. e., IR-Rluc transfected alone).

The BRET signal detected in this assay closely reflects the activation state of the IR independently of any phosphorylation reaction. It is a completely homogeneous procedure, requiring no washing step.Thus, the procedure allows for very rapid determination of the activation state of the IR and can be easily used in throughput screening tests for the search of novel compounds/drug candidates with insulin-like activity. Indeed, partially purified fusion IR can be prepared on a large scale by WGL-chromatography and stored at −80°C for subsequent use. This preparation can be distributed in an automated way in 96-well microplates and the effect of molecules on IR activity can be measured within a few minutes using the BRET method. Therefore, the same preparation can be used for multiple screening rounds. Similar procedures should be applicable to any receptor in which lignad binding induces dimerization or conformational changes de-

tectable by BRET. Thus, this assay could be a valuable tool for the search of compounds/drug candidates with anti-diabetic properties.

For screening purposes it turned out that the *in vitro* rather than the cell-based assay has to be used (Boute et al. 2001). The chimeric IR are correctly expressed and functional in HEK293 cells, but an unexpected high basal BRET signal was observed. Obviously, the choice between an *in vivo* and *in vitro* assay has to be done on a case-by-case basis. However, it must be kept in mind that in an intact cell assay, cells have to be distributed and cultured in microtiter plates for each screening round, which is highly time-consuming.

Comparison with FRET Technology

Before the development of BRET in 1999, fluorescence resonance energy transfer (FRET) has been used widely to study protein-protein interactions or to monitor conformational changes within a given protein. In the FRET methodology, luciferase is replaced by a fluorophore that is excited using monochromatic light at the appropriate wavelength (Cubitt et al. 1995, Hovius et al. 2000, Zacharias et al. 2000). A major advantage of FRET is to permit, under microscopic observation, visualization in a single living cell of protein-protein interactions at the subcellular level (Wouters et al. 2001). This is difficult to perform with the present version of the BRET methodology because of the low intensity of light emission by luciferase.

However, FRET presents several disadvantages that make BRET a technology of choice in many cases. In FRET, the donor fluorophore must be excited using monochromatic light. Because of the overlapping absorption and emission spectra of the existing mutants of GFP, direct excitation of the acceptor fluorophore by the light used to excite the donor often complicates the interpretation of the results. This obviously does not occur in BRET because excitation of the donor partner does not require exogenous illumination. Therefore, the quantification of resonance energy transfer is much easier in BRET than in FRET (Tsien 1998). Another related advantage of BRET is that the relative levels of expression of donor and acceptor partners can be quantified independently by measuring the luminescence of the donor and the fluorescence of the acceptor (Xu et al. 2002). Moreover, in FRET, excitation of the donor by illumination of the sample can induce photobleaching of the donor fluorophore, which results in loss of signal with time (Tsien et al. 1993, Cubitt et al. 1995). In addition, in FRET, illumination of the sample often induces autofluorescence that is emitted by endogenous cell components. The resulting background can easily be dealt with when FRET is assessed in a single cell with imaging techniques, by using an unlabeled region of the cell as an internal reference for the autofluorescence background (Tsien 1998). However, this background might become a serious problem when interactions are measured on populations of cells or molecules using non-imaging methods, such as fluorometry in microtiter plates (as would be desirable for throughput screening assays). Recent studies indicate that a tenfold improvement in sensitivity could be attained by using BRET rather than FRET, in an otherwise identical assay (Arai et al. 2000, 2001). Finally, it must be taken into account that the instrumentation requirements for BRET are simpler than those for FRET, which needs an excitation light source. A comparative evaluation of BRET *vs.* FRET technologies with emphasis in their putative application in high-throughput screening has been provided by Boute and coworkers (2002). A chimeric human insulin receptor, in which one-receptor β-subunit was fused to *Renilla* luciferase and the other receptor β-subunit was fused to yellow fluorescent protein, was produced in HEK cells and partially purified by wheat germ lectin chromatography. Insulin-induced conformation change could be detected as an increase in energy transfer (BRET signal) between *Renilla* luciferase and the yellow fluorescent protein.

K.6.3.1.3
IR Tyrosine Phosphorylation

K.6.3.1.3.1
Phosphorylation with Purified IR

PROCEDURE

Preparation of Purified IR

IR is extracted and purified from human placenta as described by Yamaguchi and coworkers (1983) with modifications from Ozawa and coworkers (1998). After preparation of placental membranes from one piece of fresh normal human placenta by differential centrifugation, a suspension containing the membrane proteins is mixed with the same volume of a 50 mM Tris/HCl buffer (pH 7.4) containing 2% Triton X-100 and protein inhibitors (2 mM BAEE, 1 mg/ml pepstatin, 1 mg/ml aprotinin, 1 mg/ml leupeptin and 0.1 mM PMSF) for 45 min at 4°C with stirring. A clear supernatant is obtained by centrifugation (100,000 × *g*, 90 min, 4°C) and is transferred to 40 ml of a WGA-Sepharose affinity column. The fractions including the protein are pooled and applied to 6.3 ml of an insulin-Sepharose column. After thorough washing of the column with 50 mM Tris-HCl (pH 7.4) containing 1.0 M

NaCl, 0.1% Triton X-100 and 0.1 mM PMSF, the IR is eluted with 50 mM acetate buffer (pH 5.0) containing 1.0 M NaCl and 0.1% Triton X-100. The active fractions assessed by ^{125}I-insulin binding activity are collected and concentrated by pressured dialysis using a Diaflo ultrafiltration membrane PM-30 (Amicon Inc.). The purified IR is stored at −80°C. The purity of the IR is assessed by SDS-PAGE and silver staining. The purified IR results in two bands of 135 and 90 kDa, which correspond to α- and β-subunits of the IR, respectively. The stability of the purified IR is determined by the kinase activity of IR at various time intervals after elution of the insulin-Sepharose column. There is no apparent change for the kinase activity up to 1 month, which is evaluated from the magnitude of phosphorylated artificial substrate, poly(Glu^{80}Tyr^{20}), incubated with insulin and its receptor. The IR prepared by the present method is thus of sufficient stability. Kinase activities of purified IR are typically found to change from one extraction to another. In order to control this kinase activity so that it would to be the same throughout the experiment, the concentration of the purified IR has to be adjusted by dilution before the IR is applied for measurements in the present method.

Radioactive Assay

The direct effect of insulin/compounds/drug candidates on the purified IR is assessed by using random copolymers of (Glu^{80}Tyr^{20})$_n$ serving as a substrate for the IR kinase according to Braun and coworkers (1984). The purified IR is pre-incubated with 0.48 µM insulin at 22°C for 1 h in 630 µl of a solution (solution A) containing 25 µM ATP and 5.0 mM $MnCl_2$. The random copolymer of (Glu^{80}Tyr^{20})$_n$ is dissolved in a buffer solution (solution B) containing 0.1% Triton X-100, 5.0 mM $MnCl_2$, 10 mM $MgCl_2$, 50 µCi [γ-^{32}P]ATP, and 50 mM HEPES/KOH (pH 7.4) to its final concentration of 0.5 mg/ml. A 30-µl portion of solution B is taken into a microtube. Phosphorylation of (Glu^{80}Tyr^{20})$_n$ is initiated by adding 15 µl of the pre-incubated IR solution into the microtube, and the solution is incubated for 2 to 120 min. After each incubation time, the sample is applied to filter paper (Whatman 3MM). The filter paper is washed 6 times with 10% TCA and then with acetone and finally air-dried. Radioactivity is counted with a liquid scintillation counter. The magnitude of phosphorylated random copolymers incubated with maximally effective concentrations of insulin is about 4- to 6- times higher than that without insulin at each time, demonstrating the activity of the IR preparation by the present purification method. The insulin-like activity of compounds/drug candidates is calculated as percentage of the maximal insulin effect.

K.6.3.1.3.2 Phosphorylation with Intact Cells

K.6.3.1.3.2.1 Detection by Immunoblotting

IR is immunoprecipitated from cell lysates (9×10^6 cells) by incubating with rabbit anti-IR antibody (3 µg) in buffer A (10 mM sodium phosphate, pH 7.4, 150 mM NaCl, 1% Nonidet-P40, 1% sodium deoxycholate, 0.1% SDS, 1 mM sodium pyrophosphate, 100 µM pervanadate, complete protease inhibitor mix tablets) overnight at 4°C with rotating. Prewashed protein G-sepharose beads (50 µl of packed beads) are added and the solution is mixed in a rotator for 2 h at 4°C. The beads are washed three times in buffer A and protein is eluted using SDS sample buffer (65 mM Tris/HCl, pH 6.8, 1.3% SDS, 13% glycerol, and bromophenol blue) with heating at 95°C for 5 min. SDS-PAGE is carried out by the method of Laemmli on 10% polyacrylamide gels using a mini-apparatus (e. g. Novex) in 25 mM Tris base, pH 8.3, 192 mM glycine, 0.1% SDS at 140 V constant voltage. Electrophoretic transfer from SDS-polyacrylamide gels to polyvinylidene fluoride (PVDF) (antiphosphotyrosine probing) or nitrocellulose (anti-IR probing) is carried out in a mini-blot apparatus (e. g. Novex). The blotting conditions are 40 V for 2 h in 12 mM Tris base, pH 8.3, 96 mM glycine, 20% methanol. Membranes are blocked in 1% polyvinylpyrrolidone (PVP-40, PVDF membranes) or 5% non-fat milk (nitrocellulose) and washed in 25 mM Tris (pH 7.2), 150 mM NaCl, 0.1% Tween 20. Phosphotyrosine-containing proteins are detected using antiphosphotyrosine (4G10) antibody-HRP-conjugated diluted 1:2,000 in 1% PVP-40. The β-subunit of the IR is detected using rabbit anti-IR diluted 1:1,000 in 5% milk followed by 1:2,000 dilution of anti-rabbit-HRP. Reactive proteins are visualized using chemiluminescent detection and a LumiImager.

K.6.3.1.3.2.2 Detection by ELISA

PURPOSE AND RATIONALE

A new assay method has been introduced by Ozawa and coworkers (1998) for the identification and evaluation of compounds/drug candidates with insulin-like activity and interfering with the insulin signaling pathway. It is based on the on/off switching mechanism of the IR-mediated insulin signaling. The Y939 sub-

strate peptide, a synthetic peptide of 12 amino acid residues, consists of a tyrosine-phosphorylated domain of IRS-1 and of a binding domain of IRS-1 to PI-3K. The Y939 peptide is immobilized on an avidin-coated 96-well microtiter plate. Upon binding of insulin to the IR prepared in total or immunoprecipitated from lysates of treated cells, insulin stimulates its receptor kinase activity in a sample solution and phosphorylates the tyrosine residue of the Y939 peptide immobilized on the well surface. The sample solution is washed out, and a selective binding protein for the phosphorylated tyrosine, monoclonal anti-phosphotyrosine antibody labeled with horseradish peroxidase, is added and forms a phosphorylated peptide-antibody complex. The amount of complex thus formed is detected by enzymatic amplification with horseradish peroxidase that can produce a green-color product with an absorbance at 727 nm capable of being detected by colorimetry. The amount of phosphorylated Y939 peptide thus measured is expected to be a selective and sensitive measure of the extent of the insulin signaling induced by compounds/drug candidates.

PROCEDURE

Preparation of Biotin-Y939 Substrate Peptide

The Y939 substrate peptide is biotinylated by reaction of a maleimide group of biotin-$PEAC_5$-maleimide with a thiol group of cysteine introduced at the carboxy-terminal end of the Y939 peptide. 1.0 mg of Y939 peptide (7.2×10^{-7} mol) is dissolved in 160 µl of PBS buffer (150 mM NaCl, 3.0 mM KCl, 10 mM phosphate buffer, pH 7.2), and 2.5 mg of biotin-$PEAC_5$-maleimide (3.6×10^{-6} mol) dissolved in 40 µl of DMSO is added dropwise to the Y939 peptide solution with gentle stirring. The reaction mixture is left for 12 h at 25°C. The reactants are purified by reverse phase HPLC performed on a 801-SC system (Japan Spectroscopic Co., Japan), equipped with a Kaseisorb LC ODS-300–5 column and a UV detector, using a linear gradient of 0–80% acetonitrile in 0.05% trifluoroacetic acid at a constant flow rate of 1.0 ml/min over 60 min. The eluents are monitored by UV absorbance at 220 nm. 10 ml of an eluent containing biotinylated peptide are collected and lyophilized. To evaluate the ratio of covalently immobilized biotin molecules to the Y939 peptide, the amounts of the Y939-immobilized biotin and the Y939 peptide in the eluent are determined as follows. After lyophilization, the biotin-Y939 conjugate is dissolved in 1.0 ml of a PBS buffer and its absorbance at 280 nm is measured. Assuming that the observed absorbance is due to a tyrosine residue in a Y939 peptide, total amount of Y939 peptide is obtained from the absorbance and molar absorptivity for tyrosine of 1.34×10^3 M^{-1} cm^{-1}. The amount of Y939-conjugated D-biotin is evaluated by a spectrophotometric assay method.

Immobilization of the Y939 Peptide on a 96-Well Microtiter Plate

All 96 wells of a microtiter plate are incubated with 150 µl each of avidin solution (0.1 mg/ml avidin in PBS buffer) over 18 h at 4°C. After the immobilization of avidin on the well, each well of the plate is washed with a PBS-T buffer solution (0.05% Tween 20 in PBS buffer). To fill up space between the immobilized avidin molecules with BSA molecules, a 200-µl portion of a BSA solution (1.0% BSA in PBS buffer) is added to each well and the plate is left for 4 h at 4°C. The BSA solution is discarded, and each well is washed four times with the PBS-T solution. After washing with the PBS-T solution, 150 µl of biotin-Y939 conjugates (1.0 µg/ml in the PBS-T solution) is added to each well and biotin-avidin complexation is carried out for 1 h at 4°C. An excess of the conjugates is discarded, and the well is washed four times with the PBS-T solution.

Kinase Reaction

A sample solution is prepared in a microtube, consisting of 0.05% Triton X-100, 50 µM ATP, 1.7 mM $MnCl_2$, a given concentration of IR, 50 mM HEPES/NaOH (pH 7.4), and each concentration of insulin. The sample solution is incubated in a microtube at 25°C for 10 min, and 150-µl portion of the sample solution thus prepared is introduced in a given well. For obtaining a background absorbance, the sample solution without insulin is also introduced in one of the wells. The plate is shaken on a mixer for 1 h at 37°C to react the IR immunecomplex with the Y939 peptide immobilized on the well surface. The plate is washed three times with the PBS-T solution and then two times with a TBS solution (20 mM NaCl, 3.0 mM KCl, and 20 mM Tris/HCl, pH 7.4).

Enzymatic Reaction and Absorptiometric Assay

After dilution of monoclonal anti-phosphotyrosine antibody labeled with horseradish peroxidase in the TBS solution to its final concentration of 0.5 µg/ml, 150-µl of the solution is added into each well. After standing for 2 h at room temperature without shaking, the plate is washed six times with a TBS-T (0.05% Tween 20 in the TBS buffer) solution. To evaluate the amount of the antibody specifically bound to the phosphorylated Y939 peptide, 175 µl of a DA-64 solution

(0.4 mg/mL of DA-64 in 2.0% H_2O_2, 50 mM citric acid, and 100 mM Na_2HPO_4) is added to each well and is incubated with shaking for 1 h at 37°C in the dark. After the enzymatic reaction, the DA-64 solution is subjected to absorbance measurement. A 150-µl portion of the DA-64 solution is diluted with 1.0 ml of Milli-Q water, and the absorbance of the solution in a 1.0-ml cuvette is measured at 727 nm against water with a spectrophotometer.

EVALUATION

For obtaining net insulin-dependent signals (absorbance), a background absorbance obtained by introducing a buffer solution without insulin is subtracted from the observed absorbance in the presence of a given concentration of insulin. Changes in absolute value of this net absorbance are not negligible from one microtiter plate to another, seemingly because of unexpected alteration in the experimental conditions such as concentration of antibody and/or a decrease in activities for IR kinase. In order for the net absorbances obtained from one microtiter plate to be comparable to those obtained from another, the measured net absorbance for a given concentration of insulin is normalized against absorbance for 1.0 µM insulin in terms of $B/B_{max} \times 100$, where B is the absorbance for each concentration of insulin and B_{max} that for 1.0 µM insulin.

K.6.3.1.3.2.3 Detection by TRF

PURPOSE AND RATIONALE

A time-resolved fluorescent assay using Wallac's DELFIA system (DELFIA assay) has been developed to monitor changes in IR tyrosine phosphorylation. Usually phosphorylation levels are analyzed by measuring the incorporation of radioactive phosphate (Tornqvist and Avruch 1988), by immunoblotting, or by ELISA (Krutzfeldt et al. 1999) using phosphotyrosine antibodies (see K.6.3.1.3). These methods suffer from various drawbacks including the use of radioisotopes, tedious and limited sample analysis with respect to immunoblotting, and low dynamic range, in particular in colorimetric assays using ELISA. In contrast, the DELFIA assay using time-resolved fluorometry is a highly sensitive, non-radioactive assay performed in microtiter plates amenable to automation. A formate similar to that of the DELFIA assay has been used by Okada and coworkers (1998) to measure the effect of sodium orthovanadate on IR autophosphorylation of erythrocytes from normal and diabetic patients.

PROCEDURE

Cell Culture

Chinese hamster ovary (CHO) cells overexpressing the hIR (CHO-hIR) are maintained in DMEM, 10% (by vol.) FBS and 1% (by vol.) penicillin-streptomycin at 37°C under 5% CO_2. Before treatment with insulin/compounds/drug candidates, cells are serum-starved for at least 14 h by incubation in DMEM, 0.5% (w/v) BSA, 1% penicillin–streptomycin.

In Vitro Phosphorylation of the IR

Wheat germ agglutinin-purified hIR is prepared from total membranes of CHO-hIR as described (K.6.3.1.1.2 and K.6.3.1.3.1) and then phosphorylated by incubating 700 µg of hIR with 50 mM HEPES (pH 7.4), 10 mM $MnCl_2$, 0.1% (by vol.) Triton X-100, 1 µM insulin, 0.5 mM ATP, and 100 µM sodium orthovanadate for 1 h at room temperature. The phosphorylated hIR is purified by passing the solution over a PD-10 column (Pharmacia) in 50 mM HEPES (pH 7.4), 0.1% Triton X-100, 100 µM sodium orthovanadate and concentrated by centrifugation in a 2-ml Amicon concentrator (30MWCO).

Biotinylation of Anti-IR Antibody

Anti-IR antibody Ab-3 (800 µl of 1.3 mg/ml, Upstate Biotechnology) is biotinylated by incubating overnight at 4°C with 60 µM of freshly prepared Sulf-NHS-LC-biotin (Pierce) dissolved in 4 mM bicarbonate (pH 7.8), 35 mM NaCl, 1% (by vol.) glycerol (final vol. 1 ml). Buffer exchange (PBS) and excess biotin removal are facilitated by diluting and concentrating in centricon units (30MWCO). The level of biotin incorporation is quantitated by comparing to a standard curve constructed using the biotin-induced displacement of avidin from the dye 2-(4-hydroxybenzene azo benzoic acid (HABA; Pierce; absorption of HABA–avidin 500 nm) according to the manufacturer's instructions. The typical yield is between 4 and 10 moles of biotin per mole of protein.

Preparation of Phosphorylated IR from Cells

Cells are grown in 6-well plates until ~60% confluency and serum-starved overnight. The cells are washed with DMEM, incubated in 2 ml of the same medium, and treated with various concentrations of insulin/compounds/drug candidates for 5–10 min. Following the treatments the medium is removed and the cells are immediately frozen in liquid nitrogen and then stored at −80°C until cell lysis. Cells are lysed in 200 µl of lysis buffer (50 mM Tris, pH 7.4,

150 mM NaCl, 1% Triton X-100, 1 mM pyrophosphate, 100 µM pervanadate, "Complete" protease inhibitor tablet). The cells are gently scraped from the dishes and centrifuged (14,000 rpm, 15 min, 4°C, Eppendorf centrifuge). The supernatants are used in the DELFIA assay.

Quantitation of Receptor Phosphorylation

All incubations of the DELFIA assay are carried out at room temperature with agitation in a final volume of 200 µl of DELFIA assay buffer unless otherwise stated. Streptavidin-coated plates are washed with DELFIA wash buffer for 15 min. After removal of wash buffer, anti-IR–biotin or anti-EGFR–biotin (100 ng/well) is added for 30 min. The plate is washed three times with wash buffer and cell lysates are added and the plate is incubated for 1 h. The plate is again washed three times with wash buffer, europium-labeled anti-phosphotyrosine antibody (100 ng/well) is added, and the plate is incubated for 1 h. Following extensive washing (at least five times), 180 µl of enhancement solution is added. The plate is shaken vigorously for 30 min and read in a microtiter plate reader using an europium protocol (excitation at 340 nm, emission at 615 nm, delay 400 µs, 1000 µs/cycle).

Optimization of Conditions

This time-resolved fluorescent (TRF) assay for measuring tyrosine-phosphorylated proteins in cells has been optimized by Waddleton and coworkers (2002). For this, biotinylated anti-IR antibody is used to capture both phosphorylated and non-phosphorylated IR from cells and for immobilization to the streptavidin-coated plate. Europium-labeled anti-phosphotyrosine antibody is used to bind only the phosphorylated IR. Time-resolved fluorometry of europium is then used to measure the level of phosphorylated IR. To establish conditions for the DELFIA assay, *in vitro* phosphorylated IR partially purified from CHO hIR cells is used. The optimum concentrations of both the capture antibody (anti-IR antibody) and the anti-phosphotyrosine antibody is typically ~100 ng. Using *in vitro* phosphorylated partially purified CHO hIR (0.13–0.52 µg/ml) the Eu signal typically reaches three orders of magnitude and remains linear to up to ~ 800,000 Eu counts. The minimal amount of phosphorylated IR necessary for a reliable signal is ~ 0.1 pmole (in 200 µl). The signal is specific for the phosphorylated form of IR since non-phosphorylated IR tested at similar concentrations does not produce a significant increase in background signal. Establishing the optimal conditions for the DELFIA assay it has been demonstrated that the phosphorylation status of the IR does not affect the ability of the capture antibody to immunoprecipitate IR from cell lysates.

EVALUATION

Stimulation of the cells with insulin followed by measurement of IR phosphorylation by DELFIA resulted in an EC_{50} of ~25 nM. This is similar to that reported by Biazzo-Ashnault and coworkers (2001) who used a FRET assay to measure IR tyrosine kinase activity by following phosphorylation of a synthetic peptide. Using the non-specific, protein tyrosine phosphatase (PTP) inhibitor, pervanadate, a 10-fold increase in basal IR phosphorylation is typically detected by the DELFIA assay, whereas analysis of the same samples by immunoblotting reveals a 3-fold increase, only. This difference is likely due to enhanced sensitivity of the DELFIA assay, particularly in the lower range where quantitation of scanned immunoblots is less accurate. Pervanadate results in a 50% increase in insulin-induced IR phosphorylation compared to treatment with ligand alone (10 nM), as measured by both DELFIA and immunoblotting. Comparing the well-established technique of immunoblotting with anti-phosphotyrosine antibodies to the DELFIA assay, similar results are usually obtained. In addition, Waddleton and coworkers (2002) demonstrated that this assay can be used to monitor IR phosphorylation in a normal (i. e. IR non-overexpressing) cell line and in response to phosphatase inhibitors. They also show the rapid and easy adaptation of the Delphia format assay to monitor changes in the phosphorylation status of other cellular proteins. These findings provide strong evidence that changes in the phosphorylation status of the IR in response to PTP inhibitors and most likely insulin-like compounds/drug candidates can be monitored using the DELFIA assay.

K.6.3.1.3.2.4 Yeast-Based Method

GENERAL CONSIDERATIONS

A number of mammalian cell-based assays have been developed in order to analyze IR kinase activity in response to compounds/candidate drugs in a cellular environment that most closely resembles the natural physiological conditions (see K.6.3.1.3.2 and K.6.3.1.2; Sims and Allbritton 2003, Sato et al. 2002). However, mammalian cell-based assays are expensive and time-consuming. Moreover, the effects of redundant processes on the measured output can be difficult to control and to distinguish from the effects that are specific for the IR. The yeast *Saccharomyces cere-*

visiae represents an inexpensive and rapid alternative for measuring the activity of the IR in a heterologous, yet eukaryotic environment. The fact that yeast does not have any endogenous RTKs and no *bona fide* non-receptor tyrosine kinases offers the advantage of a null background for the expression of the mammalian IR and for the measurement of the effects of compounds/drug candidates on the specific target (Barberis 2002, Gunde 2004, Hughes 2002). A yeast growth selection system for monitoring mammalian RTK activities and for detecting inhibition by specific inhibitors, which is based on the Ras-recruitment system (RRS) developed by Aronheim and collaborators has been introduced recently (Broder et al. 1998, Aronheim et al. 1994, 1998) and further modified and improved by Gunde and Barberis (2005). In particular, it may be useful for the throughput-screening for insulin-like compounds/drug candidates acting directly at the IR.

PURPOSE AND RATIONALE

Cdc25p, the yeast homolog of mammalian son of sevenless (Sos), is a Ras guanyl nucleotide exchange factor (Ras-GEF) functioning upstream of the Ras proteins in *S. cerevisiae*. The yeast temperature sensitive *cdc25–2* strain cannot grow at 37°C, because the mutant Cdc25 protein carried by this strain is unable to activate the endogenous Ras protein at this non-permissive temperature. Aronheim and coworkers (1994, 1998) have shown that membrane targeting of the mammalian Sos is sufficient to activate Ras leading to complementation of the *cdc25–2* temperature sensitive allele. The yeast growth selection system for monitoring human IR is based on the RRS.

PROCEDURE

Yeast Strains and Yeast Spotting Assay

Cells from the yeast strain cdc25–2 (Matα, ade5, cdc25–2, his7, lys2, met10, trp1, ura3–52, leu2) transformed with the hIR are plated on 2% glucose agar plates. Four different colonies of each transformation are picked and spotted onto two sets of galactose plates (3% galactose, 2% raffinose, and 2% glycerol) that are incubated at 25°C or 37°C. For this spotting assay, the yeast suspensions are not adjusted to the same concentration prior to spotting, whereas for the serial dilutions, the yeast cultures are adjusted to the same concentration. Plates incubated at 25°C are scanned after 4 days, whereas plates incubated at 37°C are scanned after 7 days. For serial dilutions, exponentially growing cultures are serially diluted in sterile water starting with a concentration of 4×10^7 cells/ml. 5 µl of each dilution are spotted onto two sets of galactose plates, corresponding to about 100,000, 20,000, 4000, 800, 160, and 32 cells *per* spot. Plates are incubated at 25°C and 37°C and scanned after 4 and 11 days, respectively.

Preparation of Yeast Extracts and Immunoblot Analysis

Exponentially growing *S. cerevisiae* cultures expressing the hIR are diluted to a final absorbance at 600 nm (A_{600}) of 0.5 in 4 ml of Ura/-Leu/-Trp dropout medium containing 2% glucose and are grown for 4 h. Cells are harvested by centrifugation, and whole cell extracts are prepared as described (Kaiser et al. 1994). Samples of whole cell extracts subjected to SDS-PAGE and blotted on nitrocellulose membranes following standard protocols.

Growth

Exponentially growing cultures expressing hIR are washed once with water and diluted to a final A_{600} of 0.1 ml of Ura/-Leu/-Trp dropout medium containing 3% galactose, 2% raffinose, and 2% glycerol. As a control, cells expressing M-Grb2-Ras(Q61L)ÄF are similarly grown, washed, and diluted to a final A_{600} of 0.03. 150 µl of the diluted cells are added to 96-well plates containing 1.5 µl of the compounds/drug candidates at the desired concentrations (1% final DMSO concentration). The plates are incubated at 37°C, and growth at the indicated time points is quantified by measuring A_{595} with a microtiter plate reader.

EVALUATION

As alternatives to this yeast Sos-recruitment system (RRS) to monitor protein-protein interactions at the plasma membrane, the reverse RRS for the identification of protein-protein interactions with integral membrane proteins (Köhler and Muller 2003), the split-ubiquitin system (Hubsman et al. 2001), and the SCINEX-P system (Stagljar et al. 2001) have been developed during the last decade. The split-ubiquitin system has been used to detect novel proteins that are associated with the mammalian ErbB3 RTK (Thaminy et al. 2003). Ehrhard and coworkers (2000) developed a method that uses the yeast G-protein signaling pathway as readout to select for protein-protein interactions. This assay has been validated with known binding partners, such as the RTK fibroblast growth factor receptor 3 (FGFR3) and SNT-1, that constitutively binds to the FGFR3 intracellular domain. The latter two methods are feasible for detection of interactions between an integral membrane protein and a soluble cytoplasmic protein, but, in contrast to the direct RTK assays, the binding of cytoplasmic proteins to the RTKs is independent of receptor activity.

Furthermore, Köhler and Muller (2003) recently applied an adaptation of the RRS to the analysis of interactions between two membrane-associated proteins, namely the myristylated and phosphorylated EGFR intracellular domain and a myristylated Grb2-Ras fusion protein. Due to the fact that yeast cells do not have endogenous mammalian-type tyrosine kinases, the yeast-based growth selection system offers the advantage of a null background eukaryotic organism for expression of these mammalian membrane-bound kinases, such as the IR. This assay may be of value in throughput screenings for the identification of cell-active activators (and inhibitors) of RTKs.

K.6.3.2 Phosphorylation of Signaling Components by Insulin and Insulin-Like Stimuli

GENERAL CONSIDERATIONS

Protein kinases (PK) and phosphatases (PP) have been implicated in a variety of cellular processes such as proliferation, differentiation, metabolism and apoptosis. Over one-third of the proteins in the human proteome are phosphoproteins and the family of PK and PP represents up to 5% of the human genome. These enzymes may cause an increase in or suppression of the activity of other enzymes, receptors, regulatory proteins or transcription factors, mark proteins for destruction, allow proteins to move from one subcellular compartment to another, or enhance or impede protein–protein interactions. In many cases these components and processes are embedded in various signaling pathways, such as the insulin signal transduction cascades. Thus, any change in the level, activity, or localization of PK and PP has a major impact on the regulation of these processes. Not surprisingly, the dysregulation of protein phosphorylation has been associated with diabetes.

There are estimated to be over 500 different PK in the human proteome that catalyze the transfer of phosphate from ATP to serine, threonine, and tyrosine. PK can be divided into two broad classes, serine/threonine and tyrosine kinases, although a few PK are able to phosphorylate both types of amino acid residues (dual-specificity kinases). Because of the key role that PK play in cellular functions, they have become one of the most important drug targets. As such, protein phosphorylation is in the focus of much interest for the development of compounds to selectively regulate the activity of diabetes-related PK. Thus, there is a need for assay systems that monitor the activity of these enzymes under a variety of experimental conditions and for the development of selective inhibitors or activators of these enzymes for a variety of therapeutic applications, among them metabolic diseases, such as diabetes.

PURPOSE AND RATIONALE

One strategy is based on the identification of selective novel inhibitors of PK, which have been implicated with interference of insulin signal transduction *via* serine phosphorylation of key signaling components, such as IRS-1 (see K.6.3 and K.6.3.4), thereby blocking activation of downstream components, such as PI3-K. These compounds/drug candidates should act as insulin-sensitizers bypassing the insulin resistance in muscle and liver tissues of type II diabetic patients. The other strategy relies on the identification of activators of PK, which function as positive elements in the insulin signal transduction cascade, such as the IR. These compounds/drug candiates may induce insulin-like signals in muscle and liver tissues of type II diabetic patients. In any case, the effect of large libraries of compounds on the phosphorylation of specific insulin signaling components has to be analyzed in a rapid, reliable and sensitive fashion.

PROCEDURE

Numerous methods have been designed to measure PK activity. Early methods require physical separation of substrate protein or peptide from its phosphorylated product. One method is to use radiolabeled ATP that allows the incorporated phosphate to be detected after the capture of the protein/peptide substrate by binding to phosphocellulose membranes (Witt and Roskoski 1975). This type of PK assay requires multiple steps and the use of radioactivity with its accompanying hazards and costs. Previously, a very selective and highly sensitive assay for various protein kinases was developed that is based on the use of biotinylated peptide substrates and [γ-^{32}P]ATP. This assay is fast, quantitative, and does not require any alteration of the peptide consensus sequence of the optimal PK substrate, which is routinely done with phosphocellulose membrane-based kinase assays. Although this assay system offers many advantages such as specificity, sensitivity, and convenience, it suffers from the fact that it is not homogeneous, i. e., it requires transfer of reaction products to a filter plate, and it is radioactive. Others have developed assays for measuring the enzyme activity of PK that are homogeneous and increase throughput for measuring the PK activity of many samples. Some of these are radioactivity-based assays, such as the scintillation proximity assays (SPA) or fluorescence-based

assays, such as time-resolved fluorescence resonance energy transfer (FRET) and fluorescence polarization (FP). The SPA and flashplate assay have been used as a high-throughput homogeneous assay of PK activity that does not require an antibody (Braunwalder et al. 1996, Antonsson et al. 1999), but still has some disadvantages. Although the signal-to-noise ratio (S/N) is high for the SPA, it uses radioactivity ([γ-^{33}P]ATP), and its efficiency is dependent on the energy of the isotope used ([γ-^{33}P]ATP is preferred over ([α-^{32}P]ATP). It also requires centrifugation or washing steps. Homogeneous non-radioactive assay formats measuring PK activity, that include FP and FRET, have been developed to eliminate the disadvantages of radioactivity and washing steps (Seethala and Menzel 1997, Park et al. 1999). FP is a ratiometric technique that reflects the rotational motion of a fluorescent molecule in solution with the rotational velocity dependent on the apparent molecular size (Pope et al. 1999). Although FRET and FP are non-radioactive, their signal-to-noise ratios are low and they rely on the availability of very high affinity and selective antibodies. This represents a major drawback of FRET, its reliability on the dual-label format in which an anti-phosphopeptide antibody is labeled with a fluorescence donor and is brought into close proximity to the peptide conjugated to a fluorescence acceptor, and only when these two molecules are within close proximity does transfer occur. FP on the other hand, uses only one labeled fluorescent molecule and it is ratiometric and thus minimizes interference by sample quenching. The disadvantages, however, are the very low S/N ratio that in some cases is less than 1.5, depending on the assay. The optimization of the assay may be difficult to attain because one cannot easily predict the appropriate location and spatial configuration for the fluorescent label. A major disadvantage of both FP and FRET assays is that they are dependent on the availability of a phospho-specific antibody. Another drawback to the use of antibodies is that their high specificity for a given phosphopeptide often prevents the same antibody from being used with different substrates. Anti-phosphotyrosine-specific antibodies are broadly reactive since they are relatively insensitive to the surrounding amino acid context. In contrast, anti-phosphoserine-/phosphothreonine-specific antibodies are highly dependent on the amino acid sequence surrounding the phosphorylated residue and thus tend to only bind a limited diversity of phosphorylated sites (Wu et al. 2000). In general, a new antibody must be generated for each different substrate, which can be both time consuming and expensive. There are also ELISA-based assays for PK activity, but these also require multiple steps in addition to being dependent on availability of a phospho-specific antibody to capture product (Angeles et al. 1996).

Several antibody-free non-radioactive assays for PK activity have been reported. One of these is based on the differential electrophoretic mobility of the fluorescent peptide substrate and its phosphorylated product using capillary electrophoresis and is compatible with throughput formats. This type of assay requires specialized high-throughput capillary electrophoresis setup and equipment. Another assay method replaces ATP in the reaction with ATPγS leading to the formation of a thiophosphorylated peptide product (Jeong and Nikiforov 1999). This product is then chemically biotinylated by a sulfur-specific biotinylation reagent. Streptavidin is then added to the fluorescently tagged peptide and an FP measurement is taken to measure the amount of product formed. The potential disadvantages of this assay include long incubation times and altered kinetics for some PK due to the ATPγS. Another antibody-free FP assay of PK activity that has been reported uses polyarginine to discriminate fluorescently labeled phosphorylated and non-phosphorylated peptides based on charge interaction of the phosphate group and the positively charged high molecular weight polyarginine (see K.6.3.2.3; Coffin et al. 2000, Simeonov et al. 2002). Another potential antibody-free assay of PK activity is the so-called IMAP assay that employs trivalent metal ions immobilized on nanoparticles to bind phosphate groups on molecules and thus increase their FP values (Huang et al. 2002). This approach is similar in concept to immobilized metal affinity chromatography (IMAC) used to specifically isolate phosphopeptides from mixtures containing both phosphorylated and non-phosphorylated peptides (Anderson and Porath 1986). Finally, the development of microchip instruments has led to an additional approach for measuring the PK activity (Cohen et al. 1999). In the microfluidic assay of PK activity, fluorophore-labeled peptide substrate and product are separated based on a difference in their charge-to-mass ratio. Separation of product and substrate is achieved by electrophoresis through an electric field, followed by quantitation of the individual fluorescent peaks. The currently most important and widely used PK assay technologies as well as novel ones with interesting future applications are described briefly.

K.6.3.2.1 Scintillation Proximity Assay (SPA)

For the scintillation proximity assay (SPA), the final assay conditions are 50 mM Tris (pH 8.0), 10 mM $MgCl_2$, 0.01% Triton X-100, 1 mM DTT, 1 or 3.75 µM ATP, 0.375 µM biotinylated peptide substrate, 160 ng/reaction kinase, 10 µM compound (in 10 mM DMSO, diluted 1:100 at least) and 0.125 µCi/reaction of [^{33}P]ATP. The 40-µl reactions are incubated at room temperature for 4 h. A stop reagent (40 µl per well) containing 0.2 mg streptavidin-coated SPA beads (Amersham), 40 mM EDTA, and 74% CsCl is added to the reaction. After sealing the plates and incubating for 2 h at room temperature, the plates are read on a microtiter plate TopCount scintillation counter.

K.6.3.2.2 Fluorescence Polarization (FP) Assay

PURPOSE AND RATIONALE

FP is a solution-based non-radioactive homogeneous assay that requires no separation of components for the analysis and in many but not all cases (see below) depends on the availability of appropriate phosphosite-specific antibodies. FP, first described in 1926, depends on the differing rotational properties of small (<10,000 Da) *vs.* large (> 100,000 Da) molecules. Fluorescent molecules excited by a plane of polarized light emit light in that same plane if the molecules do not move or rotate during the course of the excited state (1–5 ns). If the fluorescent molecules change position during their existence in the excited state, the polarized light will be emitted in a plane different with respect to the excitation plane. Large molecules such as proteins (or small molecules bound to proteins) do not rotate or move significantly during the lifetime of the excited state. Therefore, they do not become depolarized during the course of an FP experiment. Small molecules, such as peptides, tumble more rapidly and thus become depolarized during the course of the FP experiment. This change in polarization can be detected by monitoring the amount of fluorescence in the vertical *vs.* the horizontal plane following excitation in the vertical plane. Mathematically this can be expressed as polarization value $(P) = (I_V\text{-}I_H)/(I_V+I_H)$, where I_V and I_H are the intensities of the vertical and horizontal components of the emission light, respectively. FP is a dimensionless entity and is not dependent on the intensity of the emitted light or on the concentration of the fluorophore. This is a fundamental advantage of FP, in that each sample has an internal calibration that thus limits variations in intensity due to source fluctuation, fluorescence quenching by contaminants or inhibitors, or scattering caused by turbidity. The major limitation of FP lies in the limited sensitivity and signal-to-noise ratio, requiring specialized fluorimeters.

PROCEDURE

Most commercially available FP-based assays of PK activity require a anti-phospho-specific antibody. There are several disadvantages to the use of antibodies in FP assays. Although anti-phosphotyrosine-specific antibodies are common and relatively amino acid context independent, they are expensive. Anti-phosphoserine- or phosphothreonine-specific antibodies can be difficult and costly to produce and are sensitive to amino acid sequence surrounding the phosphorylation site and hence cannot be used for all serine/threonine peptide substrates (see K.6.3.2 and K.6.3.3.4). Unlike most other homogeneous fluorescent assays of PK activity, reagents required for the zinc FP assay are simply a fluorescein-labeled peptide and commonly used, inexpensive laboratory reagents, with no antibody required.

Modifications of the method have been established which are based on the use of Zinc (Scott and Carpenter 2003, polyarginine (Coffin et al. 2000) and competitive mode of assaying (Seethala and Menzel 1998, Turek et al. 2001, Kristjansdottir and Rudolph 2003).

K.6.3.2.3 Fluorescence-Based Assay

PURPOSE AND RATIONALE

To address the various drawbacks of existing assays, a novel, robust system to measure the activity of several PK has been developed. This assay is rapid, can be completed in less than 2 h, and can be carried out in multiwell plate formats such as 96- or 384-well plates. The signal-to-noise ratio is very high, and unlike FRET or FP, it uses a simple measure of fluorescence intensity. The assay also does not rely on the availability of high-affinity and selective antibodies, as is the case with other existing technologies. Finally, the assay is easily adapted to robotic systems for drug discovery programs.

PROCEDURE

It has been reported that phosphorylation of peptides on serine (Murray et al. 1996) or tyrosine (Dass and Mahalakshmi 1996) decreases the proteolytic activity of proteases. Thus, phosphorylation of peptides by PK

can be monitored by the increase in resistance to protease cleavage of the phosphorylated product. The difference in cleavage rate of the peptide in the absence and presence of phosphorylation can be used as a measure of the PK activity. It is noteworthy that the activity of PP can also be determined using a similar approach. The cleavage rate can be monitored by HPLC separation of the peptides before and after phosphorylation. However, this approach is tedious, time-consuming, requires large amounts of substrates and PK/PP, and is not practical for a large number of samples. To develop a PK assay based on this principle that is sensitive, simple, and scalable to high-throughput formats, Kupcho and coworkers (2003) introduced a fluorescence technology based on the use of Rhodamine 110 (R110)-modified peptide substrates.

