K.8 Monitoring of Diabetic Late Complications

K.8.1 Aldose Reductase Activity

GENERAL CONSIDERATIONS

Secondary symptoms of long lasting diabetes mellitus are diabetic neuropathy with sensory symptoms, motoric disturbances due to reduced nerve conduction velocity and diabetic cataracts. Both are related to enhanced conversion of glucose to polyols, such as sorbitol, by the enzyme aldose reductase (van Heyningen 1959, Clements 1979). Sorbitol is converted to fructose by sorbitol-dehydrogenase. A low activity of this enzyme enhances the accumulation of sorbitol, thus contributing to cellular damage. Inhibitors of aldose reductase have been developed with positive results in diabetic patients (Kador et al. 1985).

There are even some experimental hints for the benefit of aldose reductase inhibitors in diabetic cardiomyopathy (Cameron et al. 1989). Experimental data provide also evidence for possible beneficial effects in diabetic neuropathy, retinopathy, measured by nerve conduction velocity or electroretinography, lens cataract formation, vascular permeability and filtration (Williamson et al. 1987, Tilton et al. 1988 and 1989, Pugliese et al. 1990) and nephropathy (Sarges and Oates 1993).

Geisen and coworkers (1994) reported on sorbitol-accumulating pyrimidine derivatives which inhibited sorbitol dehydrogenase, induced a dose-dependent increase of tissue sorbitol and accelerated cataract development. Surprisingly, an acceleration of motor nerve conduction velocity in normal and diabetic rats and a normalization of glomerular filtration rates in diabetic rats were found.

K.8.1.1 Measurement with Normal Lenses

PURPOSE AND RATIONALE

The enzyme aldose reductase from bovine lens has been characterized by Hayman and Kinoshita (1965). Using this preparation, the *in vitro* effectiveness of various aldose reductase inhibitors can be determined (Varma and Kinoshita 1976, Billon et al. 1990).

PROCEDURE

Aldose reductase from lenses of calf eyes is isolated from the homogenates by ammonium sulfate precipitation of the concomitant proteins and by column chromatography on DEAE-cellulose. DL-Glyceraldehyde is used as substrate. The activity is expressed as the rate of OD_{340} [nm] due to the utilization of NADPH in the reaction. The reaction mixture contains 0.1 M phosphate buffer (pH 6.2), NADPH 2.5×10^{-4} M, DL-glyceraldehyde 1.5×10^{-3} M and the enzyme. The total volume of the reaction mixture is 1 ml. The reference blank consists of all the above compounds except the substrate. The effects of inhibitors on the enzyme activity are determined by including the compound being tested at the desired concentration in the reaction mixture. Appropriate blanks are used to correct for nonspecific reduction of NADPH and absorption by the compounds being tested. The test compounds are added first in 10^{-3} M solution and diluted as desired.

EVALUATION

Percentage of inhibition is tested at various concentrations and IC_{50}-values are calculated.

K.8.1.2 Measurement with Cataract Lenses

PURPOSE AND RATIONALE

The effect of aldose reductase inhibitors can be tested by determining the level of aldose reductase, NADPH and $NADP^+$ in the lenses of galactose treated or streptozotocin diabetic rats after treatment with the inhibitor compared to controls.

PROCEDURE

Galactose Treatment

Cataract formation can be induced by galactose feeding to young rats. Male Sprague-Dawley rats weighing 40–50 g are randomly divided into 2 groups. One

group is fed a laboratory chow, the other group is fed a galactose diet containing 50% galactose, 20% cornstarch, 15% casein, 9% hydrogenated oil, 4% salt mixture, and 2% cod liver oil. Diabetes is induced in male Sprague-Dawley rats weighing 80–90 g by a single intravenous dose of 100 mg/kg streptozotocin.

Streptozotocin Treatment

Diabetes is induced in 230–260 g male Sprague-Dawley rats by administration of a single tail vein injection of streptozotocin (55 mg kg^{-1}) 2–4 weeks prior to study. Streptozotocin is dissolved in freshly prepared 0.05 M citrate buffer (pH 4.5) and administered under light isoflurane anaesthesia. Animals are glycosuric 24 h after streptozotocin treatment. The weight of the control animals is matched to that of the 2–4 week diabetics. Animals were allowed *ad libitum* access to a standard rat chow (Diet RM1, SDS Ltd, UK) and water until the time of experimentation, with the exception of those subjected to an overnight fast. For all experimental procedures animals are terminally anaesthetized with intraperitoneal pentobarbitone sodium (90 mg kg^{-1}) before removal of eyes. The progression of cataracts is observed in controls and in rats treated with the aldose reductase inhibitor.

Assay

At appropriate times, the rats are sacrificed and the lenses are dissected. They are frozen on solid CO_2 and stored at –70°C until analysis. Single rat lenses are homogenized in 200 µl of 10 mM sodium phosphate buffer containing 5 mM 2-mercaptoethanol (pH 7.0) for 0.5 min at 0°C. A cell-free extract is obtained by centrifuging (17,300 × *g*, 10 min) the total lens homogenate. The enzyme reaction mixture (final volume 1 ml) contains 0.4 M $(NH_4)_2SO_4$, 0.1 M HEPES/NaOH buffer (pH 7.0), 10 mM DL-glyceraldehyde and 0.12 mM NADPH. A 20-ml aliquot of supernatant is added to initiate the reaction. Decrease in absorbance at 340 nm is followed spectrophotometrically. Enzymatic activity is expressed as nM of NADPH oxidized per min.

EVALUATION

Results are expressed as aldose reductase units/mg lens (wet weight). Means ± SE are calculated and compared using Student's non-paired *t*-test.

MODIFICATIONS OF THE METHOD

Naeser and coworkers (1988) studied sorbitol metabolism in the retina, optic nerve, and sural nerve of diabetic rats treated with an aldose reductase inhibitor. Activities of aldose reductase, sorbitol-dehydrogenase, and content of sorbitol were assayed in these tissues.

Freeze-dried tissue samples are sonicated for 5–10 s in 215 µl of 0.04 M Tris (pH 6.8). For determination of aldose reductase, the homogenate is centrifuged for 45 min at 37,000 rpm and 100 µl is taken from the supernatant for analysis. The remaining sample is centrifuged further (96,000 rpm, 2 h) and the supernatant used for sorbitol determination. For determination of aldose reductase, 10 µl of the sample are mixed with 15 µl buffer solution containing 0.14 mM Tris, 151 µM NADH, and 0.6 M glucose. After incubation in a water bath for 20 min at 38°C, the incubation is stopped by transfer to ice. Samples mixed with buffer solution without glucose serve as blanks. Twenty µl of the incubated material are then mixed with 1.25 ml of 0.04 M NaOH solution containing 1.7 mM NaCl. Fluorescence is measured in a Farrand Ratio Fluorometer with primary filters 5860 and 5970 (Corning Glass Works) and secondary filters 2A (Turner Optical Co), 4308 and 3387 (Corning Glass Works). The amount of NADPH consumed serves as measure for aldose reductase activity.

Sorbitol-dehydrogenase is measured by adding 5 µl of fresh homogenate to 20 µl of a buffer composed of 0.1 mM Tris (pH 6.8), 1.25 mM NAD and 50 mM sorbitol. After incubation for 30 min at 38°C, the reaction is stopped by the addition of 5 µl 0.1 N NaOH and transfer to ice. The amount of NAD^+ converted to NADH is determined luminometrically in 10 µl samples with 100 µl of NAD(P)H reagent (Roche Diagnostics) containing 5 mg/L luciferase, 25 mM potassium phosphate, 100 mM dithiothreitol, 38 U/L Triton-X 100, and 20 mM myristic aldehyde. The flux of light is instantly registered, using a photomultiplier.

Sorbitol is determined in the centrifugation supernatant. After immersion in boiling water for 5 min, aliquots of 15 µl are added to 10 µl buffer containing 0.1 M Tris (pH 8.6), 3.5 mM NAD, and 2.7 U/ml sorbitol-dehydrogenase. Tissue blanks are run without sorbitol-dehydrogenase. The incubation is terminated and the amount of NADH formed is determined as for the sorbitol-dehydrogenase assay.

Gonzales and coworkers (1986) studied the effect of an aldose reductase inhibitor on integration of polyol pathway, pentose phosphate pathway and glycolytic route in diabetic rat lens. Diabetes was induced in male Wistar rats weighing about 230 g by subcutaneous injection of 200 mg/kg alloxan monohydrate. After one week, in the diabetic rat lens was an ap-

parent increase in the flux of glucose through the pentose phosphate pathway, as measured by the difference in the yields of $^{14}CO_2$ from [1-^{14}C]glucose and [6-^{14}C]glucose [C1–C6]. Treatment with the aldose reductase inhibitor reduced the values toward normal. With glucose tritiated on carbons 2 or 3, it has been shown that the flux of glucose through the polyol route is increased, whereas the flux through the glycolytic pathway is decreased in the diabetic rat lens. Both parameters were restored to normal in diabetic rats treated with the aldose reductase inhibitor.

Meydani and coworkers (1994) investigated the onset and progression of cataract in weanling Sprague Dawley rats fed 10, 15, 20 and 30% dietary galactose for 45–226 days.

Ohta and coworkers (1999) studied cataract development in 12-months-old rats fed a 25% galactose diet and its relation to osmotic stress and oxidative damage.

Using phosphorus-31 nuclear magnetic resonance spectroscopy, Sakagami and coworkers (1999) investigated the metabolic kinetics of organophosphate compounds in the rat lens during cataract development induced by different doses of galactose added to rat chow.

Mackic and coworkers (1994) developed a model of galactose-induced cataract formation in guinea pigs and studied the morphologic changes and accumulation of galactitol.

Sato and coworkers (1998) demonstrated that the formation and progression sugar cataracts in galactose-fed dogs can be dose-dependently inhibited by the aldose reductase inhibitors.

K.8.2 Nerve Conduction Velocity

PURPOSE AND RATIONALE

Aldose reductase inhibitors can be tested in rats with diabetes induced with streptozotocin by measuring nerve conduction velocity (Miyoshi and Goto 1973, Mayer and Tomlinson 1983, Tomlinson et al. 1882, 1984, Yue et al. 1982) and resistance to ischemic conduction block (Price et al. 1988).

PROCEDURE

Male Wistar rats weighing 100–150 g are rendered diabetic with an i.v. injection of 60 mg/kg streptozotocin. Diabetes is confirmed by the presence of glucosuria and elevated blood glucose levels 24 h after injection. The rats are kept on standard diet and water ad libitum for 28 days after streptozotocin treatment. Groups of rats are treated with the test compound (aldose reductase inhibitor) or the vehicle once daily by gavage starting 24 h after streptozotocin injection. One group of age-matched rats serves as control.

For measurement of sciatic nerve conduction velocity, rats are anesthetized with 2% halothane in oxygen and placed in a Perspex chamber that is maintained at a constant temperature by a copper coil in the base through which warm water is circulated. A fine needle thermocouple is inserted in the lateral aspect of the left hind limb, and the subcutaneous temperature is measured with an electronic thermometer. The conduction velocity of the left sciatic-tibial nerve is measured by a modification of the method of Sharma and Thomas (1974). Two fine platinum stimulating electrodes are inserted in the sciatic notch, and two more are inserted through the skin of the ankle to lie adjacently to the tibial nerve. The electrodes are 5 mm apart, the distal end being the cathode. A recording electrode is inserted under the skin of the lateral side of the foot and another between the third and fourth toes. A ground electrode is inserted under the skin on the dorsum of the foot. Both stimulation and recording are carried out with a neurophysiological unit (e. g., model MS92a, Medelec, Old Woking, UK). The nerve is stimulated supramaximally with square-wave pulses of 0.1 ms duration. The conduction velocity is calculated as the distance between the distal electrodes divided by the difference between the latencies at the two stimulation points. The mean of three recordings

is taken. The coefficient of variation of nerve conduction velocity is calculated by measuring nerve conduction velocity six times in one rat from each treatment group, withdrawing and reinserting the electrodes each time.

To measure resistance to ischemic conduction block, two fine platinum stimulating electrodes (1 cm apart) are inserted in the lateral aspect of the tail 3 cm from the base. Two recording electrodes are inserted near the tip, and a ground electrode is inserted midway between these and the stimulating electrodes. A thermocouple is attached to the middle of the tail. Both stimulation and recording are carried out as described above. To render the tail ischemic, a small sphygmomanometer cuff is inflated to 240 mm Hg around the base of the tail. The nerve is stimulated at 2.5 min intervals until the action potential disappears. The tail temperature is maintained at 32°C. At the end of the experiment, 5 ml blood is taken by cardiac puncture. The animal is then sacrificed, the sciatic nerves are removed, cleaned, weighed, snap-frozen in liquid nitrogen and stored at –20°C for subsequent estimation of polyol level.

Nerve polyol estimation is performed by the method of Stribling and coworkers (1985). Frozen nerves are thawed, placed in 1 ml water containing 60 µg of α-methylmannoside as an internal standard, and boiled for 20 min. Zinc sulfate (200 µl of a 5% solution) is added, samples are homogenized with a Polytron homogenizer, 200 µl 0.3 N barium hydroxide solution is added, and the samples rehomogenized. After centrifugation, the supernatant is freeze-dried overnight. The residue is silylated with 250 ml of a mixture of pyridine/hexamethyldisilazane/ trimethylchlorosilane (10/2/1, Pierce) at room temperature for 24 h. The reaction is stopped by adding 2 ml water, and 200 µl cyclohexane is added. Samples are shaken and 2 µl of the organic phase is injected into a gas chromatograph. Plasma glucose levels are measured with the use of a glucose analyzer. Plasma fructosamine, which reflects plasma protein glycosylation, is measured with the use of a commercial kit. Plasma glucose, plasma fructosamine and nerve sorbitol are increased and nerve conduction velocity decreased in streptozotocin treated rats.

EVALUATION

Data from diabetic rats treated with the aldose-reductase inhibitor are compared with the values of untreated diabetic rats and normal controls. Statistical comparisons are made by use of the Mann-Whitney *U* test.

MODIFICATIONS OF THE METHOD

Sima and coworkers (1990) studied motor nerve conduction velocity and neuroanatomical abnormalities in insulin-deficient diabetic Bio-Breeding rats (BB-rat) with and without long-term administration of an aldose reductase inhibitor. Their findings of a significant, but incomplete prevention of neuropathy in these animals by aldose reductase inhibition suggest that additional mechanisms besides polyol-pathway activation may be of importance in the pathogenesis of diabetic neuropathy. Carrington and coworkers (1991) studied effects on impulse conduction after aldose reductase inhibition with imirestat in sciatic nerves of streptozotocin-diabetic rats both *in vivo* and *in vitro*. Cameron and coworkers (1991) studied nerve blood flow monitored by microelectrode polarography and hydrogen clearance in experimental diabetes in rats in relation to conduction deficits. Using these methods, Cameron and Cotter (2003) studied the effects of 5-hydroxytryptamine 5-HT_2 receptor antagonists on nerve conduction velocity and endoneurial perfusion in diabetic rats.

Schmidt and coworkers (1991) performed ultrastructural studies in mesenteric nerves of streptozotocin-induced diabetic rats.

K.8.3 Nerve Blood Flow (Doppler Flux)

PURPOSE AND RATIONALE

In addition to nerve conduction studies, Calcutt and coworkers (1994) described a method to measure nerve blood flow by laser Doppler flowmetry in rats with streptozotocin induced diabetes treated with aldose reductase inhibitors.

PROCEDURE

Diabetes is induced in female Sprague-Dawley rats weighing 200–280 g by a single i.p. injection of 50 mg/kg streptozotocin after an overnight fast and is confirmed 2 days later by blood glucose determinations. Aldose-reductase inhibitor treated rats receive the test compound orally by gavage once a day for 2 months. For the experiment, the animals are anesthetized with an intraperitoneal injection (2 ml/kg) consisting of pentobarbital (12.5 mg/ml) and diazepam (1.25 mg/ml) in 0.9% NaCl. For estimation of nerve blood flow, a laser Doppler flowmeter (TSI model BPM 403A, MN) with a wavelength of 780 nm is used. Flow determinations are made with a filter frequency of 30 Hz to 18 kHz and, depending on the magnitude of the reflected signal, one of four band widths (30 Hz to 1.3 kHz, 30 Hz to 3 kHz, 30 Hz to 7.5 kHz, or 30 Hz to 18 kHz). The flow meter continuously displays a moving average for the preceding 5 s in units of $\text{Hz} \times 10^2$. For flow measurements, the sciatic nerve is exposed and the probe tip of the flow-meter placed 1 mm above the mid-thigh region of the nerve using a micromanipulator. After a 10 s stabilization period, the first measurement is recorded. The probe is then advanced 1 mm distally for a second measurement and this process repeated until 10 readings are recorded over 1 cm of nerve. The mean of 10 values is taken as average nerve laser Doppler flow. Blood flow velocity, expressed in m/s, is reduced in diabetic rats.

EVALUATION

The effects of streptozotocin diabetes and of aldose reductase treatment are assessed by one factor analysis of variance (ANOVA). Individual post-hoc comparisons are made with the Newman-Keuls method when the F ratio is $P < 0.05$.

K.8.4 Electroretinogram

PURPOSE AND RATIONALE

Diabetic neuropathy is one of the important symptoms of long-lasting diabetes (Engerman 1989). Several animal studies with aldose reductase inhibitors have been performed (Lightman et al. 1987, Hotta et al. 1988, Nagata and Robison 1988). Segawa and coworkers (1988) measured the development of electroretinogram abnormalities and the possible role of polyol pathway activity in diabetic hyperglycemia and galactosemia in the rat.

PROCEDURE

Male Sprague-Dawley rats weighing 310–400 g are dark-adapted for 20 min and anesthetized with i.p injections of ketamine, 50–80 mg/kg and atropine sulfate, 2 mg/kg. Electroretinography is performed monocularly with the pupil maximally dilated. Photic stimulation is delivered with an intensity of one J in 20 s interstimulus intervals. Using a contact lens-type electrode, electroretinograms (ERG) evoked by strong flushes are amplified by a preamplifier, displayed on an oscilloscope and summed using a signal averager which also provides a copy of the averaged ERG. The amplitudes of the a- and b-waves are measured from the base line to the trough of the a-wave and from the trough of the a-wave to the crest of the b-wave, respectively. The amplitudes of the oscillatory potentials are measured. The peak latencies are measured as the intervals between the stimulus onset and the peak of the corresponding a- and b-waves and oscillatory potentials. The oscillatory potentials (designated O_1, O_2, and O_3 in order of appearance on the ascending limb of the b-wave) are added together. The sum of these amplitudes is expressed as the wavelet index.

For inducing galactosemia, male Sprague-Dawley rats weighing 140–185 g at the beginning of the study, receive a diet of 30% galactose. Test compounds are given as 0.1% to the diet.

EVALUATION

Data are calculated as mean ± SEM and significance levels are estimated using the Wilcoxon rank sum test for unpaired data (two-sided). Linear regression is calculated by the least square method. A p-value of < 0.05 is regarded as statistically significant.

MODIFICATIONS OF THE METHOD

De la Cruz et al. (2003) studied the effects of clopidogrel and ticlopidine on experimental ischemic retinopathy in streptozotocin-diabetic rats. The percentage of the retinal surface occupied by horseradish peroxidase-permeable vessels was recorded.

K.8.5 Streptozotocin-Induced Cataract

PURPOSE AND RATIONALE

The increased incidence of cataracts, i. e. changes in the transparency or of the refractory index of the lens, in diabetic patients is well known. Evidence has accumulated for the involvement of polyol metabolism and the enzyme aldose reductase in diabetic cataractogenesis (van Heyningen 1959, Pirie and van Heyningen 1964). The enzyme aldose reductase catalyzes the reduction of aldoses such as glucose and galactose to the corresponding polyols, i. e., sorbitol and dulcitol. Sugar-induced cataractogenesis has been shown to parallel lenticular polyol accumulation (Kinoshita 1965). Since polyols do not readily diffuse through intact cellular membranes, they create a severe osmotic stress within the lenticular cells which leads to cellular swelling and loss of integrity of the cellular membrane (Kinoshita 1974). Aldose reductase inhibitors have been shown to prevent sugar induced cataracts (Dvornik et al. 1973, Varma and Kinoshita 1976, Kinoshita et al. 1979, Muller et al. 1985).

PROCEDURE

Experimental diabetes is induced in Wistar rats weighing 150–180 g by intravenous injection of 50 mg/kg streptozotocin (Griffin et al. 1984).

EVALUATION

The values of animals treated with the aldose reductase inhibitor are compared with the values of rats treated with streptozotocin only.

MODIFICATION OF THE METHOD

Instead of systemic application, the aldose reductase inhibitor is applied twice daily for 6 weeks in solution as eye drops to female Sprague-Dawley rats with a starting weight of 120–140 g after diabetes induction with 70 m/kg streptozotocin i.v. Body weight and blood sugar are registered twice a week. The progression of cataractous changes is followed by slit-lamp and Scheimpflug photography analysis every second week. At the end of the experiment, the animals are sacrificed and the lenses analyzed for their content of ATP, ADP, AMP, glucose, sorbitol, fructose, glucose-6-phosphate, and fructose-6-phosphate.

K.8.6 Naphthalene-Induced Cataract

PURPOSE AND RATIONALE

Systemic application of naphthalene induces cataract in Brown-Norway rats. Aldose reductase inhibitors are tested for prevention of the cataract changes by parallel systemic or topical application (as eye drops).

PROCEDURE

Female Brown-Norway rats at an age of 6–7 weeks with a starting weight of 70–100 g are used. They are fed standard lab chow and receive water ad libitum. Naphthalene is dissolved in warm paraffin oil (10 g/100 ml) and is administered orally by gavage every second day in a dose of 1 g/kg. The test compound is administered orally every day or applied topically as suspension every day once, twice or four times to the right eye. The duration of the treatment is 6 weeks. Slit lamp microscopy (Zeiss photo slit lamp) during mydriasis with 1% atropine eye drops is performed in weekly intervals, including a baseline examination before the start of the treatment and a final examination prior to sacrifice. Scheimpflug photography of the anterior eye segment (Topcon SL-45 Scheimpflug camera) is carried out at the baseline examination, after 3 weeks of treatment and at the end of the experiment. Prior to sacrifice blood samples are taken by cardiac puncture under ether anesthesia. After sacrifice, lens fresh weight, concentration of oxidized and reduced glutathione, and the concentration of the aldose reductase inhibitor in the lenses and in blood samples are determined.

EVALUATION

The values of animals treated with the aldose reductase inhibitor are compared with the values of rats treated with naphthalene only.

MODIFICATIONS OF THE METHOD

Rathbun and coworkers (1996a) induced rapid-onset cataracts in SPF C57 bl/6 mice by i.p. administration of naphthalene following cytochrome P-450 induction with phenobarbital. Rathbun and coworkers (1996b) assessed the activity of a L-cysteine prodrug suitable for glutathione biosynthesis rat lenses *in vitro* and as an agent for the prevention of acetaminophen- and naphthalene-induced murine cataract in genetically susceptible mice. Holmen and coworkers (1999) compared different methods of photographic evaluation of cataract formation in rats in response to different regimes of naphthalene treatment.

K.8.7 Determination of Advanced Glycation End Products (AGE)

GENERAL CONSIDERATIONS

Common to both type I and type II diabetes is the development of inflammatory and vascular complications that, over time, might portend significant morbidity and early mortality in affected subjects. Although multiple studies have suggested a direct role for adverse effects of glucose itself in modulating cellular properties, both in the extra- and intracellular milieu (Greene et al. 1987, Inoguchi et al. 1994, Xia et al. 1994, Nishikawa et al. 2000), recent observations suggest an emerging role for the products of non-enzymatic glycoxidation of proteins and/or lipids, the advanced glycation endproducts (AGE), in the pathogenesis of diabetic complications.

Formation of AGE

The non-enzymatic glycation and oxidation of proteins and/or lipids is a well-recognized phenomenon that occurs naturally, albeit at a very slow rate, during the course of aging. However, certain conditions within the cellular environment might enhance the formation of these modified structures. Specifically in the context of diabetes, hyperglycemia is a major trigger for the accelerated formation and deposition of

AGEs (Brownlee 1995, Ruderman et al. 1992). Multiple specific AGE, formed by glycation and/or oxidation, such as carboxy(methyl)lysine (CML), pentosidine and pyralline, have been identified in diabetic tissues (Ikeda et al. 1996, Reddy et al. 1995). It is speculated that, in diabetes, hyperglycemia alone might not be the sole perturbant driving formation of these modified structures, as AGE formation is enhanced in pro-oxidant states, such as that observed in diabetes itself (Baynes 1991). The observation that products of glycoxidation have been noted in hyperlipidemic atherosclerotic lesions, even in euglycemia, supports this concept. A recent suggestion is that *in vitro* AGE formation might be driven by the myeloperoxidase–hydrogen peroxide–chloride system, thereby providing a mechanism for conversion of hydroxy-amino-acids into glycolaldehyde, a precursor in the steps leading to formation of CML. Thus, these findings could have implications for AGEs in inflammatory settings, once confirmation *in vivo* has been established. It is important to note that, in diverse conditions, such as renal failure and Alzheimer's disease, AGE epitopes have also been identified within affected structures (Miyata et al. 1996), thereby providing a contributory mechanism for the cellular stress observed in these settings.

AGE and Mechanisms of Cellular Perturbation

It is likely that AGEs exert their effects *via* a number of mechanisms. Accumulation of cross-linking AGEs that tend to become insoluble, such as pentosidine, are thought to contribute to the tissue perturbation and rigidity that typify advanced diabetes, especially in the skin and basement membranes (Sell et al. 1992, Beiswenger et al. 1993). These factors are potentially linked to vascular leakiness and hyperpermeability. Vlassara and coworkers (1995) identified galectin-2 as a high-affinity binding protein for AGE. In addition, work from M. Brownlee's laboratory suggests that intracellular formation of AGE might modify the activity of growth factors, such as basic fibroblast growth factor.

Beyond the direct effects of AGEs on modulating cellular structure and function are those effects postulated to occur during ligation of specific cell surface receptors. In this context, the best-characterized receptor for AGEs (RAGE) is a multi-ligand member of the immunoglobulin (Ig) superfamily of cell surface molecules (Schmidt et al. 1992, Neeper et al. 1992). RAGE is composed of an extracellular region containing one 'V'-type Ig domain, followed by two 'C'-type Ig domains. This portion of the molecule confers the ligand-binding properties, which are probably specific to the 'V'-domain. This portion of the molecule is followed by a hydrophobic transmembrane-spanning domain and, lastly, by a highly charged, short cytosolic domain that is essential for RAGE-mediated cellular effects upon engagement of ligand (Kislinger et al. 1999a, b; Yamamoto et al. 2001; Arancio et al. 2004; Hadding et al. 2004).

PURPOSE AND RATIONALE

Interactions between AGE and their binding proteins lead to the activation of a range of secondary messenger systems and increases the production of cytokines, including TGF-β, PDGF, and IL-1 (Ikeda et al. 1996). Recently, compounds that can cleave established AGE cross-links (Reddy et al. 1995), such as ALT711, a stable 4,5-dimethylthiazolium derivative of the prototype compound *N*-phenyl-thiazolium bromide, have been investigated. *In vivo* efficacy has been demonstrated in animal models, showing that these compounds can result in reduced AGE accumulation and can reverse age- and diabetes-dependent increases in arterial stiffness (Baynes 1991). RAGE as target for the prevention and treatment of the vascular and inflammatory complications of diabetes has been critically reviewed by Schmidt and Stern (2000a, b). The following assays enable the study of the AGE-RAGE interaction including its cellular effects as well as the modulation of both processes by compounds/drug candidates, which may be helpful for future therapy of diabetic late complications.

PROCEDURE

Cell Culture

The well-characterized normal rat kidney epithelial cell line (NRK-52E) can be obtained from the American Tissue Culture Collection. NRK-52E cells are believed to be of a proximal tubular origin on the basis of patterns of collagen secretion, C-type natriuretic peptide secretion, and the presence of EGF receptors. Cells are maintained in DMEM containing 4.5 g/l glucose with 10% FCS at 37°C in a 5% CO_2 atmosphere and passaged twice a week.

In Vitro Preparation of AGE Ligands

Procedures for the preparation of AGE ligands have been given by Oldfield and coworkers (2001) and Kislinger and coworkers (1999a and b). For preparation of AGE-BSA and AGE-RNase, BSA (10 mg/ml) or RNase (10 mg/ml) is incubated at 37°C for 6 weeks with D-glucose (90 g/l) in a 0.4-M phosphate buffer

containing azide (Vlassara et al. 1985). Control preparations are treated identically except that glucose is omitted. Preparations are extensively dialyzed against phosphate buffer to remove free glucose. The extent of advanced glycation is assessed by characteristic fluorescence (excitation 370, emission 440 nm). Advanced glycation is associated with an approximately 10-fold increase in fluorescence compared with controls.

For preparation of human AGE-IgG, human IgG (5 mg/ml in PBS) is subjected to non-enzymatic glycation by incubation in PBS containing 25 mM D-ribose. The solution is sterile-filtered (0.2 µm) and then incubated at 37°C for 6 weeks under aerobic conditions. At the end of that time, the mixture is extensively dialyzed *versus* PBS at 4°C to remove unreacted ribose. This material is then chromatographed onto resin containing Affi-Gel 10 (Bio-Rad) to which had previously been adsorbed to recombinant human soluble RAGE. After incubation, the resin is washed extensively with 10-column volumes of TBS (20 mM Tris, pH 7.4, 100 mM NaCl). Bound components are eluted by 20 mM glycine (pH 2.5). The absorbance at 280 nm of each fraction is determined. Positive fractions are immediately neutralized and dialyzed *versus* TBS.

For preparation of carboxymethyl lysine–modified BSA (CML-BSA) (Kislinger et al. 1999a, b), 50 mg/ml aliquots of BSA are incubated with increasing concentrations of glyoxylic acid (5–90 mM) in the presence of approximately 5-fold molar excess of sodium cyanoborohydride. Control proteins are prepared under the same conditions, except that glyoxylic acid was omitted. The extent of chemical modification of lysine residues is determined as described previously using 2,4,6-trinitrobenzenesulfonic acid (Cayot and Tainturier 1997). The extent of lysine modification was up to 34% for CML-BSA preparations.

Iodination of AGE-BSA

AGE-BSA was iodinated by incubating AGE-BSA with chloramine-T (Greenwood et al. 1963). Bound ^{125}I was separated from free ^{125}I using a Biogel P6DG desalting gel (Bio-Rad Laboratories Inc.). Specific activity of the tracer is typically 400 Ci/mM.

Membrane Preparation

Membranes are prepared based on the method of Skolnik and coworkers (1991). NRK-52E cells are grown to confluence in 150-cm^2 tissue-culture flasks. Cells are washed twice with PBS, then detached from plates using a HEPES (100 mM) solution containing BSA (0.1%) and Triton X-100 (0.1%) with EDTA (5 mM), leupeptin (1 µM), and PMSF (2 mM). Cells are centrifuged (2,000 × *g*, 5 min) and resuspended in the above buffer before disruption by ultrasound. Cell debris is removed by further centrifugation (2,000 × *g*, 10 min) and the supernatant centrifuged (100,000 × *g*, 1 h, 4°C). The supernatant is discarded, and the cell membranes in the precipitate are resolubilized in the above buffer. Protein concentrations are determined by the method of Bradford. The membrane preparation is used in binding studies and for ligand and Western blot analysis.

Binding Assay with Radiolabeled AGE

For binding studies according to the procedure of Oldfield and coworkers (2001), cell membrane extracts are incubated with ^{125}I-AGE-BSA (0.5 nM) and increasing concentrations of unlabeled AGE-BSA (0.015–7.46 µmol) in the absence or presence of compounds/drug candidates for 3 h at 4°C in HEPES (100 mM) binding buffer with BSA (0.1%), Triton X-100 (0.1%), leupeptin (1 µM), and PMSF (2 mM). A Brandel cell filter (Biomedical Research and Development Laboratories) is used to separate bound and free radioligand. A Tris-HCl (10 mM) polyethylene glycol (6.6%) buffer is used to wash components through the apparatus onto glass filter papers, which are counted in a γ-counter for 1 min. Binding experiments are performed in duplicate in five separate experiments, and the specificity of binding is assessed in further experiments using unlabeled, unmodified BSA (1 µmol) as the competitor. Binding data were analyzed using a specific binding program (LIGAND).

Binding Assay with Radiolabeled RAGE

Human soluble recombinant RAGE (sRAGE) prepared as described above is radiolabeled with ^{125}I by incubation with IODO-BEADS (Pierce) to a specific activity of ~4,000–5,000 cpm/ng protein. In all cases, after radioiodination, precipitation of the radiolabeled material in TCA exceeded 90%. CML modifications of proteins or native, unmodified proteins are loaded onto the wells of plastic dishes (5 ng/well) in bicarbonate/carbonate buffer (pH 9.6) and incubated for 16 h at 4°C. Material in the wells is aspirated, and unoccupied sites are blocked by incubation with PBS containing 1% BSA for 2 h at 37°C. Wells are washed twice with PBS containing 0.005% octyl β-glucoside. Radioligand binding assay is performed in PBS containing 0.2% BSA with increasing concentrations of ^{125}I-human sRAGE alone or in the presence of a 50-fold molar excess of unlabeled human sRAGE or compounds/drug candidates for 2 h at 37°C. At the end of that time, wells are washed rapidly five times with

washing buffer. Elution of bound material is performed in a solution containing 1 mg/ml heparin. Solution is aspirated from the wells and counted in a γ-counter.

EVALUATION

Equilibrium binding data are analyzed according to the equation of Klotz and Hunston (1984): $B = nKA/1 + KA$, where B indicates specifically bound ligand (total binding, wells incubated with tracer alone, minus nonspecific binding, wells incubated with tracer in the presence of excess unlabeled material), n indicates sites/cell, K indicates the dissociation constant, and A indicates free ligand concentration) using non-linear least squares analysis. Specific binding of CML-BSA to radiolabeled RAGE is further determined by subtraction of nonspecific binding (counts obtained upon binding of radiolabeled sRAGE to immobilized BSA) from that obtained upon binding of radiolabeled sRAGE to immobilized CML-BSA. In case of binding to immobilized BSA, counts are negligible and less than 10% that observed in the presence of CML-BSA. Pretreatment with either antibodies, soluble RAGE, or the potential competitors and competitors/drug candidates is performed for 2 h prior to binding assay. Sometimes, it may be helpful to use materials eluted from the RAGE-Affi-Gel 10 columns (after passage of AGE-IgG) isolated RAGE domains for testing as unlabeled competitor in the binding assay. For this, human RAGE cDNA encoding the V, C1, or C2 domain is inserted into the *Eco*RI site of pGEX4T vector containing GST. Fusion proteins, V-GST, C1-GST, and C2-GST, are expressed in *E. coli*, purified on a glutathione-Sepharose column, and cleaved with thrombin (Amersham Pharmacia). RAGE domains are then purified to homogeneity using glutathione-Sepharose and characterized by SDS-PAGE and amino-terminal sequencing prior to testing in the radioligand binding assay.

Ligand and Immunoblotting Analysis

Cell membrane extracts (20 µg of membrane protein per lane) are subjected to non-reducing SDS (12–15%) PAGE and electroblotted onto nitrocellulose membranes (Hybond, Amersham Pharmacia). For ligand blotting the membranes are blocked overnight at 4°C in 10 mM Tris (pH 7.4), 150 mM NaCl, 0.1% Tween buffer containing 2.5% BSA, before incubation with ^{125}I-AGE-BSA (110 ng/ml) for 2 h at room temperature. After washing with 10 mM Tris (pH 7.4), 150 mM NaCl, and 0.1% Tween, the membrane is exposed to Kodak Biomax MS film for 1–4 h. Receptor-ligand binding specificity is studied in competitive experiments where unlabeled AGE-BSA, AGE-RNase, BSA, and RNase (all 100 µg/ml) are added as competing ligands.

In immunoblotting experiments, the nitrocellulose membrane is incubated at room temperature for 1 h with a polyclonal goat Ab against human RAGE 1:2,000 (Soulis et al. 1997, Brett et al. 1993). Membranes are washed before a 15-min incubation with a biotinylated secondary antibody and a streptavidin-horseradish peroxidase conjugate. Immunoreactivity is detected using an enhanced chemiluminescence kit (Amersham Pharmacia Biotech). Primary antibodies are omitted in experiments as negative controls and RAGE antibody specificity is confirmed by preincubation of the membrane with recombinant RAGE before the addition of RAGE antibody.

Isolation of Human Serum Albumin and Immunoblotting for AGE

Plasma samples are obtained from human donors with diabetes, renal failure, or age-matched healthy controls in accordance with the laws of the respective national ethics committees. Samples (2 ml) are dialyzed for 16 h at 4°C in 20 mM phosphate buffer (pH 7.1) in a total volume of 4 ml. After dialysis, samples are subjected to filtration (0.8 µm), and then chromatographed onto columns containing Affi-Gel blue resin (Bio-Rad) previously equilibrated in 20 mM phosphate buffer (pH 7.1). 5 ml of resin are employed per ml of plasma. The resin is washed in 2.5 column volumes of phosphate buffer as above, and human serum albumin is eluted by application of phosphate buffer containing 1.4 M NaCl. The absorbance at 280 nm for each fraction is determined, and positive fractions are determined by SDS-PAGE followed by staining with silver. For immunoblotting, the materials (30 µg of protein, each) are employed to SDS-PAGE gels (8%). Simultaneously, marker proteins are added. After electrophoretic separation and transfer of the proteins to nitrocellulose membranes, the unoccupied sites on the membranes are blocked in the presence of non-fat dry milk (13.5%) in TBS for 4 h at room temperature. Immunoblotting is performed using affinity-purified anti-CML IgG as above (10–20 µg/ml) in milk buffer (5%) for 1.5 h at 37°C. Membranes are washed extensively in TBS containing 0.1% Tween 20 . The membranes are incubated with goat anti-rabbit IgG labeled with horseradish peroxidase for 1 h at 37°C, washed extensively in the above buffer. Visualization of antibody binding was performed employing the ECL detection system (Amersham Pharmacia). Quantitative evalua-

tion of band intensity is performed using Molecular Dynamics/ImageQuant.

K.8.8 Measurement of Reactive Oxygen Species (ROS) Production

GENERAL CONSIDERATIONS

All forms of diabetes, both inherited and aquired, are typified by hyperglycemia, a relative or absolute lack of insulin, and the development of diabetes-specific microvascular pathology in the retina (retinopathy), renal glomerulus (nephropathy) and peripheral nerve (neuropathy). At the molecular cell biology level, three major hypotheses regarding the mechanisms by which hyperglycemia causes diabetic complications, i. e. the aldose reductase pathway (see above), formation of AGE (see above) and activation of PKC, have each generated a great deal of supporting data (Brownlee 1995, Koya and King 1998, Schmidt and Stern 2000b). Seminal work from Michael Brownlee's laboratory has shed new light on the mechanisms by which elevated concentrations of glucose perturb cellular properties in a fundamental way, thereby joining these three pathways into a unifying hypothesis for hyperglycemia-induced late complications (Nishikawa et al. 2000). In endothelial cells subjected to physiologically relevant glucose concentrations as a model system, the non-insulin-dependent uptake of glucose *via* GLUT1 leads to oxidative stress (OS) with concomitant generation of reactive oxygen species (ROS), the increase of both is positively correlated to the glucose concentration. Several pathways are considered as likely candidates for the emergence of OS and the formation of oxygen free radicals in cells, including the accelerated flux of glucose through glycolysis and feeding of pyruvate, thus formed, to the tricarboxylic acid cycle, which overloads mitochondria and thereby causes excessive generation of ROS. In turn, OS and ROS has recently been shown to cause upregulation of the mitochondrial uncoupling protein 2 (UCP-2), leading to a vicious cycle of increased electron flux *via* the respiratory chain and concomitant elevated production of ROS. Most importantly, it has been demonstrated recently, that suppression of intracellular ROS, using low molecular weight inhibitors or by expression of the anti-oxidant enzyme, manganese-dependent superoxide dismutase (MnSOD), prevents each of the three molecular mechanisms mentioned above (Nishikawa et al. 2000). Consequently, glucose-induced formation of oxidants is a proximal step in cellular perturbation prelevant during diabetes. Thus, assays which monitor the generation of OS and ROS in response to compounds/drug candidates may be helpful for the finding and characterization of future anti-diabetic drugs, which may reduce the risk for the development of diabetic late complications.

PURPOSE AND RATIONALE

Although there are various methods to assess oxidative damage of cells, such as measuring lipid peroxidation products and DNA adducts (Holley and Cheeseman 1993), none of them evaluate the OS directly. With the first description of using 2′,7′-dichlorofluorescin diacetate (DCFH-DA) as a fluorometric assay for hydrogen peroxide (Keston and Brandt 1965), it became popular to use dichlorofluorescin (DCFH) as a probe to evaluate intracellular hydrogen peroxide formation by flow cytometry. The theory behind using DCFH-DA is that nonfluorescent fluorescin derivatives will emit fluorescence after being oxidized by hydrogen peroxide (LeBel et al. 1992). The emitted fluorescence is directly proportional to the concentration of hydrogen peroxide. When applied to intact cells, the nonionic, nonpolar DCFH-DA crosses cell membranes and is hydrolyzed enzymatically by intracellular esterases to nonfluorescent DCFH (LeBel et al. 1992, Bass et al. 1982). In the presence of reactive oxygen species (ROS), DCFH is oxidized to highly fluorescent dichlorofluorescein (DCF) (LeBel et al. 1992). Therefore, the intracellular DCF fluorescence can be used as an index to quantify the overall OS in cells.

Many studies have used fluorescent microscopy to quantify OS in cells using DCFH-DA. This method has the problem of inducing photooxidation of DCFH to DCF intracellularly and emitting fluorescence, because it is difficult to control the time of light exposure when trying to locate and focus cells under the microscope. In addition to the problem of photooxidation, there is no standard way to quantify the OS using a microscope. In order to prevent the overestimation of the OS due to photooxidation, an instrument equipped with fast light excitation and fast fluorescence capturing, which will not induce excessive photooxidation, is needed. Wang and Joseph (1999) have introduced a fluorescent microplate reader-based method to evaluate OS in cultured cells, induced by applying various free radical generators extracellularly, using DCFH as the probe.

PROCEDURE

Measurement of OS

Cells (e. g. PC12) are grown in growth medium containing 85% RPMI-1640 with *l*-glutamine, 10% heat-

inactivated horse serum, 5% FBS, 100 U/ml penicillin G sodium, and 100 µg/ml streptomycin sulfate. The cells are maintained in collagen-coated plates in 5% CO_2/95% air at 37°C. The culture medium is changed twice every week and the cells are split 1:4 or 1:8 every week. Cells were split and counted by trypan blue exclusion. Viable cells (10^4/well) are plated into 96-well collagen-coated plates one day before the experiments. On the day of the experiments, after removing the medium, the cells in the plates are washed with KRH buffer and then incubated with 100 µM 6-carboxy-2′,7′-dichlorofluorescin diacetate (DCFH-DA; Molecular Probes Inc. USA) in the loading medium in 5% CO_2/95% air at 37°C for 30 min. For loading the cells with DCFH, DCFH-DA from a 10-mM stock solution in DMSO is mixed with loading medium (99% RPMI-1640 and 1% FBS) to a final concentration of 100 µM. After DCFH-DA is removed, the cells are washed and incubated with KRH buffer (with different concentrations of one of the free radical generators, e. g. H_2O_2, dopamine) in the absence of presence of high glucose concentration. The fluorescence of the cells from each well is measured and recorded.

For OS measurement, DCFH-DA-loaded cells are placed in a CytoFluor Series 4000 multiwell fluorescence plate reader with temperature maintained at 37°C. The excitation filter is set at 485 nm and the emission filter is set at 530 nm. The fluorescence from each well is captured, digitized, and stored on a computer using Cytofluor (Version 4.0) (PerSeptive Biosystems Inc. USA). Data points are taken every 5 min for 30 min and the data are exported to Excel (Microsoft, USA) spreadsheet software for analysis.

Measurement of ROS

For measurement of ROS production according to the procedure of Freeman and coworkers (2006), a 10-mM stock solution of H_2DCFDA-SE (2′,7′-dichlorofluorescein diacetate with a succinimidyl ester group, DCF, Molecular Probes) is prepared in DMSO, stored at −70°C, and diluted with KRB (pH 7.0) just before use to a final concentration of 10 µM. The cells are plated in 24-well cell culture plates overnight. They are then washed twice with PBS, incubated in PBS *plus* DCF for 30 min at 37°C, washed with PBS, and incubated in KRB containing 5.5 or 20 mM glucose for a further 30 min. They are imaged at room temperature using an IonOptix fluorescence system, with 495 nm excitation and 520 nm emission. The background fluorescence is subtracted. 0.5 mM menadione is used as a generator of ROS as a control. The Ros concentrations are determined from a standard curve of H_2O_2 (5–50 µM). To confrom that glucose generates ROS, dihydroethidium (DHE) conversion to ethidium by oxidation can be measured according the procedure of Russell and coworkers (2002). The ratio of DHE:ethidium is determined using a fluorimeter and standarized against cellular protein. DHE is measured using 355 nm excitation and 430 nm emission, and ethidium is measured using 518 nm excitation and 605 nm emission.

Measurement of Mitochondrial ROS Production

To evaluate the direct production of mitochondrial ROS in cells, the DCFDA measurements have to be combined with ROS-specific staining by using the reduced Mito Tracker Red probe (CM-H_2Xros; Molecular Probes Inc. USA) according to the procedure described by Degli Esposti and coworkers (1999). For this, the cells suspended in growth medium at 1×10^6/ml are incubated for 15 min at room temperature with freshly prepared CM-H_2XRos (0.5 µM), then washed twice with PBS, and collected on a slide using a Cytospin apparatus (Wolvetang et al. 1994). The cells are fixed with 3.7% formaldehyde in PBS, followed by washing first with PBS containing 30 mM NH_4Cl and then with distilled water. In some experiments, the fixed cells are counterstained with Hoechst 33342 before mounting with anti-fade medium, and the slides are stored at 4°C in the dark. In parallel experiments, mitochondrial staining to analyze membrane potential can be performed using 100 nM oxidized Mito Tracker Red (CM-XRos) following the same protocol as outlined above for CM-H_2XRos. Confocal microscopy is undertaken with a Krypton/Argon instrument, usually with a 40 × oil objective and intermediate laser and photomultiplier voltage. The 590-nm bandpass filter is used to detect the red fluorescence of CM-XRos staining (Wolter et al. 1997). Epifluorescence is evaluated with a microscope using a Texas Red filter and a CCD camera attached to a microcomputer image analyzer.

EVALUATION

The percentage increase in fluorescence per well is calculated by the formula $[(Ft_{30}\text{-}Ft_0)/Ft_0 * 100]$, where Ft_{30} = fluorescence at time 30 min and Ft_0 = fluorescence at time 0 min. This method of analysis has advantages over analyzing just the net change in fluorescence in that, not only did the calculated data directly reflect the percentage changes of fluorescence over time from the cells in the same well, they also effectively control for variability among wells. This method also cancels out the background

fluorescence in each well, and therefore, a "no cell" control is not needed.

Various free radical generators produce concentration-dependent changes in DCF fluorescence, indicating the indiscriminate nature of DCF. Due to the indiscriminate nature of DCFH, which can be oxidized by various ROS and not just H_2O_2, the increase of intracellular DCF fluorescence does not necessarily reflect the levels of ROS directly, but rather an overall OS index in cells. Quantifying cellular OS by the DCF assay using a fluorescent microplate reader is an easy and efficient method with low variability which can be used to quantify the potency of pro-oxidants or can be adapted to evaluate the efficacy of antioxidants against ROS in various cell lines. The use of a 96-well microplate reader enables the generation of a large amount of data with low variability.

Measurement of Mitochondrial Size

Since glucose-induced ROS production and swelling of mitochondria seem to be correlated (Russell et al. 2002), determination of alterations in the size of mitochondria exposed to OS may be indicative for the generation of mitochondrial ROS. For measurement of the mitochondrial size, cells are loaded with Mitotracker orange (CMTMRos; Molecular Probes Inc. USA) using confocal microscopy with 540 nm excitation. Each mitochondrion is a complex fractal-like network, making accurate analysis of volume difficult. Therefore, the maximum cross-sectional area is determined from identification of each individual mitochondrion throughout the z-series. All distinguishable mitochondria at each step level in the z-series are measured at the largest cross-sectional area of the mitochondrion. The size of the mitochondria is determined using the perimeter of visible CMTMRos and reflects the mitochondrial area at the measured level. Identical methods of identification and measurement are applied to each mitochondrion in each cell and in each condition, thus reducing the effect of technical artifact. The mitochondrial areas are then averaged for each neuron and, where necessary, results are first converted to a log normal distribution before obtaining descriptive statistics or performing tests of inference about the data set. Results are obtained for > 100 mitochondria in at least 10 randomly measured neurons per condition.

K.9 Insulin Analogs: Assessment of Insulin Mitogenicity and IGF-I Activity[2]

K.9.1 Introduction and Application to Insulin Analogs

The metabolic activity of insulin has been studied extensively in-vitro and in-vivo, based on the initial assessment of insulin receptor affinity, followed by methods to estimate the metabolic activity in vitro. These estimates provides some guidance about the biological activity which will be found in-vivo, they need to be confirmed and supplemented by testing the glucose lowering activity in animals (mice, rats, dogs, pigs). The biological effects (hypoglycemic activity) are related to the direct activation of the insulin receptor and subsequent signaling through intracellular mechanisms. The second group of biological effects is related to cell proliferation (mitogenic activity), which may be mediated by the insulin receptor, by the IGF-I receptor and by hybrids of the two receptors. The evaluation of the relevance of mitogenicity estimates may be performed in in vitro and in-vivo. One approach is cell proliferation in benign and malignant cell lines, for example on mammary epithelial cell lines MCF-10 and MCF-7 (Milazzo et al. 1997).

In the in-vivo evaluation, the metabolic activity is determined in animals (see chapter K.3) using the rat or rabbit bioassay (Lin et al. 1999) by intravenous injection, to confirm the blood glucose lowering activity after direct receptor activation. This initial test confirms intrinsic activity at the receptor level, However, it does not indicate depot activity and is applicable in the same manner to fast acting insulin analogs (lispro, aspart, glulisine), and to long-acting analogs (glargine, detemir). The rat bioassay by intravenous injection is preferred is the initial test for in-vivo biological activity. In order to evaluate depot activity, the time action profile after subcutaneous injection may be determined subsequently, in order to distinguish between the rapid acting insulin analogs and long acting insulin analogs. This has been done in clinical studies by measuring the glucose lowering, and the residence of 125-I-labeled insulin analogs at the subcutaneous injection site (Kang et al. 1991a).

[2] Amendment by J. Sandow

In a practical approach, testing for depot activity may be performed by the pharmacodynamics of glucose lowering, preferably in intact dogs. Such studies may be later be followed up by euglycemic clamp studies. The pharmacokinetics can be based on nonspecific measuring of immunoreactive insulin, and concentration changes of C-peptides. More specific determination of the insulin analog concentrations require advanced methods, for example there is the specific radioimmunoassay for lispro insulin (Bowsher et al. 1999, von Mach et al. 2002).

GENERAL CONSIDERATIONS

A general approach may be suggested for the in vitro evaluation of new insulins. This approach is based on the consideration that insulin has metabolic as well as mitogenic activity which is mediated predominantly by signaling via the insulin receptor, and at high concentrations - as used in vitro - may also be mediated by signaling via the IGF-I receptor. The primary step is determination of insulin receptor affinity, followed by IGF-I receptor affinity (Baehr et al. 1997). There is one important reference compounds, [B10-Asp] insulin which should be used in these evaluations as comparator (Berti et al. 1998), because of the toxicological findings with [B10-Asp] insulin which have raised concern about enhanced mitogenic activity of insulins with prolonged residence time at the insulin receptor (Jorgensen et al. 1992). [B10-Asp] insulin was evaluated as fast acting insulin analog in early clinical trials (Kang et al. 1991b, Nielsen etal. 1995), and was subsequently found to induce benign and malignant mammary gland tumours in rats, during twelve-month toxicology studies. This has been attributed to enhanced mitogenic signaling via the insulin receptor, and alternatively to increased affinity for the IGF-I receptor with subsequent growth promoting effects on mammary gland tissue. A guideline regarding the evaluation of new insulin analogs for carcinogenicity was issued by the European Agency for the Evaluation of Medicinal Products (EMEA 2001), with specific guidance about the in vitro and in-vivo evaluation to be performed. In this guideline, the specific reference compounds mentioned a human insulin, [B10-Asp] insulin and IGF-I (somatomedin C).

PURPOSE AND RATIONALE

The structure and approach to the evaluation of new insulins is directed towards efficacy in terms of glucose lowering, in the predictive manner to differentiate between monomeric insulins with fast absorption kinetics, and long acting insulins with delayed absorption from the subcutaneous injection site.

PROCEDURE

The initial steps are performed in vitro, focused on receptor interaction. Subsequent steps in vitro to explore the receptor-mediated signaling, which is however at the present time difficult to attribute precisely to biological and clinical effects. This is due to the wide concentration range permissible during in vitro studies, whereas the narrowly limited clinical concentration range needs to be kept in mind during any interpretation of clinical relevance (Zib and Raskin 2006).

The main aim of the in vitro evaluation is to establish the relation of metabolic activity to mitogenic activity, as previously done for structure activity studies on insulin analogs, and subsequently directed to predicting clinical relevance of these observations, when comparing new compounds with the established biochemical and toxicological profile of [B10-Asp] insulin, and the clinically used fast acting and long-acting insulin analogs.

MODIFICATIONS OF THE METHOD

The primary step of measuring insulin receptor affinity may be performed in several modifications, depending on the receptor preparation, and on the source of insulin receptors e. g. from fibroblasts, placental membranes, skeletal muscle cells and other sources. The second step of measuring IGF-I receptor affinity also has several options, for research on the IGF-I receptor a human osteosarcoma cell line (SAOS B10) was in several instances applied due to the high number of IGF receptors and lower number of insulin receptors on the cells (Kurtzhals et al. 2000).

The biological profile in animals is directed at predicting clinical utility either as a fast acting (mealtime) insulin, or at establishing depot activity in a suitable animal species. Blood glucose lowering (hypoglycemic) activity is also important for the design of safety studies depending on the preclinical metabolic to mitogenic ratio. In the chronic toxicity studies, and where applicable in carcinogenicity studies, the dose range from biologically effective dose to maximum tolerated dose may be 50–100fold, the results than need to be interpreted carefully for their relevance in relation to the therapeutic concentrations found in clinical therapy.

CRITICAL ASSESSMENT OF THE METHOD

When considering the extensive knowledge on three fast acting insulins and two long acting insulins cur-

rently in clinical use, the predictive relevance of the methods described here can be assessed in each case, and selection of the appropriate study design is based on existing clinical experience.

K.9.2 Insulin Receptor Affinity

GENERAL CONSIDERATIONS

An initial step in the evaluation of insulin analogs is determination of their affinity for the insulin receptor (Lee and Pilch 1994). The studies may include receptor association and dissociation as well as the signalling via the insulin receptor (insulin receptor tyrosine kinase activity and tyrosine phosphorylation of substrates). These methods provide some guidance about the biological potency to be expected, although they provide only limited information about the time action profile.

Receptor affinity data to be extended by evaluation of post-receptor events (signaling), The time action profile in animals and humans, which may differ considerably from the predictions derived from the receptor affinity alone.

PURPOSE AND RATIONALE

These methods described the initial binding of insulin analogs to the receptor preparation obtained from different sources. Tissues differ in their receptor content, the early methods used membrane receptors isolated from different organs, and more recent methods use solubilised human insulin receptor protein.

PROCEDURE

There are several important modifications of the assay principle. This depends on selection of the initial source of receptor (tissue), the preparation of the receptor protein, and the procedure to determine receptor affinity using a radioactive labeled insulin preparation. Some details of the methods are described in section K.6.3.2.1.1of this chapter.

Slieker et al. 1997 described the method using placental membranes and mammary epithelial cells as the receptor preparations for [125I]-Insulin and [125I]-IGF-I binding assays. The placental assay employed incubating 30–40 mg of membrane protein with approximately 10 fmol of iodinated ligand in a final volume of 500 ml of 100 mmol/l HEPES, pH 7.8, 120 mmol/l NaCl, 5 mmol/l KCl, 1.2 mmol/l MgSO4, 8 mmol/l glucose and 0.25% BSA for 16–18 h at 4°C. Membranes were collected on glass fiber filters pre-treated with 0.1% polyethyleneimine by using a cell harvester (Skatron, Lier, Norway). Binding assays with mammary epithelial cells were performed under similar conditions using confluent cells on either P12 (IGF-I receptor) or P6 (insulin receptor) plates (Costar, Cambridge, Mass., USA). Monolayers were incubated in insulin-free medium for 24 h prior to initiating the binding assay. Cells were incubated in the above buffer containing iodinated IGF-I and cold competing ligands for 16–18 h at 4°C. After washing the monolayers with cold assay buffer, cells were solubilized in 0.1 N NaOH and counted for 125I. EC50 values were determined by fitting displacement data to a four-parameter model by nonlinear regression. Dissociation constants for TyrA14-[125I]-Insulin, – LysB28ProB29 HI, and -AspB10 HI were obtained according to the method of Drejer et al. (1991).

For the quantification of receptor numbers of insulin and IGF-I on Chinese hamster ovary cells (CHO) using the [125-I] labeled ligands, Hansen et al. (1996) are applied the method which was also modified for time course studies of binding to these receptors.

CHO-hIR and CHO-K1 cells were seeded on 24-well Nunclon plates at a density of 5x10% cells/well in DMEM containing 20 mM Hepes, 1ug/l human albumin, 10% fetal calf serum, 1% non-essential amino acids and 0.1% bacitracin (pH 7.4); cells were used at confluence. The numbers of insulin and IGF-1 receptors present at the surface of the CHO-K1 and CHO-hIR cells were determined by saturation of the respective receptors with unlabeled ligand. Cells were incubated overnight at 4°C with 50 pM 125I-labeled insulin or [125I]IGF-1 in the presence of increasing amounts of unlabeled insulin or IGF-1 respectively. The number of receptors was estimated with the aid of the LIGAND program fitting a two-site model [Munson and Rodbard 1980]. The native CHO-K1 cells were estimated to express approx. 3.000 high-affinity binding sites for insulin and 50.000 IGF-1 receptors, whereas CHO-hIR cells were found to express 60.000 IRs and 50.000 IGF-1 receptors.

For the time course of receptor association, the procedure was as follows (Hansen et al. 1996). CHO-hIR cells were cultivated in DMEM containing 2 mM glutamine, 50 units/ml penicillin, 50ug/ml streptomycin, 10% fetal calf serum, 1% non-essential amino acids and 1 lM methotrexate. Cells were grown to 80% confluence in 60 mm dishes, 6-well plates (IRTK activity assay) or 12-well plates before the experiments were carried out. Before stimulation with insulin or analog, the cells were starved for 18 h in serum-free medium supplemented with 0.5% insulin-free BSA. The cells were stimulated with 1 ml of 0.1 lM insulin or analog for 30 min, then washed thoroughly 3–5 times (2–5 ml each wash) and subsequently incubated in serum- and insulin-free medium. Because of the large variations in receptor kinetics and potencies of the analogs, the high concentration of 0.1 μM and the 30 min stimulation time were used to ensure maximal stimulation. At various times post-stimulation (0–180 min) the medium was removed and the cells processed further (insulin receptor tyrosine kinase activity IRTK and tyrosine phosphorylation of IR, IRS-1 and Shc).

Kurtzhals et al. (2000) used a preparation of human solubilised insulin receptor protein. Human insulin receptor (hIR) (isoform without exon 11) was isolated from transfected baby hamster kidney (BHK) cells by solubilization and partial purification on a wheat germ agglutinin column. For binding experiments, human insulin receptor (hIR) was incubated with 3 pmol/l TyrA14[125I] human insulin and various concentrations of unlabeled human insulin or insulin analog in a binding buffer containing 0.1 mol/l HEPES, 0.1 mol/l NaCl, 0.01 mol/l MgSO4, 0.5% HSA, 0.2% g-globulin, and 0.025% Triton X-100, pH 7.8, for 42 h at 4°C. Bound tracer was isolated by precipitation with 400 μl 25% PEG 8000 and washing with 1 ml 15% PEG 8000. The data were fitted to a 4-parameter logistic function where *B*max and *B*min were fixed and slope and concentration required for half-maximal effect (EC50) varied. The relative affinity of an insulin analog was calculated as the ratio between the EC50 value for human insulin and that of the insulin analog.

Dissociation from the insulin receptor was determined by Kurtzhals et al. (2000) using CHO cells. Dissociation constants for A14Tyr[125I]-insulins were determined as previously described using Chinese hamster ovary (CHO) cells overexpressing the human insulin receptor (CHOhIR cells) (9). The cells were cultured at 37°C in a 5% CO2 humidified atmosphere in Dulbecco's modified Eagle's

medium (DMEM) supplemented with 10% (vol/vol) fetal calf serum (FCS), 1% nonessential amino acids, 50 µg/ml streptomycin, 50 U/ml penicillin, and 1 µmol/l methotrexate. Cells were subcultured at a 1:5 split ratio every 3–4 days for maintenance. For dissociation studies, cells were seeded on 24-well plates at a density of 5 3 104 cells/well in DMEM containing 10% FCS, 1% nonessential amino acids, 20 mmol/l HEPES, 0.1% HSA, and 0.1% bacitracin (pH 7.4). Cells were used at confluence and were incubated with 50 pmol/l A14Tyr[125I]-insulin or analog for 3 h at 4°C. Cells were washed quickly twice with ice-cold HEPES-buffered DMEM (pH 7.4), and the dissociation of radioactivity was measured after the addition of HEPES-buffered DMEM containing 0.1 µmol/l unlabeled human insulin to measure the maximal accelerated dissociation rate. Cell-associated radioactivity was measured as a function of time, and the dissociation rate constant (*k*d) was calculated from the fitted monoexponential dissociation profiles using the following equation: $B = B_{min} + (B_{max} - B_{min})$ 3 exp(–*k*d 3*t*), where *B* represents cell-associated radioactivity.

MODIFICATIONS OF THE METHOD

The main modifications are related to the selection of receptor protein (membranes or solubilised receptor protein, cells transfected with the human insulin receptor – CHOhIR cells)

CRITICAL ASSESSMENT OF THE METHOD

It is important to use the same system when comparing the insulin receptor affinity of several insulins. To some extent, this can be used as the selection tool in structure activity studies. There are however considerable limitations when comparing affinities with in vitro potency, and ultimately with in-vivo hypoglycemic activity. Therefore, results of the insulin receptor affinity need to be supplemented by data on receptor association and dissociation, as well as post-receptor signaling mechanisms.

K.9.3 Signaling Via Insulin Receptor

GENERAL CONSIDERATIONS

The postreceptor events after stimulation of the insulin receptor are of considerable interest for understanding the effects on different tissues, changes associated with insulin resistance and mitogenic activation of normal tissue and tumor tissues. This is a very complex area of research, because the mitogenic signalling is concentration dependent and many effects may be obtained in vitro which have no equivalent within the therapeutic range of insulin application in patients. Due to the complexities of the signaling mechanisms, and their redundancy with regard to cell proliferation, apoptosis and tissue growth, these investigations are necessary for better understanding, but not sufficient at the present time to fully explained the antiapoptotic and mitogenic activities *in vivo* and the clinical relevance.

PURPOSE AND RATIONALE

Studies on signaling of insulin analogs via the insulin receptor over a wide range of concentrations in vitro are performed to elucidate the intracellular mechanisms, and the components of the signaling chain.

PROCEDURE

Among the many procedures and protocols used for investigation of signaling in cells stimulated with insulin analogs, Hennige et al. (2005) provide an example for the assessment of the fast acting insulin glulisine. Their tests were performed in 10-week-old male C57BL/6 mice from Charles River acclimatized for 2 weeks before entering the study. The mice were maintained on a normal light/dark cycle and kept on a regular diet. Glucose levels were sampled from mouse tail bleeds using a Glucometer Elite (Bayer, Elkhart, IN).

The procedures for in -vivo insulin stimulation and Western blot analysis were described for a short term experiment, by single dose stimulation with regular human insulin or insulin glulisine (1 IU/kg body wt) injected intraperitoneally. For short-term stimulation, 2 IU of insulin were injected into the inferior vena cava. Control animals received a comparable amount of diluent. Tissues (liver, muscle, and hypothalamus) were removed at the indicated time points and homogenized at 4°C, as previously described (8). Homogenates were allowed to solubilize for 30 min on ice and were clarified by centrifugation at 12,000 *g* for 20 min. To detect insulin-stimulated tyrosine phosphorylation, supernatants containing 0.5 mg of total protein were immunoprecipitated with antibodies directed against the COOH-terminal sequences of the insulin receptor, and of the insulin receptor substrates IRS-1 and IRS-2 . Visualization of immunocomplexes after gel electrophoresis and Western blotting with the antiphosphotyrosine antibody 4G10 was performed with the nonradioactive enhanced chemiluminescence system. Blots were subsequently stripped and reprobed to reveal expression of total protein. To assess activation of downstream signaling elements, tissue lysates were separated by SDS-PAGE and transferred to nitrocellulose. Membranes were probed with anti–phospho-AKT and anti–phosphomitogen-activated protein (MAP) kinase antibodies (Cell Signaling, Beverly, MA), respectively.

Assay of PI 3-kinase activity: Tissue lysates were immunopurified with anti-PY20 (Santa Cruz Biotechnology, Santa Cruz, CA) antibodies and immunocomplexes were absorbed to protein a-sepharose for 12 h. Immunoprecipitates were washed three times and pellets were directly incubated with 0.1 mg/ml L-PI (Sigma) and 50 mol/l [32P]-ATP (Perkin Elmer) at room temperature for 10 min. After 1501 of 1 mol/l HCl was added, lipids were extracted twice with 4501 chloroform/methanol (1:1 by vol). Products were separated by thin-layer chromatography, as previously described (9). ^{32}P-labeled phospholipids were detected by autoradiography.

[3H]thymidine incorporation into C2C12 myoblasts: To measure [3H]thymidine incorporation, C2C12 cells were grown in Dulbecco's modified Eagle's medium (4.5 g/l glucose and 10% FCS) in six-well culture plates, and subsequently starved for 24 h in serum-free medium. After cells were stimulated with insulin for 16 h, [3H]thymidine (0.5 Ci/ml) was added for 4 h. The dishes were then rinsed twice with ice-cold PBS and once with 10% trichloroacetic acid. After 20 min, dishes were washed once with ice-cold 10% trichloroacetic acid. Cells were then lysed with 5001 of 0.2 N NaOH/1% SDS and neutralized with 0.5 ml of 0.2 N HCl. Radioactivity was determined by liquid scintillation counting.

MODIFICATIONS OF THE METHOD

There are many options to analyze the postreceptor events to characterise signaling in insulin stimulated cells (Gronborg et al. 1993, Chang et al. 2004), with considerable overlap towards the IGF-I stimulated signaling (Valentinis and Baserga 2001). For the practical approach of risk assessment for insulin analogs, these methods are not suitable, due to the complexity and the as yet only partially defined relation to proliferative activity in normal tissues, and in pre-existing tumors. The research potential of these methods in defined cell lines in culture is very important, the application to insulin stimulated animals and their tissues is also of considerable heuristic relevance.

CRITICAL ASSESSMENT OF THE METHOD

Exploration of the insulin receptor related signaling mechanisms is at present an active research area with many a well-defined methods (see Sect. K.6 in this chapter).

K.9.4 IGF-I Receptor Affinity

GENERAL CONSIDERATIONS

IGF-I receptor affinity is characterised by binding of IGF-I to receptors on cell membranes, or to the IGF-I receptor protein. The cell lines which have been selected for their high density of IGF-I receptors provide estimates of affinity which may vary considerably, and need to be supplemented by methods for interaction of insulin analogs with the receptor (dissociation, residence time), and receptor-mediated effects on proliferation in normal tissues, and in tumor cell lines.

For the IGF-1 receptor affinity of insulin analogs, cell lines have been used with a favorable relation of IGF-I receptors to insulin receptors. Clearly, results differ with the test system used, therefore the determination of IGF-I receptor affinity is considered a preselection step for the further investigation of signalling via the IGF-I receptor and the insulin receptor. Placental membranes or mammary epithelial cell lines (Slieker et al. 1997), and human skeletal muscle cells (Ciaraldi et al. 2001) have been used for structure activity studies, and full investigations on signaling (Ciaraldi et al. 2005),

PURPOSE AND RATIONALE

Studies are performed to obtain an estimate of the proliferative and antiapoptotic activity to be expected raised on the affinity for the IGF-I receptor (DeMeyts et al. 1994, Rubin and Baserga 1995), and to explore the mitogenic/metabolic ratio in preparation of detailed investigation of the effects on cells (e. g. thymidine incorporation), and on postreceptor signaling (Leroith et al. 994).

PROCEDURE

Human skeletal muscle cells (Ciaraldi et al. 2001) are used for the assessment of insulin analog interaction with insulin receptors and IGF-I receptors.

Cell Culture

Biopsy of the vastus lateralis muscle was performed according to published procedures (19). Human skeletal muscle cells were isolated and grown in culture as described in detail previously (Henry et al. 1995). When myoblasts attained 80–90% confluence, the growth medium was changed to MEM supplemented with 2% FBS and antibiotics to induce fusion to multinucleated myotubes. The medium was changed every other day during cell fusion. All studies were performed on cells after one passage.

Insulin and IGF-I Binding Assays

Hormone binding assays were performed by the modification of a method described previously (Henry et al. 1995). Fully differentiated human skeletal muscle cells from nondiabetic subjects and patients with type 2 diabetes were washed four times with reaction buffer, then incubated with reaction buffer and [125I-Tyr A14]insulin (final concentration, 67 pm) or [125I-Tyr A14]IGF-I (final concentration, 39 pm) for 4 h at 12 C in the absence or presence of varying concentrations of unlabeled hormone. Results were calculated based on the displacement of specific insulin/ IGF-I binding normalized to protein concentrations in cells from both nondiabetic subjects and patients with type 2 diabetes.

MODIFICATIONS OF THE METHOD

One particular assay based on IGF receptor affinity in an osteosarcoma cell line SAOS B10 was used extensively in the preclinical evaluation of mitogenic activity (Kurtzhals et al. 2000). This cell line was initially selected for research on IGF-I, and subsequently adapted to structure activity studies. The finding of slightly increased IGF-1 receptor affinity in the presence of a rate of receptor dissociation similar to human insulin is not associated with any biological consequences, as shown by the subsequent extensive studies on absence of toxicity and carcinogenicity mice and rats (Stammberger et al. 2002).

CRITICAL ASSESSMENT OF THE METHOD

It remains the highly active and controversial area of research to define which mechanisms are involved and contribute to a significant extent to cell proliferation and apoptosis via the insulin receptor and/or the IGF-I receptor (Blakesley et al. 1996, DeMeyts 1994, DeMeyts et al. 1995a, DeMeyts et al. 1995b). Evidence for these mechanisms relies to significant extent on the time factor of interaction with the insulin receptor, prolonged residence time as conclude from the incidence

of [B10-Asp] insulin would be dissociated with stimulation of tissue proliferation, and could have an effect on tumor progression (Prager and Melmed 1993, LeRoith 1994, DeMeyts 1995b, Strobl et al. 1995).