Free R110 is a fluorescent molecule but when it is covalently linked *via* both its amino groups in a bisamide form both its visible absorption nd its fluorescence are suppressed. Upon enzymatic cleavage, the non-fluorescent bisamide substrate is converted in a two-step process, first to the fluorescent monoamide and then to the fluorescent monoamide and then to the even more fluorescent free R110. Both of these hydrolysis products exhibit spectral properties similar to those of fluorescein, with peak excitation and emission wavelengths of 496 and 520 nm, respectively. When the peptide substrate is not phosphorylated, it can be digested by aminopeptidase, which releases free R110 and thus enhances fluorescence at 520 nm. Phosphorylation of the peptide slows down the proteolytic cleavage of the peptide and thus minimal change is observed in the fluorescence. Using the appropriate consensus sequence for the peptide substrates, which have to be coupled to R110 in a bisamide form according to the protocol from Kupcho and coworkers (2003), the activity of a multitude of different PK can be monitored.

K.6.3.2.4 Capillary Electrophoresis-Based Assay

PURPOSE AND RATIONALE

Separation of non-phosphorylated substrate from the phosphorylated product can be accomplished by capillary zone electrophoresis. Dawson and coworkers (1994). Although the separations are very efficient, each separation run takes about 10–15 min, making this apporach too slow for the screening of large chemical libraries. The microchip is uniquely suited for the development of PK assays based on separation of substrate and product. Using computer control, it is possible to dispense nanoliter volumes of reagent solutions into the channel network. Enzymatic phosphorylation of the substrate takes place while the mixture is flowing through a reaction channel. An aliquot of the mixture is then injected into a separation channel where substrates and product are electrophoretically separated. The separation requires only a fraction of the time needed in traditional capillary electrophoresis. Cohen and coworkers (1999) presented the successful development of a microchip-based assay for a model PK, PKA, activity. This assay format may be applied to a wide range of different PK, for which fluorogenic substrates do not exist but where the outcome of the enzymatic reaction can be assessed by the separation of substrate from product.

PROCEDURE

The assay buffer for on-chip experiments using PKA is 100 mM HEPES/KOH (pH 7.5), 5 mM MgCl2, 100 μM ATP, 50 μM cAMP, and 1 M NDSB-195 (dimethylethylammonium propane sulfate) and is filtered through a 0.22-μm disposable Millipore syringe filter. The design and fabrication of the chips is given in the published report (Cohen et al. 1999). Prior to use, the chips are thoroughly cleaned with deionized water, 2-propanol, a filtered solution of 1 N NaOH for 15–30 min, rinsed with water and finally filled with assay buffer. To run experiments, the microchips are filled with the required reagents and placed in a specially constructed holder on the stage of an epifluorescent inverted microscope (480/40-nm excitation filter; 535/40-nm emission filter). A lid containing Pt electrodes is placed over the chip. Upon lid closure, the electrodes are inserted into the wells of the chip. These electrodes are connected to the high-voltage controller. Currents and voltages are applied to platinum wire electrodes immersed in reagent wells on the microchip.

EVALUATION

The capillary electrophoresis-based assay format may replace other methods of analysis of PK, namely radiolabel assays and other more cumbersome heterogeneous formats, the true appeal of the microchip is its potential for application to high-throughput screening. Significant reductions in assay time and reagent consumption will offset the expense by the need for instrumentation and software development. Optimization of channel dimension for the direct introduction of compounds/drug candidates from a microtiter plate into the on-chip reagent stream of substrate and enzyme as well as of reagent concentrations as methods to manipulate on-chip incubation times for enzymes of varying turnover rates have meanwhile been achieved.

K.6.3.3 Dephosphorylation of Insulin and Insulin-Like Signaling Components

GENERAL CONSIDERATIONS

The PTP (protein tyrosine phosphatases) are a structurally diverse family of both receptor-like and non-transmembrane hydrolases that have been implicated in the control of numerous physiological processes, including growth, differentiation and metabolism (Johnson et al. 2002). Approximately 75 PTPs have been identified to date. These enzymes are characterized by the presence of a conserved catalytic domain of 240 residues which contains the unique signature motif, $C(X_5)R$, that defines this enzyme superfamily (Andersen et al. 2001, Alonso et al. 2004). The structural diversity is manifested by the variability in non-catalytic sequences fused to the amino- or carboxy-terminus of the catalytic domain. These non-catalytic segments frequently serve a regulatory function, including ligand binding for receptor PTPs and targeting of cytoplasmic PTPs to defined subcellular locations. Despite variations in primary structure and differences in substrate specificity, key structural features in the catalytic site and mechanism are conserved among all members of the PTP superfamily (Barford et al. 1994 and 1998, Zhang 2003). Although great progress has been made in illustrating the, somewhat unexpected, structural diversity within this large enzyme family, relatively little is known of the physiological function of individual PTP. Presumably this structural diversity reflects a broad range of functions for the PTP family *in vivo*. However, it is clear on the basis of the role of protein tyrosine phosporylation in insulin signal transduction that PTP play important roles in the down-regulation of the insulin signal either for the physiological termination of insulin action after removal of insulin from the circulation or during the pathogenesis of type II diabetes in course of the development of insulin resistance in peripheral tissues. In particular, the potential role of PTP1B as a negative regulator of insulin action, causally related to the pathogenesis of insulin resistance and type II diabetes has been suggested by a number of studies using knock-out animals and cultured cells with ectopic overexpression and inhibition by small molecules or antisence oligonucleotides (Johnson et al. 2002, Elchebly et al. 1999). Consequently, PTP, in general, and PTP1B, in particular, have been recognized as attractive targets for the identification of insulin-like/sensitizing drugs for future anti-diabetic therapy.

PURPOSE AND RATIONALE

Considerable work has been directed at identifying PTP that dephosphorylate IR as possible targets for insulin-like compounds/drug candidates. Several receptor PTP (e. g. PTP-α, LAR) and non-receptor PTP (PTEN, PTP1B) have been considered candidates based on studies of their overexpression, substrate-trapping mutants, mouse knockout models, and other approaches (Cheng et al. 2002, Tonks 2003, Bourdeau et al. 2005). Since the inhibition of PTP1B causes prolonged and increased IR phosphorylation, it is a potential therapeutic target in the treatment of type II diabetes and insulin resistance.

As interest in understanding PTP1B and its role in the regulation of insulin signal transduction and pathogenesis of type II diabetes grows, the accurate measurement of tyrosine phosphorylation on proteins becomes increasingly important. Therefore to aid in the identification of selective, potent PTP1B inhibitors novel assays have recently been designed to follow changes in tyrosine phosphorylation of the IR and of additional so far unknown substrate proteins as well as for the identification of novel PTP1B substrate proteins in normal and insulin-resistant muscle, adipose and hepatoma cell lines which all express functional PTP1B and IR.

In addition to PP, lipid phosphatases have also been implicated as negative regulators of insulin signaling and ac tion, in general, and insulin-stimulated GLUT4 translocation, in particular. In addition to positive regulators of GLUT4 translocation, negative regulators have also been studied intensely because they might provide opportunities for pharmacological interventions. For example, the endogenous attenuation of PI3-K signaling occurs through the dephosphorylation of phosphatidylinositol-3,4,5-trisphosphate [PtdIns(3,4,5)P_3,]. Two phosphoinositide phosphateses, SHIP2 (type-II SH2-domain-containing inositol 5′-phosphatase) and PTEN (phosphatase and tensin homolog deleted on chromosome ten), have been implicated in negatively regulating insulin signaling (Jiang and Zhang, 2002). SHIP2 removes the 5′ phosphate from PtdIns(3,4,5)P_3 to generate phosphatidylinositol-3,4-bisphosphate [PtdIns(3,4)P_2]. Although the *Ship2* KO mice die shortly after birth and are severely hypoglycemic, heterozygous animals show improved glucose tolerance and enhanced insulin sensitivity (Clement et al. 2001).

In contrast to SHIP2, PTEN is a 3′-specific PtdIns(3,4,5)P_3 phosphatase that generates PtdIns(4,5)P_2). Overexpression of PTEN prevents the accumulation of PtdIns(3,4,5)P_3 and also inhibits

insulin-stimulated GLUT4 translocation in 3T3L1 adipocytes (Nakashima et al. 2000). Moreover, the genetic ablation of PTEN in adipose tissue of mice has recently been shown to enhance insulin sensitivity and resistance to pharmacologically induced diabetes (Kurlawalla-Martinez et al. 2005).

K.6.3.3.1 Protein Tyrosine Phosphatase (PTP) Activity Measurement Using DIFMUP

PURPOSE AND RATIONALE

A variety of substrates have been developed for measurement of the hydrolytic activity of PTP with the rather unspecific *para*-nitrophenylphosphate (PNPP) and specific phosphotyrosine-containing peptides being most widely used. These assays have significantly improved our understanding of substrate specificity and catalytic mechanism of PTP. However, their use for routine inhibitor screening is rather limited due to a variety of reasons, in particular, the requirement for synthesis of a phosphopeptide, low sensitivity in detection, susceptibility to color interference, and discontinuous nature (i. e. termination of the reaction by addition of acidic malachite green reagent or alkaline solution; Zhang and Dixon 1994, Zhang et al. 1993). A number of fluorogenic compounds used for the analysis and characterization of PTP have been described. Recently, Huang and coworkers (1999) and Wang and coworkers (1999) described the development of fluorescein monosulfate monophosphate as a dual fluorogenic substrate for both phosphoserine/threonine phosphatases and PTP. The similarity in their reaction mechanisms seems to be the reason that phosphatases from the different families can use these small non-peptidic substrates, albeit with pronounced differences in their catalytic efficiencies. Wang and coworkers (1999) described the development of fluorescein monosulfate monophosphate and their use as sensitive fluorogenic substrates for several PTP. The demonstrated catalytic efficiencies which are comparable to those of phosphopeptide substrates favor their use in alternative more sensitive assay designs. Recently, another fluorogenic substrate, 6,8-difluoro-4-methylumbiliferyl phosphate (DIFMUP) was found to be appropriate for measurement of PTP activity (Welte et al. 2003). This substrate has initially been developed for phosphoserine/threonine phosphatases (Gee et al. 1999) and subsequently optimized for use in the high-throughput assay format (Welte et al. 2005). The DIFMUP-based assay may be helpful for the kinetic analysis and characterization of small-molecule inhibitors for PTP, which have been implicated as negative regulators in insulin signalling (e. g. PTPα, LAR, CD45, TC-PTP, YOP, SHP2), in general, and PTP1B, in particular.

PROCEDURE

All reactions are carried out at 37°C in black polystyrol 96-well plates with flat bottoms. For measurement of PTP1B, PTPα, LAR, CD45, TC-PTP, YOP, and SHP2, the reaction buffer contains 50 mM HEPES (pH 6.9), 150 mM NaCl, 1 mM EDTA, 2 mM DTT, and for VHR, the reaction buffer contains 50 mM sodium acetate (pH 5.6), 100 mM NaCl, 1 mM EDTA, 2 mM DTT. The substrate stock solution is prepared in DMSO at a final concentration of 10 mM and stored at −20°C. For measurement, DIFMUP is diluted 10-fold in the desired reaction buffer, yielding a final concentration of 1 mM. Fluorescence excitation of hydrolyzed DIFMUP (Molecular Probes) and the fluorescent standard DIFMU is measured at 358 nm and emission is detected at 455 nm in a fluorescence plate reader (e. g. Spectramax, Molecular Devices).

For kinetic analysis, the DIFMUP stock solution is pre-diluted in reaction buffer and added to the reaction mixture to yield final concentrations of 0–300 µM. The assay is initiated by adding 10 µl of substrate to 90 µl of reaction buffer containing the prediluted PTP (final concentrations: PTP1B, 100 ng/ml; PTPα, 500 ng/ml; LAR, 125 ng/ml; CD45, 100 ng/ml; TC-PTP, 100 ng/ml; SHP2, 2 µg/ml, YOP, 50 ng/ml).

Compounds/drug candidates are pre-diluted in reaction buffer containing 100 ng PTP1B to the indicated final concentrations ranging from 0.8 to 80 µM in a final volume of 90 µl. The reaction is started by adding 10 µl of substrate buffer containing 1 mM DIFMUP and the intensity of released DIFMU is monitored continuously for 5 min. Malachite green and PNPP assays are performed as described (Zhang and Dixon 1994, Zhang et al. 1993). Initial velocities of the reactions are used to calculate kinetic constants using Sigma Plot software. The initial velocities are plotted against the inhibitor concentrations and the IC_{50} is calculated.

Detailed analysis of the binding mode of compounds/candidate drugs is performed as follows. For analysis of the time dependence of inhibition, different inhibitors are incubated at their IC_{50} concentrations with PTP1B for 0, 10, and 15 min. The reaction is started by adding 10 µl of substrate buffer containing 1 mM DIFMUP and the reaction is followed for 10 min. For analysis of the reversibility of inhibition, compounds/drug candidates are incubated for 10 min

with PTP1B. After addition of DIFMUP to a final concentration of 10 µM, the reactions are followed continuously until the fluorescence emission do not increase further. The reactions are restarted by adding DIFMUP to a final concentration of 100 µM and the release of DIFMU is monitored for an additional 10 min.

EVALUATION

The fluorogenic substrate, DIFMUP, was developed as a substrate for phosphoserine/threonine phosphatases to enable continuous measurement of activity (Gee et al. 1999). Its hydrolysis by a phosphatase results in the release of fluorescent DIFMU, which can be easily followed in continuous mode by a fluorescence reader. A great advantage of this substrate is its low pK_a value of 4.7 compatible with pH 7.0 during the reaction without prior alkalization (Sun et al. 1998). Furthermore, the substrate yields a higher fluorescence quantum than other frequently used fluorogenic substrates, such as 4-methylumbelliferyl phosphate. This substrate is accepted a recombinant fragment of human PTP1B (Welte et al. 2003). This finding has meanwhile been extended by a detailed kinetic and comparative analysis of PTP reactions using DIFMUP and other substrates (Welte et al. 2005). Compared to PNPP, DIFMUP is a better substrate for PTP1B as reflected in both its lower K_m and higher turnover number. However, dephosphorylation of a phosphotyrosine-containing peptide derived from the IR is even more efficient, indicating the requirement of amino acids adjacent to the phosphoamino acids.

DIFMUP is accepted by other PTP from different families. These include CD45, PTPα, SHP2, YOP, LAR, and TC-PTP. For these PTP a clear relationship between the relative fluorescence signal and the enzyme concentration is detected, which, however, with regard to the protein amount required differed by two orders of magnitude between LAR, TC-PTP, CD45, YOP (50–500 µg) and PTPα, SHP2 (0.5–2 µg) with PTP1B and the closely related TC-PTP showing the highest affinity for DIFMUP (Welte et al. 2005). These findings hint at subtle differences in the catalytic sites between these PTP for hydrolysis of optimally bound DIFMUP. Taken together, differences in the substrate recognition and catalytic sites of the various PTP are presumably monitored in the course of DIFMUP binding and cleavage. In contrast, no major kinetic differences between a number of phosphatases were reported for the hydrolysis of 3,6-fluorescein diphosphate and other fluorogenic substrates (Huang et al. 1999, Wang et al. 1999), arguing for similar and more flexible binding modes to the substrate recognition and catalytic sites of these apparently more unspecific substrates.

The search for inhibitors of PTPs requires a robust test system to assay a large number of compounds for a multitude of different enzymes. A novel non-peptidic inhibitor, a benzooxathiazoldioxide derivative (Petry et al. 2002, Liu et al. 2002) exhibits in different PTP1B assays using either DIFMUP, PNPP, or the IR phosphopeptide as substrate an IC_{50} of 3.8, 5.1 and 3.9 µM, respectively. DMSO used as solvent for the inhibitors did not affect cleavage of DIFMUP to up to 4% final concentration during the assay, reflecting the robustness of the assay.

PTP all share a nucleophilic cysteine residue located in the catalytic cleft, which is sensitive to oxidation or covalent modification (Zhang 2003, Johnson et al. 2002). Therefore, characterization of the nature of their inhibition by small-molecule inhibitors is important, which requires detailed kinetic studies. The possibility of continuous measurement of DIFMUP hydrolysis allows rapid characterization of the reversible nature of inhibition. For this, the enzyme is incubated in the absence or presence of inhibitor in the presence of 10 µM DIFMUP. After incubation for 10 min, when hydrolysis of DIFMUP stops due to substrate depletion (as revealed by approaching a plateau level of fluorescent DIFMU generated), a 10-fold excess of fresh DIFMUP is added to the reaction. This leads to complete reversion of inhibition of DIFMUP hydrolysis as reflected in the almost identical initial velocities of the reactions containing or lacking (control) the inhibitor after fresh DIFMUP has been added. The degree of inhibition is often found to depend strictly on the incubation time of the inhibitor with PTP1B prior to DIFMUP addition.

In summary, the high sensitivity and compatibility with a broad pH range of the fluorogenic DIFMUP assay provide advantages with regard to saving enzyme and miniaturization. Consequently, the DIFMUP assay will be useful for the development of throughput screening assays for a variety of physiologically important PTP as has been already been demonstrated for the receptor PTP, LAR (Pastula et al. 2003). In addition to its technical advantages, DIFMUP seems to reflect the binding mode of phosphotyrosine-containing peptide substrates more closely than the widely used non-peptidic substrates, PNPP and 3,6-fluorescein diphosphate. These characteristics may facilitate the future search for competitive and reversible PTP inhibitors as.

K.6.3.3.2 PTP Identification Using Substrate Trapping

PURPOSE AND RATIONALE

To understand fully the role of PTP in cellular function, in general, and in insulin signal transduction, in particular, it will be necessary to identify multitude of the physiological substrates of the individual members of the PTP family. It has shown in numerous studies that alteration of the nucleophilic Cys to Ser or Ala allows some PTPs to be isolated in a complex with their target substrates. Thus it appears that the Cys ⟶ Ser/Ala mutants may be utilized to isolate all combinations of PTP1B and its substrates. Additional alternative "substrate-trapping" PTP mutants have been identified by systematic mutational analysis of the invariant residues that were predicted from the crystal structure to be important in catalysis. In one such mutant form of PTP1B Asp-181, the residue that functions as a general acid to facilitate cleavage of the scissile P–O bond in the substrate, has been altered to Ala. Clearly, a definition of the spectrum of phosphotyrosyl proteins dephosphorylated by PTP1B *in vivo* will be a prerequisite for the elucidation of the physiological function of that enzyme. Such substrate identification or trapping may be achieved by the following method.

PROCEDURE

Immunoprecipitation, Immunofluorescence and Activity Assay

Cells transformed or transfected with vectors coding for PP are lysed 44–48 h after transfection in 50 mM Tris/HCl (pH 7.5), 5 mM EDTA, 150 mM NaCl, 1% Triton X-100, 5 mM iodoacetic acid, 10 mM sodium pyrophosphate, 10 mM NaF, 5 µg/ml leupeptin, 5 µg/ml aprotinin, 1 mM benzamidine (1 ml per 10-cm dish, 0.5 ml per 6-cm dish). PTP1B is immunoprecipitated from lysates with a monoclonal antibody (mAb). GST-PTP1B fusion proteins are precipitated with glutathione-Sepharose. Precipitates are collected by centrifugation (5,000 × *g*, 15 s, 4°C), washed four times with 0.7 ml of ice-cold lysis buffer, and finally heated at 95°C for 5 min in 60 µl of 2 × Laemmli sample buffer. mAb to phosphotyrosine are typically used for immunoblotting at the following concentrations: 4G10 (Upstate Biotechnology) 2 µg/ml, RC20b (Transduction Laboratories) 0.5 µ g/ml. The levels of expression of wild-type, C215A, and mutant PTP1B should always be equivalent. For immunofluorescence experiments, cells are seeded onto glass coverslips at $2.5–3 \times 10^5$ per 6-cm dish, transfected with 10 µg of PTP1B cDNA, wild-type or mutant, and processed for immunofluorescence staining at 36 h after transfection as described by Lorenzen and coworkers (1995).

EVALUATION

Considering that the substrate-trapping mutant, PTP have the ability, through interaction with phosphotyrosine residues, to increase the basal phosphorylation of their target substrates, one might expect them to promote ligand-independent signaling. However because these mutants form stable complexes with target substrates, they may also interfere with signaling *in vivo* in a manner analogous to the wild-type phosphatase. Thus, if the site of tyrosine phosphorylation on the substrate is critical for a protein-protein interaction required for signaling or if the substrate is an enzyme and the phosphorylation site is located close to the active site, steric hindrance resulting from binding of the mutant PTP may exert an effect that is functionally equivalent to dephosphorylation.

The successful application of this technique to identify additional substrates of PTP1B, and substrates of other PTP, will require expression of the Asp ⟶ Ala mutant PTP in cells and selection of an appropriate stimulus to trigger tyrosine phosphorylation of the substrate and accumulation of a complex with the mutant PTP. For PTP1B, IR is naturally abundant in myocytes, hepatocytes and adipocytes, and its basal rate of autophosphorylation generates enough tyrosine-phosphorylated protein to be trapped by PTP1B-D181A and to be detected by anti-phosphotyrosine immunoblotting. Its high molecular weight, characteristic of growth factor receptors, facilitates identification. Of the less-phosphorylated substrates of PTP1B, the finding that phosphorylation of p70 is enhanced upon cotransfection with v-src and D181A may enable enough of this substrate to be isolated to allow its identification by peptide sequencing. In addition to the use of trapping mutants to identify novel PTP substrates, it also may be possible to identify the site within the cell at which a PTP acts on a particular target, through colocalization of the substrate and the Asp ⟶ Ala mutant PTP.

These findings indicate that PTP1B can display substrate specificity *in vivo* and bolster the hypothesis that the subcellular targeting is an important mechanism by which such specificity is achieved. The substrate-trapping mutant introduced by Flint and coworkers (1997) is altered in a residue that is an invariant catalytic acid in all members of the PTP family. Therefore, the use of this mutation should be generally applicable to any PTP and may represent a powerful tool with which

to delineate the physiological substrate specificity of other members of the family, thereby revealing important insights into their function *in vivo* and their potential as drug targets.

K.6.3.3.3 Lipid Phosphatase Activity Measurement

PURPOSE AND RATIONALE

The methods currently available for the assay of lipid-metabolizing enzymes, in general, and lipid phosphatases, in particular, rely on the release of radioactive isotopes with some form of substrate/product separation step before quantitation. Estimation of cellular mass of phosphoinositides usually requires labeling of cells with [^{3}H]inositol or [^{32}P]orthophosphate followed by deacylation and HPLC analysis. Estimation of phosphoinositide mass in tissues is at present restricted to PtdIns(3,4,5)P_3 and requires extraction of the lipids and removal of the phosphoinositol head groups followed by a radiometric displacement assay which also requires synthesis of radiolabeled inositol(1,3,4,5)tetrakisphosphate. These assays also suffer from the drawback that the labeled substrates or precursors required are expensive and samples require extensive processing before analysis.

A novel assay for quantification of phosphoinositides based on their ability to bind specifically to certain pleckstrin homology (PH) domains (Gray et al. 2003). PH domains are the major intracellular targets of PtdIns(3,4,5)P_3, PtdIns(3,4)P_2, and several other phosphoinositides. Recently the number of characterized PH domains binding inositol lipids with a broad range of affinity and specificity has increased (Lemmon and Fergusson, 2001). Other recently discovered phosphoinositide binding domains, like the phox homology domain (Xu et al. 2001, Bravo et al. 2001) and FYVE domains (Gillooly et al. 2001), could potentially also be used in the assay formats described herein. Other critical components of the assay concept are biologically active short acyl chain phosphoinositides that recently have become commercially available. Important structural features of these include short acyl side chains (diC4 to diC8), rendering them water soluble, and the addition of biotin to the terminus of the *sn*-1 acyl chain while still allowing selective recognition of the inositol head group. Finally, sensitive non-radioactive detection of lipid/PH domain complexes relies on either TR-FRET using Lance reagents (e. g. Perkin–Elmer Wallac) or the recently introduced AlphaScreen technology (BioSignal Packard). In both cases, PtdIns(3,4)P_2 or PtdIns(3,4,5)P_3 present in samples is detected in competition assays by its ability to dissociate signal-generating complexes between PH domain, biotinylated lipid, and detection reagents. The assay systems presented here allow the assay of lipid phosphatases in a homogeneous format compatible with throughput screening and, in the case of the TR-FRET format, capable of real-time kinetic measurements.

PROCEDURE

Detection of Biotinylated Phosphoinositide/PH Domain Complexes

The GRP1 PH domain (amino acids 263 to 380) is PCR cloned from a mouse brain cDNA library as described by Gray and coworkers (1999). The protein is expressed from the pGEX 4T1 vector (Amersham Pharmacia) in *Escherichia coli* and affinity purified on glutathione–agarose using the manufacturer's standard protocols. The purified PH domains are labeled with Lance chelate according to the manufacturer's protocols.

AlphaScreen detection is performed in 384-well microtiterplates in 50 mM HEPES/KOH (pH 7.4), 50 mM NaCl, and 0.1% BSA. Biotinylated, short-chain (diC6) phosphoinositides and GRP1 PH–GST are added at 15 and 3.75 nM, respectively. Donor and acceptor AlphaScreen beads (Perkin–Elmer) are added at 5 µg/ml to a final volume of 50 µl. Plates are incubated in the dark for 5 h to ensure binding is complete and then read in an AlphaQuest AD instrument (Perkin–Elmer) using standard settings. The TR-FRET sensor complex consists of 50 mM HEPES (pH 7.4), 150 mM NaCl, 5 mM DTT, and 0.05% CHAPS with APC–streptavidin) 32 nM and 120 nM biotinylated, short-chain (diC6) phosphoinositides, and 35 nM Lance chelate labeled GST-PH domain. Alternatively the TR-FRET sensor complex contains 21 nM Lance chelate labeled anti-GST antibody and unlabeled PH domain in a final volume of 50 µl. All assays contain CHAPS at low concentration to prevent loss of lipids by adsorption onto plastic surfaces.

For all assays plates are read with the following settings: excitation 360–35 nm filter, emission 665 nm filter, dichroic filter 505 nm, PMT 1000 V set to digital sensitivity 2, 100 flashes per well, 10-ms interval between flashes, read 50 ms after flash, and integration 1000 ms.

The TR-FRET assays are conducted in 50 mM HEPES/KOH (pH 7.4), 150 mM NaCl, 5 mM $MgCl_2$, 5 mM DTT, 0.05% CHAPS (assay buffer) using a two-component reaction. The first component is a twofold-concentrated sensor complex consisting

of 32 nM APC–Streptavidin, 120 nM biotinylated diC6PtdIns(3,4,5)P_3, and 35 nM Lance chelate labeled GST–PH domain. Alternatively the sensor complex contains 21 nM Lance chelate labeled anti-GST antibody and unlabeled PH domain. The first component also contains 100 ng recombinant PI3-kinase γ in a final volume of 25 µl assay buffer. The second component contains the diC8PtdIns(4,5)P_2 at two times the required final concentrations and ATP at 100 µM again in 25 µl assay buffer. The assays are started by mixing the two components in a 96-well plate and reading at the required time intervals to obtain rates of reaction.

EVALUATION

A novel approach to quantitation of phosphoinositides in cell extracts and *in vitro* enzyme-catalyzed reactions using suitably tagged and/or labeled PH domains as probes (Gray et al. 2003). Stable complexes are formed between the biotinylated target lipid and an appropriate PH domain, and phosphoinositides present in samples are detected by their ability to compete for binding to the PH domain. Complexes are detected using AlphaScreen technology or time-resolved FRET. The assay procedure has been validated using recombinant PI3-K γ with diC8PtdIns(4,5)P_2 as substrate and general receptor for phosphoinositides-1 (GRP1) PH domain as a PtdIns(3,4,5)P_3-specific probe. This PI3-K assay is robust and suitable for throughput screening,. The approach is adaptable to lipid phosphatases as demonstrated by assays for PTEN, a phosphoinositide 3-phosphatase, which is measured using the same reagents but with diC8PtdIns(3,4,5)P_3 as substrate. PtdIns(3,4,5)P_3 present in lipid extracts of growth factor-stimulated Swiss 3T3 and HL60 cells is also detectable at picomole sensitivity. Gray and coworkers (2003) therefore proposed that similar procedures should be capable of measuring any known phosphoinositide present in cell and tissue extracts or produced in PK and PP assays by using one of several well-characterized protein domains with appropriate phosphoinositide-binding specificity

PtdIns(3,4,5)P_3 Measurements

Alternatively to the above method of quantification of phosphoinositides by using phosphoinositide-binding proteins, PtdIns(3,4,5)P_3 can be measured directly by prior radiolabeling as described by Blero and coworkers (2005). For this, cells (1.5×10^6), which have been pretreated with compounds/drug candidates, are cultured in 10% serum overnight. Cells are washed twice in medium without serum and twice in medium without either phosphate or serum. They are labeled for at least 4 h in medium with [^{32}P]orthophosphate (250 µCi/ml) but without serum. Cells may be stimulated with compounds/drug candidates during the labeling period, in addition or alternatively. The reaction is terminated by 5 ml cold PBS. Cells are lysed in 3.75 ml of 2.4 N HCl. Lipids are extracted in 3 ml methanol and 4.5 ml $CHCl_3$. After TLC and deacylation of the phosphoinositides, separation is performed by HPLC on Whatman SAX columns (Pesesse et al. 2001). Radioactivity is estimated with an online detector (e. g. Raytest, Germany). PtdIns(4,5)P_2 is also determined by labelling the cells with [^{3}H]inositol as reported by Serunian and coworkers (1991). The various 3-phosphorylated phosphoinositides standards have to be prepared in insulin-stimulated CHO-IR cells or in platelets as reported (Blero et al. 2001, Giuriato et al. 2003).

Measurement of Recombinant SHIP2 Activity

For the identification and characterization of compounds/drug candidates which directly interfere with the activity of SHIP2 and may represent future antidiabetic drugs the activity of SHIP2 can be assayed with cells transfected with recombinant SHIP2 by HPLC analysis of their phosphoinositides after radiolabeling *in vivo* according to the procedure of Wada and coworkers (2001).

In Vivo Generation of ^{32}P-Labeled Phosphoinositides and HPLC Analysis

The same numbers of 3T3-L1 adipocytes transfected with LacZ, wildtype WT-SHIP2, or phosphatase-defective ΔIP-SHIP2 are phosphate-starved overnight in phosphate-free DMEM, followed by serum starvation for 3 h. [^{32}P]orthophosphate (0.1 mCi/ml) is then added, and the cells are cultured for an additional 2 h. Following the labeling period, the cells are incubated without or with compounds/drug candidates for 15 min. The reaction is terminated by washing once with ice-cold PBS, followed by the addition of methanol/1 N HCI (1/1). The labeling of the cells with [^{32}P]orthophosphate is conducted at the same time in all three sets of transfected cells. Phospholipids are then extracted with chloroform. The extracted lipid is deacylated and subjected to amino-exchange HPLC using a Partisphere strong anion-exchange column as described previously (Serunian et al. 1991, Funaki et al. 1999). The PI(3,4)P2 and PI(3,4,5)P3 levels in the same sample for each cell line are measured within a single HPLC run. The radioactivity is detected with an on-line radiochemical detector.

MODIFICATION OF THE METHOD

Lin and coworkers (2003) reported about the separation of phospholipids, such as phosphoinositides, in microfluidic chip devices and its application to homogeneous high-throughput screening assays for lipid-modifying enzymes. The method takes advantage of the high-separation power of the microchips that separate lipids based on micellar electrokinetic capillary chromatography (MEKC) and the high sensitivity of fluorescence detection. The assay format consists of two steps: an on-plate enzymatic reaction using fluorescently labeled substrates followed by an on-chip MEKC separation of the reaction products from the substrates. The utility of the assay format for screening is demonstrated using phospholipase A_2 but may be extended to other phospholipases and lipid phosphatases with the advantages of avoidance of the use of radioactive substrates and tedious separation/washing steps and the detection of both substrate and product simultaneously.

K.6.3.3.4 Generic Assay for Protein Kinases (PK) and Phosphatases (PP) Based on Phosphate Release

PURPOSE AND RATIONALE

PK and PP produce or consume inorganic phosphate (P_i). Detection of an increase or decrease of the P_i concentration in the environment of these enzymes is a common way to monitor the enzymatic activity. Assays capable of measuring a change in the inorganic phosphate concentration serve as uniform readout for the activity of these enzymes (Ellen Chan and Swaminathan 1986, Brune et al. 1994). A number of colorimetric and fluorometric assays have been reported for the determination of inorganic phosphate (Itaya and Ui 1966, Kirkbright et al. 1972, Sebbon and Fynn 1973). Most of these assays are based on complexation reactions with the free phosphate. In addition, some methods for phosphate measurements have been developed based on the enzymatic conversion of phosphate and a substrate to a UV-absorbing product (Webb 1992, Ungerer et al. 1993). The disadvantages of all these methods are that they are slow, lack sensitivity or are sensitive to interfering compounds (Ellen Chang and Swaminathan, 1986, Tashima 1975, Hwang 1976).

To circumvent these problems, Brune and coworkers (1994, 1998) developed a continuous-flow phosphate assay. As an improvement Schenk and coworkers (2003) introduced a probe for the rapid measurement of P_i, in particular to follow its release in real time from enzymes such as phosphatases. The probe consists of phosphate-binding protein (PBP) labeled with a fluorophore, *N*-(2-(1-maleimidyl)ethyl]-7-(diethylamino)coumarin-3-carboxamide (MDCC). Upon binding of P_i under physiological conditions a ~13-fold increase in fluorescence is observed. The binding of Pi to MDCC-PBP is very fast, has a high affinity, and is very sensitive. These characteristics make the reaction between P_i and MDCC-PBP very suitable for dynamic P_i detection assays and thus for application in a continuous-flow phosphate assay. A further increase in sensitivity of a continuous-flow generic fluorescent assay for PK and PP was achieved by Schenk and coworkers (2003) by coupling to liquid chromatography (LC).

K.6.3.3.5 Cellular PTP Assays

The development of cell-based assays for the identification as well as evaluation of the biological activity of PTP inhibitors which positively affect insulin signaling and reduce insulin resistance (e. g. PTP1B, see above) is hampered by a number of issues. The typical functional readout for PTP1B inhibition has been to measure IR phosphorylation (see K.6.3.1.3). Yet, the increase in IR phosphorylation due to PTP1B inhibition is usually variable, dependent on cell type and at most two- to three-fold over controls, thus, making it unsuitable for screening. Furthermore, because many of the current potent PTP1B inhibitors contain a phosphonate or a phosphate mimetic they are highly charged and therefore cell permeability becomes an issue. Without a robust cellular functional readout and questionable cell permeability of PP inhibitors, it becomes difficult to reconcile the reason for the lack of activity of PTP inhibitors in cell-based assays. In order to circumvent some of these issues, yeast- and insect cell-based PTP1B assays have been developed.

K.6.3.3.5.1 Yeast-Based Assay

PURPOSE AND RATIONALE

Yeast has been used as a model system for the screening of various compounds/drug candidates. It provides a cellular environment to prevent PP oxidation and measuring yeast growth is both an easy and sensitive screening assay (Melese and Hieter 2002). In addition, yeast cell permeability has been shown not to be an issue in concentrating compounds internally, but like mammalian cells, the rate-limiting factor in internalization of compounds has been due to the function of

efflux pumps. v-Src, a tyrosine kinase from the Rous Sarcoma virus, is lethal when overexpressed in the yeast Saccharomyces cerevisiae (Brugge et al. 1987). the lethality of v-Src has been attributed to the hypertyrosine phosphorylation of multiple yeast proteins leading to mitotic dysfunction but the exact target responsible for the toxicity remains to be identified (Kornbluth et al. 1987, Florio et al. 1994, Trager et al. 1997). Yeast can be rescued from the v-Src lethality by co-expressing the catalytic domain of PTP1B (Florio et al. 1994). This rescue is presumably due to the activity of PTP1B in dephosphorylating the various yeast proteins phosphorylated by v-Src. Based on these observations Montalibet and Kennedy (2004) developed and optimized a yeast-based assay to screen for PTP1B inhibitors.

PROCEDURE

Yeast with leucine and uracil deficiency markers are transformed with the plasmids coding for v-Src and the appropriate PTP (here PTP1B) and the colonies formed three days after are transferred to leucine and uracil dropout media containing raffinose as the sole carbon source and grown overnight. Serial dilutions of the inhibitors are arrayed in 96-well plates containing leucine and uracil dropout media with 4% galactose. The plates are inoculated with the overnight yeast cultures at a final concentration of 10^6 per ml in the absence or presence of increasing concentrations of compounds/drug candidates (Hammonds et al. 1998). The wells are overlaid with mineral oil, incubated at 30°C and read periodically at 600 nm for 4 days. The growth curves generated are used to obtain EC_{50}-values for the putative PTP1B inhibitors.

EVALUATION

Based on the previous observation that co-expression of PTP1B can rescue yeast from v-Src lethality, Montalibet and Kennedy (2004) optimized the expression levels of PTP1B and v-Src such that inhibition of PTP1B activity results in growth interference. PTP1B catalytic activity was shown to be absolutely required for yeast growth since the catalytically inactive PTP1B mutants C215S and D181A failed to overcome the lethality of v-Src. A certain stoichiometry between PTP1B and v-Src expression is required to obtain a robust growth phenotype and at the same time to ensure sensitivity toward inhibitors. Screening can be carried out in 96-well plates and growth of th eliquid culture measured by absorbance at 600 nm. The PTP inhibitor, vanadate, specifically inhibited PTP1B-dependent growth in a concentration-dependent manner with an EC_{50} of 0.92 mM. This simple yeast growth interference assay may be useful for throughput screening for inhibitors of PTP1B, in particular, and PTP, in general.

K.6.3.3.5.2 Insect Cell-Based Assay

PURPOSE AND RATIONALE

Cromlish and coworkers (1999) described an intact cell-based assay for the discovery of cell-permeable, selective PTP inhibitors utilizing the baculovirus expression system, where a PTP of interest is expressed in Sf9 insect cells and a direct readout of the PP activity within these cells is obtained from the amount of hydrolysis of the cell-permeable substrate, *para*-nitrophenylpyrophosphate (pNPP).

PROCEDURE

Baculoviruses recombinant for the cDNA coding for the desired PTP (e. g. PTP1B) is prepared using the Bac-to-Bac Baculovirus Expression System and recovered from the supernatant medium from transfected Sf9 insect cells after three rounds of amplification to up to a total viral stock volume of 500 ml. Sf9 cells are infected with the recombinant or control baculovirus (Cromlish and Kennedy 1996), collected 29 hpi by centrifugation ($48 \times g$, 5 min), washed once in assay buffer (Hanks' solution buffered with 15 mM HEPES/KOH, pH 7.4) and re-centrifuged ($21 \times g$, 10 min). The cells are resuspended gently in assay buffer and examined using a hemocytometer and microscope for cell density as well as trypan blue exclusion. Assays are performed using a pipetting robot, programmed to mix gently after each addition. 200-µl Hanks' solution containing the cells. Following a 15-min incubation with compounds/drug candidates at 37°C, the cells are challenged with 1–50 mM of tissue culture-grade pNPP for 15 min. The cells are centrifuged ($410 \times g$, 3 min, 4°C). 100-µl samples of the supernatants are transferred to fresh clear polystyrene 96-well plates, and the amount of hydrolysis of pNPP is determined spectrophotometrically at OD of 405 nm. The pNPP hydrolysis window obtained between PTP-expressing cells and control-infected cells represents the amount of phosphatase activity due to the PTP of interest.

EVALUATION

Inhibitions are calculated by comparing pNPP hydrolysis of the inhibitor-treated PTP-expressing cells with that of DMSO-treated PTP-expressing cells. For the PTP Sf9 cell-based assay to be useful in screening for

PTP inhibitors, it is necessary to harvest the cells at a time point when sufficient amounts of the protein of interest are produced, yet the cells are healthy and viable prior to the deleterious effects associated with the later stages of the viral infection.

K.6.3.3.5.3 Bacterial Cell-Based Assay

PURPOSE AND RATIONALE

Senn and Wolosiuk (2005) developed a high-throughput screening assay for the detection of phosphatase activity in bacterial colonies overexpressing mammalian phosphatases. Unlike the insect cell-based method, this procedure is compatible with the use of physiological substrates but nevertheless is versatile, since it is based on the detection of the common product of all phosphatase reactions, P_i. In this method, substrates diffuse from a filter paper across a nitrocellulose membrane to bacterial colonies located on the opposite face, and then the reaction products flow back to the paper. Finally, a colorimetric reagent discloses the presence of orthophosphate in the filter paper.

PROCEDURE

Escherichia coli cells are transformed with vectors coding for the corresponding PP under a strong inducible promoter and after appropriate dilution grown directly over a nitrocellullose membrane that lay on Luria-Bertani (LB) agar supplemented with 100 µg/ml ampicillin. When the diameter of colonies is 1 mm (~24 h), the expression of the PP is induced by spreading 0.2 ml of inducer (e. g. 40 mM IPTG, 10% agarose) onto the agar surface. After 3 h, the nitrocellulose membrane (pore size 0.2 µm; Bio-Rad, USA) is withdrawn from the Petri dish and placed with bacteria facing up for 10 min on a Whatman filter paper soaked in water. After this washing step has been repeated twice, the nitrocellulose membrane is similarly placed for 5–10 min on another Whatman filter paper previously soaked in the corresponding solution for catalysis. The catalytic solution employed to detect the PP activity is 50 mM Tris/HCl (pH 7.8), 10 mM $MgCl_2$, and 0.1–1 mM phosphopeptide designed according to the consensus sequence for the relevant PP. The nitrocellulose membrane is withdrawn and can be stored for additional PP assays. The filter paper is first dipped gently for 2 s into the reagent (1.2 N sulfuric acid, 0.5% ammonium molybdate, 2% ascorbic acid) of Chen and coworkers (1956) for the assay of P_i and subsequently placed onto an absorbent paper to remove the excess of liquid until blue spots appeared.

EVALUATION

The bacterial cell-based procedure is sensitive enough to detect endogenous phosphate activity of bacteria under some experimental conditions. Although this feature appears to be useful for searching bacterial phosphatases, it can be a drawback when studying cloned mammalian PP. In those cases, *E. coli* strains with diminished phosphatase activity at the pH of interest should be used. In addition, plasmids of a high number of copies could be employed to reduce the time of catalysis and the background signal generated by chromosomal phosphatases. In most cases, the differentiation between the cloned PP activity and background phosphatase activity should be feasible.

Many currently used high-throughput procedures for the detection of compounds modulating PP activity are based on non-physiological substrates holding a colored or fluorescent moiety that facilitates the analysis of the reaction (Wahler and Reymond 2001) but generally impairs the intrinsic activity (Goddard and Reymond 2004). The bacterial cell-based assay for phosphatase activity offers the advantages of the use of specific protein or peptide substrates and the possibility of testing different experimental conditions using the same bacterial lawn. This feature may be helpful for the evaluation of the selectivity of PP.

K.6.3.4 Expression, Phosphorylation, Activity and Interaction of Insulin Signaling Components

PURPOSE AND RATIONALE

Signal transduction from the cell surface to the nucleus was found to occur predominantly by serine/threonine- and tyrosine-specific PK participating in cascades involving phosphorylation of multiple substrates. The role of protein phosphorylation in signal transduction is well characterized in the case of the insulin signaling cascade in insulin-responsive target cells, such as liver, muscle and adipose cells (for reviews see Chen 2006, White et al. 1994, 1998, 2003).

In the past decade, it has been increasingly recognized that insulin resistance is associated with chronic, low-grade systemic inflammation. These celllar inflammatory responses are thought to be mediated by serine/threonine phosphorylation by PK, such as IKKβ (Yuan et al. 2001, Gao et al. 2002), JNK1 (Hirosumi et al. 2002), PKCθ (Yu et al. 2002), or direct interaction with inhibitory proteins, such as SOCS (Mooney et al. 2001, Steppan et al. 2005, Ueki et al. 2004), of key components of insulin signaling, such as the IRS proteins, which thereby undergo inactivation or downregulation. The molecular mechanism of insulin-like compounds/drug candidates can be studied in appropriate assay systems monitoring the phosphorylation state or protein-protein interaction of the individual insulin signaling components.

K.6.3.4.1 Preparation of Cytosolic Extracts

PROCEDURE

Cultured Adipocytes

Cultured mouse or human adipocytes are incubated with insulin/compounds/drugs in 12- or 24-well plates for 10–20 min, then washed twice with 50 mM HEPES/KOH (pH 7.5), 150 mM NaCl, 1 mM $CaCl_2$, 1 mM $MgCl_2$, 10 mM EDTA, 10 mM glycerol-3-phosphate, 10 mM $Na_4P_2O_7$, 2 mM Na_3VO_4, 100 mM NaF. Cells are solubilized in the above buffer containing 1% (by vol.) Triton X-100, 0.1% sodium deoxycholate, 10% glycerol and protease inhibitors (20 µg/ml leupeptin, 10 µg/ml pepstatin A, 50 µg/ml aprotinin, 10 µM E-64, 0.5 mM PMSF = lysis buffer) by scraping with a Teflon policeman (adherent cells). Total lysates are centrifuged (25,000 × *g*, 20 min, 18°C). The infranatant is aspirated taking care to avoid contamination by the upper fat layer and recentrifuged to obtain the defatted cell lysate (cytosolic extract).

Primary Rat Adipocytes

Adipocytes ($1–3 \times 10^6$ cells/ml) are incubated with insulin/compounds/drug candidates and then separated from the medium by flotation and lysed in 1 ml of chilled buffer containing 20 mM Tris/HCl (pH 7.4), 150 mM NaCl, 10% glycerol, 2 mM EDTA, 1 mM Na_3VO_4, 50 mM $Na_4P_2O_7$, 10 mM NaF, 10 mM glycerol-3-phosphate, 0.2 mM PMSF, 20 µg/ml leupeptin, 10 µg/ml pepstatin, 25 µg/ml aprotinin by

10 strokes in a loose-fitting Teflon-in-glass homogenizer at 15°C. The fat-free homogenate, prepared by centrifugation (500 × *g*, 3 min, 15°C), is supplemented with Triton X-100 (1% final conc.) and sodium deoxycholate (0.5% final conc.), incubated for 30 min at 4°C and finally centrifuged (13,000 × *g*, 10 min).

Liver

Portions of frozen liver (0.2–1 g wet weight), which has been perfused as described (see K.5.2.1) are homogenized in a buffer containing 50 mM HEPES/KOH (pH 7.4), 140 mM NaCl, 250 mM sucrose, 1 mM $MgCl_2$, 1 mM $CaCl_2$, 2 mM EDTA, 2.5 mM Na_3VO_4, 10 mM glycerol-3-phosphate, 20 mM $NaPP_i$, 20 mM NaF, 1 mM phenylphosphate, 5 µM okadaic acid (sodium salt), 1% Nonidet P-40, 10% glycerol and protease inhibitors (10 µg/ml leupeptin, 5 µg/ml pepstatin A, 75 µg/ml aprotinin, 100 µM benzamidine, 2 µg/ml antipain, 10 µg/ml soybean trypsin inhibitor, 5 µM microcystin, 5 µM E-64, 0.2 mM PMSF) using an Ultraturrax T25 basic (three 10-s cycles at 2,000 rpm on ice) and then a tight-fitting Teflon-in-glass homogenizer (5 strokes at 500 rpm on ice). The total homogenate is centrifuged (48,000 × *g*, 30 min, 4°C). The supernatant is carefully removed to avoid contamination with the upper fat layer and re-centrifuged. The fat-free supernatant obtained is stored in liquid N_2 and used as cytosolic extract (3–5 mg protein per ml).

Diaphragm

After incubation with insulin/compounds/drug candidates, the hemidiaphragms (80–100 mg wet weight) are rapidly liberated from the rib cage, rinsed once with homogenization buffer (25 mM Hepes/KOH, pH 7.4, 140 mM NaCl, 10% glycerol, 1 mM EDTA, 1 mM sodium vanadate, 50 mM sodium pyrophosphate, 100 mM NaF, 10 mM glycerol-3-phosphate, 0.2 mM PMSF, 10 µg/ml leupeptin, 10 µg/ml pepstatin, 5 µg/ml antipain, 25 µg/ml aprotinin), frozen in liquid N_2 and then homogenized in 2 ml of ice-cold homogenization buffer in a porcelain mortar on ice. After centrifugation (1,500 × *g*, 10 min, 4°C), the fat-free supernatant is supplemented with Triton X-100 (0.5% final conc.), incubated (30 min, 4°C) and centrifuged (18,000 × *g*, 20 min, 4°C) to yield the cytosolic extract.

Skeletal Muscle

Rats at week 10 of age and housed in a temperature-controlled room (22°C) with a 12:12-h light-dark cycle with free access to chow and water are deeply anesthetized with an i.p. injection of pentobarbital sodium (50 mg/kg). Intact epitrochlearis muscles (type II muscle consisting primarily of both type IIa and IIb fibers) and strips of soleus muscles (consisting primarily of type I fibers) are prepared (~30 mg). Soleus strips and epitrochlearis muscles are incubated for 60 min at 37°C in 3 ml of oxygenated (95% O_2/5% CO_2) KHB containing 14 mM $NaHCO_3$ and then for 10 min with KHB supplemented with 8 mM glucose, 32 mM mannitol, 0.1% BSA in the presence of insulin/compounds/drugs. Thereafter, the muscles are rinsed for 10 min at 37°C in 3 ml of oxygenated KHB containing 40 mM mannitol, 0.1% BSA, then trimmed of fat and connective tissue, quickly frozen between aluminium blocks cooled with liquid N_2 and weighed. Frozen muscles are homogenized in 8 vol. of ice-cold lysis buffer (50 mM HEPES/KOH, pH 7.5, 150 mM NaCl, 20 mM sodium pyrophosphate, 20 mM glycerolphosphate, 10 mM NaF, 2 mM Na_3VO_4, 2 mM EDTA, 1% TX-100, 10% glycerol, 1 mM $MgCl_2$, 1 mM $CaCl_2$, 10 µg/ml aprotinin, 10 µg/ml leupeptin, 0.5 µg/ml pepstatin, 2 mM PMSF). Lysates are incubated on ice for 20 min and then centrifuged (13,000 × *g*, 20 min, 4°C) to yield the cytosolic extract.

K.6.3.4.2 Immunoprecipitation

Up to 1 -ml portions of cytosol (equal amounts of protein) are precleared (30 -min incubation at 4°C, 2-min centrifugation at 10,000 × *g*) with protein A/G-Sepharose (50 mg, Pharmacia) and then supplemented with typically 2–10 µg/ml appropriate antibodies: anti-IRS-1 (rabbit, polyclonal, protein A-purified, raised against a peptide corresponding to amino acids 1220–1235 of rat IRS-1, Upstate Biotechnology), anti-IRS-2 (raised against peptide mixture corresponding to amino acids 618–747 and 976–1094 of mouse IRS-2), anti-IRβ (raised against a peptide corresponding to the 100 carboxy-terminal amino acids of human IR, Upstate Biotechnology), anti-GSK-3β (mouse monoclonal, protein G-purified, raised against a peptide corresponding to amino acids 203–219 of Drosophila GSK-3β, Upstate Biotechnology, preadsorbed on protein A-Sepharose). After incubation (4 -20 h, 4°C, end-over-end rotation) and centrifugation (10,000 × *g*, 2 min, 4°C), the collected immune complexes are washed twice with 1 ml each of immunoprecipitation buffer (50 mM HEPES/KOH, pH 7.4, 500 mM NaCl, 100 mM NaF, 10 mM EDTA, 20 mM glycerol-3-phosphate, 10 mM NaP_i, 2.5 mM Na_3VO_4) containing 1% Nonidet P-40 (omitted for sequential immunoprecipitation), then twice with 1 ml each of im-

munoprecipitation buffer containing 150 mM NaCl and 0.1% NP-40 and once with 1 ml of immunoprecipitation buffer containing 150 mM NaCl and twice with immunoprecipitation buffer lacking detergent and salt. The washed immune complexes are finally suspended in 50 µl of Laemmli buffer (2% SDS, 5% 2-mercaptoethanol), heated (95°C, 2 min) and centrifuged. The supernatant samples are analyzed by SDS-PAGE. 4–12% Bis-Tris precast gel, pH 6.4, morpholinoethanesulfonic acid (MES)/SDS running buffer, e. g. Novex) under reducing conditions. For sequential immunoprecipitation, the supernatant samples (50 µl) are supplemented with 1 ml of immunoprecipitation buffer containing 1% NP-40 and 1–10 µl of the relevant antiserum. After incubation (12 h, 4°C), 50 µl of protein A-Sepharose (100 mg/ml in immunoprecipitation buffer) is added and the incubation continued (4 h, end-over-end rotation). The immunecomplexes are collected, washed and processed for SDS-PAGE.

K.6.3.4.3 Immunoblotting

Immunoblotting is performed as described previously by Towbin (1979), Frick and coworkers (1998) and Müller and coworkers (2000) with minor modifications. Briefly, after SDS-PAGE and electrophoretic transfer of the proteins (2 h, 400 mA in 20% methanol, 192 mM glycine, 25 mM Tris, 0.005% SDS) to PVDF membranes (Immobilon, Millipore, Germany), the blocked membrane (1 h in blotting buffer containing 20 mM Tris/HCl, pH 7.6, 150 mM NaCl, 0.05% Tween 20, 0.1% Brij, 0.01% NP-40 and supplemented with either 1% ovalbumin or 1% BSA or 5% nonfat dried milk according to manufacturer's instructions and the unspecific background signal obtained) is incubated (2 h, 25°C) with the appropriate antibodies (often 1:200–1:5,000). The membranes are washed (four times with Tris-buffered saline (TBS) containing 1% (by vol.) Nonidet-P40 and 0.5% Tween 20, twice with TBS containing 0.5% Tween 20, three times with TBS containing 0.05% Tween 20, twice with TBS). After incubation (1 h, 25°C) of the membranes with either [^{125}I]protein A (5 µCi/ml, Amersham-Pharmacia) or secondary goat anti-mouse or anti-rabbit antibody conjugated with horse-radish peroxidase (HRP, Santa Cruz Biotechnology) in the same blocking medium, the membranes are washed five times and then subjected in case of the radioactive method to autoradiography (Kodak X-Omat AR) or phosphorimaging (Molecular Dynamics, Storm 860) or in case of the non-radioactive method to an enhanced chemiluminescence (ECL, Amersham-Pharmacia or Renaissance Chemiluminescence Detection System, NEN/DuPont) detection system.

EVALUATION

The band intensities on the autoradiographs are quantified on a scanning densitometer. The ECL-blots are visualized by a LumiImager (Roche) and quantified using IMAGEQUANT software (Roche). The recovery in the amounts of immunoprecipitated protein is corrected (data on fold- or % stimulation) for the amount of protein actually applied onto the gel as revealed by homologous immunoblotting. Each experiment should be performed with samples from at least four different cell incubations or tissue preparations with antibody incubations/blots performed in triplicate, each.

K.6.3.4.4 Immunecomplex Kinase Assay

PURPOSE AND RATIONALE

In case of high expression and/or high specific activity, the relevant PK can be assayed directly using total cytosolic extracts from cells/tissues which have been incubated with compounds/drug candidates, provided the assay used displays sufficient specificity (e. g. due to specific substrate peptide). However, in most cases the relevant kinase has to be enriched by specific immunoprecipitation (see K.6.3.4.2) using antibodies which do not interfere with the subsequent measurement of the PK activity within the immunecomplex. This immunecomplex kinase assay also eliminates the need for specific peptide or protein substrates not accepted by PK which may be contained in the total cytosolic extracts used and lead to unspecific activity measurements.

The immunecomplexes prepared as described (see K.6.2.9.2) are washed in kinase buffer (50 mM HEPES/KOH, pH 7.4, 100 mM NaCl, 5 mM $MnCl_2$, 1 mM $MgCl_2$, 0.5 mM DTT, 20 mM NaF, 1 mM Na_3VO_4) and then suspended in 25 µl of kinase buffer. The PK reactions are started by addition of ATP (unlabeled or ^{32}P- or ^{33}P-labeled, final conc. 5 µM, 0.2 mCi/ml to up to 100 µM, 0.5 mCi/ml) and incubated (often 3–15 min, 22°C) in the absence (autophosphorylation) or presence of recombinant substrate protein (often 0.1–1 µg) or peptide (5–25 µg) in a final volume of 50 µl. Autophosphorylation reactions are terminated by addition of 50 µl of ice-cold 2-fold stop buffer (100 mM HEPES/KOH, pH 7.4, 300 mM NaCl, 200 mM ATP, 0.1% Triton X-100) and wash-

ing of the beads (10,000 × *g*, 2 min, 4°C) twice with 1 ml of stop buffer and once with 1 ml of stop buffer lacking detergent and salt prior to addition of 20 µl of Laemmli sample buffer and boiling (95°C, 5 min). Substrate phosphorylation reactions are terminated by addition of 20 µl of 4-fold concentrated Laemmli sample buffer and boiling. The phosphoproteins contained in the supernatant of a spin (10,000 × *g*, 5 min) are separated on SDS-PAGE (10% Bis-Tris resolving gel, morpholinopropanesulfonic acid/SDS running buffer) and analyzed by phosphorimaging directly (use of [$^{32/33}$P]ATP) or after immunoblotting with anti-phosphotyrosine or anti-pan-phosphoserine/ threonine antibodies (use of unlabeled ATP). Under these conditions the PK reactions are linear with time for the assay period. Protein concentration is determined by the BCA protein assay with crystalline BSA as standard. Phosphorimaging is performed with a phosphorimager Storm 860 and quantitatively evaluated using ImageQuant software (Molecular Dynamics).

EVALUATION

Differences in recovery in the amounts of immunoprecipitated protein during a specific experiment are corrected in each case (data on fold- or % stimulation) for the amount of protein actually applied onto the gel by homologous immunoblotting. The data should be confirmed by running independent experiments with different batches of cytosolic fractions prepared from independent cell/tissue incubations, each, with two to five parallel independent immunoprecipitation/kinase assay analyses.

K.6.3.4.4.1 Phosphatidylinositol-3′-Kinase (PI3-K)

Portions of the anti-IRS-1/2 immunecomplexes (see K.6.3.4.4) are assayed for PI3-K activity by incubating in 100 µl of 20 mM Tris/HCl (pH 7.0), 50 µM [γ-^{32}P]ATP (5 µCi), 10 mM $MgCl_2$, 2 mM $MnCl_2$, 100 mM NaCl, 2 mM EDTA, 0.5 µM wortmannin (for control incubations, only) containing 10 µg of phosphatidylinositol and 1 µg of phosphatidylserine (Avanti Polar Lipids) for 15 min at 22°C. After addition of 20 µl of 8 M HCl and 160 µl of a 1/1 mixture of methanol/chloroform, the extracted phospholipids are resolved by TLC on plates (Silica Gel 60, Merck, Darmstadt) coated with 1% oxalate and developed in chloroform/methanol/water/ammonia (60/47/11.3/3.2, by vol.). Radiolabeled phosphatidylinositol-3-phosphate (PI3-P, average R_f value of 0.41 under these conditions) is visualized by autoradiography and quantitated by phosphorimage analysis. For calculation of wortmannin-sensitive PI3-K, all values are corrected for PI3-P radiolabeled in the presence of wortmannin.

K.6.3.4.4.2 Phosphoinositide-Dependent Kinase-1/2 (PDK-1/2)

Akt-1/2 represents the major substrate of PDK-1/2 within the insulin signaling cascade (see K.6.3). Its phosphorylation can therefore be used as measure for specific increases in PDK-1/2 activity in response to insulin/compounds/drug candidates. For this, cytosolic extracts are prepared (see K.6.3.4.1) from cells/tissues which have been incubated with insulin/compounds/drug candidates. After centrifugation (150,000 × *g*, 60 min, 4°C), 1-ml portions of the supernatant are immunoprecipitated with 10 µg anti-Akt-1/2 antibodies coupled to protein G-Sepharose beads. The immunoprecipitates are washed and finally suspended in 50 µl of Laemmli sample buffer (2% SDS), heated (95°C, 2 min) and centrifuged (12,000 × *g*, 2 min). After dilution with 1 ml of immunoprecipitation buffer containing 10 µg/ml aprotinin, 20 µg/ml pepstatin, 10 µg/ml leupeptin, 1 mM PMSF and subsequent centrifugation again (12,000 × *g*, 2 min), the supernatant is supplemented with 20 µg of a kit containing four different monoclonal anti-phosphoserine antibodies (Biomol, Hamburg, Germany; clones 1C8, 4A3, 4A9, 4H4) and the monoclonal anti-phosphothreonine antibodies (clone 1E11). After incubation (4 h, 4°C), the antibodies complexes are precipitates during a 2-h incubation with 50 µl of 50 mg protein A-Sepharose per ml of 50 mM HEPES/KOH (pH 7.4), 0.1% Triton X-100. The collected immunoprecipitates (12,000 × *g*, 2 min) are washed three times with 1 ml each of 50 mM HEPES/KOH (pH 7.4), 150 mM NaCl, 100 mM NaF, 0.2 mM Na_3VO_4, 0.1% SDS, 1% Triton X-100 and finally twice with buffer lacking Triton X-100. Phosphoproteins are eluted from the washed precipitates by incubation with 500 µl of 50 mM HEPES/KOH (pH 7.4) containing 50 mM *p*-nitrophenylphosphate for 30 min at 4°C. The supernatants obtained by centrifugation are precipitated with TCA. The acetone-washed pellets are suspended in 50 µl of Laemmli sample buffer and analyzed by SDS-PAGE. Phosphorylated Akt-1/2 is detected by immunoblotting with anti-Akt-1/2 antibodies as described above. In case of high expression/phosphorylation of Akt, immunoblotting with the anti-AktpS473 (PDK-1) or pT307 (PDK-2) antibody (1:400) may be sufficient for the direct detection of Akt phosphorylation and consequently for evaluation of PDK-1/2 activity.

K.6.3.4.4.3 Protein Kinase B (Akt-1/2)

Cytosolic fractions prepared from cells/tissues which have been incubated with insulin/compounds/drug candidates. 900 µl of cytosolic extract are incubated with 100 µl of anti-Akt-1/2 antibody (raised in rabbits by immunization with a synthetic peptide corresponding to residues 465–480 of the human PKB sequence, 10 µg pre-coupled to 10 mg of protein A-Sepharose in 100 µl of lysis buffer for 2 h at 4°C). The immunoprecipitates are collected by centrifugation (12,000 × *g*, 2 min, 4°C), washed twice with 1 ml each of Akt assay buffer (20 mM Mops, pH 7.0, 1 mM EDTA, 1 mM EGTA, 10 mM $Na_4P_2O_7$, 50 mM NaF, 1 mM Na_3VO_4, 1 µM microcystin, 1 µM okadaic acid, 10 µg/ml pepstatin, 25 µg/ml leupeptin, 1 µg/ml antipain, 10 µg/ml aprotinin, 0.1 mM PMSF, 0.01% Brij35, 5% glycerol) containing 1% Nonidet P-40, 0.5 M NaCl and three times with 1 ml each of assay buffer lacking salt and detergent. The immunoprecipitates are finally resuspended in 45 µl of PKB assay buffer containing 10 mM $MgCl_2$, 1 mM DTT, 2.5 µM PKA inhibitor peptide (IP_{20}) and either the synthetic substrate peptide, Crosstide (100 µM final conc.), which is based on the sequence surrounding the serine phosphorylation site of GSK-3 (Ser21 of GSK-3α and Ser9 of GSK-3β) or alternatively, histone 2B (150 µg/ml). The assay is initiated by the addition of 5 µl of [γ-^{32}P]ATP (50 µM, 4 µCi) and terminated after incubation for 15 min at 30°C by placing the test tubes on ice. For determination of Crosstide phosphorylation, the 10-µl portions of the samples are adsorbed on p81 phosphocellulose paper and extensively washed as described for the MAPK assay (see K.6.3.4.4.6). The radioactivity associated with the paper is counted by liquid scintillation counting. For determination of histone 2B phosphorylation, the samples are separated on a 12% SDS-PAGE. The autoradiogram is quantitated by densitometry. Exposure times are chosen which guarantee that the intensity of the bands is linearly related to the quantity of protein contained in the bands.

K.6.3.4.4.4 Glycogen Synthase-3β (GSK-3β)

GSK-3β activity is determined using immunecomplexes from cytosolic extracts of treated cells/tissues (see K.6.3.4.1 and K.6.3.4.2) with phospho-glycogen synthase peptide 2 (P-GS 2) as a substrate (Eldar-Finkelman et al. 1996, Wang et al. 1994). The GSK-3β immunecomplexes (with antibodies raised in sheep by immunization with a synthetic peptide corresponding to amino acids 471–483 of rat GSK-3β and coupled to BSA) are precipitated with 2 mg of anti-sheep IgG coupled to agarose in 50 µl of lysis buffer (under rotation for 2 h at 4°C). The beads are collected by centrifugation (12,000 × *g*, 2 min), washed once with 1 ml of 100 mM Tris/HCl (pH 7.4) containing 0.2% Nonidet P-40, 0.5 M NaCl, 0.5 M LiCl, once with 10 mM Tris/HCl and twice with GSK-3 assay buffer (20 mM HEPES/KOH, pH 7.4, 10 mM $MgCl_2$, 1 mM DTT, 10 mM NaF, 10 mM $Na_4P_2O_7$) and then suspended in 20 µl of assay buffer containing 0.4 mg/ml BSA, 30 µM [γ-^{32}P]ATP (3,000 Ci/mmol, 1 mCi/ml) and 20 µM P-GS2. After incubation (15 min, 30°C), the reactions are terminated by addition of 20 µl of 20% TCA and centrifugation (10,000 × *g*, 5 min). Then, 15-µl portions of the supernatant are spotted on 1 × 1-cm pieces of Whatman P81 phosphocellulose paper. 20 s later, the filters are washed five times with 0.75% phosphoric acid (for at least 5 min each time) and once with acetone. The dried filters are counted for radioactivity in the presence of 5 ml of scintillation fluid (e. g. ACS, Amersham-Pharmacia). $^{32}P_i$ incorporation into the negative control peptide (glycogen synthase peptide 2 [Ala21]) is subtracted from values obtained using P-GS 2. No activity is typically measured with immunoprecipitates using non-immune IgG. In some experiments recombinant PP2A inhibitor (PP2AI, 1 µg, Calbiochem) is used as substrate instead of P-GS1. In this case the PK reaction (conditions as above) is terminated by rapid centrifugation (12,000 × *g*, 1 min, 4°C) and separation of the supernatant from the immunecomplex pellet. The supernatant of a precipitation (10% TCA for 1 h on ice, 15,000 × *g*, 15 min, 4°C) containing the phosphorylated PP2AI is suspended in 50 µl of 2-fold Laemmli sample buffer, heated (95°C, 5 min) and centrifuged (12,000 × *g*, 2 min). The supernatants are run on SDS-PAGE and phosphorylated PP2AI and GSK-3 are visualized by autoradiography and quantitated by phosphorimaging.

K.6.3.4.4.5 MAPK/ERK Kinase (MEK)

MEK activity is determined using immunecomplexes from cytosolic extracts of treated cells/tissues (see K.6.3.4.1 and K.6.3.4.2) with recombinant MAPK/ERK2 (Upstate Biotechnology) as substrate. The assay mix contains 4 mM MOPS buffer (pH 7.5), 5 mM glycerol-3-phosphate, 1.25 mM EGTA, 0.2 mM sodium orthovanadate, 0.2 mM DTT, 10 mM $MgCl_2$, 0.15 mM ATP, and 0.04 µCi/µl [γ-^{32}P]ATP. The concentration of MAPK/ERK2 (0.5 ng/µl) is chosen to

approximate the concentration of MAPK/ERK2 that would be assayed in rat adipocyte cell lysates.

K.6.3.4.4.6 Mitogen-Activated Protein Kinase (MAPK)

MAPK activity is determined using immunecomplexes from cytosolic extracts of cells/tissues treated with compounds/drug candidates (see K.6.3.4.1 and K.6.3.4.2) with myelin basic protein (MBP) as substrate. Adipocytes incubated with insulin/compounds/drugs are washed with KRP-HEPES by flotation and then lysed in 1 ml of 50 mM HEPES/KOH (pH 7.2), 100 mM NaCl, 2 mM EDTA, 1% Nonidet P-40, 0.5 mM Na_3VO_4, 40 mM *p*-nitrophenylphosphate, 10 mM glycerol-3-phosphate, 10 mM NaF, 0.2 mM PMSF, 25 µg/ml leupeptin, 25 µg/ml aprotinin by incubation for 30 min on ice and vigorous vortexing three times for 10 s at 10-min intervals. Lysates are cleared by centrifugation (12,000 × *g*, 10 min, 4°C). The infranatant below the fat cake is removed using a syringe, re-centrifuged and used for measurement of MAPK by addition of 250-µl portions to 250 µl of protein A-Sepharose (50 mg/ml of 50 mM HEPES/KOH, pH 7.2, 100 mM NaCl), which had been precoupled with 10 µl of rabbit anti-p42MAPK antiserum (raised against rat p42MAPK, Upstate Biotechnology) and 5 µl of rabbit anti-p44MAPK antiserum (raised against the carboxyl-terminal 14 amino acids of rat p44MAPK), and incubation for 2 h at 4°C. The beads are collected by centrifugation (12,000 × *g*, 2 min, 4°C), washed three times with 1 ml each of lysis buffer and three times with 1 ml each of 10 mM HEPES/KOH (pH 7.4), 10 mM $MgCl_2$ and then resuspended in 45 µl of kinase buffer (50 mM glycerol-3-phosphate, pH 7.3, 5 mM $Na_4P_2O_7$, 10 mM NaF, 0.5 mM EDTA, 15 mM $MgCl_2$, 2 mM DTT, 4.4 mM PK inhibitor peptide) containing 0.5 mg/ml MBP. The kinase reaction is initiated by the addition of 5 µl of 0.5 mM [γ-^{32}P]ATP (700 mCi/mmol). Following a 10-min incubation at 30°C, reactions are terminated by spotting 10 µl of the reaction mixture onto p81 phosphocellulose papers (Whatman), which are immediately immersed in 0.85% orthophosphoric acid under stirring and washed once in 95% ethanol for 5 min. Papers are dried and ^{32}P is quantitated by liquid scintillation counting.

K.6.3.4.5 Phosphoproteomics

GENERAL CONSIDERATIONS

The above methods for the detection of the phosphorylation state of insulin signalling components encompassing the IR and its downstream elements enable their individual analysis, only. Taking into account the expenditure in time and costs, their simultaneous analysis in a phosphoproteomic approach may be of great advantage. Innovations in the area of 2-D gel electrophoresis, protein analysis and computer databases are moving proteomics from futuristic possibilities into common laboratory procedures. The main aim of classic proteome studies is the separation of complex protein mixtures in order to visualize the relative levels of as many proteins as possible. Improvements of analytical techniques for protein identification, such as peptide mass fingerprinting, have enabled analysis of changes in proteomes on a large scale. However, obtaining information on co- and post-translational modifications within the analyzed proteome remains a major challenge. A wide variety of post-translational modifications, such as phosphorylation, glycosylation, acylation, methylation and acetylation, are known to play key roles in regulating the function, localization, binding specificity and stability of target proteins. To analyze this additional layer of protein diversity and to reveal its complexity, the traditional protein-by-protein approach clearly will not suffice to meet the huge magnitude of variation created by post-translational modifications. Therefore, development of proteome-based technology is required to analyze post-translational modifications of proteins, in general and phosphorylation, in particular.

PURPOSE AND RATIONALE

Since protein phosphorylation is an essential post-translational process in a variety of cellular processes, it is not surprising that perturbations in the equilibrium of PK and PP activities are fundamentally involved in metabolic diseases, such as type II diabetes and obesity. These pathogenetic changes in protein phosphorylation are preferably analyzed in parallel ("phosphoproteomics") rather than sequential fashion (e. g. immunoblotting, immunoprecipitation).

PROCEDURE

Various techniques can be used to detect phosphorylated proteins. In many approaches detection of phosphorylated proteins separated on 2-D gels is activated by incubating cells with [^{32}P] or [^{33}P]orthophosphate. However, when radiolabeling is used to detect phosphoproteins it has to be considered that constitutively phosphorylated proteins with slow phosphate turnover rates, which hence only incorporate small amounts of radioactive phosphate, may be poorly detected. Furthermore, care is necessary when comparing ra-

tios of phosphorylated threonine, serine and tyrosine residues. Similarly, different metabolic phosphorylation/dephosphorylation rates cause unequal incorporation of [^{32}P] into different types of amino acids. The use of poly- and monoclonal antibodies directed against phosphoamino acids represents an alternative procedure to detect phosphorylated proteins blotted onto a membrane. This method is very sensitive since antibodies can detect as little as a few fmol of epitope. Among other strategies, antibodies recognizing phosphotyrosine (pY), phosphothreonine (pT) and phosphoserine (pS) have been generated by cross-linking of a phosphoamino acid-containing hapten to keyhole limpet hemocyanin or BSA. Anti-pT, pY and pS antibodies are commercially available and particularly pY antibodies are now widely used. It was found that different anti-pY antibodies bind to essentially the same proteins in immunoblotting analysis, independent of the exact nature of the immunogen against which the antibodies were raised. Little to no cross-reactivity to non-phosphorylated tyrosine, pT, pS, AMP or ATP has been observed. The sensitivity of the anti-pY antibody is very high, since tyrosine phosphorylation in normal and unstimulated cells and tissues is 100- to 1,000-fold less abundant than pS, accounting for only 0.02% of phosphoamino acids. However, phosphorylation-specific antibodies may not detect certain phosphorylated proteins due to steric hindrance of the recognition site, which is especially true for anti-pT and pS antibodies. In addition, lack of antigenicity conferred by pT and pS (in contrast to pY) has precluded rigorous and unquestionable detection of threonine and serine phosphorylation in proteins. More often pT and pS can be identified specially in the context of a larger epitope, only, thus precluding whole proteome analysis. However, many groups of substrates have overlapping epitopes, for example those with a proline in the +1 position of a phosphorylated Ser or Thr (the archetypal MAPK or CIK sites) forwhich monoclonal antibodies have recently been introduced. Once more common phosphorylation motifs have been determined, more antibodies will become available, thus facilitating phosphorylation analysis of the whole proteome (= phosphoproteomics; for a review see Kaufmann et al. 2001).

Extensive reviews cover the most critical tasks of lysis of mammalian cells, sequential extraction (Mollow et al. 1999), pre-fractionation (Cordwell et al. 2000), sample preparation (Herbert 1999, O'Farrell 1975), sample solubilization for isoelectric focusing (Rabilloud et al. 1997) and two-dimensional gel electrophoresis (Görg et al. 2000) and finally detection of phosphoproteins by immunoblotting (see K.6.3.1.3.2.1 and K.6.3.4.3) and ot total proteins by chemical staining (Dunn 1999, Birkelund et al. 1997)

EVALUATION

Detection of phosphorylated proteins within complex protein mixtures separated by 2-D gel electrophoresis followed by immunoblotting represents a relatively simple and sensitive method. Antibodies directed against pT, pS and pY have been successfully used in proteome studies to identify and characterize phosphoproteins. A strategy is recommended that allows high-throughput identification of phosphorylated proteins. The protein-by-protein approach for elucidating complex biological regulatory processes mediated by protein phosphorylation can now be replaced by analysis of the phospho-proteome under varying conditions.

However, the described methodology has its limits. Especially specific anti-pS and anti-pT antibodies are not able to recognize all proteins harboring phosphates on these residues. Therefore, immunoblotting analysis should be combined with radiolabelling techniques to obtain highly accurate and complete pictures of the phospho-proteome. A major challenge in creating phospho-proteome maps remains the low abundance of many phosphorylated key regulatory proteins, such as signal transduction molecules. Improvement of the sensitivity of protein identification techniques, such as peptide-mass fingerprinting by matrix-assisted laser-desorption-ionization-time-of-flight (MALDI-TOF) mass spectrometry will be the key to overcome this obstacle.

K.6.3.4.6 Multiplex Bead Immunoassay

PURPOSE AND RATIONALE

The introduction of methodologies that allow the simultaneous measurement of interrelated markers, e. g. phosphoproteins within a common signal transduction pathway, has revoltionized the drug discorvery and evaluation process. Monitoring multiple proteins in a single sample and experiment saves time, labor costs and sample volume. The multiplex bead immunoassay developed by BioSource Inc. (CA, USA) in conjunction with the Luminex xMAP™ detection system and fluorescently encoded microspheres enables the simultaneous measurement of up to 100 different biological markers depending on the availability of appropriate (phosphosite-specific) antibodies. Each microsphere is labeled with a distinguishable fluorophore that allows

it to be assigned or gated to a particular region by the scanner. Antibodies specific for the (phospho-)protein of interest, are covalently linked to beads of a unique fluorescent region. The combination of different beads allows the user to simultaneously measure various protein markers of interest. The reagent and antibody bead kits offered by BioSource are intended for the quantitative determination of the (phospho-)protein in total cellular lysates and tissue homogenates.

The multiplex bead immunoassay is a solid phase sandwich immunoassay, which is designed to be analyzed with a Luminex 100™ instrument. The spectral properties of 100 distinct bead regions can be monitored with this instrument, a capability that affords this assay system the potential for measuring up to 100 different marker (phospho-)proteins ina single sample. Beads of defined spectral properties conjugated to marker-specific capture antibodies and samples (including standards of known marker concentration, blank controls etc.) are pipetted into wells of a filter bottom microplate and incubated for 2 h. During this first incubation, the marker (phospho-) proteins bind to the capture antibodies on the beads. After washing the beads, marker (phosphosite-) specific detector antibodies are added and incubated with the beads for 1 h. During this second incubation, the marker specific detector antibodies recognize their (phosphorylated) epitopes and bind to the appropriate immobilized marker (phospho-)proteins. After removal of excess detector antibodies, an anti-rabbit R-phycoerythrin (RPE) conjugated secondary antibody is added for 30 min. During this final incubation, the anti-rabbit RPE binds to the detector antibodies associated with the immunecomplexes on the beads, forming four-membered solid phase sandwiches. After washing to remove unbound anti-rabbit RPE, the beads are analyzed with the Luminex 100™ instrument. By monitoring the spectral properties of the beads and the amount of associated RPE fluorescence, the concentration of one or more analytes can be determined.

The multiple bead immunoassay has been initially introduced for the determination of the concentration of a panel of cytokines circulating in human serum (e. g. of patients suffering from primary Sjorens syndrome or bacterial infection; Szodoray et al. 2004, Pickering et al. 2004), but can meanwhile be applied successfully for the analysis of phosphorylation state of a number (currently seven) of key components of the insulin signal transduction cascade undergoing either tyrosine phosphorylation (IR, IGF-1 receptor, IRS-1) or serine/threonine phosphorylation (GSK-3, Akt, p70S6 kinase, p42/44 MAPK). Using this method the quantitative evaluation of changes in their phosphorylation state in response to treatment of insulin target cells requires one single-well reaction, only, rather than seven separate immunoprecipitation reactions followed by seven immunoblotting and fluorescent/luminescent imaging procedures. Thus, this method will significantly facilitate the throughput characterization of compounds/drug candidates with insulin-like and/or insulin-sensitzing activity and concomitantly increase its accuracy and resolution.

K.6.3.4.7 Protein Interaction Analysis

PURPOSE AND RATIONALE

In addition to protein phosphorylation, protein-protein interaction represents the major molecular mechanism for insulin signal transduction in insulin target cells (see K.6.3 and K.6.3.4), as exemplified by binding to and activation by IRS of PI3-K. Protein-protein interaction can be measured by (i) coimmunoprecipitation of one partner and subsequent immunoblotting of the coimmunoprecipitate for presence of the binding partner, (ii) pull-down of one partner *via* its tag (e. g. GST, His) and subsequent immunoblotting of the recovered material for presence of the (tagged) binding partner and (iii) the optical phenomenon called surface plasmon resonance (SPR). More than one decade after its introduction (Jönsson et al. 1991), latter method (iii) combined with a miniaturized flow system and a sophisticated surface designhas gained a lot of attractiveness since it enables many biomolecular interactions to be investigated conveniently in real time and does depend neither on the availability of a pair of compatible antibodies as is the case for coimmunoprecipitation (i) nor on the generation of recombinant tagged or labeled binding partners as is required for pull-down (ii) and furthermore allows kinetic and real-time rather than sole steady-state analysis of the interaction.

SPR defines the characteristics of proteins interms of their specificity of interaction with other molecules, the rates at which they interact (association and dissociation) and their affinity, which can be determined from the level of binding at equilibrium (seen as a constant signal) as a function of sample concentration as well as from kinetic measurements. Even the formation of multimolecular complexes can be monitored.

The natural phenomenon of SPR is utilized by the Biacore protein interaction analysis system (Biacore

AB, Sweden) to deliver high-quality data in real time, without the use of labels. The SPR phenomenon occurs when polarised light, under conditions of total internal reflection, strikes an electrically conducting gold layer at the interface between media of different refractive index, the glass of a sensor surface (high refractive index) and a buffer (low refractive index). In Biacore systems, a sensor chip and microfluidics system form flow cells through which samples flow over the sensor surface. As molecules from the injected sample bind to the immobilised molecules, an alteration in refractive index occurs that is proportional to the change in mass concentration at the surface. Using the SPR phenomenon, these changes are detected in real time and data is presented as a sensorgram (SPR response plotted against real time).

PROCEDURE

In a typical experiment one of the components (binding partner, ligand) in a biospecific pair is immobilized on the sensor chip surface (Löfas et al. 1995), and the counterpart (the analyte) which interacts with the ligand is in solution and passed over the gold film in a continuous flow. In the flow system (Sjölander and Urbaniczky 1991), samples and reagents can be introduced over the sensor surface. Automation of flow properties and sample injection gives the experiment control over temperature, flow and concentration properties as well as permitting reaction conditions on the surface to be changed easily.

The surface properties of the sensor chips are central to BiaCore technology. The surface of the gold film that is needed for SPR detection is modified to avoid protein adsorption to the detector surface itself. This is achieved by a self-assembled monolayer of alkanethiols to which dextran is coupled by epoxy chemistry (Johnsson et al. 1991, Löfas 1995). the surface properties are of great importance for the evaluation of results from real-time biomolecular interaction analysis. Unwanted interactions can be identified and to some extent compensated for by proper control surfaces in multidetection approaches (Karlsson and Stählberg 1995). Nordin and coworkers (2005) analyzed small molecule interactions with PK using SPR biosensors

EVALUATION

A range of methods based on BiaCore technology have been developed for different purposes over the past years which have been reviewed by Malmqvist and Karlsson (1997). Biacore's system facilitates the elucidation of disease mechanisms and the discovery of drug candidates by characterising native and recombinant protein interactions. The system enables the definition of potential drug targets, and the development of assays to characterize the interaction of target proteins with low-molecular-weight compounds. Other applications may include the selection of protein therapeutic candidates (e. g. recombinant insulin analogs) according to their on-/off-rates of binding to the target (e. g. IR) as well as the detection and characterization of immune responses during preclinical and clinical development.

Regarding application of BiaCore technology to PK-inhibitor interaction, Nordlin and coworkers (2005) found the immobilization conditions to be critical and they developed several strategies for preserving the binding capacity for inhibitors and ATP. The composition of the assay buffer is developed for optimized kinase assay performance. The assays include kinetic characterization of inhibitor binding to PK and analysis of binding characteristics in the presence of ATP for identification of ATP-competitive binders. The effect of PK phosphorylation on the binding of ATP and inhibitors can also be investigated, as is the PK isotype specificity. Furthermore, a complementary activity assay revealed the correlation between binding to the PK and inhibition of the PK. Thus, the biosensor technology offers a useful tool in PK-targeted compound identification and drug evaluation.

K.6.3.5 *O*-Linked Glycosylation (*O*-GlcNAc) of Insulin Signaling Components

GENERAL CONSIDERATIONS

Hyperglycemia is a consequence of type II diabetes and constitutes a self-perpetuating condition that contributes to poor metabolic control by impairing both insulin action and insulin secretion (Kruszynska and Olefsky 1996, Karam 1996, Yki-Järvinen 1992). The deleterious effects of hyperglycemia have been collectively referred to as "glucose toxicity" (Rossetti et al. 1990 and 1995, Rossetti 1996), the most prominent one of which is insulin resistance. Studies of humans and animals with spontaneous or experimentally induced insulin resistance have revealed much about the multiple pathways that can lead to insulin resistance. However, the primary events that trigger insulin resistance remain incompletely understood. Experimental induction of insulin resistance in isolated cells or tissues can be a useful approach for the identification of early events because it provides considerable experimental control.