The assessment of IGF-I receptor affinity and its that the physiological role becomes even more complicated with the unresolved role of insulin/IGF-I hybrid receptors (Soos et al. 1993, Takata and Kobayashi 1994), which may also have a role in the microvascular and macrovascular complications of diabetes (Li et al. 2005). At present time, there is no evidence for a pathophysiological role of slightly increased IGF-I receptor affinity in the presence of physiological residence time at the receptor, with dissociation rates similar to human insulin. Investigation of insulin glargine has shown that there is no effect on proliferation of benign and malignant mammary cell lines (Staiger etal 20059, and no effect on tumor formation in rodent carcinogenicity studies (Stammberger et al. 2002). There is also no evidence for any proliferative effect of the clinically used fast acting insulin analogs in animal toxicology studies (EPARs for insulin lispro, insulin aspart, and insulin glulisine). Investigation of mammary gland tissue for proliferation markers after a six-month and twelve-months treatment in rats has shown no proliferative effect (Stammberger etal 2006).

K.9.5 Signaling via IGF-1 Receptor

The insulin receptor (IR) and the insulin-like growth factor I receptor (IGF-IR) belong to the same subfamily of receptor tyrosine kinases with two extracellular ·-subunits and two transmembrane β-subunits. They share a high similarity of structure and intracellular signalling events (Dupont and Leroith 2002). However, the IR and the IGF-IR mediate different effects on metabolism, cell proliferation, apoptosis and differentiation. Although some of the variation can be attributed to a different tissue distribution or subcellu-

lar localization, it can also be explained by structural differences in the β-subunit, which may result in activation of specific substrates and signal pathways.

The presence and formation of hybrid receptors, heterodimers composed of the subunits of the insulin receptor and IGF-I receptor has been documented both in normal tissue and in tumor tissue samples (Salzman et al. 1984, Schumacher etal 1991, Soos et al. 1993, Siddle et al. 1994). It has been proposed that signaling in tumor tissue may proceed via such hybrid receptors.

In cells expressing the insulin receptor isoform A (IRA) and the insulin like growth factor-1 receptor (IGF1R), the presence of hybrid receptors, constituted of an alphabeta-IRA chain associated with an alphabeta-IGF1R chain, has been demonstrated. These heterodimers are found in normal cells, and also appear to play crucial roles in a number of cancers (Belfiore etal 1999, Frasca et al. 2003, Pandini et al. 1999). However, they remain difficult to study, due to the concomitant presence of IRA and IGF1R homodimers. Using bioluminescence resonance energy transfer (BRET), Siddle and Blanquart et al. (2005) have developed assays to specifically monitor the activation state of IRA/IGF1R hybrids, both in vitro and in living cells. In the first assay, only hybrid receptors were BRET competent. In the second assay, the activation state of IRA/IGF1R hybrids was monitored in real time, in living cells. In hybrid receptors, trans-phosphorylation of the kinase-dead alpha/beta-Rluc moiety by the wild-type alpha/beta moiety induced the recruitment of YFP-PTP1B-D181A-Cter, resulting in a hybrid-specific ligand-induced BRET signal. Both methods allow monitoring of the activity of IRA/IGF1R hybrid receptor and could be used to detect molecules of therapeutic interest for the treatment of cancer (Blanquart et al. 2005).

CRITICAL ASSESSMENT OF THE METHOD

There are presently a number of methods applicable for the detection of insulin/IGF-I hybrid receptors, and their state of activation. It will be important to investigate insulin analogs with reference to their effects on hybrid receptors, and signaling in normal tissue (Lamphere and Lienhard 1992) as well as in tumor tissue. There are observations of adaptive changes in the formation of insulin/IGF-I hybrid receptors in type 2 diabetic patients, attributed to chronic hyperinsulinaemia (Mosthaf et al. 1991, Federici et al. 1998a, 1998b), as well as alterations of the hybrid receptor ratio in tumor as such as thyroid cancer (Belfiore et al. 1999), and breast cancer (Pandini et al. 1999, Frasca et al. 2003).

K.9.6 Mitogenic Activity

GENERAL CONSIDERATIONS

The determination of mitogenic activity on benign and malignant cell lines is a preliminary approach which has been proposed in the points-to-consider.document of the EMEA safety working party. Enhanced cell proliferation may be the result of signaling via the insulin receptor at near physiological concentrations, via the IGF-I receptor at supraphysiological concentrations, and presumably also related to the presence of hybrid receptors which are preferentially stimulated by IGF-I (Li et al. 2005, Slaaby et al. 2006)

PURPOSE AND RATIONALE

The tests for mitogenic activity are considered to be in early toxicology procedure which provides guidance about the subsequent toxicological evaluation to be performed. In case of enhanced mitogenicity found with the particular cell line, the six-month of 12 month toxicology studies may include histological investigation of specific organ tissues, together with proliferation markers in these tissues (as an example, referred to Stammberger et al. 2006 for investigation of mammary gland tissue in rats).

PROCEDURE

The procedure by Slieker et al. (1996) is based on stimulation of human mammary epithelial cells (HMEC)**.** Mitogenicity was assessed by measuring insulin analog- stimulated growth of human mammary epithelial cells (HMEC) in culture. HMECwere obtained from Clonetics Corporation (San Diego, Calif., USA) at passage 7 and were expanded and frozen at passage 8. A fresh ampule was used for each experiment so that cells were not grown beyond passage 9. Cells were maintained inMCDB 170 medium containing bovine insulin (5 mg/ml), recombinant human epidermal growth factor (10 ng/ml), hydrocortisone (0.5 mg/ml), bovine pituitary extract (50 mg/ml) and gentamycin/amphotericin B. For a growth experiment, cells were plated in 96-well trays at adensity of 12500 cells/cm2 in the above-medium modified as follows: 0.1%BSAwas added and 5 mg/ml bovine insulin was substituted by a graded dose of human insulin or analog from 0 to 1000 nmol/l final concentration. Trays were incubated for 72 h and the cells were counted by Coulter counter (Coulter Electronics, Hialeah, Fla., USA) after trypsinization. Typically, the maximal growth response was between 3- and 4-fold stimulation over basal and did not differ between analogs. Response data were normalized to between 0 and 100% response equal to 100 ' (response at dose X – response at zero dose) divided by (response at maximal dose – response at zero dose). Dose-response data were fit by non-linear regression employing JMP (SAS Institute, Inc., Cary, N.C., USA).

The method by Trueb and Froesch in human osteosarcoma cells (SAOS-B10) for determination of the binding of insulin analogs to the IGF receptor, and proliferative activity was developed in 1995 and subsequently applied by Kurtzhals et al. (2000). Human osteosarcoma cells (B10, a subline of Saos-2, supplied by S.B. and G.A.Rodan, West Point, Pennsylvania) are used because they exhibit a high rate of proliferation and high number of IGF-1 receptors on the cell surface. From competition of 125-I-insulin by unlabeled human insulin, a number of only 740 insulin binding sites per cell has been calculated whereas 21,000 or 39,000 IGF-1 binding sites per cell were determined in two separate experiments. IGF-1 receptor binding is measured (Competition with 125-I IGF-I). The dilution of the stock solutions of the various analogs and natural insulins are performed with HBB/1% HSA (HBB: 118 mM NaCI, 5 mM KCI, 1.2 mM MgSO4, 8.8 mM D-Glucose, 100 mM Hepes, pH 8.0). In the studies by Froesch, possible concentration of the stock dilution was 5.5–10" M for insulin glargine and the related Arg(B31)Arg(B32) insulin due to a lower solubility of both substances at neutral pH.

Therefore, the maximum final concentration in the competition experiment was limited to 5.10∼M for these analogs (10- M for human insulin and the animal insulins). The limitations of preparing stock solutions for insulin analogs with a marked change in isoelectric point should be considered in the experimental design. In another series, initial stock solutions with a standard concentration of 5.5 + 10" M were used, again limiting the final maximum concentration to 5.1 0" M for the insulin analogs in the competition experiment.

Osteosarcoma cells (BlO, passage 27, 125,000 or 150,000 per well) were seeded in 24-well tissue cul-

ture plates and kept overnight at 37°C in DMEM/F12 (1:1) with the addition of 10% fetal calf serum. For deinduction the medium was changed to 500 µl serum-free medium for 4 hours, then the cells were incubated with 200 µl HBB/1% HSA-[125-I] -IGF-1 tracer (0.03 pick/well = 52,000 cam, 8.1×10^{-13} M final concentration) + 20 µl insulin analog or reference in the respective dilution overnight at 4°C. Plates are washed three times with cold PBS and dried at room temperature. Then 200 µl 2 N NaOH are added to each well for 1 hour at room temperature. The lysed cells are transferred to scintillation vials (each well washed with additional 200 µl NaOH) counted for bound radioactivity with a gamma-counter (triplicate measurements).

Mitogenic activity was tested by thymidine incorporation. The dilution of the stock solutions of the various analogs and natural insulins was performed with the basic medium (F12/1 g BSA). The concentration range used was between 10(-11) and 10(-6) M. Cells (50,000) were seeded in 24-well tissue culture plates and kept overnight in DMEM/F12 (1:l) with the addition of 10% fetal calf serum at 37°C. The medium was changed to DMEM/F12 1:l with 5% fetal calf serum for a second overnight incubation period, followed by F12/1 g BSA/L for 30 minutes. The medium was then changed to 400 µl (200 µl in another study) F12/1 BSA + 40 µl (20 µl in another study) insulin analog or reference compound in the respective dilution. Cells were kept at 37°C for 17 hours, then 30 µl (20 µl in another study) 3H-methylthymidine was added (0.3 pCi/well). After 3 to 4 hours at 37°C the medium was aspirated, plates were washed three times in cold PBS, and 500 µl 10% TCA added to each well for 30 minutes at 4°C. After aspiration, wells are washed twice with 10% TCA and dried at room temperature (30 minutes). Then 500 µl 1 N KOH is added to each well for 1 hour at room temperature. 250 µl are removed from each well for liquid scintillation counting (gamma-counter, triplicate counting) after mixing the sample first with 250 µl 1N-HCI and second with 5 ml scintillation fluid.

The method for mitogenic potency described by Kurtzhals etal (2000) is based on thymidine incorporation of the SAOS-B10 line with predominant IGF-I receptors and very few insulin receptors, previously used as SAOS cells extensively for research on chondrocytes and bone formation. The human osteosarcoma cell line Saos/B10 (20), a subclone of Saos-2 (ATCC HTB-85), was used by Kurtzhals. B10 cells express ~30,000 IGF-I receptors and < 1,000 insulin receptors per cell. Cells were cultured in DMEM/F12 supplemented with 10% FCS, L-glutamine, and penicillin/streptomycin. During the entire experiment, cells were grown and kept at 37°C in a humidified atmosphere with 5% CO2. For experiments, cells were trypsinized, plated in 24-well dishes at ~75–100 3 103 cells per well, and cultured for 16 h. Growth medium was then removed and replaced with test buffer (DMEM/F12 without FCS but with 0.5% BSA), and the cells were starved for 4 h. Then, the medium was withdrawn, and cells were incubated with test buffer containing 0.8 pmol/l to 0.8 mmol/l insulin analog for 16 h at 37°C before addition of [3H]methyl-thymidine. [3H]thymidine incorporation was allowed to take place for 4 h at 37°C. The cells were then washed 3 times with ice-cold phosphate-buffered saline and lysed in 10% trichloroacetic acid for 15 min under constant gentle rocking at 4°C. The soluble free [3H]thymidine was removed by 3 consecutive washes in ice-cold 10% trichloroacetic acid. The high molecular weight part of the cell lysates was resolubilized in 1 mol/l KOH and neutralized with an equal volume of 1 mol/l HCl, and DNA-incorporated [^{3}H]thymidine was measured in a b-counter. Each concentration was assayed in triplicate for each experiment. The experiments were repeated 3 times. To compare the mitogenic potential of the insulin analogs with that of human insulin, log-dose response profiles were generated, and EC50 values were estimated using a 4-parameter logistic function (19). Relative mitogenic potency was calculated as the ratio between the estimated EC_{50} values (EC50,HI/EC50,analog), assuming parallelism of the log-dose response profiles.

The relevance of these mitogenicity estimates in a special cell line with predominant IGF-I receptors has been challenged, in a particular because insulin glargine, which showed slightly enhanced mitogenic activity in this test dissociate is rapidly from the insulin receptor (similar to human insulin), and does not stimulate the IGF-I receptor at therapeutic concentrations in humans, because it's affinity for the IGF receptor over the therapeutic dose range is much lower than that of endogenous IGF-I at physiological concentrations.

MODIFICATIONS OF THE METHOD

These tests may be performed on cell lines in vitro, or on tissue specimens ex-vivo.

CRITICAL ASSESSMENT OF THE METHOD

Mitogenicity estimates our guidance for subsequent evaluation of tissues in animal toxicology studies.

K.9.7 Insulin and IGF-1 Assays

GENERAL CONSIDERATIONS

Methods for the quantitation the determination of plasma concentrations of insulin, IGF-I and the IGF binding proteins (not considered here in detail) have been developed based on diverse analytical principles such as radioimmunoassay, enzyme-linked assays, chemiluminescence assays and other principles. Their particular application is to the measurement of concentration changes of insulin, IGF-I and binding proteins during repeated dose treatment of animals, and of course the main application in clinical chemistry is to the evaluation of type 2 diabetes, and growth disorders in children.

PURPOSE AND RATIONALE

The main purpose is to establish a relation of pharmacokinetics and pharmacodynamics, namely in states of insulin resistance (increased insulin concentrations) and during the treatment of diabetes (from decompensation before treatment to established glycemic control).

MODIFICATIONS OF THE METHOD

Specific methods for determination have been established for insulin analogs, for example aspart insulin (Andresen et al. 2000), lispro insulin (Bowsher et al. 1999; Cao et al. 2001), and some of these assays are available commercially (e. g., Linco assay for lispro insulin). For other insulin analogs, methods have been adapted for pharmacokinetic determination (e. g., Mudaliar et al. 2000;Kuerzel et al. 2003 for insulin glargine). There are many sensitive assays for animal insulins and for human insulin, which can be adapted for animal experimentation (Temple et al. 1992; Clark and Hales 1994), the insulin assays have been particularly useful in establishing physiological and pathological secretory patterns (Polonsky et al. 1988a, 1988b). Many of the studies have been extended and supplemented by the measurement of human or animal C-peptide in order to assess endogenous insulin production, and suppression of endogenous insulin during treatment (Ashby and Frier 1981; Bonser and Garcia-Webb 1981; Tillil et al. 1988). Measurement of excretion of C-peptide in the urine is also a helpful method of evaluating secretion rates.

Concerning the methods for determination of IGF-1, many methods were developed for pediatric applications and subsequently their use has been extended to other questions (Teale and Marks 1986; Quarmby et al. 1988; Tchao et al. 1995; Moses et al. 1996; Frystyk et al. 1999; Juul 2003; Elmlinger et al. 2004, 2005; Khosravi et al. 2005; Yakar et al. 2005). Methods for the determination of IGF binding proteins have been reviewed (Rutanen and Pekonen 1991), and several options are now available. In this context, the classical assays for IGF-I activity also need to be mentioned but no longer have practical relevance for the evaluation of the effects of insulin analogs (Zapf 1998).

In the context of measuring circulating concentrations, it may also be helpful to measure of the adaptation of receptor concentrations in tissues by using the appropriate insulin and IGF receptor assays *ex vivo* (Pedersen 1983; Taylor 1984; Johansson and Arnquist 2006).

CRITICAL ASSESSMENT OF THE METHOD

Selection of the appropriate methods for the measurement of insulin, C-peptide, IGF-I and IGF binding proteins is facilitated by a number of options, based on laboratory developed methods and an increasing number of commercially available assays which have been extensively validated.

K.9.8 Assessment of Metabolic-Mitogenic Ratio In Vitro

GENERAL CONSIDERATIONS

When structure activity studies are performed with insulin analogs, it is useful to determine the relative contributions of the hypoglycemic activity (metabolic), and the proliferative activity (mitogenic). Both activities are intrinsic to the insulin molecule, it is important to realise that they are activated at vastly different concentrations in vitro, and that the wide concentration range for testing is permissible in such studies. The metabolic-mitogenic ratio needs to be supplemented by data on the receptor association/dissociation, because experimental evidence for the [B10-Asp] insulin with enhanced mitogenic activity and causing tumor stimulation in rodent toxicology studies indicates that prolonged residence time and decreased rate of dissociation from the insulin receptor may be the critical factor. As a consequence, this information is critical a required for a new insulin analogs. When additional information about enhanced affinity for the IGF-I receptor is obtained, mitogenicity may be tested by methods described here in K9.6 and needs to be followed up by studies on mammary epithelial cells, when available also on other benign and malignant tissue derived cell lines, and ultimately by assessment of carcinogenic potential in animals.

K.9.9 Assessment of Hypoglycemic Activity In Vivo

GENERAL CONSIDERATIONS

Methods for the assay of hypoglycemic activity in animals are reviewed in section K.3 and will be discussed here only with reference to the application and structure activity studies with insulin analogs. For the two classes of insulin analogs of clinical interest, a different experimental design is needed.

Tests by intravenous injection indicate the intrinsic activity, human insulin may be used as the comparator (Lin et al. 1999).

The time-action profiles of fast acting insulins are tested by subcutaneous injection in rats, rabbits or dogs, with regular human insulin as the reference preparation. The drug concentration of test insulin and reference human insulin needs to be identical, for meaningful comparisons. When dilution is a compared, they should have the same insulin concentration. The preferred test is by using the under eluted insulin analog at the concentration equivalent to U-100. The test interval depends on the insulin dose selected, for fast acting insulins test periods of four to six hours are considered sufficient.

The time-action profiles of long acting insulin analogs are tested by subcutaneous injection preferably in dogs or pigs, as a preliminary procedure they may also be tested in rabbits. Human NPH insulin is used as the comparator. The preferred test concentrations are those equivalent to U-100 insulin. The zinc content of formulations is often of interest and will be tested at increasing zinc content, keeping the insulin drug concentration constant.

PURPOSE AND RATIONALE

The biological activity predicted by in vitro studies needs to be confirmed in animals, there may be considerable differences between the in vitro result and the *in vivo* activity due to the pharmacokinetics of the selected drug candidate. The first stage is always testing by intravenous injection to enable immediate contact with the insulin receptor.

K.9.9.1 Depot Activity of Insulin Analogs in Rabbits

PROCEDURE

This test by subcutaneous injection is suitable for the evaluation of depot activity of long acting insulins and insulin depot preparations. Adult male rabbits body weight 2,5–3,5 kg are suitable for the test, the animals

may be used repeatedly when treatment free intervals of at least two weeks (recovery periods) are inserted after each treatment day. In each group, eight to 10 Rabbits are treated on the test day. Insulin analogs and insulin depot preparations are compared for reference. The insulin analogs (long acting) or depot preparations of human insulin as reference compounds (NPH insulin) are injected subcutaneously for example at a dose 0.3 IU/kg by microliter syringes, using the undiluted original concentration (straight concentrations) equivalent to U-100 insulin.

Blood samples for glucose determination are obtained from an ear vein immediately before treatment, and then hourly up to 8 hours after subcutaneous injection. The blood glucose may be determined by enzymatic assay, for example in 10 µl of native blood using a commercial test kit.

Evaluation of blood glucose data is was performed descriptively and by explorative statistics.For descriptive evaluation of time-action blood glucose profiles (time point and extent of maximum decrease, centroid time, duration/maximal decrease ratio and total area of blood glucose decrease are used.

In this experimental design, the concentration of the insulins and the composition may be varied, for example by changing the zinc content. To test statistically for dependency on insulin concentration or zinc content of the formulation, the drug concentration-dependency and/or the zinc concentration-dependency of two or more groups is compared using exact one-sided Wilcoxon tests (Hollander and Wolfe 1973, Streitberg and Röhmel 1987).

The test parameters are total peak area and ratio of duration to maximal decrease, accepting an increase within each of these parameters as the relevant test direction for increasing concentrations of drug (insulin) or zinc content (formulation). Each test is performed separately at a significance level of 5 %.

Streitberg B, Röhmel J (1987) Exakte Verteilung für Rang- und Randomisierungstests im allgemeinen Stichprobenproblem; EDV in Medizin und Biologie 18; pp 12–19: Verlag Eugen Ulmer GmbH & Co., Stuttgart; Gustav Fisher Verlag KG, Stuttgart

MODIFICATIONS OF THE METHOD

The principal modifications of this method are the selection of insulin concentrations to be tested. It is established that depot activity depends on local concentration at the injection site, therefore it is advisable to inject smaller volumes by microsyringe, rather than use dilution is of the original concentration to be evaluated.

CRITICAL ASSESSMENT OF THE METHOD

Testing of depot activity in rabbits is an earlier option, but not as trustworthy as extended testing for depot activity in dogs or pigs.

K.9.9.2 Depot Activity of Insulin Analogs in Fasted Dogs

GENERAL CONSIDERATIONS

The time action profile of long acting insulin analogs after subcutaneous injection varies considerably depending on the species used for testing. In general, proof of depot activity cannot be obtained in mice and rats, is difficult to obtain in rabbits unless high dose is a tested, and is readily obtained by testing in in dogs or pigs.

PURPOSE AND RATIONALE

The test procedure in dogs is based on experience with human NPH insulin and with insulin zinc suspensions (intermediate acting insulins). It has shown to be very reliable in the preclinical evaluation of insulin glargine (Seipke et al. 2000),

PROCEDURE

Adult male beagle dogs are used for this study, feed is withheld for 17 hours. Groups of dogs (six to 10 animals) are treated with the insulin to be tested for depot activity. Human regular insulin (soluble) and/or human NPH insulin are used as the reference compounds. Tests may be performed sequentially, in parallel or by cross over. Insulin preparations are injected subcutaneously at the flank of the animal, alternating between the right and left flank. Blood samples for glucose determination are obtained by leg vein puncture, immediately before treatemnt and hourly up to 10 hours after treatment, additional samples may be obtained 12, 14 and 16 hours after administration,. Blood glucose iss determined enzymatically, for example in 10 µl native blood using the Glucoquant test kit (Boehringer Mannheim) with the EPOS Analyzer 5060 (Eppendorf). For evaluation of the glucose data, means and standard error of the mean at each measuring point of the raw data [or using data converted to percent of the initial values] were used for tabular and/ or graphical representation of the time response curves.

For statistical evaluation of the depot activity, centroid times are calculated and, for evaluation of the blood glucose decreasing activity, the area of blood glucose decrease for each group is calculated. In both cases, a two-way ANOVA is performed at a significance level of 5%.

The mean blood glucose decrease was calculated by the trapezoidal rule and the centroid time (C_t) by

$$C_t = \frac{\sum_{i=1}^{n}(T_i * F_i)}{\sum_{i=1}^{n} F_i} \quad \text{where} \quad T_i = \frac{t_{i+1} + t_i}{2} \quad \text{and}$$

$$F_i = \frac{(t_{i+1} - t_i)(c_{i+1} - c_i)}{2}$$

t_i = times of measurement (i = 1,...,n),
c_0 = base line glucose concentration and
c_i = glucose concentration at measurement time t_i.

Calculation of the centroid time and of the areas of blood glucose decrease is performed with the raw data. The point of onset and endpoint of the blood glucose decrease are defined by intersection of the blood glucose curve with the baseline in the descending or ascending phase, respectively.

K.9.10 Mitogenic Risk and Safety Evaluation In Vivo

GENERAL CONSIDERATIONS

An intense discussion was raised by the findings that one fast acting insulin analog [B10-Asp] insulin showed unexpected toxicity on proliferation and tumor development of rat mammary glands. This finding was attributed tentatively to mitogenic signaling via the insulin receptor, and/or mitogenic signaling via the IGF-I receptor, based on the finding that on the insulin receptor residence time was prolonged and the rate of dissociation was much lower than found with human insulin, and that affinity for the IGF-I receptor was enhanced. This compound has therefore become the reference standard for the assessment of enhanced mitogenicity and its effect in toxicology. The preclinical evaluation of insulin analogs for the risk of enhanced mitogenicity therefore includes determination of the metabolic and mitogenic in vitro characteristics, by affinity for the insulin receptor and rate of association/dissociation, affinity for the IGF-I receptor, evaluation of enhanced mitogenic signaling e. g. by thymidine incorporation into proliferating cells, and details of signaling via the insulin receptor and IGF-I receptor (e. g. tyrosin phosphorylation, phosphorylation of receptor substrates).

Anti-obesity Activity[1]

[1] Reviewed by M. Bickel, contributions by A.W. Herling

L.1 Methods to Induce Experimental Obesity

L.1.0.1 General Considerations

Influence of the central nervous system, in particular of the hypothalamus, on development of obesity has been suspected since the early clinical observations of Babinski (1900) and Fröhlich (1901), Biedl 1916). Experiments reported by Smith (1927, 1930) showed that injections of chromic acid into the suprasellular region of rats with lesion of the hypothalamus induced obesity in rats (Bomskov 1939). Hetherington and Ranson (1939) found that electrolytic lesions, restricted to the ventromedial region of the hypothalamus, could be associated with the development of obesity.

A virally induced obesity syndrome in mice was described by Lyons et al. (1982).

Chan (1995) gave a review on β-cell stimulus-secretion coupling defects in rodent models of obesity.

Leiter and Herberg (1997) reviewed the advances in understanding the molecular bases for monogenic obe-

sity mutations capable of producing obesity-induced diabetes, or diabesity in mice.

Astrup and Lundsgaard (1998) discussed pharmacological mechanisms of anti-obesity drugs.

L.1.0.2 Food-Induced Obesity

PURPOSE AND RATIONALE

Obesity can be induced in rats by offering a diet containing corn oil and condensed milk.

PROCEDURE

Male Sprague Dawley rats are housed in individual wire-bottom suspended cages in rooms maintained at 22–23°C with 12 h light-dark cycles. At the age of 6 months (body weight about 450 g) the animals are divided in 2 groups: group I is fed ordinary Purina Rodent Chow, group II a special diet containing Purina Rodent Chow, corn oil and condensed milk, resulting in a composition of 14.7% protein, 44.2% carbohydrate, 15.8% lipid, 2.5% fiber, 1.2% vitamin mixture, and 19% water. Body weight and food intakes are measured, and diet replaced, every 3 to 4 days.

Three months from the start of the experiment, the rats are sacrificed by decapitation for determination of adipose tissue cell size and number, carcass composition and plasma lipids, and hormone and glucose levels.

The dorsal subcutaneous (inguinal) pad, the retroperitoneal pad, and one epididymal fat pad are sampled for determination of lipid content by the method of Folch et al. (1957). The method consists of homogenizing the tissue with a 2:1 chloroform-methanol mixture and washing the extract by addition to it of 0.2 its volume of water. The resulting mixture separates into two phases. The lower phase is the total pure lipid extract. Cell number in each pad is determined by the osmium fixation method of Hirsch and Gallian (1968) using a Coulter counter. Total epididymal pad weights are based on doubling the weight of the individual pads sampled.

EVALUATION

Intergroup comparisons are made with the use of a two-tailed Student's *t*-test.

MODIFICATIONS OF THE METHOD

Scalfani and Springer (1976) induced obesity in adult female rats by adding a variety of supermarket foods to lab chow (**"cafeteria diet"**). In behavioral tests, the authors found similarities to hypothalamic and human obesity syndromes.

Rothwell et al. (1982) compared the effects of feeding a cafeteria diet on energy balance and diet-induced thermogenesis in four strains of rats.

Stock and Rothwell (1979) discussed the influence of various forms of feeding, high-fat diets, insulin injections, tube-feeding, and cafeteria feeding on energy balance in laboratory animals.

Rolls et al. (1980) found persistent obesity in rats following a period of consumption of a mixed, high energy diet. When the high energy foods were withdrawn after 90 days and just chow was available, the obese rats maintained their elevated body weights.

Hill et al. (1992) studied the influence of amount and composition of dietary fat on development of obesity in rats. Adult male Wistar rats were fed high fat (HF; 60% of calories) or low fat (LF; 20% of calories) diets for 28 weeks. Half of the rats in each condition received diets with saturated fat (lard) or with polyunsaturated fat (corn oil). There was some indication that unsaturated fat diets were associated with greater ac-

cumulation of fat in subcutaneous tissue depots than saturated fat diets. The effects of the type of fat were less than those of the amount of dietary fat.

Wade and Gray (1979) reviewed the gonadal effects on food intake and adiposity in rats. Estradiol and testosterone decrease adiposity, while progesterone increases carcass fat content.

Thermogenesis induced by various diets has been discussed by Rothwell and Stock (1986).

Harris (1993) studied the impact of high- or low-fat cafeteria foods on nutrient intake and growth of rats consuming a diet containing 30% energy as fat.

Segues et al. (1994) studied long-term effects of cafeteria diet feeding on young female Wistar rats by comparing the circulating levels of glucose, lactate, glycerol, 3-hydroxybutyrate and urea, and liver glycogen.

Llado et al. (1997) studied fatty acid composition of brown adipose tissue in dietary obese rats. Long time exposure to a hypercaloric high-fat diet such as the cafeteria diet induced an important fatty acid accumulation in brown adipose tissue, mainly for the major saturated and monounsaturated fatty acids.

LeBlanc and Labrie (1997) investigated the role of palatability of the food in diet-induced thermogenesis.

Selective breeding for diet-induced obesity and resistance in Sprague-Dawley rats was reported by Levin et al. (1997).

Herberg et al. (1974) reported the effects of either a high-carbohydrate diet or a high-fat diet over prolonged periods in metabolically intact and in obese NZO **mice**.

West et al. (1992) evaluated the effects of a 7 week consumption of a diet containing 32.6% of kilocalories as fat (condensed milk) on body composition and energy intake in nine strains of inbred mice. Relative to Chow diet controls, the condensed milk diet significantly increased carcass lipid content in six strains (AKR/J, C57L/J, A/J, C3H/HeJ, DBA/2J, and C57BL/6J), but had no or a marginal effect on adiposity in 3 strains of mice (SJL/J, I/STN, and SWR/J).

West et al. (1994) studied the genetics of dietary obesity in AKR/J x RWR/J mice. Pups were weaned between the ages of 29 and 34 days onto Purina Chow ad libitum until they were switched to a high fat, condensed milk diet containing 32.6%, 15.0%, and 52.4% of kilocalories as fat, protein, and carbohydrate, respectively.

Strain-specific response to β_3-adrenergic receptor agonist treatment of diet-induced obesity in mice was reported by Collins et al. (1997).

L.1.0.3 Hypothalamic Obesity

PURPOSE AND RATIONALE

Hyperphagia in rats has been reported after hypothalamic lesions (Liu and Yin 1974). Surgical techniques were described by Leibowitz et al. (1981), Vander Tuig et al. (1985).

PROCEDURE

Female Sprague Dawley rats, weighing about 190 g body weight, receive during a 5–9 days initial period of adjustment a high-fat diet. They are then fasted overnight, anesthetized with 35 mg/kg pentobarbital sodium and additionally 1 mg atropine methyl nitrate intraperitoneally. Bilateral wire knife cuts or electrolytic lesions are sterotaxically positioned in the hypothalamus (David Kopf Instruments, CA). With the incision bar positioned at –3.0 mm, parasagittal wire knife cuts are placed between the medial and lateral hypothalamus using a retractable wire knife according to Gold et al. (1973). The cuts are made 1.0 mm lateral to the midline and extended from 8.5 to 5.5 mm anterior to the ear bars and from the base of the brain dorsally 3.0 mm.

To produce electrolytic lesions in the ventromedial hypothalamus, the incision bar is positioned at +5.0 mm and a stainless steel electrode, insulated except for 0.5 mm at the tip, is lowered 0.6 mm lateral to the midline and 5.8 mm anterior to the ear bars. With the tip of the electrode 0.7 mm above the base of the brain, lesions are made by passing 2.0 mA of anodal current for 20 s to a rectal electrode.

Sham-operated rats serve as controls. Separate rats that are fasted overnight are killed at the time of surgery to provide data on initial body composition.

Histological verification of placement of knife cuts and lesions is made in brains fixed in 10% buffered formaldehyde solution and embedded in paraffin. Serial sections through the hypothalamic area of the brain are examined histologically.

EVALUATION

Not only food consumption and increase of body weight can be determined after hypothalamic lesions, but also brown adipose tissue enzymes and guanosine diphosphate binding to brown adipose tissue mitochondria and noradrenaline turnover in various organs.

MODIFICATIONS OF THE METHOD

A survey on hypothalamic and genetic obesity in experimental animals was given by Bray and York (1979).

Caloric compensation to gastric loads in rats with hypothalamic hyperphagia was reported by Liu and Yin (1974).

Sclafani and Aravich (1983) adapted adult female Sprague Dawley rats to a macronutrient self-selection regimen which allowed them ad libitum access to separate sources of protein, carbohydrate, and fat. The rats were then given either ventromedial hypothalamic lesions, paraventricular hypothalamic lesions, parasagittal knife cuts through medial hypothalamus or sham lesions. Following surgery, all lesioned rats overate and became obese as compared to sham operated controls. The group with parasagittal knife cuts through medial hypothalamus gained more weight than the groups with ventromedial hypothalamic lesions and paraventricular hypothalamic lesions.

Enhanced expression of rat obese (ob) gene in adipose tissue of ventromedial hypothalamus (VMH)-lesioned rats was described by Funahashi et al. (1995).

Elmquist et al. (1999) discussed the role of leptin and other peptide hormones in different areas of the hypothalamus in controlling food intake and body weight.

L.1.0.4 Goldthioglucose-Induced Obesity

PURPOSE AND RATIONALE

Intraperitoneal or intramuscular injection of goldthioglucose induces obesity in mice. The effect is related to destruction of hypothalamic and extrahypothalamic areas of the brain (Perry and Liebelt 1961).

PROCEDURE

Swiss albino mice of either sex are fed with commercial mouse chow (Altromin R) ad libitum. At the age of 6 weeks, the animals receive a single intraperitoneal injection of 30–40 mg/kg goldthioglucose.

EVALUATION

Food intake is registered for 2 weeks and body weight for a period of 3 months and compared with untreated controls.

MODIFICATIONS OF THE METHOD

Debons et al. (1962, 1968, 1977) administered 800 mg/kg goldthioglucose by a single intraperitoneal injection to female CBA mice.

Obesity was induced in rats by implants of goldthioglucose in the hypothalamus (Smith and Britt 1971; Smith 1972).

Several other compounds produce obesity concomitantly with brain lesions.

Single intraperitoneal injection of bipiperidyl mustard (N,N′-bis-[β-chloroethyl]-4,4′-bipiperidine) in doses between 5 to 50 mg/kg induced obesity in mice (Rutman et al. 1966). Brain lesions and obesity by bipiperidyl mustard could also produced in rats (Laughton and Powley 1981).

Massive and persistent obesity was induced in mice by a single intracerebral injection with 4-nitroquinoline 1-oxide (Mizutani 1977).

L.1.0.5 Monosodium Glutamate-Induced Obesity

PURPOSE AND RATIONALE

Adiposity can be induced in mice by repeated subcutaneous injections of monosodium-L-glutamate at an early stage of life (Olney 1969).

PROCEDURE

Male Charles River mice are treated immediately after birth with daily subcutaneous injections of 2 g/kg monosodium-L-glutamate for 5 consecutive days. Control mice are treated with physiological saline. The animals are weaned at 3 weeks of age, housed under controlled temperature and artificial light/dark cycle and provided with commercial powdered chow and tap water at libitum.

EVALUATION

Food consumption and weight gain is measured at weekly intervals.

MODIFICATIONS OF THE METHOD

Tokuyama and Himms-Hagen (1986) studied brown adipose tissue thermogenesis, torpor, and obesity in glutamate-treated C57B1/6J mice offered either normal chow or a cafeteria diet and found that the high metabolic efficiency and obesity of the glutamate-obese animals are principally a consequence of their

maintenance of a hypothermic torpid state for more than 50% of the time.

Seress (1982) injected young albino **rats** with either single or repeated doses of 0.1–6.0 mg/g body weight of monosodium L-glutamate between the ages of 2 and 40 days. The smallest, single effective dose was 0.25 mg/g body weight administered during the first week of life. The sensitivity to monosodium L-glutamate decreased with age. In adult rats an 80–90% loss of neurons in the anterior part of the arcuate nucleus was found.

Remke et al. (1988) reported on development of hypothalamic obesity after subcutaneous administration of monosodium glutamate to neonate rats.

L.2 Genetically Obese Animals

L.2.0.1 General Considerations

Obesity and diabetes are syndromes quite often linked in patients (maturity onset diabetes) and hereditary animal models. Hunt et al. (1976) described animal models of diabetes and obesity including the PBB-Ld mouse. A survey on hypothalamic and genetic obesity in experimental animals was given by Bray and York (1979). The inheritance of obesity in animal models of obesity was discussed by Festing (1979). Cawthorne (1979) discussed the use of animal models in the detection and evaluation of compounds for the treatment of obesity. The regulation of body weight in animals by leptin was reviewed by Friedman and Halaas (1998).

Symptoms of diabetes and obesity are overlapping in many animal models (see also K.2: Genetically diabetic animals).

L.2.0.2 Spontaneously Obese Rats

The occurrence of spontaneous obesity has been reported in several strains of rats:

WBN/KOB RAT

Spontaneous hyperglycemia, glucosuria and glucose intolerance have been observed in aged males of an inbred Wistar strain, named the WBN/Kob rat (Nakama et al. 1985; Tsuchitani et al. 1985; Koizumi 1989). These animals exhibit impaired glucose tolerance and glucosuria at 21 weeks of age. Obvious decreases in the number and size of islets are found already after 12 weeks of age. Fibrinous exudation and degeneration of pancreatic tissue are observed in the exocrine part, mainly around degenerated islets and pancreatic ducts in 16 weeks old males.

Zucker-Fatty Rat

The Zucker-fatty rat is a classic model of hyperinsulinemic obesity. (Zucker 1965). Obesity is due to a simple autosomal recessive (*fa*) gene and develops at an early age. Obese Zucker rats manifest mild glucose intolerance, hyperinsulinemia, and peripheral insulin resistance similar to human NIDDM. However, their blood sugar level is usually normal throughout life (Bray 1977; Clark et al. 1983; McCaleb and Sredy 1992; Abadie et al. 1993; Alamzadeh et al. 1993; Kasim et al. 1993; Galante et al. 1994).

Truett et al. (1991) found evidence that the rat obesity gene fatty (*fa*) has homology with the mouse gene diabetes (*db*).

Triscari and Sullivan (1987) reported a normalizing effect of an inhibitor of thromboxane synthase on the hyperinsulinemic state of obese Zucker rats and diet-induced obese rats.

Rouru et al. (1993) described the effect of chronic treatment with a 5-HT_1 receptor agonist on food intake, weight gain, plasma insulin and neuropeptide Y mRNA expression in obese Zucker rats.

Santti et al. (1994) studied the potentiation of the anti-obesity effect of a β_3-adrenoceptor agonist in obese Zucker rats by exercise.

Savontaus et al. (1997) investigated the anti-obesity effect of a imidazoline derivative in genetically obese (*fa*/*fa*) Zucker rats.

Zhang et al. (1996) reported downregulation of the expression of the *obese* gene by an antidiabetic thiazolidinedione in Zucker diabetic fatty rats and *db/db* mice.

Lynch et al. (1992) identified several adipocyte proteins, among them pyruvate decarboxylase contributing to the increased lipogenic capacity of young obese Zucker adipocytes.

WDF/TA-FA RAT

The WDF/Ta-fa rat, commonly referred to as the Wistar fatty rat, is a genetically obese, hyperglycemic rat established by the transfer of the fatty (*fa*) gene from the Zucker rat to the Wistar Kyoto rat. (Ikeda et al. 1981; Kava et al. 1989; Velasquez et al. 1990). The Wistar fatty rat exhibits obesity, hyperinsulinemia, glucose intolerance, hyperlipidemia, and hyperphagia similar to Zucker rats being, however, more glucose intolerant and insulin resistant than Zucker rats. Hyperglycemia is usually not observed in females but can be induced by addition of sucrose to the diet.

Kobayashi et al. (1992) found an increase of insulin sensitivity by activation of insulin receptor kinase by Pioglitazone in Wistar fatty rats (*fa/fa*).

Mazusaki et al. (1996) found an augmented expression of the *obese* (*ob*) gene during the process of obesity in genetically obese-hyperglycemic Wistar fatty (*fa/fa*) rats.

OLETF Rat

A spontaneously diabetic rat with polyuria, polydipsia, and mild obesity was discovered in 1984 in an outbred colony of Long-Evans rats. A strain of rats developed from this rat by selective breeding has since been maintained at the Tokushima Research Institute (Otsuka Pharmaceutical, Tokushima, Japan) and named OLETF. The characteristic features of OLETF rats are: (1) late onset of hyperglycemia (after 18 weeks of age), (2) a chronic course of disease, (3) mild obesity, (4) inheritance by males, (5) hyperplastic foci of pancreatic islets, and (6) renal complications (nodular lesions). The clinical and pathological features of disease in OLETF rats resemble those of human NIDDM.

Administration of diazoxide (0.2% in diet), an inhibitor of insulin secretion, to OLETF rats from the age of 4 to 12 weeks completely prevented the development of obesity and insulin resistance (Aizawa et al. 1995).

Ishida et al. (1995) found that insulin resistance preceded impaired insulin secretion in OLETF rats.

Umekawa et al. (1997) determined induction of uncoupling protein and activation of GLUT4 in OLETF rats after administration of a specific β_3-adrenoceptor agonist.

Obese SHR Rat

The strain of obese SHR rats was developed by Koletsky (1973, 1975) by mating a spontaneous hypertensive female rat of the Kyoto-Wistar strain with a normotensive Sprague Dawley male. After several generations of selective inbreeding, these obese SHR exhibited obesity, hypertension, and hyperlipidemia. In addition, some rats developed hyperglycemia and glucosuria associated with giant hyperplasia of pancreatic islets.

JCR:LA-Corpulent Rat

Several substrains were developed from obese SHR rats, such as the JCR:LA-corpulent rat which exhibits a syndrome characterized by obesity, hypertriglyceridemia and hyperinsulinemia with impaired glucose tolerance and is susceptible to vascular arteriosclerotic lesions (Russell et al. 1986a, b, 1994).

Compared to fatty Zucker rats, the JCR:LA-corpulent rats have higher levels of the insulin releasing hormone gastric inhibitory polypeptide and higher insulin levels (Pederson et al. 1991).

Vydelingum et al. (1995) found an overexpression of the obese gene in the JCR:LA-corpulent rat.

L.2.0.3 Spontaneously Obese Mice

Yellow Obese (A^YA) Mouse

The yellow obese mouse in the only example of obesity inherited through a dominant gene and was described as early as 1883 by Lataste and in 1905 by Cuenot. It is located on chromosome 2 at linkage group 5, the agouti locus (Bateson 1903). Since the genes controlling obesity and the agouti coat colors are so closely linked, the obesity is associated with a change of pigmentation from black to yellow. Such an association allows the early identification of pre-obese mice as soon as the coat hair begins to grow.

Since the original description of the yellow (A^ya) mouse, a number of additional alleles have appeared at the agouti locus. The homozygous dominant yellow mutation (A^y/A^y) is lethal in utero (Robertson 1942; Eaton and Green 1962) with approximately 25% of any litter from A^ya matings dying from an abnormal development after the trophoblast stage (Pedersen 1974).

Yellow (A^ya) mice develop a moderate form of obesity and diabetes. Increased body weight first appears at the time of puberty (8–12 wk) (Dickie and Wooley 1946; Carpenter and Mayer 1958), after which body weight increases slowly to reach values of approximately 40 g. In contrast to other forms of obesity, yellow mice are characterized by increased linear growth. Plasma insulin concentrations are increased and food is stored more efficiently than in lean mice (Dickerson and Gowan 1967). Food intake returns to normal in older A^ya mice and the animals lose body weight (Hollifield and Parson 1957). The obesity may be exaggerated by being fed high-fat diets (Fenton and Chase 1951; Silberberg and Silberberg 1957; Carpenter and Mayer 1958). Food restriction may normalize body weight but the animals still remain obese (Fenton and Chase 1951; Hollifield and Parson 1957). Metabolic rate of A^ya mice is depressed when related to body surface, although oxygen consumption per animal is identical to the homozygous recessive agouti (a/a) mouse (Bartke and Gorecki 1968).

Gill and Yen (1991) studied the effect of ciglitazone on endogenous plasma islet amyloid polypeptide

(amylin) and insulin sensitivity in obese-diabetic viable yellow mice (VY/Wfl-A^{vy}/a).

KK-A^Y Mouse

Iwatsuka et al. (1970) reported on yellow KK mice (also named KK-A^y mice), carrying the yellow obese gene (A^y). These mice develop marked adiposity and diabetic symptoms in comparison with their littermates, black KK mice. Blood glucose and circulating insulin levels as well as HbA_{1c} levels were increased progressively from 5 weeks of age. Degranulation and glycogen infiltration of B cells were followed by hypertrophy and central cavitation of islets. Lipogenesis by liver and adipose tissue were increased. Insulin sensitivity of adipose tissue was more remarkably reduced than in black KK mice to its complete loss at 16 weeks of age. Renal involvement is uniquely marked by early onset and rapid development of glomerular basement membrane thickening (Diani et al. 1987).

KK-A^y mice can be used to demonstrate the extra-pancreatic action of antidiabetic drugs, such as glimepiride, a novel sulfonylurea (Satoh et al. 1994).

Sohda et al. (1990) evaluated ciglitazone and a series of 5-[4-(pyridylalkoxy)benzyl]-2,4-thiazolidinediones for hypoglycemic and hypolipemic activities in yellow KK mice.

Hofmann et al. (1992) evaluated the expression of the liver glucose transporter GLUT2 and the activity and the expression of phosphoenolpyruvate carboxykinase in the liver of obese KKA^Y mice after treatment with the oral antidiabetic agent pioglitazone.

Yoshida et al. (1991) compared brown adipose tissue thermogenesis, resting metabolic rate, insulin receptors in adipocytes, and blood glucose and serum insulin levels during a glucose overloading test in yellow KK mice with C57B1 control mice after a β_3-adrenoceptor agonist.

Yoshida et al. (1996) determined body weight, food intake, white adipose tissue weight, brown adipose tissue weight and its thermogenesis, noradrenaline turnover, blood glucose and serum insulin levels and GLUT4 in diabetic yellow KK mice compared with C57B1 mice after mazindol.

OBESE HYPERGLYCEMIC (OB/OB) MICE

Ingalls et al. (1950), Mayer et al. (1951), Bleisch et al. (1952) observed hereditary diabetes in genetically obese mice. The obese hyperglycemic mice were glycosuric, the non-fasting blood sugar levels were about 300 mg%, but neither ketonuria nor coma were observed. One of the most interesting features was insulin-resistance; doses as high as 400 IU/kg had little effect on blood sugar. The

serum insulin-like activity was high, the islands of Langerhans were hypertrophic, their insulin content was increased and the liver glycogen stores were decreased. Kidneys and other organs did not show pathological changes. Obviously, the diabetic condition of this and other strains of obese hyperglycemic mice is different from that of the human diabetic patient.

Reduced oxygen consumption has been noted as early as 10–18 days of age in *ob/ob* mice (Boissenault et al. 1976; Trayhurn 1977).

Other strains or substrains of mice with obesity and hyperglycemia have been described by Dickie (1962), Westman (1968), Stein et al. (1970), Coleman and Hummel (1973), Herberg and Coleman (1977).

Strautz (1970) implanted *ob/ob* mice with Millipore diffusion chambers containing islets isolated from pancreas of normal littermates.

Trayhurn et al. (1977) found a thermogenic defect in pre-obese *ob/ob* mice. Rectal temperature of 17 days old pre-obese mice in response to an environmental temperature of 4°C fell much more than in lean controls.

Chlouverakis (1972) performed parabiotic experiments of obese-hyperglycemic mice (*ob/ob*) with lean littermates and determined body weight, glucose, serum insulin and triglycerides as well as insulin-sensitivity of diaphragm muscle and epididymal fat pad.

Parabiosis of obese (*ob/ob*) with diabetes (*db/db*) mice caused the obese partner to become hypoglycemic, to lose weight and to die of starvation, while no abnormal changes were observed in the diabetic partner (Coleman 1973).

Cresto et al. (1977) compared the rate of insulin degradation in normal and in*ob/ob* mice.

Zhang et al. (1994) succeeded in positional cloning of the mouse *obese* gene and its human homologue.

Pelleymounter et al. (1995) investigated the effects of the *obese* gene product on body weight regulation in *ob/ob* mice. The OB protein was expressed in *E. coli* and purified to homogeneity as a 16-kilodalton monomer. Daily intraperitoneal injections of the recombinant OB protein to *ob/ob* mice lowered their body weight, percent body fat, food intake, and serum concentrations of glucose and insulin.

Halaas et al. (1995) reported that daily intraperitoneal injections of either mouse or human recombinant OB protein reduced the body weight of *ob/ob* mice but had no effect on *db/db* mice.

Campfield et al. (1995) found that peripheral and central administration of microgram doses of recombinant mouse OB protein reduced food intake and body weight of *ob/ob* and diet-induced obese mice but not in *db/db* obese mice.

Trayhurn et al. (1996) studied the effects of fasting and refeeding on *ob* gene expression in white adipose tissue of lean and obese *(ob/ob)* mice using a 33-mer antisense oligonucleotide as a probe for the rapid chemiluminescence-based detection of *ob* mRNA.

Sterility defect in homozygous obese female mice could be corrected by treatment with the human recombinant OB protein leptin (Chehab et al. 1996).

Roupas et al. (1990) used isolated adipocytes from *ob/ob* mice to study the diabetogenic action of growth hormone.

BL/6 Obese Mice

An obese mutation occurred in a noninbred stock (Ingalls et al. 1950) but was established later, and has been maintained, in the C5BL/6J (BL/6) strain. BL/6 obese mice are characterized by marked obesity, hyperphagia, transient hyperglycemia and markedly elevated plasma insulin concentrations associated with an increase in number and size of beta cells in the islets of Langerhans (Coleman and Hummel 1973; Genuth et al. 1971). The mutation is autosomal recessive and homozygous mutants of both sexes are infertile. Obese mutants are obtained by mating known heterozygotes. A primary metabolic disturbance in the adipocyte has been postulated since increased adipocyte size has been observed as early as 14 days of age well before any obesity or hyperinsulinemia are observed (Joosten and van der Kroon 1974).

NZO Mouse

The New Zealand obese (NZO) mouse was first described in 1953 by Bielschowsky and Bielschowsky. The strain was developed by selective inbreeding of obese mice from a mixed colony, beginning from a pair of agouti mice, which also gave rise to the NZB black strain (Melez et al. 1980). NZO mice develop obesity, mild hyperglycemia, glucose intolerance, hyperinsulinemia, and insulin resistance. The adult NZO mouse normally attains a body weight of 50–70 g by 6–8 months, although weight gain continues slowly after this age (Crofford and Davis 1965; Herberg et al. 1970). Hyperglycemia and glucose intolerance increase continuously with advancing age of the animals.

Renal disease in NZO mice is seen by 6 months of age. NZO mice have a high prevalence of autoimmune disorders.

Diabetes Obesity Syndrome in CBA/CA Mice

A spontaneous maturity onset diabetes obesity syndrome occurs in a small proportion (10–20%) of male CBA/Ca mice. Inbreeding can increase the incidence to 80%. It occurs at 12–16 weeks of age, and is characterized by hyperphagia, obesity, hyperglycemia, hypertriglyceridemia, hyperinsulinemia, and an impaired glucose tolerance. The mice are also resistant to exogenous insulin. Female mice remain normal except

for a slight increase in serum insulin. The male obese diabetic mice have a normal life expectancy.

FAT/FAT Mice

Fat mice carry an autosomal recessive mutation and display a rang of abnormalities, including progressive adult onset obesity, hyperinsulinemia and infertility (Coleman and Eicher 1990). The mutant allele of *fat* was identified and shown to be a missense (serin ⟶ proline) mutation in carboxypeptidase E which abolishes enzyme activity in a variety of neuroendocrine tissues (Naggert et al. 1995). Carboxypeptidase E is required for both sorting and proteolytic processing of a variety of prohormones including proinsulin and POMC (Cool et al. 1997). As carboxypeptidase E is expressed in the CNS, defective processing of a variety of hypothalamic neuropeptides – such as POMC and MCH – may trigger obesity in these animals (Rovere et al. 1996).

Tubby Mice

Tubby is an autosomal recessive mutation in mice (Coleman and Eicher 1990) which display a tripartite phenotype of blindness, deafness and maturity onset obesity. In response to weight gain, these mice gradually increase their food intake in proportion to body weight and increase plasma insulin levels thereby maintaining normoglycemia. The progressive retinal degeneration in *tubby* mice results from apoptotic loss of photoreceptor cells, with abnormal electroretinograms detected as early as 3 weeks of age (Heckenlively et al. 1955). The mouse obesity gene *tubby* has been identified and characterized (Noben-Trauth et al. 1996; Kleyn et al. 1996).

L.2.0.4 Transgenic ANIMALS

PURPOSE AND RATIONALE

Transgenic animals will offer a new approach to study development of obesity and therapeutic possibilities. Lowell et al. (1993) used a transgenic toxigene approach to create transgenic mice with primary deficiency of brown adipose tissue.

The potential for inserting new genetic material into mammals has produced numerous transgenic mice with increased or decreased quantities of body fat (Bray and Bouchard 1997).

Jensen et al. (1997) reported prevention of diet-induced obesity in transgenic mice overexpressing skeletal muscle lipoprotein lipase. The authors hypothesized that the potential to increase lipoprotein lipase activity in muscle by gene or drug delivery may prove an effective tool in preventing and/or treating obesity in humans.

L.3 Assays of Anti-obesity Activity

L.3.1 Anorectic Activity

L.3.1.1 Food Consumption in Rats

PURPOSE AND RATIONALE

Food intake is measured in acute experiments in normal or obese rats. Additionally, in semichronic experiments body weight gain is recorded.

PROCEDURE

Female Zucker rats weighing 250–350 g are maintained under standard conditions (temperature, light-dark cycle, ground rodent pellet chow, tap water). Measurements of food intake begin on day –2. The food is offered in special dishes to reduce spillage. Food intake and body weight are measured daily between 8:00 and 9:00 A.M. At this time any spilled food from the collecting paper under the cage is gathered, air-dried if necessary, and weighed. Individual food intakes in grams are recorded. The tests compounds are either administered with the food or injected intraperitoneally. Groups of 5–10 animals are used for control or treatment with various doses of the test compound or the standard. Mazindol, 3 m/kg i.p. or 10 mg/kg p.o. can serve as standard. Treatment is continued for 7 days.

EVALUATION

Average food intake and body weight is recorded for each day. Average values of test drugs are compared statistically for each day with the control group. Results after oral administration have to be confirmed by parenteral route in order to exclude errors due to palatability.

MODIFICATIONS OF THE METHOD

Hull and Maher, Maher and Hull (1990) used male Sprague-Dawley rats placed on a mush diet composed of equal parts of ground rodent chow and of 4% nutrient agar solution. The agar-based chow allows a more accurate measurement of food intake and has been shown to be sufficient for maintaining normal growth in rats. The rats were made hyperphagic by food deprivation for 4 h at the beginning of the dark cycle.

Mennini et al. (1991) and Anelli et al. (1992) studied the anorectic activity of various compounds in different species, such as mice, rats, and guinea pigs.

Bowden et al. (1988) used metabolism cages equipped with automated feeding monitors. Food was provided as 45 mg pellets which were singly delivered to a feeding trough. A photodetector sensed the removal of the pellet, and the number of pellets delivered over a specified time interval was recorded.

Samanin et al. (1979) described anorexia in rats induced by the central serotonin agonist m-chlorophenylpiperazine.

Blavet et al. (1982) studied food intake in fasted rats after treatment with several typical anorexigenic agents.

Dourish et al. (1985) investigated the effects of the serotonin agonist 8-OH-DPAT on food intake in non-deprived male rats. This effect was prevented by p-chlorophenylalanine (Dourish et al. 1986).

The anxiolytics gespirone, buspirone and ipsapirone increased free feeding in rats and did not inhibit feeding induced by 8-OH-DPAT (Gilbert and Dourish 1987).

Jackson et al. (1997) investigated the mechanisms underlying the hypophagic effects of the 5-HT and noradrenaline reuptake inhibitor, sibutramine, in the rat.

Simansky and Vaidya (1990) tested the anorectic action of a serotonin uptake inhibitor by measuring the volume of milk consumed by food-deprived rats.

Stevens and Edwards (1996) induced anorexia by subcutaneous injection of 5 mg/kg 5-hydroxytryptamine in Wistar rats habituated to a restricted feeding regime and tested the effects of a 5-HT_3 antagonist.

Rouru et al. (1992) investigated in genetically obese male Zucker rats the effect of subchronic metformin treatment on food intake, weight gain and plasma insulin and corticosterone levels and somatostatin concentrations in the pancreas.

Robert et al. (1989) found an enhanced food intake after intracerebroventricular administration of the tetrapeptide FMRF-amide (Phe-Met-Arg-Phe-NH_2) in obese "cafeteria" rats.

Cooper et al. (1990a, b) used non-deprived rats to study anorectic effects in a test of palatable food consumption and in nocturnal free-feeding.

Cooper et al. (1990c) tested not only food consumption but also the frequency of feeding bouts and duration of individual feeding episodes.

Eberle-Wang and Simansky (1992) studied the influence on the anorectic action of CCK and serotonin by measuring the uptake of sweetened mash mixture in rats.

Voigt et al. (1995) studied the involvement of the 5-HT_{1A} receptor in CCK induced satiety by recording food intake during a 2 h test meal in food deprived and in freely feeding rats.

Influence on postprandial satiety in rats was tested by Rosofsky and Geary (1989). Rats were given pelleted chow and water ad libitum. Near the middle of the bright phase of the light-dark cycle, pellets were removed, the animals treated and condensed milk presented 30 min later. Milk consumption was measured at 4-min intervals for 40 min.

Rats show a dramatic and reliable reduction of food intake if they are prefed a low-protein basal diet and then offered a diet that is imbalanced in any of the essential amino acids (Leung and Rogers 1969). This anorectic response has been used by Hammer et al. (1990) to test $serotonin_3$ receptor antagonists.

Tail pinch is an effective stimulant of eating in rats (Antelman and Szechtman 1975; Fray et al. 1982). Clark et al. (1992) reported that N-methyl-D-aspartate lesions of the lateral hypothalamus do not reduce amphetamine or fenfluramine anorexia but enhance the acquisition of eating in response to tail pinch in the rat.

Thurlby and Samanin (1981) studied the effect of anorectic drugs on food-rewarded runway behavior.

Ferrari et al. (1992) studied the effects on anorexia induced by ACTH and immobilization in rats in an X-maze with alternate open and covered arms, each baited with laboratory chow.

Cooper et al. (1993) studied dopamine D-1 receptor antagonists in rats with chronic gastric fistula which were trained to sham-feed a 10% sucrose solution in a 60 min test.

Bickel et al. (2004) analyzed anorectic effects in rodents by measurement of food consumption. Mice or rats were individually placed in Macrolon cages equipped with a device for continuous monitoring of food consumption consisting of a container filled with feed, hanging on an electronic balance. The balance transmits the weight changes of the feed container continuously to a central unit. Data were stored and processed at the end of the experiment. This system, obtained from TSE, Bad Homburg, Germany, can measure food consumption for up to 3 weeks from more than 199 feeding sensors simultaneously. Similar equipment was used by Bauhofer et al. (2002) and Gaetani et al. (2003).

In wild rodents, **hoarding of food** covers the long term alimentary need. In the laboratory, hoarding behavior does not occur in ad libitum fed rats. On the contrary, rats whose energy balance is threatened by previous food restriction hoard as soon as experimental conditions allow to do so. When such a rat gets free access to a food stock (placed outside its usual territory), it carries food into its shelter and accumulates an amount proportionate to its body weight. Fantino et al. (1980, 1986, 1988), Nishida et al. (1990) used the reduction of the amount of food hoarded during a period of 3 h as parameter for anorectic activity of drugs.

Caccia et al. (1993) studied the anorectic effect of D-fenfluramine in the **marmoset** (*Callithrix jacchus*).

Knoll (1979, 1984) described satietin, a anorectic substance which has been isolated from serum of humans and several animal species. Satietin has been reported to be a 50000–70000 dalton MW glycoprotein, containing 14–15% amino acids and 70–75% carbohydrates, surviving digestion with proteases and boiling. Purification of bovine serum satietin was reported by Nagy (1994). These factors suppressed feeding in rats after peripheral and after intracerebroventricular administration.

L.3.1.2 Computer-Assisted Measurement of Food Consumption in Rats

PURPOSE AND RATIONALE

Techniques have been developed for continuous measurement of food consumption in rats.

PROCEDURE

Animals are placed individually in cages (Macrolon cage Type 4, size: 44 × 26 × 15 cm) equipped with a device for continuous monitoring of feed consumption. This device is a container filled with feed and hanging on an electronic balance in the cage. The balance transmits the weight changes of the feed container continuously to a central unit. The data are stored and processed at the end of the experiment. This system can measure feed consumption continuously for up to 2 weeks from up to 64 feeding sensors (animals) simultaneously. The feeding monitoring system and data processing hardware and software (Release V3.07) can be obtained from TSE-Systems, Bad Homburg, Germany. Software options: the data are presented in the form of a matrix. The matrix delivers cumulatively or sequentially feed consumption in grams (g) for given time intervals for each individual animal. The advantages of this system are that the animals are kept in their home cages, that the feed monitoring period is long and, most of all, the animals are left undisturbed during the experimental session. An additional program for microstructural analysis calculates the parameters for feed consumption over a given time (24 h). Parameters delivered are: number of meals (Nm/time), inter-meal breaks (IMB) (min), average meal size (g) and average meal duration (min). In the present study, a meal was defined to be $\geq$0.5 g and the IMB $\geq$15 min. Using this system we have determined the anorectic activity of the central acting anorectic agents amphetamine, sibutramine, and dexfenfluramine (Bickel et al. 2000), as well as the peripheral acting anorectic SR146131, a CCK_A-receptor antagonist (Bickel et al. 2002), and HMR1426, an anorectic drug that powerfully inhibits gastric emptying rate (Bickel et al. 2004).

A 2-week treatment with HMR1426 in Zucker fatty rats fed a normal standard rat diet (1 g feed = 12.1 kJ) reduced the body weight increase significantly by 5% (Gossel et al. 2001). In Zucker fatty rats fed a fat-rich diet (1 g feed = 20.2 kJ), 3 weeks of treatment with HMR1426 caused a significant loss of body weight of 33% (Bickel et al. 2003).

L.3.1.3 The Endocannabinoid System

PURPOSE AND RATIONALE

Recent discovery of cannabinoid receptors and their natural ligands, the endocannabinoids, has initiated the development of synthetic antagonists and agonist of these receptors to better understand the physiological role of the endocannabinoid system. Two types of receptors have been so far identified: the CB_1-receptor present in brain and periphery and the CB_2-receptor found in the periphery only. Both types of receptors are negatively coupled to Ca^{2+} channels through G-proteins (Pertwee 1997; Howlett et al. 2002). Kogan and Mechoulam (2006) gave an overview on the chemistry of endocannabinoids as well as of some synthetic molecules that affect the endocannabinoid system. Matias and Di Marzo (2006) described the enzymes involved in endocannabinoid synthesis and degradation. The endocannabinoid system has emerged as an important neuromodulatory system in the brain (Marsicano and Lutz 2006). Endocannabinoids play important roles in the gastrointestinal tract (Massa and Monory 2006) and in energy metabolism (Pagotto and Pasquali 2006).

For further studies on the pharmacological effects of cannabinoids and cannabinoid antagonists and on cannabinoid receptor binding see Sects. H.1.1.8, H.1.1.8.1, and H.1.1.8.2.

The appetite-stimulating effect of marijuana with its main active ingredient Δ^9-tetrahydrocannabinoid (Δ^9-

THC) has been known for a long time. The demonstration that the endogenous endocannabinoid anandamide induces overeating in rats suggests a physiological role for endocannabinoids (Williams and Kirkham 1999). Further support for this hypothesis came from CB1 receptor knockout mice ($CB1^{-/-}$) which were hypophagic and lean compared to wild-type mice (Cota et al. 2003).

The search for CB_1-receptor antagonists with anorectic properties led to the discovery of SR141716 (rimonabant). The compound inhibited CB_1-receptors in rat brain synaptosomes with an $IC_{50} = 2.35 \pm 0.47$ nM (Rinaldi-Carmona et al. 1996). A large number of different investigators have confirmed the powerful anorectic and antiobesic effect of this drug in various models. Simiand et al. (1998) investigated the anorectic effect in marmosets. Colombo et al. (1998) tested the anorectic effect and body weight reduction in non-obese Wistar rats. Ravinet-Trillou et al. (2003) showed anorectic properties of SR141716 in diet-induced obese mice.

PROCEDURE

Mice were housed on a reverse light-dark cycle (lights off 0900–2100 hours) in a room with temperature (22±2°C) and humidity control. They were fed either a high-fat diet (HFD) of 4.7 cal/g energy density (TD 97366, Harlan; 49% fat, 18% protein, 33% carbohydrate) or a standard mouse diet (STD) containing 2.9 kcal/g (A04C, UAR; 8% fat, 19% protein, 73% carbohydrate). SR141716 [*N*-piperidino-5-(4-chlorophenyl)-1-(2,4-dichlorophenyl)-4-methylpyrazole-3-carboxamide] was administered orally in distilled water with 0.1% Tween 80 just before the onset of the dark phase. A habituation to treatment with the vehicle was performed during the week before the start of treatment.

SR141716 Treatment in DIO Mice

Six-week-old C57BL/6J male mice were given HFD or STD diets for 12–17 weeks before drug treatment started. The mice were weight matched and assigned to one of the following three groups: high-fat diet fed/vehicle-treated (HFD-Veh), high-fat diet fed/SR141716-treated (10 mg/kg) (HFD-SR 10 mg), and standard-diet fed/vehicle-treated (STD-Veh). Body weight and individual food intake were recorded daily. The energy intake was determined taking into account the caloric density of each diet and the average daily energy intake was calculated weekly for each of the 5 weeks of treatment. To balance the wide difference in body weight between the groups, the relative energy intake was calculated by correcting for body weight and was expressed as kilocalories per gram mouse per day × 100. After a 30-day treatment, body fat and lean masses of anesthetized mice were estimated using a small research animal body composition analyzer (model SA-3000, EM-SCAN). The measurement principle is based on the high electrical conductivity in all lean tissues relative to lipids when exposed to an oscillating radio frequency. We previously calibrated the device by using carcass analysis of mice fed a standard or a high-fat diet. Regression models integrating total body electrical conductivity (TOBEC) values and body weights were fitted to chemically analyzed whole-body protein and fat contents (adjusted $r^2 = 0.96$, $P < 0.0001$ for protein, adjusted $r^2 = 0.93$, $P < 0.0001$ for fat). Food deprivation was shown to produce a reduction of metabolic rate in rodents and body weight loss during fasting was reported to be an indicator of this metabolic rate. Thus body weight change during a 24-h fast was measured after 5 weeks of treatment. Finally, additional 18-h-fasted mice were injected intraperitoneally with human recombinant insulin (Sigma) at the dose of 0.6 U/kg. Glycemia was measured before and 30, 60, 90, 120, and 180 min after insulin injection using a glucose analyzer (Bayer Diagnostics) to assess insulin sensitivity.

Another experiment compared a 3-day SR141716 treatment with a caloric restriction. Obese mice were randomized into one of the three treatment groups: a group treated with vehicle, a group treated with SR141716 at the dose of 10 mg/kg per day for 3 days, and a vehicle-treated pair-fed group (HFD-PFVeh) that was fed the same quantity of diet as that consumed by the animals receiving SR141716. Food intake and body weight were monitored daily; lumbar white adipose pads were weighed after death.

SR141716 Treatment in CB1 Receptor Knockout Mice

CB1 receptor knockout ($CB1^{-/-}$) mice were generated. For constructing the targeting vector, a 9-kb *Kpn*I-*Kpn*I fragment including the entire coding region of the CB1-receptor gene was cloned from a 129SvJ6 mouse genomic library. An *Apa*I-*Apa*I fragment containing part of the coding region was inactivated by substitution with a neomycin resistance cassette. The targeting vector was transfected into embryonic stem cells from the 129/Ola line. Then, mutated ES cells were injected into C57BL/6 blastocytes to generate chimeric founder mice. Germline transmission of the targeted allele was determined by PCR analysis of mouse tail genomic DNA. The homozygous $CB1^{-/-}$ mice used in this work were on a C57BL/6X129/Ola

F2 genetic background. The lack of binding of the synthetic CB1 receptor agonist [^{3}H]CP55,940 in these mice was checked by autoradiography in various brain sections. After 6 weeks of a high-fat diet, 15-week-old male CB1$^{-/-}$ mice were either given SR141716 orally at the dose of 10 mg/kg per day or treated with vehicle alone. Body weight and food intake were monitored daily throughout the 3-week treatment period as previously described.

EVALUATION

ANOVA and post hoc analyses were performed using SAS version 8.2. A repeated two-way ANOVA for treatment and time (repeated measures on food intake and body weight) or one-way ANOVA for treatment (all other variables) was used to determine statistical significance. When a single dose of SR141716 was included in the experiment, post hoc comparisons between the SR141716-treated group, obese, and lean control groups were performed after Holm's adjustment. When two doses of SR141716 were studied, comparisons among dietary obese mice receiving each of SR141716 doses versus vehicle were performed by Dunnett's test. When the hypotheses necessary for the application of parametric tests were not achieved, appropriate transformations were applied. The results are presented as means ± SEM.

MODIFICATIONS OF THE METHOD

SR147778, a CB_1-receptor antagonist, was shown to cause a long-lasting anorectic effect in fasted and non-deprived rats and to reduce ethanol drinking in mice. In CHO-cells expressing the *h*CB1-receptor the K_i was 3.5 ± 0.29 nM, whereas the K_i for *h*CB2-receptors was 442 ± 30 nM (Rinaldi-Carmona et al. 2004).

Animals

Male Sprague-Dawley rats (180–250 g) were used for *in vitro* and food intake studies. Male Wistar rats (300 g) obtained from Charles River were used for schedule-induced polydipsia (SIP) studies.

Drug Preparation and Administration

For *in vivo* experiments, drugs were suspended with 0.01% Tween 80 plus DMSO in saline (NaCl 0.9%) for i.v. administration or distilled water for other routes. SR147778 was administered by i.p., p.o., or s.c. routes in a volume of 20 ml/kg body weight.

Voluntary Ethanol Consumption

The test was performed as described by Arnone et al. (1997). One week before testing, mice were singly housed in cages equipped with two bottles of plain water. Mice were then subjected to five daily 6-h test sessions during which they had a free choice between one bottle of water or one filled with a 10% (v/v) non-sweetened ethanol solution. The quantities of the different liquids consumed were measured by weighing the bottle before and after each session. The bottles were regularly checked for possible leakage. SR147778 was administered 30 min before each experiment session.

Spontaneous Sucrose Drinking

Two weeks prior to testing, rats caged individually were given access to a sucrose solution (5%) in their home cage during daily 4-h sessions (without food and water). At the end of the training periods, rats displaying a poor sucrose drinking response were discarded from the study. On the day of the test, rats were administered orally with SR147778 or vehicle in a volume of 2 ml/kg 1 h before the presentation of the sucrose solution. The amount of the sucrose solution drunk by each rat (n = 6–8 per group) was measured by weighing each bottle before and at the end of the 4-h drinking period.

Food Intake in 18-h Fasted Rats

Over a period of 10 days before the experiment, rats were fasted for 18 h and allowed access to food for only 6 h between 10:00 a.m. and 4:00 p.m. each day. Water was available ad libitum. At the end of this adaptation phase, SR147778 or vehicle was administered orally, in a volume of 5 ml/kg, at 9:00 a.m., 1 h after a preweighed amount of food (A04 standard rat laboratory diet) was introduced into the cage, and then food intake was measured (taking into account spillage) at different times.

Spontaneous Feeding in Non-deprived Rats

Rats were maintained in a reversed light/dark cycle (lights off 9:00 a.m. to 9:00 p.m.) with food and water ad libitum. On the day of the experiment, food was removed from the cage at 8:00 a.m., and animals were administered orally with SR147778 or vehicle in a volume of 5 ml/kg at 9:00 a.m. (at the beginning of the dark phase). One hour after, a preweighed amount of food (A04 standard rat laboratory diet) was introduced into the cage, and then food intake was measured (taking into account spillage) at different times.

Schedule-Induced Ethanol Polydipsia

Rats were randomly allocated to drinking either water or ethanol in a protocol of SIP (Falk et al. 1972). They were food deprived (food available for 1 h per

day) but not water deprived. They were trained in operant chambers (40.5 × 31 × 31 cm; Imetronic, Pessac, France) fitted with a food tray where food pellets (45 mg; Bioserv, Phymep, Paris) were delivered every 60 s (FT-60s). Visits to the food tray were automatically recorded. A metal drinking tube protruded into the chamber near the food magazine and was connected to a drinking bottle. Licks of the drinking tube were numbered by the closure of an electric circuit. Bottles were weighed to the nearest 0.1 g at the end of each SIP session. Both groups were trained for 2 weeks, 5 days per week, under the SIP procedure until they drank about 10 ml of plain water, which was then substituted for slightly sweetened solutions (0.05% weight/volume saccharose) of either water or ethanol. Over the next 2 weeks of training, the concentration of ethanol was progressively increased by steps of 2% to reach the final 10% concentration. Fluid consumption was allowed to stabilize over five daily training sessions. Then, each group (ethanol or water) was divided into two subgroups: one treated with one dose of SR147778 administered i.p. 1 h before testing and the other subgroup administered with the corresponding vehicle. As a control, SR141716 was tested at 10 mg/kg in the same conditions. The four subgroups of rats were tested once a week (1-h test session) with a different dose of SR147778 and trained daily (1-h training session) on the 4 remaining days. In the same rats and in the same experimental conditions, the activity of the reference CB1 antagonist, SR141716, had previously been investigated at 10 mg/kg i.p. Data are presented as the mean quantities of water or ethanol consumed during each test session; they were analyzed with Student's *t*-test to compare the quantities of water or ethanol rats drank after administration of SR147778 or vehicle during a given test session.

Data Analysis

Data from competition experiments (IC_{50}, EC_{50}, and DE_{50}) were analyzed using a non-linear least-squares method. K_d values of 0.09± 0.01 nM (brain), 0.309± 0.031 nM (hCB1), 0.17± 0.03 nM (spleen), and 0.49± 0.11 nM (hCB2) were used to determine K_i values. A Schild plot was constructed to estimate the pA_2 value in mouse vas deferens and adenylyl cyclase studies. Statistical significance was determined by Student's *t*-test, and $p < 0.05$ was considered significant. For *in vivo* pharmacological tests, statistical analysis was performed using ANOVA followed by Dunnett's *t*-test. ID_{50} values were calculated using the Pharmacofit method.

Matias et al. (2006a) described regulation of the levels of endogenous cannabinoids in the brain and peripheral tissues and the control of food intake.

Mechoulam et al. (2006) reviewed the effects of endocannabinoids on feeding and suckling.

Regulation, function and dysregulation of endocannabinoids in models of adipose and β-pancreatic cells and in obesity and hyperglycemia are described by Matias et al. (2006b).

L.3.2 Metabolic Activity

L.3.2.1 GDP-Binding in Brown Adipose Tissue

PURPOSE AND RATIONALE

Brown adipose tissue is the major site for non-shivering thermogenesis in rodents (Ricquier and Mory 1984; Foster 1986). Drugs activating brown adipose tissue thermogenesis via β-adrenoceptors cause uncoupling of oxidative phosphorylation from electron transport (Arch et al. 1984; Nicholls et al. 1986). The binding of the nucleotide guanosine diphosphate (GDP) to brown adipose tissue membrane protein, the uncoupling protein or thermogenin (Ricquier and Bouillaud 1986), is an established indicator of the thermogenetic activity of brown adipose tissue (Milner et al. 1988).

PROCEDURE

Obese male fatty Zucker rats at the age of 13 weeks weighing about 450 g receive various doses of the test compound in the drinking water or tap water as control for 21 days. Food intake is measured every day and body weight every other day. At the end of the treatment, the rats are sacrificed by decapitation and interscapular brown adipose tissue is quickly dissected from surrounding tissue.

According to the method published by Nicholls (1976) brown adipose tissue is minced, diluted with 250 mM sucrose and homogenized with a Potter S homogenizer (B. Braun Melsungen, Germany). The homogenate is centrifuged for 10 min at 8500 *g*. The pellet is diluted with 250 mM sucrose and centrifuged at 700 *g* for 10 min. The supernatant is collected and centrifuged at 8500 *g* for 10 min. Bovine serum albumin at 0.2% is added to wash the suspension of the pellet, which now consists of mitochondria. After centrifugation (8500 *g*) the resulting pellet is suspended in albumin-free sucrose buffer. The binding of [3H]-GDP (DuPont NEN, Boston MA) to mitochondria of single rats is determined by incubating mitochondria in a basic medium containing 100 mM sucrose, 20 mM TES (*N*-tris-[hydroxymethyl]-methyl-2-aminoethanesulphonic acid), 1 mM EDTA, 10 mM choline chloride, 2 µM rotenone, [^{14}C]sucrose (0.125 µCi ml^{-1}) and 10 µM [^{3}H]-GDP (0.53 Ci mmol^{-1}) at room temperature. Non-specific binding is assessed in the presence of unlabelled GDP (1 mM). After 10 min of incubation, the reaction is terminated by filtration the mixture through Thomas A/E glass fibre filters by using a Brandel cell harvester. The radioactivity is measured with the Opti Phase 'High Safe' II scintillation cocktail and a scintillation counter enabling the samples to be counted for both ^{3}H and ^{14}C. The protein content of the mitochondrial suspensions is assayed according to the method of Peterson (1977).

EVALUATION

GDP binding is assessed from ^{3}H radioactivity with a correction for trapped medium using [^{14}C]-sucrose. Two way analysis of variance (ANOVA) is performed.

MODIFICATIONS OF THE METHOD

Glucose is a minor substrate for isolated brown adipocytes, fuelling thermogenesis by a maximum of 16% (Isler et al. 1987).

The mechanism of anti-obesity action of a dihydropyridine calcium antagonist was studied by Yoshida et al. (1994b). Obesity was induced by subcutaneous injection of 2 g/kg monosodium-L-glutamate immediately after birth for 5 consecutive days in ICR female mice. Binding of GDP and cytochrome c oxidase activity in brown adipose tissue mitochondria were significantly increased after 4 weeks drug treatment incorporated in the diet.

Yoshida et al. (1984, 1985) found a reduced norepinephrine turnover in brown adipose tissue of mice with monosodium glutamate-induced obesity.

Kajita et al. (1994), Takahashi et al. (1994) determined regional blood flow in brown adipose tissue by the microsphere method in anesthetized rats.

Yoshida et al. (1996) determined the effect of mazindol on noradrenaline turnover in brown adipose tissue of yellow KK mice and C57B1 control mice.

L.3.2.2 Uncoupling Protein and GLUT4 in Brown Adipose Tissue

PURPOSE AND RATIONALE

Uncoupling proteins (UCPs) are a family of inner mitochondrial membrane transporters which dissipate the proton gradient, releasing stored energy as heat. UCP1 is expressed exclusively in brown adipocytes, UCP2 is expressed widely, while UCP3 is found in skeletal muscle and brown adipose tissue (Vidal-Puig et al. 1997; Fleury et al. 1997; Masaki et al. 1997; Matsuda et al. 1997; Boss et al. 1997; Gong et al. 1997; Larkin et al. 1997). They are upregulated by thyroid hormones (Larkin 1997; Masaki 1997; Branco et al. 1999; Lanni et al. 1999). Mao et al. (1999) identified and characterized a novel member of the human uncoupling protein family, termed uncoupling protein-4 (UCP4).

In addition to the binding of the nucleotide guanosine diphosphate (GDP) to brown adipose tissue membrane protein, the uncoupling protein itself, and the glucose transporter 4 (GLUT4) were determined by RNA (Northern blot) analysis and by protein (Western blot) analysis as indicators of the thermogenetic activity of brown adipose tissue.

PROCEDURE

Male fatty (OLETF fatty) rats at the age of 10 weeks are given subcutaneous injection of test compound or

solvent once daily. After 14 weeks treatment, the rats are sacrificed and brown and white adipose tissue samples rapidly removed.

Northern Blot Analysis

Total RNA is extracted from 0.1–1 g of tissue using TRIzol (Gibco) and the concentration determined from the absorbance at 260 nm. Total RNA (20 mg) is separated on a 1.5% agarose/formaldehyde gel, and transferred to and fixed on a nylon membrane. A 488 bp uncoupling protein cDNA probe corresponding to the coding region of rat uncoupling protein is prepared by digesting the whole uncoupling protein cDNA with BamHI. The uncoupling protein probe and GLUT4 cDNA are labeled with α-[^{32}P]dCTP (deoxy-cytidine-triphosphate). The blots are hybridized to the labeled probes at 42°C for 20 h in the presence of 500 µg/ml salmon sperm DNA, and exposed to an X-ray film for autoradiography and an imaging plate of BAS1000 (Fuji Film) for quantitative analysis.

Western Blot Analysis

Each tissue is homogenized in 5–10 volumes of a solution containing 10 mmol/l Tris-HCl and 1 mmol/l EDTA (pH 7.4) for 30 s with a Polytron. After centrifugation at 1500 *g* for 5 min, the fat cake is discarded, and the infranatant (fat-free extract) is used for protein determination according to Lowry et al. (1951) and cytochrome C oxidase activity (Yonetani and Ray 1965). Uncoupling protein and GLUT4 protein in the fat-free extract is measured by Western blot analysis. The fat-free extracts (10 µg protein of brown adipose tissue, 20 µg of white adipose tissue) are solubilized, subjected to sodium dodecyl sulfate-polyacrylamide gel electrophoresis, and transferred to a nitrocellulose filter. After blocking with 5% non-fat dry milk, the filter is incubated with rabbit antiserum against rat uncoupling protein or GLUT4. The rabbit antisera against rat uncoupling protein and GLUT4 are prepared by immunizing purified rat uncoupling protein (Lin and Klingenberg 1980) and a 12-amino acid peptide corresponding to GLUT4 (residues 498–509, TELEYLGPDEND) (Shimizu et al. 1993) respectively, coupled with keyhole limpet hemocyanin. Then the filter is incubated with [^{125}I]protein A (ICN). The dry blot is exposed to an X-ray film for autoradiography and an imaging plate of BAS1000 (Fuji Film) for quantitative analysis.

EVALUATION

Data are expressed as means ± SEM and are analyzed by two-way ANOVA followed by Bonferroni *t*-test.

MODIFICATIONS OF THE METHOD

A radioimmunoassay to measure uncoupling protein was used by Milner et al. (1988).

Scarpace et al. (2000) performed unilateral surgical denervation of the interscapular BAT in rats under pentobarbital anesthesia according to Bartness et al. (1986). A transverse incision was made just anterior to the BAT, separating the BAT from the muscles of the scapulae. The BAT was raised to expose the five intercostal nerve bundles entering each pad. On one side, a section of each nerve bundle was removed with scissors. Denervation can be verified by assessing norepinephrine levels in the innervated compared with the denervated BAT pads (Scarpace and Matheny 1996).

Puigserver et al. (1996) studied the effects of retinoic acid isomers on the appearance of uncoupling protein in primary cultures of brown adipocytes, in the brown adipocyte cell line HIB 1B and directly in intact mice.

Shimabukuro et al. (1997) reported the induction of uncoupling protein-2 mRNA in the pancreatic islets of Zucker diabetic fatty rats by troglitazone.

Foellmi-Adams et al. (1996) found a synergy between norepinephrine and pioglitazone in induction of uncoupling protein in mice.

Kotz et al. (2000) determined uncoupling protein 1 (UCP1) in brown adipose tissue, UCP2 in white adipose tissue and UCP3 in muscle of male Sprague Dawley rats after injection of neuropeptide Y into the hypothalamic paraventricular nucleus.

Great efforts have been devoted to study the influence of **β_3-adrenergic agonists** on formation of uncoupling protein.

Umekawa et al. (1997) found an induction of uncoupling protein and activation of GLUT4 in white fat of Otsuka Long-Evans Tokushima fatty rats after treatment with a specific β_3-adrenoceptor agonist.

Ghorbani and Himms-Hagen (1997) found appearance of abundant densely-stained brown adipocytes expressing uncoupling protein in white adipose tissue during reversal of obesity and diabetes in Zucker fa/fa rats induced by the β_3-adrenoceptor agonist CL316,243.

Nagase et al. (1996) found in yellow obese KK mice after treatment with a β_3-adrenergic agonist a significant reduction of body weight, associated with a marked decrease of white fat pad weight and hypertrophy of the interscapular brown adipose tissue with a sixfold increase in mitochondrial uncoupling protein content.

Liu et al. (1995, 1996), Stock (1997) reported an increase of glucose utilization in rat brown adipose tis-

sue after treatment with a β_3-adrenoreceptor agonist or with sibutramine, a serotonin and noradrenaline reuptake inhibitor.

Savontaus et al. (1998) reported an increase of UCP3 and UCP1 in brown adipose tissue of obese fa/fa Zucker rats after chronic administration of a β_3-adrenoreceptor agonist.

The effects of β_3-adrenoceptor agonists on uncoupling protein-1 and leptin in culture-differentiated rat brown fat cells are antagonized by a β_3-adrenoreceptor antagonist (Tonello et al. 1998).

Berraondo et al. (2000) found an up-regulation of muscle UCP2 gene expression by a β_3-adrenoreceptor agonist in obese rodents, but down-regulation in lean animals.

Paulik and Lennard (1997) found an increased expression of uncoupling protein in C3H10T1/2 cells, a pluripotent stem-cell line, after addition of **thiazolidinediones**.

L.3.2.3 Resting Metabolic Rate

PURPOSE AND RATIONALE

Resting metabolic rate can be influenced by various drugs both in normal and obese animals.

PROCEDURE

Female yellow KK mice and female C57B1 mice at the age of 12 weeks are housed under controlled temperature and artificial light/dark conditions and are fed with commercial powdered chow and tap water ad libitum. Groups of each strain are treated with doses of test drug or solvent by daily intramuscular injections for 2 weeks. Daily food intake and body weight is measured.

Resting metabolic rate is estimated by means of a closed-circuit metabolic system (Molnar et al. 1986). The system consists of a chamber, circulating pump, desiccant and CO_2-absorbent canisters, solenoid valve, regulated gas source, and modified liquid crystal display calculator. The internal volume of a chamber for a single rat should be 4.5 liters. Food cups are placed on the door for convenient access when refilling. Water is supplied in a tray filled intermittently by means of a stopcock in the chamber wall. A shallow stainless steel funnel-shaped tray for urine collection is located in the bottom of the chamber.

Animals are placed in the chamber and the door is sealed airtight. Chamber air circulates by means of a peristaltic pump at a rate of 2.3 l/min through an external loop containing canisters of desiccant and CO_2-absorbent. In this manner, water vapor pressure remains constant and the respiration by-product, CO_2, is removed. Consumption of O_2 produces a pressure drop in the sealed system which actuates the pressure sensor for O_2 replacement.

The pressure sensor has two input ports, low and high, producing a simple contact closure whenever the high pressure exceeds the low by ~1 Torr. The low port is connected to the interior of the metabolic chamber by a length of tubing attached to a threaded connector, whereas the high port is open to the atmosphere. Thus the contact closes whenever the pressure within the chamber falls to more than 1 Torr below atmospheric pressure.

The contact closure is routed to the control unit where a precise pulse of fixed duration is triggered. This pulse activates a solid-state relay through an emitter-follower transistor circuit. The relay output is in series with a solenoid valve and line voltage, so that contact closure results in opening of the valve for a fixed duration. Since the input port of the valve is at a constant pressure, a predictable, highly repeatable volume of gas flows into the chamber. This raises the chamber pressure and opens the pressure sensor contacts. The entire cycle repeats after sufficient metabolism to again decrease the chamber pressure and close the sensor contacts.

After a stable baseline has been achieved after 30 min, drugs are administered and resting metabolic rate is measured for one hour at an ambient temperature of 22°C.

EVALUATION

Data are presented as means ± SEM. Statistical analysis is performed by Student's *t*-test.

MODIFICATIONS OF THE METHOD

Poon and Cameron (1978) measured oxygen consumption utilizing a standard Machlett manometer connected to a desiccator that accommodated a single mouse. The desiccator was placed in a 20°C water bath to ensure constant temperature throughout and CO_2 was absorbed by means of soda lime UPS. After a 5-min equilibration period, measurements of oxy-

gen consumption were obtained over a 5-min period. The procedure was repeated twice within 1 h for each mouse.

In order to study differential antagonism to amphetamine-induced oxygen consumption and agitation by psychoactive drugs Niemegeers and Janssen (1979) placed groups of 3 rats with a total weight of 235 ± 5 g consisting of 2 parts, a bottom and a cover, both made up from clear glass. The cover, containing a thermometer, was used to seal the chamber airtight. Inside the chamber a perforate plate was placed as animal platform. Containers filled with calcium oxide were placed below and above the animal holder. The chamber was flushed with oxygen for 3 min at an overpressure of 50 units as measured by a manometer connected to one outlet of the chamber. Test drugs were administered subcutaneously 60 min before the animals were placed in the test chambers and 45 min before 2.5 mg/kg amphetamine were injected. Oxygen consumption was measured as decrease of manometer pressure over one hour.

Rothwell (1989) measured central activation of thermogesesis by prostaglandins by resting oxygen consumption in individual closed-circuit calorimeters (Stock 1975) and by registration of colonic temperature in conscious rats.

Jensen et al. (2001) described a self-correcting indirect calorimeter system for the measurement of energy balance in small animals.

Himms-Hagen et al. (1994) tested the effect of a thermogenic β_3-agonist on energy balance in rats. Twenty-four hours energy expenditure, resting metabolic rate, and thermic effect of food were measured using open-circuit indirect calorimetry. The rat was placed in a respiration chamber (44 × 22 × 18 cm), airflow was measured with a Brooks thermal mass flowmeter (Brooks Instrument Division, Emerson Electric, Hatfield, PA), and the flow of outside air through the chamber was controlled at a variable rate by two adjustable peristaltic pumps that maintained CO_2 concentration at <1%. Temperature was maintained at 23 ± 1.0°C. Humidity was measured by an electronic psychrometer, barometric pressure was recorded, and feeding activity was monitored by an infrared detector. The rat was placed into the chamber at 09:30 and removed at 08:30 at the following morning. Food was available to the rat only between 16:30 and 07:30. Total energy expenditure was measured for 23. Resting metabolic rate was determined from the lowest energy expenditure at rest between 11:00 and 16:00. Thermic effect of food was determined from the difference between resting metabolic rate and the lowest energy expenditure at rest between 24:00 and 07:00. For the measurement of minimum metabolic rate, the rat was anesthetized (pentobarbital sodium, 60 mg/kg) and then placed in a small chamber filled with warm circulating water in which it was submerged except for the head. Core temperature was measured with a digital thermometer immediately after induction of anesthesia, and this temperature was maintained (± 0.1°C) by adjusting the temperature of the circulating water bath. The chamber was sealed and minimum metabolic rate determined with the same equipment as was used for the 24-h energy expenditure. Measurements of minimum metabolic rate were made for 5–15 min between 08:30 and 09:30 after a stabilization period of 5–10 min.

Ghorbani et al. (1997) tested the effect of a β_3-adrenoreceptor agonist on resting metabolic rate in rats by placing the animal in a water-jacketed chamber at 28°C, volume 1 liter, through which air, also at 28°C, was drawn at a rate of 1 l/min. Oxygen entering and leaving the chamber was measured with an oxygen analyzer (Beckman Industrial Oxygen Analyzer, model 755).

Paulik et al. (1998) described a robust technique to measure thermogenesis of **yeast cells** cultured in microtiter plates using infrared thermography. Thermogenesis increased after exposing yeast to uncoupling protein-2, or troglitazone or β_3-adrenoreceptor agonists.

L.3.2.4 β_3-Adrenoceptor

PURPOSE AND RATIONALE

β_3-adrenoreceptor agonists produce weight loss in obese rodents (Yoshida et al. 1994; Weyer et al. 1999) which is almost entirely accounted for a reduction in body fat. As this effect is observed without a decrease in food intake, it is thought to be due to increased thermogenesis in brown adipose tissue, increased lipolysis in white adipose tissue, and suppression of leptin gene expression and serum leptin levels (Arch and Wilson 1996; Kumar et al. 1999).

The β_3-adrenoreceptor has been cloned and characterized in animals (Granneman et al. 1991; Nahmias et al. 1991; Evans et al. 1996) as well as from man (Emorine et al. 1989; Strosberg 1997). However, the physiological function of the human β_3-adrenoreceptor, the significance of animal data with β_3-adrenoreceptor agonists, and even the presence of a putative fourth β-adrenoreceptor in human adipose tissue are still a matter of debate (Emorine et al. 1994; Galitzky et al. 1998; Kaumann et al. 1998; Sarsero et al. 1998; Strosberg et al. 1998; Weyer et al. 1999).

The development of a Chinese hamster ovary cell transfection system, using the human β_3-adrenoreceptor gene resulted in potential new selective β_3-agonists being identified (Carruba et al. 1998). Human β_1-, β_2- and β_3-adrenoreceptors expressed in Chinese hamster ovary (CHO) cells were used to evaluate potential β_3-adrenoreceptor agonists by He et al. (2000).

PROCEDURE

cAMP Response Element-Luciferase Receptor Gene Assay

CHO cells stably expressing human β_1-, β_2- or β_3-adrenoreceptor populations are transfected with cAMP response element-luciferase plasmids using electroporation with a single 70-ms, 150-V pulse (Vansal and Fellner 1999). The transfected cells are seeded at a density of 40000/well in 96-well microtiter plates and allowed to grow for 20 h. After 20 h, the cells are treated with varying drug concentrations (10^{-11} to 10^{-4} M) for 4 h. Following drug exposure, the cells are lysed and luciferase activity is measured using the LucLite assay kit (Packard). Changes in light production are measured by a Topcount luminometer (Packard).

EVALUATION

Data are analyzed in duplicate at each concentration and expressed as percent luciferase response relative to the maximum response to (–)-isoproterenol (10^{-6} M). Results are expressed as the mean ± SEM.

MODIFICATIONS OF THE METHOD

Gettys et al. (1996) reported that the β_3-adrenergic receptor inhibits insulin-stimulated leptin secretion from isolated rat white adipocytes.

Using reverse transcription-polymerase chain reaction, Evans et al. (1998) compared levels of β_3-adrenoreceptor mRNA in white adipose tissue, brown adipose tissue, ileum and colon from genetically obese (*ob/ob*) and lean (+/+) C57BL/6J mice.

Bioassays

Tomiyama et al. (1998) studied β-adrenoreceptor subtypes mediating ureteral relaxation in rats, rabbits and dogs. β_3-adrenoreceptor agonists were more effective in relaxing canine ureter than β_1- and β_2-adrenoreceptor agonists.

Koike et al. (1997) reported that the relaxant responses in the guinea pig taenia caecum are mediated by both the β_2- and β_3-adrenoreceptors.

L.4 Assays of Obesity-Regulating Peptide Hormones

L.4.0.1 Hormonal Regulation of Food Intake

Food intake and fat deposition are regulated by neurotransmitters peptides, most of the located in the brain, particularly in the hypothalamus (Elmquist et al. 1999; Kalra et al. 1999) and in the gut. This includes peptides that are **orexigenic** (appetite-stimulating) signals and **anorectic** peptides. A review was given on investigational antiobesity agents and obesity therapeutic treatment targets by Bays (2004).

Neuropeptide Y (NPY), orexins A and B, galanin, melanin concentrating hormone (MCH), and **agouti-related peptide (AgRP)** all act to stimulate feeding, while **alpha-melanocyte stimulating hormone (αMSH)**, (see N.10.1), **corticotropin releasing hormone (CRH)**, (see N.9.4), **cholecystokinin (CCK)**, (see J.7.0.10), **cocaine and amphetamine regulated transcript (CART), neurotensin, glucagon-like peptide 1 (GLP_1)**, (see K.4.0.3), **calcitonin gene related peptide (CGRP)**, (see N.10.3), **bombesin** (see J.3.1.8) and **ciliary neurotropic factor** (Xu et al. 1998) have anorectic actions (Tritos et al. 1999).

Mutations reducing the functional activity of leptin, the leptin receptor, α-MSH, and the melanocortin-4 receptors lead to obesity in animals. *Mc4r*-deficient ($Mc4r^{-/-}$) mice do not respond to the anorectic actions of MTII, an MSH-like antagonist, suggesting that α-MSH inhibits feeding primarily by activating Mc4r (Marsh et al. 1999).

Leptin (see L.4.1) is a 167 amino acid protein that is synthesized and secreted primarily by white adipose tissue, circulates in the blood and acts on receptors in the hypothalamus to decrease food intake and increase energy expenditure (Friedman and Halaas 1998; Trayhurn et al. 1999). Leptin and its derivatives are candidates for treatment of obesity, however, clinical studies (Considine et al. (1996) showed that most of obese humans have higher plasma levels of leptin than non-obese individuals, suggesting that obesity is associated with leptin resistance rather than leptin deficiency.

Neuropeptide Y (NPY) (see L.4.2) is a 36 amino acid peptide that is widely distributed throughout both the central and peripheral nervous systems and which plays a key role in the control of body weight. Central administration of NPY increases food intake (Stanley et al. 1992), while a reduction in endogenous neuropeptide Y leads to a decrease of food intake (Lambert et al. 1993). NPY antagonists are candidates for anti-obesity drugs.

Orexin-A and orexin-B (see L.4.3) are 33- and 28-residue peptides, also called hypocrites, which were originally isolated from rat hypothalamus (Sakurai et al. 1998). These peptides are located predominantly in the hypothalamus and locus coeruleus but are also found elsewhere in the brain. The orexins have a broad range of physiological functions, including the con-

trol of feeding and energy metabolism. Food consumption is dose-dependently increased after intracerebroventricular infusion of orexin A and orexin B to rats (Jain et al. 2000). Orexin antagonists are potential anti-obesity drugs (Parker 1999).

Galanin (see L.4.4) is 29 amino acid C-terminally amidated peptide (30 amino acids in humans) which is localized mainly in the mammalian CNS, but also in other organs. Central administration of galanin increases and administration of galanin receptor antagonists (Crawley et al. 1990; Leibowitz and Kim 1992) decreases food intake. These data suggest the use of galanin receptor antagonists as anti-obesity agents.

Agouti-related protein affects pigmentation when its expression is limited to the skin, but ubiquitous expression causes obesity (Ollmann et al. 1997). The hypothalamic expression of agouti related protein is regulated by leptin, and overexpression of agouti related protein results in obesity and diabetes (Rosenfeld et al. 1998). Recombinant Agouti-related protein is a potent, selective antagonist at MC3R and MC4R, melanocortin receptor subtypes implicated in weight regulation (Fong et al. 1997; Shutter et al. 1997; Tota et al. 1999). Ubiquitous expression of human Agouti-related protein complementary DNA in transgenic mice caused obesity without altering pigmentation. Agouti-related protein is a neuropeptide implicated in the normal control of body weigh downstream of leptin signaling. Ollmann et al. (1998) used a sensitive bioassay based on *Xenopus* melanophores to characterize pharmacological properties of recombinant Agouti protein.

Melanin concentrating hormone (MCH) is a cyclic 19 amino acid neuropeptide that was originally found to regulate pigmentation in fish. It plays a role in the central feeding behavior increasing food consumption (Qu et al. 1996; Rossi et al. 1999). Mice carrying a targeted deletion of the MCH gene are hypophagic and lean (Shimada et al. 1998). Among other factors, MCH may be a target of leptin signaling in the hypothalamus (Sahu 1998; Huang et al. 1999). Melanin-concentrating hormone is a functional melanocortin antagonist in the hypothalamus (Ludwig et al. 1998). MCH has been identified as the natural ligand for the orphan somatostatin-like receptor 1 (SLC-1) (Bacher et al. 1999; Chambers et al. 1999; Shimomura et al. 1999) which has been characterized by Saito et al. (1999). High binding capacity for MCH was found in human keratinocytes (Burgaud et al. (1997). Radioligands for the mammalian MCH receptor were described by Hintermann et al. (1999).

Cocaine- and amphetamine-regulated transcript (CART), a brain located peptide, has potent appetite suppressing activity and is closely associated with the actions of leptin and neuropeptide Y (Lambert et al. 1998; Kuhar and Dall-Vechia 1999). When injected intracerebroventricularly into rats, recombinant CART peptide inhibits both normal and starvation-induced feeding, and completely blocks the feeding response induced by neuropeptide Y (Kristensen et al. 1998). In the rat the CART gene encodes a peptide of either 129 or 116 amino acids whereas only the short form exists in humans (Thim et al. 1998a, b). A role of CART peptides in substance abuse and addiction is suggested by psychomotor-stimulant regulation of CART transcription in the striatum, as well as its localization within neural circuits that mediate reward and reinforcing behaviors (Couceyro and Lambert 1999). CART has been found not only in the hypothalamus and other brain areas (Broberger 1999; Koylu et al. 1998, 1999) but also in other organs, such as the pancreas (Jensen et al. 1999), in the rat sympatho-adrenal axis (Dun et al. 2000), or in the vagal afferent neurons sensitive to cholecystokinin (Broberger et al. 1999). CART can cross the blood-brain barrier (Kastin and Akerström 1999). CART receptor agonists are potential anti-obesity drugs (Couceyro and Lambert 1999).

Resistin

Steppan et al. (2001a), Berger (2001), Steppan and Lazar (2002, 2004), and Banerjee and Lazar (2004) showed that adipocytes secrete a signaling molecule with 114 amino acids in length which is called **resistin** (for resistance to insulin) and which links obesity to diabetes (Haluzik and Haluzikova (2006). Circulating resistin levels in mice are increased in diet-induced and genetic forms of obesity and are decreased by thiazolidindiones (see K.5.0.6). Central administration of resistin promotes short-term satiety in rats (Tovar et al. 2005). Administration of anti-resistin antibody improves blood sugar and insulin action in mice with diet-induced obesity. Treatment of normal mice with recombinant resistin impairs glucose tolerance and insulin action. Insulin-stimulated glucose uptake by adipocytes ins enhanced by neutralization of resistin and is reduced by resistin treatment. Resistin with slightly modified amino acid sequence has also been found in humans.

Steppan et al. (2001b) described a family of tissue-specific **resistin-like-molecules (RELMs).** RELMα is a secreted protein that has a restricted tissue distribution with highest levels in adipose tissue. Another family member, RELMβ, is a secreted protein expressed

only in the gastrointestinal tract, particularly in the colon, in both mouse and human. RELMβ gene expression is highest in proliferative epithelial cells and is markedly increased in tumors, suggesting a role in intestinal proliferation.

Banerjee et al. (2004) generated mice deficient in resistin by replacing the coding exons of the resistin gene(*rstn*) with the reporter gene *lacZ*. The mice exhibited low blood glucose levels after fasting due to reduced hepatic glucose production indicating a physiological function of resistin in maintenance of blood glucose during fasting. The lack of resistin diminished the increase in post-fast glucose associated with increased weight, suggesting a role for resistin in mediating hyperglycemia associated with obesity.

L.4.1
Leptin

L.4.1.1
General Considerations on the Obese Gene Product Leptin

The obese gene product leptin is a cytokine-like nonglycosylated peptide of 146 amino acids that is secreted from adipose tissue. It is an important circulating hormone for the regulation of body weight (Arch and Beeley 1996; Hamann and Matthaei 1996; Friedman and Halaas 1998; Trayhurn 1999). MacDougald et al. (1995) described the expression of the obese gene product (leptin) in white adipose tissue and 3T3-L1 adipocytes.

The mouse obese gene and its human homologue which show approximately 85% amino acid homology have been cloned by Zhang et al. (1994). Leptin binding was first reported in rat hypothalamic membranes (Stephens et al. (1995).

A **leptin receptor** was subsequently identified by expression cloning from a mouse chorioid plexus cDNA library (Tartaglia et al. 1995). Several transcripts of the leptin receptor as a result of alternative splicing which have different length of cytoplasmatic region have been identified in mice and rats (Guan et al. 1997; Igel et al. 1997; Murakami et al. 1997) as well as leptin receptors in man (Maffei et al. 1995, 1996; Liu et al. 1997; Strosberg and Issad 1999). There are at least five different isoforms of the leptin receptor in mice. Mutations in the leptin receptor lead to massive obesity in *db* mice and *fa* rats (Friedman and Halaas 1998).

Administration of recombinant human leptin to mice increases thermogenesis and lipid oxidation in brown fat coupled with increased lipolysis and decreased fat synthesis in white and brown fat, which lead to a rapid reduction in the body weight (Sarmiento et al. 1997).

Leptin increases uncoupling protein expression in brown adipose tissue and oxygen consumption in mice (Scarpace et al. 1997).

Intracerebroventricular injection of recombinant murine leptin produces a dose-dependent reduction of laboratory diet in normal rats. This effect is attenuated in rats with diet-induced obesity (Widdowson et al. 1997).

The role of leptin in human obesity is controversial. Rare forms of human obesity have been identified where mutations in leptin or its receptor play a major role in the development of the disease. Leptin may be a signal for the onset of puberty in humans (Strosberg and Issad 1999). Leptin activates leptin-receptor expressing neurons in the arcuate region of the hypothalamus. Projections from these neurones stimulate melanocortin MC_4 receptors and neuropeptide Y-containing neurones to activate the sympathetic nervous system which controls lipolysis in white adipose tissue. The firing of gonadotrophin-releasing hormone-containing neurons and secretion of gonadotrophin-releasing hormone to the pituitary is elicited by leptin-mediated activation of leptin-receptor-expressing neurons and by other factors that control the reproductive axis (Chebab 2000).

Grasso et al. (1997, 1999) found inhibitory effects of leptin-related synthetic peptides on food intake and body weight gain after intraperitoneal administration in female C57BL/6J*ob/ob* mice which may have potential application to the treatment of human obesity.

Ducy et al. (2000) and Takeda et al. (2002) suggest that leptin inhibits bone formation, probably via the sympathetic nervous system.

Dumond et al. (2003) showed in rats that leptin strongly stimulated anabolic functions of chondrocytes and induced the synthesis of IGF-1 and TGFβ 1 in cartilage at both the messenger RNA and protein levels. A key role of leptin in osteoarthritis was assumed.

L.4.1.2 Determination of Leptin mRNA Level in Adipose Tissue

PURPOSE AND RATIONALE

Leptin mRNA levels in adipose tissue can be determined by Northern blot analysis (Friedrich et al. 1995; Harris et al. 1996; Zachwieja et al. 1997; Kochan et al. 1999).

PROCEDURE

Male Wistar rats weighing approximately 230 g treated for 14 days with test drug are sacrificed by decapitation. Liver, epididymal white adipose tissue and intracapsular brown adipose tissue are rapidly removed and frozen in liquid nitrogen. Total RNA is extracted from frozen tissues by a guanidinium thiocyanate-phenol/chloroform method (Chomczynski and Sacchi 1987). The RNA (10 µg per lane) is fractionated by horizontal gel electrophoresis. The RNA is transferred to a positively charged nylon membrane and fixed with UV-light. Pre-hybridization is performed at 42°C for 45 min in pre-hybridization solution containing 7% sodium dodecyl sulfate, 50% formamide, 5× saline-sodium citrate buffer, 2% blocking reagent (Boehringer Mannheim, Mannheim, Germany), 50 mM sodium phosphate (pH 7.0) and 0.1% N-laurylsarcosine. Hybridization is performed at 42°C overnight in pre-hybridization solution containing oligonucleotide probe (25 ng/ml) specific to leptin, malic enzyme or 185 RNA. The following post-hybridization washes are performed: twice for 5 min in 2× saline-sodium citrate buffer/0.1% sodium dodecyl sulfate (at room temperature): twice for 15 min in 0.1× saline-sodium citrate buffer/0.1% sodium dodecyl sulfate (at 48°C). The membranes are then rinsed briefly with washing buffer containing 0.1 M maleic acid (pH 7.5), 0.15 M NaCl and 0.3% Tween 20. They are blocked by incubation for 30 min at room temperature with blocking buffer (1% blocking agent, 0.1 M maleic acid (pH 7.5), 0.15 M NaCl) and incubated (at the same conditions as described above) with blocking buffer containing a polyclonal antibody against digoxigenin conjugated to alkaline phosphatase. After washing twice for 15 min with washing buffer, the membranes are rinsed for 5 min with detection buffer (0.1 M Tris-Cl, pH 9.5, 0.1 M NaCl) and immersed for 5 min in CDP-Star solution (Boehringer Mannheim, Mannheim, Germany). Membranes are exposed to Kodak XAR film for 15 min to 1 h (Karbowska et al. 1999).

EVALUATION

Signals are scanned and quantified using the NIH-Image software. The level of mRNA for leptin and malic enzyme as well as for 185 RNA is estimated using PeakFit software (Jandel Scientific). The values for leptin and malic enzyme mRNA are normalized to the corresponding amount of 185 RNA. Results expressed in arbitrary units are presented as means ± SEM of samples of 10 rats. The statistical difference between groups is assessed by one-way analysis of variance (ANOVA) followed by Student's *t*-test or by Mann-Whitney test.

MODIFICATIONS OF THE METHOD

Richards et al. (2000) described quantitative analysis of leptin mRNA using competitive reverse transcription polymerase chain reaction and capillary electrophoresis with laser-induced fluorescence detection.

Shintani et al. (2000) determined leptin mRNA levels in primary cultured rat adipocytes.

Li et al. (1999) used an anti-leptin polyclonal antiserum to detect leptin-immunoreactivity in the central nervous system in rats.

L.4.1.3 Determination of Plasma Leptin

PURPOSE AND RATIONALE

Plasma leptin levels are determined by radioimmunoassay using a rat-specific antibody (Ciba-Geigy, Basel, Switzerland) (Zachwieja et al. 1997) or with a double-antibody radioimmunoassay kit based on a mouse standard (Linco Research, St. Louis, MO) (Surwit et al. 1997; Van Heek et al. 1997). A radioimmunoassay for leptin in human plasma was described McGregor et al. (1996).

PROCEDURE

The peptide VPIQKVQDDTKTLIKTIVT representing the first twenty amino acids of the predicted sequence of mature leptin protein (leptin 1–20) was synthesized with 9-fluorenyl methyl oxycarbonyl-(Fmoc)-protected L-amino acids on a applied Biosystems peptide synthesizer and purified by HPLC on a Dynamax column developed with a 0.1% trifluoroacetic acid (TFA)/H_2O/acetonitrile (8% to 40%) gradient. The peptide is conjugated to thyroglobulin using carbodiimide as coupling reagent. Rabbits are immunized by intradermal injections and boosted at 4 weeks intervals.

A peptide identical to the one used for antibody generation except for a tyrosine residue added to the C-terminal end is labelled with ^{125}I using the oxidizing agent Iodogen (Pierce, USA) and purified on HPLC. For radioimmunoassay, the buffer consists of Tris-HCl 1 M, pH 7.4; 0.1% gelatin; 0.1% Triton X-100, and 0.01% NaN_3. Unlabelled ob peptide is used for standards. 100 µl of standard or unknown, 200 µ l buffer, 100 µl antibody at a final concentration of 1:80000 and 100 µl ^{125}I-leptin peptide (approximately 5000 cpm) are added to polystyrene tubes and incubated for 48 h at 4°C. Antibody-bound and unbound peptide are separated by addition of goat anti-rabbit immunoglobulin antibody followed by centrifugation. The precipitates are counted on a computer-linked gamma-counter and the leptin concentrations of the samples are obtained using the "RIA-Calc" program.

EVALUATION

Results are expressed as means ± SD, and statistical comparisons are made with the use of Student's *t*-test. Linear regression analysis is performed with the method of least squares.

MODIFICATIONS OF THE METHOD

Maffei et al. (1995) used an immunoprecipitation assay to measure plasma leptin levels. A quantitative increase of the signal intensity was seen on Western blots when increasing amounts of recombinant protein were added to *ob* mouse serum, which does not have leptin. Densitometry was used to compare the signal intensity of the native protein in mouse plasma to the standard. The level of leptin-like immunoreactivity was quantified as nanograms per ml.

L.4.2 Neuropeptide Y

L.4.2.1 General Considerations on Neuropeptide Y and Related Peptides

Neuropeptide Y (NPY), peptide YY (PYY) and pancreatic polypeptide (PP) are endogenous 36-amino acid peptides belonging to the same family, which is characterized by a tertiary structure termed 'PP-fold' (Larhammar 1996; Berglund et al. 2003). They have different tissue distributions (Sundler et al. 1993) and act in different physiological systems, mostly neuronal for NPY and endocrine for PYY and PP (Wettstein et al. 1995; Playford and Cox 1996; Goumain et al. 1998).

Neuropeptide Y plays a key role in the control of body weight (Leibowitz 1994; Kalra and Kalra 2004). Central administration of neuropeptide Y increases food intake and decreases thermogenesis in satiated animals (Billington et al. (1991, Stanley et al. 1992), while a reduction in endogenous neuropeptide Y leads to a decrease of food intake (Lambert et al. 1993). Hypothalamic neuropeptide Y and mRNA levels are increased after fasting and in genetically obese mice (Stephens et al. 1995). Neuropeptide Y is required for the maintenance of the obese phenotype of the leptin-deficient *ob/ob* mice (Erickson et al. 1996). Conversely, leptin appears to decrease food intake and body weight in part by decreasing neuropeptide Y synthesis and release (Stephens et al. 1995). These data suggest that neuropeptide Y is a key modulator of body weight and that neuropeptide Y receptor antagonists may be useful anti-obesity agents.

Neuropeptide Y mediates its physiological effects via interaction with at least six distinct G protein-coupled receptors, designated Y_1, Y_2, Y_3, Y_4, Y_5 and Y_6.(Marsh et al. 1998; Michel et al. 1998; Wyss et al. 1998; Iyengar et al. 1999; Larhammer and Salaneck 2004; Lin et al. 2004).

Central administration of peptide analogues of neuropeptide Y has been used to study the physiological roles of neuropeptide Y, especially the role of the peptide in feeding behavior. Kanatani et al. (1999) demonstrated an anorexogenic effect against NPY induced feeding in rats by an Y_1 antagonist with high selectivity and potency for the Y_1 receptor. Central administration of peptides that activate the Y_5 receptor, peptide YY (PYY), PYY(3–36), [Leu^{31},Pro^{34}]NPY, and human pancreatic polypeptide elicit feeding, whereas central administration of central administration of peptides that are inactive at the Y_5 receptor do not elicit feeding (Gerald et al. 1996). Fuhlendorff et al. (1990) described [Leu^{31}, Pro^{34}]neuropeptide Y as a specific Y_1 receptor agonist. While other neuropeptide Y analogues or fragments interacts with several neuropeptide Y receptors, [D-Trp^{32}]NPY is a completely selective Y_5 agonist that elicits feeding at relatively high doses (Gerald et al. 1996). Peptides with activity on the Y_1 receptor produce conflicting effects on feeding. $DesAA^{10–17}$[$Cys^{7–21}$,Pro^{34}]NPY is a Y_1 receptor agonist with a potency equivalent to neuropeptide Y, but does not elicit feeding after central administration (Kirby et al. 1995).

Schaffhauser et al. (1997) described inhibition of food intake after intracerebroventricular injection of neuropeptide Y Y_5 receptor antisense oligodeoxynucleotides in rats.

Dumont et al. (2004) recommended receptor autoradiography as means to explore the possible functional relevance of neuropeptides such as neuropeptide Y.

Criscione et al. (1998) reported inhibition of food intake in rats by an Y_5 receptor antagonist under various conditions. Several neuropeptide Y antagonists were synthesized which inhibit food intake in rodents and may be used as anorectic agents (Matthews et al. 1997; Kask et al. 1998; Parker et al. 1998; Shigeri et al. 1998; Wieland et al. 1998; Zarrinmayeh et al. 1998).

Besides the stimulation of feeding, NPY and PYY show several other activities: influence on gastric motility (Chen et al. 1997), antisecretory effects in the gastrointestinal tract (Souli et al. 1997), anti-stress activity (Heilig 2004), anti-epileptic activity (Baraban 2004; Vezzani and Sperk 2004), central and peripheral control of the cardiovascular system (Lew et al. 1996; Tadepalli et al. 1996; Hudspith and Muglani 1997; McCloskey et al. 1997), effects on renal function (Blaze et al. 1997; Bischoff et al. 1997), antinociceptive effects (Broqua et al. 1996), or release of ACTH (Small et al. 1997). Kask et al. (2001) described the effects of a neuropeptide Y Y_5 receptor antagonist on food intake and anxiety-related behavior in the rat.

Sajdyk et al. (1999) found that amygdalar neuropeptide Y Y_1 receptors mediate the anxiolytic-like actions of neuropeptide Y in the social interaction test, whereas neuropeptide Y-Y_2 receptors mediate anxiety in the amygdala (Sajdyk et al. 2002).

Neuropeptide Y plays a role in neurobiological responses to ethanol and drugs of abuse (Thiele et al. 2004).

NPY receptor agonists show anxiolytic effects in rat conflict tests (Britton et al. 1997; Kask et al. 2002); neuropeptide Y_1 antagonists have anxiogenic-like effects (Kask et al. 1996).

Goumain et al. (1998) generated a rat Y_5 clone by reverse transcription from rat brain, polymerase chain reaction and transfection to COS-7 cells. Isolated jejunal crypt and villus cells and colon epithelial cells were analyzed for the Y_5 receptor by reverse transcription and polymerase chain reaction. Inhibition of binding of [^{125}I]peptide YY in these cells by various peptides was studied.

Mullins et al. (2000) characterized the cloned neuropeptide Y y_6 receptor in mice.

L.4.2.2 Receptor Assay of Neuropeptide Y

PURPOSE AND RATIONALE

At least six distinct G protein-coupled receptors of neuropeptide Y have been identified, designated Y_1, Y_2, Y_3, Y_4, Y_5 and Y_6 (Doods and Krause 1991; Marsh et al. 1998; Michel et al. 1998; Bischoff and Michel 1999).

Sheikh et al. (1989) described a receptor binding assay for neuropeptide Y.

PROCEDURE

^{125}*I-Labeling*

^{125}I-labeled NPY is prepared using carrier-free Na^{125}I and 1,3,4,6-tetrachloro-3α,α6-diphenylglycouril (Ser-

va Heidelberg, Germany) as oxidizing agent. Synthetic porcine NPY (7 nmol) in 40 µl of sodium phosphate buffer (pH 7.4, 0.1 M) and 1 mCi of $Na^{125}I$ in 10 µl of dilute NaOH is added to a reaction vial which has been coated with 20 µg of chlorglycouril by evaporation of 20 µ l of a solution of glycouril in methylene chloride. Following incubation in ice for 5 min, 50 µl of 35% acetonitrile is added prior to HPLC.

Purification by Reverse Phase-High Performance Liquid Chromatography

A prepacked Nucleosil 300–5 C_{18} cartridge is used. The chromatography is performed at 50°C with a flow rate of 1 ml 35% acetonitrile/min. Fractions of 0.5 ml are collected into tubes containing 0.1 ml of acetic acid (0.5 M) containing 10 mg/liter bovine serum albumin. Aliquots of 10 µl are counted in a γ-counter, and fractions containing the radiolabeled peptide are pooled and stored at –20°C.

Preparation of Synaptosomal Membranes

Synaptosomal membranes are prepared from the hippocampus of Danish LYY-strain landrace/Yorkshire pigs. The tissue is homogenized in 0.32 M sucrose in a Sorval Omni-Mixer at 0°C for 5 min, followed by centrifugation (1000 *g*, 10 min). The supernatant is removed and centrifuged (20,000 *g*, 30 min) to form the crude mitochondrial fraction. After resuspension in 3 ml of sucrose, this fraction is subfractionated on a discontinuous density gradient consisting of 0.8 M and 1.2 M sucrose (3 ml of each) in a SW 27 rotor and a Beckman ultracentrifuge (100,000 *g*, 90 min). The synaptosomes which concentrate at the interface between the two sucrose concentrations are collected and recentrifuged (50,000 *g*, 10 min). The resulting pellet is washed with HEPES buffer (pH 7.4, 25 mM) containing $CaCl_2$ (2.5 mM) and $MgCl_2$ (1 mM), centrifuged (50,000 *g*, 10 min), and resuspended in HEPES buffer. The protein concentration is determined using the Bio-Rad protein assay with bovine serum albumin as standard. The membrane preparation is diluted in binding buffer to a protein concentration of 2 g/liter and stored at –80°C.

Receptor Binding Assay

The binding buffer is a HEPES buffer (pH 7.4, 25 mM) containing $CaCl_2$ (2.5 mM) and $MgCl_2$ (1 mM), bovine serum albumin (10 g/liter), and bacitracin (0.5 g/liter). The incubation mixture consists of 0.5 ml of membrane suspension, diluted with binding buffer to a protein concentration of 200 mg/liter, 0.05 ml of unlabeled peptide, and 0.5 ml of ^{125}I-labeled peptide (40,000 cpm). After 1 h of incubation, triplicate aliquots of the incubation medium are transferred to polypropylene tubes (0.4 × 4.5 cm), containing 200 µl of ice-cold buffer. Membrane-bound, radiolabeled peptide is separated from the free peptide by centrifugation (7500 *g*, 2 min) in a Beckman Microfuge B. The supernatant is aspirated, and the tube and pellet are gently washed with buffer (0.5 ml). The tip of the tube is the cut off and counted in the γ-counter.

EVALUATION

The specific binding is calculated as the difference between the amount of ^{125}I-labeled peptide bound in the absence (total binding) and presence (nonspecific binding) if 10 µM unlabeled peptide.

The concentration dependence of the receptor binding is determined by incubating the membranes with increasing concentrations of radiolabeled peptide in the absence or presence of unlabeled peptide.

MODIFICATIONS OF THE METHOD

Rose et al. (1995) reported cloning and functional expression of a cDNA encoding a human type 2 neuropeptide Y receptor.

Gehlert et al. (1996) recommended [^{125}I][Leu^{31}, Pro^{34}]peptide YY as selective radioligand for the neuropeptide Y Y_1 receptor and for human pancreatic polypeptide 1 receptors.

Robin-Jagerschmidt et al. (1998) investigated the ligand binding site of neuropeptide Y at the rat Y_1 receptor by construction of mutant receptors and [^3H]NPY binding studies.

Dumont et al. (1998) investigated the respective distribution of neuropeptide Y Y_1, Y_2, Y_4, and Y_5 receptor subtypes in rodents (rat and mouse), guinea pig, and primates (marmoset and vervet monkey and human) brains, representing three orders of mammals.

Primus et al. (1998) measured guanyl 5′(γ[^{35}S]-thio)-triphosphate binding to NPY receptor-activated G-proteins in adult rat brain sections in order to determine the neuroanatomical distribution of NPY receptor subtypes.

Wyss et al. (1998) administered various doses of synthetic neuropeptide Y agonists intracerebroventricularly to rats in order to establish dose-response curves and to estimate ED_{50} values of feeding. These values were compared with binding affinities (IC_{50}) for rat NPY receptor subtypes Y_1, Y_2, Y_4, and Y_5 *in vitro*. Mouse fibroblast cell lines (LMTK–) were stably transfected with the rat Y_1, Y_2 and the Y_4 recep-

tor, whereas human embryonic kidney HEK-293 cells were used for transfection with the rat Y_5 receptor.

Parker et al. (1998) determined the agonist and antagonist potency of neuropeptide Y and various analogues for cloned human and rat neuropeptide Y receptors expressed in CHO or 293 cells.

Wieland et al. (1998) studied the subtype selectivity of a nonpeptide Y_1 receptor antagonist using membranes from rat hypothalamus, from SK-N-MC (neuroblastoma) cells and from SMS-KAN (neuroblastoma) cells; human Y_1 receptor stably expressed in baby hamster kidney (BHK) cells, rat Y_1 receptor expressing human embryonic kidney (HEK) 293 cells, human Y_2 receptor stably expressed in BHK cells, rat Y_4 stably transfected in BHK cells, and human Y_5 receptor stably transfected in HEK 293 cells.

Several groups reported screening results of neuropeptide Y antagonists mostly using receptor binding experiments (Murakami et al. 1999; Fotsch et al. 2001; Islam et al. 2002; Poindexter et al. 2002; Andres et al. 2003; Hammond et al. 2003; Blum et al. 2004; Gillman et al. 2006; Kakui et al. 2006).

Dautzenberg et al. (2005) established robust functional assays for the characterization of neuropeptide Y receptors. The human neuropeptide Y (NPY) receptors 1 (hY_1), 2 (hY_2), 4 (hY_4), and the mouse type 5 (mY_5) receptor were expressed in human embryonic kidney 293 (HEK293) cells. The receptors bound a radioiodinated NPY ligand with high affinity and various NPY analogs competed for binding in a receptor-selective manner. Similarly, cAMP inhibition and GTPγ S binding assays were established. The four NPY receptors were further tested in the fluorimetric imaging plate reader (FLIPR) format, a cellular high-throughput assay, in the absence and presence of chimeric G proteins, Gq_{o5}, Gq_{i5} and Gq_{i9}.

PROCEDURE

Cell Transfections

cDNAs of the four NPY receptors inserted into pcDNA3 (5 µg each) or Gq_{i5}, Gq_{o5} and Gq_{i9} (10 µg each) inserted into pcDNA5 (Invitrogen) were transiently transfected into HEK293 cells with the FUGENE reagent (Roche Molecular Biochemicals, Mannheim, Germany) according to the manufacturer's protocol. Cell lines stably expressing the various NPY receptors together with Gq_{i9} were generated by transfecting receptor cDNA (0.5 µg each), the Gq_{i9} cDNA (1 µg) and the pOG44 vector (10 µg) encoding the cDNA for the DNA recombinase used in the Flip-in system (Invitrogen) with the FUGENE reagent. Two days after transfection, Geneticin (500 µg/ml) and hygromycin (50 µg/ml) selection was initiated and stable cell clones robustly responding in the FLIPR assay were selected.

Radioreceptor Binding Assays

Membranes from NPY-receptor-expressing HEK cells were prepared according to Dautzenberg et al. 2005. Competition binding assays were performed with 5 (hY_2 or hY_4), 25 (mY_5) and 40 µg (hY_1) of membrane proteins prepared from the four NPY receptors under assay conditions according to Rist et al. (1996), using 96-well plates (Beckmann Instruments, Fullertown, Calif., USA) and a scintillation proximity assay (SPA; Dautzenberg et al. 2000}). The membranes, 1 mg wheat germ agglutinin SPA beads (Amersham Pharmacia Biotech), 100 pM [^{125}I]PYY and unlabeled peptides (10^{-5} M to 10^{-11} M) were added. The reaction mixture was incubated on a shaker for 120 min at 22°C and then read in a TopCount (Packard). Nonspecific binding was determined as residual binding in the presence of 10 µM PYY. The dissociation constant K_d, the inhibition constant K_i, and the maximum receptor concentration, B_{max}, were calculated using the interactive curve fitting program Xlfit (Hoffmann-La Roche). Under these conditions less than 10% of the total radioactivity was specifically bound by the various receptor constructs.

cAMP Inhibition Assay

The inhibition of forskolin-mediated cAMP accumulation by NPY analogs in 96-well plates was determined as previously described (Dautzenberg et al. 2001). Briefly 20,000 cells were incubated in Krebs-Ringer-HEPES-buffered solution (KHR; 124 mM NaCl, 5 mM KCl, 1.25 mM $MgSO_4$, 1.5 mM $CaCl_2$, 1.25 mM KH_2PO_4, 25 mM HEPES, pH 7.4) in the presence of 1 µM forskolin (Sigma, Munich, Germany) with increasing concentrations of agonists (10 pM to 10 µM) for 60 min at 37°C. Reactions were stopped by the addition of 0.12 ml ice-cold ethanol and stored at –80°C for at least 4 h. The cAMP content was determined from the supernatant using the Biotrak non-radioactive cAMP kit (Amersham Pharmacia Biotech) according to the manufacturer's instructions.

GTPγ S Binding Assay

Agonist-mediated binding of GTPγ^{35}S was investigated in the SPA format using 96-well plates (Rover et al. 2000}) and membranes prepared from cells transfected with the hY_1, hY_2, hY_4 and mY_5 receptors. Binding was performed in 200 µ l of 20 mM HEPES-buffer (pH 7.4, plus 6 mM $MgCl_2$ and 100 mM NaCl),

supplemented with 20 µM GDP, 10 µM cold GTPγ S and 0.3 nM GTPγ^{35}S. Then, 20 µg (hY_2, hY_4, mY_5) to 40 µg (hY_1) membranes, 1 mg wheatgerm agglutinin SPA beads, NPY analogs or synthetic compounds (10^{-4} M to 10^{-11} M) were added. For antagonist assays, a submaximal (EC_{80}) concentration of PYY was added together with increasing antagonist concentrations (10^{-4} to 10^{-11} M). The reaction mixture was incubated on a shaker for 60 min at 22°C and then centrifuged for 5 min at 1500 rpm in an Eppendorf 5403 centrifuge. Finally the plates were read in a TopCount reader (Packard).

Calcium Mobilization Assays

HEK293 transiently stably expressing the four NPY receptors with or without chimeric G-proteins were seeded at a density of 100,000 cells into poly-D-lysine-coated 96-well blackwall, clear-bottom microtiter plates (Corning, NY) (Dautzenberg et al. 2004). One day later, the medium was removed and 100 µl loading medium [DMEM high glucose, without serum, supplemented with 10 mM HEPES acid, 0.1% BSA, 5 mM probenecid and 2 µM Fluo-3AM (Molecular Probes, Leiden, The Netherlands)] was added. Cells were loaded for 1 h at 37°C, washed twice with 100 µl assay buffer (5 mM HEPES acid, 140 mM NaCl, 1 mM $MgCl_2$, 5 mM KCl, 10 mM glucose) and then 150 µl assay buffer was added. Cells were further preincubated at room temperature before adding agonists or agonists plus antagonists in 50 µl assay buffer and then measured on a T-channel fluorimetric imaging plate reader (FLIPR, Molecular Devices, Sunnyvale, Calif., USA). Maximum change in fluorescence over baseline was used to determine agonist response.

EVALUATION

Statistical analyses of the binding, cAMP, GTPγ S and calcium mobilization data were performed on a Macintosh PC using StatView software (SAS, Cary, N.C., USA) by one-way analyses of variance (ANOVAs) across experimental groups followed by the Dunnett's test with the alpha set at 0.05.

Beauverger et al. (2005) characterized antagonists specific to human neuropeptide Y receptor subtype 5 using a **luciferase reporter gene assay**.

PROCEDURE

CRE-Luciferase Reporter Assay

Standardization of this assay consisted of testing various cell densities and incubation times to optimize the signal-to-background ratio. Briefly, HEK293-hMT1 cells grown to ≈ 80% confluence were transfected in batches with lipofectAMINE Plus (Life Technologies) using 20 ng of pcDOR8, 500 ng of pΔ MC16-Luc and 1 µg of either pcDNA3.1 or pcDNA3.1-Y5 per million of cells. Then, 24 h after transfection, cells were detached by agitation, centrifuged and recovered at 10^6 cells/ml in phenol-red-free DMEM medium supplemented with 2% fetal calf serum. They were then seeded as 50-µl aliquots into white 96-well tissue culture plates containing the drugs previously diluted in the same medium and distributed as 50-µ l aliquots. After a 20-h incubation period, the luciferase activity was measured by adding 100 µl per well of Luclite buffer (Packard) followed by a 30-min incubation in the dark at room temperature and a use of a Topcount (Packard).

Savontaus et al. (1998) measured expression of preproneuropeptide Y mRNA in the arcuate nucleus and preprocorticotropin-releasing factor mRNA in the paraventricular nucleus by *in situ* hybridization technique after short and long-term treatment with a β_3-adrenoreceptor agonist.

Bioassays have been used for characterization and classification of neuropeptide Y receptors (Hedge et al. 1995; Pheng and Regoli 1998; Dumont et al. 2000a, b). Some isolated organs appear to be "monoreceptor" systems, e. g., the rat tail artery (Gicquiaux et al. 1996), the rabbit saphenous vein (Pheng and Regoli 1998; Feletou et al. 1999) or the isolated perfused kidney of the rat (Hedge et al. 1995) for the Y_1 receptor. The dog saphenous vein, the rat vas deferens and the rat colon can be used for the Y_2 receptor, the rat colon for the Y_4 receptor, and the rabbit ileum for the Y_5 receptor (Pheng et al. 1997).

L.4.3 Orexin

L.4.3.1 General Considerations on Orexin

Orexin-A and orexin-B are 33- and 28-residue peptides, also called hypocretins, which were originally isolated from rat hypothalamus (De Lecea et al. 1998; Sakurai et al. 1998). Both peptides are derived from a 130 amino acid precursor, preproorexin, which is encoded by a gene localized to chromosome 17q21 in humans. These peptides are located predominantly in the hypothalamus and locus coeruleus (Evans et al. 1999), but are also found elsewhere in the brain, and in the spinal cord (Smart 1999; Van den Pol 1999). The orexins have a broad range of physiological functions, including the control of feeding and energy metabolism (Dube et al. 1999; Mondal et al. 1999; Sakurai 1999, 2006), stimulation of insulin secretion (Nowak et al. 2000, 2005), modulation of neuro-endocrine function (Date et al. 1999), regulation of the sleep-wake cycle (Piper et al. 2000), narcolepsy (Taheri et al. 2002; Wille et al. 2003; Mieda et al. 2004), stress and anxiety, behavioral activities (Ida et al. 1999; Siegel 2003), cardiovascular (Shirasaka et al. 1999; Chen et al. 2000), adrenal function (Jöhren et al. 2004), and sexual and reproductive functions (Pu et al. 1998; deLecea and Sutcliffe 1999; Tamura et al. 1999). Food consumption is dose-dependently increased after intracerebroventricular infusion of orexin A and orexin B to rats which can be suppressed by a NPY Y_1 antagonist (Jain et al. 2000). Food intake could inhibited by central injection of an anti-orexin antibody in fasted rats (Yamada et al. 2000). Novak et al. (2000) found an increase of insulin secretion after subcutaneous injection of orexins to rats.

Orexin antagonists are potential anti-obesity drugs (Parker 1999).

L.4.3.2 Receptor Assay of Orexin

PURPOSE AND RATIONALE

The peptides orexin A and orexin B bind both to two receptors, orexin-1 (OX_1) and orexin-2 (OX_2), although orexin B has a low affinity for OX_1 (Sakurai et al. 1998). Differential expression of orexin receptor 1 and 2 in rat brain was reported by Marcus et al. (2001) and distinct recognition of OX_1 and OX_2 receptors by orexin peptides by Ammoun et al. (2005).

PROCEDURE

Orexin OX_1 and OX_2 receptors are produced by polymerase chain reaction from foetal and adult brain cDNA libraries, using primers located across the start and stop codons. The receptors are subcloned into the pCDN vector (with neomycin resistance) and transfected into CHO cells using lipofectamine (Life Technologies). Clones are selected using 400 µg/ml G418 (Life Technologies) and single clones are produced by limiting dilution cloning.

CHO-OX_1 and CHO-OX_2 cells are routinely grown as monolayers in MEM-Alpha medium supplemented with 10% fetal calf serum and 400 µ g/ml G418 and maintained under 95% O_2/5% CO_2 at 37°C. Cells are passaged every 3–4 days.

Synthetic human orexin A is ^{125}I-labeled at Tyr17 by chloramine-T oxidation in the presence of $Na^{125}I$ (2000 Ci/mmol). Monoiodinated peptide is purified by C^{18} reverse-phase HPLC (Takigawa et al. 1995). Stable transfectant CHO cell lines expressing human OX_1R or OX_2R are each seeded onto 12-well plates at a density of 3×10^3 cells per well. After an overnight culture, medium is discarded and cells are incubated at 20°C for 90 min with binding buffer (HEPES-buffered saline/5% bovine serum albumin) containing 10^{-10} M [^{125}I]orexin A plus designated concentrations of unlabeled competitors. Cells are then washed three times with ice-cold phosphate-buffered saline and lysed in 0.1 N NaOH. Cell-bound radioactivity is determined by a γ-counter.

EVALUATION

Data are expressed as the percentage of saturably bound reactivity in the absence of nonradioactive peptide. For each experiment each value is determined in duplicate, and the results are expressed as the means ± standard errors of at least 3 separate experiments.

MODIFICATIONS OF THE METHOD

Smart et al. (1999) studied the pharmacology of recombinant orexin receptors using the fluorescence imaging plate recorder (FLIPR). CHO-OX_1 or CHO-OX_2 cells were seeded into black walled clear base 96 well plates at a density of 20000 cells per well in MEM-Alpha medium supplemented with 10% fetal calf serum and 400 µg/ml G418 and cultured overnight. The cells were then incubated with MEM-Alpha medium containing the cytoplasmatic calcium indicator, Fluo-3AM (4 µM) and 2.5 mM probenecid at 37°C for 60 min. The cells were washed four times with, and finally resuspended in, Tyrode's medium containing 2.5 mM probenecid and 1% gelatin, be-

fore being incubated for 30 min at 37°C with either buffer alone (control) or buffer containing various signal transduction modifying agents. The plates were then placed into an FLIPR (Molecular Devices, U.K.) to monitor cell fluorescence ($\lambda = 488$ nM, $\lambda = 540$ nM) (Sullivan et al. 1999) before and after the addition of orexin A or orexin B.

L.4.3.3 Radioimmunoassay for Orexin

PURPOSE AND RATIONALE

A radioimmunoassay for orexin A has been developed by Mitsuma et al. (2000).

PROCEDURE

Synthetic orexin A is conjugated on an equal weight basis to BSA using glutaraldehyde. New Zealand white rabbits are immunized with an emulsion of this conjugate in one ml of water and complete Freund's adjuvant (1:2, v/v) which is injected into the foot pad at intervals of 3 weeks. Blood is withdrawn one week after each injection, and the presence of anti-orexin is checked by radioimmunoassay.

Radioiodination of orexin A is performed with the chloramine T method. The radioiodinated materials are chromatographed on Sephadex G-25, eluted with 0.01 M phosphate buffer (pH 7.4), and collected in 1.0 ml fractions. The first peak is orexin A-I^{125}.

For determination of tissue concentrations, brain tissues of rats are dissected into the hypothalamus, cerebral cortex, thalamus, striatum, hippocampal formation, brain stem and cerebellum.

For the extraction of orexin A, the freshly obtained tissues are weighed and placed in 5.0 ml acid-acetone, homogenized and centrifuged.

For the double antibody radioimmunoassay, 0.1 ml of standard or samples, 0.1 ml of antibody (1:1000), 0.1 ml orexin A I^{125}, and 0,5 ml buffer are incubated for 24 h at 4°C. Then 0.1 ml of the second antibody solution is added and incubated again for 24 h at 4°C. The samples are centrifuged, the supernatants decanted and radioactivity counted in the precipitates.

EVALUATION

Bound/total count is calculated and standard curves versus synthetic orexin A are established.

MODIFICATIONS OF THE METHOD

Using separate radioimmunoassays for orexin A and orexin B, Mondal et al. (1999) determined their distribution in microdissected nuclei of the diencephalon and brainstem of rats.

L.4.4 Galanin

L.4.4.1 General Considerations on Galanin

Galanin is a neuropeptide of 29 amino acids in length (30 amino acids in humans) which was first isolated from porcine intestine (Tatemoto et al. 1983) and is localized mainly in the mammalian CNS (Skofitsch and

Jacobowitz 1985; Melander et al. 1986), but also in other organs (Baltazar et al. 2000). Central administration of galanin increases food intake in satiated rats (Crawley et al. 1990). Conversely, reduction of central galanin levels by antisense oligonucleotide techniques (Akabayashi et al. 1994) or central administration of galanin receptor antagonists (Leibowitz and Kim 1992) decreases food intake. The activity of galanin in the hypothalamus is modulated by metabolic hormones and by the ingestion of nutrients (Wang et al. 1998).

These data suggest the use of galanin receptor antagonists as anti-obesity agents. More recent studies concentrate on pain and CNS effects (Kask et al. 1997; Holmes et al. 2000; O'Meara et al. 2000; Xu et al. 2000; Counts et al. 2003; Elliott-Hunt et al. 2004; Krasnow et al. 2004; Badie-Mahdavi et al. 2005a; Lundström et al. 2005).

Physiological actions of peripherally administered galanin include contraction of smooth muscle (Ekblad et al. 1989; Ahtaridis et al. 1998; Korolkiewicz et al. 1998; Niiro et al. 1998), inhibition of glucose-stimulated insulin release (McDonald et al. 1985; Leonhardt et al. 1989), influence on learning and memory behavior (McDonald and Crawley 1997; McDonald et al. 1998a, b; Gleason et al. 1999; ögren et al. 1999; Zachariou et al. 1999), antinociceptive activity in rats with experimentally induced neuropathy (Burazin and Gundlach 1998; Ma and Bisby 1999; Yu et al. 1999; Kerr et al. 2000; Wang et al. 2000). Based on pharmacological and molecular biological evidence, Mazarati et al. (2001) discussed the hypothesis that galanin works as an endogenous anticonvulsant. A nonpeptide galanin receptor agonist showed anticonvulsant activity (Shi et al. 2002).

Galanin-overexpressing transgenic mice showed no anxiety-related behaviors in three different tests (Holmes et al. 2002), whereas galanin GAL-R1 receptor null mutant mice displayed increased anxiety-like behavior (Holmes et al. 2003).

Galanin has been found to influence secretion of growth hormone (Ottlecz et al. 1988; Murakami et al. 1987), LH (Todd et al. 1998), luteinizing hormone (Finn et al. 1998), and prolactin (Koshiyama et al. 1987; Cai et al. 1998; Wynick et al. 1998), to inhibit dopamine release from the median eminence (Nordström et al. 1987), to influence ACh release from rat brain (Fisone et al. 1987; Kasa et al. 1998), to inhibit norepinephrine release from the hypothalamus (Tsuda et al. (1989) and to modulate 5-HT_{1A} receptors in the ventral limbic cortex of the rat (Diaz-Cabiale et al. 2000).