Marshall and coworkers provided ample evidence that excessive flux of glucose through the hexosamine biosynthesis pathway (HBP) triggers various adaptive responses that restore intracellular glucose homeostasis. One such response is reduction of glucose uptake through desensitization of the insulin-responsive glucose transport system (GTS). Since the glucose-sensing/signal transductional capability of the HBP constitutes only one function of this ubiquitous pathway, this regulatory arm of the HBP has been named the hexosamine signaling pathway (HSP) (Marshall and Rumberger 2000, Marshall 2002).

In exploring the functional role of the HSP and the underlying mechanisms, glucosamine (GlcN) is often used as a pharmacological tool since it can readily undergo internalization through the GLUT1/4 and directly enter the HBP at the level of GlcN-6-P (Marshall et al. 1991a, 2004). Thus, GlcN was found to mimic glucose-induced desensitization in adipocytes and was shown to be > 40 times more potent than glucose. Although it was originally thought of that glucose and GlcN were causing desensitization through a common mechanism, this premise was later questioned when actinomycin-D was found to completely block glucose-induced desensitization but not GlcN-induced desensitization (Marshall et al. 1991b, Han et al. 2003). Thus, glucose-induced desensitization is mediated through a mechanism involving changes in gene expression, whereas GlcN-induced desensitization occurs through an alternate and unidentified mechanism. In conclusion, Marshall and colleagues hypothesized that flux through the HBP serves as a glucose sensor in adipocytes, and potentially other insulin target cells, and by some unknown negative feedback loop, regulates glucose transport provoking glucose-induced insulin resistance.

PURPOSE AND RATIONALE

The studies of Hebert and coworkers (1996), Cooksey and McClain (2002) and Gazdag and coworkers (2000) demonstrated an inverse relationship between cellular UDP-GlcNAc levels and insulin action, but did not reveal a specific mechanism for the association. UDP-GlcNAc is a substrate for O-GlcNAc transferase (uridine diphospho-*N*-acetyl-glucosamine/polypeptide-*N*-acetylglucosaminyltrans-ferase) that transfers single *N*-acetylglucosamine moieties to the hydroxyl group of serine and threonine residues on cellular target proteins in a dynamic and reversible process known as O-GlcNAcylation (Wells et al. 2001). The extent of cellular O-GlcNAcylation appears to be regulated, at least in part, by the cellular concentration of the UDP-GlcNAc substrate (Kreppel and Hart 1999). McClain and coworkers (2002) recently found direct evidence that O-GlcNAc transferase plays an important role in insulin action by overexpressing O-GlcNAc transferase in skeletal muscle and fat in transgenic mice and inducing insulin resistance.

O-GlcNAcase (β-*N*-acetylglucosaminidase) is responsible for specific removal of single O-GlcNAc modifications from cellular proteins. Both O-GlcNAc transferase and O-GlcNAcase exhibit nuclear and cytoplasmic localization and are highly conserved (Dong and Hart 1994). Wells and coworkers (2001) have hypothesized that O-GlcNAcylation of proteins is a type of post-translational modification that may be analogous to PK and PP regulation of phosphorylation and thus compete for similar or adjacent phosphorylation sites in a reciprocal manner. It seems possible that, in addition to flux through the HBP, regulation of either O-GlcNAc transferase (McClain et al. 2002) or O-GlcNAcase (Vosseller et al. 2001, 2002) may influence insulin action. O-(2-acetamido-2-deoxy-D-glucopyranosylidene) amino-*N*-phenylcarbamate (PUGNAc) is a potent and nontoxic inhibitor of O-GlcNAcase in various cell lines (Haltiwanger et al. 1998). Arias and coworkers (2004) found that prolonged incubation in PUGNAc results in increased protein-O-linked glycosylation and insulin resistance in rat skeletal muscle. The following assays represent model systems for the induction and analysis of glucose-induced insulin resistance which is mediated by O-GlcNAcylation and can be modified by compounds/drug candidates.

K.6.3.5.1 Induction of *O*-Glc-NAc Modification in Adipocytes, Myocytes and Muscles

Primary Adipocytes

Isolated adipocytes are obtained from the epididymal fat pads of male Sprague–Dawley rats (180–225 g) by collagenase digestion as described above with modifications introduced by Marshall and coworkers (2005). After digestion, cells are washed three times in HEPES-buffered balanced saline solution (HBSS) consisting of 25 mM HEPES (pH 7.6), 120 mM NaCl, 0.8 mM $MgSO_4$, 2 mM $CaCl_2$, 5.4 mM KCl, 1 mM NaH_2PO_4, 1 mM sodium pyruvate, 100 U/ml penicillin, 100 µg/ml streptomycin, and 1% BSA. Cells are then diluted to a final concentration of 5×10^5 cells/ml (12 ml HBSS per 1 g initial fat weight). From a common pool of cells, 200-µl portions of the adipocyte suspension in 12 × 75-mm sterile polystyrene tubes are in-

cubated at 37°C in the absence or presence of insulin (10 nM final conc.) to stimulate the glucose transport system and to facilitate the subsequent uptake of GlcN. After 20–30 min, GlcN is added and adipocytes are further incubated at 37°C.

3T3-L1 Adipocytes

3T3-L1 adipocytes are cultured for 16 h in DMEM containing 4 mM glucose in the absence of serum and containing PUGNAc (100 µM). After 16 h, cells are refed with identical media for 3 h. For GlcN and/or chronic insulin/glucose treatment of cells, 3T3-L1 adipocytes are cultured for 16 h in DMEM containing 4 mM glucose in the absence of serum with 0.2% BSA and containing 5 mM GlcN/5 mM HEPES (pH 7.6) and/or insulin (1 nM). After 16 h, cells are washed twice and refed with identical media used during 16-h treatment, but lacking insulin. Cells are then washed twice with Krebs-Ringer's phosphate buffer (KRP) and stimulated in KRP with various concentrations of insulin for the indicated time at 37°C.

Myocytes

C2C12 cells are cultured to confluence in growing conditions in DMEM containing 25 mM glucose and 10% fetal bovine serum (FBS) in collagen type I-coated culture plate according to the procedure described by Fujita and coworkers (2005). When cell confluence is attained, cells are cultured for 4 days with DMEM containing 25 mM glucose, 2% horse serum, and with or without 10 mM GlcN. After 4 d, the change in cell morphology induced by GlcN is observed by an optical microscope.

Muscles

Epitrochlearis muscles are quickly excised from rats (140–160 g) anesthetized with an intraperitoneal injection of sodium pentobarbital (5 mg/100 g body weight) upon loss of pedal reflexes and then transferred into the tissue incubation medium. Muscles are incubated (18 h) in flasks containing 1.5 ml of low glucose (5.5 mM) DMEM supplemented with $CaCl_2$ (final conc. 2.5 mM), $NaHCO_3$ (final conc. 25 mM), insulin (final conc. 0.6 nM) and BSA (0.1%). Insulin is included for the initial 18 h of incubation because this prevents the increase in basal glucose transport observed with prolonged incubation of isolated skeletal muscle. Flasks are placed in a shaking water bath at 35°C and continuously gassed with 95% O_2/5% CO_2. The media are replaced with fresh DMEM every 6 h during the initial 18-h incubation. To minimize bacterial contamination during prolonged incubation, 100 µU/ml penicillin and 100 µg/ml streptomycin are added to the DMEM and Teflon air filters are used to minimize aerosol contaminants.

Following the 18-h incubation in supplemented DMEM, muscles are rinsed in KHB supplemented with 0.1% BSA, 100 µU/ml penicillin, 100 µg/ml streptomycin, 2 mM sodium pyruvate and 5 mM mannitol for two 30-min periods at 30°C for removal of glucose and DMEM. During the rinse steps, the KHB buffer is supplemented with 0, 0.6 or 12 nM insulin. Muscles treated with inhibitors of GFAT in the initial incubation steps continued to be exposed to up to 100 µM inhibitor during the subsequent rinse steps. Muscles are then rapidly blotted, trimmed, clamp frozen with aluminium tongs cooled to the temperature of liquid N_2 and stored at −80°C until further processing. Total frozen muscles are weighed, transferred to pre-chilled glass tissue grinding tubes and homogenized in ice-cold lysis buffer (1 ml/muscle) containing 20 mM Tris/HCl (pH 7.4), 150 mM NaCl, 1% NP-40, 2 mM EDTA, 2 mM EGTA, 1 mM DTT, 2.5 mM sodium pyrophosphate, 10 mM NaF, 2 mM Na_3VO_4, 20 mM glycerol-3-phosphate, 1 µg/ml leupeptin, 1 µg/ml pepstatin, 1 µg/ml aprotinin, 1 mM PMSF in the absence or presence of up to 100 µM of PUGNAc. Homogenates are transferred to microfuge tubes, rotated for 1–2 h at 4°C, and then centrifuged (12,000 × *g*, 15 min, room temperature) to remove insoluble material. Following homogenization, processed muscle samples are used for determination of the levels of GlcNAc-6-phosphate and UDP-GlcNAc as well as the amount of *O*-GlcNAc-modified proteins.

K.6.3.5.2 Assay for Glutamine/Fructose-6-Phosphate Amidotransferase (GFAT)

Fluorometric Method

GFA activity is assayed according to previously described methods (Yki-Järvinen et al. 1997) with modifications. Cells corresponding to 5–15 mg protein is homogenized for 10 s on ice and sonicated for 10 bursts in a Branson 250 sonifier in 10 ml of homogenization buffer (50 mM sodium phosphate, pH 7.5, 100 mM KCl, 1 mM EDTA). The sample is then centrifuged (60,000 × *g*, 15 min, 4°C) and the supernatant is used for assay of GFA activity. All samples are assayed immediately after homogenization. 50 µl of homogenate is incubated (45 min, 37°C) in a reaction mix (final volume 100 µl) containing 12 mM fructose-6-phosphate, 12 mM glutamine, 40 mM sodium phosphate (pH 7.4), 1 mM EDTA, 1 mM DTT in the ab-

sence or presence of 0.5 mM of UDP-GlcNAc. The reaction is terminated with 50 µl of 1 M perchloric acid, vortexed, and centrifuged (15,000 × *g*, 15 min, 4°C). The deproteinized supernatant (145 µl) is then treated with 258 µl of a 1/4 mixture of tri-N-ocytlamine/1,1,2-trifluoroethane, vortexed and centrifuged (15,000 × *g*, 1 min). The aqueous phase is then filtered through a 0.2-µm filter and 50 µl is derivatized with an equal volume of O-phtaldialdehyde (OPA) solution (4 mg OPA dissolved in 50 µl of ethanol and added to 5 ml of 0.1 M sodium borate and 10 µl mercaptoethanol). Immediately thereafter samples are separated over a reverse-phase C18 column (25 cm × 4.6 mm) equilibrated with 15 mM sodium phosphate (pH 7.2), 5% acetonitril, and 5% isopropanol. Absorbance of the sample eluent is analyzed using a fluorescent detector and the peak area is integrated. OPA-derivatized GlcN6P standards are run separately to determine the retention time and to generate a standard curve for correlation of area to activity. The correlation coefficient between the concentration of GlcN6P standards and the area under the GlcN6Ppeak is typically 0.999 or higher. The recovery of samples spiked with GlcN6P prior to derivatization is usually more than 95%.

Radiometric Method

A highly sensitive and rapid method for the separation of radiolabeled fructose-6-phosphate from glucosamine-6-phosphate has been developed by Broschat and coworkers (2002), which can be used in a disposable column or a 96-well formate and is > 10-fold more sensitive than the HPLC method. The column assay has a broad range of linearity with low variation between samples. When performed in the 96-well formate, the assay is linear with time and enzyme concentration and greatly improves the rapidity and accuracy with which GFAT activity can be measured.

Research Formate

Cells are homogenized as described for the fluorometric assay using the cytosolic fraction obtained by 100,000 × *g* spin for 1 h. The final assay conditions contain 20 µM fructose-6-phosphate (300,000 cpm), 400 µM glutamine, 20 mM imidazole buffer (pH 6.8), 1 mM EDTA, 10 mM KCl, 1 mg/ml BSA and 1 mM DTT in a total volume of 50 µl. All assays are conducted at room temperature. Just prior to the assay, the samples prepared in stabilizing buffer containing glucose-6-phosphate (Zhou et al. 1995) are buffer-exchanged on PD-10 columns equilibrated in the GFAT assay buffer. The reaction is stopped by dilution of the enzyme reaction with 1 ml of 10 mM $NaHCO_3$ (pH 3.0). Separation of GlcN-6-phosphate from substrate is performed immediately at room temperature. Unbound [^{14}C]GlcN-6-phosphate is collected in scintillation vials and quantified by scintillation counting.

Screening Formate

Strong anion exchange resin (AG1X8, 400 mesh, formate form) is prepared prior to the assay and stored for 2 weeks at room temperature or at 4°C for longer periods. The resin is suspended in batch in a 5-volume excess of 10 mM $NaHCO_3$ (pH 3.0) and allowed to settle for 20 min. The fines and excess buffer are decanted, and the procedure is repeated until no fine material remained, usually three to four times. The pH of the formate buffer above the resin should be unchanged by the resin after the equilibration is complete. GFAT activity is measured in a total volume of 50 µl in U-bottomed deep-well 96-well plates. The substrates, 20 µM [^{14}C]fructose-6-phosphate (75,000 cpm per well) and 400 µM glutamine are mixed and the reaction is terminated by the addition of a 150-µl suspension of Dowex AG1X8 (400 mesh) in 10 mM $NaHCO_3$, containing 50 µl resin and 100 µl buffer by volume. Suspension of the resin is maintained using a stir plate prior to transfer. The resin is allowed to settle for 5 min, after which a 50-µl aliquot of the supernatant is removed using a programmable liquid transfer device and transferred to a 96-well topcount plate. After addition of 150 µl of scintillation cocktail, the plates are sealed, shaken for 5 min and counted for radioactivity in a topcount reader.

K.6.3.5.3 Assay for *O*-GlcNAc Transferase

Cells corresponding to 2–5 mg protein (bicinchoninic acid method using BSA as standard) are homogenized in 6 × volume (µl/mg) of homogenizing buffer containing 20 mM HEPES/KOH (pH 7.0), 10 mM $MgCl_2$, 0.4 mM Na_3VO_4, 1 mM EDTA, 4 µM benzamidine, 0.5 mM PMSF, 1 µg/ml pepstatin, 1 ng/ml leupeptin, 0.5 µg/ml antipain and 250 mM sucrose (HBS) in a glass homogenizer for 30 sec on ice. The homogenate is centrifuged (100,000 × *g*, 25 min, 4°C). The supernatant (cytosol) is mixed with an equal volume of 30% PEG8000 and incubated on ice for 30 min to precipitate proteins. The precipitated material is pelleted by brief centrifugation (10,000 × *g*, 2 min). The supernatant is discarded and the pellet is washed once with HBS and resuspended in half the original volume of HBS. *O*-GlcNAc transferase is measured as described by Haltiwanger and cowork-

ers (1992) with slight modifications. Both methods derive their specificity by utilizing peptide substrates that are modelled after *O*-glucosaminylation motifs of known *O*-GlcNAcylated proteins. The method recommended utilizes an Arg-tagged peptide which binds firmly to phosphocellulose paper. Reactions are conducted in 45-µl mixtures containing 1–5 µg of cytosolic protein in 20 mM HEPES/KOH (pH 8.0), 250 mM sucrose, 0.5 mM EDTA, 5 mM peptide substrate (TITSETPSSTTTQITKR) and 0.2 µCi UDP-[6-^{3}H]-N-acetylglucosamine (25 Ci/mmol). The reactions are incubated (60 min, 25°C). At the end of the incubations, 40-µl portions are spotted onto 1-cm^2 Whatman P81 ion exchange papers. The paper squares are immediately immersed in 50 mM formic acid, washed extensively with 4 × 4 ml of 50 mM formic acid per square and then counted for radioactivity in 5 ml scintillation cocktail per square. All assays should be conducted in the linear range for time, peptide concentration and homogenate protein.

K.6.3.5.4 Measurement of GlcN-6-P Levels

For determination of the GlcN-6-P levels according to the procedure of Marshall and coworkers (2005b), adipocytes or myocytes after treatment with compounds/drug candidates are transferred to 1.5-ml microfuge tubes and washed 3 times with ice-cold, BSA-free HBSS. During the final wash, the cell volume is reduced to 150 µl and 0.4 ml of cold perchloric acid (0.3 M) is added to the cells for 10 min. The mixture is then centrifuged (20,800 × *g*, 10 min, 4°C) and the deproteinated metabolite extract (420 µl) is transferred to a new microfuge tube. After the extract is neutralized by adding a small amount of K_2CO_3 (5 M), extracts are frozen and stored at −20°C. The concentration GlcN-6-P is measured in the extracts by HPLC as previously described (Marshall et al. 2004, 2005a) by a method that entailed derivatization of GlcN-6-P with O-pthaldialdehyde (OPA) so that it can be detected fluorometrically (following separation by reverse phase HPLC).

K.6.3.5.5 Measurement of UDP-GlcNAc Levels

This assay is performed essentially as described previously by Robinson and coworkers (1995). To avoid degradation of UDP-GlcNAc, isolated tissue samples are frozen immediately in liquid nitrogen, and then the procedure for the extraction of UDP-GlcNAc is carried out as quickly as possible. Frozen muscle or liver tissue (~150 mg) is homogenized at 4°C in 5 volumes of PBS. A small aliquot of tissue homogenate is used for protein assay. 100% (w/v) TCA is added to tissue homogenate (10% final conc.). Samples are mixed well and the precipitates are pelleted by centrifugation (10,000 × *g*, 15 min, 4°C). To eliminate TCA from the supernatant, two volumes of diethylether are added and mixed well. After centrifugation (1,000 × *g*, 3 min, room temperature), the diethylether phase is discarded. This TCA elimination step is repeated 10 times. The aqueous samples are dried up and dissolved in 30 µl distilled water. The extracts are centrifuged (20,000 × *g*, 10 min, room temperature), and high pressure liquid chromatography (HPLC) is performed on a SAX anion-exchange column (4.6 × 250 mm, e. g. Whatman Partisil) eluted with 40 mM ammonium phosphate at a flow rate of 1 ml/min. The amount of UDP-GlcNAc in the samples is quantified by ultraviolet absorption (A_{254}), and calculated from the height of peak against standard series of UDP-GlcNAc. The retention-time of the peak of UDP-GlcNAc is 12.0 min.

K.6.3.5.6 Detection of *O*-GlcNAc-Modified Proteins

Immunological Detection

For immunological detection of O-GlcNAc-modified proteins according to the procedure introduced by Vosseller and coworkers (2002), whole-cell lysates for immunoblotting are prepared by scraping 3T3-L1 cells from 6-cm culture dishes in 400 µl of 1% SDS, transferring to Eppendorf tubes, and boiling for 10 min. Laemmli sample buffer is added directly to lysates for SDS-PAGE. Lysates for immunoprecipitations are obtained by scraping cells in 1% Nonidet P-40 buffer containing 15 mM Tris/HCl (pH 7.5), 150 mM NaCl, 1 mM EDTA, protease inhibitors, and 1 µM PUGNAc to inhibit deglycosylation during lysis. Protein concentrations in lysates are determined by using the Bio-Rad protein reagent. The anti-O-GlcNAc antibody used is a mouse monoclonal IgM from ascites designated 110.6 (Comer et al. 2001). For these immunoprecipitations, antibody is bound and covalently coupled by using dimethyl pimelimidate (Pierce) to agarose-conjugated anti-IgM. For immunoblotting, secondary antibody is horseradish peroxidase-conjugated goat anti-mouse IgM (µ chain-specific). In all cases, immunoblots are developed with ECL reagent and imaged on hyperfilm (Amersham Pharmacia). Immunoprecipitations with indicated antibodies are performed

overnight at 4°C and captured with protein A/G-Sepharose (Santa Cruz Biotechnology) unless otherwise indicated, washed in RIPA buffer (1% Nonidet P-40 buffer described above, but including 0.1% SDS, 0.25% sodium deoxycholate, and not containing protease inhibitors or PUGNAc), followed by washing in TBS. Proteins are boiled off Sepharose beads in Laemmli sample buffer for SDS-PAGE with precast minigels (Bio-Rad). The separated proteins are transferred to polyvinylidene difluoride (Immobilon-P, Millipore), blocked at least 1 h in TBS containing 4% BSA and 0.1% Tween20, and probed with indicated antibodies overnight at 4°C. After binding of appropriate horseradish peroxidase-coupled secondary antibodies, ECL detection is used. In cases where densitometry is used to quantitate Western blot signals, the Flourchem imaging system and software (Alpha Innotech, CA) are used.

Enzymatic Detection

Terminally *O*-GlcNAc-modified membrane proteins are identified by the galactosyltransferase probe method using purified UDP-Gal-GlcNAc-Galβ-(1–4) galactosyltransferase (Gal-transferase) and UDP-[^{3}H]galactose as described by Roquemore and coworkers (1994) with modifications introduced by Buse and coworkers (2002). Briefly, 0.5 or 1 mg of total crude membrane proteins in 50 mM HEPES (pH 7.4), 150 mM NaCl, and 0.5% CHAPS is incubated for 1 h at 37°C with the addition of 10 mM HEPES (pH 7.3), 10 mM galactose, 5 mM $MnCl_2$, 1 mM DTT, 25 mM 5′-AMP, 20 µCi/ml UDP-[6-^{3}H]galactose (40 Ci/mmol), and 1 U/ml galactosyltransferase (previously autogalactosylated for 30 min at 37°C in 50 mM Tris/HCl, pH 7.3, 5 mM $MgCl_2$, 1 mM mercaptoethanol, 0.4 mM UDP-galactose, and 0.1 mg/ml aprotinin). Enzyme reactions are terminated by the addition of 10 mM EDTA. Immunoprecipitation of galactosylated membranes is described below.

K.6.3.6 Insulin-Like Signal Transduction via Plasma Membrane Microdomains (Caveolae and Lipid Rafts)

GENERAL CONSIDERATIONS

Caveolae

Caveolae were discovered as non-coated small flask-shaped invaginations (25–100 nm) of the plasma membrane by electron microscopy of endothelial cells (Fan et al. 1983, for a review see Anderson 1993a, 1993b, 1998, 1999, 2002, Shaul and Anderson 1998). It is possible that caveolae are formed from non-invaginated lipid rafts in the presence of the principal structural caveolae protein, caveolin (Kurzchalia et al. 1994, Lisanti et al. 1994, Parton 1996, Schlegel et al. 1998, Müller 1999 and 2000, Müller and Welte 2002e). Caveolae and the so called lipid rafts are believed to be enriched in the bulk membrane lipids, such as phosphatidylinositol, cholesterol, sphingomyelin and glycolipids, such as glycosylphosphatidylinositol and the ganglioside GM1 (for reviews see Rietveld and Simons 1998, Bickel 2002). Due to the high concentration of cholesterol and sphingomyelin, caveolae and lipid rafts are much more resistant to solubilization by detergents than are other parts of the plasma membrane and intracellular membranes (Brown and Rose 1992, Brown and London 1997 and 1998, Harder et al. 1998, Müller 2002d, Edidin 2003). The concentrations of various lipids in caveolae and rafts suggest great variations between different cell types, but also reflect the different experimental approaches used. Moreover, caveolae constitute between cell types a very variable, and usually unknown, fraction of the plasma membrane. Figures for enrichment of various components in caveolae compared to the total plasma membrane therefore reflect, to a large extent, this property of the particular cell type under investigation. In addition to the high content of cholesterol and sphingolipids, caveolae are stabilized by one or more caveolin isoforms. The caveolins are a family of 21–25-kDa integral membrane proteins that from the coat structure of caveolae (Glenney 1992, Okamoto et al. 1998, Smart et al. 1999). An unsual hairpin membrane domain results in both the amino- and carboxy-termini facing the cytoplasm. Caveolins avidly bind cholesterol, which may be the basis for their association with the liquid-ordered phase of the plasma membrane. In adipocytes caveolin-1 is the most prominent isoform (Rothberg et al. 1992) and its ablation leads to a total loss of caveolae.

Caveolae are believed to be involved in a number of cellular processes, such as receptor mediated uptake and organization of transmembrane signaling (Shaul and Anderson 1998). Caveolae and lipid rafts harbor a number of components of various intracellular signal transduction pathways including G-protein-coupled receptors, heterotrimeric G-proteins, RTK (Src family tyrosine kinases), components of the Ras-mitogen-activated protein kinase (MAPK) pathway, protein kinase C isoforms, and endothelial nitric oxide synthase (eNOS) (Schlegel et al. 1999, Shaul and Anderson 1998, Smart et al. 1999). As a consequence, they may function as locations for the direct physical interaction of signaling elements where the cross-talk between the corresponding signaling pathways takes place (Okamoto et al. 1998). Lisanti and coworkers demonstrated direct binding of a common domain within caveolin, the caveolin-scaffolding do-

main (CSD) to the corresponding caveolin-binding domain (CBD) of a variety of signaling proteins which are thereby kept in a basal inactive state, however competent for future activation (Couet et al. 1997a, Ju et al. 1997, Mineo et al. 1998, Müller 2001b, Moffett et al. 2000). The inhibitory interaction between caveolin and signaling molecules should be accessible for modulation in response to extracellular/intracellular signals. Activation of signaling pathways engaging CBD-harboring signaling molecules requires their relief from binding to/inhibition by caveolin both in short and long term (Couet et al. 1997a and b, Kobzik et al. 1996).

Lipid Rafts

Discovery of the intracellular molecules and pathways that mediate insulin action has preoccupied many investigators for many years, but controversy and confusion remain. An emerging concept to explain such signaling specificity in the face of molecular promiscuity is that specialized scaffold, anchor, and adapter proteins segregate signaling molecules into specific cellular compartments *via* protein-protein interactions (Mastick et al. 1998). One level of spatial organization proposed for the plasma membrane is that of the liquid-ordered phase. According to a model proposed by Simons and Ikonen (1997) and Simons and Toomre (2000), lipids in the liquid-ordered phase pack together to form dynamic "rafts" in the plasma membrane, and these lipid rafts either recruit or exclude specific molecules, including signaling proteins. The biophysical and biochemical microenvironment of the rafts (e. g., membrane fluidity) may influence the function of the raft proteins. Also, the physical segregation of proteins into such "microdomains" may regulate the accessibility of those proteins to regulatory or effector molecules. The structural bases suggested for protein association with rafts include glycophosphatidylinositol (GPI) anchors (e. g., folate receptor), dual fatty acylation by myristylation and palmitoylation (e. g., Src family tyrosine kinases), transmembrane domain structure (e. g., influenza hemagglutinin polypeptide), cholesterol binding (e. g., caveolins), and protein-protein interactions (e. g., caveolin-interacting proteins). On the basis of their ability to sort proteins, rafts have been implicated in a number of cell functions, including signal transduction.

Signaling Function of Lipid Rafts and Caveolae

A pathway for insulin activation of glucose transport has been identified in insulin-sensitive cells which involves rafts/caveolae and the in- and out-movement of signaling proteins (Baumann et al. 2000, Ribon et al. 1998). Thus, rafts/caveolae seem to harbor signaling components for insulin-stimulated glucose transport and regulate their activity by interaction with caveolin and additional caveolar structural proteins that may serve as scaffolding proteins for concentrating and activating/inhibiting specific insulin signaling components. In addition, Baumann (2001) and coworkers presented a large body of evidence that a signal generated at the lipid rafts of adipocytes in response to insulin is required for insulin-stimulated glucose transport, in addition to that elicited by the PI3-K pathway (see K.6.3.6.3).

Interestingly, compounds which manage to modulate the interaction of caveolin/caveolae with CBD-containing signaling proteins and, in consequence, the activation state of the corresponding downstream signaling cascades have been described. A study by Müller and coworkers (2001a, b) demonstrated that in isolated rat adipocytes, the non-RTK, $pp59^{Lyn}$ and $pp125^{Fak}$, are down-regulated by localization in caveolae/binding to caveolin and up-regulated by release from caveolae/dissociation from caveolin in response to phosphoinositolglycans (PIG), degradation products of GPI membrane protein anchors (Jones and Varela-Nieto 1999, Müller and Frick 1999), and the sulfonylurea drug, glimepiride (Langtry and Balfour 1998). The short term redistribution of these kinases from caveolae/rafts induces insulin-independent activation of the metabolic insulin signaling cascade. These findings suggest that the concentration of signaling proteins at caveolae/caveolin may be regulated by diverse physiological and pharmacological stimuli thereby integrating cross-talk to various signal transduction pathways.

PURPOSE AND RATIONALE

In rat adipocytes and in 3T3-L1 adipocytes the IR is localized to caveolae (Müller et al. 2002c, Gustavsson et al. 1999). The immediate downstream signaling molecule, IRS1, on the other hand, has been reported not to be associated with the plasma membrane in rat adipocytes. In rat adipocytes the disruption of caveolar integrity by cholesterol depletion using β-cyclodextrin, reversibly makes the cells insulin resistant by inhibiting the IR from phosphorylating IRS1. On the other hand, insulin signalling for mitogenic control *via* MAPK, ERK1 and 2, is not impaired in the rat cells (Gustavsson et al. 1996). The importance of caveolae for insulin action is reinforced by the finding that, in response to insulin stimulation, the insulin-regulated glucose transporter, GLUT4, is translocated

to caveolae for glucose uptake (Gustavsson et al. 1996, Kandror et al. 1995), and that some of the downstream signalling for enhanced glucose uptake may take place in caveolae.

In addition, destruction of caveolae causes a reduced uptake of long-chain fatty acids in 3T3-L1 cells and HepG2 cells (Pohl et al. 2002, Meshulam et al. 2006), and the major structural protein of caveolae, caveolin, and the caveolae-localized protein, CD36, both bind fatty acids. Caveolin has been implicated in TAG metabolism through its association with lipid bodies and LD in 3T3-L1 adipocytes and other cell lines (Fujimoto et al. 2001, Ostermeyer et al. 2001, Pol et al. 2001) and its mediation of the interaction between perilipin and the catalytic subunit of PKA which is required for β-adrenergic-dependent phosphorylation of perilipin and activation of lipolysis in adipocytes (Cohen et al. 2004). Caveolin-$1^{-/-}$ mice that are deficient in caveolin and caveolae have, moreover, been found to have deranged lipid metabolism and atrophied adipose tissue (Drab et al. 2001, Razani et al. 2001, 2002a, for a review see Razani et al. 2002b). Furthermore, caveolin-$1^{-/-}$ mice show a 90% decrease in IR expression selectively in adipose tissue, greatly reduced insulin-induced phosphorylation of PKB, and insulin resistance (Capozza et al. 2005, Oshikawa et al. 2004, for a review see Ishikawa et al. 2005). These findings indicate that intact caveolae are important for normal insulin signalling and (insulin) regulation of metabolism of carbohydrates and lipids in adipocytes. The following methods enable the analysis of the role of rafts/caveolae in insulin and insulin-like signal transduction in adipocytes as well as of their participation in the insulin-like activity of compounds/drug candidates.

K.6.3.6.1 Preparation of Plasma Membranes

Lipid rafts are routinely prepared from the plasma membranes of differentiated mammalian cells, preferably primary and cultured adipocytes or lung endothelial cells, due to their relative abundance.

K.6.3.6.1.1 Sucrose Gradient-Based Method

Basal and insulin/compound-stimulated adipocytes are homogenized in 10 mM Tris/HCl (pH 7.4), 1 mM EDTA, 0.5 mM EGTA, 0.25 M sucrose, 25 mM NaF, 1 mM pyrophosphate with protease inhibitors (10 µM leupeptin, 1 µM pepstatin, 1 µM aprotinin, 4 mM iodoacetate and 50 mM PMSF) using a motor-driven Teflon-in-glass homogenizer at room temperature. Subsequent procedures are carried out at 4°C. Cell debris and nuclei are removed by centrifugation at (1,000 × *g*, 10 min). A plasma membrane-containing pellet, obtained by centrifugation (16,000 × *g*, 20 min) is resuspended in 10 mM Tris/HCl (pH 7.4), 1 mM EDTA and protease inhibitors. The plasma membranes are purified by sucrose density gradient centrifugation (Avruch and Wallach 1971).

K.6.3.6.1.2 OptiPrep-Step Gradient-Based Method

Purification of plasma membranes from total membranes is performed by fractionation using the OptiPrep gradient (AXIS-Shield) according to the procedure of Pohl and coworkers (2005). Monolayers of confluent 3T3-L1 adipocytes are washed once in PBS to remove the culture medium and then once in the homogenization buffer (10 mM Tris/HCl, pH 7.4, 25 mM sucrose, 0.5 mM EDTA). Thereafter, cells are scraped in 3 ml of homogenization buffer and centrifuged (1,000 × *g*, 5 min). The pellet is resuspended in 2 ml of homogenization buffer. Cells are lysed by 10 passages through a fine syringe needle followed by treatment with a tight-fitting Dounce homogenisator. The homogenate is centrifuged (1,000 × *g*, 10 min). The resulting post-nuclear supernatant is centrifuged (100,000 × *g*, 40 min). The resulting total membrane pellet is resuspended in 1 ml of homogenization buffer containing 25% (w/v) iodixnol and loaded onto a nine-step OptiPrep gradient, which consisted of 25, 22, 19, 16, 13, 10, 7, 4, and 1% (w/v) iodixnol. After centrifugation (200,000 × *g*, 3 h, 4°C, Beckman SW41Ti), 18 fractions are collected from the bottom of each centrifuge tube. A portion of each fraction can be analyzed by SDS-PAGE and immunoblotting for markers of the plasma membranes. Fractions 5, 6 and 7 are used as purified plasma membranes according to their enrichment of Na^+/K^+-ATPase, CD36 and caveolin-1.

K.6.3.6.1.3 Affinity Partitioning-Based Method

All work including the two-phase systems is done at 4°C in a well-tempered cold room as two-phase partitioning is critically dependent on temperature. Male Sprague–Dawley rats, weighing 200–300 g, are starved overnight and killed by decapitation. Lungs are excised and thoroughly perfused with ice-cold homogenization medium (0.25 M sucrose, 5 mM Tris/HCl, pH 8.0). They are cut into pieces and squashed in a garlic press. Four grams of lungs are transferred to a Potter–Elvehjem homogenizer containing a 30-g

two-phase system including the lung tissue. The two-phase system consisted of 5.7% (w/w) dextran T500 (bottom phase) and 5.7% (w/w) PEG 3350 (top phase) in 15 mM Tris/H_2SO_4 (pH 7.8) (final concentrations in the system). Homogenization is done by 5 up and down strokes by a motor-driven homogenizer with a Teflon pestle at 1,000 rpm. The homogenate is transferred to a Dounce homogenizer and further homogenized by 10 strokes with a loose-fitting pestle followed by 10 strokes with a tight-fitting one. After homogenization, the phases are separated by gentle centrifugation (270 × *g*, 5 min, Sorvall SS-34 rotor). The PEG-rich top phase is collected and the dextran-rich bottom phase re-extracted with fresh top phase by mixing and phase separation as above. The two top phases collected are combined and further subjected to affinity partitioning. The fresh top phase for re-extraction is obtained from a similar 30-g two-phase system as above, replacing the lung tissue with 4 g of 15 mM Tris/H_2SO_4 (pH 7.8). After weighing in the components, the system is thoroughly mixed and allowed to settle overnight before collecting the top phase to be used for re-extraction. The phases for affinity partitioning are obtained as follows: a 20-g system containing 6.0% (w/w) PEG 3350 and 6.0% (w/w) dextran T500, including 1.3 mg WGA coupled to dextran T500, in 15 mM borate/Tris (pH 7.8) (final concentrations), is weighed in. After thoroughly mixing the system and letting settle overnight, the phases are collected individually, the WGA–dextran-containing bottom phase to be used for the initial affinity partitioning step and the PEG-enriched top phase for re-extraction (Persson et al. 2001). The combined top phases from the partitioning step above are mixed thoroughly with the WGA-containing bottom phase by 20 inversions, vortexing, and another 20 inversions. After phase separation through gentle centrifugation as above, the top phase is removed and the bottom phase re-extracted in the same manner with the fresh top phase obtained from the pre-equilibrated 20-g system. The final bottom phase is collected, diluted 10-times with 0.1 M *N*-acetylglucosamine in 5 mM Tris/HCl (pH 8.0) to dissociate membranes from WGA-dextran, and centrifuged (100,000 × *g*, 90 min). The plasma membrane pellet is resuspended in homogenization medium.

K.6.3.6.2 Preparation of Lipid Rafts and Caveolae

PURPOSE AND RATIONALE

Typical preparations of lipid rafts use 1% Triton X-100 to extract whole cells and the low-density, detergent-resistant material is separated from other solubilized membrane fractions by centrifugation on a 5% to 30% sucrose gradient (Brown and Rose 1992). Subsequently, lipid rafts have been prepared using a variety of other detergents, including Lubrol WX, Lubrol PX, Brij58, Brij96, Brji98, Nonidet P40, CHAPS, and octylglucoside (for a review see Macdonald and Pike 2005). Although preparations of detergent-resistant membranes are readily isolated, several observations have raised concerns that extraction of cells with detergent may be generating clusters of raft lipids and proteins that did not exist in the intact cell. For example, examination of cells grown on coverslips and then extracted with Triton X-100 reveals a continuous membrane sheet pock-marked by large holes (Major and Maxfield 1995). Because rafts are thought to be < 50 nm in diameter (Anderson and Jacobson 2002, Edidin 2003), the residual "detergent-resistant" membranes probably form from individual rafts that coalesced as a result of the detergent treatment.

To avoid the complications associated with preparing rafts using detergent extraction procedures, several methods have been established for isolating rafts from cells fractionated in the absence of detergent. Song and coworkers (1996) sonicated cells in a pH 11 sodium carbonate buffer and isolated caveolae by centrifugation of the lysate in a discontinuous 5%/35%/45% sucrose gradient. Although this procedure is relatively easy, the spin time of 16–20 h is long and the resulting raft fraction is significantly contaminated with other membranes. A more carful fractionation of lipid rafts (Smart et al. 1995), which is based on lysis of the cells in an isotonic buffer containing EDTA and purified plasma membranes on a Percoll gradient. The plasma membranes are then sonicated and the lipid rafts isolated by flotation through a 10–20% gradient OptiPrep. This method results in the production of a relatively clean raft preparation. However, it is time-consuming and yields are poor. Furthermore, there is significant variability from preparation to preparation and from cell type to cell type. Because of the drawbacks associated with those procedures for isolating detergent-free lipid rafts, Macdonald and Pike (2005) developed an improved method that allows the rapid isolation of purified rafts in good yield. It is based on lysis of cells by shearing in an isotonic buffer containing calcium and magnesium and apparently allows isolation of a highly purified raft fraction in a single step by flotation in a 0–20% OptiPrep gradient.

Studies on caveolae structure and function would be facilitated by a convenient high-yield isolation procedure. Most isolation protocols developed involve the

detachment of caveolae from crude membranes either by Triton X-100 treatment (Sargiocomo et al. 1993, Chang et al. 1994) or by sonication (Smart et al. 1995) followed by density gradient centrifugation in either sucrose (Sargiocomo et al. 1993, Chang et al. 1994) or OptiPrep gradients (Smart et al. 1995). To obtain highly purified caveolae, however, extensive purification of a suitable plasma membrane fraction is required prior to detachment and centrifugation as was demonstrated using lung endothelial cells (Schnitzer et al. 1995a, b). Alternatively, immunoisolation protocols may be used (Oh and Schnitzer 1999, Abedinpour and Jergil 2003), although these also require prepurification steps.

PROCEDURE

Conventional plasma membrane purification protocols based on centrifugation techniques usually result in low yields. In an alternative approach rat liver plasma membranes are purified by affinity partitioning in a PEG–dextran aqueous two-phase system (see above). Partitioning conditions are chosen to direct the bulk of unfractionated membranes to the PEG-rich top phase and then selectively to attract plasma membranes to the dextran-rich bottom phase by including WGA conjugated to dextran as an affinity ligand. This lectin specifically binds to *N*-acetylglucosamine and sialic acid residues on the plasma membrane surface. The affinity purification method is rapid and resulted in plasma membranes of high purity and yield (Persson et al. 1991, Persson and Jergil 1992). The possibility of combining two-phase affinity purification of plasma membranes with density gradient centrifugation to isolate caveolae has been explored (Abedinpour and Jergil 2003). Such a method should be generally applicable for the preparation of caveolae from various tissues and cells. The isolation of a vesicular fraction from rat lung highly purified in caveolin, a caveolar marker protein, by this approach is reported.

K.6.3.6.2.1 Carbonate-Based Method

Purified plasma membranes are pelleted and resuspended in 0.5 M Na_2CO_3 (pH 11), and sonicated with a probe-type sonifier 3 × 20 s. The homogenate is then adjusted to 45% (w/v) sucrose in 12 mM MES (pH 6.5), 75 mM NaCl, 0.25 M Na_2CO_3, with protease inhibitors, and loaded under a 5–35% (w/v) discontinuous sucrose gradient in the same solution and centrifuged (39,000 rpm, 16–20 h, 4°C, Beckman SW41 rotor). The light-scattering band at the 5–35% sucrose interface is collected and referred to as standard caveolae fraction. The recovery of caveolin in the caveolae fraction is typically 25 ± 5%as determined by immunoblotting. Alternatively, for preparation from intact adipocytes, washed cells (0.5×10^7 cells) are suspended in 2 ml of sodium carbonate buffer (0.5 M Na_2CO_3, pH 11) containing protease inhibitors and homogenized sequentially using a loosely fitting Dounce homogenizer (10 strokes) and a sonicator (3x20 s bursts). The homogenate (2 ml) is then adjusted to 45% sucrose by addition of 2 ml of 90% sucrose, 50 mM MES/KOH (pH 6.5), 150 mM NaCl (final pH of the mixture 10.2). A discontinuous sucrose gradient is formed by overlaying this solution with 4 ml of 35% sucrose and 4 ml of 5% sucrose, both in the same buffer containing 0.25 M Na_2CO_3. After centrifugation (see above), 0.85-ml gradient fractions are collected to yield a total of 14 fractions. The individual gradient fractions are pooled into rafts (Fr. 4–7) and non-raft areas (Fr. 10–14). The membranes from each pooled gradient fractions obtained by either method are diluted 2- to 3-fold with 25 mM MES (pH 6.5), 150 mM NaCl, 1% TX-100, collected by centrifugation (50,000 × *g*, 30 min, 4°C) and resuspended in non-dissociating buffer (10 mM Tris/HCl, pH 7.4, 150 mM NaCl, 1% Nonidet P-40, 5 mM EDTA, 0.5 mM EGTA, 1 mM sodium orthovanadate, 50 mM NaF and protease inhibitors) or dissociating buffer (= non-dissociating buffer supplemented with 60 mM octylthioglucoside, 0.3% deoxycholate) as indicated, incubated (1 h, on ice) and used for (co)immunoprecipitation, immunoblotting or photoaffinity labeling.