A fragment of the galanin precursor protein, galanin message-associated peptide (GMAP), is present in dorsal root ganglion cells and influences the spinal nociceptor flexor reflex in rats (Xu et al. 1996).

A galanin-like peptide, named GALP, was isolated by Ohtaki et al. (1999) from porcine hypothalamus.

Some synthetic **galanin receptor agonists** were described, such as galnon (Saar et al. 2002; Bahdie-Mahdavi et al. 2005b) or galmic (Ceide et al. 2004; Bartfai et al. 2004).

Various **galanin receptor antagonists**, such as galantide (Lindskog et al. 1992; Sahu et al. 1994; Arletti et al. 1997; Ceresini et al. 1998), and other compounds (Bartfai et al. 1991; Pramanik and ögren 1992; Kask et al. 1995; Xu et al. 1995; Kakuyama et al. 1997; Pooga et al. 1998; Koegler et al. 1999; Park and Baum 1999; Katoh and Ohmori 2000; Kisfalvi et al. 2000; Swanson et al. 2005; ögren et al. 2005) were synthesized and tested.

L.4.4.2 Receptor Assay of Galanin

PURPOSE AND RATIONALE

Galanin mediates its physiological effects via interaction with at least three G protein-coupled receptors, designated GAL1, GAL2, and GAL3 receptor (Wang and Parker 1998; Iismaa and Shine 1999; Branchek et al. 2000; Waters and Krause 2000).

The first known galanin receptor GAL1 has been isolated from the human Bowes melanoma cell line (Habert-Ortoli 1994). Human GAL1 contains 349 amino acids with the structure of a G protein-coupled receptor. A rat GAL1 homologue, cloned from Rin14B cells, contains 346 amino acids (Parker et al. 1995). Human GAL1 mRNA has been detected by northern blot analysis in fetal brain and small intestinal tissue, and also by reverse transcriptase-polymerase chain reaction in the human gastrointestinal tract from

the esophagus to the rectum. Rat GAL1 mRNA has been detected by northern blot analysis in the brain, spinal cord and Rin14B cells. Human and rat GAL1 share similar binding profiles in [^{125}I]galanin binding assays (Sullivan et al. 1997).

Heuillet et al. (1994) described ligand binding and functional characteristics of the human galanin receptor in the Bowes melanoma cell line.

Jungnickel and Gundlach (2005) studied [^{125}I]-galanin binding in brain of wild-type, and galanin- and GALR1-knockout mice.

The rat GAL2 receptor has been cloned and characterized by Wang et al. (1997), Ahmad et al. (1998), the mouse GAL2 receptor by Pang et al. (1998) and the human GAL2 receptor by Bloomquist et al. (1998) and Fathi et al. (1998). Unlike GAL1, mRNA encoding rat GAL2 is widely distributed in all tissues examined including the brain and peripheral tissues. Likewise, the human GAL2 receptor is detectable by RT-PCR in several central and peripheral tissues. GalR2 plays a key role in neurite outgrowth from adult sensory neurons (Mahoney et al. 2003). Rat GAL1 and GAL2 share similar pharmacological profiles in that they possess high affinity for full-length and N-terminal fragments of galanin.

Rat and human GAL3 receptors were described by Kolakowski et al. (1998), Smith et al. (1998). Human and rat GAL3 share similar profiles in [^{125}I]galanin receptor binding assays.

Lee et al. (1999) reported the isolation of a cDNA clone named GPR54 which encodes a G-protein coupled receptor related to the galanin receptors.

PROCEDURE

Preparation of the radioligand ^{125}I-galanin is performed by iodination of galanin at room temperature by the chlor-amine-T method. Galanin, 10 µg, in 20 µl 0.05 M sodium phosphate buffer (pH 7.5) and 20 µl chloramine-T (5 mg/ml) are added in a batch containing 2 mCi Na^{125}I (245 mCi/ml). The reaction is terminated by adding 100 µl of a solution of sodium metabisulfite (1.2 mg/ml). The reaction mixture is transferred onto a column packed with SP-Sephadex C25, equilibrated with a solution of 100 µg/ml BSA, then washed and equilibrated with 0.05 M sodium phosphate buffer (pH 5.0). The excess of Na^{125}I is first eluted with 0.05 M sodium phosphate buffer (pH 5.0), while the iodinated galanin is eluted as a single peak with 0.05 M sodium phosphate buffer (pH 8.1). Fractions corresponding to a peak of ^{125}I-galanin are pooled, the pH adjusted to 6.0 with acetic acid, and the aliquots stored at –18°C until use.

Male Sprague-Dawley rats are sacrificed and their brains quickly removed. The hypothalamus is dissected for **preparation of membranes**. The tissue is homogenized (10% mass/vol) in 0.32 M sucrose buffered with 5 mM HEPES (pH 7.4). The homogenate is diluted 10-fold and centrifuged at 1000 *g* for 10 min. The supernatant is centrifuged at 10,000 *g* for 45 min, and the pellet is resuspended in 5 mM HEPES-buffered Krebs-Ringer solution (pH 7.4).

Displacement experiments are carried out with various test compounds in a final volume of 400 µl HEPES/Krebs-Ringer solution, 0.05% BSA (pH 7.4), containing 1 mM ^{125}I-galanin and 70–100 µg membrane preparation. Samples are incubated for 30 min at 37°C. Incubation is terminated by the addition of 10 ml ice-cold HEPES/Krebs-Ringer solution, followed by rapid filtration over Whatman GF/B filters, precoated for 5–6 h in 0.3% polyethyleneimine solution. Specific binding is defined as that displaceable by 1 mM rat galanin1–29.

EVALUATION

Bound/total count is calculated and displacement curves versus the standard are established.

L.4.5 Adipsin

L.4.5.1 General Considerations on Adipsin

Proteins of the alternative complement pathway are secreted by adipose tissue (Choy et al. 1992; Peake et al. 1997). **Adipsin (complement D)** was the first to be cloned from an adipose tissue cell line and shown to be synthesized and secreted by adipose tissue (Cook et al. 1987; Flier et al. 1987; Johnson et al. 1991; White et al. 1992). Adipsin is markedly suppressed in *ob/ob, db/db*, monosodium glutamate-induced obese mice, in obese JCR:LA-cp rats and in cafeteria-fed rats (Rosen et al. 1989; Dugail et al. 1990; Shillabeer et al. 1992; Spurlock et al. 1996), and is regulated by glucocorticoids, retinoic acid, sympathomimetic drugs and insulin (Kitagawa et al. 1989; Spiegelman et al. 1989; Lowell and Flier 1990; Lowell et al. 1990; Moustaid et al. 1990; Antras et al. 1991; Miner et al. 1993). In contrast to rodents, adipsin increases with adiposity in humans and in response to feeding and is decreased during fasting, cachexia and lipatrophy (Napolitano et al. 1994).

Adipsin is required for the synthesis of **acylation stimulating protein (ASP)**, a protein implicated in fat metabolism (Sniderman and Cianflone 1994; Cianflone et al. 1999; van Harmelen et al. 1999). ASP is produced by the cleavage of C3a by carboxypeptidase and is highly expressed by mature adipocytes. The synthesis of C3a from C3 requires complement factor B and adipsin. Plasma ASP increases with meals and facilitates the synthesis and storage of triglycerides. Consistent with its role as a mediator of lipogenesis, ASP deficiency increases postprandial fatty acid levels and decreases weight gain and trigylceride synthesis in mice (Murray et al. 1999, 2000).

Several other factors, such as adiponectin (Takahashi et al. 2000) are involved in the function of adipose tissue acting as target as well as an endocrine organ (Ahima and Flier 2000).

L.4.5.2 Adipsin Expression in Mice

PURPOSE AND RATIONALE

Adipsin expression at the protein and mRNA levels was studied in mice (Flier et al. 1987; Spiegelman et al. 1989; Lowell et al. 1990; Dugail et al. 1990) and rats (Miner et al. 1993).

PROCEDURE

Various strains of mice (CD-1 mice, C57BL6 *ob/ob* mice, C57BL/Ks misty diabetes (m db/m db) mice, and mice with monosodium glutamate induced obesity are treated with drugs, e. g., ephedrine (1 g/kg chow) and caffeine (1.4 g/kg chow) mixed in the diet. The effects of these regimens on fat pad weight, specific mRNAs in white epididymal and brown adipose tissue and serum adipsin concentrations are assessed.

RNA is extracted from epididymal adipose tissue, brown intercapsular adipose tissue, 3T3-F422A adipocytes and isolated rat adipocytes by the guanidium-cesium chloride technique. Total RNA is denaturated, electrophoresed in 1.5% agarose, transferred to nylon filters, and hybridized to random primed adipsin, uncoupling protein (UCP), or actin cDNAs (Flier et al. 1987).

Serum adipsin and adipsin released by 3T3-F442A cultured adipocytes are assessed by RIA. Mouse adipsin purified from Chinese hamster ovary cells stably transfected with an adipsin expression vector is iodinated using the Bolton-Hunter reagent. The labeled protein is separated from unincorporated ^{125}I using G-50 Sephadex chromatography. The first rabbit polyclonal antibody is raised to purified mouse adipsin overexpressed using a baculovirus expression system. The assay is carried out in PBS, pH 7.4, supplemented with $CaCl_2$ (0.1 g/liter), $MgCl_2$ (0.1 g/liter), and BSA (0.1%). Serum adipsin is assessed in a dilution of 1:1000–1:5000 and in culture media at a dilution of 1:100. After adding tracer, standards, and serum, the tubes are mixed and the first antibody is added at a dilution of 1:800. After an overnight incubation, the bound and unbound tracer are separated using goat anti-rabbit immunoglobulin C fixed to heat killed staphylococcus at a ratio 1:1.2.

EVALUATION

Standard curves are generated using mouse adipsin purified from stably transfected CHO cells. Serial dilutions of standards, serum, and culture media are compared.

MODIFICATIONS OF THE METHOD

Dugail et al. (1989) showed that, in sharp contrast with genetically obese mice, adipsin mRNA is not suppressed in genetically obese Zucker rats.

Platt et al. (1994) found that a tissue-specific transcription factor that regulates adipsin expression is less active in the adipose tissue of obese animals.

Napolitano et al. (1994) determined concentrations in blood and rates of adipsin secretion by adipose tissue in humans using a two-monoclonal 'sandwich' ELISA assay.

L.4.6 Ghrelin

Small synthetic molecules called growth hormone secretagogues (GHSs) (Bowers et al. 1980, 1984) stimulate the release of growth hormone (GH) from the pituitary. They act through the GHS-R, a G-protein-coupled receptor (Howard et al. 1996). The natural ligand of this receptor was discovered as a 28-amino-acid-containing peptide, called ghrelin (Kojima et al. 1999, 2000, 2001; Davenport et al. 2005), produced in the XA-like cells of the stomach (Kojima et al. 1999; Date et al. 2000); however, smaller amounts of ghrelin are also found in the small and large intestine (Hosada et al. 2000). Ghrelin and the growth hormone secretagogue receptor are expressed in the rat adrenal cortex (Andreis et al. 2003). GH, GH receptor, GH secretagogue receptor, and ghrelin are also expressed in human T cells, B cells, and neutrophils (Hattori et al. 2001).

Ghrelin is the first peptide hormone in which the third amino acid serine is modified by a fatty acid; this modification is essential for the peptide's biological activity. Beside ghrelin's GH-releasing effect, it is a powerful appetite-simulating peptide. Plasma ghrelin concentration is increased in fasting conditions and reduced after habitual feeding (Kojima and Kangawa 2005), suggesting that ghrelin may act as an initiation signal for food intake. Chronic systemic or intracerebroventricular application to rats produced hyperphagia and obesity in rats (Wren et al. 2001). The appetite-stimulatory signal of ghrelin is mediated through action on the hypothalamic neuropeptide Y (NPY) and the Y1 receptor (Asakawa et al. 2001).

[^{125}I-His^{9}]-ghrelin was recommended as a radioligand for localizing GHS and GH receptors in human and rat tissue (Katugampola et al. 2001).

Various heterocyclic compounds acting as ghrelin receptor agonists have been developed, which might be useful for the treatment of anorexia nervosa (Palucki et al. 2001). Multiple ghrelin-derived molecules produced by post-translational processing were identified indicating structural divergence of human ghrelin (Hosoda et al. 2003). Until now, however, no specific ghrelin receptor antagonist has been described, although such a compound might be an attractive approach to reduce feed intake and to decrease obesity.

Anti-Atherosclerotic Activity[1]

[1] Reviewed and amended by H.-L. Schäfer

M.1 Induction of Experimental Atherosclerosis

M.1.0.1 General Considerations

Experimental atherosclerosis was first successfully induced in rabbits by Saltykow (1908) and Ignatowski (1909). During the following years, various scientists found that dietary cholesterol was the responsible stimulus for development of atherosclerosis. Other species are also susceptible to diet-induced atherosclerosis (Reviews by Kritchevsky 1964; Hadjiinky et al. 1991). Mouse models of atherosclerosis were reviewed by Reardon and Getz (2001) and by Daugherty (2002). Tailleux et al. (2003) underlined the importance of nuclear receptors, e. g., peroxisome proliferators-activated receptors (PPARs), liver X receptors (LXR) (Joseph and Totonoz 2003; Terasaka et al. 2003) and retinoid receptors (RXR) (Staels 2001; Li et al. 2005), which are implicated in lipid metabolism and inflammation.

M.1.0.2 Cholesterol-Diet-Induced Atherosclerosis in Rabbits and Other Species

PURPOSE AND RATIONALE

Rabbits are known to be susceptible to hypercholesterolemia and arteriosclerosis after excessive cholesterol feeding. Therefore, this approach has been chosen by many authors to study the effect of potential anti-arteriosclerotic drugs.

PROCEDURE

Several modifications of the protocol have been described. Usually, male rabbits from an inbred strain, e. g., white New Zealand, at an age of 8–10 weeks are used. Body weight variation should be as low as possible. At the beginning of the experiment, blood is withdrawn from the marginal ear vein for determination of total cholesterol, total glycerides, and blood sugar. Groups of 10 animals are used for treatment with drugs or as controls. The rabbits are switched from commercial food to a diet supplemented with 0.3–2% cholesterol and kept on this regimen for a period of 10–12 weeks. One group is kept on normal diet. During and at the end of the experiment blood is taken for analysis. Usually, cholesterol and triglyceride levels increase several-fold over the original values.

The animals are sacrificed and the thoracic aorta is removed, cleaned of surrounding tissues, and longitudinally cut and opened for fixation with formaldehyde. The tissue is stained with oil red. The percentage of

the intimal surface covered by the oil red positive lesions is calculated with a computerized planimeter. In animals fed a normal diet, the aorta does not show any staining, whereas in cholesterol-fed rabbits the aorta shows severe atherogenic lesions.

EVALUATION

Data are expressed as means ± standard deviation. Statistical evaluation is performed by Dunnett's or Scheffé's test. A p-value of < 0.05 is regarded as statistically significant.

MODIFICATIONS OF THE METHOD

Shore and Shore (1976) studied two **different strains of rabbits** (New Zealand White and Dutch Belt) as models of hyperlipoproteinemia and atherosclerosis.

Tao et al. (2003) studied antioxidative, antinitrative, and vasculoprotective effects of a PPAR-γ agonist in New Zealand White rabbits with hypercholesterolemia induced by a high-cholesterol diet.

Studies of Kritchevsky et al. (1989) on experimental atherosclerosis in **rabbits** fed **cholesterol-free diets** revealed a greater influence of animal protein and of partially hydrogenated soybean oil on development of atherosclerosis than plant protein and unsaturated soybean oil.

Cockerels (Tennent et al. 1960) and **turkeys** (Simpson and Harms 1969) are very susceptible to cholesterol feeding and develop marked hypercholesterolemia in rather short periods. Atherosclerosis could also be induced in cockerels by high doses of estrogen without atherogenic diet (Caldwell and Suydam 1959).

Spontaneous arteriosclerosis in **pigeons** has been described by Clarkson and Lofland (1961).

The **Japanese sea quail** (*Coturnix coturnix japonica*) is highly susceptible to the rapid development of severe experimental atherosclerosis (Day et al. 1975, 1977, 1979, 1990; Chapman et al. 1976).

Out of 13 strains of **mice**, Roberts and Thompson (1976) selected the C57BR/cdJ and the CBA/J strain und used these strains and their hybrids as models for atherosclerosis research.

Paigen et al. (1987) described quantitative assessment of atherosclerotic lesions in mice. After 14 weeks on an atherogenetic diet C57BL/6J female mice had aortic lesions at each of the coronary arteries, at the junction of the aorta to the heart and in scattered areas of the aortic surface. The lesions increased after 9 months of atherogenic diet. Methods of evaluating the number and size of lesions were compared including sizing with a microscope eyepiece grid and computer-assisted planimetry.

Atherosclerosis susceptibility differences among progenitors of recombinant inbred strains of mice were described by Paigen et al. (1990).

Yamaguchi et al. (1993) found that addition of 10% linoleic acid to a high-cholesterol diet enhanced cholesterol deposition in the aorta of male ICR strain mice.

In **rats** hypercholesterolemia can be induced by daily administration by gavage of 1 ml/100 g body weight of a cocktail containing in 1 l peanut oil: 100 g cholesterol, 30 g propylthio-uracil, and 100 g cholic acid over a period of 7 days. The test compounds are administered simultaneously with the cocktail (Fillios et al. 1956; Lustalot et al. 1961).

Inoue et al. (1990) induced experimental atherosclerosis in the rat carotid artery by balloon de-endothelialization and atherogenic diet. A balloon catheter was introduced into the rat's carotid arteries from the iliac arteries and the endothelium was denuded.

The **hamster** is susceptible to atherosclerosis. Nistor et al. (1987) fed male hamsters a hyperlipidemic diet consisting of standard chow supplemented with 3% cholesterol and 15% commercial butter for 12 months. Serum total cholesterol doubled after 3 weeks and attained a 17-fold value after 10 months. Up to 6 months, smooth muscle cells in the intima and media of the aorta as well as endothelial cells began to load with lipids. After 10 months the affected zones looked like human atherosclerotic plaque with huge cholesterol crystal deposits, calcium deposits and necrosis.

Especially the hybrid hamster strain Bioä F_1B (Bio Breeders Fitchburg, MA, USA) is more susceptible to dietary induced atherosclerosis than other strains (Kowala et al. 1991). Early atherosclerotic lesions can be induced within a 3-months-feeding of a cholesterol/butter enriched diet. In these animals simvastin dose-dependently inhibited the development of hyperlipidemia and the plaque formation by cholesterol synthesis inhibition The histopathological examination of the aortas showed that the cholesterol/butter fed F_1B hamster developed atherosclerotic lesions and functional changes in the aorta which are closely related to man (Schäfer et al. 1999).

Soret et al. (1976) studied the diet-induced hypercholesterinemia in the diabetic and non-diabetic Chinese hamster.

Beitz and Mest (1991) used cholesterol-fed **guinea pigs** to study the antihyperlipemic effects of a potentially anti-atherosclerotic drug. Fernandez (2001) reviewed the advantages of the guinea pig as an animal model to study hepatic cholesterol, lipoprotein metabolism, and early atherosclerosis. Guinea pigs de-

velop fatty streaks after 12 weeks on a cholesterol diet; the response to cholesterol is highly individualized, and animals can be a hyper-responder or a hyporesponder to dietary cholesterol.

During the last 30 years **minpigs** have become a popular animal model for testing lipid-lowering drugs and their anti-atherosclerotic properties (Jacobsson 1987; Huff et al. 2002; Telford et al. 2003). Jacobsson and Lundholm investigated the lipid-lowering and anti-atherosclerotic effects of clofibrate, nicotinic acid, and other drugs (Lundholm 1978; Jacobsson and Lundholm 1982; Jacobsson 1987). Huff and Telford investigated the effect of atorvastatin and a bile acid absorption inhibitor on lipid metabolism and serum LDL kinetics (Huff et al. 2002; Telford et al. 2003). The benefits of the minipig are the absence of rodent-specific peroxisomal proliferation by PPAR α-agonists and closer homology to humans in absolute and relative organ sizes. The effective doses of the tested drugs in the minpig were close to clinically effective doses in humans.

Malinow et al. (1976) recommended the **cynomolgus monkey** as a model for therapeutic intervention on established coronary atherosclerosis.

This species was used by Hollander et al. (1978) to study the development atherosclerosis after a cholesterol and fat enriched diet.

Beere et al. (1992) described experimental atherosclerosis at the carotid bifurcation of the cynomolgus monkey by a cholesterol-enriched diet.

Eggen et al. (1991) studied the progression and the regression of diet-induced atherosclerotic lesions in aorta and coronary arteries on **rhesus monkeys**.

Howard (1976) recommended the **baboon** as model in atherosclerosis research because of the similarity of cholesterol metabolism and composition of the lipoproteins to man.

Kushwaha et al. (1991) determined the effect of estrogen and progesterone on plasma cholesterol concentrations and on arterial lesions in ovarectomized and hysterectomized baboons fed a high-cholesterol/high-saturated-fat diet.

Blaton an Peeters (1976) reported studies on the **chimpanzee**, the **baboon** and the **rhesus macacus** as models for atherosclerosis.

The use of normal adult **marmosets**, a species with a lipoprotein profile similar to that of humans, may be an alternative (Crook et al. 1990; Baxter et al. 1992).

Ming-Peng et al. (1990) studied high density lipoproteins and prevention of experimental atherosclerosis in **tree shrews** (*Tupaia belangera yunalis*). In contrast to rabbits, no increased lipid deposition in aortic intima after cholesterol feeding was found in tree shrews.

CRITICAL ASSESSMENT OF THE METHOD

Diet-induced hypercholesterolemia is useful for the detection of agents that interfere with the adsorption, degradation, serum clearance, and excretion of cholesterol to receive a broader effect range. It must be considered whether the effects of agents that interfere with cholesterol absorption will be enforced and therefore whether the efficacy is overestimated in those models.

Hereditary Hypercholesterolemia in Rats

A strain of genetically hypercholesterolemic rats (RICO) was described by Müller et al. (1979). In contrast to Zucker-rats, these animals are normo-triglyceridemic and non-obese. The hypercholesterolemia of the RICO rat is related to a decreased rate of catabolism of chylomicrons and LDL, but more specifically to an excessive production of these two types of lipoproteins. This strain has been proposed to study hypolipidemic drugs, particularly those designed to decrease the plasma concentrations of chylomicrons and LDL. Hypolipidemic effects of β-cyclodextrin were found in this model (Riottot et al. 1993).

Hereditary Hyperlipemia in Rabbits

Watanabe et al. (1977, 1980) described a strain of rabbits with hereditary hyperlipemia (WHHL rabbit) which has been used by several scientists to study development of atherosclerosis, as well as for histological and functional changes of the aorta. At the age of 10–14 months homozygous animals exhibit an atheromatous plaque, distributed heterogeneously over the luminal surface of the aorta. Serum cholesterol is increased up to 400–600 mg/dl. The increased levels of LDL have been studied in detail (Kita et al. 1981, 1982).

M.1.0.5 Studies in Transgenic Mice

Mice do not develop atherosclerotic lesions spontaneously. Paigen et al. (1985) fed ten inbred strains of mice an atherogenic diet containing 1.25% cholesterol, 0.5% cholic acid and 15% fat in order to study the variation in susceptibility to atherosclerosis among these strains. The strains were examined for plasma cholesterol and triglyceride levels and for formation of lipid-containing lesions in the aortic wall. The most susceptible strain was C57BL/6J mice.

Several transgenic animals as disease model were created during the last decade, mostly mice (Stoltzfus and Rubin 1993), but also rats and rabbits.

The widely used model is the Apo E knockout mouse originally created by Nubuyo Maeda, University of North Carolina, Chapell Hill, NC. These Apo E knockout mice have spontaneously elevated plasma cholesterol levels, and develop atherosclerosis even on regular chow within 3–4 months. The time dependent progression of atherosclerosis leads to lesions similar in histopathology to those observed in humans. This animal model is used as background for atherosclerosis research and target validation. Duez et al. (2002) used apolipoprotein E-deficient mice and human apoA-I transgenic apoE-deficient mice fed a Western diet to investigate the reduction of atherosclerosis by the PPARα agonist fenofibrate.

Walsh et al. (1989) and Rubin et al. (1991) integrated human apolipoprotein A-I gene in transgenic mice resulting in an increase of HDL levels.

Linton et al. (1993) described the development of transgenic mice expressing high levels of human apolipoprotein B48 and human apolipoprotein B100 which are considered to be atherogenic.

Transgenic mice expressing high levels of human apoliprotein B develop severe atherosclerotic lesions in response to a high-fat diet (Purcell-Huynh et al. 1995).

Ishibashi et al. (1994) found massive xanthomatosis of the skin and subcutaneous tissue and atherosclerosis in cholesterol-fed low density lipoprotein receptor-negative mice.

Sasan et al. (1998) reported that low density lipoprotein receptor-negative mice expressing human apolipoprotein B-100 develop complex atherosclerotic lesions on a chow diet.

Li et al. (2000) used LDL receptor-deficient mice to study the inhibition of development of atherosclerosis by PPARγ-specific agonists.

Joseph et al. (2002) investigated the inhibition of development of atherosclerosis in *LDL receptor* knockout mice and *ApoE* knockout mice by a synthetic LXR ligand.

Terasaka et al. (2003) reported inhibition of development of atherosclerosis in LDL-receptor-deficient mice by a synthetic liver X receptor ligand.

Transgenic mice lacking apolipoprotein E showed severe hypercholesterolemia and atherosclerosis (Plump et al. 1992; Zhang et al. 1992). ApoE-deficient mice develop lesions of all phases of atherosclerosis throughout the arterial tree (Nakashima et al. 1994).

Fu et al. (2003) reported that the PPARα agonist ciprofibrate severely aggravates hypercholesterolemia and accelerates the development of atherosclerosis in mice lacking apolipoprotein E.

Wang (2005) described the cardiovascular functional phenotype of ApoE knockout mice and reported that simvastatin paradoxically increased serum lipids and atherosclerosis, but decreased serum lipids and atherosclerosis in LDL receptor knockout mice.

Meier and Leitersdorf (2004) reviewed nutritional, pharmacologic, and genetic atherosclerosis intervention studies in ApoE knockout mice. Several known beneficial nutritional interventions are effective, as well as ACE inhibitors, Ang II receptor blockers, the cholesterol absorption inhibitor ezetimibe and PPARγ agonists. Meier pointed out that the model helps the understanding that atherosclerosis is a form of chronic inflammation and that, despite being imperfect, the ApoE knockout mouse is currently the most popular mouse model used by researchers around the globe.

Overexpression of apolipoprotein E in transgenic mice reduced plasma cholesterol and triglyceride levels, prevented hypercholesterolemia and inhibited the formation of fatty streak lesions (Harada et al. 1996).

Transgenic mice overexpressing the human dysfunctional apolipoprotein E variant APOE*3 Leiden develop hyperlipidemia and are highly susceptible to diet-induced atherosclerosis (Groot et al. 1996).

Sullivan et al. (1998) reported type III hyperlipoproteinemia and spontaneous atherosclerosis in mice resulting from gene replacement of mouse ApoE with human ApoE*2.

Severe hypercholesterolemia, hypertriglyceridemia, and atherosclerosis were observed in ob/ob mice lacking both leptin and the LDL receptor (Hasty et al. 2001).

Based on animal knockout, transgenic, and gene therapy studies, Bursill et al. (2004) highlighted the importance of chemokines, particularly the CC-chemokines and fractalkine, in atherosclerosis.

M.1.0.6 Evaluation of Endothelial Function in Rabbits with Atherosclerosis

PURPOSE AND RATIONALE

Cholesterol feeding of rabbits impairs the endothelium-dependent relaxation evoked by acetylcholine in the aorta. This phenomenon can be used to study the influence of vasodilators as well as the prevention by ACE-inhibitors (Becker et al. 1991).

PROCEDURE

Male white New Zealand rabbits weighing 3–4 kg receive a hypercholesterolemic diet containing 0.25 to 1% cholesterol and 3% coconut oil. Rabbits of the same weight receiving standard diet serve as controls. After several weeks, the serum cholesterol levels are increased from 30–40 mg/dl in the control group up to 900–1000 mg/dl in the cholesterol-fed group. At the end of the treatment period, the animals are sacrificed by intravenous injection of sodium pentobarbital and a complete autopsy is performed.

Intact proximal parts of the thoracic aorta are sectioned into 2 mm wide rings, cut off to strips,

and suspended at 2 g gauge in 25 ml organ chambers filled with a buffer solution of 37°C comprising 113.8 mM NaCl, 20 mM $NaHCO_3$, 4.7 mM KCl, 1.2 mM KH_2PO_4, 1.1 mM $MgSO_4$, 2.5 mM $CaCl_2$, and 5.5 mM glucose being gassed with a 95% O_2/5% CO_2 mixture to achieve a pH of 7.4. After 2 h, when a stable contractile tone is established, norepinephrine is added at a final concentration of 1×10^{-8} M, which produces a stable submaximum isotonic contraction. Then, acetylcholine is added in 10 fold incremental doses from 1×10^{-8} M up to final concentrations of 10^{-5} M. Relaxation of aortic strips is assessed as percentage decrease in contraction. Acetylcholine induced concentration-dependent relaxation is greatly impaired in aorta rings from cholesterol-fed rabbits whereas contractions to norepinephrine are only slightly diminished.

EVALUATION

The data are expressed as mean ± SEM and compared by Student's *t*-test for unpaired data.

MODIFICATIONS OF THE METHOD

Verbeuren et al. (1986, 1990) and Tagawa et al. (1991) used a bioassay for the determination of EDRF (Rubanyi et al. 1985). The donor thoracic aorta segments (3 cm long) are mounted horizontally in perfusion chambers filled with physiological salt solution which contains indomethacin (3×10^{-6} M) at 37°C; the solution is gassed with a mixture of 20% O_2, 5% CO_2, and 75% N_2. The aortas (control and atherosclerotic tissue) and a piece of glass tubing are perfused continuously with the same solution at 3 ml/min. The perfusate is dripping directly onto a segment (5 mm long) of either a control or an atherosclerotic abdominal aorta from which the endothelium was mechanically removed. The detector abdominal aortas are mounted vertically over two hooks and the development of isometric tension is monitored continuously. The initial tension of the detector aortas is set at 8 g. The perfusate of each donor aorta is analyzed both on a control and on an atherosclerotic detector preparation: the order of this double analysis is selected at random. A control and an atherosclerotic donor aorta are always analyzed in parallel and thus on the same detector tissue. Drugs are added to the perfusion medium. Before the start of the experiments, the tissues are allowed to equilibrate for 45 min in the perfusion chambers. By means of a three-way system, placed at the outlet of the donor aortas, atropine (10^{-6} M) is added to the perfusate to block any muscarinic contractile effect of acetylcholine on the detector tissue. Noradrenaline (2×10^{-6} M) is infused into the perfusate via this 3-way system causing a sustained contraction in the detector tissue.

After the stabilization of the contraction to noradrenaline, the highest dose of acetylcholine (1.6×10^{-8} mol) is added to the solution for perfusion of the tubing in order to confirm no change in the contractile response to noradrenaline in the detector tissues. Moreover, the perfusate from the control and atherosclerotic donor aortas under basal conditions does not significantly affect the contraction of the detector tissues. The tissues are allowed to equilibrate and then increasing doses of acetylcholine (0.01 to 160×10^{-10} mol) are injected into the perfusion medium close to the donor aortas. Relaxation is less pronounced in the detector tissues when atherosclerotic aortas are stimulated with acetylcholine indicating that the cholinergic agent causes a smaller release of EDRF from atherosclerotic donor aortas than from control donor aortas. The degree of the arteriosclerotic lesion can be assessed by this functional assay.

M.1.0.7 Intimal Reactions After Endothelial Injury

PURPOSE AND RATIONALE

Several attempts have been made to induce intimal injury in animals which is followed by proliferation and formation of fatty streaks similar to the alterations found in human atherosclerosis. One approach is the "balloon catheterization".

PROCEDURE

Male New Zealand White rabbits weighing 2.0–3.5 kg or male Sprague-Dawley rats weighing 350–400 g are used. An embolectomy catheter (Edwards Laboratories, size 4 French for rabbits, size 2 French for rats) is introduced into the right femoral artery under surgical anesthesia and passed to the aortic arch. After inflation with room air, the catheter is withdrawn to the iliac bifurcation, deflated and removed.

The incorporation of [^{3}H]thymidine into DNA of rabbit or rat aorta is measured 48 h after balloon catheterization. Animals are sacrificed 45 min after intravenous injection of [^{3}H]thymidine. Intima-media is prepared from whole aorta by scraping with blunt forceps. The specific activity of ^{3}H in DNA is determined after extraction of the DNA in the washed tissue homogenate using hot dilute perchloric acid. DNA is assayed by the diphenylamine method. ^{3}H Incorporation is measured in a liquid scintillation counter.

For histological examination, rabbits are injected 2 weeks after balloon catheterization intravenously with heparin (500 U/kg) and then sacrificed. Fixative (2% glutaraldehyde in 0.15 M phosphate buffer, pH 7.4) is infused at a constant pressure of 100 mm Hg via a carotid cannula and the aorta is pressure fixed *in situ* for 60 min. Intimal proliferation is quantified in the upper abdominal aorta, in the lower abdominal aorta and half-way between these points.

EVALUATION

[^{3}H]Thymidine incorporation and intimal proliferation is compared between drug treated animals and controls.

MODIFICATIONS OF THE METHOD

DeCampli et al. (1988) studied the effects of various drugs on accelerated myointimal proliferation in canine veno-arterial allografts by histological methods. An 8-cm length of femoral vein was removed, reversed, divided, and sewn end-to-end into carotid or femoral arteries of a recipient dog.

Berkenboom et al. (1989) induced experimental atherosclerosis in **canine** and **porcine** coronary arteries by endothelial denudation followed by a high-cholesterol diet.

Kawata et al. (1990) described the detection of regenerating cells in the aorta after ballooning by immunocytochemical demonstration of the thymidine analogue 5-bromo-2′-deoxyuridine.

Manderson et al. (1990) described changes in vascular reactivity of carotid arteries in rabbits following endothelial denudation.

Bocan et al. (1991) tested an ACAT inhibitor and selected lipid-lowering agents for anti-atherosclerotic activity in iliac-femoral and thoracic aortic lesions. Atherosclerotic lesion comparable in composition to human fatty streaks were induced by chronic endothelial denudation in the iliac-femoral artery inserting a sterile, indwelling, 18-cm nylon filament with a diameter of 200 µm into the lumen of the right femoral artery in hypercholesterolemic New Zealand White rabbits. Naturally occurring fatty streaks developed in the thoracic aorta following cholesterol feeding. The effect of treatment on lesion regression was evaluated in the iliac-femoral artery, while changes in the lesion progression were evaluated in the thoracic artery.

Davies et al. (1993) performed right common carotid artery bypass grafting using the ipsilateral external jugal vein in New Zealand White rabbits and studied the response to endothelin-1 in normolipidemic and hyperlipidemic animals.

Groves et al. (1993) studied platelet adhesion and thrombus formation in a **porcine** model of balloon angioplasty.

ACE inhibitor treatment reduced the neointima formation after endothelial denudation in the carotid artery of **rats** using a balloon catheter (Farhy et al. 1992; Linz and Schölkens 1992; Linz et al. 1993, 1994).

Lyle et al. (1995) tested the effect of inhibitors of factor X_a or platelet adhesion, heparin, and aspirin on platelet deposition in an atherosclerotic rabbit model of angioplastic injury. Acute ^{111}indium-labelled platelet deposition and thrombosis were assessed 4 h after balloon-injury in femoral arteries subjected to prior endothelial damage (air desiccation) and cholesterol supplementation (1 month).

M.2 Influence on Lipid Metabolism

M.2.0.1 General Considerations

Elevated lipid levels, especially hypercholesterolemia, result from increased absorption from the gut, enhanced endogenous synthesis, or inadequate clearance from serum. Therefore, there are three feasible ways to reduce hyperlipidemia: to block endogenous synthesis, decrease absorption or enhance clearance from serum. These three factors can be evaluated in normal animals without artificial diets. Clinically used lipid-lowering compounds such as PPARα agonists (fibrates), cholesterol absorption inhibitors (ezetimibe), bile acid sequestrants, and HMG-CoA reductase inhibitors (statins) can be tested in this way, and their pharmacological activity further investigated with additional tests. For the investigation of the effects on plasma lipids, the right animal model has to be chosen. For fibrates, rats and mice are appropriate models; for LDL-lowering compounds, hamster, guinea and rabbits. Earlier attempts to interfere with endogenous cholesterol synthesis resulted in the accumulation of sterols other than cholesterol (Holmes 1964). To date only the inhibition of cholesterol biosynthesis with HMG-CoA reductase inhibitors has been a clinically effective approach for LDL cholesterol lowering. Inhibition of other enzymes of the cholesterol biosynthesis pathway upstream from HMG-CoA reductase, such as squalene synthetase, were investigated by several pharmaceutical companies until the 1990s, but this development was discontinued for safety reasons. Inhibition of cholesterol biosynthesis upstream from HMG-CoA reductase leads to nonphysiological accumulation of metabolic intermediates. In the past the inhibition of cholesterol absorption by ACAT-inhibitors was a widely followed approach. ACAT-inhibitors inhibit cholesterol absorption in rodents effectively, but so far all ACAT-inhibitors have been ineffective in humans. The only compound that is effective in humans is ezetimibe, an azetidinone. The compound was discovered fortuitously in an ACAT-inhibitor program. During the development of that compound, it was found that ezetimibe inhibits cholesterol absorption independently from ACAT (Van Heek et al. 2000, 2001, 2003; Harris et al. 2003; Clader 2004). Ezetimibe inhibits cholesterol absorption in several animal models and is effective against plasma LDL-cholesterol in humans. Another approach to enhance hepatic LDL clearance is to interrupt bile acid recirculation. Compounds that inhibit bile acid absorption increase the conversion of cholesterol into bile acids, enhance hepatic clearance, and lower LDL cholesterol by LDL receptor upregulation in the liver.

Protective effects of calcium antagonists against experimental arteriosclerosis acting mainly on other mechanisms than lipid metabolism have been claimed by various authors but the clinical relevance is still questionable (Kjeldsen and Stender 1989; Fronek 1990; Knorr and Kazda 1990; Fleckenstein-Grün et al. 1992).

M.2.0.2 Hypolipidemic Activity in Rats

PURPOSE AND RATIONALE

Hyperlipoproteinemia with increased concentrations of cholesterol- and triglyceride-carrying lipoproteins is considered to be the cause of arteriosclerosis with its dual sequelae of thrombosis and infarction. Lipoproteins are divided into 6 major classes: chylomicrons, chylomicron remnants, VLDL (very low density lipoproteins), IDL (intermediate density lipoproteins), LDL (low density lipoproteins), and HDL (high density lipoproteins). HDL promotes the removal of cholesterol from peripheral cells and facilitates its delivery back to the liver. Therefore, increased levels of HDL are desirable. On the contrary, high levels of VLDL and LDL promote arteriosclerosis. LDL, especially in its oxidized form, is taken up by macrophages via a scavenger mechanism. Therefore, anti-arteriosclerotic drugs should reduce VLDL and LDL and/or elevate HDL.

PROCEDURE

Groups of ten male Wistar or Sprague Dawley rats weighing 180–200 g are used. They are given once daily in the morning over a period of 5–8 days the test compounds or the standard in various doses ranging from 1 to 100 mg/kg via a stomach tube in a volume of 5 ml/kg. The control group is given the solvent (e. g., 0.5% HEC with 0.4% Tween 80) only. The body weight of each animal is recorded at the beginning and at the end of the experiment. If the effect on VLDL and triglycerides is the focus of the experiment, animals should be non-fasted or postprandial, and food should be withdrawn for no longer than 4 h before blood sampling. On the morning of the first day, blood samples are taken under light isoflurane or CO_2 anesthesia by retro-orbital puncture. Then, the first dose is applied. During the whole period, the animals have free access to food and water. At the end of the experiment, blood samples are taken by retro-orbital puncture. Immediately thereafter, the animals are sacrificed and the liver removed, blotted free from blood and weighed. Samples of liver are frozen in liquid nitrogen and stored at –25°C for lipid analysis. The blood samples are centrifuged for 2 min at 16,000 *g*. Total cholesterol and triglycerides in each blood sample are determined.

To estimate the serum lipoproteins two methods are available: ultracentrifugation and liquid chromatography. For ultracentrifugation more than 1 ml serum is needed, so the serum has to be group-vice pooled. The serum lipoproteins are separated by means of a preparative ultracentrifuge.

The separation of fractions VLDL, LDL, HDL, and of the subnatant of HDL is carried out as follows:

VLDL	native density of the serum (1.006), 16 h at 40,000 rpm,
LDL	density range from 1.006 to 1.04, 18 h at 40,000 rpm,
HDL	density range from 1.04 to 1.21, 18 h at 40,000 rpm,
Subnatant of HDL	density > 1.21

The density is adjusted by addition of a calculated amount of NaBr solution.

Another faster approach is the separation of lipoprotein by fast protein liquid chromatography (FPLC).

Distribution of cholesterol to lipoprotein fractions is performed after separation of fractions by gel permeation chromatography, using a published method (März et al. 1993). The cholesterol and triglyceride content in the isolated lipoprotein fractions after ultracentrifugation or FPLC separation is determined using standard enzymatic assays for clinical diagnostics

(e. g., Roche-Diagnostics, CHOD-PAP method, Siedel et al. 1983). Triglycerides are also determined with standard enzymatic assays for clinical diagnostic (e. g., Roche Diagnostics, GPO-PAP method; Eggstein and Kreutz 1966a, 1966b; Wahlefeld 1974). The method of Lowry et al. (1951) is applied to determine protein content.

Frozen samples of liver are thawed, homogenized and aliquots are extracted with chloroform/methanol or dichloromethane/methanol 2:1 (v/v). The extracts are purified according to Folch et al. (1957). Solvents of aliquots of the extracts are evaporated and dissolved in isopropanol for determinations of cholesterol and triglycerides, using enzymatic assays for serum diagnostics (Herling et al. 1999).

EVALUATION

Average values of body weight, cholesterol and triglycerides are expressed as percentage of initial values for each group at the end of the experiment. Statistical differences between the controls and the treatment groups are evaluated by covariance analysis.

CRITICAL ASSESSMENT OF THE METHOD

Studies with normocholesterinemic animals are faced with the difficulty that starting cholesterol levels are relatively low, and to achieve significance for lowering of cholesterol levels requires large groups of animals. LDL cholesterol lowering can be investigated in normocholesterolemic hamster, guinea pigs or minpigs, not in mice or rats. Triglyceride-lowering drugs such as fibrates are very effective against serum triglycerides and cholesterol in normolipemic male Sprague Dawley rats.

MODIFICATIONS OF THE METHOD

Similar tests can be performed in various species, e. g.:

- male NMRI mice, weighing 25–30 g, male or female C57/bl6 mice weighing 18–24 g,
- male New Zealand obese (NZO) mice, weighing 35–40 g,
- male Syrian golden hamsters, weighing 80–120 g,
- male Pirbright guinea pigs, weighing 200–250 g,
- male miniature pigs, weighing 14–22 kg.

To study long term effects, the experiments are extended for 4 weeks or 3 months.

Schurr et al. (1976) proposed high volume screening procedures for hypobetalipoproteinemic activity in rats.

März et al. (1993) described fast lipoprotein chromatography as a new method of analysis for plasma lipoproteins.

Adipokinetic actions of several hormones in slices of perirenal adipose tissue of various species were determined by Rudman et al. (1963).

M.2.0.3 Hypolipidemic Activity in Syrian Hamsters

PURPOSE AND RATIONALE

The Syrian hamster (*Mesocricetus auratus*) is a widely used animal to study the effects of drugs and diet on lipoprotein metabolism. Several in human approved lipid lowering drug like HMG-Co A reductase inhibitors, cholestyramine or ezetimibe lower plasma cholesterol in hamster. The lipoprotein and bile acid metabolism of the hamster is closer to human than the lipoprotein and bile acid metabolism of rats and mice (Bravo et al. 1994; Suckling et al. 1991; Kris-Etheron and Dietschy 1997). The hamster has in contrast to pig, rat and mouse CETP (Cholesteryl Ester Transfer Protein) activity, similarly as seen in humans (Ha and Barter 1982, 1986; Ahn et al. 1994).

Increase in plasma cholesterol can be easily induced by adding small, physiological amounts of cholesterol to the diet (0.05–0.01 weight%). Additional saturated fat like coconut oil (5–10 weight%) has synergistic effects for induction of hyperlipidemia. (Kowala et al. 1991) A stable hyperlipidemia with a human like lipoprotein pattern can be induced in hamster within 2–3 weeks by adding 10 weight% coconut butter and 0.2% cholesterol into the diet. Hamster HDL cholesterol can be easily measured after precipitation of VLDL+LDL cholesterol with phoshotungstic acid/$MgCl_2$ (Weingand and Daggy 1990, 1991). LDL and HDL cholesterol can also be measured directly with Kits from Roche Diagnostics. A complete separation of all lipoprotein fractions can be done by FPLC on Superose 6 columns (Pharmacia) with a modified method of März et al. (1993).

PROCEDURE

Male Syrian hamsters weighing 95–125 g at the start of the experiment are randomly assigned to form groups of 6–15 animals each. Test compounds can be administrated by oral gavage, once or twice daily or mixed into the diet. If compounds are administered with diet, a different diet has to be prepared for each group. One control receives powdered or pellet standard hamster chow only; a second control and the treated groups, a cholesterol-enriched diet. If compounds are administered with diet a daily food consumption of 8 g should be taken in account for dose calculation. Cholestyramine, for example, is active when mixed into the diet in a concentration range between 0.3% to 2%. After 1–3 weeks on these diets, the animals are anesthetized with isoflurane, a blood sample is taken from the retroorbital vene plexus, the superior vena cava or the abdominal aorta, and the liver is removed and weighed. Microsomes are prepared by ultracentrifugation from the livers.

Preparation of Plasma Lipoprotein Profiles

The blood is centrifuged at 6000 *g* for 5 min and the plasma removed. The plasma is analyzed for total cholesterol and triglycerides using colorimetric enzymatic assays for clinical diagnostics, as described in the previous chapter for rats (e. g., Roche Diagnostics). The cholesterol content of HDL and LDL was determined using enzymatic assays for clinical diagnostics (Roche Diagnostics, HDL-C plus and LDL-C plus).

Quantification of High-Density-Lipoprotein Cholesterol by Differential Precipitation

Weingand and Daggy (1990) compared the validity of differential precipitation with Mg^{2+}-phosphotungstate for quantification of plasma high-density-lipoprotein cholesterol with ultracentrifugal flotation.

As precipitating agent, 0.55 mmol/l phoshotungstic acid and 25 mmol/l magnesium chloride is added. Cholesterol is determined spectrophotometrically with an

enzymatic cholesterol reagent containing microbial cholesterol esterase, in a Hitachi 705 clinical chemistry analyzer.

Fast Lipoprotein Chromatography

März et al. (1989, 1993) developed fast lipoprotein chromatography for rapid and quantitative analysis of lipoprotein fractions.

Fast lipoprotein chromatography is carried out with a chromatography system from Kontron consisting of two Model 420 pumps, a Model 432 variable-wavelength detector, and a Model 450 data system. Without using a pretreatment, 20 µl of plasma are applied to a 300-mm Superose column 6 equilibrated with 100 mmol/l Na_2HPO_4, pH 7.4, and 200 mmol/l NaCl. Lipoproteins are detected on-line at 500 nm after post-column derivatization with CHOD-PAP cholesterol reagent (Roche Diagnostics, Mannheim, Germany). The column eluate and the cholesterol reagent are mixed in a motor-driven microchamber attached to the column outlet, and the mixture is then passed through a "knitted" capillary (20–22). The flow rate of the reagent is 70 µl/min; the run time is 80 min. Under these conditions, it takes the column eluate 2 min to pass the derivatization capillary. VLDL-C, LDL-C and HDL-C are calculated on the basis of relative peak areas and total cholesterol, previously measured with an enzymatic assay in serum as described above.

Tissue Preparation

The liver is homogenized in a KCl (0.104 M) solution containing NaF (50 mM) using a glass Teflon homogenizer. The homogenate is centrifuged at 30,000 *g*, 5°C for 25 min. The supernatant is then centrifuged at 100,000 *g*, 5°C for 60 min to pellet the microsomes, which are resuspended in potassium phosphate buffer (50 mM) containing NaF (50 mM) adjusted to pH 7.4.

Determination of Enzyme Activities in Microsomal Fractions

Protein for all the following assays is determined using the method described by Bradford (1976).

HMG-CoA reductase activity is determined by quantifying the conversion of [^{14}C]HMG-CoA to [^{14}C]mevalonic acid lactone, based on the method described by Ingebritsen and Gibson (1981). ACAT activity in liver microsomes and intestinal cell homogenates is determined by the method described by Suckling et al. (1982), measuring the incorporation of [^{14}C]oleoyl-CoA into cholesteryl oleate. The cholesterol 7α-hydroxylase activity in the microsomes is quantified by determination of the percentage conversion of [^{14}C]cholesterol to 7α-hydroxy[^{14}C]cholesterol. 3 mg of microsomal protein is diluted to a volume of 5.3 ml with a potassium phosphate buffer (50 mM, pH 7.4) containing NaF (50 mM), cysteamine (31.4 mM), glucose-6-phosphate (12.7 mM) NADP (1.4 mM) and [^{14}C]cholesterol (0.22 µCi, 55 Ci/mol). After a short pre-incubation (5 min at 37°C), the reaction is started by the addition of glucose-6-phosphate dehydrogenase suspension (7 µg). The reaction is stopped 1 h later by adding methanol (5 ml). The cholesterol and 7α-hydroxy-cholesterol are extracted into a mixture of chloroform and methanol (2:1, v/v, 2 × 5 ml). The product and substrate are separated by thin-layer chromatography on silica gel eluting with toluene/ethyl acetate (3:7, v/v). The radioactive regions corresponding to cholesterol and 7α-hydroxy-cholesterol are scraped off the plates and quantified by liquid scintillation counting. An alternative non-radioactive method to determine 7α-hydroxylase activity is described in detail in Sect. M.2.0.8.

EVALUATION

Dose–response curves for standard and test drug are established using the serum LDL cholesterol value of the standard chow fed as the maximal effect and the cholesterol control data as zero.

CRITICAL ASSESSMENT OF THE METHOD

Potent drugs acting on cholesterol or bile acid absorption lower serum LDL cholesterol below the level measured in animals on standard chow. PPARα agonists (fibrates) increase liver triglycerides in hamsters on a normal or high-fat diet (Planke et al. 1988). HMG-CoA reductase inhibitors (statins) are not well tolerated, the therapeutic range of statins which is effective against LDL cholesterol is very narrow, and the animals have to been treated for longer than 3 weeks to see the maximal effects of statins on serum LDL cholesterol.

M.2.0.4 Triton-Induced Hyperlipidemia

PURPOSE AND RATIONALE

The systemic administration of the surfactant Triton to mice or rats results in a biphasic elevation of plasma cholesterol and triglycerides. Triton inhibits lipoprotein lipase (LPL) activity and so VLDL particle clearance (Frantz and Hinkelman 1955; Garattini et al. 1958, 1961; Holmes 1964; Tamasi et al. 1968; Millar et al. 2005).

PROCEDURE

Male Sprague Dawley or Wistar rats weighing 200–350 g were starved for 18 h and then injected intravenously with 200 mg/kg Triton WR 1339 (isooctyl-polyoxy-ethylene phenol). Serum triglycerides increased 20-fold in a nearly linear fashion within 1 and 8 h and serum cholesterol levels increased sharply 2–3 times within 24 h (phase I). The hypercholesterolemia decreased nearly to control levels within the next 24 h (phase II). The test drugs employed or the vehicle for the controls were administered simultaneously with the Triton injection if only the acute effect of a drug was investigated or ad 1–3 days before. Serum triglyceride cholesterol analyses were carried out 0, 2, 4, 6, and 8 h after Triton injection in order to investigate drugs that interfere with triglyceride synthesis; and 0, 6, 24, and 48 h after Triton injection for investigation of drugs that are effective against cholesterol synthesis. In 1951 it was described by Kellner et al. that intravenous injection of nonionic detergents increased serum lipids up to 48 h. Later it was shown by Schotz et al. (1957) that the hyperlipidemia is induced by inhibition of triglyceride hydrolysis by lipoprotein lipase. Since then, lipolysis inhibition has been used to determine hepatic VLDL secretion rates. The VLDL secretion rate can be calculated from the increase in triglyceride and cholesterol over time after the Triton injection. Drugs interfering with hepatic triglyceride and cholesterol biosynthesis were shown to be active in phase I, while drugs interfering with cholesterol clearance, excretion and metabolism were active in phase II.

EVALUATION

Mean values ± standard deviation are calculated for each group and time interval and compared statistically with the controls.

CRITICAL ASSESSMENT OF THE METHOD

The method employing Triton hypercholesterolemia is rather simple and rapid for detection of compounds interfering with the synthesis of triglycerides or synthesis and excretion of cholesterol. Since the test is rather artificial, the results have to be validated by other methods, e. g., *ex vivo* measurement of liver cholesterol synthesis.

M.2.0.5 Fructose-Induced Hypertriglyceridemia in Rats

PURPOSE AND RATIONALE

Rats switched from a diet low in carbohydrates and high in protein to a high intake of fructose, develop an acute hypertriglyceridemia. Compounds are tested for inhibition of this phenomenon.

PROCEDURE

Male Sprague Dawley rats weighing 200–250 g were fed over a period of 1 week a diet enriched in protein with reduced carbohydrate content, e. g., Altromin C1080 or C1009. Groups of ten animals were treated for 3 days daily with the test compound or the standard (fenofibrate 30–100 mg/kg) or the vehicle (0–5% hydroxyl-ethyl-cellulose) by oral gavage. From the second to the third day water was withheld for a period of 24 h. Immediately afterwards, the animals were offered 20% fructose solution ad libitum for a period of 20 h. After this time, which was also 20 h after the last application of the test compound, the animals were anesthetized with isoflurane or CO_2/O_2 (70/30 v/v) and 1.2 ml blood was withdrawn by retro-orbital puncture. The blood was centrifuged at 6000 *g* for 5 min and the serum removed. The serum was analyzed for total cholesterol and triglycerides and glycerol using a colorimetric enzymatic assay for clinical diagnostics, as described in the previous chapter for rats (e. g. Roche Diagnostics).

EVALUATION

The average values of total glycerol for the treated groups are compared with those for the control group using ANOVA.

M.2.0.6 Intravenous Lipid Tolerance Test in Rats

PURPOSE AND RATIONALE

Intravenous injection of a lipid emulsion results in an increase of triglycerides in serum. The lipolytic activity can be determined by measuring lipid elimination.

PROCEDURE

Male Wistar rats weighing 200–240 g are treated daily with various doses of the test compound or the vehicle over a period of 5 days. On the fifth day, two hours after the last administration of the test compound, the animals are anesthetized with isoflurane or 40–60 mg/kg sodium pentobarbital i.p. Then they are injected intravenously with 2 ml/kg of a 10% lipid emulsion (Intralipid Vitrum, Hausmann AG, St. Gallen, Switzerland). Prior to the injection and 10, 20, 30, and 40 min thereafter blood is withdrawn by retro-orbital puncture for determination of triglycerides.

EVALUATION

Peak levels as well as elimination constant and half life are determined.

M.2.0.7 Influence on Lipoprotein-Lipase Activity

PURPOSE AND RATIONALE

Post-heparin plasma lipolytic activity is measured by at least two lipase activities: hepatic lipase (HL) and lipoprotein lipase (LPL). Hypothyroid rats show a selective decline of post-heparin plasma hepatic lipase (Murase and Uchimura 1980).

For patients with familial lipoprotein lipase deficiency a rapid diagnostic test was developed (Gotoda et al. 1991). The method was used to study the influence of drugs on lipoprotein lipase activity (Tsusumi et al. 1993).

PROCEDURE

Male Wistar rats weighing 180–200 g receive either various single doses or one daily dose of test compounds over a period of several days. Blood samples are drawn from the tail vein into tubes containing 1 mg EDTA/ml. The animals are then injected with 100 U/kg heparin via the tail vein and blood samples are collected 5 min later. Plasma samples are used to determine lipoprotein lipase and hepatic lipase activity.

Lipoprotein lipase activity in postheparin plasma is measured using glycerol tri[1-^{14}C]oleate as substrate and selective blocking of hepatic lipase activity with antiserum to rat hepatic lipase. Hepatic triglyceride lipase activity in postheparin plasma is obtained by subtracting lipoprotein lipase activity from total plasma lipase activity.

EVALUATION

The dose-related increase of plasma lipoprotein lipase activity and the time course after drug administration are evaluated.

M.2.0.8 Influence on Several Steps of Cholesterol Absorption and Formation

PURPOSE AND RATIONALE

Cholesterol levels in the body result from two sources: absorption from the gut and endogenous *de novo* synthesis. Certain natural products and the azetidinone drug ezetimibe inhibit cholesterol absorption and reduce plasma cholesterol levels in experimental animals and are therefore of potential pharmacologic interest in the treatment of hypercholesterolemia. In rodents cholesterol absorption can be decreased by inhibition of acyl coenzyme A:cholesterol acyltransferase (ACAT). In humans ACAT-inhibitors are not effective. Inhibition of cholesterol resorption results in a compensatory increase of hepatic 3-hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA) reductase activity, which can be decreased by (HMG-CoA) reductase inhibitors (statins). The hepatic cholesterol biosynthesis can be measured with several radioactive tracers as described later in Sect. M.3, by conversion of radioactive precursors into cholesterol. In addition to serum LDL cholesterol, hepatic cholesterol biosynthesis is a biomarker for the *in vivo* efficacy of cholesterol absorption inhibitors. Harwood et al. (1993) and van Hek and Davis (2002) studied the pharmacologic consequences of cholesterol absorption inhibition: alteration in cholesterol metabolism and reduction in plasma cholesterol concentration induced by a synthetic saponin β-tigogenin cellobioside or ezetimibe.

PROCEDURE

Male golden Syrian hamsters, weighing 100–120 g, are housed in a reversed light-dark cycle room (light between 3:00 P.M. and 3:00 A.M.) and receive a cholesterol-poor or cholesterol-enriched diet and water ad libitum 1 week prior to use. The animals are assigned to groups of 6 animals each and are given free access to water and chow that contains the compounds to be tested in appropriate concentrations for 4 days. At 9:00 A.M. of the fourth day of the study, the animals receive a 1.0-ml oral bolus of liquid formulation of cholesterol and radiolabeled cholesterol dissolved in Intralipidcontaining 15 mg of [^{3}H]cholesterol (2.25 μCi) and 7.5 mg cholic acid for determining cholesterol absorption. At 9:00 A.M. of the fifth day (peak of the diurnal cycles of HMG-CoA reductase and cholesterol 7α-hydroxylase activities) animals are anesthetized with pentobarbital and blood samples are obtained by cardiac puncture for deter-

mining plasma cholesterol and triglyceride levels, and cholesterol absorption.

Livers are removed, weighed, rinsed in 4°C saline, and apportioned for determining hepatic cholesterol levels, hepatic HMG-CoA reductase, cholesterol 7α-hydroxylase activities, hepatic LDL receptor concentration, and cholesterol absorption.

For determination of total hepatic cholesterol, one aliquot of the liver tissue (0.5 g) is saponified in 5 ml ethanolic KOH, 3.3% (v/v) at 65°C for 1 h. After addition of 5 ml water and 2 mg 5-cholestene (internal standard), lipids are extracted with 15 ml petroleum ether. Samples are shaken several times to extract the sterols into the petroleum ether phase. Then 100 µl of the petroleum ether phase (upper phase) is transferred into an HPLC autosampler vial and the solvent is removed by air-stream. For final HPLC analysis, the samples are mixed with an equal volume of HPLC eluent. The total cholesterol content is detected at 210 nm after isocratic HPLC separation on an RP C18 column (Merck Lichrospher 100, 250 × 4 mm, 5 µm) with 2-propanol-acetonitrile (55:45 v/v) as eluent solution (0.8 ml/min) using 5-cholestene as an internal standard.

Alternatively, hepatic cholesterol concentration can also be measured with a colorimetric enzymatic assay. Frozen samples of liver are thawed, homogenized and aliquots are extracted with chloroform/methanol and analyzed as described earlier in Sect. M.2.0.2 (Herling et al. 1999).

Hepatic microsomes for measurement of hepatic HMG-CoA reductase activity and cholesterol 7α-hydroxylase activity are prepared according to Harwood et al. (1984) and Junker and Story (1985). For measurement of HMG-CoA reductase activity, 0.5 g liver are immediately homogenized at 4°C in 1 ml TEDK buffer (containing 50 mM Tris (pH 7.5), 1 mM EDTA, 5.0 mM dithiothreitol, and 70 mM KCl) using 15 strikes in a Dounce homogenizer. For measurement of cholesterol 7α-hydroxylase activity, 0.5 g liver pieces are immediately homogenized at 4°C in 1 ml PEDSKF buffer (containing 40 mM phosphate (pH 7.4), 5 mM EDTA, 5 mM DTT, 250 mM sucrose, 50 mM KCl, and 50 mM KF) using 20 strokes of a Dounce homogenizer. Homogenates are first centrifuged at 4°C for 20 min at 10,000 *g* and the resultant supernatant is then centrifuged at 4°C for 90 min at 178,000 *g*. The resulting microsomal pellets are resuspended in either 1.0 ml TEDK per g liver (HMG-CoA reductase determination) or 1 ml PEDSKF per g liver (cholesterol 7α-hydroxylase determination) by 5 strokes of a Potter-Elvehjem pestle and are stored frozen in liquid nitrogen.

For measurement of hepaticHMG-CoA reductase activity, 50 µg of microsomal protein is incubated for 30 min at 37°C in a final volume of 75 µl of TEDK buffer containing 3.4 mM $NADP^+$, 30 mM glucose-6-phosphate, 66.7 µM [^{14}C]HMG-CoA (10 cpm/pmol), 15000–20,000 cpm [^{3}H]mevalonate (0.6–1.2 Ci/mmol) as an internal standard, and 68 mM EDTA to prevent conversion of mevalonate to phosphomevalonate during incubation. After incubation, 10 µl of 6 M HCl are added to terminate the enzyme reaction and to convert the newly formed mevalonate to mevalonolactone. The mevalonolactone is then separated from unreacted substrate by silica gel thin-layer chromatography. After development in toluene-acetone 1:1, the region of the chromatogram corresponding to $R_f = 0.4–1.0$ is removed, immersed in liquid scintillation fluid, and counted using a dual channel $^3H/^{14}C$ program. HMG-CoA reductase activity is expressed as pmoles of mevalonate formed from HMG-CoA per min of incubation at 37°C per mg of microsomal protein.

Cholesterol 7 α-hydroxylase activity was determined with a modified method according to the procedure of Hylemon (1989) with the following modifications. To measure 7α-hydroxylase activity, 2 mg microsomal protein (1 ml in assay buffer) is pre-incubated for 10 min at 37°C with 20 µl cholesterol solution (1 mg/ml) in 45% hydroxypropyl-ß-cyclodextrin (ICN) in order to saturate the enzyme with cholesterol substrate. 7α-Hydroxycholesterol is measured with isocratic HPLC analysis on a C-18 reversed-phase column (Merck 250 × 4 mm, 5 µm), at 240 nm with acetonitrile:methanol (70:30 v/v) as eluent (0.7 ml/min) using 7ß-hydroxycholesterol as internal standard. The protein content of the microsomes is measured by the BCA method (Pierce).

Cholesterol 7α-hydroxylase activity is expressed as pmoles of 7α-hydroxycholesterol formed from cholesterol per minute of incubation per milligram of microsomal protein.

Hepatic *in vivo* cholesterol biosynthesis is determined with a method according to Dietschy and Spady (1984). [^{14}C]Octanoic acid sodium salt (NEC 092H, concentration 0.1 mCi/ml in ethanol, NEN, Cologne, Germany) is used as tracer. The metabolism of the tracer into liver cholesterol is investigated using the following procedure. The solution is concentrated about 20-fold under a nitrogen stream and dissolved in 0.9% NaCl to a final concentration of 50 µCi/ml. This

solution is injected into the femoral vein at a dose of 10 µCi/100 g body weight under ether anesthesia.

The animals are killed 1 h after administration and the liver removed and washed in isotonic NaCl solution. Three aliquots (0.5 g) are extracted in 30 ml of 6.6% ethanolic KOH at 65°C for 2 h. After cooling down to room temperature, 5 ml aqua is added and the cholesterol is extracted twice with 15 ml petroleum ether into a volumetric flask. The petroleum ether is removed under an air stream. The lipid phase is resolved and transferred three times with 2 ml ethanol acetone 1:1 (v/v) into a 15-ml glass vial after heating the glass container used. The cholesterol is precipitated with digitonin after adding one drop of 1M HCl, 2 ml 10% aqueous aluminum chloride, 3 ml 0.5% digitonin in ethanol water 1:1 (v/v), and incubated for 1 h at 45°C in a water bath. The liquid phase is discarded after centrifugation. The pellet is washed with 5 ml acetone three times and once with ether. Each pellet is rolled out by hand on a table until completely dry.

To cleave the digitonin–cholesterol complex, the vials are heated to 80°C and the cholesterol resolved with 0.6 ml pyridine. When the samples are cooled to room temperature, 5 ml ether is added twice, the samples are centrifuged, and the liquid phase is transferred into scintillation vials. The ether is removed under air stream, and the residual cholesterol resolved with 1 ml methanol and 10 ml scintillation cocktail (Ecolite ICN, Eschwege, Germany).

The radioactivity is counted in a ß-scintillation counter. The disintegrations per minute (DPM) are calculated per gram of liver tissue after background correction and correlated with the liver cholesterol concentration in a graph plotting liver cholesterol on the *x*-axis and radioactivity (dpm/g liver tissue) on the *y*-axis. Orientation of treated groups relative to cholesterol-fed and non-cholesterol-fed control animals gives information about sterol turnover.

Hepatic LDL receptor levels are measured by enzyme immune blotting (Cosgrove et al. 1992). One hundred –150 µl of the soluble extracts containing 100–600 µg protein are adjusted to 2% SDS and 0.2 M sucrose by addition of 0.33 volumes of electrophoresis sample buffer (containing 320 mM Tris (pH 6.8), 8% SDS, and 0.8 M sucrose). Mixtures are applied without heating and without addition of β-mercaptoethanol to 6-mm wells of a 7.5% (w/w) 0.1% SDS-containing polyacrylamide slab gel of 1.5 mm thickness. Electrophoresis is conducted at room temperature with a constant current of 15 mA/gel. Prestained molecular weight markers are included in a separate lane to monitor separation. After electrophoresis, proteins migrating into the gel are electrophoretically transferred to S&S BA85 nitrocellulose membranes at 18°C with a constant voltage of 120 V for 6–8 h in 25 mM Tris, 192 mM glycine buffer (pH 8.3), containing 20% methanol.

After transfer, the nitrocellulose paper is incubated with 100 ml of Tris buffered saline containing 3% gelatin for 30 min at room temperature with gentle shaking. After incubation, the nitrocellulose sheet is removed from the blocking solutions, immersed without rinsing into 50 ml Tris buffer solution (TBS) containing 1% gelatin and 250 µl of anti-LDL receptor peptide antiserum (final dilution 1:200) and incubated for 2 h at room temperature with gentle shaking. The nitrocellulose sheet is washed twice for 10 min each with TBS containing 0.05% Tween-20 and once for 10 min with TBS. The washed nitrocellulose sheet is incubated with 50 ml TBS containing 1% gelatin and 100 µl of goat anti-rabbit IgG-horseradish conjugate (final dilution 1:500) at room temperature for 1 h with gentle shaking. After incubation, the nitrocellulose is washed again as described above. During this final wash, 40 mg of 4-chloro-1-naphthol is dissolved in 10 ml methanol, and 50 µl cold 30% hydrogen peroxide is added to 50 ml TBS containing 1% gelatin. After draining the final TBS wash from the nitrocellulose, the two solutions are mixed and immediately added to the nitrocellulose. The mixture is incubated at room temperature with gentle shaking until the desired color development is observed. The nitrocellulose sheet is washed with running tap water for 15 min. The nitrocellulose is dried between pieces of filter paper and the intensity of color formation is quantitated by reflectance densitometry using a suitable instrument (e. g., Hoefer Scientific Instruments GS300 Transmittance/Reflectance Scanning Densitometer). Color intensity, which is a linear function of the number of LDL receptors in the analyzed fraction, is expressed in terms of mm peak height (arbitrary reflectance units).

Intestinal cholesterol absorption is estimated with the dual isotope feces ratio method using [^{3}H]sitostanol and [^{14}C]cholesterol. Each hamster received an intragastric dose of a mixture of [^{3}H]sitostanol and [^{14}C]cholesterol dissolved in Intralipid or plant oil, or in detergent mix (Tricaprin/Tricapril). The feces is collected for 48 h after dosing and homogenized with water; aliquots are oxidized in a sample oxidizer, which traps CO_2 and H_2O in separate vials mixed with liquid scintillation fluid, and counted using a background correction program. The absorption ratio can be calculated by changes of the $^{14}C/^3H$ ratio in application solution and feces with

the following formula ($^{14}C/^{3}H$ application solution – $^{14}C/^{3}H$ feces)/ $^{14}C/^{3}H$ application solution.

If a sample oxidizer is not available an alternative method is the recovery of radioactivity present in the liver and plasma 24 h after an oral bolus of [^{3}H]cholesterol. For assessment of hepatic radioactivity, 1.0-g liver pieces are placed in 50-ml polypropylene tubes and incubated with 2.5 ml of 2.5 M KOH for 2 h at 75°C. After allowing the saponification mixture to cool to room temperature, 5.0 ml of 80% ethanol, 0.1 ml [^{14}C]cholesterol (40,000 dpm, 15 dpm/nmol) as carrier and extraction standard and 10 ml of hexane are added. Tubes are capped and shaken vigorously for 1 min. Mixtures are permitted to stand to allow phase separation, and are shaken vigorously for an additional minute. Mixtures are the centrifuged at 1000 *g* for 5 min. Duplicate 3.0-ml aliquots of each hexane layer are removed, transferred to 20-ml liquid scintillation vials, mixed with 10 ml liquid scintillation fluid, and counted using a dual channel $^{3}H/^{14}C$ program.

After correction for recovery losses, hepatic radioactivity is calculated based on total liver weights. For assessment of total plasma radioactivity, 200-µl aliquots of plasma are added to 20-ml liquid scintillation vials and decolorized by addition of 25 µl of hydrogen peroxide. Then 10 ml aqueous scintillation fluid is added and the mixture assessed for radioactivity. Total radioactivity in the plasma is calculated based on the assumption that hamsters possess approximately 4.0 ml plasma per 100 g body weight. The degree of cholesterol absorption is expressed as a percentage of the total radioactivity administered that is present in the liver plus plasma 24 h after bolus administration.

For **determination of bile acids in feces**, pooled feces from each group of animals is collected over a period of 48 h (about 20 g). After addition of 9 ml ethanol, 1 ml water and hyodeoxycholate (internal standard) the mixture is continuously shaken at 90°C overnight. Samples are centrifuged and an aliquot of the liquid phase is diluted 1:5 with methanol for quantification of bile acids. Individual bile acids (deoxycholate; lithocholate; 12-oxo lithocholate) are separated and quantified by HPLC-MS (HPLC: RP C18 column Merck Purospher™, end-capped, 5 µm, 125 × 3 mm; gradient elution (20%–60% eluent B, 15 min, 0.6 ml/min; eluent A: 90% H_2O, 10% acetonitrile; eluent B: 10% H_2O, 90% acetonitrile, buffered at pH 8 with 20 mM ammonium acetate; MS detection: electrospray negative mode Hewlett Packard, 1100 MSD).