K.6.3.6.2.2 Detergent-Based Method

For preparation from intact adipocytes, washed adipocytes (3.5×10^7) are suspended in 1.5 ml of lysis buffer (25 mM MES, pH 6.0, 150 mM NaCl, 5 mM EDTA, 1% TX-100, 0.2 mM sodium orthovanadate, and protease inhibitors) and incubated for 20 min on ice. The cells are lysed with 10 strokes in a manual Teflon-in-glass homogenizer over the course of 1 h at 4°C. The lysate is centrifuged (1,300 × *g*, 5 min) to pellet unbroken cells, cellular debris, nuclei and large unsoluble material. One ml of the postnuclear supernatant is subjected to sucrose gradient centrifugation by mixing with an equal volume of 85% sucrose, 25 mM MES (pH 6.0), 150 mM NaCl, 5 mM EDTA at the bottom of a 12-ml centrifuge tube which is overlayed with 5.5 ml of 35% sucrose, and then 3.5 ml of 5% sucrose in the same medium. After centrifugation (230,000 × *g*, 18 h, 4°C, Beckman SW41 rotor), 0.9-ml

fractions are collected from top to bottom, and termed fraction Fr. 1, 2, 3, etc. The bottom fraction is Fr. 12. Fr. 5 appears as a white, light-scattering band under illumination located at 5–7% sucrose at the 35-% sucrose interface. The rafts contained in Fr. 5 are pelleted by dilution of the sucrose with 5 volumes of 50 mM HEPES/KOH containing protease inhibitors and centrifugation (200,000 × *g*, 2 h).

Alternatively, for preparation from plasma membrane fractions, Triton X-100 is added to the purified plasma membrane fraction to a final concentration of 1% (w/v) (approximately a 100-fold excess of detergent to membrane protein). The sample is incubated for 30 min at 4°C and centrifuged (100,000 × *g*, 90 min). The pellet is resuspended in homogenization medium by 10 strokes in a tight-fitting Dounce homogenizer. The resulting sample is transferred to a Beckman SW40 ultracentrifuge tube. The sample is adjusted to 40% (w/v) sucrose by addition of 80% (w/v) sucrose, before layering 5.5 ml each of 24 and 5% (w/v) sucrose on top of the sample. All sucrose solutions are made in 5 mM Tris/HCl (pH 8.0). After centrifugation (100,000 × *g*, 21 h, 4°C, Beckman SW41 rotor), 12 1-ml fractions are collected by upward displacement. The light-scattering band at the 5–35% (w/v) sucrose interface is collected as lipid rafts. The recovery of caveolin is typically 15 % as determined by immunoblotting.

K.6.3.6.2.3 Immunopurification

Lipid rafts prepared from rat adipocytes (originating from 500 µl of packed cell volume) are resuspended in 0.5 ml of homogenisation buffer (buffer H). 1% Triton X-100, 2% CHAPS, 60 mM D-octyl glycoside (final concentrations) are added to 50 µl of resuspended rafts to a final volume of 100 µl. After 1 h on ice, the fractions are centrifuged (104,000 × *g*, 1 h). The pellets containing detergent resistant rafts are resuspended in 100 µl buffer H and analyzed. For immunoprecipitations the rafts (corresponding to 750 µl of packed cell volume) and resistant to 1% Triton X-100 treatment are suspended in 300 µl buffer H and incubated for 4 h with 6 µl caveolin-1 antibody supplemented with 10 µl of packed Protein A-Sepharose during the last hour. Non-bound material is removed and the Sepharose gel is washed five times in 600 µl buffer H. The bound proteins are eluted by boiling for 15 min in buffer H supplemented with 0.6% $C_{13}E_{12}$, 48 mM NaF, 48 mM NaCl, 5% SDS, 2% β-mercaptoethanol and 5% glycerol. For GLUT-4 analysis, rafts (corresponding to 500 µl packed cell volume) are treated with 1% $C_{13}E_{12}$ and centrifuged (7000 × *g*, 10 min). The supernatant is incubated for 4 h with 4 µl caveolin-1 antibody supplemented with 7 µl packed protein A-Sepharose during the last hour. The gel is washed and eluted as described above. Each step in the immunoprecipitation procedures is performed at 4°C. The recovery of immunopurified lipid rafts is normalized by homologous immunoblotting with anti-caveolin antibodies of the same blot following stripping of the membrane.

EVALUATION

A generally applicable method for the preparation of highly purified caveolae and/or lipid rafts based on a combination of affinity preparation of plasma membranes and density gradient centrifugation has been developed. To test this approach lung tissue have been chosen as endothelial cells lining vascular ducts are rich in caveolae. In earlier studies caveolae were prepared from plasma membranes of these cells isolated by an in situ silica-coating procedure (Schnitzer et al. 1995b). Alternatively, a crude lung homogenate can be used as starting material, preparing a plasma membrane-enriched fraction by affinity partitioning (Abedinpour and Jergil 2003). To improve purity the affinity step is preceded by homogenization of the tissue directly in a conventional aqueous two-phase system followed by phase separation to remove material disturbing the affinity step. A similar approach was elaborated successfully for the purification of plasma membranes from liver (Persson and Jergil 1992, Ekblad and Jergil 2001), suggesting that the method might be applicable also to other tissues. Lung membranes have been shown similarly to liver membranes both in the conventional and in the affinity two-phase step. The overall yield of the plasma membrane marker enzyme, 5′-nucleotidase, is somewhat lower from lung (30–35%) than from liver (50–70%), however. This is primarily due to a low recovery of 5′-nucleotidase in the affinity step rather than an unfavorable distribution of the enzyme in this step or the preceding conventional two-phase step. The enrichment of 5′-nucleotidase (8-fold) compares favorably with the 5- to 10-fold enrichment of various plasma membrane markers in the earlier isolation procedure involving silica coating of lung endothelial plasma membranes. The silica coating procedure isolates the luminal part of the plasma membrane (Schnitzer et al. 1995b), while all regions of the plasma membrane are isolated by the affinity partitioning procedure (Persson et al. 1991, Persson and Jergil 1992, Ekblad and Jergil 2001).

The plasma membrane fraction obtained by the affinity procedure is suitable for the isolation of a frac-

tion highly enriched in the caveolar marker, caveolin, after dispersion of the membranes in Triton X-100 and floatation in a sucrose density gradient. The enrichment of caveolin is approximately 20-fold in this density gradient step, slightly higher than the 13-fold enrichment observed when caveolae-rich vesicles are isolated from silica-coated endothelial plasma membranes (Schnitzer et al. 1995b). However, both the affinity partitioning method presented here and the silica coating procedure result in plasma membrane material suitable for obtaining highly purified caveolae by sucrose gradient centrifugation regardless of the enrichment of caveolin attained.

Caveolae may be isolated also by a detergent-free method, gradient centrifugation by sonication of affinity purified plasma membranes. Although the yield is much lower, this nevertheless shows that the separation also works for the detergent-free preparation of caveolae-enriched material. It may be possible to optimize shearing of the plasma membrane preparation and the gradient separation to increase the yield, particularly since much vesicular material containing caveolin remained in the high-density part of the gradient. The caveolin-enriched fraction isolated after Triton X-100 treatment consists of morphologically similar closed vesicles of the same size (50–100 nm) as that of caveolae previously isolated from lung endothelial cells (Schnitzer et al. 1995a and 1995b, Stan et al. 1997). Notably no vesicles in the size range 200–700 nm are observed. Such vesicles are common in Triton-insoluble membranes prepared from crude lung homogenates, being either non-caveolar membranes or membranes occasionally having attached caveolae (Schnitzer et al. 1995d). They are not present, however, in caveolar preparations obtained by Triton X-100 treatment of endothelial plasma membranes isolated by the silica coating procedure followed by sucrose gradient centrifugation. The thin-section micrographs indicated that many of the isolated vesicles are not smoothly rounded but had an irregular shape.

K.6.3.6.3 Lipid Raft- and Caveolae-Based Assays in Insulin and Insulin-Like Signal Transduction

PURPOSE AND RATIONALE

For studying signal transduction processes which involve caveolae, these structures are isolated as rafts by biochemical methods (carbonate or detergent extraction) from primary or cultured differentiated cells, such as muscle and fat cells, after incubation with external stimuli. Rafts can be prepared either directly from total cells, or total cell lysates or (preferably) isolated (purified) plasma membranes. The use of rafts from total cells or lysates may obscure subtle changes in signaling since the (considerable) fraction of rafts present in membranes of the Golgi apparatus (where their biogenesis takes place) may respond differently (or not at all) toward external stimuli compared to the plasma membrane rafts. Subsequent analysis for the presence in/cofractionation with caveolae, direct interaction with caveolin and changes in activity of signaling proteins in response to the external stimuli requires the methods of enrichment/purification of rafts, photoaffinity labeling (of GPI proteins), coimmunoprecipitation with caveolin (of signaling proteins), immunoblotting (of signaling proteins) and immune complex kinase assays (in case of kinase activity of signaling proteins).

K.6.3.6.3.1 Co-Immunoprecipitation of Lipid Raft Proteins

Total cell lysates (25–50 µg protein) or rafts in non-dissociating buffer (10–15 µg protein) are pre-cleared (1 h, 4°C) with protein G/A-Sepharose (50 mg/ml) in a total volume of 100 µl and then supplemented with appropriate antibodies (e. g. $pp125^{Fak}$, 2 µg/sample; IRS-1, 1:50 dilution; IRS-2, 10 µg/sample; $pp59^{Lyn}$, 5 µg/sample; caveolin, 0.7 µg/sample; IRβ, 1:175 dilution) pre-adsorbed on protein G-Sepharose (monoclonal antibodies) or protein A-Sepharose (rabbit antibodies) in a total volume of 100 µl. After incubation (4 h, 4°C, end-over-end rotation) and centrifugation (3,000 × g, 2 min, 4°C), the collected immune complexes are washed twice with 1 ml each of immunoprecipitation buffer (50 mM HEPES/KOH, pH 7.4, 500 mM NaCl, 100 mM NaF, 10 mM EDTA, 10 mM sodium pyrophosphate, 1 mM sodium orthovanadate) containing 0.2% Nonidet P-40 and 0.3% deoxycholate, then twice with 1 ml each of immunoprecipitation buffer containing 150 mM NaCl and 0.2% Nonidet P-40 and once with 1 ml of immunoprecipitation buffer lacking salt and detergent and finally suspended in 50 µl of Laemmli sample buffer (4% SDS, 115 mM Tris/HCl, pH 6.8, 1 mM EDTA, 10% glycerol, 4 mg/ml bromophenol blue) supplemented with 1.2% β-mercaptoethanol (except for anti-caveolin immunoprecipitates), heated (95°C, 2 min) and centrifuged. The supernatant samples are analyzed by SDS-PAGE (4–12% Bis-Tris precast gel, pH 6.4, MES/SDS running buffer under reducing conditions) and subsequent immunoblotting (see K.6.3.4.3 and K.6.3.6.3.2). The centrifugation conditions for collection of the protein A/G-Sepharose-bound immune

complexes, do not lead to sedimentation of (non-dissociated rafts) to any significant degree according to immunoblotting with anti-caveolin antibody. The coimmunoprecipitation of proteins with caveolin from non-dissociated rafts is specific for raft-associated components, such as the GPI protein, Gce1, and the dual-acylated non-RTK, pp59^{Lyn}, since the use of non-immune IgG instead of anti-caveolin antibody or of dissociated DIGs and anti-caveolin antibody do not result in immunoprecipation of Gce1 and pp59^{Lyn}.

K.6.3.6.3.2 Immunoblotting of Lipid Raft Proteins

Immunoblotting is performed as described (see K.6.3.1.3.2.1 and K.6.3.4.3) with minor modifications. After SDS-PAGE and transfer of the proteins to PVDF membranes (2 h, 400 mA in 20% methanol, 192 mM glycine, 25 mM Tris, 0.005% SDS), the blocked membrane (1 h in 20 mM Tris/HCl, pH 7.6, 150 mM NaCl, 0.05% Tween 20, 0.1% Brij, 0.01% NP-40 and with 1% ovalbumin and 1% BSA (anti-phosphotyrosine, anti-pp59^{Lyn}, anti-IRβ) or with 5% non-fat dried milk (anti-caveolin, anti-IRS-1/2) is incubated (2 h, 25°C) with antibodies against IRS-1 (1:500), IRS-2 (1:750), caveolin (1:2,000), pp59^{Lyn} (1 µg/ml) or IRβ (2 µg/ml) diluted in the same medium, and then washed five times with the same medium. After incubation of the membranes (1 h, 25°C) with horseradish peroxidase-coupled goat anti-mouse IgG antibody or goat anti-rabbit IgG antibody diluted in the appropriate blocking buffer (1:5,000 or 1:2,500) and subsequent washing with detergent-containing (two times) and detergent-free (two times) buffer (20 mM Tris/HCl, pH 7.6, 150 mM NaCl), the labeled proteins are visualized by the enhanced chemiluminescence method.

K.6.3.6.3.3 Immunecomplex Assay for Lipid Raft PK

Immunecomplex kinase assays are performed as described (see K.6.2.9.2 and K.6.3.4.4) with minor modifications. Immune complexes are suspended 30 µl of kinase buffer (50 mM HEPES/KOH, pH 7.4, 100 mM NaCl, 1.25 mM $MnCl_2$, 12.5 mM $MgCl_2$, 1.25 mM EGTA, 0.5 mM DTT, 1 mM Na_3VO_4) containing [γ-^{32}P]ATP (final conc. 40 µM, 0.2 mCi/ml) or 1 mM ATP and incubated (e. g. for pp59^{Lyn}: 15 min, 22°C) in the presence of 1 µg heat-denatured enolase. Phosphorylation is terminated by addition of 10 µl of four-fold concentrated Laemmli buffer and boiling. The phosphoproteins are separated on SDS-PAGE (10% Bis-Tris resolving gel, MOPS/SDS running buffer) and analyzed for phosphotyrosine by phosphorimaging ([γ-^{32}P]ATP) or immunoblotting (ATP). Under these conditions the kinase reactions are linear with time for the assay period. IRS-1 immune complexes are assayed for PI3-K by incubating (10 min, 22°C) in 50 µl of 20 mM Tris/HCl (pH 7.0), 50 µM [γ-^{33}P]ATP (5 µCi), 10 mM $MgCl_2$, 2 mM $MnCl_2$, 100 mM NaCl, 2 mM EDTA, 0.5 µM wortmannin (for control incubations, only) containing 10 µg of phosphatidylinositol (PI) and 1 µg of phosphatidylserine. After addition of 10 µl of 8 M HCl and 160 µl of a 1/1 mixture of methanol/chloroform, the extracted phospholipids are resolved by TLC on plates coated with 1% oxalate and developed in chloroform/methanol/water/ammonia (60/47/11.3/3.2, by vol.). Radiolabeled PI3-P is quantitated by phosphorimage analysis. For calculation of wortmannin-sensitive PI3-K, all values are corrected for PI3-P radiolabeled in the presence of wortmannin. SDS-PAGE and subsequent immunoblotting for caveolin and the PK assumed to localize permanently or transiently at lipid rafts (e. g. protein kinase C) is performed as described (K.6.3.6.3.2).

K.6.3.6.3.4 Electron Microscopic Analysis of Caveolae

PURPOSE AND RATIONALE

Several laboratories have localized important elements of the insulin signal transduction machinery to caveolae or rafts, including the IR itself. Baumann and coworkers (2000) and Chiang and coworkers (2001) have reported the discovery of a novel insulin-signaling pathway in adipocytes that relies on proper localization of signaling molecules to lipid rafts and that is required for insulin-stimulated glucose uptake. Using a detergent-based method of lipid raft preparation, Mastick and coworkers (1995) found only trace levels of insulin receptor in the rafts of 3T3-L1 adipocytes. Müller and coworkers (2001a, b) characterized the composition of rafts from isolated rat adipocytes. The rafts and non-rafts were prepared by both detergent and detergent-free methods from total cell lysates and from plasma membranes, respectively. Representative fractions were analyzed by immunoblotting for known raft and nonraft proteins. Despite the methodological differences, there was good agreement between the proteins enriched in rafts and non-rafts by the two procedures. By both methods, the β-subunit of the IR was relatively depleted from the rats and relatively enriched in the non-rafts. However, Gustavsson and coworkers (1999) reached the opposite result by double immunogold transmission EM and detergent-free isolation of rafts. In these experiments, caveolin and

both subunits of the IR colocalized in ~50-nm-round structures that corresponded to individual caveolae and in clusters of these structures. This colocalization was confirmed by immunofluorescence microscopy in paraformaldehyde-fixed 3T3-L1 adipocyte plasma membrane sheets. The immunofluorescence labeling pattern appeared as doughnut-like spots of 0.3–0.5 μm diameter, a size that was noted to be similar to that of the caveolae clusters visualized by EM. Biochemically, the IR cofractionated with caveolin in detergent-free isolation of rafts from rat adipocyte plasma membranes. The addition of insulin was not associated with a significant change in localization of the IR, as assessed biochemically or by immunofluorescence. Even low concentrations of Triton X-100 (0.1%) completely solubilized the β-subunit of the IR from the caveolin-enriched fractions. This observation may explain why Mastick and coworkers (1998) found only trace amounts of the IR in rafts prepared on the basis of detergent insolubility. The molecular basis for the (partial or transient) localization of IR at lipid rafts may rely on the interaction of IR with caveolin-1, which is assumed to differentially modulate insulin signaling, as has been demonstrated by Nystrom and coworkers (1999).

PROCEDURE

Samples of appropriate fractions from the sucrose gradient are mixed with 10 volumes of 3% paraformaldehyde and 1.5% glutaraldehyde in 0.1 M sodium cacodylate, pH 7.4 (final conc.). The sample is incubated (40 min, 4°C) followed by centrifugation (100,000 × *g*, 90 min). The pellet is washed twice with 0.1 M sodium cacodylate (pH 7.4), treated with 1% OsO_4 for 1 h, and washed twice with 0.1 M sodium cacodylate. Samples were stepwise dehydrated in ethanol, treated with 1% uranyl acetate in ethanol, and embedded in Epon. Thin sections (50 nm) were stained with uranyl acetate and lead by standard procedures and examined and micrographed in an electron microscope.

Samples of the caveolae-enriched fractions are also examined following negative staining after fixation with 2% paraformaldehyde. The material is attached to carbon and pioloform-coated nickel grids for 20 min. The grids are washed three times for 5 min with phosphate-buffered saline before staining with 1% uranyl acetate for 2 min and micrographing in an electron microscope.

EVALUATION

An insulin-independent pathway has been described that mimics the metabolic actions of insulin in adipocytes (Müller et al. 2001a, b). This pathway can be stimulated in adipocytes by exogenous phosphoinositolglycans (PIG), cleavage products of the glycosyl-phophatidylinositol (GPI) anchor of GPI-linked proteins, which have initially been proposed to act as soluble mediators of insulin action, but do not share structural and functional similarity with the typical second messengers regulating glycogen metabolism in response to adrenergic hormones (Wasner et al. 2003). PIG treatment of isolated rat adipocytes leads to concentration-dependent increases in tyrosine phosphorylation of IRS-1, IRS-1-associated PI3-K activity, and glucose uptake in an insulin-independent fashion. A critical mechanism in this pathway may involve the dissociation of the non-RTK, Lyn and Fak, from caveolin-1 (Müller et al. 2000), their activation by tyrosine phosphorylation, and their redistribution from rafts to non-raft membranes (Müller et al. 2001b, Müller et al. 2005). Incubation of adipocytes with PIG, as with insulin, is followed by tyrosine phosphorylation of caveolin-1. The same research group succeeded in the characterization and identification of a specific binding protein for synthetic PIG in the lipid rafts of the adipocyte plasma membrane (Müller et al. 2002a, b). The involvement of lipid rafts in insulin-mimetic signaling by PIG was demonstrated by complete abrogation of redistribution of signaling proteins and IRS-1 tyrosine phosphorylation in response to PIG challenge of rat adipocytes, which have been depleted of lipid rafts by prior cholesterol removal from the plasma membrane (Müller et al. 2002e). The physiological role of this pathway and its potential cross talk with the insulin-signaling pathway in caveolae remain to be determined (Müller 2002d). These questions will be facilitated by molecular cloning and inactivation or overexpression of the gene coding for this PIG receptor in 3T3-L1 adipocytes.

Several laboratories have investigated whether there is overlap between membrane compartments that contain caveolin and GLUT4. Using biochemical isolation techniques, Scherer and coworkers (1994) detected a transient increase in GLUT4 immunoreactivity in rafts after insulin stimulation of 3T3-L1 adipocytes. Also, insulin stimulation led to an increase in plasma membrane caveolin and a corresponding decrease in caveolin detected in low-density microsomes. These investigators detected caveolin in GLUT4 vesicles immunoisolated from rat adipocytes. Kandror and coworkers (1995) conducted similar studies but arrived at a different conclusion. They found that intracellular caveolin and GLUT4 were detectable on vesicles of similar size and buoyant density and

that these vesicles translocated to the plasma membrane in response to insulin. However, in contrast to the findings of Scherer and coworkers (1994), only limited amounts of caveolin protein were present in immunoabsorbed GLUT4 vesicles, which suggested that the intracellular pools of these proteins, although biophysically similar, were distinct. Gustavsson and coworkers (1996) isolated subcellular membrane fractions from rat adipocytes and performed glucose uptake assays on intact adipocytes at various times during an insulin pulse. On basis of the results obtained, the authors propose a model such that, upon insulin stimulation, GLUT4 moves first to the PM and then to detergent-resistant plasma membrane microdomains (caveolae?), where GLUT4-mediated glucose transport occurs. Taken together, at this point the weight of the published data supports localization of a significant subset of plasma membrane IR and GLUT4 to caveolae in adipocytes, nut the issue is not settled (for a review see Bickel 2002).

K.6.3.6.4 Glycosyl-Phosphatidylinositol-Specific Phospholipase (GPI-PL) and Insulin-Like Signaling

GENERAL CONSIDERATIONS

Insulin-responsive mammalian cells and tissues express a number of GPI-proteins, the majority of them with their GPI anchor embedded in the outer leaflet of the plasma membranes as well as some lipases, the (G)PI-PLC/D, which may control down-regulation of GPI-protein cell surface expression and simultaneously up-regulation of the soluble protein moiety released into circulation (Romero et al. 1988, Low 1989 and 1990, Thomas 1990, Romero and Larner 1993, Saltiel 1990, Saltiel et al. 1986, Müller and Bandlow 1991, Varela-Nieto et al. 1996, Nosjean et al. 1997, Jones and Varela-Nieto 1999, Müller et al. 2005). In fact, soluble forms of GPI-proteins have been detected in human plasma, such as 5′-nucleotidase, Thy-1, alkaline phosphatase and CD16 receptors, and GPI-PLC have been found in human neutrophils, bovine brain, rat intestine and a human carcinoma cell line. The GPI anchor consisting of three mannose residues and a non-acetylated glucosamine, one end of which amide-linked to the protein moiety *via* a phosphoethanolamine bridge and the other end glycosidically linked to the 6-hydroxyl group of PI, is cleaved by (G)PI-PLC/D releasing diacylglycerol or phosphatidic acid, respectively, and leaving a terminal inositolglycan structure at the protein moiety harbouring (PIG) or lacking a (cyclic) phosphate residue (for reviews see Chan et al. 1988, Cross 1990, Ferguson 1991, Müller 2000).

In eukaryotes, some GPI-PLC/D are up-regulated by glucose as well as certain hormones, growth factors and drugs (e. g. insulin, glimepiride) in rodent adipocytes, myocytes and human endothelial cells (Müller et al. 1993, 1994a, 1994c, Mohavedi and Hooper 1997). In particular, the antidiabetic drug, glimepiride, which lowers blood glucose predominantly by stimulation of insulin release from pancreatic β-cells and, in addition, to a minor degree by mimicking metabolic insulin action in peripheral tissues, such as activation of glucose transport in muscle cells and inhibition of lipolysis in adipocytes (Müller et al. 1994d, Bähr et al. 1995), has been demonstrated to activate a GPI-PLC. Upon treatment of primary or cultured rodent adipocytes with pharmacological concentrations of this sulfonylurea, a potent amphiphilic-to-hydrophilic conversion of a subset of GPI-proteins by activation of a GPI-PLC has been observed (Müller et al. 1993, 1994b). The functional and physiological significance of the insulin- and glimepiride-regulated lipolytic cleavage of GPI-proteins in mammalian cells is not well understood at present, albeit initially a role as soluble mediators for metabolic insulin action has been proposed (Farese 1990, Fonteles et al. 1996, Gaulton 1994, Larner 1987, Lazar et al. 1994, Lisanti et al. 1989, Mato 1989, Low and Saltiel 1988, Lawrence et al. 1986, Müller 2002a, Romero 1990, Shaskin et al. 1997, Saltiel et al. 1988).

PURPOSE AND RATIONALE

Recently, a synthetic inositol derivative, GPI-2350, has been described which inhibits the well-characterized bacterial, trypanosomal and serum (G)PI-PLC/D with high potency and selectivity (Müller et al. 2005). Using GPI-2350, which almost completely down-regulates the insulin- and glimepiride-inducible GPI-PLC in intact rat adipocytes, a major role for this enzyme in metabolic insulin signalling and action in

these cells could be excluded. In contrast, activation of the GPI-PLC turned out to be indispensable for the insulin-mimetic effects of glimepiride *via* the recently described IR-independent cross-talk from lipid rafts to the IRS-1 protein (see above). Based on the criteria for lipid rafts, certain GPI-anchored, acylated and transmembrane signalling proteins have been found to be enriched in rafts *vs* non-raft areas of the plasma membranes. Furthermore, rafts are not homogenous in composition and structure since subspecies of higher (hcRafts) and lower cholesterol (lcRafts) content can be distinguished from one another on the basis of their lower and higher buoyant density, respectively (Müller 2005, Müller et al. 2005). Strikingly, the stimulus-induced redistribution of certain GPI-anchored as well as acylated signalling proteins from hcRafts to lcRafts (Müller et al. 2001a, b) is blocked by GPI-2350. This finding hints to a role of the mammalian GPI-PLC in the control of the localization and activation of signalling proteins within rafts during signal transduction across the plasma membrane of adipocytes. The following assays enable the analysis of the role of the GPI-PL for insulin-like signaling and metabolic action in insulin target cells as well as of the effects of compounds/drug candidates on the activity of the GPI-PL. The GPI-PL may turn out as promising target for future anti-diabetic drugs (Müller and Frick 1999, Müller 2002b, Müller and Welte 2002).

K.6.3.6.4.1 Activity Assay for GPI-PL

PROCEDURE

Adipocyte GPI-PLC

Adipocyte GPI-PLC (5–25 µg PM or hc/lcRafts) is assayed as the conversion of GPI-protein, acetylcholinesterase (AchE) from its amphiphilic version (containing the intact GPI anchor) into its hydrophilic version (containing the lipolytically cleaved GPI anchor) are assayed according to a protocol adapted from Müller and coworkers (1994b) by incubation with 10 µl of bovine erythrocyte AChE solution (12 U/ml in 10 mM Tris/HCl, pH 7.4, 144 mM NaCl, 0.1% TX-100) in 100 µl of 20 mM HEPES/KOH (pH 7.8), 144 mM NaCl, 0.1% TX-100, 0.2 mM $MgCl_2$ for 1 h at 25°C and subsequent termination by adding 5 µl of glacial acetic acid and then 0.4 ml of 10 mM Tris/HCl (pH 7.4), 144 mM NaCl. Each reaction mixture is subjected to TX-114 partitioning (see below). The GPI-PLC activity is calculated as the amphiphilic-to-hydrophilic conversion of the GPI-protein substrates from the ratio of the activities of hydrophilic 5′-Nuc or AChE measured in the TX-114-depleted phase and the total activity measured before partitioning and corrected for the non-enzymatic background in the TX-114-depleted phase (accounting for 10–20% of the total activity) as revealed by blank incubations lacking (G)PI-PLC.

TX-114 partitioning

Pelleted hc/lcRafts (10–50 µg protein) or GPI-PL reaction mixtures (0.5 ml) are separated into amphiphilic and hydrophilic proteins using partitioning between TX-114-enriched and depleted phases according to Bordier (1981) and Pryde and Phillips (1986) by suspending in 1 ml or mixing with 0.5 ml, respectively, of ice-cold 25 mM Tris/HCl (pH 7.4), 144 mM NaCl containing 1 or 2% TX-114. After incubation for 1 h on ice, the mixture is layered onto a cushion of 0.4 ml of 0.25 M sucrose and 25 mM Tris/HCl (pH 7.4) on ice. Phase separation is induced by warming up to 37°C and subsequent centrifugation (10,000 × *g*, 1 min). After re-extraction of the lower TX-114-enriched phase, aliquots of the pooled upper TX-114-depleted phase are measured for AChE activity or precipitated (15% polyethylene glycol 4000) for SDS-PAGE analysis.

EVALUATION

Concentration-response curves are established using various concentrations of standard (human insulin) and the test compounds, e. g. sulfonylureas, allowing calculation of EC_{50} values and potency ratios.

K.6.3.6.4.2 GPI-PL-Dependent Translocation of GPI Proteins Within Lipid Rafts

PROCEDURE

Photoaffinity Labeling of the GPI Protein, Gce1

Solubilized plasma membranes and rafts (5–10 µg protein) are incubated (30 min, 4°C) with 50 µCi 8-N_3-[^{32}P]cAMP (0.5 nmol) in 50 µl of 10 mM Tris/HCl (pH 7.4), 1 mM EDTA, 0.5 mM EGTA, 140 mM NaCl, 10 mM $MgCl_2$, 2 mM $MnCl_2$, 1 mM isobutylmethylxanthine, 1 mM DTT, 1 mM AMP, and protease inhibitors in the wells of microtiter plates (96-formate) and then irradiated with UV light (254 nm, 8000 µW/cm^2) at a distance of 0.5 cm for 1 min (Müller et al. 1993, 1994a, b). Subsequently, the photoaffinity labeling reaction is quenched by addition of 100 µl of the same buffer containing 10 mM cAMP. Gce1 is precipitated (5% trichloroacetic acid, 1 h on ice, 10,000 × *g*, 15 min) and solubilized in sample buffer for SDS-PAGE. Protein concentration is determined using the BCA protein determination kit from Pierce. Autoradiographs and direct photoimages

are processed and quantified by computer-assisted video densitometry (e. g. Storm 860 PhosphorImager system, Molecular Dynamics). The recovery in the amounts of immunoprecipitated protein has to be corrected (data on fold- or % stimulation) for the amount of protein actually applied onto the gel as revealed by homologous immunoblotting.

Preparation of lc/hcRafts

Pre-treated and subsequently washed adipocytes are homogenized in lysis buffer (25 mM MES, pH 6.0, 140 mM NaCl, 2 mM EDTA, 0.5 mM EGTA, 0.25 M sucrose, 50 mM NaF, 5 mM sodium pyrophosphate, 10 mM glycerol-3-phosphate, 1 mM sodium orthovanadate and protease inhibitors) using a motor-driven Teflon-in-glass homogenizer (10 strokes). Plasma mmebranes are obtained by differential centrifugation of the defatted postnuclear infranatant (= cytosolic fraction) and then purified by two sequential centrifugation steps through sucrose and Percoll cushions as described above and finally suspended in 25 mM Tris/HCl (pH 7.4), 0.25 M sucrose, 1 mM EDTA at 2 mg protein/ml. hc/lcRafts are obtained by the detergent method and discontinuous sucrose gradient centrifugation as reported above. The light-scattering opalescent bands at the 0.5–0.65 M (fractions 3 + 4) and 0.8–0.9 M (fractions 5 + 6) sucrose interfaces are collected as hcRafts and lcRafts, respectively, with density measurement using the refractive index. hc/lcRafts are collected by centrifugation (50,000 × *g*, 30 min, 4°C) after three-fold dilution of the pooled gradient fractions with 25 mM MES (pH 6.5), 1% TX-100, 150 mM NaCl, and then characterized (immunoblotting, enzyme assays) by enrichment/deprivation of relevant marker proteins as described above or subjected to TX-114 partitioning (see K.6.3.6.4.1). For immunoprecipitation of caveolin, rafts are solubilized (1 h, 4°C) in 10 mM Tris/HCl (pH 7.4), 150 mM NaCl, 1% TX-100, 60 mM β-octylglucoside, 0.3% deoxycholate, 5 mM EDTA, 0.5 mM EGTA, 1 mM sodium orthovanadate, 50 mM NaF, 1 µM microcystin and protease inhibitors and centrifuged (50,000 × *g*, 30 min). For direct immunoblotting, rafts are solubilized in two-fold Laemmli sample buffer and centrifuged (10,000 × *g*, 5 min). The supernatants are used.

EVALUATION

The following working hypothesis for signal generation in and transduction across the PM of rat adipocytes on the basis of the redistribution of lipid-modified signalling proteins, such as GPI-proteins and acylated tyrosine kinases, within rafts has been deduced from the present experimental findings (Müller 2005). (1) Amphiphilic GPI-proteins with intact GPI anchor as well as hydrophilic GPI-proteins with lipolytically cleaved GPI anchor preferentially accumulate at hcRafts versus lcRafts. (2) Only uncleaved GPI-proteins redistribute from hcRafts to lcRafts in response to glimepiride and insulin. Apparently, the GPI anchor functions as a signal for the recruitment to rafts *versus* non-raft areas, but does not determine the targeting to lcRafts or hcRafts. The current working model implicates that the PIG core structure of the GPI anchor functions as the only hcRafts-targeting signal (*via* recognition through the receptor protein, p115) for a subset of GPI-proteins which are amenable to stimulus-induced redistribution to lcRafts. The present findings strongly suggest the expression of three distinct subspecies of rafts in the plasma membranes of rat adipocytes: (i) TX-100- and Lubrol-WX-insoluble hcRafts, (ii) TX-100-soluble and Lubrol-WX-insoluble lcRafts in the basal state and (iii) TX-100- and Lubrol-WX-insoluble lcRafts upon glimepiride challenge. This is more compatible with the model of heterogenous rafts rather than that of layered rafts or homogenous rafts with selective lipid extraction as has been recently proposed for their heterogenous structure as well as their biogenesis and maintenance (Macdonald and Pike 2005). Accordingly, layered rafts are constituted of rings ranging from a liquid-ordered cholesterol- and glycosphingolipid-enriched core through less ordered regions into the liquid-disordered non-raft areas of the residual PM, the core of which is left as hcRafts after TX-100 solubilization, whereas core and immediately surrounding areas are left unsolubilized by Lubrol-WX. Homogenous rafts are liquid-ordered domains of a uniform mixture of the protein and lipid constituents are surrounded by the liquid-disordered phase of the plasma membranes which are selectively solubilized by TX-100 and Lubrol-WX (Macdonald and Pike 2005). Both models can hardly explain the existence of TX-100-insoluble lcrafts or their generation from hcrafts in response to glimepiride. In contrast, heterogenous rafts of different lipid and protein composition could coexist as separate structural entities in the membrane and be differentially solubilized by TX-100 and Lubrol-WX. It is conceivable that the glimepiride-induced translocation of certain GPI-anchored and acylated signalling proteins from distinct hcRafts accompanied by the limited loss of cholesterol results in the *de novo* generation of lcRafts of increased buoyant density retaining TX-100 insol-

ubility to a partial degree. Alternatively, the translocated raft protein components may be recruited directly from discrete hcRafts into pre-existing Lubrol-WX-insoluble (TX-100-soluble) lcRafts thereby rendering them partially insoluble in TX-100.

In conclusion, the adipocyte GPI-PL has now been recognized as a critical component specifically operating in the insulin-like signalling cascade triggered by glimepiride rather than in insulin signalling. Furthermore, insulin-like signalling by glimepiride is not significantly impaired in the insulin-resistant state as reported previously for rat adipocytes *in vitro* (Müller and Wied 1993). Therefore, the adipocyte GPI-PLC might represent a useful target for the therapy of type II diabetes mellitus.

K.6.4 Assays for Insulin and Insulin-Like Regulation of Gene and Protein Expression

Part of the blood glucose-lowering activity of insulin is based on massive and specific up- or downregulation of the gene expression for proteins/enzymes which directly regulate carbohydrate and lipid metabolism (e. g. GLUT4, PEPCK). Furthermore, changes in the intermediary metabolism provoked by insulin may secondarily lead to alterations in the gene/protein expression of other signalling/metabolic pathways. Consequently, it is important for the identification as well as characterization of compounds/drug candidates with insulin-like activity to analyze their effect on the expression of gene and proteins. For practical reasons, this analysis can be restricted to those genes/proteins which according to the present knowledge are relevant for mode of action of the compound/drug candidate. However, undoubtedly whole-genome or proteome searches for changes in the expression levels have important advantages, in particular due to its unbiased nature. However, they require considerable experimental expenditure and time on basis of conventional technology. This may change completely with the successful introduction of protein chips and DNA microarrays for the study of protein and gene expression and further increase its attractiveness for routine application in characterization of novel compounds/drug candidates.

K.6.4.1 Protein Chips

GENERAL CONSIDERATIONS

Currently, mapping the proteome and understanding the roles of these proteins are still in the very early stages, but scientists are hopeful that individual proteins, as well as constellations or "fingerprints" made up of multiple proteins (even if those proteins' functions are unknown), will soon be used regularly for the characterization of compounds/drug candidates in drug discovery programmes, in addition to application in the characterization of the probands for clinical trials regarding both desired and undesired effects of drug candidate envisioned. Indeed, the promise of these tests is so significant that many companies are already using such markers to select the most appropriate patients for clinical trials and to choose better drug candidates. Meanwhile, pharmaceutical and biotechnology companies have become acutely aware of the value of biomarkers for identifying those patients who may disproportionately benefit from a drug and those at highest risk of experiencing serious adverse effects. Biomarkers are regarded as a vital tool in streamlining drug discovery and development and accelerating approvals.

Proteins are the workhorses of the cell. Although genes represent the blueprint of life, proteins are the molecules that actually carry out the gene's instructions. In addition, because proteins are not confined to the cell that created them (as is mRNA) but float throughout the bloodstream, they are easier to find and measure. During the pre- and post-genome-sequencing euphoria of the late 1990s and early 2000, many researchers declared that the proteosome was the next frontier.

K.6.4.1.1 Challenges for Development

A major obstacle in protein chip development is the fact that proteins greatly outnumber genes. A single gene can code for multiple proteins, and each protein can undergo modifications that substantially change its activity. As a result, potentially several hundred thousand proteins can be required for the estimated 30,000 genes to do their work in the human body. This scenario helps explain the complexity of the human body despite the fact that it has relatively few genes compared with lower organisms. It also makes it much harder for scienists to completely map the proteosome. In addition, in contrast to the strandlike construction of mRNA and DNA, proteins have extremely complex structures. Within each protein's convoluted architecture there are certain "active" sites that make the most difference in terms of the protein's activity (It is in these sites that other molecules, including drugs, exert their activity). When they are placed on a substrate, such as a chip, proteins may unfold, becoming inactive and useless for study.

In terms of the technology, the traditional method of using 2-D gels for measuring the protein expression in a clinical or experimental sample is tedious and cumbersome. Initially, there was great interest in finding ways to industrialize this approach by using mass spectrometry and automated systems. With the arrival of DNA microarrays and their success in the RNA measurement field, the dawn of "proteome-wide chips" seemed imminent. But the technological hurdles facing the field have not diminished substantially and throughput in proteomics is still far behind what is achievable in areas such as gene sequencing and gene expression analysis.

As a result of the aforementioned challenges, many groups have taken a tip from the surging interest in gene-expression-profiling patterns. To develop such "signatures" of disease, researchers realized that they need only capture several proteins accurately and reproducibly. The protein marker signature does not need to be understandable. It just needs to be robust. Thus, interest in proteomics has now switched from being able to accurately quantify and identify all of the proteins in a particular sample to being able to distinguish "fingerprints" that are sufficient to separate one sample (e. g. progressive disease) from another (e. g. mild disease).

K.6.4.1.2 Technologies

Protein chips are mainly used to either identify protein-protein interactions or to find proteins in a sample. The former type of chip is primarily a drug discrovery and development tool, while the latter type can be used either in drug discovery and development or in diagnostic development. The type of molecule used to capture the proteins is the fundamental difference between chips for research purposes, which can be used to find biomarkers, and those chips that will be used to diagnose disease or predict outcomes. When searching for protein biomarker signatures, one must be sure they are examining a wide range of proteins and accurately measuring the relative levels of all of these proteins. Once the markers have been identified, one can then concentrate on a particular subset of proteins and find the ideal binding-molecules for use in a diagnostic system. Therefore, the key intermediate step is to locate the important marker proteins among the several hundred thousand proteins present in the body. A variety of molecules can be used to bind proteins, but antibodies are most often used. Primary antibodies are used to capture the protein (antigen) which is recognized by secondary antibodies (not sharing the antigenic determinant with the primary antibody but often labeled with biotin), and some type of read-out (e. g. Cy5-labeled streptavidin) signals presence of the protein (antigen). To build such arrays, each antibody placed on the chip (often in the wells of a microtiter plate) must be generated and then thoroughly tested for its cross-reactivity and binding affinity. Because proteins can share domains, or certain common structures, cross-reactivity can cause serious problems. Determining that a protein is cross-reactive requires extensive screening against other proteins. In addition, it is very difficult to get antibodies that bind tightly to a particular protein. Haab and coworkers (2001) showed that as few as 20% of antibodies out of hundreds could provide specific and accurate measurements of matching proteins on a chip. Antibodies can be exquisitely specific, however, and researchers are only now begin-

ning to learn some general rules on how to design good antibodies for proteins microarrays. A certain number of antibodies are already very well characterized. The pharmaceutical industry has been heavily reliant on these identified antibodies. The technology for making protein chips has also advanced, largely through the development of new methods to capture the proteins without degrading them.