For **lipid and lipoprotein determinations**, serum or plasma can be used. Blood samples are treated either with EDTA or heparin to prevent clotting or without an anticoagulant and are then centrifuged, as described earlier in Sects. M.2.0.2 and M.2.0.3.

EVALUATION

Inhibition of cholesterol resorption results in a decrease of hepatic cholesterol and a compensatory increase of hepatic HMG-CoA reductase activity resulting from de novo cholesterol synthesis and an increase of hepatic LDL receptor levels.

MODIFICATIONS OF THE METHOD

Ogishima and Okuda (1986) described an improved method for assay of cholesterol 7α-hydroylase activity. Cholesterol 7α-hydroxylation is performed in liver microsomes utilizing cholesterol as substrate. 7α-Hydroycholesterol is converted by the action of cholesterol oxidase into 7α-hydro-4-cholesten-3-one having an intense absorption at 240 nm.

Hylemon et al. (1989) reported a modified HPLC-spectrophotometric method for measuring cholesterol 7α-hydroxylase activity by using a C-18 reverse-phase column to separate 7α-hydroxy-4-cholesten-3-one and 4-cholestene-3-one and by adding 7β-hydroxycholesterol to each reaction mixture as an internal recovery standard. This method measures simultaneously cholesterol 7α-hydroxylase activity using endogenous cholesterol and exogenous [4-^{14}C]cholesterol as substrate.

Princen and Meijer (1990) measured cholesterol 7α-hydroxylase activity in cultured rat hepatocytes.

M.3 Inhibition of Cholesterol Biosynthesis

M.3.1 General Considerations on Cholesterol Biosynthesis

The following steps are involved in cholesterol biosynthesis:

- HMG-CoA synthase (hydroxymethylglutaryl-coenzyme A synthase)
- forming **hydroxymethylglutaryl-CoA** from acetyl-CoA and acetoacetyl-CoA
- HMG-CoA reductase (hydroxymethylglutaryl-coenzyme A reductase)
- forming **mevalonic acid** from hydroxymethylglutaryl-CoA.

Inhibition of cholesterol synthesis on this step is used at present successfully for therapy (see below)

- Mevalonate kinaseforming **5-phospho-mevalonic acid** from mevalonic acid,
- Phospho-mevalonate kinase forming **5-pyrophospho-mevalonic acid** from 5-phospho-mevalonic acid,
- Pyrophospho-mevalonate decarboxylase forming **3-isopentyl-pyrophosphate** from 5-pyrophospho-mevalonic acid,
- Isopentyl-pyrophosphate isomerase forming **3,3-dimethyl-pyrophosphate** from 3-isopentyl-pyrophosphate,
- Dimethylallyl-transferase forming in a two step process **geranyl pyrophosphate** from 3,3-dimethyl-pyrophosphate, and
- **Farnesyl pyrophosphate** from geranyl pyrophosphate,
- Squalene synthetaseforming **squalene** from farnesyl pyrophosphate,
- Squalene epoxidaseforming **2,3-oxidosqualene** from squalene,
- 2,3-Oxidosqualene cyclase forming **lanosterol** from 2,3-oxidosqualene.

Following the formation of lanosterol (4,4,14α-trimethylcholesta-8(9),24-dien-3β-ol), a series of enzyme reactions is required to produce cholesterol (Bae et al. 1999):

- to 4,4,14α-trimethylcholesta-8(9)-en-3β-ol,
- to 4,4-dimethylcholesta-8(9),14-dien-3β-ol,
- to 4,4-dimethylcholesta-8(9)-en-3β-ol,
- to cholesta-8(9)-en-3β-ol,
- to cholesta-7-en-3β-ol,
- to cholesta-5,7-dien-3β-ol (7-dehydrocholesterol), and finally
- to cholesta-5-en-3β-ol (cholesterol) by 7-dehydrocholesterol reductase.

Besides **inhibition of HMG-CoA reductase** (detailed description below) other approaches to inhibit biosynthesis of cholesterol are reported:

- **inhibition of HMG-CoA synthase** (Goldstein and Brown 1990; Miller et al. 1980; Greenspan et al. 1987; Grayson and Westkaemper 1988);
- **inhibition of squalene synthase** (Ness et al. 1994; Sliskovic and Picard 1997; Rosenberg 1998; Hiyoshi et al. 2000; Squalene synthase plays an important role in sterol biosynthesis by catalyzing the head-to-head condensation of two molecules of farnesylpyrophosphate. The enzyme is a single 47,000 Da polypeptide that is bound to the subcellular membranes of the endoplasmatic reticulum in yeast and mammalian liver (see below);
- **inhibition of squalene epoxidase** (Ryder 1992); Squalene epoxidase catalyzes the conversion of squalene to (3S)-2,3-oxidosqualene, an essential step in the biosynthesis of sterols in mammals, plants, and microorganisms (see below)
- **inhibition of 2,3-oxidosqualene cyclase** (Gerst et al. 1986; Cattel et al. 1989; Sen and Prestwich 1989; Dollis and Schuber 1994; Mark et al. 1996; Eisele et al. 1997; Morand et al. 1997; Abe et al.

1998a); The enzyme 2,3-oxidosqualene cyclase is of special interest due to its dual function: cyclization of 2,3-monoepoxysqualene to lanosterol and 2,3:22,23-diepoxysqualene to oxylanosterol. An orally active oxidosqualene:lanosterol cyclase inhibitor (Ro48–8071) showed potent noncompetitive inhibition of bacterial squalene:hopene cyclase from *Alicyclobacillus acidocaldarius*. A tritium-labeled isotopomer of this nonterpenoid inhibitor, which possesses a benzophenone photophore, was chemically synthesized as a photoaffinity label (Abe et al. 1998b);

- **inhibition of 7-dehydrocholesterol reductase** (Amin et al. 1996); Deficiency of this enzyme causes a severe developmental disorder with multiple congenital and morphogenic abnormalities, the Smith-Lemli-Opitz syndrome (Waterham and Wanders 2000).

Search and development of new cholesterol-lowering drugs is continued (Abe and Prestwich 1998). Whether the efficacy and safety of these agents in man will be on the long run superior to currently available therapies remains to be determined.

M.3.2 Determination of HMG-CoA-Reductase Inhibitory Activity

M.3.2.1 General Considerations on HMG-CoA-Reductase

More than 70% of the total production of body cholesterol in humans is derived from de novo synthesis. 3-Hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA) reductase is the rate limiting enzyme governing cholesterol biosynthesis and the synthesis of other isoprenoids in mammalian cells (Rodwell et al. 1976).

The development of HMG-CoA reductase inhibitors (called statins) offers an advance in the treatment of hypercholesterolemia by interfering with the crucial step of cholesterol biosynthesis. When inhibiting hepatic HMG-CoA reductase, the inhibitors trigger an increased production of LDL receptors in the liver. As LDL receptor activity increases, more LDL is extracted from the blood and thus the level of circulating LDL-cholesterol is reduced. Pharmacological evaluation of HMG-CoA reductase inhibitors is based on studies on the inhibition of the isolated enzyme HMG-CoA -reductase *in vitro*, on the inhibition of the incorporation of ^{14}C sodium acetate into cholesterol in isolated liver cells, and on the effect of HMG-CoA -reductase inhibitors *in vivo*. HMG-CoA reductase activity has a diurnal rhythm in liver and intestine which has to be considered for *in vivo* studies (Shapiro and Rodwell 1969; Shefer et al. 1972).

HMG-CoA reductase inhibitors have been associated with skeletal myopathy (rhabdomyolysis) in humans and experimental animals (Flint et al. 1997; Klotz 2003). The rhabdomyolysis is probably mechanism based, from the cerivastatin cases it could be concluded that the risk of rhabdomyolysis is related to active drug levels in the systemic circulation and peripheral tissues (Graham et al. 2004).

M.3.2.2 Inhibition of the Isolated Enzyme HMG-CoA-Reductase in Vitro

PURPOSE AND RATIONALE

For screening purposes, studies on the inhibition of HMG-CoA reductase obtained from rat liver microsomal fraction can be used (Avigan et al. 1975; Philipp and Shapiro 1979).

PROCEDURE

The inhibitory activity of the test compound on HMG-CoA reductase is estimated with soluble enzyme preparations obtained from the microsomal fraction of rat liver (Philipp and Shapiro 1979). The enzyme reaction is carried out with 50 µl partially

purified HMG-CoA reductase in buffer containing 25 mM Tris, 10 mM EDTA, and 10 mM dithiothreitol at pH 7.5, 20 µl of 910 µM HMG-CoA solution containing 100 nCi (3.7 KBq) of ^{14}C-HMG-CoA and 20 µl of NADPH regenerating system (5.2×10^{-2} M glucose-6-phosphate, 1 unit glucose-6-phosphate dehydrogenase, 5.3×10^{-3} M NADP), with the actual concentration of 50 mM NADPH. The final incubation volume is 200 µl. The main reaction is preceded by 20 min preincubation with the NADPH regenerating system at 37°C, followed by 20 min incubation at 37°C of the completed samples with the test compound or the standard and stopped by addition of 75 µl 2 N $HClO_4$. After 60 min at room temperature, the samples are cooled in an ice-bath and neutralized by addition of 75 µl 3 N potassium acetate. Supplementing the volume with water to 500 µl, the precipitate is centrifuged and 250 µl of the clear supernatant are applied to a column (0.6 × 8.0 cm) of BIORAD AG 1-X8 (100–200 mesh). Mevalonolactone is eluted with water discarding the first 750 µl and collecting the next 3500 µl. Five hundred µl of the eluate are used for measurement in duplicate, mixed in vials with 10 ml Quickscint (Zinsser) and measured in a liquid scintillation counter (Beckman). The assay is generally performed in triplicate. Lovastatin sodium is used as standard.

EVALUATION

The mean values with and without inhibitors are compared for the calculation of inhibition. IC_{50} values are calculated.

M.3.2.3 Inhibition of the Incorporation of ^{14}C-Sodium Acetate into Cholesterol in Isolated Liver Cells

PURPOSE AND RATIONALE

De novo synthesis of cholesterol from labelled acetate can be measured in isolated liver cells. This synthesis can be inhibited by incubation with HMG-CoA reductase inhibitors.

PROCEDURE

Monolayers of primary cell cultures from hepatocytes of female rats or of cultures of HEP-G2 cells (human hepatoma cells) are incubated in a lipoprotein deficient medium for 1 h with various concentrations of the potential HMG-CoA reductase inhibitor or the standard (Lovastatin). Thereafter, the labelled precursor ^{14}C sodium acetate is added to the medium and the incubation continued for further 3 or 24 h. To one part of the cells an internal standard of ^{3}H-cholesterol is added and the cells are saponified by alkaline. The lipids of these saponified cells are extracted with chloroform/methanol. The lipid mixture is separated by preparative thin layer chromatography. The localization of cholesterol is identified by exposure to iodine vapor and the amount of newly synthesized ^{14}C-cholesterol is determined in a scintillation counter.

Cell protein is determined in another part of the cells. A third part of the cell culture is used to control the integrity of the cells by light microscopy and tested biologically by determination of the release of lactate dehydrogenase into the incubation medium.

EVALUATION

The amount of newly synthesized cholesterol per mg cell protein is calculated. The inhibitory capacity of the test drug is estimated against a solvent control. IC_{50} values are calculated from the results of various concentrations.

MODIFICATIONS OF THE METHOD

Chen and Kandutsch (1976) studied the effects of cholesterol derivatives on sterol biosynthesis in cultures of various cell types.

Liver specificity of inhibition of sterol synthesis is studied by *in vitro* uptake into hepatocytes and human

skin fibroblasts (Scott 1990) or in slices of various tissues after oral treatment with HMG-CoA reductase inhibitors (Tsujita 1990).

Shaw et al. (1990), however, caution against the use of HEP-G2 cells which may not be the cell system of choice to demonstrate liver selectivity of inhibitors of HMG-CoA reductase.

Cultures of HEP-G2 cells have also be used to test inhibition of cytoplasmic acetoacetyl-CoA thiolase (Greenspan et al. 1989) or inhibition of squalene epoxidase (Hidaka et al. 1991).

Pearce et al. (1992) used HEP G2 cells to study the hypocholesterolemic activity of synthetic and natural tocotrienols *in vitro*.

Raiteri et al. (1997) investigated drugs acting at different steps of the mevalonate pathway on arterial smooth muscle cell proliferation. Competitive HMG-CoA reductase inhibitors dose-dependently decreased smooth muscle cell proliferation.

M.3.2.4 Ex Vivo Inhibition of Cholesterol Biosynthesis in Isolated Rat Liver Slices

PURPOSE AND RATIONALE

Inhibition of cholesterol biosynthesis in rat livers can be measured in an *ex vivo* assay after oral treatment with HMG-CoA reductase inhibitors by cholesterol synthesis from labelled sodium octanoate.

PROCEDURE

Male Sprague Dawley rats weighing 110–130 g are kept on a reverse light cycle (lights 3:00 P.M. to 3:00 A.M.) for 14 days prior to use. Throughout the period of adaptation, the rats have free access to a low cholesterol diet and tap water. On the day of the experiment, the test compounds are given orally between 9:00 and 11:00 A.M. as suspensions in 0.5% methylcellulose. After one hour, the rats are sacrificed, the livers removed and transferred to chilled oxygenated Krebs-Ringer-bicarbonate buffer (pH 7.4). The livers are then chopped into 0.8-mm^2 pieces using a McIlwain tissue chopper (e. g., Brinkmann Instr., Westbury, USA) and are suspended in the same buffer. Aliquots of the suspension are pipetted, in triplicate, into culture tubes which contain [^{14}C]sodium octanoate (300 µM/l, 6.67 Ci/M). The assay volume is 1 ml. The tubes are gassed with 95% O_2/5% CO_2 for 10 s, stoppered with a serum cap, and incubated at 37°C in a metabolic shaker at 150 oscillations/min for 90 min.

The reaction is stopped by addition of 1 ml 15% KOH in ethanol. An aliquot of the mixture is assayed for protein concentration. An internal standard [^{3}H]cholesterol (30,000 dpm) is added to determine recovery, which ranges from 70–80%. The tubes are saponified at 75°C for 2 h and then extracted with 10 ml of petroleum ether for 30 min. The lower aqueous phase is frozen in a dry ice/alcohol mixture, and the ether phase is removed, washed with 2 ml glass-distilled water and then evaporated to dryness. The [^{14}C]cholesterol synthesized is separated by thin layer chromatography on plastic silica gel plates using chloroform as eluent. After visualization with iodine, the

cholesterol spots are cut out, and radioactivity quantitated by liquid scintillation counting.

EVALUATION

Results are expressed as percentage inhibition compared to vehicle-treated control values. Using various doses, ED_{50} values of inhibition can be calculated from dose-response curves.

MODIFICATIONS OF THE METHOD

Koga et al. (1990) tested the tissue-selective inhibition of cholesterol synthesis *in vivo* by pravastin sodium in mice. Drugs were orally administered to mice 2 h prior to an intraperitoneal injection of [^{14}C]acetate. The animals were sacrificed 1 h afterwards and the cholesterol synthesis determined in various organs.

M.3.2.5 Effect of HMG-CoA-Reductase Inhibitors in Vivo

PURPOSE AND RATIONALE

A strain of rabbits with heritable hyperlipidemia, the WHHL strain, has been described by Watanabe et al. (1980, 1985, 1988). These animals develop digital xanthoma and aortic and coronary atherosclerosis already at an early age. This animal is considered to be a suitable model for the evaluation of preventive or even regressive effects of drugs on hyperlipidemia and atherosclerosis.

PROCEDURE

Male heterozygous WHHL rabbits weighing 1.8 to 2.5 kg at an age between 8 and 20 weeks are used. The animals are housed individually under standard conditions (standard rabbit diet and water ad libitum) and are allowed to accommodate 2 weeks prior to treatment. The test compounds are suspended in 0.5% methylcellulose and are administered each day orally by gavage in the afternoon to insure an increased plasma level at night, since in man HMG-CoA reductase activity has been found to be higher at night than during daytime (Shapiro and Rodwell 1969; Shefer et al. 1972) similar to the enzyme in rodents. The treatment is continued for 14 days.

Blood samples are taken in the morning without previous feeding. Two ml of blood are drawn from the outer ear vein 5 days prior to the beginning of treatment, on days 3 and 8 of treatment and 30 days after the end of treatment for the determination of biochemical parameters. In addition, 6 ml blood are drawn at the first and the last day of treatment and 10 days after the end of treatment for determination of biochemical parameters and lipoprotein profile. In order to obtain serum, blood is allowed to clot at room temperature and then centrifuged twice at 10,000 rpm.

The following biochemical parameters are determined in non-frozen samples (kept at 4°C): total cholesterol, HDL-cholesterol, triacylglycerol, as well as creatinine, total bilirubin, alkaline phosphatase, alanine amino transferase (ALAT), aspartate amino transferase (ASAT), and γ-glutamyl transferase (γ-GT) using commercially available kits.

The separation of serum lipoproteins by gel permeation chromatography is performed according to Ha and Barter (1985). This method is particularly well suited for the metabolic studies of lipoproteins, because the elution profile can be obtained from the same sample under more gentle conditions than by sequential ultracentrifugation. According to their descending particle size, the elution profile of lipoproteins in the same fraction of density (< 1.21 g/ml) shows, as the elution progresses, three major peaks which correspond to very low density lipoproteins (VLDL), low density lipoproteins (LDL) and high density lipoproteins (HDL), respectively.

Since the amount of serum collected from one rabbit is too low to determine the lipoprotein profile from each sample, the total lipoproteins are isolated by ultracentrifugation at a density < 1.21 g/ml and the lipoproteins thus obtained in each group are pooled two by two prior to injection onto the cross-linked agarose HR 50 column (Superose 6B). As a result,

each lipoprotein profile represents the lipoprotein size distribution of an equal volume of lipoproteins obtained from two rabbits. Cholesterol and triacylglycerol concentrations are determined in each 1 ml elution fraction.

EVALUATION

The data at 5 days before beginning of treatment and of day 0 of each animal are pooled and the mean is taken as reference value. Student's paired *t*-test is used to calculate for each group the significance of difference between mean values.

MODIFICATIONS OF THE METHOD

Extension of the treatment period up to 24 weeks allows to evaluate the meanwhile apparent atherosclerotic lesions in the aorta and the coronaries by gross observation and light microscopy (Tsujita 1990).

Kasim et al. (1993) studied the effect of lovastatin on the secretion of very low density lipoprotein lipids and apolipoprotein B in the Zucker obese rat which is basically a model for genetic hypertriglyceridemia.

Soma et al. (1993) studied the effects of HMG-CoA reductase inhibitors on carotid intimal thickening induced by placing a nonocclusive, biologically inert, soft, hollow Silastic collar around both carotid arteries in normocholesterolemic rabbits (Booth et al. 1989).

Bocan et al. (1994) assessed atherosclerotic lesion development in the thoracic artery and chronically denuded iliac-femoral artery of hypercholesterolemic New Zealand White rabbits using inhibitors of HMG-CoA reductase.

Krause and Newton (1995) tested the lipid-lowering activity of atorvastatin and lovostatin in several rodent species (rat models, guinea pigs, rabbits). They concluded that normal rats can be used as a preclinical tool to assess the efficacy of HMG-CoA reductase inhibitors since triglyceride lowering correlates with cholesterol lowering in LDL animal models.

Johnston et al. (2001) induced atheroma formation in the aortas of C57BL/6 mice by long-term administration of Poloxamer-407, a nonionic surfactant, and tested the potency of selected statin drugs in this model of hyperlipidemia and atherosclerosis.

Delsing et al. (2003) studied differential effects of a calcium antagonist and a statin and their combination on atherosclerosis in ApoE*3-Leiden transgenic mice.

Aoki et al. (2002) induced postprandial lipemia in rats by administration of a lipid emulsion and measured the triglyceride-lowering effect of a statin.

Ugawa et al. (2002) established an experimental model of the escape phenomenon in hamsters in which plasma cholesterol, initially reduced by statins, increases again on long-term administration, and tested the effectiveness of a squalene synthase inhibitor in this model.

Yokota et al. (2003) tested the protective effect of a HMG-CoA reductase inhibitor on experimental renal ischemia-reperfusion injury in mice.

Abletshauser et al. (2002) reported a new method for biosensing of arteriosclerotic nanoplaque formation and interaction with an HMG-CoA reductase inhibitor and recommended this method for experimental and clinical studies.

M.3.2.6 Influence of Statins on Endothelial Nitric Oxide Synthase

PURPOSE AND RATIONALE

Several studies indicate that the beneficial effects of 3-hydroxy-3-methylglutaryl coenzyme A reductase inhibitors (statins) on endothelial function and cardiovascular ischemic events may be attributed not only to their lipid-lowering effect but also to direct effects on the atherosclerotic vessel wall. One such effect is the upregulation of nitric oxide synthase, which generally leads to vasorelaxation (Kano et al. 1999; Amin-Hanjani et al. 2001; Rikitake et al. 2001; Sata et al. 2001; Sumi et al. 2001; Jones et al. 2002; Laufs et al. 2002; Mitani et al. 2003a, 2003b; Parker et al. 2003; Wassmann and Nickenig 2003; Yamamoto et al. 2003; Kumai et al. 2004).

Parker et al. (2003) compared different statins for e-NOS subcellular localization, formation of prooxidants, and endothelial-dependent vascular function.

PROCEDURE

Endothelium-Dependent Vascular Relaxation Ex Vivo in Statin-Treated Rats

Sprague Dawley rats (~160 g) on standard chow are treated with HMG-CoA reductase inhibitors for 8 days at doses that do not result in plasma cholesterol reductions as determined in previous experiments. To assay vascular relaxation, aortas are dissected out and perivascular tissue removed. Aortic rings (~5 mm) are incubated at 37°C in pH 7.4 Krebs-bicarbonate buffer with 5.mM glucose and 95% O_2/5% CO_2, and suspended on a strain gauge transducer to measure isometric circumferential tension. After adjustment basal tension to 2.0 g over 90 min, aortic rings are contracted submaximally with a thromboxane receptor agonist (U-46619) and exposed to increasing concentrations of acetylcholine (or nitroprusside as control), which is known to induce endothelium-dependent relaxation by activating e-NOS.

Data are expressed as mean (±SEM) percentage decrease in tension from the level of induced tone. Significance is determined with Student's *t*-test/two-way ANOVA.

Vascular Endothelial Cell Culture

Human arterial endothelial cells (HAECs) and human umbilical vein endothelial cells (HUVECs) are used at passages 3–8. Culture and statin incubations are conducted in Clonetics complete EGM medium (M-188-derived) with 2% serum. For experiments using redox probes, cells are grown in 24-well plates or collagen-coated glass chamber-slides to near confluency. For cell-based assays using oxyhemoglobin and cytochrome c, endothelial cell cultures are pretreated with statins in flasks, then harvested by brief trypsinization, centrifuged and suspended in KREBS-Ringer buffer with 5.5 mM glucose and 95% O_2/5% CO_2 for assay in cuvettes.

Fluorescence Assays for Intracellular Reactive Nitrogen and Oxygen Species

As peroxynitrite indicator DHR-123 is used, which is non-fluorescent and enters cells readily where it is oxidized (with limited selectivity by $^{=}$ONOO and $^{=}$OH) to the cationic, fluorescent rhodamine-123 (RH-123), which is entrapped in mitochondria (Kelm et al. 1997). Statins are added to endothelial cell cultures for 4–16 h followed by addition of DHR-123 (5 μM), bradykinin (1 μM) and A23187 (1 μM) to activate e-NOS. At the indicated times, cells are washed with PBS, and intracellular fluorescence is assayed using a fluorescent plate reader (Cytofluor-4000, $\lambda ex = 485 \pm 20$, $\lambda em = 530 \pm 25$ nm).

DHR oxidation is also assayed *ex vivo* in aortic specimens isolated from statin-treated rats. Aortic rings are incubated in 300 μl of EGM medium containing DHR-123 (5 μM), bradykinin (1 μM) and A23187 (1 μM) at 37°C for 90 min. Samples are washed twice in PBS, the homogenized in PBS + 0.1% Tween-20 +

0.1% SDS, and duplicate aliquots are taken for fluorescence readings. Protein is determined by the Bradford method. A fluorescence standard curve for DHR-123 oxidation product (HR-123) is generated and results are calculated as pmol product per mg protein.

Spectrophotometric Assay for Superoxide Anion

The assay of superoxide anion in the presence of NO in intact cells is accomplished by an adaptation of the spectrophotometric method described by Kelm et al. (1977). Endothelial cells are treated with statins in monolayer culture, then detached and resuspended in Krebs-Ringer buffer. Cells are added to cuvettes (7.5×10^5 to 1.25×10^6 cells/ml) with oxyhemoglobin (3 µM), ferricytochrome c (10 µM) and $CaCl_2$ (0.1 mM) and assayed at 37°C with continuous stirring and 95% O_2/5% CO_2 flow. Agonists are added at 5-min intervals. Absorbance spectra from 400 to 600 nm are collected at 1-min intervals using a Beckman DU-7500 diode array spectrophotometer with data capture software. The superoxide anion-specific reduction of cytochrome c is measured as the change over time in absorbance difference between 465 nm and the isosbestic wavelength 525 nm.

Fluorescence Microscopy with DHR-123 and e-NOS Immunofluorescence

Human arterial endothelial cells are grown on glass chamber slides and incubated for several hours with the statins and 10 µM DHR-123. Localization of the DHR-123 oxidized product is analyzed by epifluorescence using Nikon Microphot-FXA with Chroma High-Q resorufin filter and interference contrast optics. Images are captured using a Photometric Image Point CCD video camera. For e-NOS localization, human arterial endothelial cells are fixed and processed for immunofluorescence using rabbit polyclonal anti-eNOS antibody at 2 µg/ml and LRSC-conjugated donkey anti-rabbit IgG second antibody (Jackson Immunoresearch). Images comparing control and treated cells are obtained using the same CCD exposure times and video amplifier gain.

Subcellular Fractionation and Immunoblotting of Endothelial Cells

Human umbilical vein endothelial cells are incubated with statins followed by harvesting by scraping into 50 mM HEPES, 150 mM NaCl, 5 mM EDTA, pH 7.4, with protease inhibitors (Sigma, P-8340), and lysed by brief sonification in a glass homogenizer. Cell lysates are cleared at 500 *g* and fractionated by centrifugation at 16,000 *g*. The 16,000 *g* pellet is resuspended and ultracentrifuged in a discontinuous sucrose gradient (20 mM Tris-HCl, 1 mM EDTA, pH 7.4, with steps of 0.50 and 1.12 M sucrose) to isolate plasma membranes and Golgi/mitochondria-rich intracellular membranes. Microsomes and cytosol are isolated from the 16,000 *g* supernatant. Samples are assayed for e-NOS protein level by SDS-PAGE (4%–20% gradient gels) and western transfer to PVDF membranes (Novex LC-2002), and probed using rabbit polyclonal anti-eNOS antibody with peroxidase-linked anti-rabbit IgG for chemoluminescence and densitometry. Data are given as percentage of control absorbance units from densitometry.

Sterol Synthesis in Endothelial CELLS

Cholesterol synthesis is assayed in human arterial endothelial cells (Parker et al. 1990) grown to confluence and incubated for 16 h in serum-free standard medium + 1.0% serum albumin. Statins are added in various concentrations in DMSO vehicle and 0.5 h sterol synthesis is assayed by addition of Na-[1-^{14}C] acetate (4.0 µCi/well, 2.0 mCi/ml, 58 mCi/mmol) and incubation for 4 h at 37°C. Radiolipids in washed and lysed cells are extracted into chloroform–methanol and cell cholesterol is resolved by silica gel thin-layer chromatography. Radioactivity is determined by phosphoimager, and the 50% inhibitory concentration (IC_{50}) calculated and compared to that in vehicle controls.

EVALUATION

Data obtained by these methods suggest that the action of lipophilic statins in endothelium can shift e-NOS localization towards intracellular domains, thereby increasing the encounter with metabolically generated superoxide anion to produce peroxynitrite and related oxidants. Under some conditions, the direct action of lipophilic HMG-CoA reductase inhibitors may unbalance NO and superoxide anion fluxes and promote oxidant stress, compromising the beneficial vascular effects of e-NOS.

MODIFICATIONS OF THE METHOD

Kano et al. (1999) measured upregulation of eNOS mRNA in the rabbit aorta by a HMG-CoA reductase inhibitor using competitive reverse-transcriptase polymerase chain reaction methods.

Laufs et al. (2002) determined the expression and activity of eNOS by reverse-transcriptase polymerase chain reaction, Western blotting and arginine-citrulline assays.

Yamamoto et al. (2003) investigated the effect of a HMG-CoA reductase inhibitor on inducible nitric

oxide synthase expression in rat vascular smooth muscle cells using a modification of the semi-quantitative reverse transcription-polymerase chain reaction.

Ikeda et al. (2003) reported the protection of ischemic-reperfused myocardium in normocholesterolemic rats by a HMG-CoA reductase inhibitor.

Baetta et al. (2002) found that in the absence of lipid lowering, tissue factor expression in infiltrated inflammatory cells and macrophage accumulation in carotid lesions of cholesterol-fed rabbits are reduced by statin treatment.

Shimizu et al. (2003) performed heterotopic murine cardiac transplants in total allogenic or histocompatibility class II-mismatched combinations. Direct anti-inflammatory mechanisms of statins may contribute to the attenuation of experimental allograft arteriosclerosis.

M.3.3 Inhibition of Squalene Synthase

PURPOSE AND RATIONALE

Squalene synthase (farnesyl-diphosphate:farnesyl diphosphate farnesyl-transferase) is an enzyme vital for cholesterol biosynthesis. It catalyzes the dimerization of two farnesyl pyrophosphate molecules to form squalene, a key cholesterol precursor. Unlike HMG-CoA reductase inhibitors, squalene synthase inhibitors do not lower the levels of ubiquinone and dolicol *in vivo*, both essential for cell growth and viability. Several natural and synthetic squalene synthase inhibitors have been described (Biller et al. 1991a, 1991b; Oehlschlager et al. 1991; Baxter et al. 1992; Ciosek et al. 1993; Harris et al. 1995; Lindsey and Harwood 1995; Chan et al. 1996; Dufresne et al. 1996; McTaggart et al. 1996; Amin et al. 1996, 1997; Sliskovic and Picard 1997; Rosenberg 1998; Vaidya et al. 1998; Hiyoshi et al. 2000, 2003; Ugawa et al. 2000, 2002, 2003; Amano et al. 2003; Ishihara

et al. 2003; Nishimoto et al. 2003). Ugawa et al. (2000) determined squalene synthase activities in microsomes.

PROCEDURE

Microsomes are prepared from the livers of rats, hamsters, guinea pigs, beagle dogs and rhesus monkeys as well as from HepG2 cells. The tissues or harvested cells are homogenized in 50 mM HEPES buffer using a glass homogenizer. Homogenates are centrifuged at 500 *g* for 15 min at 4°C and the resulting supernatants are further centrifuged at 8000 *g* for 15 min at 4°C. Microsomes are then isolated from this second supernatant by ultra-centrifugation at 100,000 *g* for 60 min at 4°C. The microsome precipitates are suspended in HEPES buffer (1–5 mg/ml) and stored in aliquots at –80°C.

Squalene synthase activities of these microsomes are assayed using a modification of the technique of Amin et al. (1992). The test compounds are dissolved in DMSO and the assays carried out in 50 mM HEPES buffer, pH 7.5, containing (in mM): NaF 11, $MgCl_2$ 5.5, DTT 3, NADPH 1, farnesyl pyrophosphate (FPP) 5 µM, [^{3}H]-FPP (0.017 µM, 15 Ci/mmol), NB-598, a squalene oxidase inhibitor, 10 µM and sodium pyrophosphate decahydrate 1 mM. After preincubation of these components at 30°C for 5 min, the reaction is started by the addition of microsomes (10 µg protein). The reaction is carried out at 30°C for 20 min, then terminated by addition of 100 µl of 1:1 solution of 40% (w/v) KOH:ethanol. Synthesized [^{3}H]squalene is extracted in petroleum ether and counted in Aquasol-2 using a Beckman liquid scintillation counter.

EVALUATION

Results are expressed as mean ±SEM and compared using two-way repeated analysis of variance (ANOVA).

M.3.4 Inhibition of Squalene Epoxidase

PURPOSE AND RATIONALE

Squalene epoxidase is a microsomal enzyme that catalyses the oxidation of squalene to 2,3-oxidosqalene, the last reaction of non-sterol metabolites in the cholesterol biosynthesis pathway (Hidaka et al. 1990). Inhibitors of this enzyme are unlikely to block the production of biologically important non-sterol products, such as isoprenyl adenine, dolichol, coenzyme Q, or heme A, in contrast with HMG-CoA reductase inhibitors, which inhibit their production (Ghirlanda et al. 1993; Chugh et al. 2003). Several squalene epoxidase inhibitors have been described (Horie et al. 1990, 1991; Hikada et al. 1991; Moore et al. 1992; Gotteland et al. 1998; Sawada et al. 2001, 2004).

Sawada et al. (2001) described a modified squalene epoxidase assay.

PROCEDURE

HepG2 cells are cultured routinely in medium A (Eagle's modified minimum essential medium supplemented with 1 mM pyruvate and non-essential amino acids with 10% heat-inactivated fetal calf serum) at 37°C in a humidified 95% O_2/5% CO_2 air atmosphere.

For the assay, the cells are grown in 225-cm^2 culture flasks, and incubated for 18 h in medium A containing 10% human lipoprotein-deficient serum and 1 μM of the squalene synthase inhibitor L-654,949, to increase the squalene epoxidase activity. The HepG2 cells are washed and harvested by trypsin treatment. After centrifugation (100 *g*, 5 min at 4°C), the supernatant fraction is removed by aspiration. The cell pellet is frozen and kept at –80°C until use. On the day of the experiment, the cell pellet is thawed, ruptured by sonication (5 s at 4°C) in 0.1 M Tris-HCl, pH 7.5 containing 1 mM EDTA, mixed4$:1 with 2% Triton X-100, allowed to stand at 4°C for 30 min, and assayed for squalene epoxidase activity (Tai and Bloch 1972). Aliquots of the mixture are incubated for 90 min at 37°C with or without test compound dissolved in 1% DMSO in a final volume of 0.3 ml containing 0.1 M Tris-HCl, pH 7.5, 1 mM EDTA, 1 mM NADPH, 1 mM FAD, 0.3 mM AMO1618 (an inhibitor of 2,3-oxidosqualene cyclase), 0.17% Triton X-100, and 8 μM [^{3}H]-squalene (3.7 kBq) dispersed in 0.075% Tween 80. The reaction is stopped by the addition of 0.3 ml of 10% ethanolic KOH. After incubation for 90 min at 75°C, non-saponifiable materials are extracted with 2 ml of petroleum ether. The extracts are evaporated under a nitrogen stream. The residue is taken up in a small volume of diethyl ether, spotted on a silica gel thin layer chromatography plate and developed in benzene/ethyl acetate (99.5:0.5, v/v). The radioactivity corresponding to 2,3-oxidosqualene is counted by autoradiography.

EVALUATION

The results are expressed as means ±SD and evaluated by repeated-measures analysis of variance, followed by Dunnett's multiple comparisons.

MODIFICATIONS OF THE METHOD

A simplified squalene epoxidase assay based on HPCL separation and time-dependent UV/visible determination of squalene is published by Grieveson et al. (1997).

M.4 Inhibition of Cholesterol Absorption

M.4.1 Inhibition of ACAT (Acyl Coenzyme A: Cholesterol Acyltransferase)

M.4.1.1 General Considerations

Acyl coenzyme A:cholesterol acyltransferase (ACAT), which catalyses the intracellular formation of cholesteryl esters, plays an important role in the intestinal absorption of cholesterol, foam cell formation within the arterial wall and VLDL production in the liver. Two isoforms of the enzyme exist, ACAT1 expressed in macrophages and ACAT2 expressed in intestine and liver. Cholesterol is absorbed from the gut exclusively in the unesterified form, but appears in the lymph esterified with various long-chain unsaturated fatty acids. The enzyme responsible is ACAT, a microsomal enzyme, that utilizes long-chain fatty acyl coenzyme A and cholesterol as substrates. ACAT inhibitors also have potential actions beyond inhibition of cholesterol absorption. Inhibition of hepatic ACAT could reduce the production of cholesteryl esters for packaging into lipoproteins, while inhibition of ACAT1 in macrophages could reduce the deposition of cholesteryl esters and prevent the formation of foam cells and atherosclerotic lesions. Nevertheless, from investigations in ACAT2 knockout mice it is known that ACAT2 is not the only rate-limiting pathway for cholesterol absorption. On normal chow these mice absorp cholesterol as efficiently as wild-type mice, only if mice were fed a cholesterol-enriched diet. ACAT2 is important for cholesterol absorption (Lee et al. 2004; Repa et al. 2004). Under physiological conditions alternative pathways compensate for the ACAT2 deficiency in mice (Hussain et al. 2005).

Human ACAT cDNA was cloned from a human macrophage cDNA library and expressed in an ACAT deficient line of Chinese hamster ovary cells. The cDNA, labelled K1, encoded an integral membrane protein of 550 amino acids (Chang et al. 1993). The inhibition of ACAT as treatment for hypercholesterolemia and atherosclerosis is an attractive target.

M.4.1.2 In Vitro ACAT Inhibitory Activity

PURPOSE AND RATIONALE

In vitro ACAT inhibitory activity can be determined in microsomal preparations from liver or intestine of rabbits.

PROCEDURE

Hepatic or intestinal microsomes are prepared from rabbits. Prior to sacrifice, the animals receive chow supplemented with 2% cholesterol and 10% safflower oil for 6 weeks. Each assay contains 0.2 mg of microsomal protein and fatty acid-poor bovine serum albumin (3 mg/ml) in 0.04 M KH_2PO_4 buffer, pH 7.4, containing 0.05 M KCl, 0.03 M EDTA, and 0.3 M sucrose. Drug dilutions are made in DMSO (5 µl DMSO/200 µl total incubation volume). The reaction is started by the addition of [^{14}C]oleyl CoA (50 µM, 7 dpm/pmol). After 3 min the reaction is stopped by the addition of chloroform-methanol 2:1. [^{3}H]Cholesteryl oleate is used as an internal standard. Lipid extracts are dissolved in chloroform, spotted on TLC plates (silica gel G) and developed in hexane-petroleum ether-acetic acid 80:20:1. Unlabeled, carrier cholesterol oleate is added to the internal standard to aid band visualization with iodine vapor. The band corresponding to cholesteryl esters is then scraped into scintillation vials and radioactivity is determined by liquid scintillation spectroscopy.

EVALUATION

For each compound four concentrations are evaluated in duplicate. IC_{50} values are determined by performing a nonlinear least-squares fit of the data to a log dose-response curve.

MODIFICATIONS OF THE METHOD

Rothblatt et al. (1977) studied ACAT activity in Fu5 rat hepatoma cells under the influence of hyperlipemic serum lipoproteins.

Mathur et al. (1981) studied ACAT activity in hepatic microsomes of cynomolgus monkeys during diet-induced hypercholesterolemia.

Einarsson et al. (1989) studied acyl-CoA: cholesterol acyltransferase activity in human liver microsomes.

M.4.1.3 In Vivo Tests for ACAT Inhibitory Activity

PURPOSE AND RATIONALE

Most authors test the *in vivo* anti-atherosclerotic and antihyperlipemic effect of ACAT inhibitors in cholesterol-fed hypercholesterolemic animals (Balasubramaniam et al. 1990; Harris et al. 1992; Tanaka et al. 1944). Krause et al. (1993a) used the Zilversmit dual isotope technique (Zilversmit 1972; Cayen and Dvornik 1979) for determining cholesterol absorption in rats.

PROCEDURE

Male Sprague-Dawley rats weighing 200–225 g are fed with a diet containing 5.5% peanut oil, 0.5% cholic acid and 1.5% cholesterol with or without (controls) drugs for 1 week. On the last day, food is removed at 8:00 A.M. and the isotopes are administered beginning at 2:00 P.M. [^{3}H]cholesterol (13 µCi/rat) is given by oral gavage and [^{14}C]cholesterol (1.5 µCi/rat) is given is given by tail vein injection. The [^{3}H]cholesterol is prepared as an emulsion by dissolving 125 mg cholesterol in 1625 mg olive oil. The oil phase is suspended by sonication in 25 ml of water containing 156 mg taurocholate (sodium salt). Each animal receives 1 ml. The intravenous dose is prepared by drying the labeled cholesterol (50 µCi), and then adding 300 µl warm ethanol followed by 12.5 ml of saline. Each animal receives 0.5 ml of this colloidal suspension. The rats are allowed to consume their respective diets at 3:00 P.M., and are sacrificed 48 h after the isotope administration.

EVALUATION

The percentage of an oral dose of cholesterol absorbed is calculated from the plasma isotope ratio (% of the oral dose in 2 ml plasma/of the intravenous dose in 2 ml plasma × 100).

FURTHER IN VIVO METHODS

Heider et al. (1983) measured cholesterol absorption via the Zilversmit dual isotope method in rabbits.

Gillies et al. (1990) studied the regulation of ACAT activity by a cholesterol substrate pool during the progression and regression phases of atherosclerosis in rabbits with dietary induced atherosclerosis.

Krause et al. (1993b) compared the activities of two ACAT-inhibitors in normocholesterolemic and hypercholesterolemic rats, rabbits, guinea pigs and dogs.

Nagata et al. (1995) tested a new ACAT inhibitor in diet-induced atherosclerosis formation in female C57BL/6J mice.

Bocan et al. (1993) described a reduction of VLDL and vessel wall cholesteryl ester content in Yucatan micropigs after treatment with an ACAT inhibitor.

M.4.1.4 Lymph Fistula Model for Cholesterol Absorption

PURPOSE AND RATIONALE

Direct evidence for an inhibitory effect on cholesterol absorption can be obtained by the lymph-fistula model in rats. This model also provides an indication as to the duration of inhibition and the relative selectivity of the compound on the absorption of cholesterol versus triglyceride and phospholipid.

PROCEDURE

Rats are anesthetized by an intramuscular injection of tiletamine/zolazepam (Telazol, 40 mg/kg). Silicon rubber cannulae are placed into the main mesenteric lymph duct and into the duodenum and secured with sutures. Animals are allowed to recover from surgery overnight in restraining cages while infused intraduodenally with 2% dextrose in saline containing 0.03% KCl (2.5 ml/h). Drinking water is allowed at libitum during this recovery period.

At 6:00 A.M. the following day, the drinking water is removed and a 2-h basal lymph sample is collected. Then, the animals are given the ACAT inhibitor at a specified dose as a single bolus into the duodenal cannula using a aqueous CMC/Tween suspension vehicle. Controls receive a bolus injection of the vehicle alone. Immediately after the drug dose, a lipid emulsion containing 0.1% cholesterol, 0.11% sodium taurocholate, 15% Intralipid (20%, Kabivitrium Inc.), 2.4% safflower oil, and 82.6% saline is infused into the duodenal cannula (3 ml/h). Then, four 2-h lymph collections are obtained. The lymph samples are extracted into hexane in the presence of a stigmasterol internal standard. Total and free cholesterol are quantitated by liquid gas chromatography.

EVALUATION

Esterified cholesterol of lymph is determined from difference between total and free cholesterol.

MODIFICATIONS OF THE METHOD

The lymph fistula model can also be used to examine the effect of ACAT inhibitors on the absorption of endogenous (i. e. biliary) cholesterol. Cannulated rats are infused intraduodenally with the saline/dextrose solution to which 2% whole rat bile is added containing [^{14}C]cholesterol. No nonradiolabeled lipid other than that in bile is infused into the animals, and hence, lymph cholesterol is exclusively of biliary origin. Hourly collections of lymph are obtained with the use of fraction collectors. Lymph is extracted with 3 volumes of ethylacetate-acetone 2:1 (Slayback et al. 1977). The total ^{14}C label of an aliquot of lymph extract is determined by liquid scintillation spectroscopy. The lymph extracts are resuspended in 100 µl chloroform-methanol 2:1 and spotted on Whatman LK6D TCL plates. The plates are developed in hexane-diethylether-acetic acid 85:15:1. The distribution of ^{14}C label between the cholesteryl ester and cholesterol bands are visualized and quantified by exposing the plates to phosphor imaging plates for 16 h and then scanning the imaging screens on a Molecular Dynamics Phosphorimager.

Clark and Tercyak (1984) studied the absorption of cholesterol during inhibition of mucosal acyl-CoA: cholesterol acyltransferase in mesenteric lymph fistula rats with normal pancreatic function.

Åkerlund and Björkhem (1990), Björkhem et al. (1993) used the lymph-fistula model in rats for studies on the link between HMG-CoA reductase and cholesterol 7α-hydroxylase. The thoracic lymph duct was cannulated just proximal to the cisterna magna through an abdominal approach. The proximal part of the lymph duct was ligated. The cannula exited at the back of the animal. The lymph was allowed to flow freely from the animal to the bottom of the metabolic cages. Under these conditions, the rats could move freely in the cages during the lymphatic drainage.

CRITICAL ASSESSMENT OF THE METHOD

Gallo et al. (1987) found normal cholesterol absorption in rats in which intestinal acyl coenzyme A:cholesterol acyltransferase activity was significantly reduced by

ACAT-inhibitors. This challenges the value of ACAT-inhibition at least in normal individuals.

M.5 Interruption of Bile Acid Recirculation

M.5.0.1 Cholestyramine Binding

PURPOSE AND RATIONALE

Cholesterol is metabolized in the liver by oxidation to bile acids which undergo enterohepatic circulation. In the untreated state, approximately 95% of the bile acids that are secreted are reabsorbed and returned to the liver, while the small loss is replaced by de novo biosynthesis from cholesterol. Increased excretion of bile acids with the feces increases the rate of oxidation of cholesterol in the liver leading to a partial depletion of the hepatic cholesterol pool. A compensatory increase in uptake via the LDL receptors results in lower serum LDL levels. This can be achieved by addition of a bile acid binding resin, e. g., cholestyramine, to the food. The binding of unconjugated and conjugated bile-salt anions can be tested *in vitro* (Johns and Bates 1969).

PROCEDURE

Rabbits weighing 2.5–3 kg are switched from standard food to a diet containing 10–20% polymeric basic-anion exchanging resin, e. g. cholestyramine. Cholesterol levels in serum are measured at the beginning and at the end of a 4 weeks feeding period.

EVALUATION

Cholesterol levels as means ±SD are calculated for controls and treated animals and compared by statistical analysis.

MODIFICATION OF THE METHOD

Tennent et al. (1960) tested polymeric organic bases for action on blood cholesterol in 4-day experiments and in experiments of 7–8 weeks duration in cholesterol-fed White Leghorn cockerels. The birds were given a diet containing 2% cholesterol and 5% cotton-seed oil with or without addition of polymeric bases. The increase of cholesterol and the incidence of aortic atheromatosis was decreased by polymeric organic bases.

Day (1990) compared the hypocholesterolemic activities of the bile acid sequestrants cholestyramine and cholestipol hydrochloride in cholesterol fed sea quail.

Quaternary ammonium conjugates of bile acid inhibited cholic acid binding and transport in everted ileal sacs of guinea pigs *in vitro* (Fears et al. 1990).

M.6
Inhibition of Lipid Oxidation

M.6.0.1
General Considerations

Oxidative modification of the low density lipoproteins (LDL) has been shown to cause accelerated degradation of LDL via the scavenger receptor pathway. Under conditions of high serum LDL levels, LDL particles can migrate into the subendothelial space where oxidation of LDL can occur. The actual oxidation process is believed to begin with lipid peroxidation, followed by fragmentation to result in short-chain aldehydes. These aldehydes can form adducts with the lysine residues of apo B, creating a new epitope which is recognized by the scavenger receptor of macrophages.

During the same process, lecithin is converted to lysolecithin, which is a selective chemotactic agent for monocytes. The monocytes adhere to the arterial wall and penetrate through to the subendothelium. Once there, the monocyte changes to a tissue macrophage which takes up the oxidized LDL via the scavenger receptor. The uptake of oxidized LDL continues until the macrophage is engorged with cholesteryl esters ultimately forming a foam cell. Groups of these foam cells constitute a fatty streak. By inhibiting the oxidation of LDL, it is hoped that the modification of apo B and the production of chemotactic lysolecithin can be prevented.

The family of receptors for mammalian low-density proteins has been reviewed by Hussain et al. (1999).

M.6.0.2
Inhibition of Lipid Peroxidation of Isolated Plasma Low-Density Lipoproteins

PURPOSE AND RATIONALE

Hypercholesterolemic Watanabe rabbits are considered to be a suitable model to study the effect of antioxidants as anti-atherosclerotic agents (Carew et al. 1987; Kita et al. 1987; Steinberg et al. 1988; Dresel et al. 1990). Plasma of Watanabe heritable hyperlipidemic (WHHL) rabbits is used to test the inhibition of Cu^{2+}-induced lipid peroxidation of isolated low density lipoproteins (LDL).

PROCEDURE

Animals of a modified Watanabe heritable hyperlipidemic rabbit strain (Gallagher et al. 1988) are used. The animals are fed over a period of 12 weeks with Purina rabbit chow diet with or without 1% of test compound or standard (probucol). Plasma samples are collected in Na_2EDTA (0.1% final concentration). LDL are isolated from each rabbit plasma using a sequential ultracentrifugation technique at $d = 1.019–1.063$ g/ml (Mao et al. 1983). LDL are then dialyzed against phosphate buffered saline (PBS, 0.01 M sodium phosphate, 0.12 M NaCl, pH 7.4) at 4°C for 24 h.

For determination of LDL lipid peroxidation induced by Cu^{2+}, 100 µg of each LDL sample is adjusted

to a volume of 1.5 ml with distilled water. Lipid peroxidation is initiated by addition of $CuSO_4$ to a final concentration of 5 µM followed by an incubation at 37°C for 3 h. The reaction is stopped by adding 100 µl of 50 mM Na_2EDTA. Fifty micrograms of LDL from the reaction mixture are added to 1.5 ml of 20% trichloroacetic acid and vortexed. Finally, 1.5 ml of 0.67% thiobarbituric acid (TBA) in 0.05 N NaOH is added and the mixture is incubated at 90°C for 30 min. Samples are centrifuged at 1500 rpm for 10 min. The absorbance of the supernatant fractions is determined at 532 nm to estimate the content of lipid peroxides (thiobarbituric acid-reactive substances). A standard curve (0–5 nmol) of malondialdehyde is generated using malondialdehyde bis(dimethyl acetal) as reference to determine the lipid peroxidation content in Cu^{2+}-treated LDL.

EVALUATION

The content of lipid peroxide in LDL is plotted against the drug concentration in LDL fractions. The extent of Cu^{2+}-induced peroxidation decreases with increasing drug concentrations. The effects of test compounds are compared to the standard.

MODIFICATIONS OF THE METHOD

Inhibition of iron-dependent lipid peroxidation by test compounds was measured by Braughler et al. (1987), Yoshioka et al. 1989).

Yamamoto et al. (1986) studied the effects of probucol on lipid storage in macrophages *in vitro* in the presence of acetylated low density lipoprotein using macrophage-like cells (UE-12) established from a human histiocytic lymphoma cell line.

Barnhart et al. (1989) used LDL from human plasma to study the concentration-dependent antioxidant activity of probucol.

Parthasarathy et al. (1986) incubated LDL from human plasma samples with rabbit aortic endothelial cells and measured the increase in electrophoretic mobility, the increase in peroxides, and the increase in subsequent susceptibility to macrophage degradation.

Mansuy et al. (1986) studied the inhibition of lipid peroxidation induced in liver microsomes either chemically by $FeSO_4$ and reducing agents (cysteine or ascorbate) or enzymatically by NADPH and CCl_4.

M.7 Internalization of Labeled LDL into HepG2 Cells

PURPOSE AND RATIONALE

Enhanced uptake of low density lipoproteins (LDL) via the LDL receptor into liver cells results in reduced plasma cholesterol levels. This can be tested in the cultured hepatoma cell line HepG2.

PROCEDURE

Heterozygous WHHL rabbits are treated with the test compound over a period of 4 weeks. Blood is withdrawn twice weekly before, during, and after treatment for determination of total plasma cholesterol, low density lipoprotein cholesterol, total triglycerides, and high density lipoprotein cholesterol. Lipoprotein-deficient serum is prepared by ultracentrifugation (Goldstein et al. 1983). Serum of treated and untreated animals is used for the uptake assay being prepared by centrifugation to remove the clots, followed by heat inactivation of the complement system and sterilization through a 0.45-µm filter. In each preparation, 2 mg LDL (*d*, 1.019 to 1.050 g/ml) at 10 mg/ml are iodinated by the monochloride method to a specific activity of 300 cpm/ng (Huettinger et al. 1984).

HepG2 cells are grown in 5 cm dishes in Eagle's minimum essential medium to 60% confluence. Serum prepared from treated animals and from the same animals in the pretreatment period is added from 1% to 50% to the medium used to grow HepG2 cells. After incubation of 18 h, cells are washed and incubated in Eagle's minimum essential medium plus 2% bovine serum albumin and 8 µg labeled LDL for 3 h. The cells are then washed and solubilized in sodium hydroxide, and the content of each dish is counted for radioactivity. An aliquot is used to determine protein content.

EVALUATION

Values are given for specific uptake, which is calculated from the difference of total uptake minus uptake measured when a 40-fold excess of unlabeled LDL is present in the incubation medium of duplicate or triplicate incubations. The effect of the test drug is demonstrated by an increase of uptake with increasing percentage of serum of treated animals containing the active drug.

MODIFICATIONS OF THE METHOD

Sprague et al. (1993) measured the inhibition of scavenger receptor-mediated modified low-density lipoprotein endocytosis in cultured bovine aortic endothelial cells.

Takano and Mowri (1990) produced a monoclonal antibody which recognizes peroxidized lipoproteins.

M.8 Influence of Peroxisome Proliferator-Activated Receptors (PPARs) and Liver X Receptors (LXRs) on Development of Atherosclerosis

M.8.1 General Considerations

Peroxisome proliferator-activated receptors (PPARs) and liver X receptors (LXRs) are nuclear receptors that regulate systemic glucose and lipid metabolism. They are expressed by macrophages in which they modulate cholesterol homeostasis and inflammation. These receptors heterodimerize with retinoid X receptors (RXRs) to modulate transcription at the promoters of target genes. They act as lipid sensors and bind with micromolar affinities to ligands derived from either intracellular metabolism or dietary lipids. Endogenous ligands of PPARs include fatty acids and eicosanoids, whereas metabolites of oxidized cholesterol activate the LXRs.

M.8.2 Influence of PPAR Activation

PURPOSE AND RATIONALE

Peroxisome proliferator-activated receptors (PPARs) play a major role in atherosclerosis (Brun et al. 1996; Pineda Torra et al. 1999; Duval et al. 2002; Tailleux et al. 2003). The PPAR family consists of three proteins: α, β/δ and γ. Experimental data suggest that PPAR-α and PPAR-γ activation decreases atherosclerosis progression not only by correcting metabolic disorders, but also through direct effects on the vascular wall. PPARs modulate the recruitment of leukocytes to endothelial cells, control the inflammatory response and lipid homeostasis of monocytes/macrophages and regulate inflammatory cytokine production by smooth muscle cells. PPAR agonists, such as fibrates and thiazolidinediones, are recommended for the treatment of atherosclerosis, diabetes and obesity (Willson et al. 2000; Etgen and Mantio 2003; Francis et al. 2003; Wang and Tafuri 2003; Ferré 2004; Kota et al. 2005). Scavenger receptors are expressed in atherosclerotic lesion macrophages and regulated by activators of peroxisome proliferator-activated receptors (Chinetti et al. 2000). PPARγ is a regulator of monocyte/macrophage function (Ricote et al. 1999).

M.8.2.1 PPARα

PURPOSE AND RATIONALE

Several studies indicate the lipid-lowering role of PPARα in rodents (Chinetti et al. 2001; Vosper et al. 2002). PPARα is highly expressed in the rodent liver where activation of these receptors with fibrates induces a massive increase in peroxisomal fatty acid oxidation in hepatocytes. This provides a powerful action for the clearance of fat from the serum. Fibrates also increase the expression of the liver fatty-acid-binding protein (Lawrence et al. 2000) and the hepatocyte-secreted apolipoproteins apoAI and apoAII (Vu-Dac et al. 1995). Lee et al. (1995) demonstrated that PPARα is responsible for clofibrate-induced fatty acid oxidation by disrupting the PPARα gene in mice. Mice lacking apolipoprotein E are characterized by severe hypercholesterolemia. Tordjman et al. (2001) reported that PPARα deficiency reduces insulin resistance and atherosclerosis in apoE-null mice. Fu et al. (2003) found that the PPARα agonist ciprofibrate severely aggravates hypercholesterolemia and accelerates the development of atherosclerosis in mice lack-

ing apolipoprotein E. Species differences have to be taken in account. Lawrence et al. (2001) reported that PPARα fails to induce peroxisome proliferation-associated genes in human cells independent of the level of receptor expression.

M.8.2.1.1 Effect of PPARα Agonists in Mice

PURPOSE AND RATIONALE

Duez et al. (2002) described reduction of atherosclerosis by the peroxisome proliferator-activated receptor α agonist fenofibrate in mice.

PROCEDURE

Animals

Homozygous human apoA-I transgenic (Rubin et al. 1991) and apoE-deficient C57Bl/6 mouse strains were used. Human apoA-I transgenic mice were crossed with apoE-deficient mice to generate heterozygous human apoA-I transgenic mice in a heterozygous apoE-deficient background. These mice were further mated with homozygous apoE-deficient mice to generate human apoA-I transgenic mice in a homozygous apoE-deficient background (hapoA-I Tg × apoE-deficient mice). Human apoA-I expression was analyzed in plasma by enzyme-linked immunosorbent assay using specific antibodies (Berthou et al. 1996). Homozygous apoE-deficient mice were identified after determination of total cholesterol levels. After weaning, apoE-deficient and hapoA-I Tg × apoE-deficient male mice were maintained on a standard pellet rodent chow.

Ten-week-old apoE-deficient male mice were given a Western diet containing 20% fat and 0.2% cholesterol before the treatment period. Then one group was treated for 8 weeks with fenofibrate (0.05% added to the diet, corresponding to 100 mg/kg per day), the other group served as control. At the end of the study, blood was collected under anesthesia by retro-orbital puncture and tissues collected for further analysis.

ApoE-deficient male mice on a C57Bl/6 background were treated at an age of 20 weeks with 100 mg/kg per day fenofibrate by gavage. Another group served as control. After 6 weeks, the animal were sacrificed and their aortic cholesterol and cholesteryl ester content were determined.

Ten-week-old hapoA-I Tg × apoE-deficient male mice were given a Western diet for 2 weeks before treatment with either control or fenofibrate (0.05% added to the diet, corresponding to 100 mg/kg per day) for another 8 weeks. At the end of the study, blood and tissue samples were collected for further analysis.

Lipids, Apolipoprotein, and Lipoprotein Measurements

Plasma cholesterol and triglyceride concentrations were determined by an enzymatic assay adapted to microtiter plates using commercially available reagents. Plasma human apoA-I levels were measured by an immunoelectrophoretic assay using species-specific polyclonal antibodies (Berthou et al. 1996). Lipoprotein cholesterol profiles were obtained by fast-protein liquid chromatography. This system allows the separation of three major lipoprotein classes, very low density lipoprotein (VLDL), intermediate density lipoprotein (IDL) + LDL and HDL according to their size.

Cholesterol Measurement in the Descending Aorta

After collection of the blood, the vasculature was gently perfused through the left ventricle with cold PBS and 5 mM EDTA. For collection of aorta for biochemical analysis, all branches and adipose tissue connected to the aorta were removed, and each aorta was carefully excised from the aortic root to the right renal

artery. The aortas were kept briefly on ice in PBS, and then blotted dry, weighed, minced, and extracted with chloroform/methanol (2:1) according to Folch et al. (1957). The lipid extracts were dried down, resuspended quantitatively in chloroform/ methanol (2:1) and stored at –20°C until the time of assay. Total and free cholesterol levels in the aortic extracts were determined with an enzymatic fluorometric assay (Sparrow et al. 2001). The solvent was evaporated and the lipid residue was re-dissolved in 100 µl of reagent-grade ethanol. Aliquots of cholesterol and cholesteryl oleate standard solutions in chloroform/ ethanol (1:1) were treated similarly. To determine free cholesterol, samples and standard were incubated for 1 h at 39°C in a total volume of 1.01 ml of 0.1 M potassium phosphate buffer, pH 7.4, containing 0.03% Triton X-100 and 0.9 mM sodium cholate. Cholesterol oxidase (Roche Molecular Biochemicals), peroxidase (Roche Molecular Biochemicals) and *p*-hydroxyphenylacetic acid (Aldrich) were added for an additional 1-h incubation at 37°C. The fluorescent product was measured (excitation 325 nm, emission 425 nm). For total cholesterol determinations, cholesterol esterase (Calbiochem) was included in the first incubation step, and cholesteryl oleate was used as standard. The esterified cholesterol content in each sample was calculated by subtracting the value of free cholesterol from that of total cholesterol. All values were expressed as nmol/aorta.

Analysis of Atherosclerotic Lesions in the Aorta

Hearts and ascending aortas were fixed in formaldehyde, and serial 10-mm-thick cryosections were cut from the aortic arch to the ventricles for quantitative analysis of atherosclerosis. The distance between each section was 50 mM, and the final magnification 2.5-fold. Sections were stained with Oil Red O and counterstained with hematoxylin. The atherosclerotic lesion and the Oil Red O-stained areas of each section were quantified using a computer-assisted video imaging system. To avoid morphological heterogeneity between mice, the expression of average atherosclerotic lesion areas in the region of the aortic sinus, from the appearance to the disappearance of the aortic valves, was normalized at ten equal sections.

EVALUATION

A non-parametric Mann-Whitney test was used to analyze for significant differences between the experimental groups. Analysis of variance (ANOVA) and Tukey post-hoc tests were used for analysis of the lesion area data.

M.8.2.1.2 Effect of PPARα and PPARγ Agonists in Human Macrophages

PURPOSE AND RATIONALE

Lee and Evans (2002) reviewed the role of the peroxisome proliferator-activated receptor-γ in macrophage lipid homeostasis.

Chinetti et al. (1998) reported that PPARα and PPARγ activators induce cholesterol removal from human macrophage foam cells through stimulation of the ABCA1 pathway.

PROCEDURE

Transactivation Assays of the RPR-5 Compound

Transactivation assays are performed with the RPR-5 compound in A10 cells (a rat smooth muscle cell line) using full-length human PPARα and PPARγ and the PGL3-J_3-TK vector (Vu-Dac et al. 1995). After 24 h, luciferase activity is measured with LucLite (Packard, Meridian, Conn., USA) according to the manufacturer's instructions.

Cell Culture

Mononuclear cells are isolated from the blood of healthy normolipidic donors by Ficoll gradient centrifugation and cultured (Chinetti et al. 1998). Mature monocytes are used for experiments after 10 days of culture. For treatment with the different activators, medium is changed to medium without human serum but supplemented with 1% Nitridoma

HU (Boehringer). Efflux studies are performed in the absence of any serum. Human monocytic THP-1 cells (ATCC, Rockville, Md., USA) are maintained in RPMI 1640 medium containing 10% of FCS and differentiated for 48 h with 100 nM PMA.

RNA Extraction and Analysis

After incubation with the PPAR activators, cells are washed with PBS and used for RNA extraction. Total RNA is extracted after 10 days from differentiated macrophages and THP-1 cells treated for 24 h with the compounds using Trizol (Life Technologies, France). For Northern blot analysis, membranes are hydrolyzed containing 10 µg of total RNA with radiolabeled ABCA1 or 36B4 control cDNA probes. An *Eco*RI LXR-β and a *Hin*dIII-*Hin*cII LXR-α cDNA fragment are used as probes. For the human ABCA1 probe, a 1.1-kb cDNA fragment is cloned into a pCR4–4-TOPO vector (Invitrogen).

Transient Transfection Assay

At 24 h before transduction, COS1 cells are plated in 24-well plates at a density of 5×10^4 cells/well and cultured in Dulbecco's modified Eagle's medium supplemented with 10% fetal calf serum. Cells are transfected by lipofection using ExGen 500 (Euromedex) in OPITMEM 1 medium, with 50 ng of reporter plasmid and increasing quantities of LXR-α and RXR expression plasmids (10, 25, and 50 ng) in the presence of 50 ng of the internal control β-gal expression vector, for 3 h in serum-free medium. Fresh medium containing 0.2% fetal calf serum and 10 µM 22(R)-hydroxycholesterol (Sigma) or its solvents are subsequently added and cells are further incubated for 48 h.

Cholesterol Loading and Efflux

Ten day-old human macrophages were pretreated for 24 h and thereafter every 24 h with PPAR activators (e. g., rosiglitazone 100 nM, Wy14643 50 µM) and cholesterol loaded by incubation with AcLDL (50 µg/ml, with or without [^{3}H]cholesterol) in RPMI 1640 medium supplemented with 1% Nutridoma (Boehringer) for 48 h. After this incubation period, cells are washed twice in PBS and apoAI-mediated cholesterol efflux studies are immediately performed by adding fresh RMPI medium without Nutridoma with or without 100 µg/ml of apoAI for 24 h. Because, in macrophages, the equilibrium between esterified and free cholesterol is not obtained even after a 24-h additional incubation period, the experiments are performed in the absence of equilibrium.

EVALUATION

For transactivation assays

ED_{50} values are calculated after curve fitting with XLFit (human PPARα $EC_{50} = 0.13$ µM, PPARγ $EC_{50} = 5$ µM).

For transient transfection assay

Cell extracts are prepared and assayed for luciferase activity (Delerive et al. 2000). Results are normalized to internal control β-gal activity.

For cholesterol binding and efflux

At the end of the incubation, intracellular lipids are extracted in hexane/isopropanol, dried under nitrogen, and free cholesterol, total cholesterol and phospholipids are measured by enzymatic assays (Boehringer). Esterified cholesterol is measured as the difference between total and free cholesterol. Cellular proteins are collected by digestion in NaOH and measured by Bradford assay (BioRad). The percent change of intracellular cholesterol amounts in the presence of apoAI relative to apoAI-free medium is expressed according to the following equation:

$$\begin{aligned}&\text{Percent decrease in cellular cholesterol}\\&= \{[(\text{cellular cholesterol})_{\text{RPMI}}\\&\quad - (\text{cellular cholesterol})_{\text{apoAI}}]\\&\quad + (\text{cellular cholesterol})_{\text{RPMI}}\} \times 100\,.\end{aligned}$$

In the experiments with [^{3}H]cholesterol, radioactivity is measured, by scintillation counting, in centrifuged medium and in cellular lipids extracted with hexane/isopropanol. ApoAI-induced [^{3}H]cholesterol is measured as the fraction of total labeled cholesterol appearing in the medium in the presence of apoAI after subtraction of values for apoAI-free medium. For the phospholipid efflux study, lipids are isolated from culture medium by chloroform/methanol extraction. Extracted lipids are subsequently dried under nitrogen pressure and phospholipid mass determined by an enzymatic assay (Boehringer).

M.8.2.2 PPARγ

PURPOSE AND RATIONALE

PPARγ is a transcription factor required for the activation of many adipose-specific genes (Vosper et al. 2002). PPARγ essentially controls the accumulation of lipids in adipocytes and many experiments have demonstrated the ability of the receptor to direct adipocyte stimulation (Rosen et al. 2000). Reginato et al. (1998) reported that prostaglandins can both promote and block adipogenesis through opposing effects on PPARγ . PPARγ is a molecular target for the thiazolidine group of insulin-sensitizing drugs (Rieusset et al. 1999). PPARγ promotes lipid clearance in the liver of mice (Memon et al. 2000).

M.8.2.2.1 Effect of PPARγ Agonists in Mice

PURPOSE AND RATIONALE

Collins et al. (2001) reported the inhibition of the formation of early atherosclerotic lesions in diabetic and nondiabetic LDL receptor-deficient mice by a PPARγ agonist.

PROCEDURE

Transendothelial Monocyte Migration

THP-1 cells, a human monocytic leukemia cell line, were added to a human aortic EC monolayer covering a gelatin-coated 8-mm porous membrane and incubated for 30 min at 37°C to facilitate their attachment. Cells were then pretreated with the ligands or vehicle (dimethyl sulfoxide) for 30 min at 37°C. Migration was induced by the addition of monocyte chemoattractant protein-1 (MCP-1, 50 ng/ml) to the lower compartment. After 90 min, non-migrating THP-1 cells and human aortic ECs were removed with a cotton tip, and the membranes were fixed and stained with the Quik-Diff Stain Set (DADE, Miami, Fla., USA) to identify migrated cells. The number of migrated cells was determined per 3320 high-power field. Experiments were performed in duplicate and were repeated at least 3 times.

Western Blots

Western immunoblots were performed (Goetze et al. 1999). Membranes were incubated with rabbit polyclonal antibodies (1:1000 dilution, New England Biolabs) that recognize either: (1) total extracellular signal-regulated kinase (ERK) or (2) ERK phosphorylated on threonine 202 and tyrosine 204.

Animals and Diets

Male LDLR2/2 mice were obtained (C57BL/6J-Ldlrtm1Her, stock No. 002207, Jackson Laboratory) and were group-housed under a 12-h light and 12-h dark regimen. At 3 months of age, the mice were randomly assigned to one of five dietary regimens: (1) chow (Harlan Teklad 8604), (2) high-fat complex carbohydrate (Research Diets), (3) high-fat complex carbohydrate with 4 g troglitazone/kg of food, (4) high fructose (Research Diets), or (5) high fructose with 4 g troglitazone /kg of food. The high-fat diet consisted of 21% fat, 20% protein, 50% carbohydrate, and 0.15% cholesterol. The high-fructose diet contained 4% fat, 16% protein, 71% fructose, and 0.15% cholesterol. Mice and feed were weighed weekly, and the rate of consumption of drug was computed. The mice were fed for a period of 12 weeks.

Metabolic Measurements

Blood samples from the retro-orbital sinus were obtained from the mice before the beginning of treatment and every month thereafter and from the abdominal vena cava at euthanasia. Mice were fasted overnight before the collection of the blood samples. Plasma glucose was measured by glucose oxidase reaction (Beckman Glucose Analyzer 2, Beckman Instruments). Plasma lipids and plasma insulin were measured. Blood pressures were obtained by using an

indirect tail-cuff method with a controlled-temperature chamber.

Vessel Preparation and Image Analysis

Mice were euthanized and perfused with 7.5% sucrose in 4% paraformaldehyde. Aortas were dissected out, split longitudinally, pinned flat in a dissection pan, and stained with Sudan IV to detect lipids and determine lesion area. Images were captured by use of a Sony 3-CCD video camera and analyzed using ImagePro image analysis software. The extent of lesion formation is expressed as the percentage of the total aortic surface area covered by lesions.

Cross Sections: Determination of Intimal Macrophage Content

The largest lesions from the aortic arch were excised and embedded in paraffin. The avidin-biotin-peroxidase complex technique for immunostaining was used. Macrophages were stained by using monoclonal antibody to CD68 (titer 1:100, KP1 clone, M0814, Dako). Non-immune serum was used as a control. Primary antibody incubations were performed in 1% BSA/2% goat serum containing PBS for 60 min. Biotinylated rabbit anti-mouse (Dako) was applied; incubation with a streptavidin-peroxidase complex followed. Peroxidase activity was detected with the use of diaminobenzidine tetrahydrochloride as a chromogen. Slides were then counterstained with hematoxylin. Images of the stained sections were analyzed by using the software described above. After tracing the intimal area to be measured with a cursor, five pixels of color, which defined the anti-CD68 stain, were sampled by the operator. The area encompassed by the pixels, which was not contiguous, in the color range for anti-CD68 was then computed automatically by the software.

EVALUATION

Statistical analysis was performed by using 2-factorial ANOVA with Student-Newman-Keuls to determine the differences between individual group means.

MODIFICATIONS OF THE METHOD

Li et al. (2000) used LDL-receptor deficient mice to study the inhibition of atherosclerosis by PPARγ ligands.

Chen et al. (2001) used apolipoprotein E knockout mice to study the inhibition of atherosclerosis by a thiazolidinedione.

Gavrilova et al. (2003) used lipoatrophic A-ZIP/F-1 mice to study the contribution of peroxisome proliferator-activated receptor γ to hepatic steatosis, triglyceride clearance, and regulation of body fat mass.

Tao et al. (2003) found antioxidative, antinitrative, and vasoprotective effects of a peroxisome proliferator-activated receptor-γ agonist in hypercholesterolemic New Zealand white rabbits.

Iwaki (2003) used C57BL/KsJ (*db+/db+*) mice to study the induction of adiponectin, a fat-derived antidiabetic and antiatherogenetic factor, by nuclear receptors.

Corti et al. (2004) performed an *in vivo* study by high-resolution magnetic resonance imaging of male New Zealand white rabbits. A selective PPARγ agonist showed an additive effect on plaque regression in combination with a statin in experimental atherosclerosis.

M.8.2.2.2 Effect of PPARγ Agonists on Gene Expression in Macrophages

PURPOSE AND RATIONALE

Hodgkinson and Ye (2003) used a combination of expression microarray and Northern blot analyses to identify target genes for peroxisome proliferator-activated receptor (PPAR)γ in RAW264.7 macrophages. PPARγ natural ligand 15-deoxy-Δ12−14 prostaglandin and synthetic ligands ciglitazone and rosiglitazone increased the expression of scavenger receptor CD36 and ATP-binding cassette transporter A1, as well as adipophilin (a lipid droplet coating protein involved in intracellular lipid storage and transport), calpain (a protease implicated in ABCA1 protein degradation), and ADAM8 (a disintegrin and metalloprotease protein involved in cell adhesion).

PROCEDURE

Cell Culture

Macrophage RAW264.3 cells were purchased from ATCC and cultured in DMEM (Sigma, Poole, UK) at 37°C in a humidified atmosphere with 95% air–5% CO_2. When cells reached ~ 80% confluence, WY14,643, 15d-PGJ2, ciglitazone, rosiglitazone, and BADGE were added to the medium as described below to give final concentrations of 100, 5, 50, 1, and 500 µM, respectively.

RNA Extraction

Total RNA from RAW264.7 macrophages was extracted using the BD Clontech Nucleobond RNA purification system (BD Clontech, Basingstoke, UK). Cells were lysed by a lysis buffer containing guanidine thiocyanate. After removing cellular proteins from the lysate, RNA was precipitated, then immobilized in a column containing silica glass fibers, and subjected to RNase-free DNase I digestion to remove genomic DNA. The RNA sample was further purified by washing and finally eluted from the column into nuclease-free water. The integrity of the RNA sample was verified by spectrophoretic analysis and formaldehyde agarose gel electrophoresis.

Microarray Filters and Hybridization

cDNA microarray nylon filters were purchased from Research Genetics. Radiolabeled cDNA probes were generated by reverse transcription of RNA extracted from rosiglitazone- or ciglitazone-treated and untreated (control) RAW264.7 macrophages using a Research Genetics GeneFilters Probe Labeling and Purification kit (Invitrogen, Paisley, UK). Briefly, 4–10 µg of total RNA was mixed with 0.4 mg of oligo(dT) and incubated at 70°C for 10 min. Then, 10 nmol each of dATP, dGTP, and dTTP, 37.5 U of AMV reverse transcriptase, and 100 µCi of [α-^{33}P]dCTP (3000 Ci/mmol; Amersham, Bucks, UK) were added, and the solution (30 µl of final volume) incubated at 42°C for 2 h. The labeled cDNA probe was then purified using spin columns supplied with the kit to remove unincorporated radioactive nucleotide. Prehybridization was carried out in 5 ml of MicroHyb buffer (Research Genetics) supplemented with poly(dA) (1 µg/ml) and denatured human Cot-1 DNA (1 µg/ml) at 42°C for 2 h. Radiolabeled cDNA probe was denatured at 100°C for 3 min and then added to the above solution, followed by hybridization at 42°C overnight. The filters were then washed twice in a solution containing 2 × SSC and 1% SDS at 50°C for 20 min and a brief wash (5 min) in a solution containing 0.5 × SSC and 1% SDS at room temperature. The filters were exposed to a low-energy phosphor storage screen, which was then scanned using a Storm phosphorimager (Molecular Dynamics), and the resultant TIFF images analyzed using Pathways 4 software (Research Genetics). The intensities of the spots were normalized to mean intensities of all spots on each filter. Normalized intensities of corresponding spots were compared between two filters. In order to check the data, the filters were stripped and re-probed with the opposite radiolabeled cDNA probe, thus a filter probed with control cDNA was stripped and probed with treated cDNA and vice versa.

Northern Blot and Hybridization

RNA was denatured in 50% (v/v) formamide and 6% (w/v) formaldehyde at 65°C for 10 min and subjected to electrophoresis on 1.5% (w/v) agarose gel in MOPS buffer [20 mM MOPS, 5 mM sodium acetate, and 1 mM EDTA (pH 7.0)] containing 1.9% (w/v) formaldehyde. Integrity and equal loading of the RNA was confirmed by observing ethidium-bromide-stained 28S and 18S mRNA bands under UV illumination. The RNA was transferred overnight to Hybond-N nylon membrane (Amersham) by capillary action and the RNA linked to the membrane by baking at 80°C for 2 h. cDNA probes for ABCA1, ADAM8, adipophilin, calpain-L3, CD36, protein phosphatase 2A non-catalytic subunit, and thymosin were generated from the IMAGE clone which had been isolated, sequenced, and verified by Research Genetics. Purified plasmid DNA was cut with the appropriate restriction enzymes and the digested insert was purified by

electrophoresis on 0.8% agarose in TAE buffer [4 mM Tris, 1 mM EDTA, and 0.0114% (v/v) acetic acid (pH 7.6)] containing 1 µg/ml ethidium bromide. The purified insert was purified from the gel using a Qiagen Gel Extraction kit (Qiagen, Crawley, UK) and 25 ng of cDNA was denatured at 95°C for 2 min and the cDNA was radiolabeled with [α-32P]dCTP by random priming using the Klenow Labeling kit as supplied by Promega. Unincorporated label from cDNA labeling was removed using a QIAquick Nucleotide Removal kit (Qiagen). Hybridizations with cDNA probes were performed with PerfectHyb (Sigma, Poole, UK) at 65°C. Prehybridization was carried in 5 ml PerfectHyb supplemented with 150 µg of denatured salmon sperm DNA (Sigma) for 2 h. Hybridization with the radiolabeled cDNA probe was carried out in the same mixture overnight. Membranes were washed twice at room temperature with 2 × SSC–0.1% SDS for 10 min followed by a 10 min wash in 0.1 × SSC–0.1% SDS. A high-stringency wash (5–10 min) was performed in 0.1 × SSC–0.1% SDS at 65°C. The membranes were then subjected to autoradiography at −70°C for between 12 h and 7 days.

EVALUATION

Autoradiographs of Northern blots were scanned and analyzed using Phoretix software.

MODIFICATIONS OF THE METHOD

Tontonoz et al. (1988) reported that PPARγ promotes the differentiation of monocytes/macrophages and the uptake of oxidized LDL.

Moore et al. (2001) reviewed the role of PPARγ in macrophage differentiation and cholesterol uptake.

Arimura et al. (2004) found that the peroxisome proliferator-activated receptor γ regulates expression of the perilipin gene in adipocytes. Perilipins are a family of proteins coating the surface of lipid droplets in adipocytes.

M.8.2.3 PPARδ

PURPOSE AND RATIONALE

Vosper et al. (2001) reported that PPARδ promotes lipid accumulation in human macrophages.

PROCEDURE

Isolation of Human Monocytes and In VitroMonocyte/Macrophage Differentiation

Human monocytes were isolated from buffy coat preparations of whole blood taken from healthy volunteers. The buffy coat was mixed with OptiprepTM (Robbins Scientific) in a ratio of 2.5:1 and then overlaid with a discontinuous OptiprepTM gradient. Following centrifugation for 25 min at 600 *g* the monocyte layer formed within the top 5–10 ml of the gradient was removed, washed with phosphate-buffered saline, and resuspended in RPMI 1640, supplemented with 2 mM glutamine and 10% human serum (Sigma). Cell viability was assessed by the ability to exclude trypan blue and was typically 95%. Monocyte purity was determined by differential counts of DiffQuik-stained (Porvair Sciences) cell preparations and was typically >95%. For monocyte-macrophage differentiation, monocytes isolated as above were resuspended in culture medium at a density of 2.5×10^6/ml and seeded into 12-well tissue culture plates; medium was changed every 48 h.

Transient Transfection

COS-1 cells were transfected by the DEAE-dextran method. The reporter construct pFABPLUC contained four copies of the peroxisome proliferator response element from the human liver FABP gene in front of the herpes simplex virus-thymidine kinase promoter, cloned immediately upstream of the cDNA encoding firefly luciferase in pGLBAS (Promega). The PPAR expression vectors contained the coding sequence for human PPARα, -δ, and -γ under the control of the enhancer/promoter of the human cytomegalovirus. PSV-Gal was co-transfected with each sample to act as an internal control for transfection. Cell lysates were prepared and luciferase and β-galactosidase activities were assayed using kits as described by the manufacturer (Promega).

Data are presented as the relative light units obtained with the luciferase assay divided by the ab-

sorbance obtained at 405 nm in the β-galactosidase assays (Luc/β-galactosidase).

Culture and Differentiation of THP-1 Cells

THP-1 cells were obtained from ATCC. Cultures were grown in RPMI supplemented with 10% heat-inactivated fetal calf serum. Differentiation was initiated by the addition of 5 ng/ml PMA in the above medium. All drugs were added in Me_2SO and were replaced at intervals of 48 h. After 4 days the cells were fixed with 0.66% paraformaldehyde then stained with Oil red O and hematoxylin. Quantification of lipid accumulation was achieved by extracting Oil red O from stained cells with isopropyl alcohol and measuring the optical density of the extract at 510 nm. The value obtained using a control culture was subtracted from the resulting values. The Oil red O absorbance was corrected by co-staining DNA with SYBR green dye (Molecular Probes) and quantified on a Labsystems FluoroSkan Ascent FL microplate fluorimeter. Cell number was determined from a standard curve.

Isolation of Stable Cell Lines

The entire coding sequence of human PPAR was subcloned, in both sense and antisense orientations, into the eukaryotic expression vector pCLDN. The resulting plasmids were transfected into THP-1 cells using a modified DEAE-dextran procedure. The cells were maintained in medium containing 1 mg/ml G418 and 10% THP-1 conditioned medium, with rigorous washing procedures to remove dead cells. This was continued until cell killing stopped and robust growth was observed.

Western Blotting

Cultures were lysed in SDS-polyacrylamide gel electrophoresis loading buffer and analyzed by Western blotting using standard procedures. PPAR antiserum was used at a 1:2000 dilution and the anti-AFAR antiserum was used at a 1:3000 dilution. A peroxidase-conjugated mouse anti-rabbit IgG antiserum (Sigma) was used as a secondary detection reagent at 1:3000 and the results were visualized using enhanced chemiluminescence (ECL+) as described by the manufacturer (Amersham Pharmacia Biotech).

Lipid Extraction and Measurement

Cultures were treated as above and then extracted with methanol/chloroform/phosphate-buffered saline (1:1:1, v/v) containing stigmasterol as an internal standard for cholesterol. The organic phase was analyzed for cholesterol with and without saponification by GC-MS using a Finnegan ThermoQuest Trace 2000. Triglycerides were quantified colorimetrically using a kit from Sigma and triolein as a standard. Protein concentrations were determined using the Bio-Rad Protein assay reagent.

Cholesterol Efflux Assays

THP-1 cells were differentiated with PMA in the absence or presence of 100 nM compound F for 3 days. PPAR SENSE cells were differentiated with PMA for 3 days. The cells were labeled with 2 µCi (40 nmol) of [4-^{14}C]cholesterol in 2 ml of medium containing 10% fetal calf serum for 3 h. ApoA1-specific efflux was determined (Oliver et al. 2001). For apoA1-independent efflux assays the cells were incubated for a further 120 h in medium containing 10% fetal calf serum.

Radioactivity release into the medium was determined by scintillation counting at 1, 4, 18, 24, 48, 72, and 120 h. All cultures incorporated similar levels (between 80 and 95%) of the labeled cholesterol.

RNA Extraction and Analysis

RNA was extracted from THP-1 cells using TRIZOL reagent as recommended by the manufacturer. cDNA was synthesized from such RNA using "You-Prime Ready-To-Go" beads from Amersham Pharmacia Biotech. TAQMANTM real time PCR analysis was applied using prepared reagents from PerkinElmer LifeSciences. The primers and probes are described elsewhere (Kliewer et al. 1992). Relative levels of mRNA were calculated using the values obtained with each target gene compared with the values obtained with the 18 S ribosomal RNA probes.

EVALUATION

All graphs and statistics were prepared using Graphpad Prism for the Macintosh v3.0 (Graphpad Inc., San Diego, Calif., USA). Non-linear regression was applied using a sigmoidal response model for the dose response to compound F in transient transfection experiments. *P*-values were calculated using a standard Student's *t*-test.

MODIFICATIONS OF THE METHOD

Wang et al. (2004) described the engineering of a mouse capable of continuous running up to twice the distance of a littermate. This was achieved by targeted expression of an activated form of PPARδ in skeletal muscle, which induces a switch to form increased numbers of type I muscle fibers. Treatment of wild-type mice with PPARδ agonist elicits a similar type I fiber gene expression profile in muscle.

Forman et al. (1997) developed a conformation-based assay that screens activators for their ability to bind to PPARα/δ and induce DNA binding. Specific fatty acids, eicosanoids, and hypolipidemic drugs are ligands for PPARα or PPARδ. Because altered fatty levels are associated with obesity, atherosclerosis, hypertension, and diabetes, PPARs serve as molecular sensors that are central to the development and treatment of these metabolic disorders.

PROCEDURE

Cell Culture and Transfection

CV-1 cells were grown and transfected (Forman et al. 1995a). The reporter construct, PPREx3 TK-LUC, contained three copies of the acyl-CoA oxidase PPRE upstream of the Herpes virus thymidine kinase promoter (Kliewer et al. 1992). Expression vectors contained the cytomegalovirus IE promoter/enhancer (pCMX) upstream of wild-type mouse PPARα, mouse PPARγ 1-ΔN (Met-105-Tyr-475), mouse PPARδ-ΔN (Leu-69-Tyr-440), mouse PPARα-G (Glu-282 Gly) (Hsu et al. 1995), or *Escherichia coli* β-galactosidase as an internal control. Cells were exposed to the compounds for 24 h and then harvested and assayed for luciferase and β-galactosidase activity. All points were performed in triplicate and varied by less than 10%. Normalized luciferase activity was determined and plotted as *n*-fold activation relative to untreated cells. Each experiment was repeated three or more times with similar results.

Electrophoretic Mobility-Shift Assays

In vitro-translated mouse PPARα (0.2 µl) and human RXRα (0.1 µl) were incubated for 30 min at room temperature with 100,000 cpm of Klenow-labeled acyl-CoA oxidase PPRE as described (Forman et al. 1995b) but with 150 mM KCl.

M.8.3 Influence of Liver X Receptor Agonists

PURPOSE AND RATIONALE

Liver X receptors (LXR) are nuclear receptors that are intracellular sensors, which regulate the expression of genes controlling cholesterol absorption, excretion, catabolism and cellular efflux in target organs including small intestine, liver and macrophages. The LXRs belong to a subgroup of nuclear receptors that are considered "metabolic receptors". Also included in this group are the PPARs and FXR (farnesol-activated receptor). The endogenous ligands for these receptors are intermediates or endproducts of metabolic pathways. The two LRXs, LRXα and LRXβ , are activated by physiological concentrations of oxidized cholesterol, such as 22(R)-hydroxycholesterol and 24(S),25-epoxycholesterol. LRXα is expressed at high levels in liver, intestine adipose tissue, and macrophages, whereas LRXβ is expressed ubiquitously (Konvanen and Pentikäinen 2003; Jaye 2003; Joseph and Tontonoz 2003). Macrophage liver XC receptors are identified as inhibitors of atherosclerosis (Tangirala et al. 2002). Liver X receptors are regarded as potential therapeutic agents for dyslipidemia and atherosclerosis (Lund et al. 2003).

M.8.3.1 Stimulation of Cholesterol Efflux

PURPOSE AND RATIONALE

LXRs induce ATP binding cassette (ABC) transporters, e. g., ABCA1 (Costet et al. 2000) and ABCG1 (Venkateswaran et al. 2000), which are involved in the transport of cholesterol and phospholipids from cells to extracellular receptors.

Sparrow et al. (2002) described a potent synthetic LXR agonist that is more effective than 22(R)-hydroxycholesterol in inducing ABCA1 mRNA and stimulating cholesterol efflux.

PROCEDURE

Cells

Cells were cultured at 37°C in a humidified atmosphere consisting of 95% air and 5% carbon dioxide. Primary human fibroblasts were obtained from the Camden human cell repository. The cells were grown, handled, and cholesterol-loaded as described by Francis et al. (1955). Human primary hepatocytes were maintained in phenol red-free Dulbecco's modified Eagle's medium (high glucose) containing 10% charcoal-stripped FCS, 1% non-essential amino acids, 1% glutamine, 100 units/ml penicillin G, and 100 µg/ml streptomycin sulfate. Caco-2 cells were obtained from ATCC and grown in Opti-MEM containing 10% FCS, non-essential amino acids, and vitamins. THP-1 cells were obtained from ATCC and were grown in RPMI medium containing 10% FCS, 0.05 µM 2-mercaptoethanol, 1 mM sodium pyruvate, 2 mM L-glutamine, and antibiotic-antimyotic solution (100 units/ml penicillin, 0.1 µg/ml streptomycin, 0.25 µg/ml amphotericin B). THP-1 cells were differentiated into macrophages in six-well tissue culture dishes at a density of 1 million cells/well by incubation in the same medium plus 100 nM tetradecanoyl phorbol acetate for 3 days. After differentiation into macrophages, cells were used for mRNA measurements or for cholesterol efflux assays as described below. Human primary monocytes were prepared as described by Wright and Silverstein (1982) and differentiated to macrophages by culturing for 7 days in Teflon jars in RPMI 1640 medium supplemented with 12% human serum, 100 units/ml penicillin, and 100 µg/ml streptomycin sulfate. They were then plated in the same medium to initiate experiments.

Assays of Cholesterol Efflux Using [^{3}H]Cholesterol

Cells were labeled by incubation for 24 h in fresh growth medium containing [^{3}H]cholesterol (10 µCi/ml). In some experiments, cells were simultaneously labeled with [^{3}H]cholesterol and cholesterol-loaded using acetylated LDL. Following labeling with [^{3}H]cholesterol, cells were washed and incubated for an additional 24 h in serum-free media containing 1 mg/ml bovine serum albumin to allow for equilibration of [^{3}H]cholesterol with intracellular cholesterol. Cholesterol efflux was initiated by adding the indicated amount of apoA-I, usually 10 µg/ml, with or without APD, in serum-free medium. APD was added to cell culture medium from Me_2SO solutions, and control cells received an equivalent amount of Me_2SO, never exceeding 0.1%. After 24 h, media were harvested, and cells were dissolved in 1 mM HEPES, pH 7.5 containing 0.5% Triton X-100. Media were briefly centrifuged to remove non-adherent cells, and then aliquots of both the supernatants and the dissolved cells were subjected to liquid scintillation spectrometry to determine radioactivity.

Assays of Cholesterol Efflux Using Gas Chromatography-Mass Spectrometry

At the end of the 24-h efflux assay, cells and media were extracted. Cells were extracted twice (10 min with shaking each time) with 1 ml of hexane/isopropyl alcohol/water (3:2:0.1, v/v/v)/5 cm^2 of cell surface area. Media were extracted with 2.5 vols of chloroform/methanol (2:1, v/v). Internal standard [26,27-^{2}*H*_{6}]cholesterol, was added to the extracts, and the samples were taken to dryness under a stream of argon. Half of the cellular lipid extract was saponified for 1 h at 60°C in a solution of 3% KOH in 90% ethanol. One volume of water was added, and the mixture was extracted with 2 vols of hexane. The extracts of media and cellular lipids with or without saponification were taken to dryness under argon, derivatized to trimethylsilyl ethers by treatment with Sigma Sil-A for 1 h at 60°C, redissolved in hexane, and analyzed by gas chromatography/mass spectrometry. The amount of cholesterol in the original sample was determined using a standard curve.

Gas Chromatography/Mass Spectrometry

Gas chromatography/mass spectrometry was performed using a ThermoQuest GCQ instrument equipped with an RTX-5MS column (30 m × 0.25 mm inner diameter, 0.25-µm phase thickness; Restek, Bellefonte, Pa., USA). The gas chromatography program was 180°C for 1 min, followed by a temperature

gradient of 20°C/min to 290°C and a final elution at 290°C for 20 min. The injector was operated in the split mode (1:10 split), and the temperature was kept at 275°C. Helium was used as the carrier gas at a constant flow rate of 1 ml/min. The instrument was operated in the electron ionization mode with the electron energy set to 70 eV. The ion trap was used for the selected ion monitoring of *m*/*z* 458 and 464 for determination of cholesterol and [26,27-$^2H_6$]cholesterol, respectively.

Transactivation Assays

Expression constructs were prepared by inserting the ligand binding domain of human LXRα and LXRβ cDNAs adjacent to the yeast GAL4 transcription factor DNA binding domain in the mammalian expression vector pcDNA3 to create pcDNA3-LXRα/ GAL4 and pcDNA3-LXRβ/GAL4, respectively. The GAL4-responsive reporter construct, pUAS(5x)-tk-luciferase, contained five copies of the GAL4 response element placed adjacent to the thymidine kinase minimal promoter and the luciferase reporter gene. The transfection control vector, pEGFP-N1, contained the green fluorescence protein gene under the regulation of the cytomegalovirus promoter. For transient transfections, HEK-293 cells were seeded at 4×10^4 cells/well in 96-well plates in Dulbecco's modified Eagle's medium (high glucose) containing 10% FCS, 100 units/ml penicillin G, and 100 µg/ml streptomycin sulfate at 37°C in a humidified atmosphere of 5% CO_2. After 24 h, transfections were performed with LipofectAMINE (Invitrogen) according to the instructions of the manufacturer. Transfection mixes contained 0.002 µg of LXRα/GAL4 or LXRβ/GAL4 chimeric expression vectors, 0.02 µg of reporter vector pUAS(5x)-tk-luc, and 0.034 µg of pEGFP-N1 vector as an internal control of transfection efficiency. Compounds were characterized by incubation with transfected cells for 48 h across a range of concentrations in phenol red-free Dulbecco's modified Eagle's medium (high glucose) containing 10% charcoal-stripped FCS), 1% non-essential amino acids, 1% glutamine, and 100 units/ml penicillin G and 100 µg/ml streptomycin sulfate. Cell lysates were prepared from washed cells using cell lysis buffer (Promega, Madison, Wis., USA).

Measurement of mRNA Levels by Real-Time Quantitative Reverse Transcription-PCR (TaqMan)

Real-time quantitative PCR analysis was used to determine the relative levels of ABCA1 and ABCG1 mRNA. Reverse transcription and PCRs were performed according to the manufacturer's instructions. Sequence-specific amplification was detected with an increasing fluorescent signal of FAM (reporter dye) during the amplification cycle.

Amplification of the mRNA for the human 23-kDa highly basic protein, also called ribosomal protein L13a, was performed in the same reaction on all samples tested as an internal control for variations in RNA amounts. Levels of the different mRNAs were subsequently normalized to highly basic protein mRNA levels. Oligonucleotide primers and Taq-Man probes were designed using Primer Express software (Applied Biosystems) and were synthesized by Applied Biosystems. Sequences of forward primers, reverse primers, and probes (respectively) were as follows:

ABCA1, TGTCCAGTCCAGTAATGGTTCTGT, AAACGAGATATGGTCCGGATT, 6FAM-ACACCT GGAGAGAAGCTTTCAACGAGACTAACCTAMR A; *ABCG1*, TGCAATCTTGTGCCATATTTGA, CC AGCCGACTGTTCTGATCA, 6FAM-TACCACAAC CCAGCAGATTTTGTCATGGA-TAMRA; *SREBP-1c*, GGTAGGGCCAACGGCCT, CTGTCTTGGTT GTTGATAAGCTGAA. 6FAM - ATCGCGGAGCCA TGGATTGCACT - TAMRA; *HBP*, GCTGGAAGT ACCAGGCAGTGA, ACCGGTAGTGGATCTTGG CTTT, VIC-TCTTTCCTCTTCTCCTCCAGGGTGG CT-TAMRA.

EVALUATION

For Cholesterol Efflux

Cholesterol efflux is expressed as a percentage, calculated as ([^{3}H]cholesterol in medium)/([^{3}H]cholesterol in medium + [^{3}H]cholesterol in cells) × 100.

For Transactivation Assay

Luciferase activity in cell extracts was determined using luciferase assay buffer in a ML3000 luminometer (Dynatech Laboratories). Green fluorescence protein expression was determined using the Tecan Spectrofluor Plus at an excitation wavelength of 485 nm and emission at 535 nm. Luciferase activity was normalized to green fluorescence protein expression to account for any variation in efficiency of transfection.

MODIFICATIONS OF THE METHOD

Chawla et al. (2003) used null stem cell of mice to demonstrate that PPARδ is a very low-density lipoprotein sensor in macrophages.

M.8.3.2 Liver X Receptor Binding

PURPOSE AND RATIONALE

Several authors have studied the structure and function of the liver X receptors (Spencer et al. 2001; Yoshikawa et al. 2002; Hoerer et al. 2003; Yu et al. 2003; Williams et al. 2003).

Janowski et al. (1999) studied the structural requirement of ligands for the oxysterol liver X receptors LXRα and LXRβ and developed a ligand binding assay.

PROCEDURE

Ligands

Purchased ligands include the following: 9-*cis*-[20-*methyl*-^{3}H]retinoic acid (72 Ci/mmol; 1 Ci = 37 GBq) and [26,27-^{3}H(N)]-24(S),25-EC (76 Ci/mmol); 22(R,S)-HC, 25-HC, 7α-HC, 24,25-dehydrocholesterol, cholic acid, pregnenolone, 9-*cis*-retinoic acid (9cRA). Stereocontrolled syntheses for the following ligands were performed: 24(S),25-EC; 22(R)-hydroxy-24(S),25-EC; 24(R),25-EC; 22(S)-hydroxy-24(R),25-EC; 7-keto-, 7β-hydroxy-, and 7α-hydroxy-24(S),25-ECs; 24(S),25-iminocholesterol; and 22(R),24(S)-dihydroxycholesterol. The methyl ester and dimethylamide of cholenic acid were prepared from cholesterol trisnorcarboxylic acid via acid chloride by reaction with methanol and dimethylamine, respectively.

Cell Cotransfection Assays

CV-1 cell conditions and transient transfections were performed (Willy et al. 1995). Receptor expression plasmids encoding full-length human LXRβ (CMX-hLXRβ) or LXRα (CMX-hLXRα) (Willy et al. 1995) were cotransfected with a luciferase reporter plasmid [TK-CYP7a-LXRE(X3)-LUC] (Peet et al. 1998) containing three tandem copies of the sequence (gcttTG-GTCActcaAGTTCAagtta) from the rat *Cyp7a* gene (Chiang and Stroup 1994). Increasing concentrations of ligand (0.1–40 mM) were added to cells in media containing 5% lipid-depleted calf bovine serum. Transfection data were normalized to a β-galactosidase internal standard.

Data are presented as mean relative light units (RLU) from triplicate assays $\pm$ SEM. EC_{50} values generated from duplicate assays were determined by fitting the data to a sigmoidal dose–response curve (GRAPHPAD PRISM, GraphPad Software, San Diego, Calif., USA). Efficacy values represent the fraction of maximal fold activation of each compound relative to 24(S),25-EC. Fold activation was determined by dividing the maximal activation of each compound by the activation observed in the absence of compound.

Receptor Protein Purification

Polyhistidine human RXRα (His10-hRXRα) (Petty 1995), LXRα LBD or LXRβ LBD fusion proteins (His_6-hLXRα-LBD, His_6-hLXRβ-LBD) were expressed in *Escherichia coli* strain BL21(DE3) (Novagen). Cultures grown in Luria-Bertani medium were induced with 0.5 mM isopropyl β-D-thiogalactoside (IPTG) for 4 h at 25°C. Pellets were suspended in lysis buffer (250 mM NaCl, 16 mM Na_2HPO_4, 4 mM NaH_2PO_4, 1% Triton X-100, 10 mM imidazole, 200 mg of lysozyme per ml). The supernatant was incubated with Ni^{2+}-NTA agarose (Qiagen). The resin was washed twice with 20 vols of 50 mM Hepes, pH 7.5, 250 mM NaCl supplemented first with 50 mM then 75 mM imidazole. Protein was eluted with a linear 75–500 mM imidazole gradient. Peak fractions were tested for purity by SDS-PAGE, pooled, and cleared of imidazole over a PD-10 column (Pharmacia) equilibrated with 20 mM Hepes, pH 7.5, 200 mM NaCl, 2.5 mM EDTA, 5 mM DTT. Concentrations were determined by UV spectral analysis.

Ligand-Binding Assay

Scintillant-filled beads precoated with polylysine to permit protein binding (Amersham) were diluted in scintillation proximity assay (SPA) buffer [10 mM K_2HPO_4, 10 mM KH_2PO_4, 2 mM EDTA, 50 mM NaCl, 1 mM DTT, 2 mMCHAPS, 10% (vol/vol) glycerol, pH 7.1; CHAPS is 3-[(3-cholamidopropyl)dimethylammonio]-1-propanesulfonate] to a fi-

nal concentration of 10 mg/ml. Binding assays were performed in 96-well plates (Packard) in a total volume of 100 ml containing beads (0.2 mg per well) and His_6-hLXRα- LBD (600 ng per well), His_6-hLXRβ-LBD (250 ng per well), or His_6-hRXRα (250 ng per well). The amount of protein used did not deplete ligand concentrations. [^{3}H]-24(S),25-EC or [^{3}H]-9cRA was diluted in SPA buffer and added to wells for a final concentration of 25 nM or 5 nM, respectively. Competition binding assays using a single concentration of unlabeled competitor contained 25 mM 24(S),25-EC or 5 µmM9cRA. In other competition binding assays, unlabeled ligands were serially diluted in SPA buffer, then added at final concentrations ranging from 3 nM to 50 µM. Plates were shaken at 25°C for 3 h, and then radioactivity was measured with a Packard Topcount at 1 min per well. All concentrations were assayed in triplicate and the results were averaged. Values from wells void of competitor represented 100% binding.

EVALUATION

Generation of K_i Value

Competition curves were generated by non-linear regression analysis with GRAPHPAD PRISM, and apparent equilibrium dissociation constants (K_i values) were determined by using a method described by DeBlasi et al. (1989) based on the Cheng–Prusoff equation. K_i values for compounds that served as weak competitors in the assay (competition < 70% at the highest concentrations tested) are described as poor competitors. All K_i and SEM values reported are averages generated from duplicate or triplicate assays.

M.8.3.3 Inhibition of Atherosclerosis by LXR Ligands

PURPOSE AND RATIONALE

Several authors studied the potential antiatherosclerotic effects of LXR ligands. Alberti et al. (2001) used LXRβ-deficient mice to study hepatic cholesterol metabolism and resistance to dietary cholesterol.

Chawla et al. (2001) reported that the nuclear receptor LXRα mediates a transcriptional cascade via PPARγ, which induces ABCA1 expression and cholesterol removal from macrophages. Ligand activation of PPARγ leads to primary induction of LXRα and to coupled induction of ABCA1. Transplantation of PPARγ null bone marrow into LDLR$^{-/-}$ mice results in a significant increase in atherosclerosis, consistent with the hypothesis that regulation of LXRα and ABCA1 expression is protective *in vivo*.

PROCEDURE

Reagents

Oxysterols were dissolved in ethanol prior to addition to cells (< 1 µl/ml).

Cell Culture, Stable Cell Lines, and RNA Analysis

THP-1 cells were cultured in RPMI 1640 supplemented with 10% fetal bovine serum or 10% lipoprotein-deficient fetal bovine serum (LPDS). ES cells were cultured in the presence of rLIF (Gibco) as described (Keller et al. 1993). Macrophage differentia-

tion was induced in ES cells in a two-stage process. Initially, ES cells were differentiated into embryoid bodies. Day 6 embryoid bodies were isolated, disaggregated, and replated in the presence of interleukin-3 and macrophage colony-stimulating factor-1 to induce differentiation of monocytes and macrophages, respectively. Total RNA was isolated using TRIzol reagent (Gibco), and Northern blot analyses were performed.

Transfection Assays

Murine LXRα and β promoters were amplified by PCR using the published genomic structure and sequence. Primers for PCR of LXR promoters were: LXRα: 5′-ATCCTGTCCCTTCTGTCC-3′ and 5′-CC TCCAGAGTCAGCGTTC-3′, and LXRβ: 5′-CAGTG AGCGCATACAGGT-3′ and 5′-TCTCCGACTCTGT TGCCC-3′ . To determine the transcription initiation site for mABCA1, 5′ RACE was performed using the 5′/3′ RACE kit (Roche) with RNA from the RAW 274 cell line and mouse liver, and the gene-specific 3′ primer (5′-CTGAGGCCAACAAGCCAT-3′). The extended RACE products were used to screen a mouse genomic library (Stratagene). Sequence analysis of the isolated clones by the Blast program revealed that the identified initiation site and 5′ regulatory region of ABCA1 were identical to the sequences deposited in GenBank (accession number AJ017356). The 2.5-kb genomic fragment of the mABCA1 promoter was cloned into a pGL3-basic vector. CV-1 cells were transfected by lipofection and assayed for reporter activity as described by Forman et al. (1995). Transfections were performed in triplicate and normalized to an internal CMX-βgal control. pCMX expression vectors for the PPARs and LXRs have been described (Kliewer et al. 1994; Willy et al. 1995).

Gel Mobility Shift Assays

Gel mobility shift assays were performed using *in vitro* translated receptors and 32P end-labeled oligonucleotides in a buffer containing 20 mM HEPES (pH 7.4), 100 mM KCl, 1 mM β-mercaptoethanol, 10% glycerol, 100 mg/ml polydI-dC, and 5 mg/ml BSA. For competition studies, an excess of unlabeled oligonucleotide was added.

Cholesterol Efflux

Cholesterol efflux assays were performed as described by Venkateswaran et al. (2000), with minor modifications. Cells were plated at 50% confluence. On day 2, cells were washed and incubated for 24 h in RPMI 1640 supplemented with 10% LPDS. Cells were labelled with [^{3}H]cholesterol (1.0 mCi/ml), either in the presence of the ACAT inhibitor (58–035; 2 µg/ml) or with acLDL (50 µg/ml) in the absence of the ACAT inhibitor. Ligands for PPARβ (BRL; 5 µM), RXR (LG268; 50 nM), or LXR (22[R]-OHC; 2.0 µg/ml) were added to the cells. To equilibrate cholesterol pools, cells were washed twice with PBS and incubated for 8 h in RPMI containing 0.2% BSA plus the ligands, but lacking radiolabeled cholesterol or acLDL. Cells were again washed with PBS and incubated in RPMI containing 0.2% BSA in the absence or presence of HDL (50 µg/ml) or apoAI (15 µg/ml), for 4 h. An aliquot of the medium was removed and centrifuged at 14,000 *g* for 2 min, and the radioactivity was determined by liquid scintillation counting. Total cell-associated radioactivity was determined by dissolving the cells in isopropanol.

The data are presented as percent HDL-specific efflux or apoAI-specific efflux, which is efflux in the presence of acceptor minus efflux in the absence of acceptor. Each assay was performed in triplicate.

Bone Marrow Transplantation

LDL-R$^{-/-}$ mice backcrossed onto the C57BL/6 background were initially obtained from Jackson Laboratories. Mice were fed a chow diet ad libitum until they were enrolled into the study. PPARg2/2ES cells were injected into C57/Bl6 blastocysts to generate PPAR$\gamma^{-/-}$ chimeric mice. The majority of the chimeric mice obtained were high-percentage chimeras. Peripheral blood, spleen, and bone marrow of PPAR$\gamma^{-/-}$ chimeras were extensively analyzed by facs analysis with antibodies directed against Ly 9.1, CD11b/CD18, F4/80, CD3, B220, and Ly 6.1 to quantify the extent of chimerism. Chimeras, which were greater than 90% null in their contribution to the monocytic/macrophage lineage, were used for bone marrow transplantation, along with wild-type control mice. In all, 24 6-week-old male LDL-R$^{-/-}$ mice were γ-irradiated with 1000 rads to eliminate the majority of their bone marrow cells. Each of the γ-irradiated mice were reconstituted via a tail vein injection with 2,000,000 bone marrow cells isolated from either PPARγ +/+ mice (designated PPARγ +/+ BMT) or PPARg 2/2 mice (designated PPARg 2/2 BMT). The mice were placed on a chow diet for 4 weeks while their marrow repopulated with the donor cells. For induction of atherosclerosis, the transplanted mice were placed on an atherogenic diet containing 15.8% (wt/wt) fat and 1.25% cholesterol (no cholate; diet 94059, Harlan Teklad) for 8 weeks. At weeks 0 (before BMT), 4, and 12, blood was drawn via

the retro-orbital plexus following an 8-h fast, and total plasma cholesterol was measured via an enzymatic assay.

Lesion Analysis and Immunohistochemistry

Atherosclerotic lesions were quantified in the aortic valve of each mouse as described by Boisvert et al. (1998). The OCT-embedded, frozen aortic valves were sectioned serially at 10 µm thickness for a total of 300 µm beginning at the base of the aortic valve, where all three leaflets are first visible. Every fourth section for a total of five sections from each animal was stained with oil red O to identify the lipid-rich lesions. The stained areas were quantified using a computer-assisted video imaging system, and the mean area of the five sections from each animal was used for comparison analysis. The mouse aortic valve lesions were analyzed immunohistochemically with the following antibodies: anti-MOMA-2 (Serotec) for detection of intimal macrophages; anti-β-galactosidase (Cappel) for detection of PPAR$\gamma^{-/-}$ cells; and anti-α-actin (Dako) for detection of smooth muscle cells in the lesion. The frozen tissue sections were blocked with 5% normal sera and incubated for 2 h at room temperature with the primary antibody (1–10 µg/ml). The sections were blocked for endogenous peroxidase activity with Peroxo-Block (Zymed, South San Francisco, Calif., USA), followed by incubation with the appropriate secondary antibody (5 µg/ml) for 1 h. The washed sections were finally incubated for 30 min with Vectastain ABC Elite solution (Vector Laboratories, Burlingame, Calif., USA), developed with 9-amino-3-ethylene-carbazole (AEC; Vector Laboratories), and counterstained with hematoxylin.

EVALUATION

Statistical analysis was performed using the Mann-Whitney *U* test, and data are expressed as mean ± SD.

MODIFICATIONS OF THE METHOD

Dressel et al. (2003) used mouse myogenic C2C12 cells to study the influence of a peroxisome proliferator-activated receptor β/δ agonist on the expression of genes involved in lipid catabolism and energy uncoupling in skeletal muscle cells.

Tanaka et al. (2003) used skeletal muscle cells of mice to study the influence of peroxisome proliferator-activated receptor δ on fatty acid β-oxidation in skeletal muscle and the metabolic syndrome.

Chapter N
Endocrinology[1]

[1] Reviewed and amended by J. Sandow

N.1 Preface

In the development of methods for endocrine investigation, many changes have occurred since the early period of animal investigation, in which extensive surgical procedures were used to remove endocrine organs in order to study their function by deficiency symptoms, and their active principles were replaced by organ extracts and hormone preparations of increasing purity and specificity of action. Much of the classical endocrinology has now been replaced by investigations of ever increasing sophistication and specificity. Where possible, surgical procedures are discarded and avoided. Studies are performed on intact animals with a minimum of stress and interference (noninvasive procedures). One example of early noninvasive investigation is the study of adrenal gland hormone secretion, by investigation of the urinary excretion of adrenal steroids and changes induced by specific procedures.

Where surgical procedures cannot be avoided, techniques for anesthetizing animals have changed very markedly (new anesthetics have replaced ether anesthesia), animal husbandry has undergone major changes, and postoperative animal care has been standardized and optimized. Specific strains of animals with endocrine disease conditions have been developed by selection from naturally occurring genetic disorders, and increasingly detailed investigations are now available through the study of genetics and patterns of gene expression following the administration of test compounds and candidate drugs.

There is however a price to be paid for any method of increasing sophistication. The interpretation of the relevance of changes to the clinical situation (predictive relevance) becomes more difficult. As an example, in the chain of events from receptor binding of a drug, to the intracellular changes summarized as receptor signaling, and finally to the observed effects on patterns of gene expression, interpretation is much more tenuous and the pathway to understanding clinical relevance is often more difficult than it used to be. Endocrinologists will have to be careful and conservative when interpreting their findings, and often a set of coordinated investigations is needed before the complex early findings of an investigation can be unraveled. With these words of introduction, the following descriptions of methods are presented to encompass both historical and classical approaches, as well as the highly effective and specific investigation of detail now at hand.

N.1.1 Endocrine Survey

PURPOSE AND RATIONALE

The effects of steroid and peptide hormones as well as the influence of drugs on the endocrine system are detected by repeated administration of the test substances. The procedure is analogous to toxicology studies with repeated administration, however the dose range is limited to the intention of understanding physiological changes at concentrations of endogenous compounds found in the body, and concentrations of drugs which are intended for future therapeutic use (methods with intention to predict clinical effects and explain physiological regulations) (Sandow 1979). Animals are treated for at least several days to achieve equilibration of the physiological response to administration of compounds. After administration for a period of 1–4 weeks, the endocrine glands and the organs that are dependent on hormonal influences are weighed. Furthermore, the hormonal content of the endocrine glands and the blood levels of hormones are determined.

During treatment and at the time of animal sacrifice, blood samples or tissue samples may be obtained where needed for investigation and interpretation, and frequently the same treatment protocol may need to be repeated when taking samples during treatment, and when investigating the time sequence of induced changes, always with a minimum of interference and based on noninvasive procedures whenever possible.

PROCEDURE

The endocrine survey is performed using young or adult rats depending on the purpose of the investigation. Selection of this animal species is based on extensive knowledge of physiological data for organ development and hormone secretion. It is also based on the

technology for obtaining blood and urine samples with a minimum of stress to the animals. Separate groups of five to ten male and female Sprague-Dawley rats weighing 55–65 g are used (animals during development). For some compounds, groups of 200 or 300 g body weight may be required. They are treated daily over a period of 6–12 days with the test compound by the intended route (orally or by subcutaneous injections). For toxicological studies, a treatment period of 4 weeks is preferable. A similar protocol is applied for chronic toxicity studies in rats and dogs. On the day after the last application, the animals are sacrificed, weighed, and the parameters determined:

Parameter	Optional
Pituitary-adrenal axis	
Pituitary weight	Corticotropin-releasing hormone in hypothalamus
Adrenal weight	Pituitary content of adrenocorticotropin and vasopressin
Thymus weight	Adrenal content of corticosterone and aldosterone; corticosterone and aldosterone blood level; electrolyte (Na^+, K^+, Ca^{2+}, Cl^-) concentrations in serum; urinary excretion of corticosterone and aldosterone
Pituitary–gonadal axis	
Male reproduction	
Pituitary weight	LH-RH in hypothalamus
Weight of testes	Pituitary content of FSH, LH and prolactin
Weight of seminal vesicles	Blood levels of FSH, LH and prolactin
Weight of ventral prostate	Testosterone content in testes and serum
Weight of musculus levator ani	Growth hormone in pituitary and serum
Female reproduction	
Pituitary weight	LH-RH in hypothalamus
Weight of ovaries	Pituitary content of FSH, LH and prolactin
Weight of uterus	Blood levels of FSH, LH and prolactin; content of estradiol and progesterone in ovaries and serum
Pituitary–thyroid axis	
Pituitary weight	TRH in hypothalamus
Thyroid weight	Pituitary content of thyrotropin; serum content of TSH, T3 and T4

FSH Follicle-stimulating hormone, *LH* luteinizing hormone, *LH-RH* LH-releasing hormone, *TRH* thyrotropin-releasing hormone

After dissection, organ weights are recorded, and serum or plasma and the endocrine glands are stored frozen at −20°C for further determination of hormonal content. This method may include histology, in situ hybridization, etc. as required. In many instances, an investigation of patterns of gene expression can now be part of these studies, in particular when previous experience is available for the changes considered to be of relevance.

EVALUATION

The mean values of each parameter for the treated groups are compared with the values for the control group. The control group is generally treated with the solvent or vehicle required for administration of the test compound. In many cases a group of untreated animals, undergoing the same sampling procedures, is investigated in order to make certain of the physiological background for comparison.

MODIFICATIONS OF THE METHOD

Many modifications are possible; for example, extension of the treatment period up to 4 weeks in order to detect toxicological effects after long-term administration, inclusion of supplementary parameters, satellite groups. Further specific tests are necessary to clarify the mode of action.

N.2 Adrenal Steroid Hormones

N.2.0.1 Adrenalectomy in Rats

PURPOSE AND RATIONALE

The classical way to evaluate hormone function is to surgically ablate the hormone-producing endocrine gland and substitute with exogenously administered substances (extracts or synthetic hormones) (Biedl 1916). Many studies on the physiological role of adrenocortical hormones and the pharmacological effects of corticosteroids were performed using adrenalectomized rats.

PROCEDURE

Sprague-Dawley or Wistar rats of either sex weighing 120–150 g are used. The dorsal fur is shaved, the rat

is anesthetized and placed on a support in order to elevate the viscera. A transverse incision about 5 mm long is made in the mid-line at the costovertebral angle. To remove the left adrenal gland, the skin is retracted to the ventral side and the lumbar muscles incised just superior and anterior to the splenic shadow. The adrenal gland now appears directly beneath the incision and no exteriorization of the kidney is necessary. The periadrenal tissue is grasped between the kidney and the adrenal by small curved forceps and the intact gland together with the periadrenal fat and the mesenteric attachments is removed in toto. The bleeding is negligible in young animals so that no vessels need be tied off.

After ablation of the left adrenal, the animal is turned around and the right gland is removed through the original skin incision. A small incision through the lumbar muscles is made just above and anterior to the prominent lumbocostal arch which is seen near the costal margin. The curved forceps are inserted over the kidney and by elevating the liver, which covers the adrenal on this side, the gland is brought into view and grasped by the forceps, removing again the intact gland with the periadrenal fat and the mesenteric attachments. The incisions made in the lumbar muscles need not exceed 3 mm in length and may be made by spreading the blades of a pair of scissors; hemostasis or closure by sutures is not necessary. The incision is closed by a skin clip. The entire procedure is done in a time sufficiently short to avoid long-acting anesthetics. The animals appear normal in every aspect within a few minutes following the operation.

It is essential to provide good postoperative care for animals after adrenalectomy, and to correct the electrolyte imbalance due to deficiency of mineralocorticoid secretion (1% sodium chloride solution in water).

N.2.1
Glucocorticoid Activity

N.2.1.1
In Vitro Methods for Glucocorticoid Hormones

N.2.1.1.1
Corticoid Receptor Binding

PURPOSE AND RATIONALE

Steroid hormone receptors are intracellular metalloproteins which bind steroids with high affinity and high specificity (nuclear receptors). The lipophilic steroids enter the cell by diffusion. The binding of the hormone to its specific receptors results in a series of conformational changes, leading to an increase in affinity for specific DNA regulatory elements (steroid responsive elements). After binding, transcription of target genes is enhanced and mRNAs are produced. These mRNAs are then translocated to the cytoplasm and translated into proteins regulating cellular metabolism and initiating the cellular responses. The structure and functions of the steroid receptor superfamily have been reviewed by Carson-Jurica et al. (1990), Lazar (1991), Barnes and Adcock (1993), Distelhorst (1993), Power et al. (1993), Brinkmann (1994), Ojasoo et al. (1994, 1995), Wittliff and Raffelsberger (1995), Beato et al. (1996), and Jensen (1996). The relative binding affinities for the glucocorticoid receptor of rat liver or thymus cytosol can be measured by competitive displacement of [^{3}H]dexamethasone (Raynaud et al. 1979; Schlechte et al. 1982; Wojnar et al. 1986; Ueno et al. 1991).

PROCEDURE

A steroid receptor preparation may be obtained from rats. Male Wistar rats weighing 140–150 g are adrenalectomized under anesthesia. Two days later, the liver is excised and homogenized in a tenfold buffer containing 50 mM Tris-HCl, 1 mM EDTA, 2 mM dithiothreitol, 10 mM Na_2MoO_4, and 10% glycerol (pH 7.4). The homogenate is centrifuged for 1 h at 105,000 *g* at 4°C and collected as the supernatant fraction. The cytosol is mixed with 5 nM [^{3}H]dexamethasone in the presence or absence of appropriate concentrations of competitors and incubated for 2 h at 4°C. The reaction is terminated by the addition of hydroxyapatite in order to separate the receptor–steroid complex from the free [^{3}H]dexamethasone.

The radioactivity bound to the receptors is determined by liquid scintillation spectrometry.

EVALUATION

IC_{50} values for the receptor preparation are calculated by probit analysis.

MODIFICATIONS OF THE METHOD

Numerous modifications of the glucocorticoid receptor assay have been reported, and cloning of receptor subtypes is ongoing (Zeelen 1992; White et al. 1994). Cytosols have been prepared from rat liver, from cultured rat hepatoma cells (Rousseau and Schmit 1977), and from normal human lymphocytes (Steiner and Wittliff 1985); thymocytes, from rat thymus gland (Lefebvre et al. 1988), human leukemic lymphoid cell line, CEM C7 (Srivastava and Thompson 1990), rat lung (Druzgala et al. 1991; Hochhaus et al. 1991), human lung (Rohdewald et al. 1985), rat hippocampus (Jacobson et al. 1993) and other sources.

Differentiation of type I (mineralocorticoid) and type II (glucocorticoid) receptors has been attempted (Spencer et al. 1990; Jacobson et al. 1993).

A new affinity label for glucocorticoid receptors was described by Lopez and Simons (1991).

The solution structure of the glucocorticoid receptor DNA-binding domain has been determined (Härd et al. 1990).

Berger et al. (1992) used transient co-transfection of receptor cDNA and suitable reporter genes to study human glucocorticoid receptor function in a CV-1 mammalian cell line. A variety of natural and synthetic steroids were analyzed for their ability to activate gene expression through the human glucocorticoid receptor and to bind to extracts of cells expressing human glucocorticoid receptor cDNA. A good correlation between both *in vitro* parameters and *in vivo* anti-inflammatory activity was reported for most of the steroids tested.

Guo et al. (1995) tested the binding of various steroids to the synaptic plasma membrane, which may be a novel type of glucocorticoid receptor on neuronal membranes that is significantly different from cytosolic glucocorticoid receptors.

A general survey of steroid hormones, receptors and antagonists was given by Jensen (1996).

Teutsch et al. (1995) discussed the structure–activity correlation of hormone antagonists ("antihormones").

Yoshikawa et al. (2002) showed that the pyrazolosteroid cortivazol is a specific ligand for the glucocorticoid receptor.

N.2.1.1.2 Transactivation and Transrepression Assays for Glucocorticoids

N.2.1.1.2.1 General Considerations

PURPOSE AND RATIONALE

The effects of glucocorticoids are mediated by both transactivation and transrepression mechanisms. Classical glucocorticoids, such as prednisolone or dexamethasone, induce both mechanisms. The desired anti-inflammatory effects are mainly mediated by repression of gene expression, whereas side-effects are predominantly mediated via transactivation (Pfahl 1993; Schäcke et al. 2002; Buttgereit et al. 2005).

N.2.1.1.2.2 Transactivation Assay for Glucocorticoids

PURPOSE AND RATIONALE

Steroid agonistic and antagonistic properties can be evaluated by transactivation assays (Muhn et al. 1995; Fuhrmann et al. 1995, 1996). The transactivation assay assumes that steroid receptor proteins act as ligand-regulated transcriptional activators. After binding of hormone, the steroid receptor interacts with hormone responsive elements of hormone-regulated genes, thereby inducing a cascade of transcriptional events (Green and Chambon 1988). The hormone-dependent transcriptional activation can be determined in tissue culture by transfection of the steroid receptor under investigation and a reporter gene linked to a hormonally responsive promoter into cells. The transactivation assay allows determination of the agonistic and also the antagonistic potency of a given compound, by induction or inhibition of reporter gene activity (Fuhrmann et al. 1992).

PROCEDURE

Vector Construct

The expression plasmid pHGO containing the full-length coding sequence of the human glucocorticoid receptor driven from the SV 40 early promoter is prepared according to Hollenberg et al. (1985). The pMMTV-CAT plasmid containing the mouse mammary tumor virus promoter linked to a chloramphenicol acetyltransferase gene is prepared according to Cato et al. (1986).

Cell Culture and Transfections

CV-1 cells and COS-1 cells for transfection are cultured in Dulbecco's Modified Eagle's Medium (DMEM) supplemented with 10% fetal calf serum, 4 mmol/l L-glutamine, penicillin and streptomycin. Stable and transient transfections are performed using Lipofectin reagent (Gibco BRL) according to a procedure recommended by Felgner and Holm (1989), and Felgner et al. (1987). Stable transfections are carried out according to Fuhrmann et al. (1992). For transient transfection, 1×10^6 COS-1 or CV-1 cells are plated onto 100-mm dishes 1 day prior to transfection. Cells are typically about 80% confluent after 24 h.

Before transfection, cells are washed twice with 1 ml Opti-MEM (Gibco BRL) per dish. For each dish, 5 µg pHGO (hGR expression plasmid) and 5 µg pMMTV-CAT are diluted with 1 ml Opti-MEM; in addition, 50 µg Lipofectin Reagent is diluted with 1 ml Opti-MEM. Next, DNA and Lipofectin Reagent dilutions are combined in a polystyrene snap-cup tube to obtain 2 ml of transfection solution per dish, gently mixed, incubated at room temperature for 5 min, and added to the washed cells. After 5 h the transfection solution is replaced by 6 ml DMEM supplemented with 10% fetal calf serum.

To study the effect of the test hormones, transiently transfected cells are trypsinized, pooled and replated onto 60-mm dishes at a density of 4.5×10^5 per dish 24 h after transfection. Stably transfected cells are seeded onto 6-well dishes (1×10^5 cells per dish). Cells are cultured in medium supplemented with 3% charcoal-stripped fetal calf serum and the appropriate hormones for 48 h. As negative control for the reporter gene induction, cells are cultured with 1% ethanol. Transactivation assays with transiently or stably transfected cells are carried out at least three times.

CAT Assay

Transiently transfected cells and stably transfected cells are disrupted by freezing (ethanol/dry ice bath) and thawing (37°C water bath) three times. Protein concentrations of the cell extract are determined according to Bradford (1976). The CAT assay is performed according to Gorman et al. (1982). After the cells are spun for 15 min in an Eppendorf microfuge at 4°C, the supernatants are removed and assayed for enzyme activity. The assay mixture contains (in a final volume of 180 µl) 100 µl of 0.25 M Tris-hydrochloride (pH 7.5), 20 µl of cell extract, 1 µCi of [^{14}C]chloramphenicol (50 µCi/mmol; New England Nuclear), and 20 µl of 4 mM acetyl coenzyme A. Controls contain CAT (0.01 U; P.L. Biochemicals) instead of cell extract. All of the reagents except coenzyme A are pre-incubated together for 5 min at 37°C. After equilibration is reached at this temperature, the reaction is started by adding coenzyme A. The reaction is stopped with 2 ml cold ethyl acetate, which is also used to extract the chloramphenicol. The organic layer is dried and taken up in 30 µl of ethyl acetate, spotted on silica gel thin-layer plates, and run with chloroform:methanol (95:5), ascending. After autoradiography of the separated acetyl chloramphenicol forms, the spots are cut out and counted. Data are expressed as the amount of chloramphenicol acetylated by 20 µl of extract.

EVALUATION

CAT activity is calculated as percentage conversion from chloramphenicol to acetylated chloramphenicol. Concentration–response curves for CAT induction are established to determine the potency of the test hormone. Dexamethasone (10^{-10}–10^{-6} mol/l) serves as standard.

For antiglucocorticoid activity, CAT activity in the presence of 10^{-8} mol/l dexamethasone is set as 100% and relative CAT activity is calculated as a percentage of this value. Concentration–response curves for CAT inhibition are established with increasing concentrations of the steroid hormone antagonist RU 486 as the standard inhibitor.

CRITICAL ASSESSMENT OF THE METHOD

Hollon and Yoshimura (1989) examined the causes of high variability in data from enzymatic transient gene expression assays. Their results strongly suggested that variation in transfection efficacy is the major cause of data variation and can seriously compromise valid interpretation of data.

MODIFICATIONS OF THE METHOD

White et al. (1994) described a simple and sensitive high-throughput assay for steroid agonists and antagonists. A DNA cassette, containing a synthetic steroid-inducible promoter controlling the expression of a bacterial chloramphenicol acetyltransferase gene (GRE5-CAT), was inserted into an Epstein-Barr virus episomal vector which replicates autonomously in primate and human cells. This promoter/reporter system was used to generate two stably transfected human cell lines. In the cervical carcinoma cell line HeLa, which expresses high levels of glucocorticoid receptor, the GRE5 promoter is inducible over 100-fold by the synthetic glucocorticoid dexamethasone. In the breast carcinoma cell line T47D, which expresses progesterone and androgen receptors, the GRE5 promoter is inducible over 100-fold by either progesterone or dihydrotestosterone. These cell lines can be used to screen large numbers of natural and synthetic steroid agonists and antagonists in microtiter wells using a colorimetric chloramphenicol acetyltransferase assay.

Dias et al. (1998) recommended the use of CRE recombinase in mammalian cells for high throughput screening of chemical libraries to identify new receptor ligands. A translational fusion of CRE recombinase and the ligand binding domain of the human glucocorticoid receptor was transfected into mammalian cells with the LOX P/luciferase reporter gene (DeWet 1907). A stable transfected clone was isolated and

used to characterize the kinetics, ligand specificity, and dose–response to various receptor ligands.

N.2.1.1.2.3 Transrepression Assay for Glucocorticoids

PURPOSE AND RATIONALE

The immunosuppressive and anti-inflammatory actions of glucocorticoid hormones are mediated by transrepression of activating protein-1 (AP-1) and nuclear factor kappa B (NFκB) transcription factors. Since the anti-inflammatory effects of glucocorticoids are thought to be related to repression mechanisms and the side-effects mainly to activation mechanisms, a therapeutic benefit of dissociated glucocorticoids is expected (Vayssière et al. 1997; Vanden Berghe et al. 1999; Belvisis et al. 2001; Lin et al. 2002; Tanigawa et al. 2002; Schottelius et al. 2002, Coghlan et al. 2003; Lietal 2003; Ali et al. 2004; Hochhaus 2004; Schäke et al. 2004; Smith et al. 2005; Thompson et al. 2005). Schäke et al. (2004) investigated the dissociation of transactivation from transrepression by a selective glucocorticoid receptor agonist, leading to separation of therapeutic effects from side-effects.

PROCEDURE

Receptor-Binding Assays

Cytosol preparations of Sf9 cells, infected with recombinant baculovirus coding for the human GR, MR, or PR, were used for the binding assays. After centrifugation (15 min, 600 *g*) Sf9 pellets were resuspended in 1/20 volume of 20 mM Tris-HCl, pH 7.5; 0.5 mM EDTA, 2 mM DTT, 20% glycerol, 400 mM KCl, 20 mM sodium molybdate, 0.3 µM aprotinin, 1 µM pepstatin, 10 µM leupeptin and shock frozen in liquid nitrogen. After three freeze–thaw cycles, the homogenate was centrifuged for 1 h at 100,000 *g*. The protein concentration in the resulting supernatant was between 10 and 15 mg/ml. Aliquots were stored at −40°C.

For the binding assays for GR, MR, and PR, [^{3}H]dexamethasone (≈ 20 nM), [^{3}H]aldosterone or [^{3}H]progesterone, SF9 cytosol (100–500 µg protein), test compound, and binding buffer (10 mM Tris-HCl, pH 7.4; 1.5 mM EDTA, 10% glycerol) were mixed in a total volume of 50 µl and incubated for 1 h at room temperature. Specific binding was defined as the difference between binding of [^{3}H]dexamethasone, [^{3}H]aldosterone, and [^{3}H]progesterone in the absence and presence of 10 µM unlabeled dexamethasone, aldosterone, and progesterone.

After incubation, 50 µl of cold charcoal suspension was added for 5 min, and the mixtures were transferred to microtiter filtration plates. The mixtures were filtered into Picoplates (Canberra Packard, Dreieich, Germany) and mixed with 200 µl of Microszint-40 (Canberra Packard). The bound radioactivity was determined with a Packard Top Count plate reader. The concentration of test compound giving 50% inhibition of specific binding (IC_{50}) was determined from Hill analysis of the binding curves.

Induction of Tyrosine Aminotransferase (TAT)

Induction of TAT by test compounds was determined *in vitro* in the rat liver hepatoma cell line H4-II-

EC3. Cells were grown in MEM (Life Technologies, Karlsruhe, Germany) supplemented with 10% FBS (Life Technologies), 2 mM L-glutamine (Life Technologies), and 1% NEAA (nonessential amino acids) (Life Technologies). For compound testing, cells were seeded in 96-well plates (2×10^4 cells per well) and incubated with test compounds or dexamethasone for 20 h. Cells were then lysed and TAT activity assayed as described below for hepatic TAT induction *in vivo*.

Inhibition of IL-8 Production

IL-8 synthesis was induced by stimulation of the human promyeloic cell line THP-1 with lipopolysaccharide (LPS, *Escherichia coli* serotype 0127:B8; Sigma). Cells (2.5×10^4 cells per well) were treated with 10 µg/ml LPS in the absence or presence of test compounds or dexamethasone for 18 h. IL-8 concentration was determined in the supernatant by an IL-8-specific ELISA (Beckman Coulter).

Inhibition of Monokine Secretion

Monocytic secretion of tumor necrosis factor-alpha (TNF-α) and IL-12 p70 was determined after stimulation of peripheral blood mononuclear cells from healthy donors with 1 µg/ml LPS (*E. coli* serotype 0127:B8; Sigma) and 10 ng/ml interferon-gamma 1b (IFN-γ 1b) (Imukin, Boehringer Ingelheim). After 24 h of stimulation at 37°C, 5% CO_2, in the absence or presence of different concentrations of the compounds, the concentrations of IL-12 p70 and TNF-α in culture supernatants were determined by using commercial ELISA kits from R and D Systems (IL-12 HS Immunoassays, Nivelles, Belgium) and Bio-Source International (TNF-α EASIA, Wiesbaden, Germany). The calculated IC_{50} value represents the concentration of compound giving 50% inhibition of maximal TNF-α and IL-12 p70 production.

MODIFICATIONS OF THE METHOD

Vayssière et al. (1997) described synthetic glucocorticoids that dissociate transactivation and AP-1 transrepression as being weak transactivators of tyrosine aminotransferase (TAT) in cultured liver cells but potent inhibitors of LPS-induced IL-1β secretion in the human monocytic cell line THP1.

González et al. (2000) found that glucocorticoids antagonize AP-1 by inhibiting the activation/phosphorylation of JNK without affecting its subcellular distribution.

Kagoshima et al. (2001) reported that glucocorticoid-mediated transrepression is regulated by histone acetylation and DNA methylation.

Reichardt et al. (2001) studied the repression of inflammatory responses in the absence of DNA binding by the glucocorticoid receptor using mice with a mutation in the glucocorticoid receptor, which cannot activate glucocorticoid receptor response element promoters.

De Haij et al. (2003) reported dissociation of transrepression and transactivation in the steroid responsiveness of renal epithelial cells.

Schaaf and Cidlowski (2003) investigated the importance of ligand affinity for molecular determinants of glucocorticoid receptor mobility in living cells.

Stevens et al. (2003) investigated the role of tyrosine 735 in the dissociation of steroid receptor co-activators and nuclear receptor recruitment to the human glucocorticoid receptor.

Carballo-Jane et al. (2004) recommended skeletal muscle cells as a dual system to measure glucocorticoid-dependent transactivation and transrepression of gene regulation.

Studying transactivation and transrepression activity, Koubovec et al. (2005) found that synthetic progestins used in hormone replacement therapy have different glucocorticoid agonist properties.

Eberhardt et al. (2005) reported that dissociated glucocorticoids equipotently inhibit cytokine- and cAMP-induced matrix-degrading proteases in rat mesangial cells.

N.2.1.1.3 Induction of Tyrosine Aminotransferase (TAT) in Hepatoma Cells

PURPOSE AND RATIONALE

The synthesis of tyrosine aminotransferase in hepatoma tissue culture (HTC) cells (Thompson et al. 1966) can be induced by glucocorticoids (Giesent and Beck 1982; Raynaud et al. 1980; Rousseau et al. 1977). This effect can be abolished by glucocorticoid antagonists.

PROCEDURE

Hepatoma tissue culture (HTC) cells are grown in suspension to a density of about 8×18^5 cells/ml. The cells are washed 3 times at 0°C in a total volume of buffered saline equivalent to half of the culture medium. The suspension is centrifuged and cell pellets resuspended in serum-free medium containing 0.1% BSA and 0.1% $NaHCO_3$. Ethanol solutions of standard (dexamethasone) and test steroids in various concentrations are added to 10-ml aliquots of cell suspension, with the final ethanol concentration not exceeding 0.5%. After 16 h of incubation in tightly capped flasks on a rotary shaker (100 rev/min) at 37°C, the cells are harvested and tyrosine aminotransferase determined. The cells are washed twice and then disrupted with an ultrasonicator. The enzyme is assayed at 37°C by conversion of *p*-hydroxyphenylpyruvate to *p*-hydroxybenzaldehyde (Diamondstone 1966). One unit of activity represents the conversion of 1 µmol of p-hydroxyphenylpyruvate per minute.

EVALUATION

Enzyme-specific activity is expressed in milliunits of tyrosine aminotransferase/mg of cell protein. Dose–response curves are established for the standard

and the test preparation allowing the calculation of potency ratios with confidence limits.

N.2.1.1.4 Effect on T-Lymphocytes

PURPOSE AND RATIONALE

Corticosteroids as immunosuppressive agents have suppressive effects on T-lymphocyte function. Snijdewint et al. (1995) determined *in vitro* dose-dependent inhibition of Th1- and Th2-type cytokine production by various corticosteroids.

PROCEDURE

Culture Media

T-lymphocyte clones are maintained and expanded in Iscove's modified Dulbecco's medium (IMDM) supplemented with 10% pooled c-inactivated human serum and gentamicin (80 µg/ml). Experiments are performed in IMDM supplemented with 10% fetal calf serum (FCS), human transferrin (35 µg/ml), 2-mercaptoethanol (2-ME, 3.5 µg/l) and human insulin (1.75 IE/ml).

Peripheral Blood Lymphocytes and T-Lymphocyte Clones

Peripheral blood mononuclear cells are prepared from heparinized venous blood of healthy volunteers by flotation on Lymphoprep (Nycomed, 1.077 g/ml) and the peripheral blood lymphocytes are separated by centrifugation on a discontinuous Percoll density gradient. Peripheral blood lymphocytes are collected from the interface between densities 1.977 g/ml and 1.061 g/ml, washed three times in HBSS plus 2% FCS and suspended in IMDM plus 10% FCS. Isolated peripheral blood lymphocytes (0.5×10^6 cells/ml) are stimulated with CD2 mAb plus CD28 mAb (1.1000 final dilution of ascites) in the absence or presence of corticosteroids (Van der Pouw-Kraan et al. 1992). Supernatants are collected after 48 h for IFN-γ and IL-2 measurement, and after 96 h for IL-4 measurement.

T-lymphocyte clones specific to housedust mite (*Dermatophagoides pteronyssinus*) are generated from the peripheral blood and skin of atopic individuals (Van der Heijden et al. 1991). These clones are Th0 typed, capable of producing both IFN-γ and IL-4 (Kapsenberg et al. 1988). T-lymphocyte clone cells (0.5×10^6 cells/ml) are stimulated with CD2 and CD28 mAb (1.1000) plus 1 ng/ml phorbol 12-myristate 13-acetate (PMA) to induce optimal levels of cytokine production. Corticosteroids are added at the start of the stimulation and then 24 h after stimulation, supernatants are collected and stored at ≈ 20°C until cytokine production is analyzed.

Proliferation Assay and Cytokine Measurements

Proliferation by peripheral blood lymphocytes is measured 48 or 96 h after stimulation in 96-well flat-bottom culture plates using 10^4 cells/well, the last 16 h in the presence of 13 kBq (0.33 µC)/well of [^{3}H]TdR (Radiochemical Centre, Amersham, UK). The proliferation of T-lymphocyte clones (10^4 cells/well) is similarly measured after stimulation for 40 h, again the last 16 h in the presence of [^{3}H]TdR. Incorporation of [^{3}H]TdR is determined by liquid scintillation spectroscopy.

Measurement of IFN-γ and IL-4 in peripheral blood lymphocytes and T-lymphocyte clone supernatants is performed with specific solid-phase sandwich ELISA systems (Van der Pouw-Kraan et al. 1992). For quantification of IL-2 production, a commercial ELISA kit is used. IL-2R expression by T cells of peripheral blood lymphocytes is determined 48 h after stimulation by labeling with mouse anti-human CD25 mAb.

EVALUATION

Dose–response curves of inhibition of IFN-γ, IL-4 and IL-2 production as a percentage of initial values in peripheral blood lymphocytes and in different T-lymphocyte clones are established for various corticosteroids in the range of 10^{-10} to 10^{-6} M.

All measurements are performed in duplicate or triplicate. Data are expressed as mean ±SEM and differences are assessed using Student's *t*-test.

MODIFICATIONS OF THE METHOD

Mollison et al. (1999) compared a macrolactam inhibitor of T helper type 1 and T helper type 2 cytokine biosynthesis in various animal models with several steroid preparations used for topical treatment of inflammatory skin diseases.