New approaches to protein microarrays are also emerging. For example, mass spectrometry has recently been demonstrated to be useful for selection of certain proteins from a mixture and then to "soft land" these proteins onto a microarray while retaining their shape and activity to a very high degree. Meanwhile, a bench-top system of arrays of silicon-nitride microcantilevers with customizable surfaces has been introduced to detect interactions between proteins, antigens and DNA. This system does not require labelling because the microcantilevers bend due to the interaction between two molecules. Furthermore, a digital proteome chip has been developed for a comprehensive protein expression analysis. The technology is predicted of being unusually rapid (a single sample can be processed in one hour or less) and has unprecedented sensitivity, reproducibility, and accuracy. Very recently, isothermal rolling-circle amplification technology (RCAT) has been linked to antibodies as a means of signal amplification on traditional sandwich immunoassay-based protein chips. This detection method may be particularly useful because it remains localized and can detect protein analytes with zeptomole sensitivity and across a very broad dynamic range. Protein microarrays for interaction studies and other functional genomics studies will be most useful for drug discovery and development. By using a parallel procedure for protein production and purification technology it is assumed to generate and purify thousands of different proteins for the generation of the most diverse "portfolio of functional protein content". A comparative evaluation of selected suppliers of protein chip technology including their applications reported so far has been provided by Branca (2004).

K.6.4.2 DNA-Microarrays

PURPOSE AND RATIONALE

Changes and improvement in microarray technology have enhanced the ability to analyze transcription-factor-binding events genome-wide. Early versions of microarrays used for location analysis were manufactured by amplifying the promoter regions of genes from genomic DNA using PCR, and spotting the amplicons on glass slides. In addition to being reasonable accessible and affordable, PCR-generated probes could cover the entire proximal promoter region of a gene with a single probe. But these arrays had limitations. Double-stranded PCR products are less effective hybridization probes than single-stranded oligomers. PCR-generated probes are more susceptible to variations in quality due to the processing required to generate them and with only one probe reporting for each promoter, there is a relatively high rate of error associated with bad probes. Finally, the binding may occur anywhere within the probe sequence, which may be as long as 1 or 2 kB.

PROCEDURE

Emerging microarray applications such as aCGH (array-based comparative genomic hybridization), SNP (single nucleotide polymorphism) analysis, location analysis (ChIP, on-chip-chromatin immunoprecipitation on a microarray), methylation analysis, splice variant analysis and microRNA studies are all growing faster even than the already popular microarray application of gene expression. Inkjet-based array manufacturing processes provide the flexibility, long probe lengths and density required by these applications. The use of ChIP and microarray technology has proved a powerful combination for analyzing transcriptional regulation (for a review see Lee and Volkert 2006). One of the primary advantages of ChIP is that protein-DNA interactions are first fixed by the addition of a cross-linking agent to living cells, thus allowing for the identification of dynamic *in vivo* interactions between transcriptions factors and the genome. However, this approach has been relatively limited for exploring protein-DNA interactions across the genome as detection of the enrichment on this scale can be difficult. Enrichment is often detected by use of PCR-based assays, which are easy to perform and highly informative, but detection is limited because it is difficult to perform these assays in a sufficiently high-throughput format for genome analysis. Alternative approaches, such as cloning and sequencing of enriched DNA or direct sequencing of enriched DNA, have also been used, but are relatively labour-intensive and depend on sequencing large numbers of fragments to approach complete genome coverage. Using microarrays for the identification of enriched DNA regions has circumvented some of the difficulties in detecting enrichment genome-wide. Immuno-enriched DNA can be labeled, hybridized to arrays and compared to control DNA that has been hybridized at the same time. As arrays can be

designed to probe all known promoter regions (Boyer et al. 2005) or even the entire genome (Kim et al. 2005), this ensures complete coverage of the genome in a rapid and highly parallel fashion.

The current versions of arrays used for location analysis take advantage of newer printing technology. Features are now commonly composed of 60-mer oligonucleotides rather than long PCR amplicons. Several studies have shown that oligonucleotide probes are more sensitive than PCR probes in microarray analysis (Carter et al. 2003, Hughes et al. 2001, Li et al. 2002). Furthermore, it has been shown that results using longer oligonucleotides are more sensitive and reproducible than shorter ones. The 5070-base range seems to represent the "sweetspot" where hybridization efficiency, specificity and sensitivity are co-optimized. These oligonucleotide arrays are manufactured by commercial vendors, which translates to an increase in both the quality and consistency of the arrays. For instance, there are currently three array designs for the study of transcription factor binding in the human genome available (for a review see Lee and Volkert 2006).

EVALUATION

Future studies will focus on expanding the transcriptional regulatory network for metabolic genes. It will be interesting to identify the targets of transcription factors that are themselves targets of metabolic transcriptions factors, thus expanding the transcriptional regulatory network responsible for the genetic programme underlying the coordination of glucose and lipid metabolism. Transcription factors are responsible for recruiting additional components of the transcription apparatus, most notably chromatin-remodelling and –modifying complexes that affect transcription by regulating higher-order DNA structure. Consequently, one area of interest is identifying the targets of these various remodelling and modifying complexes and linking the network of transcriptions factors with the network of chromatin modifiers in liver, muscle, adipose and pancreatic β-cells.

K.6.4.3 siRNA

During the past decade a panel of methods has been developed for the validation of drug targets at the cellular level encompassing constitutive or regulated overexpression of the gene envisioned or its downregulation (antisense RNA, mouse embryonic fibroblasts from knockout mice and RNAi). RNAi displays a number of advantages regarding the expenditure in equipment, costs and time required. Moreover, the incomplete efficacy of RNAi in downregulating gene expression (usually by up to 80%) more closely reflects the pharmacological inhibition of transcription by small molecule compounds. In addition, there are considerable efforts to use RNAi as future therapeutics albeit many challenges have to be overcome.

RNA interference (RNAi) is an ancient mechanism of gene regulation, found in eukaryotes as diverse as yeast and mammals, and probably plays a central role in controlling gene expression in all eukaryotes (Tijsterman et al. 2002). Using small interfering RNA (siRNA) molecules, RNAi can selectively silence essentially any gene in the genome. Once in a cell, a short double-stranded RNA (dsRNA) molecule is cleaved by an RNase III, called "Dicer", into 21- to 23-nucleotide guide RNA duplexes with two-nucleotide 3′-overhangs, called siRNAs that become bound to the RNA-induced silencing complex (RISC). Within the RISC, one of the two strands of the siRNA is chosen as the antisense strand *via* cleavage of the passenger strand (Gregory et al. 2005, Rand et al. 2005), so that they can target complementary sequences in messenger RNAs involved in a disease. An RISC-associated "slicer" RNase belonging to the Argonaute2 (Ago2) family then cleaves the target in the middle of the homology, which is followed by further degradation mediated by an exosome complex (Liu et al. 2004, Rand et al. 2004) thereby interrupting the synthesis of the disease-causing protein. The RISC complex is naturally stable within the cell, enabling siRNA to cut multiple mRNA molecules consecutively and, therefore, suppressing protein synthesis in a potent and targeted way.

K.6.4.3.1 Design

The bulk of pharmaceutical applications of RNAi uses siRNA or its precursor. A completely foolproof algorithm of siRNA design for every target may remain an unattainable dream due to the inherent difficulty of predicting the various parameters that affect siRNA function (Heale et al. 2005, Amarzguioui et al. 2004, Gong and Ferrell 2004). However, some significant factors have been recognized. First, a successful application of RNAi demands that it be as specific to the target RNA as possible. Kim and coworkers (2004) demonstrated that 27-bp siRNAs are 10- to 100-times more potent and specific *in vivo* than their 21-bp counterparts. Second, Schwarz and coworkers (2003) found

that the formation of RISC is an asymmetric process in that only one strand of the siRNA is incorporated, not both. Third, it is now clear that the local secondary structure of the target RNA has dramatic influence on the accessibility for the siRNA (Vickers et al. 2003, Kretschmer-Kazemi and Sczakiel 2003, Luo and Chang 2004). Although siRNA designs have been proposed to incorporate this parameter (Heale et al. 2005, Amarzguioui and Prydz 2004, Gong and Ferrel 2004), the empirical nature of RNA structure prediction has left room for uncertainty. Fourth, a number of studies havc reported various degrees of positive and negative regulation of genes besides the intended target leading to "off-target" effects that are not easily explained by a fortuitous sequence homology of the siRNA to the off-target mRNAs (Sledz et al. 2003, Jackson et al. 2003, Bridgeet al. 2003). In conclusion, one should follow all the guidelines suggested above but remember that the ultimate test is experimental.

K.6.4.3.2 Source

It is to be realized that RNAi-based target validation or therapy exploits the physiological machinery constitutively present in the normal cell and that dsRNA is the only entity needed to activate it. In other words, therapeutic RNAi is triggered by the simple introduction of target-specific siRNA. This is commonly achieved by one of the following methods. The 21-mer siRNA with the 3′-dinucleotide overhangs can be chemically synthesized and introduced into the cell. Alternately, relatively long sense and antisense strands are transcribed *in vitro* from recombinant DNA templates, annealed to produce the dsRNA, which is digested with Dicer to generate siRNA that is then transfected into the cells. Lastly, the dsRNA can be generated *in vivo* by transfection of the corresponding DNA clone, which is then processed by the intracellular Dicer to generate the siRNA.

Synthetic siRNA

The chemistry of RNA synthesis has significantly improved over the years with an additional boost from the recent demands of the RNAi market. Short RNAs containing a variety of modifications are now commercially available (Dorsett and Tuschl 2004, Manoharan 2004). Modifications are explored for a variety of goals, such as improved RNAi activity and lower IC_{50}, enhanced stability, particularly against nucleases, and better pharmacokinetics and organ targeting. Effect of terminal and internal modifications of the siRNA on the silencing activity has been tested, and the consensus is summarized here. Additions at the 5′-end of the sense strand had little or no effect (Chiu and Rana 2003). A 5′-phosphate group on the antisense strand is essential for the incorporation into RISC. However, additions to the phosphate group are generally tolerated (Nykanen et al. 2001, Martinez et al. 2002). Tolerance at the 3′- end of the antisense depends on the derivative. While biotin, ddC, aminopropyl group and puromycin do not inhibit siRNA activity, 2-hydroxyethylphosphate, ethylene thymidine, and some fluorescent derivatives do (Schwarz et al. 2002). Of all the internal modifications, substitutions of the 2′-OH of ribose are the best studied and include -H, -OMe, -F and -NH_2. In general, all 2′-substitutions in the 3′- overhangs are tolerated (Elbashir et al. 2001, Amarzguioui et al. 2003). siRNAs with internal 2′-F are RNase-resistant and may perform better than unmodified siRNA in cell culture (Capodici et al. 2002), but not necessarily so in animals (Layzer et al. 2004). Internally, 2′-*O*-methylated siRNAs also exhibit significantly greater stability in serum with sustained silencing activity, and siRNAs with alternate 2′-OMe and 2′-F substitutions have similar advantages as well. For reasons that are unclear, 2′-NH_2 substitutions in either sense or antisense strand cause significant loss of silencing activity (Parrish et al. 2000). Replacement of the phosphodiester (P = O) backbone with phosphorothioates (P = S) or boranophosphonates (P = B) also offers nuclease resistance, but excessive substitution leads to loss of activity and/or increased toxicity (Manharan et al. 2004, Amarzguioui et al. 2003). Lastly, siRNA containing synthetic RNA-like nucleotide analog, known as "locked nucleic acid" (LNA), exhibits greatly improved biostability and enhanced inhibition of certain RNA targets (Braasch et al. 2003).

siRNA Transcribed In Vitro

Exogenous siRNA is also produced by the transcription of both strands of recombinant DNA templates, usually from a bacteriophage promoter, such as T7 or SP6 (Dudek and Picard 2004). As the resultant transcripts have 5′-triphosphates that may activate the undesirable IFN pathway, as mentioned before (Kim et al. 2005), the dsRNA product is either treated with phosphatase or trimmed with Dicer (Myers et al. 2003) *in vitro* before transfection.

Recombinant siRNA

The other common technique is to transfect target cells with DNA clones expressing shRNA, also known as DNA-directed RNAi or ddRNAi (Smith et al. 2000).

The corresponding complementary DNA (cDNA) is cloned between two converging promoters, generating dsRNA in the recipient cells that is cleaved by cellular Dicer into siRNA. In an alternate strategy, a DNA segment containing a hyphenated inverted repeat produces an shRNA of 19 bp or longer upon transcription. The shRNA is processed essentially by the miRNA pathway using Drosha and Dicer as described previously to eventually generate the siRNA. Both strategies employ RNA polymerase III promoters, such as human and mouse U6, human H1, and human 7SK promoters. The commonly used vectors are of adenoviral, lentiviral, or retroviral origin. Recombinant expression opens the avenue for inducible and/or tissue-specific expression of the siRNA (Wiznerowicz et al. 2003, Matsukura et al. 2003), which is not possible with synthetic siRNA. It also allows more sustained siRNA production over longer periods, critical in therapy for chronic diseases (see below). The potential hazards include viral infection, adverse immune reactions, and disruption or dysregulation of important genes via chromosomal integration of the viral genome (Bartosch and Cosset 2004). Furthermore, the parameters of shRNA design (such as the optimal length of the stem and the loop regions) are still ill defined and need further experimentation.

K.6.4.3.3 Delivery

There are two strategies for delivering siRNAs*in vivo*. One is to stably express siRNA precursors, such as short hairpin RNAs (shRNAs) from viral vector using gene therapy. The other is to deliver synthetic siRNAs by complexing or covalently linking the duplex RNA with lipids and/or delivery proteins. To solve the problem of cell penetration, most researchers have either complexed the RNA with a lipid or modified the RNA's phosphate backbone to minimize its charge. Despite the questions and unresolved problems, several companies are moving ahead to develop RNAi therapy for many diseases, including diabetes. The standard lipid reagents that were originally developed for DNA transfection, such as Oligofectamine (Invitrogen), continue to be the reagents of choice for cell culture studies (Spagnou et al. 2004). Recent formulations claim to be specifically improved for RNA delivery and can be used in the presence of serum in cell culture and in live animals. Current options for the synthesis and design has been reviewed by Baric (2005).

K.6.4.3.4 Use for Metabolic Diseases

Numerous studies using highly sensitive microarray analyses have demonstrated that siRNAs can have off-target effects by silencing genes relevant for the regulation of carbohydrate and lpid metabolism in adipose, liver, muscle and pancreatic β-cells. This makes siRNA to an ideal tool for the cellular validation of molecular targets (e. g. enzymes, transcription factors) for the terapy of metabolic disorders, such as diabetes and obesity, as has been demonstrated elegantly by Zhou and coworkers (2004). In addition, RNAi-based therapeutics have potentially significant advantages over traditional approaches of treating diseases, including broad apllicability, therapeuice precision, and selectivity avoiding side effects. This widespread applicability, coupled to relative ease of synthesis and low cost of production make siRNAs an attractive new class of small-molecule drugs. RNAi-based drugs are designed to destroy the target RNA and therefore stop the associated undesirable protein production required for disease progression. The putative therapeutic potential for the use of siRNA, in general, and the cure of metabolic diseases, particular, has been reviewed by Dallas and Vlassov (2006) and Rondinone (2006).

K.6.4.4 Effect on Peroxisome Proliferator-Activated Receptor

GENERAL CONSIDERATIONS

The peroxisome proliferator-activated receptors (PPARs) are ligand-activated transcription factors of

the nuclear receptor superfamily (Issemann and Green 1990, Dreyer et al. 1992). They regulate glucose, lipid, and cholesterol metabolism in response to fatty acids and their derivatives, eicosanoids, and drugs used in the treatment of hyperlipidemia and diabetes. The PPAR subfamily contains three members known as PPARα, PPARβ/δ, and PPARγ. Each PPAR subtype shows a distinct tissue distribution (Keller and Wahli 1993, Green 1995, Devchand et al. 1996, Lemberger et al. 1996, Schoonjans et al. 1996a, b, c, 1997, Willson et al. 2000, Walczak and Tontomoz 2002) and ligand preference.

PPARα is expressed predominantly in metabolically active tissues, including liver, kidney, skeletal muscle, and brown fat (Sher et al. 1993, Mukherjee et al. 1994), and its ligands include fatty acids, hypolipidemic drugs, eicosanoids and xenobiotics (Forman et al. 1997, Kliewer et al. 1997, Forman et al. 1995, Devchand et al. 1996, Lehmann 1995).

PPARγ is highly expressed in adipocytes (Elbrecht et al. 1996, Mukherjee et al. 1997), is involved in control of lipid storage, and plays a critical role in the regulation of adipocyte gene expression and the induction of adipogenesis and adipocyte differentiation (Tortonoz et al. 1994 and 1995, Brun et al. 1996, Wu 1998, Lowell 1999). Thiazolidinedione derivatives which are antidiabetic agents are potent and selective activators of PPARγ (Young et al. 1997, Henke et al. 1998, Murakami et al. 1998, Reginato et al. 1998, Ribon et al. 1998, Vázquez et al. 2002). The meanwhile widely used anti-diabetic drugs, pioglitazone and rosiglitazone, preferentially bind to the γ-isoform and modulate the expression of a number of genes in predominantly adipose tissue, but presumably also in muscle and liver tissues, ultimately leading to substantial increase in insulin sensitivity (Lehmann et al. 1995). Berger and coworkers (1996) found a correlation of antidiabetic actions of thiazolidinediones in *db/db* mice with the conformational change in PPARγ. Su and coworkers (1999) described the use of a PPARγ-specific monoclonal antibody to demonstrate thiazolidinediones induced PPARγ receptor expression *in vitro.*

Murphy and Holder (2000) suggested a therapeutic potential of PPARγ agonists in the treatment of inflammatory diseases and certain cancers. Steppan and coworkers (2001) and Berger (2001) showed that adipocytes secrete a signaling molecule which they called resistin (for resistance to insulin). Circulating resistin levels in mice are decreased by thiazolidindiones and are increased in diet-induced and genetic forms of obesity.

Although the function of PPARδ, which is expressed ubiquitously, is less well known, this nuclear receptor may be involved in the regulation of cholesterol and lipid metabolism (Oliver et al. 2001, Shi et al. 2001). Fatty acids and cyclooxygenase 2-derived prostacyclin (PGI_2) are natural ligands for PPARδ (Gupta et al. 2000). Several highly selective and potent synthetic ligands (e. g., L-165041, GW501516) activate PPARδ at nanomolar concentrations (Oliver et al. 2001, Glinghammar et al. 2003).

All subtypes share a common structural organization with a highly conserved N-terminal DNA binding domain (DBD) and a moderately conserved C-terminal ligand-binding domain (LBD) that contains a carboxy-terminal activation function motif (AF2). All of the PPAR subfamily members heterodimerize with the receptor for 9-*cis* retinoic acid (RXR) and bind to target gene peroxisome proliferator elements (PPREs), a direct repeat of the sequence AGGTCA separated by one nucleotide (DR-1) (Dreyer et al. 1992, Kliewer et al. 1992).

Unliganded nuclear receptors, such as retinoic acid receptors (RARα) and T3Rα, are able to repress basal transcription through recruitment of corepressors (Chen and Evans 1995). Among the three PPARs, PPARδ distinguishes itself by displaying remarkably potent transcriptional repression activity. In contrast, unliganded PPARα and PPARγ do not repress PPRE-mediated transcription, presumably due to their inability to bind nuclear receptor corepressors SMRT and NCoR on the PPRE DNA element (Shi et al. 2001). Agonist binding to nuclear receptor LBD provokes a conformational change of the AF-2 motif that produces a suitable binding surface for recruitment of coactivators (Xu et al. 1999).

K.6.4.4.1 Recombinant Cell Lines

PURPOSE AND RATIONALE

Because of involvement of PPARs in many critical physiological and pathological functions, in particular with regard to metabolic diseases, the identification of high-affinity ligands would create useful tools for studying the PPAR role in the normal physiological and disease states as well as for drug discovery, in particular for the therapy of metabolic diseases, such as type II diabetes. To characterize PPAR specificity of synthetic ligands, stable HeLa-derived reporter cell lines in which PPARα, PPARβ, and PPARγ agonists induce luciferase activity have been constructed. These cell lines stably express a chimeric protein con-

taining the yeast transactivator GAL4 DBD fused to LBD regions of PPARs (GAL4-PPARs) and contain a luciferase reporter gene driven by a pentamer of the GAL4 recognition sequence in front of the β-globin promoter. The GAL4-PPAR chimeric receptors has been chosen because this assay format eliminates background activity from endogenous receptors and allowed quantitation of relative activity across the three PPAR subtypes with the same reporter gene. Additional assays for the characterization of PPAR-modulating compounds and drug candidates are given in K.3.5.

K.6.4.4.2 Lipogenesis Assay

The lipogenic activity of PPARγ agonists can be assessed by determining the uptake of radioactive glucose uptake and its incorporation into the total lipids of cells (see K.6.1.2.1). The amount of glucose incorporation into lipids in these cells provides a measure of cell differentiation, since preadipocytes are less efficient in *de novo* lipogenesis compared to mature adipocytes on basis of their different expression levels of lipogenic genes, such as GLUT4 and GPAT. Moreover, the analysis of the expression of adipocyte marker genes (aP2, LPL, leptin) and of the accumulation of TAG in the cytoplasm confirmed by oil red O staining are other methods to evaluate the lipogenic activity of PPARγ agonists and thereby indirectly their binding affinity to PPARγ.

K.6.4.4.3 Protease Digestion Assay

PROCEDURE

The protease digestion assay can be performed according to the method of Allan and coworkers (1992) with minor modifications. The plasmid pSG5-hPPARγ1 is used to synthesize ^{35}S-radiolabeled PPARγ1 in a coupled transcription/translation system. The transcription/translation reactions are subsequently divided into portions of 22.5-µl volume. 2.5 µl PBS with or without a thiazolidinethione are added. The mixtures are incubated for 20 min at 25°C, separated into 4.5-µl aliquots, and 0.5 µl distilled water or distilled water-solubilized trypsin are added. The protein digestions are allowed to proceed for 10 min at 25°C, then terminated by the addition of 20 µl denaturing gel loading buffer and boiling for 5 min. The products of the digestion are separated by electrophoresis through a 1.5-mm 12%-polyacrylamide-SDS gel. After electrophoresis, the gels are fixed in 10% acetic acid/40% methanol for 30 min, treated in EN^{3}HANCE for an additional 30 min. and dried under vacuum for 2 h at 80°C. Autoradiography is then performed to visualize the radiolabeled digestion products.

EVALUATION

For evaluation of the protease digestion assay, the partially protease-resistant conformation product of PPARγ is visualized by autoradiography on SDS-PAGE after incubation with the thiazolidinedione and increasing concentrations of trypsin.

K.6.4.4.4 Living Cell Luciferase Assay

The luciferase assays were used by Seimandi and coworkers (2005) to investigate the differential responses of PPARα, PPARδ and PPARγ reporter cell lines to selective PPAR synthetic ligands. For this, cells are seeded at a density of 40,000 cells per well in 96-well white opaque tissue culture plates. Tested compounds are added 8 h later, and cells are incubated for 16 h. Experiments are performed in quadruplicate. At the end of incubation, culture medium is replaced by medium containing 3×10^{-4} M luciferin. Luciferase activity is measured for 2 s in intact living cells using a MicroBeta Wallac luminometer (Perkin-Elmer).

K.6.4.4.5 Lysed Cell Luciferase Assay

PROCEDURE

Cells are seeded at a density of 200,000 cells per well in 24-well test plates. Test compounds/drug candidates are added 8 h later, and cells are then incubated for 16 h. Cell extract preparation is done essentially as recommended by Promega. Compound-containing medium is removed, and cells are washed with PBS. Cells are lysed in 25 mM Tris/phosphate (pH 7.8), 2 mM EDTA, 1% Triton X-100, 2 mM DTT, 10% glycerol. Protein concentration is estimated with the Bradford assay kit and BSA as standard.

Cell protein extracts (100 µl) are loaded onto 96-well white opaque tissue plates, and luciferase activity is measured after injection of luciferase detection buffer (20 mM Tricine, pH 7.8, 1.1 mM ($MgCO_3$) 4.0 mM $Mg(OH)_2{\cdot}5H_2O$, 2.7 mM $MgSO_4$, 0.1 mM EDTA, 33 mM DDT) and luciferase assay substrate (0.5 mM luciferin, 0.5 mM ATP, 0.3 mM coenzyme A)

using a luminometer (e. g. Berthold Technologies). Luminescence is measured for 2 s.

EVALUATION

In the transactivation assay, each compound is tested at various concentrations in at least two independent experiments. For each experiment, tests are performed in duplicate or triplicate for each concentration, and data are analysed as means and standard deviations. Individual agonist concentration-response curves, in the absence and presence of antagonist, are fitted using the sigmoidal dose-response function of a graphics and statistics software program (e. g. GraphPad Prism, version 4.0). EC_{50} (effective concentration for half-maximal luciferase activity) and IC_{50} (half-maximal inhibitory concentration) values are calculated from equations used to fit the data in this graphic software. Transactivation data are presented as EC_{50} and IC_{50} values for each compound tested. To analyze significance of PPAR isotype activation, PPAR agonist treatment is compared with controls using one-way analysis of variance (ANOVA) with the help of GraphPad Prism software.

In this assay system, the expression of PPAR isotypes differentially modulates the reporter gene basal activity and thus provides interesting information on the recruitment of cell type-specific coregulators by PPARs. Using specific PPAR agonists and antagonists, these cell lines permit an easy, rapid, and specific identification of subtype-selective PPAR ligands in a standardized microtiter plate assay. Furthermore, since HG5LN cells are putative host cells for other GAL4 nuclear receptor chimeras, RAR, thyroid hormone receptors, and steroid receptors, the assay system may be helpful to characterize the nuclear receptor selectivity of their nuclear receptor ligands which could also play important roles in the pathogenesis and therapy of metabolic diseases.

K.6.4.5 Effect on Proliferation

PURPOSE AND RATIONALE

Both, insulin and IGF-1 stimulate growth and proliferation of cells which express the corresponding receptors at adequate number. However, they differ considerably in their relative potency with IGF-1 exerting at least 100-fold higher/lower mitogenic/metabolic activities compared to those of insulin. The *in vivo* metabolic action of IGF-1 can be compared with insulin in adult rats using the following methods (DeMeyts 1994, Ulrich and Schlessinger 1990, Schlessinger and Ulrich 1992, Simpson et al. 1998), (i) dose-dependence and time-dependence of blood sugar decrease after intravenous injection, (ii) the antilipolytic effect (decrease of non-esterified fatty acids) after i.v. injection, (iii) stimulation of glucose disposal dur-

ing euglycemic clamping after intravenous infusion. Furthermore, all other assays described for insulin can be applied. Gazzano-Santoro and coworkers (1998) described a cell-based potency assay for IGF-1.

PROCEDURE

Cell Culture

Cells from the human cell line HU-3, established from the bone marrow of a patient with acute megakaryoblastic leukemia, are adapted to grow in the presence of human thrombopoietin. Removal of thrombopoietin results in decreased proliferation and rapid loss of viability. Cells are cultured in RPMI-1640 medium with 2% heat-inactivated human serum, 2 mM glutamine, 10 mM HEPES (pH 7.2) and 5 ng/ml thrombopoietin in culture flasks. They are grown in suspension at 37°C in a humidified 5% CO_2 incubator and are routinely subcultured every two or three days when densities reach $0.8–1.5 \times 10^6$ cells/ml.

Alternatively, the proliferative potency of insulin analogs can be determined by measuring the proliferation of human mammary epithelial cells (HMEC, Clonetics USA) in culture. HMEC obtained at passage 7 and expanded and frozen at passage 8 are used at passage 10 for all experiments. Cells are cultured in growth medium (fuly supplemented MEGM, Bio Whittaker, 10 ng/ml hEGF, 5 µg/ml insulin, 0.5 µg/ml hydrocortisone, 50 µg/ml gentamycin, 50 ng/ml amphotericin-B, 13 mg/ml bovine pituitary extract) which is changed every day. For a growth experiment, the medium is changed to assay medium lacking insulin but containing 0.1% BSA.

Assay

The HU-3 cell growth assay is performed under serum-free conditions in assay medium consisting of RPMI-1640 supplemented with 0.1% BSA, 10 mM HEPES (pH 7.2) and 50 µg/ml gentamycin. HU-3 cells are washed twice in the assay medium and resuspended at a density of 0.25×10^6 cells/ml. In a typical assay, 100 µl of a cell suspension (25,000 cells/well) and 100 µl of IGF-1 at varying concentrations are added to flat bottomed 96-well tissue culture plates at 37°C and 5% CO_2 and cultured for 2 d. 40 µl of Alamar Blue™ (undiluted) are then added and the incubation continued for 7–24 h. The plates are allowed to cool to room temperature for 10 min on a shaker and the fluorescence is read using a 96-well plate fluorometer with excitation at 530 nm and emission at 590 nm.

The HMEC cell growth assay is performed in 96-well Cytostart scintillation microplates (Amerham Pharmacia). One day one, HMEC cells are seeded at a density of 4,000 cells/well in 100 µl of assay medium. Insulin in the growth medium is replaced with graded doses of recombinant human insulin or insulin analog/compounds from 0–1 µM final concentration. After 4-h incubation, 0.1 µCi of ^{14}C-thymidine in 10 µl of assay medium is added to each well and plates are read at 48 h and/or 72 h in a microtiter plate scintillation counter.

EVALUATION

Recombinant human insulin and IGF-1 are controls used in each assay run, and recombinant human insulin is on each assay plate. Results, expressed as relative fluorescence units, are plotted against IGF-1/compound concentrations using a 4-parameter curve-fitting program. Test compounds are compared with the standard. Typically, the maximal growth response is between 3- to 4-fold stimulation over basal. Response data are normalized to between 0 and 100% response equal to 100 X (response at concentration X – response at concentration zero) divided by (response at maximal concentration – response at zero concentration). Concentration-response data are fit by non-linear regression employing appropriate software. Analysis of the proliferative capacity of novel recombinant insulin analogs with improved kinetic profile in comparison to IGF-1 and insulin is of tremendous importance.

K.6.5
Assays for Insulin and Insulin-Like Regulation of Energy Metabolism

K.6.5.1
Determination of Oxygen Consumption and Extracellular Acidification Rates

PURPOSE AND RATIONALE

Accumulating experimental evidence indicates that dysregulation of energy metabolism is a fundamen-

tal process that is associated with the phenotype of metabolic disorders, in particular type II diabetes and obesity. Many current anti-diabetic drugs (metformin, glitazones) target the pathways that control glucose metabolism. Very recently, a technologies (Bionas Inc. Germany, Seahorse Bioscience Inc. USA) have been developed that manages to rapidly profile the bioenergetic pathways in a variety of cell types. These include alterations caused by drugs that target the specific metabolic pathways the cell uses to ensure its energy demands, normal metabolic functions and survival. These technologies allow a more detailed analysis of the link between glucose/lipid metabolism and energy metabolism, including interference of one or the other by compounds/drug candidates, as well as the screening for or characterization of drug candidates affecting or leaving unaffected those pathways. For this, both the oxygen consumption rate (OCR), which primarily reflects mitochondrial respiration, and the extracellular acidification rate (ECAR), which primarily reflects lactic acid production (glycolysis), are measured using the Bionas or Seahorse technology. Furthermore, the OCR and ECAR readings allow to profile the metabolic sensitivities and degree of inhibition/stimulation of a number of cell lines relevant for the study of glucose and lipid metabolism and its regulation toward modulators of anaerobic and aerobic energy metabolism (e. g. phloretin, 2-deoxyglucose, dinitrophenol). Analysis of the sensitivities of the cell lines to these modulators provides insights into their bioenergetic preferences/dependencies and their global physiological responses to the modulation. This characterization may be useful for the selection of cell lines appropriate for use in screening for compounds with anti-proliferative activity (ECAR for anaerobic energy metabolism; Boros et al. 2002) as well as insulin-like metabolic activity (OCR for aerobic energy metabolism; Wolf et al. 1997), with regard to sensitivity and responsiveness of their energy metabolism and the relevant bioenergetic pathways (Ehret et al. 2001). During the last decade multiparametric cellular microelectronic interdigitated biosensor chips for microphysiological and screening applications with living cells have been developed (Ehret et al. 2001, Lehmann et al. 2000).

PROCEDURE

Bionas 2500 Analyzing System

The Bionas 2500 analyzing system is an automated system suitable for online cell-based compound/drug candidate identification and profiling. The innovative aspect of this bioanalytical device is the adaptation of electronic chip design for a completely non-invasive and multiparametric sampling of metabolically relevant readouts in long-term tissue and cell culture. The system uses a silicon-based technology to continuously monitor minute changes in (i) solution pH resulting from the output of acid metabolites excreted by living cells into their immediate microenvironment (Lehmann et al. 2001), (ii) oxygen content resulting from oxygen consumed by living cells from their immediate microenvironment and (iii) electrical impedance resulting from the electrical isolation of intact cell membranes close to the sensor surface (adhesion/confluence) (Ehret et al. 1998). The Bionas 2500 analyzing system works in real-time, allowing the rapid and continuous monitoring of cellular activity and the measurement of recovery from a particular challenge and the process of desensitization.

Cells are seeded onto Bionas metabolic chips the day prior to the experiment and left to attach to the sensor surface overnight. The sensor chips are then transferred into the Bionas 2500 analyzing system. The system has the capacity to measure the acidification, respiration and adhesion/confluence rate from six separate sensor chips. Modified, low-buffered medium is pumped across the cells at a rate of 56 µl/min during which time the pH and the oxygen content of the microenvironment surrounding the sensor is maintained constant. To measure the rates for acidification and respiration from cells the fluid flow is periodically halted, allowed a build-up of acid metabolites and a depletion of oxygen in the chamber and, therefore, an alteration in the fluid pH and oxygen content. Flow is resumed and the acid and oxygen-depleted fluid flushed out of the chamber. This flow-on, flow-off cycle is repeated throughout the experiment. To measure the adhesion/confluence, no fluid perfusion is necessary. After collecting baseline acidification, respiration and adhesion rates, the compound/drug candidate is introduced and the effect on acidification, respiration and adhesion rates are monitored.

Seahorse XF Instrument

Adherent 3T3-L1 adipocytes, L6-myoblasts/myotubes or HepG2 cells are seeded in 24-well Seahorse cell culture microplates at various cell densities per chamber per well. Approximately 45 min prior to the assay, the culture medium is exchanged with a low-buffered RPMI assay medium to ensure accurate ECAR readings. For detection of acute drug responses, OCR and ECAR are measured for 5 min in each well to establish a baseline. Compound/drug solution is then added and followed by measurement of OCR and ECAR.

For time resolved measurements, test measurements are made at a series of time points. Non-adherent cells (primary hepatocytes and adipocytes) are seeded onto Cell-Tak-coated Seahorse cell culture microplates either before or after the compound/drug treatment. Cell-Tak treatment of plates is performed according to manufacturers instruction. Cells remain attached to the surface of the well after the measurement as determined by light microscopy. Cells are lifted from the culture surface by simple pipetting without trypsin treatment.

A unique feature of the Seahorse instrument is its ability to make accurate and repeatable measurements in as little as 5 minutes. This is accomplished by isolating an extremely small volume (less than 10 µl) of medium above the cell monolayer. Cellular metabolism causes rapid, easily measurable changes to the "microenvironment" in this small volume. Typically, a measurement cycle is performed for 2–10 min. During the time, analyte levels are measured every 8 sec until oxygen concentration drops approximately 10% and medium pH declines approximately 0.1 unit. The measurement is performed using fluorescent biosensors embedded in a sterile disposable cartridge that is placed above a 24-well tissue culture microtiterplate.

EVALUATION

Baseline metabolic rates are typically measured twice and are reported in nmol/min for OCR and mpH/min for ECAR. Compound/drug is then added to the medium and mixed for 5 min, and then the post-treatment OCR and ECAR measurements are made and repeated. As cells shift metabolic pathways, the relationship between OCR and ECAR changes. Because these measurements are non-destructive, cells can be profiled over a period of minutes, hours or days.

K.6.5.2 Metabolomics

GENERAL CONSIDERATIONS

The flow of information from DNA to cellular building blocks is the central dogma of biology. DNA is transcribed into RNA, then translated to proteins, which then make small molecules. While there may be over 25,000 genes, 100,000 to 200,000 transcripts and up to 1,000,000 proteins, it is estimated that there may be as few as 2,500 small molecule species in the human metabolome. Metabolomics is the study of the metabolome, i. e. of the repertoire of these non-proteinaceous, endogenously-synthesized small molecules present in an organism. Representative small molecules include well-known compounds such as glucose, cholesterol, ATP and soluble signaling molecules, such as cAMP, AMP, diacylglycerol. These molecules are the ultimate product of cellular metabolism. The metabolome refers to the catalogue of those roughly 2,400 known endogenous metabolites in a specific organism. Most important, the normal physiological and disease states are ultimately manifest at the level of biochemistry and more precisely, at the level of the metabolome. It is more clear-cut and more quantitative because it is known where metabolites fit in biochemical pathways and the metabolites' relative concentrations are measurable. This makes a clear difference to many of the other "omics" sciences. It seems very likely that intelligent application of this methodology in appropriate animal disease models will considerably facilitate the identification and characterization of compounds/drugs for most indications and for metabolic diseases, in particular, with regard to potency, safety, accuracy, predictability and the time required. The putative "systems" contribution of metabolomics to pharmaceutical drug discovery and development has been reviewed by Harrigan (2006).

PURPOSE AND RATIONALE

Metabolomics technology determines the small molecule repertoire of a cell or a biological sample typically using a proprietary approach of simultaneous, multidimensional molecular analysis, followed by sophisticated data analysis and visualization. Biological samples are extracted using special protocols and the resulting extracts are separated and analyzed using a variety of detection techniques. Chromatographic outputs are analyzed using multiple mass spectrometers, which accurately identify the mass for a particular molecular species. Electrochemical detectors monitor additional broad classes of compounds. By choosing appropriate types of separation and detection technologies and mass spectrometers, the cellular metabolites are analyzed according to their various properties. Modified mass spectrometers produce data streams that are automatically processed and stored in proprietary information management systems. The data are quality-checked, reduced, refined and abstracted using custom algorithms and software. Data visualization is then used to compare experimental data to a large data base of control information. Hundreds of compounds of known identity are measured in a sample and contrasted to controls. Unique unknowns are brought to light for structure elucidation.

PROCEDURE

Metabolomics research is characterized, at least I part, by two different (but not necessarily mutually exclusive) conceptual approaches broadly defined as "targeted" and "non-targeted" (Harrigan and Goodacre 2003, Goodacre et al. 2003, Vaidyanathan et al. 2005). Non-targeted approaches provide a hypothesis-free global overview of high abundance metabolites most affected by experimental perturbation or disease. Targeted approaches which highlight identified and preselected metabolic pathways may prove more relevant in evaluating the impact of a compound/drug candidate on metabolic regulation. Technology platforms for targeted approaches are based on discrete optimized analytical strategies for different classes of metabolites or pathways. This approach represents both an accommodation with the wide differences in physicochemical structure, stability and differential abundance of metabolome components. It clearly facilitates greater evaluation of low-abundance, biologically important metabolites, such as eicosanoids, other signalling lipids and hormones. A key challenge for vendors providing instrumentation to support metabolomics is in establishing an optimal balance between the accuracy and range of metabolite measurements. Targeted metabolomics approaches additionally allow adoption of flux-based methodology where specifically designed tracer-labeled substrates can be incorporated into test biological systems and their distribution and metabolic fate recorded. Metabolic flux analyses provide an operational "moving picture" rather than a compositional "snapshot" of a biological system. At present, this approach is somewhat underpresented in metabolomics but it may be pointed out that the data acquisition technologies used here are essentially that used in compositional studies. The data acquisition technologies utilised in metabolomics, primarily nuclear magnetic resonance spectroscopy and mass spectrometry have been extensively reviewed (Weljie et al. 2006).

Applications in Early Drug Discovery

There is considerably emphasis on metabolomic applications in later stages of drug discovery, including clinical trials. However, strategies to reduce attrition may be most cost-effectively implemented at the earliest stages of drug discovery, which encompasses disciplines such as target validation and high-throughput screening. In current drug discovery projects substrate/product ratios are used as mechanistic markers of enzyme function in increasing number. It is critical that a drug candidate be shown to act on its target throughout all stages of the value chain and that modulation of that target does indeed impact disease progression.

Applications in the Analysis of Animal Models

The development of drugs for the regulation of metabolic diseases, such as cardiovascular diseases, obesity and type II diabetes, clearly requires considerable efficacy and toxicological testing in animal models. Efficacy assessments also require that regulation of metabolism in animal models is reasonably well understood. A metabolomics study utilising an analytical platform developed by Lipidomics Technologies Inc. that allows quantitative measurement of more than 500 lipid metabolites in blood and tissue samples has recently been employed to probe metabolic regulation in the low density lipoprotein receptor null (LDLrKO) mouse, a model for atherosclerotic progression (Krul et al. 2006).

Correlation of Metabolome, Proteome and Transcriptome Data Sets

An increasing area of interest is correlation of metabolomic data sets with proteomic and transcriptomic data sets (Davidov et al. 2004). While the goal of such studies is presumably to provide a deeper understanding of biological systems it may be worth pointing out that if the metabolome were truly closer to phenotype, then the use of complementary data from genomics, transcriptomics and proteomics could be perceived as merely ancillary or even potentially confounding. In an integrated transcriptomic and NMR-based metabolomic study of fatty liver in the rat, an inverse correlation between stearoyl CoA desaturase mRNA levels and levels of unsaturated fatty acids described as "surprising" by the authors was revealed (Griffin et al. 2004). This observation is somewhat less surprising when placed in the context of a metabolomic demonstration that gene expression patterns in the adipose tissue of obese mice resulted in assessments of rates of fatty acid synthesis and lipogenesis that are inconsistent with direct measurements of the metabolic fluxes (Hellerstein 2003).