N.2.1.1.5 Inhibition of Cartilage Degradation

PURPOSE AND RATIONALE

The efficacy of glucocorticosteroids after intra-articular injection has been clearly demonstrated in several animal models of osteoarthritis (Van den Berg et al. 1992; Pelletier et al. 1995). Augustine and Oleksyszyn (1997) used *in vitro* experiments to study the inhibition of degradation in bovine cartilage explants stimulated with concomitant plasminogen and interleukin-1α by various glucocorticosteroids.

PROCEDURE

Preparation of Bovine Articular Cartilage Explants

Bovine (calf) radiocarpal joints are acquired from a local abattoir immediately after sacrifice and transported on ice. The specimens are washed thoroughly and placed on ice containing 25% Povidine (10% Povidone-iodine topical solution). The specimens are then dissected in a sterile hood using good sterile technique. Media (DMEM containing 4.5 g/l D-glucose and L-glutamine, without sodium pyruvate) is supplemented with HEPES buffer (3.57 g/l) and sodium bicarbonate (3.7 g/l), and the pH adjusted to 7.4. The medium is further supplemented with penicillin (100 U/ml), streptomycin (100 µg/ml) and 50 µg/ml L-ascorbic acid. The articulating cartilage surfaces are exposed, and the synovial fluid is wiped away with sterile gauze. A sterile cork-borer with a diameter of 3.5 mm is used to remove uniform cores of cartilage. The cores are placed in a sterile flask, washed 4 times with sterile medium, and then placed in an incubator (37°C, 5% CO_2/95% air, adequate humidity) and allowed to equilibrate for 1 h. The cartilage disks are then labeled en mass with [^{35}S]sulfate at 10 µC/ml for approximately 72–96 h, with hand-stirring every few hours. After labeling, explants are equilibrated with fresh medium (minimum of two washes before use in experiments).

Inhibition of IL-1-Induced Cartilage Degradation in Bovine Articular Cartilage in the Presence of Human Plasminogen

Individual explants are transferred to 96-well plates containing 250 µl of fresh medium per well, with or without plasminogen and IL-1α, and with or without glucocorticosteroids. A negative control consists of medium alone, while two positive controls are IL-1α alone, and plasminogen with IL-1α. All other groups contain the glucocorticosteroids along with recombinant human IL-1α (0.4 ng/ml) alone or concomitant human plasminogen (0.4 µM) plus IL-1α. Glucocorticosteroids are added in concentrations between 10 and 10,000 pM. Control and experimental explants are incubated for approximately 96 h (4 days) prior to counting a 50-µl sample of supernatant from each well. A 50-µl sample of a papain-digest of each explant is also counted.

EVALUATION

The data are expressed as percentage glycosaminoglycan release over the 4 days. The values for all groups with glucocorticosteroids present are then compared to the values for concomitant plasminogen and IL-1α without glucocorticosteroids, and percentage inhibitions are calculated. Dose–response curves are established for each glucocorticosteroid.

In Vivo Methods for Glucocorticoid Hormones

N.2.1.2.1
General Considerations

Muscle work tests (early fatigue) were used in early stages of adrenal gland research (Bomskov 1937; Ingle 1944; Dorfman 1962), and their description is of historical interest. The method is based upon the fact that muscular responsiveness is lost within a few hours following the removal of the adrenal glands and can be maintained by the administration of corticosteroids. Since the 11-oxygenated steroids are quite active and compounds such as desoxycorticosterone are practically without activity, it appears that the main effect monitored is on carbohydrate metabolism.

N.2.1.2.2
Adrenal and Thymus Involution

PURPOSE AND RATIONALE

Repeated administration of corticosteroids causes central and peripheral effects on pituitary hormone content and secretion, and on adrenal weight and histology. In the immature rat, thymus involution is observed in a dose-related manner.

PROCEDURE

Groups of six to ten immature male Sprague–Dawley rats weighing 60–70 g are injected subcutaneously daily for 6 days with 0.2 ml of a homogenized suspension of different doses of the test compound in 0.5% aqueous carboxymethylcellulose solution. The standard, hydrocortisone acetate, is given in daily doses of 0.05 and 0.2 mg per animal. Controls receive the vehicle. On the 7th day, the animals are sacrificed and the adrenal and thymus weights determined.

EVALUATION

The involution of the thymus gland is a measure of the catabolic activity of the compound (metabolic effect). Involution of the adrenals is a measure of the ability of the compound to inhibit the secretion of ACTH (negative steroid feedback). Dose–response curves are established for both parameters and compared with hydrocortisone and the potency ratios are calculated.

MODIFICATIONS OF THE METHOD

The numeric test result is improved when the product of thymus and adrenal weights is calculated. Dose–response curves of the product of thymus and adrenal weights are steeper than those of each individual parameter (Laschet and Hohlweg 1960).

Inhibition of uridine incorporation into the ribonucleic acid of thymocytes has been used as a parameter for agonistic and antagonistic glucocorticoid activity (Gaignault et al. 1977).

N.2.1.2.3
Eosinopenia in Adrenalectomized Mice

PURPOSE AND RATIONALE

Glucocorticoids decrease the eosinophilic cell blood count in laboratory animals as well as in humans. This effect was used to quantitate the potency of corticosteroids in adrenalectomized mice (Silber and Arcese 1964; Speirs and Meyer 1951; Tolksdorf 1959).

PROCEDURE

Male mice weighing 20–25 g (e. g., of Jax C57 Brown, subline cd strain) are adrenalectomized and maintained at 28°C with 1% sodium chloride solution in water.

Then, 15-mg pellets of desoxycorticosterone acetate are implanted at the time of operation. Steroids are dissolved in benzyl alcohol and mixed with sesame oil (1:10). Three days after operation, the mice receive 5 µg epinephrine by subcutaneous injection and 4 h later 1–6 µg of hydrocortisone (or the test substance) in 0.03 ml oil. Three doses of the unknown substance and standard are tested, using six animals per dose. Blood samples are taken from the tail before and 3 h after steroid injection. Mice with fewer than 100 eosinophils per cubic millimeter of blood before injection are discarded.

EVALUATION

The percentage decrease of eosinophil blood count after 3 h is averaged per group. From dose–response curves, potency ratios are calculated.

CRITICAL ASSESSMENT OF THE METHOD

The test is relatively simple and has the advantage of requiring little material.

N.2.1.2.4 Liver Glycogen Test in Rats

PURPOSE AND RATIONALE

The liver glycogen deposition test, as described by Stafford et al. (1955), is a simple and specific test for glucocorticoid activity (Dorfman 1962; Ringler 1964; Silber and Arcese 1964).

PROCEDURE

Male Sprague–Dawley rats weighing 140–160 g are adrenalectomized. They are fed stock laboratory diet and 1% sodium chloride solution. On the morning of the fourth postoperative day, food is withdrawn. On the morning of the fifth day, the drinking fluid is withdrawn and the rats are given the test compound by a single subcutaneous injection in appropriate dosages suspended in 0.5 ml sesame oil. Seven hours later, the rats are sacrificed. The livers are removed and blotted on filter paper to remove blood, weighed, dropped into flasks containing 10 ml hot 30% potassium hydroxide and digested on a hot plate. The digest is diluted to 100 ml and a 50-fold dilution of an aliquot is used for analysis.

Then, 10 ml 0.2% anthrone in 95% sulfuric acid is slowly added to 5 ml of liver digest dilution with cooling. The mixture is heated in a boiling water bath for 10 min and then placed into cold water. Optical density is measured in a spectrophotometer at 620 µm using the anthrone-reagent as blank. Calibration curves are established using glucose as standard. Groups of five animals are used for each dose and for the vehicle controls. Three doses of test compound and of standard are used to find dose–response activities. Standard doses of hydrocortisone are 0.5, 1.0, and 2.0 mg per animal subcutaneously or 1.25, 2.5, and 5.0 mg per animal orally.

EVALUATION

The amount of glycogen expressed as glucose is calculated per gram liver weight. Dose–response curves are established for each compound and for the standard in order to calculate potency ratios.

MODIFICATIONS OF THE METHOD

The method can be used to determine the time course and duration of action of derivatives such as corticosteroid esters compared to the free alcohol (Vogel 1963, 1965) and for evaluation of topical and systemic activity (Alpermann et al. 1982).

The liver glycogen deposition in the adrenalectomized mouse has been used by Dorfman et al. (1946) and by Venning et al. (1946) to evaluate glucocorticoid activity. Liver tryptophan peroxidase activity in the rat is decreased after adrenalectomy and increased after administration of corticosteroids (Knox and Auerbach 1955) indicating an early effect of corticoids.

The enzyme activity of tryptophan pyrrolase in guinea pig liver is increased by systemic administration of corticoids, but this effect is short-lived and achieved only with high subcutaneous doses (Albrecht et al. 1979). In contrast, the enzyme is markedly reduced by protracted application of corticoids to the skin (“dermatocorticoids”).

N.2.1.2.5 Anti-Inflammatory Activity of Corticoid Hormones

GENERAL CONSIDERATIONS

Most of the tests described in the Sect. H.3 (anti-inflammatory activity) have been used for evaluation of corticosteroids.

The effects on acute inflammation are less suitable, [Ultraviolet erythema in guinea pigs (see H.3.2.2.1), Vascular permeability in rats (see H.3.2.2.2), Paw edema in rats (see H.3.2.2.6)], whereas the methods measuring subacute inflammation are very well suited [Granuloma pouch test in rats (see H.3.2.2.8), Cotton granuloma test in rats (see H.3.2.3.1), Glass rod granuloma test in rats (see H.3.2.3.3), Sponge implantation technique (see H.3.2.3.2)].

The molecular mechanisms of the anti-inflammatory actions of glucocorticoids were reviewed by Barnes (1998). Development of dissociated steroids which are more active in transrepression (interaction with transcription factors) than transactivation (binding to glucocorticoid response elements) as reported by Vayssiere et al. (1997) was recommended.

N.2.1.2.6 Animal Studies for Corticoid Hormone Evaluation

Several examples are presented here for the specific pharmacology of corticoids. The methods applied in some instances are the same methods as for antiphlogistic and anti-inflammatory compounds. Corticosteroids intended for systemic treatment or local application are administered daily for 3–14 days, and the pharmacological effects are determined. NMRI mice (26–28 g) or Wistar rats (140–160 g) are housed according to institutional guidelines with access to food and water ad libitum; 8–11 animals may be randomly allocated to the different treatment groups.

Croton Oil-Induced Ear Inflammation

This test is performed by local application, to reduce or prevent the effect of a local irritant. Topical application of the nonspecific contact irritant croton oil, a mixture of several phorbol esters, leads to acute inflammation characterized by edema and a mainly granulocytic cell infiltration into the skin. Swelling of the ear due to inflammation is prevented by the corticoid solution or suspension. For topical application, corticosteroids are dissolved in the same vehicle as used for croton oil and may be applied separately, or together with the irritant croton oil.

Systemic application of corticosteroids (subcutaneously) may also be performed 2 h before croton oil application. At the maximum of the inflammatory reaction, animals are killed, and ears (mice, area $\approx 1\,cm^2$) or a punch biopsy (rats, 10-mm diameter) of each ear are weighed as an indicator of edema formation. The tissue samples are then snap-frozen in liquid nitrogen in polypropylene tubes and kept at −20°C for up to 24 h (Tonelli et al. 1965; Alpermann et al. 1982; Vayssière et al. 1997).

Peroxidase Activity Assay

Peroxidase activity, as a measure for total granulocyte infiltration, may be assayed in the tissue samples by using a modification of a method described by Schottelius et al. (2002).

Induction of Tyrosine Aminotransferase (TAT) in Vivo

In a similar manner as performed *in vitro*, the induction of tyrosine aminotransferase (TAT) may be investigated *ex vivo* in tissue of treated animals. TAT in-

duction is evaluated 6 h after compound administration (subcutaneously) to juvenile rats by determination of TAT activity in liver homogenates. Animals are killed, and biopsy samples (10-mm diameter) are taken from the liver and snap-frozen. Biopsy samples are homogenized in 2 ml of homogenizing buffer (140 mM KCl in 20 mM KPO_4 buffer, pH 7.6) and centrifuged at 24,000 *g* for 20 min at 4°C. Supernatants are assayed for protein content by the BCA (bicinchoninic acid) Protein Assay Kit from Pierce. Then 20 µl of supernatant diluted 1:50 in PBS is incubated for 30 min at 37°C with 200 µl of TAT-reaction buffer (tyrosine 1.2 mg/ml or 6.6 mM/45 mM KH_2PO_4/0.06 mM pyridoxal-5′-phosphate/12 mM oxoglutaric acid, adjusted to pH 7.6 with KOH). After stopping the reaction with 10 M KOH and further incubation for 30 min, extinction was measured at 340 nm, and TAT activity is calculated in relation to 500 µg/ml total protein content. TAT induction is defined as *x*-fold increase in TAT activity measured as OD at 340 nm in comparison to the TAT activity in vehicle-treated animals (Thompson et al. 1966).

ACTH Suppression in Rats

Animals are housed under conditions of minimum stress before the study, in a quiet laboratory room. Six hours after application of compounds, animals are killed with minimum stress (decapitation in a separate room), and EDTA-anticoagulated blood is collected from the abdominal aorta. Plasma ACTH content is determined using the ACTH ^{125}I-assay system (ImmuChem Double Antibody hACTH) following the manufacturer's instructions (ICN).

The method requires considerable experience because the isolation of animals and sacrificing with a minimum of stress are difficult to achieve. Refer to pretreatment with lower doses of dexamethasone to improve this test method. Treatment with increasing doses of the corticosteroids and prednisolone as the reference standard will reduce the ACTH concentrations, such tests however have an inherently high variability of the vehicle-treated control groups (Sakakura et al. 1981; Baumann et al. 1985).

Increased Blood Glucose in Rats (Hyperglycemia Induced by Corticoids)

Animals are isolated before the study to avoid stress and fasted for 16 h. Six hours after application of compounds, animals are killed, and EDTA-treated blood is collected from the abdominal aorta to assess the corticoid-induced rise in blood glucose. Glucose in plasma is measured by colorimetric serum glucose determination by using hexokinase and glucose-6-phosphate dehydrogenase with a Hitachi 904 automatic analyzer (Roche Diagnostics).

Skin Atrophy After Chronic Corticoid Application

To assess the effect of local application on collagen composition of the skin, the test compound or the reference compound prednisolone (75 µl on a marked area of 9 cm^2 in 95% ethanol/5% isopropyl myristate) was applied daily for 19 days to the dorsal skin of nude rats (strain hr-hr, 120–140 g, Iffa-Credo). Animals were killed on day 20. Skin thickness was determined by using a specifically designed dial thickness gauge. Mean values were derived by measuring two adjacent treated skin areas. To determine skin-breaking strength of treated skin, a dorsal skin patch (5 × 5 cm) was removed. The skin patch was placed on filter paper, and two double-T-piece skin strips (50 mm long, 4 mm wide at the narrowest point) were punched in a caudal–cranial direction out of the patch. The skin strips were covered with moistened filter paper to avoid drying and were fixed with the wider ends into an apparatus developed in-house to measure skin-breaking strength. At a constant rate of stretch (200 mm/min), the force necessary to tear the skin strip was determined with a pressure sensor and was expressed as the skin-breaking strength (Alpermann et al. 1982; Vogel and Petri 1985).

Effect of Chronic Treatment on Thymus, Spleen, Adrenal, and Body Weight

To determine effects of repeated-dose corticoid treatment on body weight, animals were weighed before and after completion of treatment. Thymus, spleen, and adrenal glands were removed from animals killed after systemic or topical treatment and weighed. Organ weights are expressed as absolute values or as a percentage inhibition when compared with untreated animals (Laschet et al. 1960; Stoeck et al. 2004).

EVALUATION

For the examples given here, group means were calculated and the statistical significance of the effects of TAT, glucose induction, and ACTH suppression was assessed by using Dunnett's test. Differences between test compound and the corresponding prednisolone group (used as the reference standard) were assessed by using the Mann–Whitney test.

N.2.1.3 Effects of Steroids on Mechanical Properties of Connective Tissue

N.2.1.3.1 Breaking Strength of Bones

PURPOSE AND RATIONALE

Patients with Cushing's disease or after long-term treatment with corticosteroids have an increased susceptibility for bone fractures. The related animal tests were developed as a model for corticosteroid-induced osteoporosis, and they are of historical interest. The tests are based on changes in the mechanical properties of bone. Surprisingly, in chickens as well as in rats, short-term treatment with low and medium doses of glucocorticosteroids increased the breaking strength of bones dose-dependently whereas very high doses induced a decrease of breaking strength .

PROCEDURE

White Leghorn chicken at an age of 14 days weighing 170 ± 20 g were used. The animals were treated for 14 days by intramuscular injection of 0.2 up to 100 mg/kg cortisol (reference compound) or equivalent doses of other glucocorticoids in oily solution. At autopsy, body weight and comb weight are recorded and the femur and tibia bones from both sites are weighed. Length of bone (l) and outer diameter (D) of the diaphysis are measured using calipers. The bone is fastened on both ends, supported on edges 5 mm distant from the ends, and broken in the central portion of the diaphysis by a special device attached to an Instron-instrument. Breaking load (P) is recorded. The contralateral bone is cut at the middle of the diaphyseal shaft into rings by a small saw. Inner (d) and outer diameter (D) are measured in two perpendicular directions.

EVALUATION

Breaking strength (σ) of the hollow bones is calculated according to the technical formula for hollow cylinders:

$$\sigma = \frac{8}{\pi} \times \frac{P \times 1 \times D}{D^4 - d^4} .$$

Doses between 0.2 and 2.0 mg/kg cortisol and 0.05 and 1.0 mg/kg prednisolone show a parallel increase of breaking strength allowing the calculation of potency ratios. With higher doses, the response changes to inhibition of breaking strength. Excessive doses of 50 and 100 mg/kg cortisol, which are in the range of the LD_{50}, induce a decrease of breaking strength (Vogel 1968, 1969, 1990; Vogel and Ther 1962).

MODIFICATIONS OF THE METHOD

In young and adult rats, 10 days of treatment with cortisol and other corticosteroids induce a dose-dependent increase of breaking strength, whereas with longer treatment (30 days) a bell-shaped dose–response (increase with low doses, decrease with high doses) is seen.

N.2.1.3.2 Tensile Strength of Femoral Epiphyseal Cartilage in Rats

PURPOSE AND RATIONALE

The epiphyseal cartilage of rats is very sensitive to treatment with hormones and other desmotropic drugs. The tensile strength of the distal femoral epiphyseal plate is decreased after adrenalectomy and is restored or increased by treatment with low doses of corticosteroids.

PROCEDURE

Male Sprague-Dawley rats weighing 120 ± 10 g are treated with several doses of corticosteroids or other hormones for periods of between 1 and 14 days. After sacrifice, the hind legs are exarticulated in the hip joint and fastened at the collum femoris. Longitudinal tension always results in rupture of the distal femoral epiphyseal cartilage (Ther et al. 1963; Vogel and Ther 1964; Vogel 1969). The ultimate load of the femoral epiphyseal plate is recorded by an Instron instrument at an extension rate of 5 cm/min.

Single injections of doses between 10 and 100 mg/kg cortisol acetate or 2.5 and 40 mg/kg prednisolone acetate induce a dose-dependent increase of tensile strength up to twice the control levels after 24–48 h, which subsides after 96 h. Repeated administration up to 15 days also results in a dose-dependent increase. There is a maturation-dependent increase of tensile strength in untreated rats.

The effect of other hormones, e. g., gonadal steroids, on cartilage is much smaller than that of glucocorticosteroids.

EVALUATION

Dose–response curves for steroids can be established allowing the calculation of potency ratios in experiments with single-dose or repeated-dose administration.

N.2.1.3.3 Tensile Strength of Tail Tendons in Rats

PURPOSE AND RATIONALE

The thread-like tail tendons of rats are very suitable for studying the mechanical properties of connective tissue. They are easy to prepare and consist predominantly of collagen. Like other organs of connective tissue, such as bone, cartilage, and skin, the tensile strength of tail tendons is reduced after adrenalectomy and dose-dependently increased after short-term treatment with glucocorticosteroids (Vogel 1965, 1969).

PROCEDURE

Male Sprague-Dawley rats weighing 120 ± 10 g are treated with increasing doses of corticosteroids or other hormones for periods of between 1 and 14 days. After sacrifice, the tail is amputated at its base. The tail skin and the last few coccygeal vertebrae are removed. Single tendons are pulled out from the dorsal and ventral bundles and kept in saline solution. Tendons of the same diameter (0.25 mm) are selected with a stereomicroscope. Since the diameter of the tendons may be influenced by long-term treatment of the animals, tendons of the same vertebral insertion are tested, alternatively. For this purpose, the 10th vertebra is counted from the tail tip. All six tendons (four on the ventral and two on the dorsal side) inserting on this vertebra are removed and tested. The tendons are fixed in special clamps at a distance of 2.0 cm and immersed in physiological saline. Stress–strain curves and ultimate loads are determined with an Instron instrument with an extension rate of 5 cm/min.

A single injection of cortisol acetate (10–100 mg/kg) or prednisolone acetate (2 and 20 mg/kg) causes a dose-dependent increase of tensile strength allowing the calculation of a potency ratio of 1:4 for prednisolone versus cortisol. Repeated injections of cortisol acetate in doses between 1.0 and 50 mg/kg (s.c.) or prednisolone acetate in doses between 0.05 and 50 mg/kg (s.c.) show the same dose dependence and potency ratio. The tensile strength of tail tendons is similarly changed by treatment with gonadal steroids, depending on the dose and duration of treatment, but to a much lesser degree than by corticosteroids.

EVALUATION

For changes in mechanical properties, the potency ratios of glucocorticoids versus cortisol as the standard are calculated.

MODIFICATIONS OF THE METHOD

In addition to tensile strength, other biophysical parameters can be determined in tail tendons, such as hysteresis behavior (Vogel 1984). The ratio of energy input versus energy dissipation is calculated. Furthermore, dependence on strain rate and relaxation behavior under the influence of corticosteroids (Vogel 1989) as well as retardation (strain rate under constant load) have been studied (Vogel and Schorning 1990).

N.2.1.3.4 Tensile Strength of Skin Strips in Rats

PURPOSE AND RATIONALE

Clinical experience shows a decrease of skin thickness after long-term systemic or local treatment with corticosteroids (skin atrophy, thinning). The mechanical properties of human skin after treatment with corticosteroids are difficult to measure. As with other connective tissues, in animal experiments a clear increase of tensile strength of skin has been found after short-term administration of corticosteroids (Vogel 1969, 1971a, 1971b, 1974, 1981, 1986, 1993b).

PROCEDURE

Male Sprague-Dawley rats with an initial weight of 120 ± 10 g are treated with increasing doses of corticosteroids or other substances for periods of between 1 and 14 days. After sacrifice, the back of the animals is shaved and a flap of skin measuring about 5×5 cm is removed. The skin flap is placed between two pieces of plastic material with known thickness. By these means, the actual thickness of the excised skin is measured by calipers. Two dumbbell-shaped specimens are cut with a special punch in perpendicular direction to the body axis, having in the middle a width of 4 mm. They are fixed between the clamps of an Instron instrument. In the usual experiments, stress–strain curves and ultimate loads are recorded at a strain rate of 5 cm/min. From stress–strain curves, the values of ultimate load and ultimate extension are recorded. The stress–strain curves are almost linear in part, allowing the calculation of the modulus of elasticity. Tensile strength is calculated from ultimate load divided by original cross-sectional area.

Dose–response curves for 10 and 100 mg/kg cortisol acetate or 2 and 20 mg/kg prednisolone acetate show a sharp increase of ultimate load and tensile strength up to 5 days of treatment, a continuous decrease of skin thickness upon longer treatment, and a decrease of ultimate load up to 2 months of treatment, which is below controls for ultimate load, but not for tensile strength (Vogel 1970a).

EVALUATION

Dose–response curves are established for corticosteroids versus the standard cortisol and potency ratios with confidence limits are calculated.

MODIFICATIONS OF THE METHOD

With a similar method, the tensile strength of skin wounds after treatment with corticosteroids was studied in rats (Vogel 1970a, 1970b). See also Sect. P.11.4.

Strain rate influences the values of ultimate load, tensile strength and modulus of elasticity, but not the effect of corticosteroids (Vogel 1972).

In contrast to parameters indicating the strength and elasticity of collagen, the parameters indicating plasticity, such as relaxation, hysteresis, strain at constant load (creep experiments), and isorheological behavior, are less dramatically changed by corticosteroids but indicate a decrease of viscosity or an increase of stiffness.

For a more detailed description of relaxation experiments (Vogel 1973) see Sect. P.11.2.1.5; of hysteresis experiments (Vogel 1976, 1989), see Sect. P.11.2.1.6; of creep experiments (strain at constant load) (Vogel 1977, 1989), see Sect. P.11.2.1.8; of measurement of isorheological behavior (Vogel 1987, 1989), see Sect. P.11.2.1.7; and for *in vivo* experiments in rat skin (Vogel and Denkel 1985; Vogel 1989, 1993a), see Sect. P.11.3.

N.2.1.4
Topical Effects of Glucocorticosteroids on Skin

N.2.1.4.1
Skin Thickness and Tensile Strength

PURPOSE AND RATIONALE

From clinical experience it is known that a decrease of skin thickness occurs after long-term local treatment with corticosteroids. The mechanical properties of human skin after treatment with corticosteroids are difficult to assess. A clear increase of tensile strength of skin after short-term local administration of corticosteroids has been found in animal experiments, whereas skin thickness decreased (Alpermann et al. 1982; Vogel and Petri 1985).

PROCEDURE

Male Sprague-Dawley rats with an initial weight of 150 ± 10 g are used. The animals are shaved before and once again during treatment. The animals are treated once daily over 10 days with various concentrations of the test compound or the standard or with fixed concentrations of the test compound in different galenical preparations. The test material is applied in a volume of 0.2 ml to an area of 4 cm^2 to the shaven back skin. The animals are kept in individual cages to avoid systemic absorption by mutual licking. Two days after the last treatment the animals are sacrificed, a flap of skin measuring about 5×5 cm is removed, and skin thickness is determined. The skin flap is placed between two pieces of plastic material with known thickness. The thickness of the excised skin is measured by calipers. Perpendicular to the body axis two dumbbell-shaped specimens are punched out. Stress–strain curves are recorded using an Instron instrument. The following parameters are determined:

- load at rupture (ultimate load)
- extension at rupture (ultimate strain)
- skin thickness
- tensile strength (ultimate load divided by cross-sectional area)
- modulus of elasticity (calculated from the straight part of the stress–strain curve).

EVALUATION

Dose–response curves are established for the parameters ultimate load, ultimate strain, skin thickness, tensile strength, and modulus of elasticity for the standard (prednisolone acetate) and the test compound allowing the calculation of potency ratios with confidence limits.

CRITICAL ASSESSMENT OF THE METHOD

In addition to corticosteroid-induced atrophy of the skin after topical application assessed by histology, mechanical parameters can be determined.

MODIFICATIONS OF THE METHOD

Kapp et al. (1977) used specially devised apparatus for rats covering the site of substance application, which

guarantees an exclusive dermal absorption and excludes oral ingestion of the steroid.

In addition to skin thickness and breaking strength, Töpert et al. (1990) determined thymus weight, water and glycosaminoglycan content in the skin of rats after topical application of steroids over 30 days.

Iwasaki et al. (1995) measured the skin atrophy in Wistar rats by locally applied clobetasol-17-propionate, a synthetic glucocorticoid, and the influence of simultaneously applied RU 486. Then, 24 h after the last application, the thickness of the skin was measured with a dial skin thickness gauge, with an accuracy of 0.01 mm. The treated skin was pinched lengthwise, and both skin surfaces were held vertically between two plastic discs of the gauge.

Hartop et al. (1978) measured transepithelial water loss (TEWL) in the skin of rats deficient in essential fatty acids (Prottey et al. 1976; Lowe and Stoughton 1977) after local treatment with corticosteroids.

Woodbury and Kligman (1992) recommended the hairless mouse as a model for assaying the atrophogenicity of topical steroids. Epidermal atrophy was determined by the number of cell layers of viable epidermis on five fields under ×400 magnification. Dermal thickness was determined under ×400 magnification. The total number of sebocytes in all visualizable sebaceous glands was counted in ten fields at ×250 magnification.

Van den Hoven et al. (1991) used the hairless mouse as a model to distinguish between local and systemic atrophogenic effects of topical steroids. Male hairless mice (strain h/h-NMRI) were treated on the left flank with test preparations once daily for 3 weeks. During this time, body weight was measured and the skinfold thickness of treated and untreated sides was determined using a graduated micrometer. On day 21, the animals were sacrificed and dermal thymidine uptake and weights of the thymus were determined.

Corticosteroid-induced skin atrophy in hairless mice can be prevented by tretinoin (Lesnik et al. 1989; Schwartz et al. 1994). In these studies, albino Skh-hairless-1 mice were treated topically twice daily with corticosteroids or in combination with tretinoin. At the end of the treatment, all mice were sacrificed and specimens of the dorsal skin were frozen for light microscopy and quantification of glycosaminoglycans, fibronectin, and collagen.

Wrench (1980) applied commercially available topical corticosteroid preparations to the proximal halves of albino mouse tail for 21 days and measured epidermal thickness by histology. All steroids caused epidermal thinning, except clobetasone butyrate.

Altmeyer and Buhles (1981) tested the anti-acanthogenic effect of topically applied steroids after long-term treatment of guinea pigs (up to 118 days) by histological measurement of epithelial thickness. For delimitation of the measuring lines, the upper boundary was taken as that between the stratum granulosum and the stratum corneum, and the lower boundary as that between the basal cell layer and the corium.

Kajita et al. (1986) tested epidermal beta-adrenergic adenylate cyclase responses in pigs after topical application of glucocorticoids. A significant increase of this receptor response was observed 24 h following topical application of potent glucocorticoid ointments. Domestic white-haired pigs were anesthetized with 30 mg/kg nembutal i.p. Four 5 × 5 cm areas were chosen and the following treatments were administered to each area: (1) topical administration of glucocorticoid ointments; (2) UVB irradiation alone (230 mJ/cm^2); (3) topical application of glucocorticoid ointments following UVB irradiation; (4) no treatment as a control. After 24 h the treated pigs were anesthetized again and skin specimens were obtained from the four areas by means of a Castroviejo keratome (Storz Instrument, St. Louis, Mo., USA) adjusted to the 0.3 mm setting. Each skin slice obtained by the Castroviejo keratome was cut into 5 × 5 cm squares, which were washed 3 times in RPMI 1640 medium and preincubated in RPMI 1640 medium for 37°C to standardize the cAMP level (Yoshikawa et al. 1975). After the preincubation, two pieces of skin squares were randomly selected and were incubated with various adenylate cyclase stimulators (Iizuka et al. 1985). The concentrations of epinephrine, adenosine, and histamine added to the incubation medium were 50 μM, 2 mM and 1 mM, respectively. The cAMP content in skin squares was measured by radioimmunoassay using a Yamasa cAMP assay kit (Yamasa Shoyu, Tokyo, Japan) after partial purification (Yoshikawa et al. 1975). The cAMP phosphodiesterase activities in skin squares were measured by the method of Adachi et al. (1976) who purified multiple forms of pig epidermal cyclic nucleotide phosphodiesterases by DEAE-cellulose column chromatography.

In vitro experiments measuring the effects of retinoids and glucocorticoids on the beta-adrenergic adenylate cyclase system of pig skin epidermis were performed by Iizuka et al. (1985).

N.2.1.4.2 Assay of Topical Glucocorticoid Activity in Transgenic Mice

PURPOSE AND RATIONALE

Katchman et al. (1995) proposed a transgenic mouse model as a biological assay of topical glucocorticosteroid potency.

PROCEDURE

A homozygous line of transgenic mice expressing 5.2 kilobases (kb) of the human elastin promoter region linked to the chloramphenicol acetyltransferase (CAT) reporter gene was developed (Hsu-Wong et al. 1994). For this purpose, 5.2 kb of human elastin 5′-flanking DNA is linked to a 0.7-kb CAT gene, followed by 0.3 kb of DNA with a polyadenylation signal. This linearized construct is injected into fertilized oocytes, and a line of transgenic mice expressing the human elastin promoter, as detected by CAT activity, is developed. These transgenic mice have no clinical phenotype and they do not express human elastin protein, as no part of the coding sequence is contained within the transgene. The human elastin promoter/CAT construct is expressed in a tissue-specific and developmentally regulated manner.

Test animals are 4- or 5-day-old hairless pups, homozygous for the transgene. In each experiment, pups of the same litter are used for comparison between glucocorticosteroid-treated and control preparations in parallel. Steroid preparations are tested by applying 0.03 g uniformly on their dorsal surface ($\approx 14\,mg/cm^2$). Control animals receive the same amount of cream base. The test animals are separated from each other and from their mothers and are sacrificed at different time points. Skin biopsy samples are removed immediately from the treated area.

For the CAT assay, skin is homogenized with a Polytron tissue homogenizer in 0.25 M TRIS hydrochloride (pH 7.5). The homogenates are freeze-thawed three times and centrifuged at 10,000 *g* for 15 min. The protein content of the supernatant is determined by a commercial kit and aliquots, containing 100 mg of protein, are assayed for CAT activity in the linear range of the assay (Gorman et al. 1982) (see Sect. N.2.1.1.2).

EVALUATION

The significance of differences between treatment groups is evaluated by Student's *t*-test.

N.2.1.4.3 Effect on Epidermal DNA Synthesis

PURPOSE AND RATIONALE

Du Vivier et al. (1978), Marshall and Du Vivier (1978), Marshall et al. (1981), and Clement et al. (1983) evaluated the local and systemic effects of topically applied corticosteroids on epidermal DNA synthesis in hairless mice.

PROCEDURE

Hairless mice of either sex, 2–4 months old, are dosed in groups of six with test preparations or control base: 0.03 ml of test drug formulation is spread over 3 cm^2 of the anterior dorsal skin. The posterior half of the dorsal surface of the animal is left untreated. Animals are injected subcutaneously with 25 mCi (methyl-^{3}H) thymidine, specific activity 5 Ci/mM, in the right thigh 1 h before being sacrificed 6 or 24 h after application of test formulation.

The neck and back skin samples, with at least 2 cm unsampled skin left between them (to avoid inclusion of treated skin in the back sample) are removed. The epidermis is separated from the dermis by placing the sample, dermis downwards, on a stainless steel plate at 57°C for 25 s. The epidermis can then easily be separated from the dermis with a scalpel blade. The epidermal samples are wrapped in aluminum foil and stored at 20°C until analysis.

Approximately 30 mg of epidermis in 5 ml of a 0.24 M sodium phosphate buffer solution, containing 8 M urea, 1% sodium lauryl sulfate and 1 mM EDTA at pH 6.8, is lysed using an ultrasonic disintegrator. DNA is extracted from the cell lysate by column chromatography using hydroxylapatite. The epidermal cell lysate is added to the hydroxylapatite column and washed with a buffer containing 0.24 M sodium phosphate and 8 M urea at pH 6.8 to remove RNA and protein. The urea is then removed with 50 ml of 0.14 M sodium phosphate buffer at pH 6.8. Double-stranded DNA, which binds to hydroxylapatite under low-salt buffer conditions, is eluted with 0.48 M sodium phosphate buffer at pH 6.8, and a 2-ml sample is collected.

The DNA concentration in the sample is determined by UV absorption at 260 nm in a spectrophotometer. Then 0.5-ml aliquots of the sample are added to 12 ml scintillation cocktail and 0.2 ml N HCl in scintillation vials. Each sample is prepared in triplicate and counted for 20 min/vial in a scintillation counter.

EVALUATION

The results are initially expressed as mean counts per minute (c.p.m.) for the vial triplets, converted to mean disintegrations per minute (d.p.m.) and the results expressed as d.p.m./μg DNA. The significance of differences between treatment groups is evaluated by Student's *t*-test.

MODIFICATIONS OF THE METHOD

Marks et al. (1973) described a method for the assay of topical corticosteroids in mice based on changes in thymidine incorporation after treatment. Sticky tape was applied five or six times to the dorsal skin of mature male hairless mice of the Harwell strain to remove the horny layer. A similar quantity of topical test preparations (about 70 mg) was applied on the stripped dorsal skin of each mouse. A dressing of cotton gauze lined with a plastic film was applied and secured with strapping, staying for periods of from 5 to 156 h. Then 4 h before sacrifice the mice were intraperitoneally injected with 0.15 ml of a 0.1% Colcemid solution together with 30 μCi of tritiated thymidine. The dorsal skin area previously treated was removed, fixed in 10% buffered formalin and stained with hematoxylin and eosin. For estimation of the mitotic index, cells in the prophase, anaphase, and metaphase stages were counted. To quantitate the labeling index, the number of labeled basal and suprabasal cells was estimated as a proportion of the total number of basal cells.

N.2.1.4.4 Induction of Drug-Metabolizing Enzymes

PURPOSE AND RATIONALE

Finnen et al. (1984, 1985) evaluated the effects of topical application of glucocorticosteroids on the activity of drug-metabolizing enzymes in the skin of adult hairless mice. The ability of steroid preparations to induce enzyme activity was related to their clinical potency.

PROCEDURE

Adult male and female hairless mice are treated with 0.3 g of test creams or cream base applied to the dorsal skin and rubbed in until no visible traces remain. Then 16–18 h after treatment, the animals are sacrificed, the treated area of skin removed, and placed epidermis-down on a curved surface, and subcutaneous fat and muscle are removed using a scalpel blade. Epidermis and dermis are separated by a heating technique (Thompson and Slaga 1976). The tissue is then placed in 0.1 M phosphate buffer (pH 7.4) and minced finely using surgical scissors. Scissors-minced tissue is then homogenized in ice-cold 0.1 M phosphate buffer (pH 7.4) using a Polytron homogenizer. Whole-skin homogenates are then centrifuged at 9000 *g* for 20 min and the resulting supernatant used as the source for the determination of 7-ethoxycoumarin O-deethylase (Greenlee and Poland 1978). For the determination of ethoxyresorufin O-dealkylation (Pohl and Fouts 1980) the 9000 *g* supernatants are further centrifuged at 100,000 *g* for 1 h, the resulting microsomal pellet resuspended in 0.1 M phosphate buffer (pH 7.4), and used as the enzyme source. The DNA content of the 9000 *g* pellet is estimated by the diphenylamine reaction (Burton 1956).

EVALUATION

The significance of differences between treatment groups is evaluated by Student's *t*-test.

N.2.1.4.5 Cornea Inflammation in Rabbits

PURPOSE AND RATIONALE

Leibowitz and Kupferman (1974), Leibowitz et al. (1978, 1992) and Cantrill et al. (1975) studied the anti-inflammatory efficacy of topical corticosteroids for treatment of glaucoma in rabbits. Again, this test is purely of historical interest.

PROCEDURE

New Zealand albino rabbits weighing 1.8–2.3 kg are anesthetized for approximately 5 min with 15 mg/kg i.v. thiamylal sodium. A corneal inflammatory response is produced by intralamellar inoculation of 0.03 ml of laboratory-grade clove oil. Before the induction of corneal inflammation, the rabbits are given three intravenous inoculations of 1.85×10^6 Bq/kg of an aqueous solution of tritiated thymidine (24.79×10^{10} Bq/mol) at 24-h intervals. The intracorneal injection of clove oil is given concomitantly with the third thymidine injection, and 24 h later, therapy is initiated. A standard drop (0.05 ml) of drug is instilled hourly for a total of six doses, and then, after a lapse of 18 h, one drop is administered hourly for an additional total of seven doses.

Corticosteroid preparations are tested in different concentrations. A control group is run with each experimental trial; control rabbits are handled in the same manner as experimental rabbits, except that the control rabbits receive either prednisolone acetate (positive control) or no treatment (negative control). At autopsy, a 10-mm penetrating corneal button is removed by trephination, tissue samples are placed in a commercially available solubilizing agent (Soluene 350, Packard Instrument), 1 ml per cornea, until dissolved. The samples are counted for a minimum of 10 min, measuring the amount of radioactivity in each cornea sample.

EVALUATION

The significance of differences between treatment groups is evaluated by Student's *t*-test.

N.2.1.4.6 Endotoxin-Induced Uveitis in Rats

PURPOSE AND RATIONALE

Salmonella endotoxin, a lipopolysaccharide, produces uveitis 12–24 h after injection into the footpad of rats. Uveitis is characterized by miosis, iris hyperemia, increase of protein content in aqueous humor, and inflammatory cell accumulation in the anterior uvea and aqueous humor. Glucocorticoids strongly inhibit endotoxin-induced uveitis by suppressing inflammatory mediators (Cousins et al. 1982; Tsuji et al. 1997).

PROCEDURE

Female inbred Lewis rats weighing about 160 g are used. Then 500 µg/kg *Salmonella* endotoxin dissolved in saline is injected into the footpads. Twelve hours later, the animals are sacrificed and both eyes of each animal used in the experiments. The anterior chamber of the eye is punctured, using a 27-gauge needle, to collect the aqueous humor. Then 5-µl aqueous humor samples are placed into 495 µl of phosphate-buffered saline containing 1% paraformaldehyde. The number of cells in the aqueous humor is then counted using a flow cytometry system. The cell number for both eyes of each animal is averaged for statistical analysis of the results.

In topical applications, glucocorticoids are instilled (5 µl/eye) three times at 1 h before and 3 and 7 h after lipopolysaccharide injection. For systemic application, glucocorticoids are injected subcutaneously 3 h after lipopolysaccharide injection.

Total RNA is isolated from the iris-ciliary body with a mRNA purification kit (Pharmacia Biotech, Uppsala, Sweden). Each RNA sample is extracted from the pooled iris-ciliary bodies of both eyes of each animal. The extracted RNA is quantified after which 4 µg is used for DNA synthesis via polymerase chain reaction.

EVALUATION

Dunnetts's multiple comparison test was applied for statistical analysis.

Further methods for measuring local or topical activity of corticosteroids are very suitable for evaluating local corticosteroid activity, described in Sect. H.3 "Anti-inflammatory activity", such as oxazolone-induced ear edema in mice (see Sect. H.3.2.2.4) and croton-oil-induced ear edema in rats or mice (see Sect. H.3.2.2.5).

Furthermore, methods described in Chap. I "Anti-arthrotic and immunomodulatory activity", Sect. I.2.2.4 "Passive cutaneous anaphylaxis", and Sect. I.2.2.6 "Delayed type hypersensitivity are recommended as models for testing topical corticosteroid potency".

N.2.1.4.7 Croton Oil-Induced Ear Inflammation

Topical application of the nonspecific contact irritant croton oil, a mixture of several phorbol esters, leads to acute inflammation characterized by edema and a mainly granulocytic cell infiltration into the skin. For topical application, compounds are dissolved in the same vehicle as used for croton oil and are co-applied. Systemic application of compounds (s.c.) is performed 2 h before croton oil application. At the maximum of the inflammatory reaction, animals are killed, and ears (mice, area $\approx 1\,cm^2$) or a punch biopsy (rats, 10 mm diameter) are weighed as an indicator of edema formation, then snap-frozen in liquid nitrogen in polypropylene tubes and kept at –20°C for up to 24 h.

N.2.1.5 Anti-Glucocorticoid Activity

N.2.1.5.1 Adrenal and Thymus Involution

PURPOSE AND RATIONALE

The involution of thymus and adrenal glands induced by hydrocortisone can be antagonized by compounds with anti-glucocorticoid activity (Dorfmann 1962).

PROCEDURE

Groups of six to ten immature male Sprague-Dawley rats weighing 60–70 are injected subcutaneously daily for 6 days with 0.2 ml of the antagonistic test compound in 0.5% aqueous carboxymethylcellulose solution. Hydrocortisone acetate is used as the agonist in daily doses of 0.2 mg per animal. Controls receive hydrocortisone acetate only. On the seventh day, the animals are sacrificed and the adrenal and thymus weights determined.

EVALUATION

The relative weight [quotient of adrenal or thymus weight (mg) and body weight (g)] is calculated for each rat. Means of the antagonist-treated groups are compared with the means of hydrocortisone-only controls. An increase of thymus and adrenal weight relative to the hydrocortisone control indicates anti-glucocorticoid activity.

MODIFICATIONS OF THE METHOD

Inhibition of tyrosine aminotransferase induced by corticosterone or dexamethasone was used by Vincent et al. (1997) to characterize the anti-glucocorticoid properties of a novel synthetic steroid.

N.2.2 Mineralocorticoid Activity

N.2.2.1 In Vivo Methods

N.2.2.1.1 General Considerations

Very early bioassays ("Survival tests") have been used to standardize extracts of adrenal cortex for mineralocorticoid activity (Grollman 1941; Ringler 1964; Tolksdorf et al. 1956). For evaluation of mineralocorticoid activity these tests have been replaced by bioassays measuring electrolyte excretion in the urine.

Several animal species do not survive after adrenalectomy. However, they can be kept alive by administration of mineralocorticoids. The first animal species used successfully was the adrenalectomized drake (Bülbring 1937). The methods employing adrenalectomized rats and mice (Dorfman 1962) suffered from the fact that in these species aberrant adrenal cortical tissue may occur, which is not removed by surgical adrenalectomy. In contrast, male Syrian golden hamsters weighing 50–60 g are very suitable for testing adrenocortical activity (Junkmann 1955).

N.2.2.1.2 Electrolyte Excretion

PURPOSE AND RATIONALE

Mineralocorticosteroids enhance sodium retention and potassium excretion. The sodium excretion in adrenalectomized rats is dose-dependently decreased. This parameter can be used to assess the mineralocorticoid activity of test compounds (Kagawa et al. 1952; Marcus et al. 1952).

PROCEDURE

Male Sprague-Dawley rats weighing 140–160 g are adrenalectomized. They are maintained on 1% sodium chloride solution. On the morning of the fourth postoperative day, food and drinking fluid are withdrawn. On the following day, each rat is given 5 ml water by stomach tube; 1 h later 5 ml of 0.9% sodium chloride solution is given orally. Test compounds are injected s.c. in 0.2 ml of vehicle suspension. Desoxycorticosterone acetate (DOCA; 1–40 µg per rat) is used as standard (reference compound). The rats are placed in metabolic cages, two rats per cage, three cages per dosage group, for 4 h, and then removed from the cages. The use of light, transient ether anesthesia in this method is obsolete. Urine volume is recorded and

in addition cages may be rinsed with a distilled water spray. Appropriate dilutions of urine are analyzed for sodium with a flame photometer. The amount of sodium excreted by each rat is calculated, and group means are expressed as percentage of excretion by control animals.

EVALUATION

Percent reduction of sodium excretion compared with controls is calculated for each dosage group. Potency ratios are calculated with reference to desoxycorticosterone acetate.

MODIFICATIONS OF THE METHOD

Simpson and Tait (1952) measured both urinary sodium and potassium and used the sodium-to-potassium ratio as an index of the electrolyte activity of corticoids. Nikisch et al. (1991) infused glucocorticoid-substituted adrenalectomized rats with saline-glucose solution containing aldosterone and measured sodium and potassium concentrations in 1-h fractions of urine. The anti-aldosterone activity was assessed by the ability of test compounds to reverse the aldosterone effect on the urinary Na/K ratio.

N.2.2.2 In Vitro Methods

N.2.2.2.1 Mineralocorticoid Receptor Binding

PURPOSE AND RATIONALE

Rat kidney receptor preparations and radioactively labeled aldosterone were used to test affinity for the mineralocorticoid receptor (Raynaud et al. 1975, 1979; Pasqualini and Sumida 1977; Ojasoo and Raynaud 1978; Wambach and Higgins 1971).

PROCEDURE

Kidney homogenates of adrenalectomized rats are centrifuged at 0°C for 10 min at 800 *g* in a buffer solution (10 mM Tris, 0.25 M saccharose, HCl, pH 7.4). Following addition of RU 28362 at 0.001 mM (to inhibit binding of aldosterone to the glucocorticoid receptor) the supernatant is centrifuged again at 105,000 *g* for 60 min. The supernatant (cytosol) is removed and incubated at 0°C with ^{3}H-aldosterone (5 nM) and increasing concentrations of test compounds (0–25,000 nM). Nonspecific binding is determined in the presence of 1 μM aldosterone. Free ^{3}H-aldosterone is removed from the incubation medium by charcoal-dextran absorption after 1 h or 24 h of incubation (Raynaud 1978). Following centrifugation, the concentration of receptor-bound ligand is determined in the supernatant by liquid scintillation counting.

EVALUATION

The following parameters are calculated: total binding of ^{3}H-aldosterone, nonspecific binding in the presence of 1 μM aldosterone, specific binding (= total binding–non-specific binding), % inhibition with specific binding as a percentage of the control value.

For structure–activity studies, all compounds are first tested at a single high concentration (25,000 nM) in triplicate. For those showing more than 50% inhibition a displacement curve is determined using seven to eight different concentrations of compound. The binding potency of compounds is expressed as binding affinity (RBA), relative to the standard compound (aldosterone).

MODIFICATIONS OF THE METHOD

Affinity for the mineralocorticoid receptor was tested using the cytosol of rabbit kidneys (Claire et al. 1993) or rat kidney slices (Funder et al. 1974). It is also useful to use overexpressed human mineralocorticoid receptors.

Monkey kidney COS-1 cells were transfected with plasmids containing the human mineralocorticoid receptor – cloned by Arriza et al. (1987) – and the glucocorticoid receptor for binding studies with various steroids (Rupprecht et al. 1993a, 1993b).

A survey of mineralocorticoid receptor ligands has been given by Sutano and de Kloet (1991).

Specific bioluminescent *in vitro* assays for selecting potential anti-mineralocorticoids were developed by Jausons-Loffreda et al. (1994).

Wehling (1994) found evidence for a membrane-bound mineralocorticoid receptor in human mononuclear leukocytes.

The human mineralocorticoid receptor was used by Grassy et al. (1997) to study structure–activity relationships of steroids with anti-mineralocorticoid activity.

Davioud et al. (1996) described the synthesis and biological activities of new steroidal diazoketones as potential photoaffinity labeling reagents for the mineralocorticoid receptor.

Fagart et al. (1997a) recommended [^{3}H-2]-21-diazoprogesterone as a potent photoaffinity labeling reagent for the mineralocorticoid receptor.

Fagart et al. (1997b) proposed a three-dimensional model for antagonism in the human mineralocorticoid receptor.

The biological and clinical relevance of glucocorticoid and mineralocorticoid receptors has been reviewed by Funder (1997).

Rogerson et al. (1999, 2003) studied the structural determinants of aldosterone-binding selectivity in the mineralocorticoid receptor. To characterize ligand-binding specificity, chimeras were made between the human mineralocorticoid receptor and glucocorticoid receptor ligand-binding domains. Models of the mineralocorticoid receptor ligand-binding domain bound to aldosterone and spironolactone were created based on the crystal structure of the progesterone receptor ligand-binding domain. These techniques have been used by Rogerson et al. (2004) to evaluate the differences in the determinants of eplerenone, spironolactone, and aldosterone binding to the mineralocorticoid receptor.

N.2.2.2.2 Transactivation Assay for Mineralocorticoids

PURPOSE AND RATIONALE

Steroid agonistic and antagonistic properties can be evaluated by transactivation assays (Muhn et al. 1995; Fuhrmann et al. 1995, 1996). The transactivation assay assumes that steroid receptor proteins act as ligand-regulated transcriptional activators. After binding of hormone, the steroid receptor acts with hormone responsive elements of hormone-regulated genes, thereby inducing a cascade of transcriptional events (Green and Chambon 1988). The hormone-dependent transcriptional activation can be determined in tissue culture by transfection of the steroid receptor under investigation and a reporter gene linked to a hormonally responsive promoter into cells. The transactivation assay allows determination of the agonistic and also of the antagonistic activity of a given compound, by either induction or inhibition of reporter gene activity (Fuhrmann et al. 1992).

PROCEDURE

Vector Construct

The expression plasmid pRShMR containing the full-length coding sequence of the mineralocorticoid receptor expressed from the long terminal repeat of the Rous sarcoma virus is prepared according to Arriza et al. (1987). The pMMTV-CAT plasmid containing the mouse mammary tumor virus promoter linked to a chloramphenicol acetyltransferase gene is prepared according to Cato et al. (1986).

Cell Culture and Transfections

CV-1 cells and COS-1 cells for transient infections are cultured in Dulbecco's Modified Eagle's Medium (DMEM) supplemented with 10% fetal calf serum, 4 mmol/l L-glutamine, penicillin and streptomycin. Stable and transient transfections are performed using Lipofectin reagent (Gibco BRL) according to a procedure recommended by Felgner and Holm (1989). Stable transfections are carried out according to Fuhrmann et al. (1992). For transient transfection, 1×10^6 COS-1 or CV-1 cells are plated onto 100-mm dishes 1 day prior to transfection. Cells are typically about 80% confluent after 24 h. Before transfection, cells are washed twice with 1 ml Opti-MEM (Gibco BRL) per dish. For each dish, 5 µg pRShMR (hMR expression plasmid) and 5 µg pMMTV-CAT are diluted with 1 ml Opti-MEM; in addition, 50 µg Lipofectin Reagent is diluted with 1 ml Opti-MEM. Next, DNA and Lipofectin reagent dilutions are combined in a polystyrene snap-cup tube to obtain 2 ml of transfection solution per dish, gently mixed, incubated at room temperature for 5 min, and added to the washed cells. After 5 h the transfection solution is replaced by 6 ml of DMEM supplemented with 10% fetal calf serum.

To study the effect of the test hormones, transiently transfected cells are trypsinized, pooled and replated onto 60-mm dishes at a density of 4.5×10^5 per dish 24 h after transfection. Stably transfected cells are seeded onto 6-well dishes (1×10^5 cells per dish). Cells are cultured in medium supplemented with 3% charcoal-stripped fetal calf serum and the appropriate hormones for 48 h. As negative control for the reporter gene induction, cells are cultured with 1% ethanol. Transactivation assays with transiently or stably transfected cells are carried out at least three times.

CAT Assay (Chloramphenicol Acetyltransferase)

Transiently transfected cells and stably transfected cells are disrupted by freezing (ethanol/dry ice bath) and thawing (37°C water bath) three times. Protein concentrations in the cell extract are determined according to Bradford (1976). The CAT assay is performed according to Gorman et al. (1982).

EVALUATION

CAT activity is calculated as percentage conversion from chloramphenicol to acetylated chloramphenicol. Concentration–response curves for CAT induction are established to demonstrate the potency of the test hormone. Aldosterone (10^{-10} to 10^{-6} mol/l) serves as standard.

For anti-mineralocorticoid activity, CAT activity in the presence of 10^{-8} mol/l aldosterone is set as 100% and relative CAT activity is calculated as a percentage of this value. Concentration–response curves for CAT inhibition are established with increasing concentrations of the antihormone.

CRITICAL ASSESSMENT OF THE METHOD

See N.2.1.1.2.

MODIFICATIONS OF THE METHOD

White et al. (1994) described a simple and sensitive high-throughput assay for steroid agonists and antagonists. A DNA cassette, containing a synthetic steroid-inducible promoter controlling the expression of a bacterial chloramphenicol acetyltransferase gene (GRE5-CAT), was inserted into an Epstein-Barr virus episomal vector, which replicates autonomously in primate and human cells. This promoter/reporter system was used to generate two stably transfected human

cell lines. In the cervical carcinoma cell line HeLa, which expresses high levels of glucocorticoid receptor, the GRE5 promoter is inducible over 100-fold by the synthetic glucocorticoid dexamethasone. In the breast carcinoma cell line T47D, which expresses progesterone and androgen receptors, the GRE5 promoter is inducible over 100-fold by either progesterone or dihydrotestosterone. These cell lines can be used to screen large numbers of natural and synthetic steroid agonists and antagonists in microtiter wells directly using a colorimetric chloramphenicol acetyltransferase assay.

Rupprecht et al. (1993a, 1993b) examined the functional agonistic and antagonistic activity of several steroids by co-transfecting human mineralocorticoid or human glucocorticoid receptor expression vectors, together with a mouse mammary tumor virus-luciferase (MTV-LUC) reporter gene into the human neuroblastoma cell line SK-N-MC. Transfections were performed using an electroporation system (Biotechnologies and Experimental Research, San Diego, Calif., USA).

Lombès et al. (1994) used a co-transfection assay in CV-1 cells to study the discrimination of aldosterone from natural and synthetic glucocorticoids by the human mineralocorticoid receptor. Cells were transfected by the calcium phosphate method with pRShMR, a plasmid that contains the entire coding sequence of the human mineralocorticoid receptor; pFC31Luc, which contains the mouse mammary tumor virus (MMTV) promoter driving the luciferase gene; pCH110 encoding the β-galactosidase as an internal transfection control; and pSP72 as plasmid carrier.

Lim-Tio et al. (1997) studied the determinants of specificity of transactivation by the mineralocorticoid or glucocorticoid receptor in three cell lines: CV-1 cells; a porcine renal epithelial cell line, LLC-PK1; a pig kidney cell strain, and RN33B; a neuronal medullary raphe cell line. The reporter gene used was MMTV-LUC (the long terminal repeat of the mouse mammary tumor virus promoter linked to the luciferase reporter gene). RSV-CAT (Rous sarcoma virus promoter-chloramphenicol acetyl transferase gene) was used as an internal control for the transfection efficacy.

N.2.2.3 Anti-Mineralocorticoid Activity

N.2.2.3.1 Electrolyte Excretion

PURPOSE AND RATIONALE

The method is based on the mineralocorticoid activity of desoxycorticosterone acetate (agonists) (reference compound) reversed by spironolactone (reference antagonist) and other anti-mineralocorticoids to be evaluated (test compounds).

PROCEDURE

Male Sprague-Dawley rats weighing 140–160 g are adrenalectomized and maintained on 1% NaCl solution as drinking fluid. On the morning of the fourth postoperative day, food and drinking fluid are withdrawn. On the following day, each rat is given 5 ml water by stomach tube; 1 h later it is given 5 ml 0.9% NaCl orally and injected with 40 µg desoxycorticosterone acetate. At a separate site, the antagonistic test compound is injected s.c. in 0.2 ml of vehicle suspension. Spironolactone, 50 µg or 500 µg, is injected as the reference compound with anti-mineralocorticoid activity. Rats are placed in metabolic cages, two rats per cage, three cages per dosage group, for 4 h of urine collection. Urine volume is recorded and cages rinsed over the collection cylinders with a distilled water spray. Appropriate dilutions of collected urine are analyzed for sodium and potassium with a flame photometer.

EVALUATION

The amount of water, sodium, and potassium excreted per 100 g bodyweight is calculated. The product of water volume and sodium excretion is divided by the potassium excretion. The excretion ratios (quotient) are compared for untreated adrenalectomized rats, animals treated with DOCA, and animals treated with spironolactone

MODIFICATIONS OF THE METHOD

Anti-mineralocorticoid activity of spironolactone and its analogs has been tested in adrenalectomized golden hamsters treated simultaneously with daily injections desoxycorticosterone acetate over a period of 3 weeks (Vogel, unpublished data 1965). The mean survival of adrenalectomized animals of 4.7 days was prolonged to 13.5 days by daily subcutaneous injections of 2 mg desoxycorticosterone acetate. Additional injection of 0.5 or 1.0 mg spironolactone reduced the survival time.

Losert et al. (1985) tested the ability of several steroids with progestogenic potency to inhibit the renal actions of aldosterone in adrenalectomized, glucocorticoid-treated rats. The rats were continuously infused with an isotonic solution of low sodium content (0.05% NaCl + 5.2% glucose, 3 ml/rat per hour) supplemented with D-aldosterone (1 µg/kg per h) resulting in a long-lasting reduction in renal sodium excretion, an increase in renal potassium excretion, and hence a decrease in the urinary Na/K ratio. The test drugs were administered either subcutaneously or orally 1 h before the start of infusion. The anti-mineralocorticoid activity was judged by the increase in the aldosterone-lowered Na/K ratio in urine collected at hourly intervals up to 21 h.

Cutler et al. (1978, 1979) described a potent mineralocorticoid receptor antagonist with decreased antiandrogenic activity relative to spironolactone.

De Gasparo et al. (1987) evaluated epoxy-spironolactone derivatives for their anti-mineralocorticoid activity (Kagawa test) and their antiandrogenic and progestogenic side-effects *in vitro* and *in vivo*.

Gómez-Sánchez et al. (1990) reported the effect of intracerebroventricular infusion of mineralocorticoid antagonists on the hypertension in rats produced by chronic subcutaneous administration of aldosterone.

The evolution of aldosterone antagonists has been reviewed by Garthwaite and McMahon (2004) and Hu et al. (2005) featuring eplerenone, a molecule with improved steroid receptor selectivity and pharmacokinetic properties in humans compared with spironolactone.

The beneficial effects of eplerenone have been demonstrated in rats with myocardial infarction (Masson et al. 2004; Fraccarollo et al. 2005) and in rats with autoimmune myocarditis (Wahed et al. 2005) as well as in mice with chronic heart failure (Wang et al. 2004).

N.3
Ovarian Hormones

N.3.0.1
Ovariectomy of Rats

PROCEDURE

Ovariectomy is performed in immature female rats weighing 40–60 g (Bomskov 1939; Emmens 1969; May 1971). Animals are anesthetized. A single transverse incision is made in the skin of the back. This incision can be shifted readily from one side to the other by traction on the skin. A small puncture is then made over the site of the ovary, which can be seen through the abdominal wall, embedded in a pad of fat. The top of a pair of fine forceps is introduced and the fat around the ovary is grasped, care being taken not to rupture the capsule around the ovary. The tip of the uterine horn is crushed with a pair of artery forceps and the ovary, together with the fallopian tube, is removed with a single cut by a pair of fine scissors. Usually, no bleeding is observed. In older rats, the tip of the uterine horn may be ligated and the ovary removed distally from the ligature. The ovary of the other side is removed in the same way. The skin wound is closed by one or two clips. The animal recovers immediately.

Ovariectomized rats are now obtained from commercial suppliers when needed, the surgical procedure however is easy to learn, and licenses for animal experimentation are readily obtained for qualified laboratory personnel.

In Vitro Methods

N.3.1.1.1
Estrogen Receptor Binding

PURPOSE AND RATIONALE

The nuclear receptor assays are used to estimate the estrogenic activity of test compounds. Estradiol-17β is used as the reference compound. Estrogen receptors are prepared from mouse uteri or from human endometrium. Measurements of association rates and dissociation rates at different temperatures allow evaluation of relative binding affinities (Bouton and Raynaud 1977, 1978). Binding to the cytosolic and the nuclear fractions is measured.

PROCEDURE

Cytosol Preparation

Uteri from 18-day-old female Swiss mice are removed and homogenized at 0°C in 1:50 (w/v) of 10 mM Tris-HCl (pH 7.4), 0.25 M sucrose buffer in a conical homogenizer. Human endometrium from menopausal women is frozen within 2 h of hysterectomy and stored in liquid nitrogen until use. The frozen endometrium is pulverized and homogenized in 1:5 (w/v) Tris-sucrose buffer. Homogenates are centrifuged for 1 h at 105,000 *g*.

Dextran-Coated Charcoal (DCC) Adsorption Technique

Binding is measured as follows. A 100-µl aliquot of incubated cytosol is stirred for 10 min at 0°C in a microtiter plate with 100 µl of Dextran-coated charcoal

(DCC) suspension (0.625% Dextran 80000, 1.25% charcoal Norit A) and then centrifuged for 10 min at 800 *g*. The concentration of bound steroid is determined by measuring the radioactivity in a 100-µl aliquot of supernatant.

Determination of Specific Binding in Mouse Uterus Cytosol as a Function of Steroid Concentration, Incubation Time and Temperature

Triplicate aliquots of 125 µl of cytosol are incubated with 5 or 25 nM labeled steroid (estradiol-17ß) either for 2 or 24 h at 0°C or for 2 or 5 h at 25°C in the absence (total binding) or presence (nonspecific binding) of a 100-fold excess of radio-inert steroid. Bound steroid is measured by DCC adsorption.

Measurement of Association Rate at 0°C

For this, 1 or 5 nM concentration of labeled steroid is added to cytosol maintained at 0°C. Every 5 min for 1 h after addition of the labeled steroid, a 100-µl aliquot is transferred into a 5000 nM radio-inert steroid solution in a microtiter plate to stop the reaction. Bound radioactivity is determined by DCC adsorption.

Measurement of Dissociation Rate at 25°C

Dissociation rate is measured by the isotopic dilution technique. Radio-inert steroid (2500 nM) is added to crude cytosol previously incubated with 5 nm labeled steroid for 15 h at 0°C. After different times of incubation at 25°C, 100-µl samples are treated with DCC at 0°C in order to determine bound radioactivity. Specific binding is evaluated by subtracting nonspecific binding from total binding.

Nuclear Uptake

Homogenate samples (0.5 ml; two uteri per 0.5 ml) are incubated with 2.5, 5 or 25 nM labeled steroid for 5 or 60 min at 25°C, then cooled on ice and centrifuged at 800 *g* for 10 min at 0°C. The pellet (crude nuclei) is washed 3 times with 1 ml Tris-sucrose buffer, dissolved in 0.5 ml Soluene (Packard) and counted.

Nuclear Extract Preparation

After incubation with 25 nM labeled steroid for 1 h at 25°C, the crude nuclei are resuspended in 0.5 ml Tris-sucrose buffer, to which 50 µl of 4 M KCl is added. The suspension is stirred (vortex), left for 30 min at 0°C and then centrifuged for 30 min at 105,000 *g*. The radioactivity in a 100-µl supernatant sample (nuclear extract) is counted.

EVALUATION

Relative binding affinity is calculated from the percentage of radioligand bound in the presence of competitor compared to radioligand bound in its absence, plotted against the concentration of unlabeled competing steroid. A standard curve for the competition of the unlabeled radioligand is constructed with the use of nine to ten concentrations; five or six concentrations of the competitor are tested. These are chosen to provide a linear portion of the semilog plot which crosses the point of 50% competition. From this plot, the molar concentration of unlabeled radioligand or steroid competitor is determined that reduces radioligand binding by 50%.

The relative affinity of a test compound is the ratio of unlabeled radioligand concentration to competitor concentration, at 50% competition. This ratio is multiplied by 100.

Association rate (k_{+1}) is calculated by the slope of the line

$$k_{+1}t = (2.3/E_0 - R_0)\log(E\,R_0/R\,E_0)$$

where E_0 and E represent free steroid and R_0 and R free receptor at time $t = 0$ and time t, respectively.

Dissociation rate (k_{-1}) is calculated from the slope of the line

$$k_{-1} = -2.3\log B/B_0$$

where B_0 and B represent bound steroid at time $t = 0$ and time t, respectively.

Similar studies were reported by: Raynaud et al. 1975; Clark et al. 1976; Katzenellenbogen et al. 1977; Ojasoo and Raynaud 1978; Clark et al. 1982; Mukawa et al. 1988; Smanik et al. 1989; Labrie et al. 1990; Chander et al. 1991; Dhar et al. 1994.

MODIFICATIONS OF THE METHOD

Sheep uteri were used for the preparation of cytosol by Shutt and Cox (1972).

Pons et al. (1990) described receptor binding of estrogens and anti-estrogens in the estrogen-receptor-positive breast cancer cell line MCF-7, using the firefly luciferase assay (Brasier et al. 1989) as endpoint.

Ludwig et al. (1990) described a microliter well assay for quantitative measurement of estrogen receptor binding to estrogen-responsive elements.

Hwang et al. (1992) studied the use of tetrahydrochrysenes, inherently fluorescent, which are high-affinity ligands for the estrogen receptor.

Estrogen receptor binding has also been used to study the mechanism of action of nonsteroidal anti-es-

trogens (Jordan et al. 1977; Wakeling and Slater 1980; Astroff and Safe 1988).

The sequence and expression of human estrogen receptor complementary DNA was reported by Greene et al. (1986).

Solution structure of the DNA-binding domain of the estrogen receptor has been described by Schwabe et al. (1990).

Obourn et al. (1993) studied the hormone- and DNA-binding mechanisms of the recombinant human estrogen receptor overproduced in insect cells using a baculovirus expression system.

Cloning, chromosomal localization, and functional analysis of the murine estrogen receptor β are reported by Tremblay et al. (1997).

Nichols et al. (1998) showed that agonists and antagonists differently position the C-terminus of the ligand-binding domain (helix 12) and the F domain of the estrogen receptor.

N.3.1.1.2 Transactivation Assay for Estrogens

PURPOSE AND RATIONALE

Transient transfection of a suitable cell culture with a reporter gene controlled by an estrogen-responsive element (ERE) has become a convenient assay for estrogens.

Steroid agonistic and antagonistic properties can be evaluated by transactivation assays (Muhn et al. 1995; Fuhrmann et al. 1995, 1996). The transactivation assay assumes that steroid receptor proteins act as ligand-regulated transcriptional activators. After binding of hormone, the steroid receptor interacts with hormone-responsive elements of hormone-regulated genes, thereby inducing a cascade of transcriptional events (Green and Chambon 1988).

The assay in the estrogen-receptor-positive human breast cancer cell line MCF-7, described by Meyer et al. (1994) as a rapid luciferase transfection assay for transcription activation of estrogenic drugs, has been used for evaluation of synthetic estrogen antagonists by Von Angerer et al. (1994, 1995) and Biberger and Von Angerer (1996).

PROCEDURE

MCF-7 cells used for transfection are grown in Dulbecco's Modified Essential Medium supplemented with 10% fetal calf serum, 100 U penicillin, 100 µg streptomycin and 150 mg L-glutamine in 500 ml of medium without phenol red. Shortly before confluence, the cells are washed with 10 ml of PBS. Cells are gently shaken for a few seconds with trypsin-EDTA solution (4 ml) and after removal of the solution incubated for 2 min at 37°C. After addition of 10 ml of medium, the cell suspension (0.5 ml/well) is transferred to 6-well plates containing 2 ml of medium. Cells are grown until the density of the monolayer is about 50% (1–2 days) before 2 µg of the luciferase reporter plasmid EREwtc luc, harboring the luciferase gene from *Photinus pyralis*, is added. For a successful transfection, it is necessary to generate a very fine precipitate of the DNA by subsequent dilution with 45% water, 5% M $CaCl_2$, and 50% HBS buffer and continuous shaking. After 20 min at room temperature, an opalescent solution should be obtained.

After addition of the DNA solution, the medium is removed and the cells are washed with 2 ml of PBS, followed by treatment with glycerol (15% in PBS) for 2 min. After washing with PBS, fresh medium containing the test substances is added. The maximum of luciferase expression is reached 18 h after addition of the transfection solution. At this time, the medium is removed and cells are washed with PBS. Cell lysis and quantification of luminescence is performed according to the procedure described in the luciferase assay system E1500 of PROMEGA (Serva, Heidelberg, Germany). Luminescence is measured in a luminometer Lumat LB (Berthold, Wildbad, Germany) as relative light units, which are converted into fg luciferase by a calibration curve.

EVALUATION

Dose–response curves of luciferase activity after induction by the test substances and estradiol as control (10^{-14} to 10^{-9} M) are established.

CRITICAL ASSESSMENT OF THE METHOD

See N.2.1.1.2. Variation in transfection efficacy is the major cause of data variation and needs to be controlled for valid interpretation of data.

MODIFICATIONS OF THE METHOD

With the same method as for MCF-7 cells, Von Angerer et al. (1994) and Biberger and Von Angerer (1996) transfected HeLa-cells using the estrogen expression receptors HE0, HEG0, HE15 and HEG19, together with the receptor plasmid EREwtc luc.