Future Metabolomics Technologies

The development of a new methodology for determining the concentration of protein-unbound FFA in intracellular and extracellular milieu entitled "Fluorescent Probes for Hydrophobic Metabolites" represents a particularly intriguing programme. Although FFA levels are clearly critical in many diseases, monitoring of

unbound FFA profiles remains technically challenging and improved detection methodologies can only help facilitate drug candidate progression in a range of therapeutic areas. The use of fluorescently labeled metabolite probes is also a theme in a proposal "Glycolipid Metabolism in Single Cells" to dissect glycolipid metabolism in single neurons. This proposal will focus on the development of different fluorescently labeled substrates within two different glycolipid metabolite pathways and offers particular promise in pharmacological evaluations of neuroactive agents. Another cellular neuro-metabolomic proposal "Technologies for Cellular Neurometabolomics" addresses the use of a suite of technology developments including unique sampling protocols, microfluidically-based sample conditioning unit with integrated electrophoretic separations, followed by native fluorescence and mass spectrometric detection and capture of appropriate metabolites into nl-volume capillaries for nl-volume NMR spectroscopic characterization.

EVALUATION

Companies (e. g. Metabolon Inc.) have developed proprietary software to link the resulting profile directly to metabolic pathway maps. This linkage greatly facilitates the identification of particular pathways that are affected in the biological sample relative to controls. In this way, the genes, RNAs, and proteins involved in a disease can be quickly and efficiently elucidated. By analyzing a sample using multiple mass spectrometry-based technologies, integrating the data, and analyzing through proprietary software and algorithms, the characterization of compounds/drugs in animal disease models, in general, for metabolic diseases such as type II diabetes, in particular, can be achieved much faster and more accurately than previously possible. Moreover, academic efforts have recently been initiated supporting well-conceived and technically feasible innovations that have the potential to drive metabolomics as a biologically informed science and provide metabolomic data that can be integrated into early drug candidate evaluation and also guide subsequent biomarker-enabled *in vivo* studies.

K.6.6
Assays for the Expression and Release of Insulin and Glucose-Regulating Peptide Hormones from Pancreatic β-Cells

K.6.6.1
Insulin Release from the Isolated Perfused Rat Pancreas

PURPOSE AND RATIONALE

The *in vitro* perfusion of the isolated rat pancreas as described by Anderson and Long (1947), Ross (1972), Grodsky and coworkers (1983, 1984) and Muñoz and

coworkers (1995) offers the advantage to study the influence of carbohydrates, hormones and drugs such as sulfonylureas not only on insulin but also on glucagon and somatostatin secretion without interference of secondary effects resulting from changes in hepatic, pituitary or adrenal functions.

PROCEDURE

The insulin concentration of the perfusate of the rat pancreas prepared as described (see K.5.4.1) is determined with the RIAgnost kit using rat insulin as standard in every second sample. The determination is done immediately after the end of an experiment.

K.6.6.2 Insulin Release from the Isolated Perifused Rat Pancreatic Islets

PURPOSE AND RATIONALE

An assay with isolated pancreatic islets to study the dynamic response and transitions between various metabolic states has been recommended by Idahl (1972). A further description and discussion of the method were given by Malaisse-Lagae and Malaisse (1984).

PROCEDURE

The insulin concentration of the perifusate of the rat islets prepared as described (K.5.4.2) is determined with the RIAgnost kit using rat insulin as standard in every second sample. The determination is done immediately after the end of an experiment.

EVALUATION

The raw data are expressed in µU insulin per islet/min. Mean and standard error of the mean of each time interval are calculated for graphical representation. The values under exposure to drug are compared with the values under perifusion with glucose only, and with the effect of elevated glucose.

K.6.6.3 Insulin Release from Cultured β-Cells

PURPOSE AND RATIONALE

Insulin released into the supernatant of monolayers of cultured β-cells grown in 96-well culture dishes as described above is determined radioimmunochemically (see above) using a guinea pig anti-rat insulin antibody, ^{125}I-labeled human insulin as tracer and rat insulin as standard. Free and bound radioactivity is separated using an anti-IgG (goat anti-guinea pig) antibody. Typically, the sensitivity of this assay is 17 pM, and the coefficient of variation is less than 3% at both low and high levels.

PROCEDURE

Insulin Secretion from MIN6 Cells

Cultured MIN6 cells (1×10^5) are replated and cultured (see K.5.4.4) for 24 h before being used in secretion assays. Insulin secretion is measured during 1 h static incubations in KRBH(118.5 mM NaCl, 2.54 mM $CaCl_2$, 1.19 mM KH_2PO_4, 4.74 mM KCl, 25 mM $NaHCO_3$, 1.19 mM $MgSO_4$, 10 mM HEPES, pH 7.4) containing 0–20 mM glucose (basal or glucose-induced secretion) and/or compounds/drugs. Samples of the supernatant are assayed for insulin. To determine total insulin content, insulin is extracted using 95/5 ethanol/acetic acid. Insulin is measured using a mouse insulin ELISA kit.

Insulin Secretion from RINm5F Cells

One day prior to the experiment, approximately 1×10^6 RINm5F cells, grown as described above, are seeded into 24-well test plates. At the time of the experiment, the culture medium is aspirated, and the cells are washed with 1 ml of a modified KRBH containing 10 mM HEPES/KOH (pH 7.4), 5 mM $NaHCO_3$, 0.5% BSA and 0–20 mM glucose. After pre-incubation for 30 min at 37°C with the above buffer, compounds/drug candidates dissolved in DMSO at 10 mM are added (final concentration range from 10 nM to 100 µM) and incubated for 30 min at 37°C. The incubation is stopped by aspiration of the buffer which is stored at −80°C until measurement of insulin by ELISA or RIA. After the aspiration, the cells are washed with PBS and dissolved in 0.5 ml NaOH (0.1 M). After overnight incubation, the resulting solution is collected for assay of cellular protein content.

Insulin Secretion from INS1 Cells

INS1 cells (5×10^4 per well in 12-well plates) are treated with RPMI 1640 medium containing 3–20 mM glucose and 0.5 mM FFA or a mixture of oleic and palmitic acids in equal ratio, with a total concentration of 0.5 mM. Control wells contained 0.5% fatty acid-free BSA in medium. After 24 h, the cells are washed in PBS and pre-incubated for 2 h in KRBH containing 0–20 mM glucose (119 mM NaCl, 4.75 mM KCl, 5 mM $NaHCO_3$, 1.2 mM $MgSO_4$, 1.18 mM KH_2PO_4, 20 mM HEPES, pH 7.4, 2.54 mM $CaCl_2$). Glucose responsiveness is evaluated by an initial 30-min incubation in KRH containing 3 mM glucose followed by incubation for 30 min in KRH containing 20 mM glucose. Samples are collected for insulin measurement using RIA or ELISA with CV 4.5% and minimal detection 0.15 µg/l.

Insulin Secretion from Attached INS-1E Cells

The secretory responses to glucose and other secretagogues are tested in INS-1E cells between passages 54–95 according to the procedure of Merglen and coworkers (2004). Before the experiments, cells are maintained for 2 h in glucose-free culture medium. The cells are then washed twice and preincubated for 30 min at 37 C in glucose-free KRBH (135 mM NaCl, 3.6 mM KCl, 5 mM $NaHCO_3$, 0.5 mM NaH_2PO_4, 0.5 mM $MgCl_2$, 1.5 mM $CaCl_2$, and 10 mM HEPES, pH 7.4) BSA (0.1%) is added as an insulin carrier. Next, cells are washed once with glucose-free KRBH and then incubated for 30 min in KRBH and compounds/drug candidates. Incubation is stopped by putting the plates on ice. The supernatants are collected for insulin secretion, and cellular insulin contents are determined from acid-ethanol extracts. Insulin secretion is measured by RIA or ELISA using rat insulin as standard (see K.4.1).

Perifusion of INS-1E Cell Clusters

Spheroid clusters composed of INS-1E cells are preincubated for 2 h in glucose-free culture medium. After low speed centrifugation (500 rpm), cell clusters are resuspended in glucose-free KRBH and counted, and about 500 spheroids are distributed per chamber in a 250-µl volume thermostated at 37°C. The flow rate is set at 0.5 ml/min, and fractions are collected every minute after a 20-min washing period at basal 2.5 mM glucose. At the end of the perifusion, cell clusters are collected, and insulin contents are determined from acid-ethanol extracts.

Total Insulin Content

Cells from 4 wells of 24-well culture dishes are scraped into ice-cold PBS containing 5.5 mM glucose and 0.1% fatty acid-free BSA and immediately frozen in liquid N_2. Frozen cells are sonicated in acidic ethanol (0.2 M HCl in 87.5% ethanol). The samples are then centrifuged. The supernatant is used for measurement of total insulin content. Insulin in the perifusion fractions and cell extracts is determined by RIA or ELISA (see K.4.1).

K.6.6.4 Lipolysis in β-Cells

PURPOSE AND RATIONALE

Besides the *de novo* synthesis of LC-CoA starting with the ACC reaction and malonyl-CoA formation, leading to inhibition of the translocation of LC-CoA into mitochondria, lipid-derived signaling molecules involved

in insulin secretion may also originate from the breakdown of TAG stores in β-cells. This may occur through activation of HSL, the enzyme that exerts a major control in TAG hydrolysis in adipose tissue (for a review see Yeaman 2004).

It was first demonstrated in 1999 that HSL is expressed and active in the β-cells of the pancreatic islet (Mulder et al. 1999). Two isoforms are expressed in the β-cell, the 84-kDa protein seen in adipocytes and other tissues and an 89-kDa protein (Mulder et al. 1999) encoded by exons 1–9 *plus* exon A, which is spliced to exon 1, introducing an additional 43 amino acids into the polypeptide (Lindvall et al. 2004).

The role of HSL in the β-cell has yet to be fully established. Two studies have independently looked at insulin secretion in HSL-knockout mice (Roduit et al. 2001, Fex et al. 2004). Both demonstrate features of insulin resistance in peripheral tissues, but differ in the effect of the knockout on insulin secretion from the pancreas. In one study, the glucose-responsiveness of insulin secretion was impaired (Roduit et al. 2001), both *in vivo* and in pancreatic islets isolated from the mice. The islets from the HSL knockout mice were totally unresponsive to glucose, but showed a normal response to depolarizing concentrations of KCl. This work is consistent with a key role for HSL in coupling of glucose metabolism to increased insulin secretion, perhaps by generating a lipid messenger such as DAG or fatty acyl-CoA from intracellular stores of TAG (Mulder et al. 1999, Roduit et al. 2001, Yaney et al. 2000). Also consistent with this role is the increased expression of HSL in response to high concentrations of glucose, with the elevated glucose ensuring an appropriate supply of the lipid mediators (Sorhede-Winzell 2001). The second study in HSL null mice demonstrated that insulin secretion was essentially unimpaired, with an increase in islet mass being found, presumably as a result of the insulin resistance in peripheral tissues (Fex et al. 2004). Possible reasons for the apparent discrepancies between the two studies may rely on the genetic background of the mice.

However, recent studies on transgenic mice that overexpress HSL specifically in the β-cell have provided evidence for a role for HSL in mediating the lipotoxicity associated with type II diabetes. These mice showed impaired glucose tolerance and had defective GSIS when fed a high-fat diet, accompanied by lower levels of β-cell TAG than found in control mice fed the same diet (Sorhede-Winzell 2003a). One proposed mechanism for this is that HSL provides endogenous ligands for lipid-activated transcription factors, including the PPAR-activated receptors. In this regard, it would appear that, in control animals, the accumulation of intracellular TAG is actually a protective mechanism (Listenberger et al. 2003), with the lipotoxicity being manifested when the storage capacity is exceeded or when the lipid stores are mobilized by HSL. Consistent with this is the observation that long-term feeding with a high-fat diet leads to down-regulation of pancreatic HSL levels by as much as 75%, presumably as a protective mechanism against the generation of these lipid metabolites (Sorhede-Winzell 2003b).

PROCEDURE

Lipolysis in cultured β-cells is determined as the release of glycerol into the incubation medium. Since FFA and glycerol are the end-products of lipolysis and glycerol is not metabolized by the β-cell due to low expression of glycerol kinase, glycerol release actually reflects the degree of lipolysis in cultured β-cells. Cells grown in 24-well culture dishes are incubated in 500 µl of RPMI 1640 medium containing 10% (by vol.) heat-inactivated fetal calf serum, 50 IU/ml penicillin, 0.25 µg/ml amphotericin B and 50 µg/ml streptomycin in the presence of increasing concentrations of glucose (2.8–16.7 mM) at 37°C for up to 4 h in an atmosphere of humidified air/CO_2 (19/1). After certain periods of time, 20-µl portions are transferred to a 96-well culture plate and incubated with glycerol kinase (50 U/ml) and luciferin/luciferase reagent. After addition of 10 µl of 1 mM ATP, the luminescence is measured in a luminometer after 4, 8 and 12 min. The glycerol concentration is calculated from the standard curve.

K.6.6.5 Measurement of Ca^{2+} Levels

Imaging

For imaging of cultured β-cells according to the protocol of Toye and coworkers (2005) with the modifiactions adapted from Freeman and coworkers (2006), MIN6 cells are cultured on 35-mm Fluorodishes (World Precision Instruments) and incubated with DMEM *plus* 3 µM Fura-2-AM (Molecular Probes) for 40 min at 37°C. They are imaged at room temperature (20–24°C) using an IonOptix fluorescence system with 340 nm and 380 nm dual excitation. The 510 nm emission ratio is collected at 1 Hz. Background subtraction is performed by measuring fluorescence from a cell-free region in the field of view. Cells are perfused continuously with extracellular solution containing 137 mM NaCl, 5.6 mM KCl, 2.6 mM $CaCl_2$, 1.2 mM $MgCl_2$, 10 mM HEPES/NaOH (pH 7.4) *plus* glucose or compounds/drug candidates.

Fluorometry

Calcium levels are monitored in cells transduced the day before the experiment with the calcium-sensitive photoprotein aequorin. Measurements of mitochondrial and cytosolic calcium are performed using the corresponding adenovirus constructs, AdCA-mtAeq and AdCA-cyAeq, respectively. The 2-h preincubation period also serves to load cells with the aequorin prosthetic group, i. e. 5 µM coelenterazine [2-(*p*-hydroxybenzyl)-6-(*p*-hydroxyphenyl)-8-benzyl-imidazo[1,2-]pyrazin-3-(7H)-one; Calbiochem]. Calibration is calculated based on the total counts obtained at the end of the trace following permeabilization of the cells with 50 µM digitonin and 10 mM $CaCl_2$ exposure.

K.6.6.6 Measurement of $^{86}Rb^+$ Efflux

PURPOSE AND RATIONALE

The binding of a sulfonylurea to its receptor SUR1, a subunit of the ATP-sensitive K^+ channel of β-cells, leads to blockade of the channel activity and concomitant decrease in the K^+ efflux (Boyd III et al. 1991). The resulting depolarization of the β-cell plasma membrane causes opening of the voltage-gated Ca^{2+} channel (Nelson et al. 1987, Niki et al. 1989, Rorsman and Trube 1986, Nichols et al. 1996). The rise in the intracellular [Ca^{2+}] triggers the exocytosis of insulin. $^{86}Rb^+$ efflux can be used as marker for K^+ efflux and analyzed in response to treatment of cultured β-cells with compounds/drug candidates.

PROCEDURE

RINm5F cells are grown and plated at a density of 200,000 cells/well (24-well tissue culture plates). $^{86}Rb^+$ efflux experiments are performed at 37°C and overnight equilibration of cells in RPMI 1640 medium supplemented with 10% FCS, 0.1 µCi/ml $^{86}RbCl$ and 0.2 µCi/ml L-[^{3}H]leucine (internal marker of cell recovery). After removing the medium, cells are preincubated in a medium containing 120 mM NaCl, 1.8 mM $CaCl_2$, 0.8 mM $MgCl_2$, 10 mM KCl, 20 mM HEPES/NaOH (pH 7.5) supplemented with 0.1 µCi $^{86}RbCl$, 0.24 mg/ml oligomycin, 1 mM 2-deoxy-D-glucose and several concentrations of compounds/drug candidates as well as sulfonylureas (as positive controls). $^{86}Rb^+$ efflux studies are initiated by removing the pre-incubation medium and incubating the cells with 200 µl of the same medium/well without $^{86}Rb^+$, oligomycin, and 2-deoxy-D-glucose. Efflux is stopped by removing this medium and washing the cells three times with 1 ml of 0.1 M $MgCl_2$ at 37°C. Cells are extracted with 2 × 1 ml of 0.1 N NaOH and counted. Total intracellular concentrations of ATP are measured after extracting the cells with 1% Triton X-100 by using the luciferase-luciferin technique.

EVALUATION

Inhibition is measured as percent of maximum $^{86}Rb^+$ efflux. Half maximum inhibition constants can be calculated.

MODIFICATIONS OF THE METHOD

Daniel and coworkers (1991) recommended a high through-put ^{86}Rb efflux assay in human medulloblastoma cells TE671 for screening of potassium channel modulators. Hu and coworkers (1995) cloned a voltage-regulated K channel from human hippocampus for transfection into CHO cells. The authors recommended this method as a high through-put assay to identify isotype-specific K-channel modulators.

K.6.6.7 Measurement of Cell Membrane Potential

PURPOSE AND RATIONALE

ATP-sensitive potassium (K_{ATP}) channels couple cell metabolism to electrical activity of the plasma membrane by regulating membrane K^+ fluxes (for a review see Ashcroft 2005). A reduction in metabolism opens K_{ATP} channels, producing K^+ efflux, membrane hyperpolarization, and suppression of electrical activity. Conversely, increased metabolism closes K_{ATP} channels. The consequent membrane depolarization stimulates electrical activity and may thereby trigger cellular responses such as the release of hormones and neurotransmitters, or muscle contraction.

Studies on isolated cells and tissues, and more recently on genetically modified mice and patients with mutations in K_{ATP} channel genes, have demonstrated that K_{ATP} channels play a multitude of physiological roles (Seino and Miki 2004). They contribute to glucose homeostasis by regulating insulin secretion from pancreatic β-cells (Ashcroft and Rorsman 1989, Henquin 2000, Gribble and Reimann 2003, Rorsman et al. 1994, Koster et al. 2000, Seghers et al. 2000, Dunne et al. 2004), glucagon secretion from pancreatic α-cells (Gopel et al. 2000a), somatostatin secretion from D cells (Gopel et al. 2000b), and GLP-1 secretion from L cells (Gribble et al. 2003). In ventromedial hypothalamic neurons they mediate the counter-regulatory response to glucose (Miki et al. 2001), and in arcuate nucleus neurons they may be involved in appetite regulation. In these glucose-sensing cells, K_{ATP} channels respond to fluctuating changes in blood glucose concentration. In many other tissues, however, they are largely closed under resting conditions and open only in response to ischemia, hormones, or neurotransmitters. In cardiac muscle and central neurons the resulting reduction in electrical activity helps protect against cardiac stress and brain seizures (Zingman et al. 2002, Yamada et al. 2001). K_{ATP} channels are involved in ischemic preconditioning in heart (Gumina et al. 2003) and the regulation of vascular smooth muscle tone (opening of K_{ATP} channels leads to relaxation) (Daut et al. 1994, Chutkow et al. 2002). Given their critical role in regulating electrical excitability in many cells, it is perhaps not surprising that disruption of K_{ATP} channel function can lead to disease. To date, mutations in K_{ATP} channel genes have been shown to cause neonatal diabetes (Gloyn et al. 2004, Magge et al. 2004), hyperinsulinemia (Dunne et al. 2004, Glaser et al. 2000, Thomas and Lightner 1996, Huopio et al. 2000). The effect of compounds/drug candidates on the open/closed state of K_{ATP} channel and the electrical activity of β-cell plasma membranes can be assayed with the following assays, which may be helpful for the identification of insulin secretagogues and sensitizers for GSIS as potential drug in the anti-diabetic therapy.

PROCEDURE

Rat insulinoma cells RINm5F (Gögelein et al. 1998) or cultured pancreatic β-cells from NMRI mice (Rorsman and Trube 1985, Zünkler et al. 1985) or HIT T15 β-cells (Niki et al. 1989) are used. Whole cell patch-clamp experiments are performed according to Hamill and coworkers (1981), Rajan and coworkers

(1993), Lindau and Neher (1988) at room temperature with cells bathed in an external solution of 140 mM NaCl, 4 mM KCl, 10 mM HEPES (pH 7.4). The patch pipettes are mounted on a suction pipette holder. The outlet is connected to silicon rubber tubing through which the suction is applied. The pipette solution contains 135 mM KCl, 1 mM $MgCl_2$, 1 mM EGTA, 10 mM HEPES (pH 7.5), 0.3 mM NaATP. Pipettes are prepared by pulling from borosilicate glass, coated with silicon rubber, and heat polished at the tip. Pipette resistances are ranging between 4 and 7 MΩ. A patch-clamp amplifier (e. g. EPC 7, List Electronic, Darmstadt, FRG) is used which allows capacitance and series resistance compensation. The series resistance after achieving the whole cell recording configuration is 5–20 MΩ and 50% series resistance compensation is used to keep the voltage error during current flow below 2 mV. The cell membrane potential is held at –70 to –80 mV and hyper- and depolarizing voltage pulses of 10 mV amplitude are applied alternatively every 2 s. Voltage-dependent currents, i. e., the Ca^{2+} inward current and the delayed K^+ outward current are not activated by these low pulse amplitudes and, therefore, most of the current is flowing through ATP-dependent K^+ channels. Inside-out patches are prepared according to Hamill and coworkers (1981) by disrupting the outer vesicle membrane.

EVALUATION

The current and voltage signals are stored on magnetic tape or filtered by a 4-pole Bessel filter and displayed on a digital oscilloscope. Outward currents flowing from the cell to the bath are indicated by upward deflections and inward currents by downward deflections. Half maximal effective concentrations are calculated as EC_{50} values.

MODIFICATIONS OF THE METHOD

Henquin and Meissner (1984), Henquin and coworkers (1984, 1985), Meissner (1990) measured membrane potential of mouse pancreatic β-cells. Hu and coworkers (2000) compared the effects of netaglinide, a non-sulfonylurea hypoglycemic agent, with sulfonylureas on pancreatic β-cell K_{ATP} channel activity with the whole-cell configuration of the patch-clamp technique in primary cultures of rat pancreatic β-cells. Wang and Giebisch (1991) reported a dual modulation of the renal ATP-sensitive K^+ channel by PKA and PKC in cells of the cortical collecting duct of rabbit kidneys using the cell-attached and inside-out modification. Shieh and coworkers (2000) characterized K_{ATP} channel opener-activated currents in pig and guinea pig bladder smooth muscle cells using the whole-cell patch-clamp technique. Shindo and coworkers (2000) examined with the whole-cell configuration of the patch-clamp technique the effects of a vascular relaxing agent on the heterologously expressed pancreatic-type ATP-sensitive K^+ channels SUR1/Ki6.2, SUR2A/Ki6.2, and SUR2B/Ki6.2 in human embryonic kidney 293T cells. Using whole-cell and single-channel patch-clamp recording, Gomora and Enyeart (1999) studied pharmacological properties of a cyclic AMP-sensitive potassium channel, I_{AC}, which is distinctive among K^+ channels both in its activation by ATP and inhibition by cyclic AMP. Alternatively, Maechler and coworkers (2004) monitored the cell membrane potential using 100 nM of the fluorescent probe bis-oxonol [bis-(1,3-diethylthiobarbituric acid) trimethine oxonol; Molecular Probes]. Filters used for excitation and emission had wavelength optima at 544 and 590 nm, respectively.

K.6.6.8 Measurement of Mitochondrial Membrane Potential

PROCEDURE

Mitochondrial membrane potential ($\Delta\psi_m$) is measured using the fluorescent probe, rhodamine 123. Cells cultured in 24-well plates are maintained for 2 h in 2.5 mM glucose medium at 37°C before loading with 10 µg/ml rhodamine 123 (Molecular Probes) for 20 min at 37 C in KRBH. The $\Delta\psi_m$ is monitored with excitation and emission filters set at 485 and 520 nm, respectively. Glucose (additions on top of the basal concentration of 2.5 mM) and then the protonophore carbonyl cyanide *p*-trifluoromethoxyphenylhydrazone (FCCP) is added to each well.

K.6.6.9 Measurement of cAMP Production

Approximately 1×10^6 cultured β-cells (grown as described above) in 0.45 ml buffer (113 mM NaCl, 4.7 mM KCl, 1.2 mM KH_2PO_4, 10 mM HEPES, pH 7.4, 2.5 mM $CaCl_2$ and 1.2 mM $MgSO_4$) containing 1% human serum albumin are pre-incubated for 10 min at 37°C, and then incubated for 10 min after the addition of 2 µl of IBMX (50 mM) in order to prevent the breakdown of cAMP. The reaction is then started by the addition of 50 µl of a peptide solution dissolved in the above buffer (final concentration range from 10 pM to 1 µM). After incubation for 10 min at 37°C, the reaction is stopped by the addition of 200 µl of 12% TCA. The reaction mixture is sonicated for 30 s at

25 W (e. g., Heat system, Ultrasonics) and centrifuged (11,500 × *g*, 2 min). HCl (25 µl, 1 M) is added to 0.5 ml supernatant. TCA dissolved in the supernatant is removed by diethyl ether (3 × 1 ml) and the resulting supernatant is stored at −80°C until cAMP assays being performed by use of a RIA kit.

K.6.6.10 Measurement of Cytosolic ATP Levels

Cytosolic ATP levels are monitored in cells expressing the ATP-sensitive bioluminescent probe luciferase 1 d after transduction with the specific AdRIP-Luc viral construct according to Maechler and coworkers (1998) and Rubi and coworkers (2001). After the preincubation steps described above, the 24-well plates are transferred to the plate reader in the luminometer mode. The luciferase substrate, 100 µM beetle luciferin (Promega), is added to the KRBH. After a 10-min period in basal 2.5 mM glucose, cells are stimulated with the indicated glucose concentrations, and 20 min later the mitochondrial poison NaN_3 (2 mM) is added (as a control).

K.6.6.11 Analysis of Lipotoxicity

GENERAL CONSIDERATIONS

There is increasing experimental evidence that sustained elevated plasma and intracellular lipid concentrations result in impaired insulin action and secretion *in vivo* and *in vitro*. This has implications for the causal relationship between the pathogenesis of obesity and type II diabetes (Carpentier et al. 2001, Dobbins et al. 2002). It is known that increased plasma FFA concentrations reduce insulin-mediated glucose uptake and metabolism in muscle tissue presumably *via* the glucose-fatty acid (Randle) cycle (Randle et al. 1963), but the exact mechanism of action of FFA on the β-cell to modulate glucose-stimulated insulin secretion (GSIS) (Zhou and Grill 1994, Roche et al. 1998, Unger and Orci 2002) remains to be elucidated. A complex interrelationship between the metabolism of glucose and lipids in β-cells has been described (Prentki and Corkey 1996), and this critically depends on the duration of exposure (acute or chronic) to the lipid metabolites (Zhou et al. 1994, Roche et al. 1998). In conclusion, it is now generally accepted that in rodent β-cells and islets lipids and/or lipid precursors/metabolites interfere with GSIS and β-cell functionality (Maedler et 2001, El Assaad et al. 2003, Cnop et al. 2001), but their nature (e. g. TAG, FFA, acyl-CoA, DAG) and molecular mode of action still remains a matter of intense research and debate.

However, serious doubts have been raised against the hypothesis of FFA-induced impairment of GSIS and β-cell death as playing a major role in the pathophysiology of human type II diabetes. Although increased plasma FFA and lipid (as lipoprotein TAG) concentrations and alterations in their composition occur in obesity in humans (Wang et al. 2003), this condition is not invariably linked to the onset of type II diabetes. Fewer than 12% of obese subjects with elevated lipid profiles suffer from diabetes (Ford et al. 2002). Furthermore, the concept of glucolipotoxity (Poitout and Robertson 2002) proposes that, in type II diabetes, the elevation of both glucose and FFA could contribute to the decrease in pancreatic islet function as a result of both β-cell apoptotic death and decreased insulin secretion.

PURPOSE AND RATIONALE

The following assay systems enable the determination of effects of compounds/drug candidates on the fatty acid-induced (and glucose-induced) modulation of GSIS, cell death and TAG concentration, composition and localisation in cultured β-cells. They may be helpful for the identification and characterization of compounds/drugs with the potential of abrogating the lipo(gluco)toxic effects of lipid (metabolites) in β-cells in response to certain (patho)physiological stimuli (e. g. stress, reactive oxygen species, see K.8.8).

PROCEDURE

Viability Assay

INS1 cells are plated into 8-well Permanox slides (Gibco) and treated for 24 h with 0.1, 0.25, 0.5 and 1 mM of FFA in 3 or 20 mM glucose. Adjustments to the stock solution are made to ensure a constant BSA concentration. Following incubation, cells are rinsed in PBS, incubated for a further 30 min in PBS containing 10 µM calcein-AM (Sigma) at 37°C and fixed in 2.5% paraformaldehyde for 30 min. Slides are rinsed twice more in PBS and the slides mounted in Vectorshield containing propidium iodide (Vector Laboratories). Viability is quantified by counting the propidium-iodide-positive nuclei and calcein-AM-positive cells (average cell count = 60 cells per field) and determining the percentage of propidium-iodide-positive nuclei in at least three fields of view per condition.

TAG and Phospholipid Content and Composition

INS1 or COS7 cells are seeded into 6-well plates at 2×10^5 cells per well and treated for 24 h with 0.5 mM

specific fatty acids. Total lipids are extracted from cells in chloroform/methanol (2/1) and lipid fractions are separated using solid-phase extraction (Burdge et al. 2000). The TAG and phospholipid fractions are collected and fatty acid methyl esters prepared using methanolic sulphuric acid. The fatty acid methyl esters are separated by gas chromatography (e. g. Agilent 6890 GC equipped with a DB-Wax 30 m capillary column coated with a polyethylene glycol stationary phase, internal diameter 0.25 mm, film thickness 0.25 µm; Agilent Technologies). Fatty acids are separated according to fatty acyl carbon chain length and degree of saturation. Intact TAG analyses are performed by high-temperature gas chromatography (HTGC; e. g. Hewlett Packard 5890 series II GC with a DB1-HT 15 m fused silica capillary column, internal diameter 0.32 mm, film thickness 0.1 mm). Hydrogen is the carrier gas and a flame ionisation detector is employed to monitor column eluent. HTGC analyses separates the TAG according to their carbon number. The absolute concentrations of individual fatty acids and TAG are determined typically by reference to internal standards (heptadecanoic acid [17:0] for NEFA; tripentadecanoin [15:0] for TAG; phosphatidylcholine, diheptadecanoyl [17:0] for phospholipid).

Light Microscopy

INS1 and cells are incubated in 8-well Permanox or glass slides (Gibco) with compounds/drug candidates for 24 h in the absence or presence of 3 or 20 mM glucose and 1 mM FFA. Cells are washed in PBS and fixed in 2.5% PFA and then stained for lipids. A stock solution of 0.5% (saturated) oil red O in propan-2-ol is freshly diluted (three parts stock solution in two parts distilled water) and filtered immediately before use. Cells are stained for 30 min at 37°C, then briefly destained in 60% isopropanol and washed in water before mounting in PBS/glycerol. A freshly prepared 1% Nile blue-solution in distilled water is filtered and an aliquot is further diluted in water to 0.02%. Fixed cells are washed twice in PBS. Nile blue solution (1%) is added to the cells for 10 min at 65°C or 70°C, after which the cells are washed in water and destained in 1% acetic acid (65°C) for 30 s. Cells are restained for 15 min in 0.02% Nile blue at 65°C or 70°C before being washed in water and mounted in PBS/glycerol.

Electron Microscopy

INS1 cells for morphological analysis are incubated with compounds/drug candidates in 25-cm^2 flasks for 24 h as described above. Cells are removed and gently prepared as a pellet, fixed in 2.5% glutaraldehyde (minimum 1 h) at room temperature (or for a 10-min period at 70°C), post-fixed in 2% osmium, dehydrated and embedded in Spurr resin. Cells for immunoelectron microscopy are fixed in ice-cold 4% paraformaldehyde (10 min) followed by 8% paraformaldehyde at room temperature (50 min), washed in PBS, dehydrated in methanol and embedded in LR Gold resin. Ultrathin sections are cut onto nickel grids and contrast-enhanced with uranyl acetate and lead citrate. Sections are examined in an electron microscope with an accelerating voltage of 80 kV.

K.6.6.12 Interaction with β-Cell Plasma Membranes and K_{ATP} Channels

It is now established that increasing the closed probability of the β-cell ATP-dependent potassium channel (K_{ATP}) is the major mechanism through which sulfonylureas as well as glucose (*via* transport, phosphorylation and metabolism for generation of ATP) stimulate insulin release from pancreatic β-cells (for reviews see Ashcroft and Ashcroft 1992, Ashcroft 2005, Bryan and Aguilar-Bryan 1997, Gribble and Reimann 2003, Henquin 2000, Inagaki et al. 1996). The resulting reduction in potassium ion efflux causes depolarization of the β-cell plasma membrane which in turn leads to opening of voltage-sensitive Ca^{2+} channels of the L-type. The increased influx of Ca^{2+} and thus the elevated cytosolic Ca^{2+} levels trigger the fusion of insulin-containing secretory granules with the plasma membrane, presumably mediated by Ca^{2+}/calmodulin-dependent protein kinase and additional unknown mechanisms (Philipson 1995, Aguilar-Bryan and Bryan 1999). The β-cell K_{ATP} consists of the regulatory sulfonylurea receptor subunits (SUR), such as SUR1, and the physically associated pore-forming potassium ion inwardly rectifying subunit, KIR6.2, in a multimeric assembly with the SUR and KIR6.2 subunits in 1:1-stoichiometry and four identical SUR/KIR6.2 complexes per functional channel unit (size of the channel holocomplex $[SUR/KIR6.2]_4$ about 1000 kDa; Skeer et al. 1994, Clement et al. 1997a and b, Bryan and Aquilar-Bryan 1999, Shyng and Nichols 1997). SUR1, which is predominantly expressed in neuronal/pancreatic β-cells, is an ATP-binding cassette (ABC) protein or transport ATPase, which closely resembles members of the multidrug resistance associated protein family with 17 predicted transmembrane domains (TMD) and two nucleotide-binding folds (NBF), which bind specifically (Mg^{2+})ATP/ADP (Bryan et al. 1995, Inagaki et al. 1995 and 1996, Ueda et al. 1999, Gribble et al. 1997). The KIR6.2 subunits have two TMDs which somehow contribute to the K^+ conductivity and selectivity (Babenko et al. 1998). The glibenclamide-binding site of SUR1 is proposed to consist of a benzamido (meglitinide)-binding site on TMDs 1–5 and the sulfonylurea (tolbutamide)-binding site on TMDs 12–17 based on photolabeling with [^{125}I]iodoglibenclamide and chimeric receptors (Ashfield et al. 1999, Babenko et al. 1999, Chutkow et al. 1996, Isomoto et al. 1996, Tanabe et al. 1999, Aguilar-Bryan et al. 1995). Interaction with both the benzamido- and sulfonylurea-binding sites could account for the several thousand-fold increase in affinity of glibenclamide vs. tolbutamide. SUR2A/B are splice variants of a single SUR2 gene differing in 42 amino acids at the carboxy-terminus, exclusively, with SUR2A expressed mainly in cardiac/skeletal muscle cells (Chutkow et al. 1996, Inagaki et al. 1996) and SUR2B in vascular/non-vascular smooth muscle cells and brain (Isomoto et al. 1996, Aguilar-Bryan et al. 1998). K^+-channel openers (KCOs) bind to SURs at the tolbutamide-binding site encompassing those (flanking) TMDs 12–17 which surround the central core region of the tolbutamide-binding site (Uhde et al. 1999). SURs define the sensitivity of the K_{ATP} channel holocomplex for its sensitivity toward both sulfonylureas and KCOs with SUR1 mediating high sensitivity for sulfonylureas/low sensitivity toward KCOs and *vice versa* SUR2A/2B mediating low sensitivity for sulfonylureas/high sensitivity for KCOs (for a review see Ashcroft 2005).

The following assays enable the investigation of the direct binding of compounds/drug candidates to the K_{ATP} channels and their SUR subunits, which may be helpful for the identification of insulin releasers acting like sulfonylureas or glinides, which have been used successfully in the anti-diabetic therapy since decades.

K.6.6.12.1 Isolation of Membranes

PROCEDURE

For receptor binding studies, membranes are isolated from adenoma tissue suspension, cerebral cortex of Wistar rats (Kaubisch et al. 1982, Geisen et al. 1985) or from RINm5F cells (Müller et al. 1994a).

Cerebral Cortex Homogenates

The homogenates are prepared from decapitated Wistar rats. The cortices are immersed in ice-cold buffer, pH 7.5, and are homogenized under cooling in an Ultraturrax tissue homogenizer. The cell membranes are

centrifuged (50,000 × *g*, 1 h, 4°C) resuspended in fresh phosphate buffer and recentrifuged at thea same speed. The resulting pellet is suspended in phosphate buffer, the final dilution being 1:50, based on wet weight of the cerebral cortex. One ml aliquot of this cell suspension is used for the incubations.

β-Cell Adenoma Tissue

The tissue is dissected from rats of the strain NEDH, is homogenized in 25 mM HEPES/KOH (pH 7.4), 0.25 M sucrose, 0.5 mM EDTA, 100 µM PMSF (50 ml/g tissue) under cooling with ice (3 × 5 s) with an Ultraturrax homogenizer. After centrifugation (3,000 × *g*, 5 min) the supernatant is transferred into new tubes and centrifuged (200,000 × *g*, 1 h, 4°C). The pellet is washed with 2 × 5 ml of the same buffer, resuspended in 2 volumes of the same buffer and centrifuged again (75,000 × *g*, 30 min). The pellet is resuspended again in the membrane buffer.

Membranes from Cultured β-Cells

Insulin producing cells from RINm5F cell culture (one culture flask) are washed twice with 25 mM HEPES/KOH (pH 7.4), 0.25 M sucrose, 0.5 mM EDTA, scraped with 20 ml of the same buffer and homogenized with 10 strokes of a tight fitting Potter-Elvehjem homogenizer followed by sonication (bath sonicator, 4°C, 10 s, maximal power). After centrifugation (200,000 × *g*, 45 min, 4°C) the pellet is suspended in 10 ml of 25 mM HEPES/KOH (pH 7.4), 0.25 M sucrose, 100 mM NaCl, 0.5 mM EDTA, 200 µM PMSF and recentrifuged (1,000 × *g*, 10 min). The supernatant is transferred to a new tube and centrifuged (50,000 × *g*, 30 min, 4°C). The pellet is washed once with 25 mM HEPES/KOH (pH 7.4) and finally suspended in membrane buffer (25 mM HEPES/KOH, pH 7.4, 150 mM NaCl, 1 mM EDTA, 100 µM PMSF, 10 µg/ml soybean/trypsin inhibitor, 10 µM leupeptin, 1 mM iodoacetamide at 5 mg protein/ml). Aliquots are stored at –80°C.

K.6.6.12.2 Binding to Membranes

PURPOSE AND RATIONALE

Sulfonylureas block K_{ATP} channel in the β-cell plasma membrane (Schmid-Antomarchi et al. 1987a, b). Binding to the receptor and depolarization of the membrane initiates a chain of events leading to the release of insulin (Boyd 1992). The high affinity sulfonylurea receptor is considered to be an integral part of the K_{ATP} channel (Aguilar-Bryan et al. 1992). Binding studies of sulfonylureas and other drugs can be performed with isolated pancreatic islets, isolated insulinoma cells, isolated intact membranes or solubilized membranes from primary or cultured cells or intact cells (Geisen et al. 1985, Gaines et al. 1988, Panten et al. 1989, 1992, 1993, Müller et al. 1994a).

PROCEDURE

Filter binding assays are performed in a total volume of 1 ml containing 5 mg membrane protein, 25 mM MOPS/KOH (pH 7.4), 0.1 mM $CaCl_2$ and labeled sulfonylurea, e. g. [^{3}H]glibenclamide or [^{3}H]glimepiride at concentrations between 0.1 and 20 nM. After incubation for 45 min at 25°C, the binding reaction is terminated by rapid filtration through Whatman GF/F filters soaked with the same buffer. The filters are washed three times with 5 ml of ice-cold 25 mM HEPES/KOH (pH 7.4), 100 mM NaCl, 1 mM EDTA, 200 µM PMSF, 0.5 µg/ml leupeptin, 0.75 µg/ml pepstatin and two times with 5 ml of ice-cold HEPES/KOH (pH 7.4), placed in 10 ml of ACSII scintillation cocktail and after incubation overnight counted for radioactivity in a liquid scintillation counter. Non-specific binding is determined in parallel samples in the presence of 1 µM unlabeled ligand.

K.6.6.12.3 Binding to Cells

Culture

Cultured cells producing the β-cell sulfonylurea receptor, SUR1, include the hamster insulin secreting tumor cell line, HIT-T15 (passage 65–75; CRL1777 ATCC). Cells are maintained in T-175 culture flasks as monolayers in DMEM containing high glucose supplemented with 10% fetal bovine serum, 100 U, 7 ml penicillin and 0.1 mg/ml streptomycin. Cells are grown in 5% CO_2 at 37°C, maintained in subconfluent cultures, fed three times a week, and subcultured as needed. To subculture, confluent cells are detached with 0.05% trypsin/EDTA, resuspended in supplemented DMEM/high glucose and replated at 1/10 of the original density.

Steady-State Analysis

After growth to 70% confluency, cells are treated with trypsin (0.02% trypsin in 0.9% NaCl/0.2 mM EDTA), washed with 3 × 10 ml KRBH containing 20 mM HEPES/KOH (pH 7.4), 125 mM NaCl, 5 mM KCl, 7.5 mM $NaHCIO_3$, 2 mM $CaCl_2$, 0.8 mM $MgSO_4$, suspended at a density of 2×10^7cells/ml in the same buffer and then incubated for 45 min at 4°C at

a density of 4×10^6 cells per 0.5 ml assay volume with labeled sulfonylurea, e. g., [^{3}H]glibenclamide or [^{3}H]glimepiride at concentrations between 0.1 and 20 nM. For determination of non-specific binding, 1 µM unlabeled ligand is included. The incubation mixture is rapidly filtered on Whatman GF/C filters soaked with ice-cold buffer under reduced pressure. Filtration and washing has to take less than 30 s. The filters are washed three times with 6 ml ice-cold buffer containing 100 µM PMSF, 0.5 µg/ml leupeptin, 0.75 mg/ml pepstatin, 1 µg/ml aprotinin, 50 mg/ml antipapain dihydrochloride, placed in 10 ml of ACSII scintillation cocktail and after incubation overnight counted for radioactivity in a liquid scintillation counter.

Kinetic Analysis

For studying the association kinetics, the binding reaction is started by addition of radiolabeled ligand and terminated after predetermined periods of time by rapid filtration. For studying the dissociation kinetics, displacement of radiolabeled ligand at equilibrium (60 min incubation) is initiated by addition of unlabeled drug (final concentration 1 µM) and terminated after given periods of time. For termination, the incubation mixtures are rapidly chilled to 2–4°C by placing the assay tube in a dry ice/methanol bath for 1 s immediately prior to filtration in a filtration apparatus located in a cool bench. Further processing is performed as described above.

EVALUATION

K_d as well as B_{max}-values are calculated from Scatchard plot analyses and K_{on} and K_{off} values from kinetic studies. Curvilinear Scatchard plots allow the assumption of more than one binding site. IC_{50} values for half maximal inhibition of [^{3}H]sulfonylurea binding can be calculated from competition-inhibition plots.

MODIFICATIONS OF THE METHOD

Masuda and coworkers (1995) tested the effect of troglitazone on sulfonylurea receptor binding in rat pancreatic islet cells and in HIT cells. They concluded that troglitazone has a non-competitive binding site at, or in the vicinity of, the sulfonylurea receptor.

K.6.6.12.4 Photoaffinity Labeling of Membranes

PURPOSE AND RATIONALE

Binding sites of sulfonylureas have been identified in pancreatic β-cell membranes and in other tissues such as brain. The technique of photoaffinity labeling allows the identification and purification of membrane receptors (Bernardi et al. 1988, Yip 1984, Kramer et al. 1994, Aguilar-Bryan et al. 1990, Boyd III 1991, Müller et al. 1994a, Geisen et al. 1985, Gaines et al. 1988, Kaubisch et al. 1982, Rajan et al. 1993, Sakura et al. 1995, Tanabe et al. 1998).

PROCEDURE

Photoaffinity Labeling with Glibenclamide

Samples of membrane suspension are prepared as described above. 600 µg of β-cell membranes, suspended in 100 mM sodium phosphate buffer (pH 7.4), are incubated in a total volume of 200 µl with 40–60 nM (0.3–0.4 µCi) [^{3}H]glibenclamide at 20°C in the dark for 60 min. Irradiation is performed in a Rayonet RPR 100 photochemical reactor (Southern Ultraviolet Co., CT), equipped with RPR 2530 Å lamps at a distance of 10 cm from the lamps. After irradiation at 254 nm for 2 min the membranes are diluted with 1 ml of 10 mM Tris/HEPES buffer (pH 7.4) containing 4 mM EDTA, 4 mM iodoacetamide, 4 mM PMSF and centrifuged (48,000 × g, 30 min). The resulting pellet is resuspended in 200 µl water and protein precipitated according to Wessel and Flügge (1984).

Differential Photoaffinity Labeling

600 µg of β-cell membranes are incubated with various concentrations (10^{-9} to 10^{-4} M) of glibenclamide or the test compounds. After incubation with 60 nM (0.37 µCi) [^{3}H]glibenclamide in the dark, the membranes are photolabeled at 254 nm for 2 min. After washing of the membranes, the proteins are separated by SDS gel electrophoresis.

SDS-PAGE Analysis

The protein precipitates are dissolved in 70 µl of 62.5 mM Tris/HCl buffer (pH 6.8) containing 2% SDS, 5% mercaptoethanol, 0.005% bromophenol blue by shaking on a mixer for 60 min. After centrifugation (15,000 × g, 10 min), the clear supernatants are subjected to SDS gel electrophoresis on 150 × 180 × 1.5 mm slab gels (Kramer et al. 1988). After fixing and staining, the gels are scanned with a densitometer (e. g. CD50, Desaga, Heidelberg). The radioactivity is determined by liquid scintillation counting after slicing the gels into 2 mm pieces and after digestion of proteins with Biolute.

EVALUATION

The radioactive peak of [^{3}H]glibenclamide bound to the receptor protein is decreased depending on the

concentration of unlabeled glibenclamide or test compounds. IC_{50} values can be calculated.

K.6.6.12.5 Binding to Recombinant SUR1

PROCEDURE

Heterologous Expression of SUR1

Chinese hamster ovary and COS (1, m6, 7) cell lines do not produce SUR1 and are used for heterologous SUR1 expression. For transient transfection, COS cells are plated at 50–60% confluence. Cells are transfected using either a DEAE-dextran or a lipofectamine protocol. 3-day-old cultures of COS cells are trypsinized and replated at a density of 3.5×10^5 cells per 35-mm well (six-well dish) and allowed to attach overnight. Typically, 5 µg of a SUR1 plasmid is mixed with 5 µg of a KIR6.2 plasmid and brought up to 7.5 µl final volume in TBS (8 g/l NaCl, 0.4 g/l KCl, 0.2 g/l Na_2HPO_4, 3 g/l Tris base, 0.2 g/l $CaCl_2$, 0.1 g/l $MgCl_2$, pH 7.5) before addition of DEAE-dextran (30 µl of a 5 mg/ml solution in TBS). The samples are vortexed, collected by spinning in a microfuge, then incubated (15 min, 22°C) prior to addition of 0.5 ml of 10% FBS in TBS. Cells are washed twice with Hanks' balanced salt solution (HBSS), the DNA mix is added, and the cells are maintained in a CO_2 incubator at 37°C. After 4 h incubation, the DNA mix is decanted and the cells shocked for 5 min in 1 ml HBS and 10% dimethyl sulfoxide, then placed in 2 ml of DMEM/high glucose containing 2% FBS and 10 µM chloroquine and kept in the incubator for 4 h. Thereafter the cells are washed three times with HBSS and incubated in normal growth media until assayed.

Alternatively, lipofectamine is used for transfection instead of DEAE-dextran. COS cells are plated in six-well dishes and are used at 70–80% confluency. Typically 1 µg of a SUR1 plasmid and 1 µg of a KIR6.2 plasmid are mixed with 375 µl of Opti-Mem reduced serum medium (Life Technologies, Inc.), then added to 375 µl of Opti-Mem containing 9 µl of lipofectamine. After 1 h incubation, the mixture is supplemented with Opti-Mem to 1 ml final volume and added to the cells, which had been washed twice with 3 ml of Opti-Mem each. After 5 h incubation, the Opti-Mem is replaced with DMEM/high glucose containing 10% FBS. Transfections are scaled up based on the area of the plates used. For instance, 150-mm plates used for membrane isolations are transfected with 100 µg of each plasmid using the DEAE-dextran protocol. Transfected cells are used for determination of sulfonylurea binding and photolabeling or $^{86}Rb^+$ efflux 36–72 h post-transfection.

Membrane Preparation

Membranes are prepared from 15–25 150-mm dishes. Cells are washed three times in PBS (pH 7.4), then scraped in PBS and collected in 10-ml plastic tubes. The cells are pelleted, resuspended in 10 ml of hypotonic buffer (10 mM Tris/HCl, pH 7.4, 1 mM EDTA), and allowed to swell for 1 h on ice. Cells are then homogenized, transferred to a 15-ml glass tube, and spun ($2{,}000 \times g$, 20 min, 4°C) to remove nuclei and unbroken cells. The supernatant is then transferred to a polycarbonate centrifuge tube and membranes are collected by centrifugation (50,000 rpm, 90 min, Ti80 fixed-angle rotor). The pelleted membranes are resuspended in 5–200 µl of membrane buffer (25 mM Tris/HCl, pH 7.4, 2 mM EDTA, 250 mM sucrose, 0.2 mM PMSF, 10 µg/ml leupeptin) and stored frozen in aliquots in liquid N_2.

Membrane Solubilization

Membranes are rapidly thawed, resuspended using a Teflon-in-glass homogenizer, and mixed with ice-cold digitonin (25% w/v, in deionized water, prepared daily) to a final protein concentration of 3 mg/ml and 1% digitonin. Subsequent steps are performed at 25°C in the presence of 0.2 mM PMSF, 10 µg/ml leupeptin, 20 µg/ml pepstatin, 0.2 mM phenanthroline). After 30 min of incubation, solubilized membrane proteins are separated from insoluble material by centrifugation ($100{,}000 \times g$, 1 h, 4°C). Alternatively, the thawed and re-homogenized membranes are mixed with the same volume (resulting in 3 mg/ml protein) of ice-cold 0.2% (w/v) phosphatidylcholine, 20% (w/v) glycerol, 280 mM KCl, 4 mM EDTA, 0.4 mM PMSF, 20 µg/ml leupeptin, 50 mM HEPES/KOH (pH 7.4), 2.5% (w/v) Triton X-100 or CHAPS, incubated on ice for 1 h (under gentle stirring) and then centrifuged ($150{,}000 \times g$, 1 h, 4°C). The supernatants are collected and stored frozen in liquid N_2.

Partial Purification of SUR1

For purification of the 140-kDa core glycosylated species of SUR1, 4-ml aliquots of digitonin-solubilized membranes are cycled for times over a 1-ml concanavalin A-Sepharose column equilibrated with 40 mM Tris/HCl (pH 7.5), 0.2 M NaCl, 1 mM EDTA, 1% digitonin. The column is washed with 8 ml of the equilibrating buffer and eluted with 4 ml of the equilibrating buffer containing 0.5 M methyl α-methylmannopyranoside. The eluted protein is stored

in liquid nitrogen. For purification of the 150-kDa complex glycosylated SUR1, wheat germ agglutinin-Sepharose is used instead of concanavalin A-Sepharose. The procedure is the same as described with the exception of elution of the receptor using 0.3 M N-acetylgluosamine.

The eluate for the lectin columns is cycled twice over a 1-ml column of Reactive Green 19-agarose equilibrated with 40 mM HEPES/KOH (pH 8.5), 1 mM EDTA, 0.5% (w/v) digitonin. After washing with 10 ml of equilibrating buffer, and 10 ml of the same buffer supplemented with 0.5 M NaCl, the protein is eluted with 4 ml of equilibrating buffer containing 1.5 M NaCl. The eluate from the Reactive Green-19 purification step is diluted 1:2 with 40 mM HEPES/KOH (pH 8.5), 1 mM EDTA, 0.2% digitonin, then cycled twice over a 1-ml phenylboronate-10 Sepharose column. The phenylboronate column is washed with 10 ml of the HEPES buffer, followed by 2 ml of 0.1 M Tris/HCl (pH 7.5), 1 mM EDTA, and 0.2% digitonin. The protein is eluted with 4 ml of 0.1 M Tris/HCl (pH 7.5), 1 mM EDTA, 0.15% (w/v) sodium dodecyl sulfate. Prior to binding measurements, pooled samples from the various column steps are concentrated by centrifugation ($3{,}000 \times g$, 30 min, 4°C) through 100,000 molecular weight cut-off filters (Amicon), which have been pretreated with 5% (v/v) Tween 20 for 14 h at 4°C.

K.6.6.12.6 Interaction with Extrapancreatic Tissues

In addition to β-cells and hypothalamic neurons (Angel and Bidet 1991), SUR1 is also expressed in human adipocytes (Shi et al. 1999). Closure of the K_{ATP} by sulfonylurea binding to the adipocyte SUR1 leads to depolarization of the plasma membrane, opening of voltage-dependent Ca^{2+} channels and concomitant increase of the cytosolic Ca^{2+} concentration. Thus, adipocytes and determination of intracellular Ca^{2+} may be used for assaying the potency of sulfonylureas with regard to binding to SUR1.

Prior to fluorometric Ca^{2+} measurement, the adipocytes are washed three times (by flotation) with HBSS (140 mM NaCl, 0.8 mM $MgSO_4$, 1.8 mM $CaCl_2$, 0.9 mM NaH_2PO_4, 4 mM $NaHCO_3$, 5 mM glucose, 2 mM sodium pyruvate, 2 mM glutamine, 20 mM HEPES, 1% BSA). The cells are then loaded with Fura-2-acetoxymethyl ester (10 µM) in the same buffer for 45 min at 37°C in the dark with continuous shaking. For removal of extracellular dye, the cells are washed three times with HBSS and resuspended in HBSS at 3.5×10^5 cells/ml. Cytosolic Ca^{2+} is determined using dual excitation (340 and 380 nm) and single emission (510 nm) fluorometry. After establishment of a stable baseline in the absence or presence of the K_{ATP} channel openers, diazoxide and nitrendipine, the response to sulfonylureas is determined. Digitonin (25 µM) and Tris/EGTA (100 mM) are used to measure maximal and minimal fluorescence to calibrate the signals. Cytosolic Ca^{2+} is calculated by the equation of Grynkiewicz and coworkers (1985).

Direct effects of sulfonylurea agents on glucose transport (Cooper et al. 1990, Rogers et al. 1987, Müller 2000), insulin-induced decrease in 5′-nucleotidase activity in skeletal muscle membranes (Klip et al. 1987), diacylglycerol-like activation of protein kinase C (Cooper et al. 1990) were studied in BC_3H_1 myocytes, rat cardiomyocytes (Bähr et al. 1995) and rat diaphragms (Müller et al. 1994b). Augmentation of the effects of insulin and insulin-like growth factors I and II on glucose uptake by sulfonylureas (Wang et al. 1987), coordinate regulation of glucose transporter function, and gene expression by insulin and sulfonylureas (Wang et al. 1989), glyburide-stimulated glucose transport *via* PKC-mediated pathway (Davidson et al. 1991) were studied in the same cell line. For glimepiride, a sulfonylurea of the 3rd generation, but not for sulfonylureas of the 2nd or 1st generation (glibenclamide or tolbutamide, respectively), its direct interaction with lipid rafts at the plasma membranes of rat adipocytes, presumably *via* spontaneous intercalation between raft glyco(sphingo)lipids has been reported (Müller and Geisen 1996, Müller and Welte 2002). This is associated with activation of the GPI-PL (see K.6.3.6.4) and the translocation of certain GPI-proteins and non-RTK from high cholesterol-containing rafts to low cholesterol-containing rafts accompanied by their activation. This redistribution of signaling components which ultimately leads to the IR-independent tyrosine phosphorylation of IRS-1 and downstream signaling to the glucose transport system in rat adipocytes (Müller et al. 2001, for reviews see Müller 2002, 2005) may represent the molecular basis for the so-called extrapancreatic activity of certain sulfonylurea drugs, i. e. the blood glucose lowering in the absence of additional insulin release. The effects of compounds/drug candidates on the redistribution and activation of lipid raft proteins in rat adipocytes can be assayed as described (see K.6.3.6.4.2).

K.7 Measurement of Glucose Absorption

K.7.1 Inhibition of Polysaccharide-Degrading Enzymes

GENERAL CONSIDERATIONS

Starch as the predominant ingredient of human food is rapidly degraded in the gastrointestinal tract by salivary and pancreatic α-amylase to maltose which is further hydrolyzed by maltase localized in the brush border of the small intestine to glucose. Glucose is immediately absorbed leading to hyperglycemia and consequently to hyperinsulinemia. Both phenomena are undesirable in diabetics and in obese patients. Inhibition of the digestion of starch leads to a decrease and a retardation of glucose absorption. In nature, α-amylase inhibitors are found in wheat and other grains (Shainkin and Birk, 1970). Several inhibitors of amylase and α-glucosidase have been developed (Bischoff 1991). Animal experiments with high doses of absorbable α-glucosidase inhibitors indicate that lysosomal storage of glycogen may occur (Lembcke et al. 1991).

K.7.1.1 Assay for α-Amylase

PURPOSE AND RATIONALE

α-Amylase activity can be measured by determination of the reducing groups arising from hydrolysis of soluble starch by isolated pancreatic α-amylase according to the protocol of Rick and Stegbauer (1970). The reduction of 3,5-dinitrosalicylic acid to nitroaminosalicylic acid produces a color shift which is followed photometrically by changes in the absorbance at 546 nm. Inhibition of starch hydrolysis by an α-amylase inhibitor results in a diminished absorbance at 546 nm in comparison with the controls.

PROCEDURE

Commercially available pancreatic α-amylase (Merck, Germany) is used. Various concentrations of the α-amylase inhibitor are dissolved in 1 ml 20 mM Sörensen buffer, pH 6.9 and 10 mM NaCl. 0.1 ml pancreatic α-amylase solution in 0.4% BSA is added. After prior incubation at 25°C, the enzymatic reaction is started by addition of 1.0 ml soluble starch solution. The reaction is stopped after 10 min with 1.0 ml of dinitrosalicylic acid reagent. The mixture is heated in a boiling water bath for 10 min, and after cooling measured at 546 nm against the reagent blank.

K.7.1.2 Assay for α-Glucosidase

PURPOSE AND RATIONALE

Inhibition of glucosidase can be measured *in vitro* using glucosidase from porcine small intestinal mucosa.

PROCEDURE

Glucosidase is prepared from rat or porcine small intestinal mucosa or porcine pancreas. The enzyme activity is assayed according to Dahlqvist (1964). The inhibitory activity is determined by incubating a solution (20 µl) of an enzyme preparation with 80 mM sodium phosphate buffer, pH 7.0 (500 µl) containing 37 mM sucrose or maltose, or 3.7 mM isomaltose and a solution (20 ml) containing various concentrations of the inhibitor at 37°C for 20 min. The reaction mixture is heated for 2 min in a boiling water bath to stop the reaction. The amount of liberated glucose is measured by the glucose oxidase method. Matsuo and coworkers (1992), Ikeda and coworkers (1991) and Glick and Bray (1983) studied the effect of intestinal disaccharidase inhibitors on obesity and diabetes.

K.7.1.3 Everted Sac Technique for Assaying α-Glucosidase

PURPOSE AND RATIONALE

The everted sac technique allows to study the effects of intestinal enzymes on substrates in an incubation vial.

PROCEDURE

Male rats weighing 120–140 g are sacrificed and the small intestines removed by cutting across the upper end of the duodenal junction. The intestine is stripped of the mesentery and the entire intestinal content is rinsed with cold saline solution. The intestine is divided into 7 to 8 cm-segments and turned inside out using a Pasteur pipette. The everted intestine is ligated at one end with a cotton thread and a second ligature is placed loosely around the opposite end ready for tying. A 1 ml syringe with Krebs-Henseleit-buffer is introduced into the lumen sac. The end of the sac is ligated and placed in a 25 ml Erlenmeyer flask containing 6 ml of 1% starch, dissolved in Krebs-Henseleit-buffer, with or without various concentrations of the α-amylase inhibitor. Pork α-amylase (4000 U/g starch) is also included in the 6 ml starch solution. Following gassing with 95% O_2/5% CO_2, the flask is tightly capped and incubated in a shaking bath at 37°C for 120 min. The reaction is terminated by the addition of 10 µl 1 N HCl. At the end of the incubation period, the sac is removed from the flask and the inner fluid is collected by cutting one end of the sac. The final volumes of the solute in the serosal and the mucosal side and the level of glucose liberation are measured.

EVALUATION

Glucose liberated in the presence of various concentrations of the α-amylase inhibitor is expressed as percentage of glucose found without the inhibitor. Dose-

response curves can be drawn plotting percent inhibition versus concentration of the inhibitor

K.7.2 Assays for GLUT2 Transport Activity

GENERAL CONSIDERATIONS

Diabetes management is directed toward control of postprandial fluctuations or excursions in blood glucose, which reflect the relative rates of delivery from the intestine and disposal to the tissues. While much is known about the impact of disposal mechanisms on blood glucose, rather less is known about delivery mechanisms, including gastric emptying, membrane hydrolysis, and sugar absorption itself.

Intestinal sugar absorption is increased in experimental diabetes (Csaky and Fischer 1981, Debnam et al. 1990, Thomson et al. 1981). Knowledge of sugar absorption has been based primarily on the mechanism of Na^+/glucose cotransport by Na^+/glucose cotransporter (SGLT1) and its long-term regulation by diet (Ferraris 2001). Recently, however, we have discovered a new pathway of sugar absorption, the apical GLUT2 pathway, which operates within minutes when high concentrations of primary digestion products, i. e., sugars, disaccharides, and α-dextrins, are presented to or generated at the apical membrane of the small intestine. This process is reversed when these sugars are absent from the lumen *in vivo*. The first indication of the existence of this mechanism was obtained in a study of the increase in fructose absorption in experimental diabetes (Corpe et al. 1996).

Dietary glucose crosses the apical membrane of the enterocyte by SGLT1 and exits across the basolateral membrane through the facilitative transporter GLUT2 (Thorens et al. 1990). Plasma glucose is maintained at ~5 mM. When the glucose concentration in the lumen is lower than in plasma, SGLT1 transports glucose uphill against its concentration gradient. This transcellular pathway is powered by a downhill gradient of Na^+ across the apical membrane, maintained by the basolateral Na^+/K^+-ATPase. The cloning of SGLT1 by Wright′s laboratory (Hediger et al. 1987) and GLUT2 by Thorens' laboratory (Thorens et al. 1990) began the molecular biological era of intestinal nutrient transport

PURPOSE AND RATIONALE

Recent experimental evidence hints to a refined model for intestinal glucose absorption (for a review see Kellett and Brot-Laroche 2005, Kellett and Helliwell 2000) whereby a long-term diet containing high–glycemic index sugars is priming the rapid induction of the translocation to and insertion into the apical plasma membrane of GLUT2 by simple dietary sugars. Most importantly, the apical GLUT2 component of absorption seems to be several times greater than the active component at high glucose concentrations. According to this hypothesis, apical GLUT2 and SGLT1 act in tandem to cover the entire concentration range with SGLT1 playing an important regulatory role in the control of apical GLUT2. Apical GLUT2 is not only tightly regulated by long- and short-term supply of dietary sugars, but also by local and endocrine hormones, cellular energy status, stress, and diabetes; regulation occurs through a network of intracellular signaling pathways. Accordingly, apical GLUT2 can provide a major route of sugar absorption by which absorptive capacity is rapidly and precisely upregulated to match the dietary intake of sugars during assimilation of a meal (for a review see Kellett and Brot-Laroche 2005). Apical GLUT2 provides a safety factor by preventing high sugar loads from reaching the colon (Cheeseman 2002). Moreover, the consequent rapid delivery of sugar into the blood might increase the postprandial excursions, especially when glycemic control is poor. Apical GLUT2 is therefore a potential therapeutic target for novel dietary or pharmacological approaches to control intestinal sugar delivery and thereby improve glycemic control. The following assays enable the analysis of effects of compounds/drug candidates on the regulation (*via* insertion into the apical memebrane) and transport activity of GLUT2 and may be helpful for the identification and characterization of a new class of glucose absorption inhibitors as putative future anti-diabetic drugs.

K.7.2.1 Perfusion of Jejunal Loops

PROCEDURE

Helliwell and coworkers (2000) described the perfusion of jejunal loops. Male Wistar rats (240–260 g) fed *ad libitum* on standard diet with free access to water are anaesthetized with an intraperitoneal injec-

tion of a mixture of 1.0 ml of Hypnorm (Janssen U.K.) and 0.4 ml of Hypnovel (Roche Diagnostics) per kg of body weight. The intestine is exposed by a laparotomy. A 30-cm segment just below the ligament of Trietz is cannulated, flushed free of nutrients and perfused with a single-pass system at a flow rate of 0.5ml/min with a modified Krebs bicarbonate saline (118 mM NaCl, 4.74 mM KCl, 1.2 mM KH_2PO_4, 1.25 mM $CaCl_2$ and 24.8 mM $NaHCO_3$) segmented with 95% O_2/5% CO_2. The effluent is collected every 5-min using a fraction collector. The jugular vein is cannulated with a silastic tube and infused with saline at a flow rate of 3 ml/h. Radiolabeled substrate is added to the perfusate and radiolabeled PEG4000 is included as a non-absorbable marker to allow for the correction of fluid movements. At the end of the perfusion period the intestine is removed, weighed wet and then dried overnight before reweighing. For the addition of phloretin the luminal solution required the use of modified Krebs bicarbonate saline (see above) to keep the inhibitor in solution. Phloretin is initially made up as a stock solution in DMSO and 200 µl of stock, then added to 150 ml of perfusate to give a final concentration of 1 mM. Final DMSO concentration is therefore 0.13% (v/v), which has been demonstrated previously to have no effect on tissue permeability. Phloretin can be used in solution for the length of the experiment.

Compound Application

Because compounds take some time to become effective in whole tissue and because there is a limit to the time of viability for isolated loops *in vitro*, the following procedure for the treatment of jejunum with drugs has been adopted. Jejunum is first perfused luminally *in vivo* with 5 mM D-fructose (plus 1 mM β-hydroxybutyrate as an energy source) in the presence or absence of compound. The perfusion system is a gas-segmented, single-pass system with perfusate and gas flow rates of 0.75 and 0.38 ml/min respectively. Jejunum is perfused with compound for 30 min. At the end of the *in vivo* treatment period, the cannulated loop is then excised and perfused *in vitro* using the gas-segmented, recirculated flow system: 5 mM D-glucose or fructose in combination with the compound at the end of the *in vivo* treatment period are perfused luminally through the jejunum for 60 min; the flow rates of perfusate and gas were 7.0 and 3.4 ml/min respectively. Control perfusions are performed in which no compounds are present. These show that there is no falling off in the glucose/fructose uptake rate after the initial approach to the steady state, confirming that this approach to compound treatment and perfusion ensured that the jejunum is viable for the whole experimental period from the start of the *in vivo* to the finish of the *in vitro* perfusion. Samples (0.05 ml) are taken from the perfusate at 5-min intervals throughout the *in vitro* perfusion. After measurement of glucose/fructose concentration with a COBAS automatic analyser (Roche Diagnostics) using a test kit from the same supplier, the amount of glucose/fructose remaining in the perfusate is calculated, with correction for losses in perfusate volume caused by water transport. Because the perfusate is recirculated, the concentration of fructose decreases with time; it is therefore necessary to limit the period over which the rate of transport is measured to one in which the concentration decreased by no more than 20%. Over such periods, plots of luminal perfusate content versus time are effectively linear. The rate of glucose/fructose transport, expressed as µmol/min· (g of dry weight)$^{-1}$, is therefore determined by linear regression analysis as the average rate of disappearance over this period from the luminal perfusate *in vitro*.

Dually Perfused in Situ Jejunum

Dual perfusion of the jejunum is typically performed as described by Hirsh and Cheeseman (1998). Male Sprague-Dawley rats (200–350 g) are fed a standard chow diet and water *ad libitum*. Before the start of the experiment, food is withdrawn for approximately 24 h to minimize intestinal lumenal contents during surgery. All rats are anesthetized prior to surgery using sodium pentobarbital given by intraperitoneal injection (60 mg/kg body weight) and placed on a heated (37°C) surgical table. After performing a laparotomy, the blood supply to the spleen, rectum, colon, cecum, stomach, and ileum are tied off and the tissues removed. The vasculature to the pancreas and duodenum are also ligated. A 35-cm segment of jejunum, starting 5 cm distal from the ligament of Trietz, is isolated and the lumenal contents removed by gently flushing with 20 ml of warm saline (0.9%), and the jejunum is cannulated at both ends. The lumen is perfused with a Krebs-bicarbonate saline solution (120 mM NaCl, 4 mM KCl, 2.5 mM $MgSO_4$, 1.2 mM KH_2PO_4, 25 mM $NaHCO_3$, 1 mM $CaCl_2$) using a pump. The solution containing 5 mM 3-*O*-MG or 5 mM 3-*O*-MG and 5 mM D-fructose, is maintained at 37°C and gassed with 95% O_2, 5% CO_2. Isotopically labeled hexoses, 10 µCi of either 3-*O*-methyl-D-[1-^{3}H]glucose, or both 3-*O*-methyl-D-[1-^{3}H]glucose and D-[U-^{14}C]fructose, are added to the lumenal circuit immediately after portal vein cannulation. The single-pass lumenal circuit is perfused at a flow rate of 1.6 ml/min, and the so-

lution is segmented by 95% O_2/5% CO_2 gas bubbles. The gas bubbles are introduced into the lumenal perfusate through a Y piece at a flow rate which ensured that bubbles occupied the diameter of the perfusion tube. This not only exposes the tissue to a saturating gas partial pressure, but also helps to mix the solution in the tissue lumen. After a single-pass through the segment of jejunum the lumenal perfusate is discarded. The aorta, proximal to the superior mesenteric artery, is ligated just prior to insertion of a cannula into the superior mesenteric artery. The single-pass vascular circuit is perfused at a rate of 1.6 ml/min with fresh Krebs-bicarbonate saline solution, containing 5 mM D-glucose, 0.034 mM streptomycin sulfate, 5 mM L-glutamine, 1120 USP units heparin, and 10% w/v Ficoll 70 as a plasma expander, which is maintained at 37°C and gassed with 95% O_2/5% CO_2 maintaining the pH at 7.4. Once the vascular circuit is established, the rat is euthanized and the vascular perfusate is collected *via* cannula placed in the hepatic portal vein. The effluent is collected continuously for up to 80 min using a fraction collector.

Washout Studies in the Dually Perfused Jejunum

This procedure is similar to the one used by Boyd and Parsons (1979). This washout model is useful for indirectly indicating the locus of compound/drug action. When the labeled 3-*O*-MG is washed out in the presence of an equimolar concentration of unlabeled mannitol in the lumen, the rate of washout into the vascular bed can be described by the sum of two exponential terms (assuming a two-compartmental model applies). The contributing compartments are a fast releasing (vascular flow rate dependent) and a slow releasing one (vascular flow rate independent), which represent: 1) Q_{01} mucosal epithelium layer and 2) Q_{02} deeper submucosal (muscle) layer. Assuming that each pool unloads independently, then each pool will have its own rate constant: the fast, K_1 and the slow, K_2.

EVALUATION

Tissue ion conductance (G) is calculated from PD and I_{sc} according to Ohm's law. For the measurement of basal glucose fluxes, the tissue is clamped at zero voltage by continuously introducing an appropriate I_{sc} with an automatic voltage clamp every 5 min, except for 5–10 s when PD is measured by removing the voltage clamp. Tissue pairs are matched for conductance and discarded if conductance varied by >20%. The non-metabolizable glucose analog 3-*O*-methyl-D-[1-^{3}H]glucose (5 μCi) is added either to the serosal or mucosal side after mounting and the tissue is allowed to equilibrate for 20 min. Net directional flux from mucosal-to-serosal surface is determined for conductance-matched tissues by measuring four consecutive 5-min fluxes before the addition of compound/drug candidate and four 5-min fluxes following the addition of the agent.

MODIFICATION OF THE METHOD

Epithelial glucose uptake can be measured according to the method described by Walker and coworkers (2005).

K.7.2.2 Transport Activity of Brush Border Membrane Vesicles

Preparation of Intestinal Brush Border Membrane Vesicles

Brush-border membrane vesicles (BBMV) are prepared from mucosal scrapings as described by Corpe and coworkers (1996) on basis of a standard procedure introduced by Maenz and Cheeseman (1986). Every stage of the preparation is performed at 0–4°C to prevent changes in trafficking after the intestine had been excised. Briefly, the jejuna of two rats are perfused with compounds/drugs as described above. The timing of the final *in vitro* perfusion is such as to get as direct a correspondence as possible between rates of transport and extent of trafficking. Perfusions for vesicle preparations are therefore terminated at a point corresponding to half the time period over which the average rate of transport is determined, as described above. Immediately after perfusion, each jejunum is rinsed with ice-cold buffered mannitol (20 mM imidazole buffer, pH 7.5, containing 250 mM mannitol and 0.1 mM PMSF), placed on an ice-cold glass plate and slit longitudinally so that the muscle of the jejunum flattened out on to the cold plate. The mucosa is scraped off with a microscope slide and placed in 65 ml of ice-cold mannitol/Tris buffer (300 mM mannitol, 5 mM EGTA, 12 mM Tris/HCl, pH 7.4, and 0.1 mM PMSF). The tissue is homogenized in a Polytron homogenizer (four 30 s bursts using the large probe at setting 7) before addition of $MgCl_2$ to a final concentration of 12 mM. After stirring the solution on ice for 15 min the solution is centrifuged (1,600 × *g*, 15min) to remove debris. The supernatant is further centrifuged (20,000 × *g*, 30 min) and the pellet homogenized in half-strength mannitol/Tris buffer (150 mM mannitol, 2.5 mM EGTA, 6 mM Tris/HCl, pH 7.4, and 0.05 mM PMSF) with a glass homogenizer before further addition of $MgCl_2$. After stirring on ice the centrifugation is repeated as before, and the pellet is then washed

(300 mM mannitol/5mM Tris/HCl, pH7.4) before repelleting (20,000 × *g*). This BBMV preparation is diluted to a protein concentration of 8 mg/ml. Enrichment of sucrase activity in these highly purified preparations typically range from 16- to 20-fold. There is no significant enrichment of Na^+/K^+-ATPase activity.

Preparation of Renal Brush Border Membrane Vesicles

Both kidneys are removed from anaesthetized animals and placed in ice-cold 154 mM NaCl. After removal of the renal capsule, the kidneys are weighed and then sliced into 2-mm thick sections and the cortex dissected away. Cortical fragments from six kidneys are pooled, weighed and suspended in 30 ml of 300 mM mannitol, 12 mM Tris/HCl (pH 7.4), 5 mM EGTA. The resulting suspension was homogenized for 2 min (Ultra Turrax homogenizer) at half speed, followed by the addition of 42 ml of cold distilled water and $MgCl_2$ to a concentration of 12 mM, and then stirred on ice for 15 min. The solution is then centrifuged (2,000 × *g*, 15 min) and the supernatant then re-centrifuged (21,000 × *g*, 30 min). The pellet is suspended in 20 ml of 150 mM mannitol, 6 mM Tris/HCl (pH 7.4), 2.5 mM EGTA using 10 cycles of a hand-operated glass-Teflon homogenizer. $MgCl_2$ is added to a concentration of 12 mM and, after stirring on ice for 15 min, low and high-speed centrifugations described above are repeated. The pellet is then re-suspended in 20 ml of 300 mM mannitol, 12 mM Tris/HCl (pH 7.4), 2.5 mM EGTA and centrifuged (21,000 × *g*, 30 min). The purified BBMV pellet is finally resuspended in the same buffer to a protein concentration of 3–6 mg/ml using 5–6 passes through a syringe fitted with a 21-gauge needle. All steps are carried out at 4°C. The concentration of protein (Bradford 1976) and activity of alkaline phosphatase and Na^+/K^+-ATPase in the initial homogenate and BBMV preparation are determined in order to derive values for enrichment of these marker enzymes (see Corpe et al. 1996).

Glucose Transport

Transport studies are carried out at 20°C on freshly prepared BBMV as described (Sharp and Debnam, 1994). The transport process is initiated by mixing equal volumes of BBMV suspension and uptake buffer consisting of 200 mM NaSCN, 20 mM HEPES, 0.1 mM $MgSO_4$ containing D-[^{3}H]glucose (9 Ci/mmol) and such that the final concentration of glucose is 5–500 µM. Due to the wide glucose concentration range used, the osmotic balance is maintained by adding mannitol to give a final glucose *plus* mannitol concentration of 100 mM. Uptake is terminated after 4 s by the addition of 3 ml of ice-cold 154 mM NaCl containing 0.5 mM phlorizin, followed by vacuum filtration through 0.45-µm nitrocellulose filters (Sartorius, Germany). Three further washes with stop solution are carried out.

EVALUATION

Scintillation counting of the filters is used to calculate glucose accumulation and this is expressed as nmol (mg protein)$^{-1}$ (4 s)$^{-1}$. The kinetic parameters of V_{max} (maximum transport capacity) and K_t (glucose concentration at half V_{max}) for phlorizin-sensitive uptake were derived using a non-linear least squares curve-fitting program.

Parallel uptakes using buffer containing 1 mM phlorizin to block SGLT-mediated transport indicated that uptake is > 90% phlorizin-sensitive. In order to assess GLUT-mediated transport, a higher glucose concentration (20 mM) is used in the presence of 1 mM phlorizin. This value is consistent with the low affinity of GLUT transporters for glucose binding. In addition, uptake of L-glucose at both 100 µM and 20 mM should be performed to establish the contribution of passive glucose transport.

K.7.2.3 Apical Expression of GLUT2

Biotinylation of Surface Proteins

The method of surface protein biotinylation for analysis of GLUT2 expression at apical membranes has been introduced by Au and coworkers (2002). For the detection of GLUT2 in the apical membrane of enterocytes, i. e. of the translocation of GLUT2 from intracellular vesicles to the apical cell surface, proteins expressed on the apical surface of jejunal enterocytes are labeled with *N*-hydroxysuccinimido (NHS)-SS-biotin introduced into the intestinal lumen. At the end of the *in vivo* perfusion the intestine is maintained *in situ*, but cooled on ice. The luminal solution containing NHS-SS-biotin, 1.5 mg/ml in 10 mM triethanolamine/2.5 mM $CaCl_2$/250 mM sucrose buffer (pH 9.0), is introduced into the lumen and left for 30 min. The lumen is then flushed with a PBS/100 mM glycine buffer to quench the free biotin before two final washings with PBS. Mucosal scrapings are then used to make protein extracts as described below.

Isolation of Biotinylated Proteins

Proteins are extracted from the homogenate for 1h at 4°C using the following buffer: 1% Triton X-100, 150 mM NaCl, 5 mM EDTA and 50 mM Tris (pH7.5).

After centrifugation (14,000 × *g*, 10 min) the supernatant is collected and incubated overnight with streptavidin beads. After washing twice with the Triton X-100 buffer to remove non-linked protein, the beads are washed with a high-salt buffer (500 mM NaCl) and finally with a no-salt buffer (10 mM Tris, pH 7.5). The isolated biotinylated proteins are then solubilized in Laemmli sample buffer to be run on SDS-PAGE for immunoblotting. Comparisons of total cell GLUT2 with apical GLUT2 are made by running samples of the supernatant after spinning down the streptavidin-coated beads on the same immunoblots as samples of recovered biotinylated protein.

Detection of Apical GLUT2 by Immunoblotting

Membranes (15 µg of protein) are solubilized in Laemmli sample buffer and separated by SDS-PAGE (10% gel). The proteins are blotted on to nitrocellulose membrane by electrotransfer for 75 min at 4°C. The membranes are stained for total protein with Ponceau S to ascertain that equivalent amounts of protein are loaded and transferred from each lane. Blocking of the membrane is carried out in 3% non-fat milk in PBST (0.05% Tween 20/PBS, pH 7.4) for 1 h and then incubated with 1:1,000 rabbit polyclonal antibody to rat GLUT2 in 3% non-fat dry milk in PBST overnight at 4°C. The membrane is washed three times in 3% non-fat dry milk/PBST for 15 min, 1 h and 15 min respectively. The nitrocellulose membrane was then incubated with a secondary antibody, anti-rabbit IgG coupled to horseradish peroxidase diluted 1:2,000 in 3% non-fat dry milk/PBST for 1 h. Three subsequent washes followed as described above. Finally, the membrane is treated with the ECL detection solution (Amersham-Pharmacia) before autoradiography for 30 s using Kodak XAR-5 film with an intensifying screen. The specificity of the antibody was determined by running parallel lanes of isolated biotinylated proteins and probing them with the native antibody or with antiserum which had been pre-incubated at room temperature for 1 h with the peptide used to raise the antibody. Two antibodies are employed, one that recognizes an epitope in the large extracellular loop between transmembrane segments 1 and 2, amino acids 40–55 (SHYRHVLGVPLDDRRA; Biogenesis, UK) and a second which recognized a portion of the C-terminal sequence of rat GLUT2 (CVQMEFLGSSETV; Research Diagnostics, USA).

K.7.3 Evaluation of Glucose Absorption In Vivo

PURPOSE AND RATIONALE

The inhibition of glucose absorption can be determined by measuring blood glucose after administration of starch or disaccharides with and without the inhibitor. In addition, non-absorbed starch or disaccharides can be determined in the intestine.

PROCEDURE

Male Wistar rats are kept on a standard diet with free access to tap water at constant temperature (24 ± 1°C). Sixteen hours prior to the experiment food but not water is withheld. Groups of rats receive by stomach tube 2.5 g/kg raw starch in a water suspension without or with various doses of the α-amylase inhibitor. After 10, 20, 30, 60, 120 and 240 min, blood is withdrawn for determination of blood glucose and non-esterified fatty acids. The animals are sacrificed after these intervals and the residual starch in the stomach and the intestine determined. Definitely more starch is found in the intestine after simultaneous application of the α-amylase inhibitor. Similar experiments are performed in dogs for determination of serum insulin. The increase of blood glucose and serum insulin as well as the decrease of NEFA are inhibited.

EVALUATION

The values of starch content in stomach and intestine, as well as the blood glucose-, serum insulin- and NEFA-values are compared between control and treated animals.

MODIFICATIONS OF THE METHOD

In order to test the inhibition of glucosidase in addition, loading tests with sucrose or other disaccharides are performed (Puls and Keup 1973, Puls et al. 1977, Matsuo et al. 1992). Matsuo and coworkers (1992) performed experiments with genetically or experimentally obese rats (female Zucker fatty rats or female ventromedial hypothalamic nuclei-lesioned rats) and male yellow *KK*-mice. LeMarchand-Brustel and coworkers (1990) studied the effect of an α-glycosidase inhibitor on experimentally induced obesity in mice. Male Swiss albino mice were rendered obese by injection of goldthioglucose at the age of 3 weeks. Since goldthioglucose treatment does not produce obesity in all injected mice, pro-obese mice were selected at 8 weeks of age on the basis of their body weight gain. They were divided in a control group receiving chow without drug and a treated group receiv-

ing chow containing the glycosidase inhibitor. Weight gain, glycemia and insulinemia were followed over 120 days. Madar and Omusky (1991) studied the inhibition of intestinal α-glucosidase activity and postprandial hyperglycemia by α-glucosidase inhibitors in *fa/fa* rats. Various starch sources were used. Blood samples were taken at various intervals after starch load. Takami and coworkers (1991) studied the antidiabetic actions of a disaccharidase inhibitor in spontaneously diabetic (GK) rats. Okada and coworkers (1992) reported anti-obesity and antidiabetic actions of a new potent disaccharidase inhibitor in genetically obese-diabetic mice.