Bergmann et al. (1994) determined estrogenic activity by a transient transfection assay in CHO cells deficient in estrogen receptors (ER) transfected with an expression vector encoding the ER using an estrogen-responsive reporter gene construct, $(ERE)_2$-TATA-CAT, containing two estrogen-response elements linked to a TATA promoter and the chloramphenicol transferase reporter gene.

For assessing environmental chemicals for estrogenicity, Shelby et al. (1996) recommended a transcriptional activation assay in ER-transfected HeLa cells using the estrogen-responsive reporter, ERE81CAT, and the pRSV vector containing the mouse ER cDNA without the neomycin resistance cassette. Triplicate samples for each hormone concentration were harvested at 28 h post-transfection and assayed for CAT protein using the CAT-ELISA kit (Boehringer Mannheim).

Several authors used yeast for assays of estrogenicity (McDonnell et al. 1991; Pierrat et al. 1992; Kohno et al. 1994; Bush et al. 1996; Tran et al. 1996; Odum et al. 1997).

Pierrat et al. (1992) constructed yeast strains in which the *Saccharomyces cerevisiae* URA3 gene is induced by the human estrogen receptor. Promoter sequences required for both basal and activated transcription of URA3 were replaced with estrogen-response elements positioned upstream of the native TATA box. These constructs were integrated at the TRP1 locus of a yeast strain in which the natural URA3 gene has been deleted and the integrants were transformed with shuttle plasmids expressing wild-type or truncated derivatives of human estrogen recep-

tor. Transformants were assayed for growth on uracil-deficient medium plus or minus estradiol, for resistance to 5-fluoroorotic acid, and for activity of orotidine-5′-monophosphate decarboxylase, the product of the URA3 gene.

Tran et al. (1996) used the yeast strain ER(wt) expressing human estrogen receptor and an estrogen-sensitive reporter to characterize the estrogenic or anti-estrogenic activities of polynuclear aromatic hydrocarbons.

Gaido et al. (1997) described a yeast-base steroid hormone receptor gene transcription assay to evaluate estrogenic and androgenic activity. The yeasts contain two separate plasmids: (1) an expression plasmid which contains the CUP1 metallothionein promoter fused to the human estrogen receptor cDND, and (2) a receptor plasmid carrying two estrogen-response elements or a reporter plasmid carrying two copies of a progesterone/androgen-responsive element upstream of the structural gene for β-galactosidase.

Chu et al. (2004) described transrepression of estrogen receptor β signaling by nuclear factor-κB in ovarian granulosa cells.

N.3.1.1.3 Estrogen-Dependent Cell Proliferation

PURPOSE AND RATIONALE

Specific cell proliferation induced by estrogens is the principle of these assays. Some human breast cancer cell lines, such as MCF-7 and T47-D cells, respond to estrogens with proliferation (Zondek 1935; Eisler 1964). This effect has been used for assays of estrogenic and antiestrogenic activity (Miller and Katzenellenbogen 1983; Scholl et al. 1983; Thompson et al. 1984; Palkowitz et al. 1997; Zacharewski 1997).

PROCEDURE

MCF-7 breast adenocarcinoma cells are maintained in MEM (Minimal Essential Medium), minus phenol red (which is estrogenic at high concentrations) supplemented with 10% fetal bovine serum (FBS), 2 μM L-glutamine, 1 μM sodium pyruvate, 10 μM HEPES, nonessential amino acids and 1 mg/ml bovine insulin. Ten days prior to assay, MCF-7 cells are switched to maintenance medium supplemented with 10% dextran-coated FBS in place of 10% FBS to deplete internal stores of steroids. MCF-7 cells are

removed from maintenance flasks using cell dissociation medium [Ca^{2+}/Mg^{2+}-free HBSS (phenol red-free) supplemented with 10 µM HEPES and 2 nM EDTA]. Cells are washed twice with assay medium and adjusted to 80,000 cells/ml. Approximately 100 µl (8000 cells) is added to flat-bottomed microculture wells and incubated at 37°C in a 5% CO_2 humidified incubator for 48 h to allow for cell adherence and equilibration transfer. Serial dilutions of test compounds, or dimethylsulfoxide (DMSO) as a diluent control, are prepared in assay medium and 50 µl transferred to triplicate microcultures, followed by 50 µl assay medium for a final volume of 200 µl. After an additional 48 h incubation, microcultures are pulsed with 1 µCi [^{3}H]thymidine (specific activity 6.7 Ci/mmol) for the last 4–6 h of culture and the assay terminated by freezing at −70°C. Microcultures are then thawed and harvested using a Skatron semiautomatic cell harvester. Samples are counted by liquid scintillation using a Wallace BetaPlate β-counter.

EVALUATION

Plotting of dpm versus compound concentration is used to determine the half-maximal effective concentrations EC_{50} or inhibitory concentration IC_{50}.

N.3.1.2 In Vivo Methods

N.3.1.2.1 Vaginal Cornification Assay

PURPOSE AND RATIONALE

This is an early bioassay for estrogenic activity based on epithelial proliferation. The Allen-Doisy test for vaginal cornification in rodents (Allen and Doisy 1923) is based on the observations of Stockard and Papanicolaou (1917), who first reported the cyclic cornification of the vaginal epithelium in guinea pigs.

PROCEDURE

Immature female Sprague-Dawley rats weighing about 55 g are ovariectomized. They are kept for about 1 week on standard laboratory diet and water ad libitum. The test compounds are administered orally or subcutaneously in 0.5% solution of carboxymethylcellulose or in cotton seed oil injected at several doses to groups of 10–20 rats. Doses of 0.02, 0.1, and 0.5 µg estradiol per animal are used as standard. The compounds are dosed twice daily, for example, on two following days at 10:00 a.m. and 5:00 p.m. At 5:00 p.m. of the third day and at 10:00 a.m. of the fourth day vaginal smears are taken using cotton swabs moistened with saline. The smears are transferred to a glass slide and stained for 10 min with 5% aqueous methylene blue solution. They are evaluated microscopically according to the following scores:

0 diestrus smear, mainly leukocytes, few epithelia cells
1 mixture of leukocytes and epithelial cells
2 proestrus smear, nucleated or nucleated plus cornified cells
3 estrus smear, cornified cells only.

Only animals showing a score of 2 or 3 of cornification are considered to be positive.

EVALUATION

The number of positive animals in each dosage group is recorded. ED_{50} values are calculated and potency ratios compared with the standard estradiol may be determined.

MODIFICATIONS OF THE METHOD

The sensitivity of the assay is increased by local vaginal application of estrogens in ovariectomized rats or mice (Emmens 1969).

N.3.1.2.2 Uterine Weight Assay

PURPOSE AND RATIONALE

This is an early bioassay for estrogenic activity based on myometrial/endometrial proliferation. Repeated administration of estrogens induces a dose-dependent increase of uterine weight in ovariectomized rats.

PROCEDURE

Immature female Sprague-Dawley rats weighing about 55 g are ovariectomized. Groups of five to ten animals are injected daily with several doses of the test compound or the standard (estradiol 0.03 to 0.06 µg per animal s.c.) for 7 days. The test compound is administered orally or subcutaneously in 0.5% solution of carboxymethylcellulose or in cotton seed oil. Controls receive the vehicle. On the 8th day, the animals are sacrificed and uterine weights determined.

EVALUATION

Dose–response curves are established and potency ratios are calculated, using at least two doses of test compound and oestradiol standard.

Similar studies were reported by: Zondek 1935; Junkmann 1957; Emmens 1969; Nishino et al. 1991; Van de Velde et al. 1994)

MODIFICATIONS OF THE METHOD

Rubin et al. (1951) used albino mice 23–25 days of age weighing approximately 8 g. The mice are given subcutaneous injections once daily for 3 days of an oil solution of the hormone. Then, 24 h after the last injection, the animals are sacrificed and uterine and body weights recorded. The uterine ratio is calculated by dividing uterine weight in milligrams by body weight in grams, multiplied by 100 (relative uterine weight). Two groups receive a standard preparation and two groups the unknown.

Bhakoo and Katzenellenbogen (1977) showed that one of the earliest biosynthetic tissue responses after estrogen binding in the rat uterus, the synthesis of a specific uterine protein called “induced protein”, is antagonized by progesterone.

In addition to uterus weight, Branham et al. (1993) studied luminal and glandular epithelium height in cross-sections of the uterine horns of rats by histomorphology.

Uterine peroxidase activity was proposed as a marker for estrogen action by Lyttle and DeSombre (1977) and Astroff and Safe (1991).

Odum et al. (1997) compared the rodent uterotrophic assay with a yeast estrogenicity assay.

N.3.1.2.3 Chick Oviduct Method

PURPOSE AND RATIONALE

This is an early bioassay for estrogenic activity based on proliferation of the oviduct. The weight of the oviduct of young chickens is increased dose depen-

dently by natural and synthetic estrogens (Tullner and Hertz 1956; Lerner et al. 1958; Dorfmann 1969).

PROCEDURE

Seven-day-old pullet chicks are injected subcutaneously twice daily with solutions of the test compound in various doses for 6 days. Doses between 0.02 and 0.5 µg estradiol-17β per animal serve as standard. Six to ten chicks are used for each dosage group. On the day after the last injection, the animals are sacrificed and the weights of the body and oviduct determined.

EVALUATION

The ratio oviduct weight/body weight is calculated for each animal (relative weight). Mean values are plotted as dose–response curves in order to calculate potency ratios.

MODIFICATION OF THE METHOD

The assay was used for evaluation of anti-estrogenic activity using simultaneous injection of 0.6 µg estradiol-17β 1 and the inhibitor, e. g., progestagens, and calculation of the percentage of oviduct weight in estrogen/anti-estrogen-treated animals versus the estrogen control group.

N.3.1.3 Anti-Estrogenic Activity

N.3.1.3.1 Antagonism of Estrogen Effect on Uterus Weight

PURPOSE AND RATIONALE

These assays are modifications of estrogen bioassays. The effect of estrogen treatment on uterine weight in ovariectomized rats was antagonized by anti-estrogenic compounds.

PROCEDURE

Immature female Sprague-Dawley rats weighing about 55 g are ovariectomized. Groups of five to ten animals are injected daily for 7 days with estradiol 0.03 to 0.06 µg per animal s.c. and various doses of the test compound or estradiol alone. The test compound is administered in 0.5% solution of carboxymethylcellulose or in cotton seed oil either orally or injected subcutaneously. On day 8, the weight of the uterus is determined and the inhibitory effect of anti-estrogenic compounds is assessed.

EVALUATION

The anti-estrogenic effect is expressed as a percentage reduction of estrogen-stimulated uterine weight by test compounds.

Similar studies were reported by: Byrnes and Shipley 1955; Dorfmann 1969; Terenius 1971; Wakeling and Bowler 1988; Levesque et al. 1991; Kangas 1992; Nique et al. 1994)

MODIFICATIONS OF THE METHOD

Three-week old female NMRI mice can be used for determination of uterus weight (Lerner et al. 1958).

The inhibition by anti-estrogens of vaginal cornification induced by estradiol can be used as the assessment parameter.

The chick oviduct weight can be adapted for the assay of anti-estrogenic activity (Tullner and Hertz 1956).

Anti-estrogenic activity may also be determined in castrated immature male rats. The animals show an increase in seminal vesicle weight when treated with 20 µg estradiol for 5 days, and the effect is counteracted by anti-estrogenic steroids (Byrnes et al. 1953).

N.3.1.3.2 Aromatase Inhibition

PURPOSE AND RATIONALE

Estrogen synthesis by local action of the enzyme aromatase occurs in various tissues, and is also found in estrogen-dependent tumors (Brodie 1992). Specific aromatase (estrogen synthetase) inhibitors are potential therapeutic agent for estrogen-dependent tumors, e. g., some breast cancers. 4-Hydroxyandrostandione (4-OHA) inhibits aromatase completely but also causes destruction of the enzyme (irreversible inhibitor). Test compounds can be evaluated both *in vitro* (Häusler et al. 1989) and *in vivo* (Geelen et al. 1991). Tests are based on stimulation of estrogen biosynthesis by luteinizing hormone (LH) and inhibition of this effect by aromatase inhibitors.

PROCEDURE

For *in vitro* experiments, ovarian tissue from adult golden hamsters (*Mesocricetus auratus*) is used. Estrus cycle is monitored for at least three consecutive 4-day estrus cycles prior to the experiment. The experiments for evaluating inhibitor effects are performed with ovaries obtained from animals sacrificed on day 4 (proestrus), at the time of preferred estrogen synthesis. The ovaries are excised, freed from adhering fat tissue, and quartered. The quarters are transferred to plastic incubation flasks with 2 ml of Krebs-Ringer-bicarbonate (KBR) salt solution, pH 7.6, containing 8.4 mM glucose. The flasks are gassed with O_2/CO_2 (95%/5%), tightly closed, and placed in a shaker/water bath (37°C) for incubation of the fragments. The incubation media are replaced with fresh KBR after preincubation for 1 h.

The ovaries are further incubated for 4 h in the presence or absence of ovine LH (100 ng/ml) and inhibitors to be tested. 4-OH-Androstendione is used as standard in concentrations between 0.33 and 330 µM. At the end of the experiment, the incubation media are removed and centrifuged. In the supernatant, estrogen, progesterone, and testosterone are determined by radioimmunoassay.

EVALUATION

The results are expressed as percentage inhibition of oestradiol synthesis relative to control incubations containing 100 ng/ml LH in the absence of inhibitor. Statistical analyses are performed using Dunnetts's *t*-test.

MODIFICATIONS OF THE METHOD

Geelen et al. (1991) determined the *in vivo* aromatase activity of test compounds in hypophysectomized rats treated with the estrogen precursor dehydroepiandrosterone (DHEA) sulfate, using the inhibition of cornification of vaginal epithelium and estradiol levels in plasma as parameters. Furthermore, aromatase activity was determined in homogenized ovaries. To the supernatant, [1β-^{3}H]androst-4-ene-3,17-dione was added. Incubation was performed with a NADPH-generating system for 1 h at 37°C. Incubations were terminated by placing the tubes on ice followed by an extraction with chloroform. After phase separation by centrifugation, the aqueous phase was diluted with an equal volume of dextran-coated charcoal suspension. Following centrifugation, the ^3H_2O content was determined by liquid scintillation counting. The amount of ^3H_2O is a measure of the amount of estrogen produced.

Zaccheo et al. (1989) studied the antitumor activity of aromatase inhibitors in rats with tumors induced by 7,12-dimethylbenzanthracene (DMBA).

Wouters et al. (1993) studied the inhibition of aromatase activity in FSH-stimulated rat granulosa cells by vorozole, a selective, nonsteroidal aromatase inhibitor.

Suzuki et al. (1996) described changes in prostate volume and histopathological findings in androstenedione-treated castrated beagle dogs as a bioassay for an aromatase inhibitor.

Takahashi et al. (1997) tested the inhibition of aromatase activity in the microsomes from fresh human placentae by the amount of tritiated water released from [1β-^{3}H]androstenedione. For biological proof, the dose-dependent suppression of androstenedione-induced uterine hypertrophy in immature rats was measured.

N.3.1.3.3 Anti-Estrogenic Effect on MCF-7 Breast Cancer Cells

PURPOSE AND RATIONALE

The MCF-7 cell line, derived from a pleural effusion of a malignant breast cancer, is a widely studied model for hormone-dependent human breast cancer. These cells contain functional estrogen receptors and show a pleiotropic response to estrogen which can be used to evaluate anti-estrogenic effects (Miller and Katzenellenbogen 1983; Scholl et al. 1983; Thompson et al. 1988). The MCF-7 cells proliferate and invade through an artificial basement membrane. Anti-estrogens reduce both the proliferation and invasiveness of MCF-7 cells.

PROCEDURE

MCF-7 cells are maintained in T75 flasks in IMEM (Biofluids, Rockville, Md., USA) supplemented with 2 mM glutamine and 10% fetal bovine serum. To deplete estrogen, the cells are passaged for at least 2 weeks in IMEM supplemented with 5% calf serum which has been treated sequentially with sulfatase and dextran-coated charcoal (DCC) to remove endogenous estrogen.

Estrogen and Anti-Estrogen Treatment

Cells are trypsinized, reseeded in tissue culture dishes (1×10^6 cells/10-cm-diameter Falcon dish), and allowed to adhere overnight in a humidified incubator (37°C, 5% CO_2, 95% air). The cells are treated the next day with either 17β-estradiol (10^{-9} M) or the anti-estrogen or 0.1% ethanol alone. Four days later, the cells are harvested with trypsin, washed twice in IMEM containing 0.1% BSA, counted with a Coulter cell counter and tested for chemotaxis and chemoinvasion activities.

Chemoinvasion Assay

Boyden chambers are used (Albini et al. 1987). Polycarbonate filters (12-µm pore, polyvinylpyrrolidone-free, Nucleopore) are coated with matrigel (25 µg/filter), a mixture of basement membrane components (Kleinman et al. 1986), which is dried and then reconstituted at 37°C into a solid, even layer over the surface of the filter. Fibroblast-conditioned medium, obtained by incubating confluent NIH-3T3 cells for 24 h with IMEM, is used as the chemoattractant. Cells are harvested with trypsin, washed twice with BSA/IMEM, and added to the top chamber (300,000 cells/chamber). Chambers are incubated in a humidified incubator at 37°C in 5% CO_2 in air for 6, 9, or 12 h. The cells which have traversed the matrigel and attached to the lower surface of the filter are stained with Diff-Quick (American Scientific Products) and quantitated electronically with the Optimax V image analyzer.

Chemotaxis Assay

Chemotaxis assays are performed as described for the chemoinvasion studies with the single exception that the filter surfaces are coated with 5 µg collagen IV instead of the layer of matrigel. This coats the interstices of the filters but does not form a barrier over the surface. Chemotaxis assays are performed in parallel to the chemoinvasion assays using the same cells and conditioned medium.

EVALUATION

One-way analysis of variance is performed on the data from each experiment.

N.3.2 Progestional Activity

N.3.2.1 In Vitro Methods

N.3.2.1.1 Gestagen Receptor Binding

PURPOSE AND RATIONALE

Progesterone receptor preparations may be obtained from numerous sources of tissue: uteri from estrogen-primed rabbits (Ojasoo and Raynaud 1978; Boonkasemsanti et al. 1989; Phillips et al. 1990; Cook et al. 1992), castrated-estrogen-treated mice or rats (Philibert and Raynaud 1977; Li et al. 1997), MCF-7 cells derived from human breast tumor (Bergink et al. 1983; Kloosterboer et al. 1988a, 1988b, 1994), breast cancer T47D cells (Meyer et al. 1990), the quail fibroblast cell line QT6 (Schowalter et al. 1991) or human uteri obtained after hysterectomy (Jänne et al. 1976; Pollow et al. 1989a, 1989b, 1992). Tritium-labeled progesterone and R 5020 ([6,7-^{3}H]17,21-dimethyl-19-norpregna-4,9-diene-3,20-dione) are used as ligands (Moguilewsky and Raynaud 1979).

PROCEDURE

Relative Binding Affinities

Human uteri obtained after hysterectomy are snap-frozen in liquid nitrogen and stored at −80°C until use. For cytosol preparations, uterine tissues are minced and homogenized with an Ultra-Turrax at 0–4°C in ice-cold buffer composed of 10 mM KH_2PO_4, 10 mM K_2HPO_4, 1.5 mM EDTA, 3 mM NaN_3, 10% glycerol, pH 7.5 (PENG buffer). The homogenates are then centrifuged at 105,000 *g* at 4°C for 30 min. The supernatant is taken as cytosol. The cytosol preparations are incubated with ^{3}H-R 5020 as radioligand at a concentration of 8 nmol/l and increasing concentrations (1×10^{-10} to 1×10^{-5} mol/l) of the competitor steroids overnight at 4°C. Then, unbound steroids are adsorbed by incubating with 0.5 ml of DCC (0.5% Norit A, 0.05% dextran T400 in PENG buffer) for 10 min at 4°C. After centrifugation (10 min at 1500 *g* at 4°C) 0.5 ml of the supernatant is withdrawn and counted for radioactivity.

Association rate and dissociation rate are determined as described for the estrogen receptor.

EVALUATION

For calculation of **relative binding affinity**, the percentage of radioligand bound in the presence of competitor compared to that bound in its absence is plotted against the concentration of unlabeled steroid. A standard curve for the unlabeled radioligand (progesterone) is constructed with of nine to ten concentrations; five or six concentrations of the competitor are tested. The molar concentrations of unlabeled radioligand and steroid competitors that reduce radioligand binding by 50% are determined. The ratio of unlabeled radioligand and competitor for 50% competition multiplied by 100 is calculated for relative binding affinity.

Association rate (k_{+1}) is calculated by the slope of the line

$$k_{+1}t = (2.3/E_0 - R_0)\log(E\,R_0/R\,E_0)$$

where E_0 and E represent free steroid and R_0 and R free receptor at time $t = 0$ and time t, respectively.

Dissociation rate (k_{-1}) is calculated from the slope of the line

$$k_{-1} = -2.3\log B/B_0$$

where B_0 and B represent bound steroid at time $t = 0$ and time t, respectively.

MODIFICATIONS OF THE METHOD

For screening procedures homogenates of rabbit uteri may be used (Philibert et al. 1977).

The binding of the progesterone agonist R 5020 and of the progesterone antagonist RU 486 to the progesterone receptor from calf uterus was characterized by Hurd and Moudgil (1988).

A high-affinity ligand and novel photoaffinity labeling reagent for the progesterone receptor ([^{3}H]DU41165) was described by Pinney et al. (1990).

The different DNA-binding properties of the calf uterine estrogen and progesterone receptors were explained by different dimerization constants (Skafar 1991).

Mutations of the progesterone receptor were found to be responsible for species specificity and have been used for evaluation of agonistic and antagonistic activity (Benhamou et al. 1992; Garcia et al. 1992).

The complete amino acid sequence of the human progesterone receptor has been deduced from cloned cDNA by Misrani et al. (1987).

Structural requirements of the ligand and mapping of the hormone-binding site of the progestin receptor have been discussed by Ojasoo and Raynaud (1990).

Allan et al. (1992) studied conformational changes in the ligand-binding domain induced by various progestins and antiprogestins.

Collins (1994) recommended the ratio between the affinity of a compound to progesterone receptors to the

affinity to androgen receptors as a selection criterion for new oral contraceptives.

Comparative pharmacology of newer progestagens has been reviewed by Kuhl (1996).

Oñate et al. (1994) found that the DNA-binding protein HMG-1 enhances progesterone receptor binding to its target DNA sequences.

The concept of two categories of progestin antagonists based on differences in how they interact with and inactivate the progestin receptor has been discussed by Edwards et al. (1995).

Carbajo et al. (1996) studied the binding of [^{3}H]progesterone to the human progesterone receptor existing in two isoforms hPR-A and hPR-B which differ in that hPR-A lacks 164 amino acids at the amino terminus of hPR-B.

N.3.2.1.2 Transactivation Assay for Gestagens

PURPOSE AND RATIONALE

Steroid agonistic and antagonistic properties can be evaluated by transactivation assays (Muhn et al. 1995; Fuhrmann et al. 1996). The transactivation assay assumes that steroid receptor proteins act as ligand-regulated transcriptional activators. After binding of hormone, the steroid receptor acts with hormone-responsive elements of hormone-regulated genes, thereby inducing a cascade of transcriptional events (Green and Chambon 1988).

Transactivation assays were used by several authors to test the progestional and antiprogestional activity of steroidal and nonsteroidal compounds (Sobek et al. 1994; Pathirana et al. 1995; Fuhrmann et al. 1996; Jones et al. 1996; Dijkema et al. 1998; Edwards et al. 1998; Schoonen et al. 1998; Zhi et al. 1998).

PROCEDURE

CV-1 cells (African green monkey kidney fibroblasts) are grown in Dulbecco's modified Eagle medium containing 10% charcoal resin-stripped fetal bovine serum, 2 mM glutamine, and 55 µg/ml gentamicin. Cells are maintained in an environment of 4% carbon dioxide and routinely passaged from T-255 flasks to 96-well microtiter plates (1.5×10^5 cells/well, 70% confluent) 1 day before transfection.

Cells are transiently transfected by the standard calcium phosphate co-precipitation procedure with 50 ng/well of plasmids coding for: human progesterone receptor-B (hPR-B1) and pRS-β-Gal under constitutive control and a reporter (MTV-LUC) containing a response element for the progesterone receptor. After 6 h, the medium is replaced with medium containing progesterone at concentrations between 10^{-11} and 10^{-5} M or another progestagen. After a 40-h incubation, wells are washed with phosphate-buffered saline and the cells are lysed with Triton X-100-based buffer. An aliquot of lysate (20 µl) is then transferred to Dynatech 96-well plates containing 1.6 mM ATP. LUC activity (chemiluminescence upon addition of luciferin substrate) is determined using a Dynatech ML1000 luminometer, according to the equation:

$$\text{LUC units} = \text{relative LUC unit} \times 10^4 .$$

β-Gal activity is determined from the remaining lysate in the original 96-well plates. The substrate, *o*-nitrophenol-β-galactoside, is added to the plates, followed by incubation at 37°C. The incubation is terminated by addition of sodium carbonate when the average absorbance, as determined by visual observation of the yellow product (*o*-nitrophenol), is within a standard range. Absorbance at a wavelength of 415 nm is then quantified spectrophotometrically. β-Gal rates are calculated according to the following equation:

$$\beta\text{-Gal rate} = \frac{\beta\text{-Gal absorbance} \times 10^5}{\beta\text{-Gal incubation time}} .$$

For each set of replicate wells, normalized response is calculated according the following equation:

$$\text{Normalized response} = \text{LUC units}/\beta\text{-Gal rate}$$

EVALUATION

Agonist activity is determined by examining the amount of LUC expression (normalized response). The effective concentration that produces 50% of the maximal response (EC_{50}) is quantified. The efficacy is a function of the LUC expression relative to the maximal LUC expression produced by the reference agonist, e. g., progesterone. Antagonist activity is determined by testing the amount of LUC expression in

the presence of a fixed concentration (equal to its agonist EC_{50}) of reference agonist. The concentration of test compound that inhibits the gene expression induced by the reference compound by 50% is quantified (IC_{50}). In addition, the efficacy of antagonists is determined as a function of maximal inhibition (LUC expression = basal activity).

CRITICAL ASSESSMENT OF THE METHOD

See Sect. N.2.1.1.2. for the importance of controlling transfection efficacy.

MODIFICATIONS OF THE METHOD

For transactivation studies, hPRA-A-MMTV-LUC and hPR-B-MMTV-LUC and stably co-transfected CHO cells were used by Dijekema et al. (1998) and Schoonen et al. (1998).

N.3.2.1.3 Alkaline Phosphatase Assay

PURPOSE AND RATIONALE

Progestins induce the *de novo* synthesis of alkaline phosphatase (Di Lorenzo et al. 1991, 1993). The progestin induction of the nonspecific tissue alkaline phosphatase is not altered by other steroid hormones or synthetic analogs. This finding has been used by Sobek et al. (1994), Pathirana et al. (1995), and Li et al. (1997) to measure the progestogenic and antiprogestogenic actions in a microplate assay.

PROCEDURE

T47D cells are grown in 96-well plates to near confluence and then treated with 0.1%–0.2% alcohol (control) or steroid agonists; otherwise R 5020 plus potential antagonist for 2 days. The cells are then fixed with 3.7% formaldehyde in phosphate-buffered saline for 15 min at 15°C, washed with 200 µl phosphate-buffered saline and stored at −90°C. After thawing, each well is incubated with 100 µl *p*-nitrophenyl phosphate (1 mg pNPP/ml) in DEAM (1 M diethanolamine, pH 9.8, containing 0.5 mM $MgCl_2$, and 20 µM $ZnSO_4$). The enzyme reaction is allowed to proceed in the dark at 37°C. Formation of *p*-nitrophenol is monitored periodically at 405 nm in a microplate reader. In each microtiter plate, blanks, *p*-nitrophenol, and alkaline phosphatase standards are measured together with the samples. One unit of alkaline phosphatase is defined as the amount of enzyme capable of transforming 1 µmol of substrate in 1 min at 37°C. Enzyme assays are performed under conditions of linearity relative to the substrate and to the concentration of proteins.

EVALUATION

Progestin concentrations corresponding to half the maximal increase in alkaline phosphatase activity (ED_{50}) are calculated graphically and by computer-assisted analysis using the ImmunoFit EIA/RIA analysis software (Beckman Instruments).

N.3.2.2
In Vivo Methods

N.3.2.2.1
Clauberg (McPhail) Test in Rabbits

PURPOSE AND RATIONALE

In this historical bioassay, Clauberg (1930a, 1930b, 1930c, 1930d) first described the histological changes of the endometrium in estrogen-pretreated rabbits after administration of progestional compounds. The test was further studied by Butenandt et al. (1934) and systematically examined by McPhail (1934) who introduced scoring the changes of the endometrium.

PROCEDURE

Immature female rabbits (Yellow Silver or New Zealand strain), weighing 550–650 g, receive daily injections of 5.0 µg estradiol benzoate per animal in sesame oil solution for a period of 6 days (priming). From days 7–12 (treatment for 5 days) the test compound or standard is administered at several doses, three to four animals per group. Standard doses are: 0.02, 0.08 and 2.0 mg progesterone per day and animal s.c. in sesame oil solution, or 0.01, 0.02, and 0.04 mg medroxyprogesterone acetate orally. Controls receive either the vehicles or estradiol benzoate only. At autopsy on day 15, both horns of the uterus are removed and fixed in 10% formalin. Sections from the middle part of each uterine horn are low examined by histology.

EVALUATION

Pretreatment with oestradiol stimulates uterine weight developmental (priming), progestagens induce further proliferation and secretory transformation. The following scores are established:

0 ramification of the uterus mucosa, but no proliferation (estrogen treatment only)
1 slight proliferation of the uterus mucosa
2 medium proliferation of the uterus mucosa, slight additional ramification
3 pronounced proliferation of the uterus mucosa
4 very pronounced proliferation of the uterus mucosa, pronounced ramification.

The scores from each dosage group are averaged. Dose–response curves are constructed in order to calculate potency ratios versus the standard (progesterone). The morphological evaluation needs to be done by an experienced investigator. Preliminary experiments with standard drugs and photographical documentation of the histological findings are recommended.

Similar studies were reported by: Zondek 1935; Junkmann 1957; Elton and Edgren 1958; Miyake 1962; Wiechert and Neumann 1965

MODIFICATIONS OF THE METHOD

In order to study the prolonged activity of progestogen esters, the animals are primed with estradiol for 6 days, followed by a single subcutaneous injection of the test compound or hydroxyprogesterone caproate standard. Daily treatment with estradiol is continued and the rabbits sacrificed at increasing intervals up to 4 weeks.

McGinty et al. (1939) established a local **progestional test** which involves the direct injection of progesterone into a uterine segment. The test is performed in immature rabbits primed for 6 days with estrogen. On day 7, the uterus is exposed by laparotomy. The upper middle segment of each horn is ligated without disturbance of blood circulation. A solution of the gestagen in oil is injected into the lumen of one segment through the lower ligature, which is closed tightly after the injection. In the opposite horn, only the vehicle is injected. The animals are sacrificed 3 days later and sections of the horn are evaluated histologically according to the McPhail scores (Tayama et al. 1979).

Pincus et al. (1957) improved the quantitative aspects of the McPhail test with the planimetric measurement of the endometrial proliferation.

N.3.2.2.2 Endometrial Carbonic Anhydrase Assay

PURPOSE AND RATIONALE

Carbonic anhydrase activity in the endometrium is increased after administration of progesterone. Carbonic anhydrase activity in the endometrium of rabbits was used for a quantitative progestin assay (Lutwak-Mann 1955; Pincus et al. 1957; Elton and Edgren 1958; Miyake and Pincus 1958; Eisler 1964).

PROCEDURE

Immature female rabbits are estrogen primed and progestin treated as described in the Clauberg test. After sacrifice of the animals, the uteri are opened longitudinally. Endometrium is dissected, weighed and homogenized with a tenfold volume in a glass homogenizer. After centrifugation, carbonic anhydrase is determined in the supernatant with the colorimetric method of Philpot and Philpot (1936) using bromothymol as indicator.

EVALUATION

Mean values of carbonic anhydrase activity/g wet tissue are calculated and potency ratios for test compound and standard established.

N.3.2.2.3 Deciduoma Formation

PURPOSE AND RATIONALE

This is a classical bioassay for progestagens. The deciduoma tests are based on the fact that the endometrium of the estrogen-primed, progesterone-treated rodent is sensitive to local stimuli such as scratching (Astwood 1939), chemical irritation, and electrical stimulation. The effect of local irritation produces a deciduoma, similar to the formation of a maternal placenta (Astwood 1939; Elton and Edgren 1958; Zarrow et al. 1958; Miyake 1962; Eisler 1964; Sreenivasulu 1993).

PROCEDURE

Adult female Sprague-Dawley rats weighing 200–250 g are ovariectomized and 1 week later treated with 0.5 µg estradiol/animal once daily subcutaneously for 4 days, followed by 9 days of progesterone or the test compound in various doses. The uterus is exposed on day 5 of progesterone treatment and 1.0 mg histamine dihydrochloride is injected into the lumen of one horn. The animals are sacrificed after the last treatment. Both uterine horns are removed and weighed. The degree of deciduoma formation is evaluated by the percentage increase in weight of the histamine-injected uterine horn as compared with the untreated control horn.

EVALUATION

Dose–response curves are established plotting percentage increase in weight of the treated uterus horn versus logarithm of dose of test compound and standard in order to calculate potency ratios.

N.3.2.2.4
Pregnancy Maintenance Assay

PURPOSE AND RATIONALE

This is a historical bioassay for progestational activity. In the rat, ovariectomy performed during the first half of pregnancy terminates gestation, but ovariectomy during the second half of pregnancy does not result in abortion, because the placenta now provides estrogens and progesterone for maintenance of pregnancy. In early pregnancy, maintenance of pregnancy after ovariectomy can be achieved by sufficient exogenous progestin with and without estrogen (Stucki 1958; Miyake 1962; Eisler 1964; Hebborn 1971; Phillips et al. 1984; Kuhnz und Beier 1994).

PROCEDURE

Mature Sprague-Dawley female rats are inseminated by being placed with males overnight. Presence of sperm is assessed by vaginal lavage and, if positive, is considered to be day 1 of pregnancy. On day 8, the females are ovariectomized if found pregnant upon examination of the uterus. Test compounds are administered once daily, subcutaneously, for 13 days beginning immediately after ovariectomy. Estradiol (0.1 µg/day) is administered concomitantly with the test compound. At autopsy on day 21, the presence or absence of implantation sites, and the numbers of live embryos are recorded.

EVALUATION

Normal pregnant rats have an average of 11 implantation sites and about 10 live embryos. Maintenance of pregnancy is assessed with reference to these normal values.

MODIFICATIONS OF THE METHOD

Similar tests have been performed in rabbits (Elton and Edgren 1958), in mice (McGinty 1959), and in hamsters (Shipley 1965). In rabbits, abortion can be induced by intravenous injection of oxytocin from day 30 of pregnancy onwards. The abortifacient effect can be suppressed by progestagens.

N.3.2.3
Anti-Progestional Activity

N.3.2.3.1
Progesterone Antagonism (Anti-Progestins)

PURPOSE AND RATIONALE

The anti-progestional activity of a test compound may be determined by antagonism against the effect of progesterone in the Clauberg/McPhail assay in rabbits (N.3.2.2.1) or the McGinty test (N.3.2.2.1) and in the deciduoma formation assay in rats (N.3.2.2.3) (Miyake 1965; Tamaya et al. 1979; Oettel and Kurischko 1980; Philibert et al. 1985; Cook 1994; Teutsch and Philibert 1994).

MODIFICATIONS OF THE METHOD

Progesterone control of cervical ripening in the guinea pig and the tree shrew *Tupaja belangeri* has been used for the evaluation of progesterone antagonists (Chwalisz et al. 1991; Chwalisz 1994). The effects of progesterone antagonists on surgically induced endometriosis in rats have been studied by Stöckemann and Chwalisz (1993).

Michna et al. (1991) developed a bioassay which allows quantification of the antiproliferative potency of progesterone antagonists on the mammary gland in rats. Female Wistar rats with a body weight of 100 g were ovarectomized. One week after ovariectomy the rats were substituted with 10 µg estrone and 3 mg progesterone for 3 days. The animals in the experimental groups simultaneously received the progesterone antagonist. The animals were then sacrificed and the inguinal mammary glands dissected: the right gland for biochemical analysis (DNA), the left for morphometrical analysis. The entire inguinal mammary gland was prepared for conventional paraffin sections and stained with ferric ammonium sulfate. Microphotographs were taken in transmitted light. The number of tubulo-alveolar buds was counted in the whole mount preparations using a 40-fold magnification. In the neighborhood of the inguinal node, a square of 2.5 mm^2 was quantified and calculated for a tissue volume of 100 mm^3 in more than ten animals. The antiproliferative action of progesterone antagonists on the amount of tubulo-alveolar buds was estimated for an 80% confidence interval of mean inhibition.

CRITICAL ASSESSMENT OF THE METHOD

This method is very detailed and time-consuming, it appears to be suitable for the advanced stages of drug evaluation for anti-progestins. In contrast to the only biochemical assessment, the method provides detailed information which is also applicable to toxicological evaluations.

N.3.2.3.2 Luteolytic Activity of Prostaglandins

PURPOSE AND RATIONALE

Synthetic prostaglandins are used for synchronization of estrus and for treatment of anestrus caused by a persistent corpus luteum in cattle. Furthermore, synthetic prostaglandins were studied for termination of early pregnancy in humans (Karim et al. 1977; Takagi et al. 1977, 1978; Toppozada et al. 1979, Dwivedy 1979). The most useful animal model for luteolytic activity is the hamster (Gutknecht et al. 1971; Labhsetwar 1971, 1972a; Dukes et al. 1974; Bartmann et al. 1979; Galliani et al. 1984; Roy et al. 1987). The effects of prostaglandins on reproductive function in other species such as rat (Fuchs et al. 1974), mouse (Labhsetwar 1972b), and guinea pig (Blatchley and Donovan 1969) have also been studied.

PROCEDURE

Adult female golden hamsters (*Mesocricetus auratus*), weighing approximately 100 g, with regular, 4-day estrus cycles are housed under controlled light and temperature conditions and given a standard diet. They are caged with fertile males on the day before expected vaginal discharge and the next morning vaginal smears are taken. If clumps of spermatozoa are found in the smear, this day is designated as day 1 of pregnancy (see similar procedure in rats). Groups of

ten animals are treated on days 4, 5, and 6 with four different doses of standard (prostaglandin $F_{2\alpha}$) or test compound. On day 13 of pregnancy, the hamsters are sacrificed and the number of implantation scars in the uterus is counted as the parameter of luteolytic activity causing early termination of pregnancy.

EVALUATION

The luteolytic activity is expressed as the median effective dose for termination of pregnancy in 50% of the treated animals (ED_{50}).

MODIFICATIONS OF THE METHOD

The mode of action of luteolysis by prostaglandins has been studied by various authors both *in vitro* (Speroff and Ramwell 1970; O'Grady et al. 1972; Henderson and McNatty 1975; Kenny and Robinson 1986; Brambaifa 1988) and *in vivo* (Pharriss and Wyngarden 1969; Johnston and Hunter 1970; McCracken et al. 1970; Chatterjee 1973; Buhr et al. 1983; Torjesen and Aakvaag 1984, 1986).

Cao and Chan (1993) investigated the effects of oxytocin and luteal prostaglandins on the functional regression of the corpus luteum in pseudopregnant rats.

Motta et al. (1996) studied the effect of an oxytocin receptor antagonist on ovarian and uterine synthesis and release of prostaglandin $F_{2\alpha}$ in pseudopregnant rats.

Stocco and Deis (1998) examined the participation of intraluteal progesterone and prostaglandin $F_{2\alpha}$ in LH-induced luteolysis in pregnant rats.

Luteolysis by prostaglandins in the rhesus monkey has been studied by Auletta and Kelm (1994) and Auletta et al. (1995).

The ewe as a model for regulation of luteal regression has been recommended by Hoyer (1998).

N.4
Testicular Steroid Hormones

N.4.0.1
Castration of Male Rats (Orchiectomy)

PROCEDURE

Castration of young male rats is performed with minimal bleeding in animals weighing less than 60 g. The animal is anesthetized. A small transversal incision is made in the skin on the ventral site over the symphysis. The testis lying in the scrotum is gently pushed into the abdominal cavity. With a pair of fine forceps, the abdominal wall is opened. The epididymal fat pad, easily seen, is grasped with the forceps and the testis with the epididymis is pulled out from the wound. The ductus deferens with the testicular vessels is crushed with artery forceps and the testis together with the epididymal fad pad cut off with a pair of fine scissors. There is almost no bleeding in young animals. In older animals, ligation of the testicular vessels together with the ductus deferens may be necessary. The same procedure is performed on the other side. The skin wound is closed with one or two wound clips. The animal recovers immediately. With some skill, the operation can be performed very rapidly (Bomskov 1939).

MODIFICATIONS OF THE METHODS

Dorfman (1969) recommended removing the testes through an incision in the tip of the scrotum. In our hands, the procedure described above was preferable.

N.4.0.2
Caponizing of Cockerels (Orchiectomy)

PROCEDURE

This is a classical bioassay for androgens. White Leghorn cockerels are used for surgery at approximately 6 weeks of age. The animals, fasted 24 h prior to surgery, were anesthetized with ether and placed on their sides. An incision is made between the last two ribs, the muscle layer is divided, and the incision is pulled apart with small retractors. The testis is found close to the midline of the posterior abdominal wall, alongside the vena cava. The capsule enclosing the testis is cut and the gonad is removed. It is imperative to remove the testis intact, as fragments left behind are usually vascularized and persist, giving rise to incompletely caponized animals. The incision is closed by a suture. The contralateral testis is removed in a similar fashion (Bomskov 1939).

N.4.1
Androgenic and Anabolic Activity

N.4.1.1
In Vitro Methods

N.4.1.1.1
Androgen Receptor Binding

PURPOSE AND RATIONALE

Rat ventral prostate (Bonne and Raynaud 1974; Liao et al. 1974; Grover and Odell 1975; Ojasoo and Raynaud 1978; Raynaud et al. 1979; Winnecker et al. 1989; Duc et al. 1995) or mouse kidney (Isomaa et al. 1982) serve as sources for androgen receptors. Human androgen receptors have been prepared from trans-

fected COS-1 cells (Teutsch et al. 1994). Labeled androstanolone, 5α-dihydrotestosterone, testosterone, and, more recently, methyltrienolone (R 1881) have been used as radioligands.

PROCEDURE

Androgen Receptor Assay

Cytosol is prepared from ventral prostate glands of adult male rats castrated approximately 24 h before use. The tissue is homogenized in TMDG buffer (10 mM Tris, 20 mM sodium molybdate, 2 mM dithiothreitol, 10% glycerol, pH = 7.4) at room temperature using a motor-driven glass homogenizer and centrifuged at 135,000 *g* for 1 h. Aliquots of the supernatant (cytosol) are diluted to contain 40 mg tissue/ml and incubated for 1 h or overnight with [17α-methyl-^{3}H]R 1881 (methyltrienolone, 5 nM final concentration, 87 Ci/mmol, New England Nuclear) in either the absence or presence of increasing concentrations (1 nM to 10 µM) of R 1881 or test compounds. Because R 1881 binds weakly to progesterone and glucocorticoid receptors, cytosols are pretreated with 1 µM triamcinolone acetonide to block these interactions. After a 1- or 18-h incubation period, a suspension of dextran-coated charcoal (1% charcoal, 0.05% dextran T-70, 0.05% BSA) is added to the ligand-cytosol mixture and incubated for 5 min. The charcoal is removed by centrifugation at 1500 *g* for 10 min and the supernatant (protein-bound [^{3}H]R 1881) counted using 10 ml of scintillation fluid (New England Nuclear) in a liquid scintillation spectrometer.

Nuclear Androgen Receptor Exchange Assay

Ventral prostates are homogenized at 100 mg/ml in hexylene glycol buffer (1 M hexylene glycol, 1 mM $MgCl_2$, 2.0 mM dithiothreitol, 5.0 mM EGTA, 1.0 mM PIPES, pH = 7.4) using a motor-driven ground glass homogenizer. Homogenates are centrifuged at 1500 *g* for 10 min. The nuclear pellet is washed 3 times in homogenization buffer by gently resuspending the pellet in a Dounce homogenizer and centrifugation at 1500 *g* for 10 min. The washed nuclear pellet is resuspended in pyridoxal-5′-phosphate extraction buffer (20 mM sodium barbital, 5 mM pyridoxal-5′-phosphate, 5.0 mM dithiothreitol, 1.5 mM EDTA, 150 mM KCl, 20% glycerol, pH = 7.4) for 60 min at a final concentration of 60 mg tissue/ml. The extracted nuclei are centrifuged at 25,000 *g* for 30 min with the resulting supernatant being used in the same single saturating dose assay as described for prostate cytosol.

EVALUATION

Binding of test substances to the androgen receptor (receptor affinity) is quantified by calculating relative binding affinity (ratio of the molar concentration of unlabeled R 1881 to test substance required to inhibit the binding of [^{3}H]R 1881 by 50% after correction for nonspecific binding) and equilibrium inhibitory binding constant ($K_i = IC_{50}/(1 + C)/K_d$, where C = the concentration of [^{3}H]R 1881 and the K_d for R 1881 is 1.3 nM).

In the nuclear androgen receptor exchange assay treatment group means are compared to control means, using ANOVA and Dunnett's multiple comparison tests.

MODIFICATIONS OF THE METHOD

Cell assays and animal assays are described for evaluation of androgens and anti-androgens (Raynaud et.al. 1975; Liang et al. 1977; Sivelle et al. 1982; Liao et al. 1984; Traish et al. 1986; Stobaugh and Blickenstaff 1990; Christiansen et al. 1990; Humm and Schneider 1990; Neubauer et al. 1993).

Brown et al. (1981) studied anti-androgen effects on androgen receptor binding in cultured human newborn foreskin fibroblasts.

Tezón et al. (1982) studied the intracellular distribution of the androgen receptor in the rat epididymis under the influence of androgens and anti-androgens.

The use of tritiated 7α,17α-dimethyl-19-nortestosterone for the assay of androgen receptors was recommended by Schilling and Liao (1984).

Characterization and expression of a cDNA encoding the human androgen receptor was described by Tilley et al. (1989).

Hoyte et al. (1993) recommended 7α-methyl-17α-(E-2′-[^{125}I]iodovinyl)-19-nortestosterone as radioligand for the detection of the androgen receptor.

Structure–affinity relationships of various steroids structurally related to nomegestrol and progesterone for [^{3}H]testosterone binding to rat ventral prostate cytosol were reported by Botella et al. (1987).

Molecular cloning of human androgen receptor complementary cDNA has been reported by Chang et al. (1988) and Lubahn et al. (1988).

DNA-binding of androgen receptor overexpressed in COS-1 cells has been reported by Von Krempelhuber et al. (1994).

Thoth et al. (1995) studied *in vitro* binding of 16-methylated C-18 and C-19 steroid derivates to the androgen receptor using cytosol of castrated rat prostate and [^{3}H]R 1881 as radioligand.

Chang et al. (1995) reviewed the structure and function of the androgen receptor and its role in the function of the mammalian system.

The interaction of androgen receptors with the androgen-response element in intact cells was investigated by Karvonen et al. (1997).

N.4.1.1.2 Transactivation Assay for Androgens

PURPOSE AND RATIONALE

Steroid agonistic and antagonistic properties can be evaluated by transactivation assays (Muhn et al. 1995; Fuhrmann et al. 1995, 1996). The transactivation assay assumes that steroid receptor proteins act as ligand-regulated transcriptional activators. After binding of hormone, the steroid receptor interacts with hormone-responsive elements of hormone-regulated genes, in-

ducing a cascade of transcriptional events (Green and Chambon 1988). The hormone-dependent transcriptional activation can be determined in tissue culture by transfection of the steroid receptor under investigation and a reporter gene linked to a hormonally responsive promoter into cells. The transactivation assay allows determination of the agonistic and also the antagonistic potency of a given compound, by either induction or inhibition of reporter gene activity (Fuhrmann et al. 1992).

PROCEDURE

Vector Construct

CV-1 cells are stably transfected with the rat androgen receptor and pMMTV-CAT7. The pMMTV-CAT plasmid containing the mouse mammary tumor virus promoter linked to a chloramphenicol acetyltransferase gene is prepared according to Cato et al. (1986).

Cell Culture and Transfections

The culture medium of CV-1 cells stably transfected with the rat androgen receptor and pMMTV-CAT7 is supplemented with 400 µg/ml G418 (Gibco BRL) and 5 µg/ml puromycin.

Stable and transient transfections are performed using Lipofectin reagent (Gibco BRL) according to a procedure recommended by Felgner and Holm (1989). Stable transfections are carried out according to Fuhrmann et al. (1992). For transient transfection, 1×10^6 COS-1 or CV-1 cells are plated onto 100-mm dishes 1 day prior to transfection. Cells are typically about 80% confluent after 24 h. Before transfection, cells are washed twice with 1 ml Opti-MEM (Gibco BRL) per dish. For each dish, 5 µg hAR expression plasmid and 5 µg pMMTV-CAT are diluted with 1 ml Opti-MEM; in addition, 50 µg Lipofectin Reagent is diluted with 1 ml Opti-MEM. Next, DNA and Lipofectin Reagent dilutions are combined in a polystyrene snap-cup tube to obtain 2 ml of transfection solution per dish, gently mixed, incubated at room temperature for 5 min, and added to the washed cells. After 5 h the transfection solution is replaced by 6 ml DMEM supplemented with 10% fetal calf serum.

To study the effect of the test hormones, transiently transfected cells are trypsinized, pooled and replated onto 60-mm dishes at a density of 4.5×10^5 per dish 24 h after transfection. Stably transfected cells are seeded onto 6-well dishes (1×10^5 cells per dish). Cells are cultured in medium supplemented with 3% charcoal-stripped fetal calf serum and the appropriate hormones for 48 h. Cells are cultured with 1% ethanol as a negative control for the reporter gene induction. Transactivation assays with transiently or stably transfected cells are carried out at least three times.

CAT Assay

Transiently transfected cells and stably transfected cells are disrupted by freezing (ethanol/dry ice bath) and thawing (37°C water bath) three times. Protein concentrations of the cell extract are determined according to Bradford (1976). The CAT assay is performed according to Gorman et al. (1982).

EVALUATION

CAT activity is calculated as percentage conversion from chloramphenicol to acetylated chloramphenicol. Concentration–response curves for CAT induction are established to demonstrate the potency of the test hormone. The synthetic androgen R 1881 (10^{-10} to 10^{-6} mol/l) is used as the standard.

For anti-androgenic activity, CAT activity in the presence of 0.5 nmol/l R 1881 is set as 100% and relative CAT activity is calculated as a percentage of this value. Concentration–response curves for CAT inhibition are established with increasing concentrations of the antihormone.

CRITICAL ASSESSMENT OF THE METHOD

See N.2.1.1.2.

MODIFICATIONS OF THE METHOD

Warriar et al. (1993) examined the ability of dihydrotestosterone (DHT) and various antiandrogens to stimulate or to inhibit the transcription activation of mouse mammary tumor virus-bacterial chloramphenicol acetyltransferase (MMTV-CAT) in CV-1 cells.

White et al. (1994) described a simple and sensitive high-throughput assay which can be adapted for several classes of steroid agonists and antagonists. A DNA cassette, containing a synthetic steroid-inducible promoter controlling the expression of a bacterial chloramphenicol acetyltransferase gene (GRE5-CAT), was inserted into an Epstein-Barr virus episomal vector which replicates autonomously in primate and human cells. This promoter/reporter system was used to generate two stably transfected human cell lines. In the cervical carcinoma cell line HeLa, which expresses high level of glucocorticoid receptor, the GRE5 promoter is inducible over 100-fold by the synthetic glucocorticoid dexamethasone. In the breast carcinoma cell line T47D, which expresses progesterone and androgen receptors, the GRE5 promoter is inducible over 100-fold by either progesterone or dihydrotestosterone

(DHT). These cell lines can be used to screen large numbers of natural and synthetic steroid agonists and antagonists in microtiter wells directly using a colorimetric chloramphenicol acetyltransferase (CAT) assay.

N.4.1.2 In Vivo Methods

N.4.1.2.1 Chicken Comb Method for Androgen Activity

PURPOSE AND RATIONALE

This is a historical bioassay based on the response of the comb of castrate cockerels (capons). The method has been used by many authors to assay androgenic activity and has been found to be extremely useful for the isolation and structural elucidation of natural androgens. Many modifications have been published (reviewed by Dorfman 1969).

PROCEDURE

Prior to assay, the surface area (sum of the length plus height of each individual comb) is determined by a millimeter rule placed directly on the comb. The capons are injected q.d. intramuscularly for 5 days consecutively with a solution or suspension of the test compound and reference animals are treated with the androgen standard in 1 ml olive oil. Then 24 h after the last injection, the combs are measured again and the growth of the comb is expressed as the sum of length and height in millimeters. Groups of eight animals are used for at least two doses of the test compound and the standard. In this method, animals can be used repeatedly.

EVALUATION

The experimental parameter is the surface area of the comb. The mean values of each group are calculated, dose–response curve for the test compound and the standard are plotted, and potency ratios are calculated where possible.

Similar studies were reported by: Gallagher and Koch 1935; Greenwood et al. 1935; Oesting and Webster 1938

MODIFICATIONS OF THE METHOD

The hormones, dissolved in oil, have been applied locally to the capon's comb instead of by injection. A greater sensitivity has been achieved with this modification (Fussgänger 1934; McCullagh and Cuyler 1939).

Newly hatched chicks of either sex have been used to study the growth of combs after systemic or local administration (Frank et al. 1942; Dorfman 1948). White Leghorn chicks are used at an age of 2–3 days. They are kept in a brooder with thermostatic control. An oily solution (0.05 ml) of the test compound or the standard is applied to the comb daily for a period of 7 days. Then 24 h after the last application, the animals are autopsied. Body weights are determined. The combs are removed by two longitudinal incisions along the base of the comb at its juncture with the scalp. The comb is freed from the scalp, touched lightly on a towel to remove blood and weighed. Dose–response curves are established.

N.4.1.2.2 Weight of Androgen-Dependent Organs in Rats

PURPOSE AND RATIONALE

Androgens affect the development of secondary sex organs in the male rat (ventral prostate, seminal vesicles). The growth of the ventral prostate, the seminal vesicles and the musculus levator ani is dependent on the presence of male sexual hormones. Weight development of the musculus levator ani was considered to indicate anabolic activity, and weight development of the ventral prostate and seminal vesicles was considered to indicate androgenic activity (Dorfmann 1969).

PROCEDURE

Immature male Sprague-Dawley rats weighing about 55 g are orchiectomized. Animal body weight is recorded at the beginning and at the end of the experiment.

The animals are treated with test compounds by gavage (orally) in 0.5 ml 0.5% carboxymethylcellulose or by subcutaneous injection in 0.2 ml sesame oil suspension once per day over a period of 10 days. Testosterone is given in doses of 0.02, 0.1, and 0.5 mg per animal subcutaneously, and methyltestosterone orally in doses of 0.25, 1.5, and 5 mg per animal. Controls receive the respective vehicle. Ten animals are used for each group. On day 10 at autopsy, the seminal vesicles, ventral prostate, and levator ani muscle are dissected out and weighed. The seminal vesicles are squeezed and dried to remove the fluid.

Dissection of the levator ani muscle is performed after removal of the skin in the scrotal area between the base of the penis and the anus. The posterior aspect of the perineal complex is cleared of fat and connective tissue with forceps, particular care being taken to expose the constrictions at either end of the levator ani where it joins the bulbocavernosus muscle. The rectum is transected just caudad to the point where the musculus levator ani loops around it dorsally. The body of the levator ani is then freed of the rectum and is removed by incisions at the points of attachment to the bulbocavernosus muscle. The levator ani is cleared of any connective tissue and weighed to the nearest 0.1 mg.

EVALUATION

The ratio of organ weight to body weight is calculated for every animal and each organ (relative organ weights). Dose–response curves are constructed for each organ comparing the test compound with the standard in order to calculate potency ratios. An increase in the weight of seminal vesicles and ventral prostate indicates androgenic activity, whereas an increase in the weight of musculus levator ani is considered to indicate anabolic activity.

In evaluating steroids for possible use as anabolic agents, Hershberger et al. (1953) suggested the use of the levator ani:ventral prostate ratio, which is defined as the ratio of the increase in levator ani weight divided by the increase in ventral prostate weight.

The method has been useb by several authors: Korenchevsky and Dennison 1935; Eisenberg and Gordon 1950; Junkmann 1957; Kincl 1965; Eisler 1964; Dorfmann 1969; Kuhnz and Beier 1994.

N.4.1.2.3 Nitrogen Retention

PURPOSE AND RATIONALE

Anabolic agents induce positive nitrogen balance in the living organism (Polish 1964; Dorfmann 1969). Many modifications of this assay principle have evolved. Stafford et al. (1954) suggested a method involving the measurement of nitrogen excretion in the castrated rat fed a liquid diet and in nitrogen balance.

PROCEDURE

Twenty-five-day-old rats are castrated and kept untreated for 67 days, reaching about 300 g in body weight on normal laboratory diet. After 67 days, they are changed to a liquid diet, forced-feeding regime. The diet contains carbohydrates and fat, as well as casein and brewer's yeast as a nitrogen source. At the start, the rats receive 10 ml of feed per day, and this is increased to 26 ml per day. Feeding is continued for 30 days with simultaneous administration of the test drug once a day. Twenty-four-hour urine specimens are collected 3 times weekly and analyzed for total nitrogen.

EVALUATION

Indices are calculated, such as greatest daily retention, which is defined as the difference between the lowest daily nitrogen value after the beginning of treatment and the preinjection mean; the total nitrogen retention, which is the sum of the differences between the preinjection excretion and the daily values during the retention period; and the number of days in the retention period.

MODIFICATIONS OF THE METHOD

A method for the assay of anabolic steroids in the monkey (*Macaca mulatta*) has been suggested by Stucki et al. (1960). Nitrogen retention expressed as total nitrogen retained per day during the treatment period is chosen as the end point.

CRITICAL ASSESSMENT OF THE METHOD

The assay is time-consuming and labor-intensive, and its use is no longer recommended.

N.4.2 Anti-Androgenic Activity

N.4.2.0.1 General Considerations

Anti-androgens may exhibit their activity both peripherally on androgen-dependent tissues and by feedback action at a central site (Neumann et al. 1970; Mainwaring 1977; Neri 1977; Neumann et al. 1977; Raynaud et al. 1977; Neumann 1985; Moguilewski and Bouton 1988). They compete with the peripheral androgen receptors and thus inhibit the effect of endogenous or exogenous androgens. Centrally, they inhibit gonadotropin secretion and thereby diminish testosterone production by the gonads. In addition to their effects on reproduction and accessory sexual organs, anti-androgens inhibit sebum production (anti-acne drugs) and delay androgen-dependent hair loss (alopecia). The methods to detect and quantify gonadotropin inhibition are described in Sect. N.7.1.8.

Inhibition of 5α-reductase, an enzyme located in tissues such as the prostate, is one pharmacological approach to inhibit benign prostate hyperplasia in men. Such inhibitors reduced the conversion from testosterone to 5α-dihydrotestosterone (DHT).

N.4.2.1 In Vitro Methods

N.4.2.1.1 Inhibition of 5α-Reductase

PURPOSE AND RATIONALE

Testosterone is converted to 5α-dihydrotestosterone (DHT) by the enzyme 5α-reductase which is specifically localized in some androgen-responsive target tissues (e. g., prostate, seminal vesicle, epididymis, skin and sebaceous glands), whereas in other androgen-sensitive tissues, such as the skeletal muscles and the central structures, the androgenic hormone is testosterone. Inhibition of 5α-reductase provides a selective approach to androgen deprivation in DHT-target tissues, such as the prostate. The 5α-reductase inhibitors are applied in the therapy of benign prostate hyperplasia.

PROCEDURE

5α-Reductase preparations are obtainable from prostates of various species, such as human, dog, and rat.

Frozen human prostates from benign prostatic hyperplasia patients are thawed and minced with a pair of scissors. The minced tissue is homogenized in three tissue volumes of medium A (20 mM potassium phosphate, pH 6.5, containing 0.32 M sucrose, 1 mM dithiothreitol and 50 µM NADPH) with a Brinkmann Polytron and a glass-glass homogenizer. The homogenate is centrifuged at 140,000 *g* for 60 min and the pellets are washed with approximately three tissue volumes of medium A. The washed pellets are suspended at a concentration of 5–10 mg protein/ml in 20 mM potassium phosphate, pH 6.5, containing 20% glycerol and 1 mM dithiothreitol.

Dog prostatic particulates are prepared from either fresh or frozen specimens of male mature dogs as described for human prostate. The washed pellets are suspended in medium A at a concentration of 30–60 mg protein/ml.

Ventral prostates from male Sprague-Dawley rats weighing 400 g are processed as described for human prostate, except that medium A without NADPH is used throughout the procedures. NADPH prevents inactivation of human and dog 5α-reductases during the preparation, the rat enzyme however is stable without the coenzyme.

For the 5α-reductase assay, reaction solutions are prepared in duplicate tubes containing 1 µM [^{14}C]testosterone, 1 mM dithiothreitol, 40 mM buffer (potassium phosphate, pH 6.5, for the rat and for the dog enzymes; Tris-citrate, pH 5.0, for the human enzyme), prostatic particulate (1 mg protein), and NADPH (50 µM for reaction with rat enzyme, 500 µM for reaction with human and dog enzyme) in a final volume of 0.5 ml. Test compounds or standard as inhibitors are added in 5 µl ethanol at concentrations between 10^{-9} and 10^{-5} M. The control tubes receive the same volume of ethanol. The reactions for the rat and dog enzymes are started by the addition of the prostatic particulates. The human prostatic particulate is premixed with NADPH before starting the reaction. The reactions are linear for at least 1 h at 37°C. The reactions are carried out for 10–30 min and are stopped with 2 ml ethyl acetate containing testosterone, 5α-dihydrotestosterone, and androstenedione (10 µg each). After centrifugation at 1000 *g* for 5 min, the ethyl acetate phase is transferred to a tube and evaporated under nitrogen to dryness. The steroids are taken up in 50 µl ethyl acetate. The solutions are applied to Whatman LK5DF silica plates and the plates are developed in either ethyl acetate:cyclohexane (1:1) at 25°C or chloroform:methanol (96:4) at 4°C. The plates are air-dried and the chromatography is repeated. Nonradioactive steroid standards are located by UV and by spraying with 1% $CeSO_4$/10% H_2SO_4 solution followed by heating. The radioactivity profiles are determined by scanning the plates or by scraping the silica in sections and counting in a scintillation counter. 5α-Dihydrotestosterone is the only radioactive product for the rat and human enzymes. With the dog enzyme 5α-dihydrotestosterone, 3α,17β-androstanediol, androstan-3,17-dione, and androstenedione are formed. The radioactivities of the first three products are combined for the calculation of the 5α-reductase activity.

EVALUATION

IC_{50} values are calculated based on at least five dilutions of test preparations or standard.

MODIFICATIONS OF THE METHOD

The method has been useb by several authors: Bruchovsky and Wilson 1968; Corvol et al. 1975; Brooks et al. 1981; Liang et al. 1985; Rhodes et al. 1993; di Salle et al. 1993; Sudduth and Koronkowski 1993; di Salle et al. 1994

Using human genital skin fibroblasts and simian COS cells, specific inhibition of 5α-reductase type 1 has been observed (Hirsch et al. 1993).

Wennbo et al. (1997) reported that **transgenic mice** overexpressing the prolactin gene develop dramatic enlargement of the prostate gland.

Sigimura et al. (1994) described age-related changes of the prostate gland in the senescence-accelerated mouse and recommended this strain as a model of age-related changes in the prostate gland.

Neubauer et al. (1993) measured prostatic 5α-reductase in rats both *in vitro* and *ex vivo* and determined *in vivo* uptake of [^{3}H]testosterone by the prostate.

At least two isoforms of 5α-reductase have been isolated (Andersson and Russell 1990; Jenkins et al. 1992). Recombinant human prostatic 5α-reductase type I and II were expressed using the baculovirus-directed insect cell expression system (Iehlè et al. 1993).

Iehlè et al. (1995) and di Salle et al. (1998) tested synthetic 5α-reductase inhibitors against both isoforms.

Tolman et al. (1995) identified a 4-azasteroid as a scalp isoenzyme selective inhibitor.

N.4.2.2 In Vivo Methods

N.4.2.2.1 Chick Comb Method

PURPOSE AND RATIONALE

This method is now obsolete for the evaluation of anti-androgens. Several modifications of the chick comb method have been described for anti-androgens applied either systemically or locally to the comb of intact cockerels (Dorfmann 1960, 1969).

PROCEDURE

Male or female, 1- to 3-day-old White Leghorn chicks are housed at constant temperature in a heated incubator. Testosterone is incorporated into the finely ground chick starting mash at a concentration of 80 mg/kg of food to stimulate comb growth. The chicks are placed on this diet on day 1. The anti-androgen to be tested is

dissolved in sesame oil and injected for several days. At 24 hours after the last injection, the animals are sacrificed, the combs removed and blotted to remove blood, and weighed rapidly to the nearest 0.5 mg. Body weights are also determined.

EVALUATION

The results may be expressed as absolute comb weights or as milligram of comb per gram of body weight. Dose–response curves for groups treated with increasing doses of anti-androgen are plotted.

N.4.2.2.2 Antagonism of Androgen Action in Castrated Rats

PURPOSE AND RATIONALE

In this modification, anti-androgens are administered to reduce or inhibit testosterone action's on androgen-dependent organs.

PROCEDURE

Male Sprague-Dawley rats weighing 50–70 g are orchiectomized. Starting 1 day after castration, the rats are injected once daily for 7 days with 0.15 mg testosterone propionate in 0.1 ml sesame oil (agonist action). The test compounds (anti-androgens) are dissolved in sesame oil or suspended and injected subcutaneously daily at a separate site for the same test period of 7 days. Six to ten animals are used per group. At autopsy on day 8, weights of ventral prostate, seminal vesicles and musculus levator ani as well as body weight are recorded.

EVALUATION

The organ weight to body weight ratio is calculated for each order, preferably based on relative organ weight to 100 g of body weight. The inhibition by the anti-androgen is compared with agonist action in the groups of animals receiving testosterone propionate alone. Dose–response curves may be plotted for each organ, and expressed as percentage inhibition of the agonist effect of testosterone by the anti-androgen.

MODIFICATIONS OF THE METHOD

Dorfman (1962) described an anti-androgen assay using the castrated mouse. Weights of prostate and seminal vesicles were determined after injection of the anti-androgen test compounds and simultaneous injections of 2 mg testosterone over a period of 7 days.

APPLICATIONS OF THE METHOD

The intrinsic anti-androgenic activity is an important parameter in the evaluation of the pharmacological activity of H2-receptor antagonists (Winters et al. 1979; Broulik 1980; Baba et al. 1981; Sivelle et al. 1982; Foldesy et al. 1985; Takeda et al. 1982; Neubauer et al. 1990). In general pharmacology studies, there is rarely any need for specific anti-hormonal tests. However, in toxicology studies, tests for anti-androgen activity may be warranted when the effects on the testes and androgen-dependent organs are found in repeated-dose studies.

N.4.2.2.3 Anti-Androgenic Activity in Female Rats

PURPOSE AND RATIONALE

This is another historical bioassay of interest due to the design of exploring anti-androgenic activity. Neumann and Elger (1966) described a method for testing the anti-androgenic activity of compounds in immature female rats. The inhibition by the anti-androgen cyproterone of the trophic effect of testosterone on uterine and preputial growth was studied in intact as well as in castrated female rats (Neri et al. 1972; Snyder et al. 1989) .

PROCEDURE

Female Sprague-Dawley rats weighing 40–45 g are ovariectomized. One week later, the treatment is started for 12 days with daily subcutaneous injections of 0.3 mg testosterone propionate and several doses of the antagonist. Controls receive testosterone propionate only. At autopsy on day 13, the uteri and preputial glands are distracted out and weighed. The weight increase of female accessory sexual organs caused by testosterone's action is dose-dependently reduced by the anti-androgen (in this case, cyproterone). Similar results are found using intact immature female rats.

EVALUATION

Dose–response curves were established for increasing doses of the anti-androgen at a given dose of testosterone propionate or for increasing doses of testosterone propionate at a given dose of the anti-androgen, cyproterone.

CRITICAL ASSESSMENT OF THE METHOD

The method is time-consuming and was directed to the specific investigation of cyproterone and cyproterone acetate in precocious puberty and androgen-dependent disorders.

N.4.2.2.4 Intra-Uterine Feminizing/Virilizing Effect

PURPOSE AND RATIONALE

From clinical observations as well as from experimental data (Neumann and Junkmann 1963; Neumann and Kramer 1964), it is well known that the external genitalia of female fetuses can be masculinized by tumors secreting endogenous androgens or by steroids with androgenic activity. This effect can be antagonized by an anti-androgen.

The method is of interest for assessment of reproductive toxicology.

PROCEDURE

Adult female Sprague-Dawley rats are mated and the beginning of pregnancy is determined by vaginal smears. From day 16 to day 19 of pregnancy, the antiandrogens are administered in various doses subcutaneously in sesame oil. Testosterone propionate is used in doses between 1.0 and 10.0 mg as the androgenic stimulus. The dams are sacrificed on the 20th day of pregnancy and the external genitalia of the female embryos examined. The sex of the embryos is recognized by the presence of ovaries and uterus. A dose of 10 mg

testosterone propionate leads to total masculinization of female embryos with loss of female and the appearance of male sex characteristics. The anogenital distance in female rat fetuses measured macroscopically and microscopically is dose-dependently increased by testosterone propionate. This characteristic androgen effect is diminished by an anti-androgen.

EVALUATION

The androgen-dependent decrease of the anogenital distance in female fetuses by various doses of the anti-androgen is expressed as percentage inhibition of the testosterone-induced virilization.

MODIFICATIONS OF THE METHOD

Feminization of male rats was induced by treatment of pregnant rats during the second half of gestation and of the newborn fetuses during weeks 1–3 post partum with an anti-androgen, e. g., cyproterone acetate (Neumann and Elger 1966; Nishino et al. 1988; review by Neumann 1994). A decrease of the anogenital distance in the male fetuses of anti-androgen-treated rats is expressed as percentage inhibition relative to fetuses from untreated mothers.

In feminized male rats, nipples and associated glandular tissues develop after birth as in normal female rats (Neumann and Elger 1967).

Feminization of male rats treated *in utero* was also observed with nonsteroidal anti-androgens and a 5α-reductase inhibitor (Imperato-McGinley et al. 1992).

N.4.2.2.5 Anti-Androgenic Activity on Sebaceous Glands

PURPOSE AND RATIONALE

Bioassays for topical anti-androgens are based on inhibition of sebum secretion. Sebum production is increased by endogenous or exogenous androgens in many species including humans. In the mouse (Lapière and Chèvremont 1953; Neumann and Elger 1966), the Mongolian gerbil (Mitchell 1965), and the golden hamster (Hamilton and Montagna 1950), the male sex hormone stimulates sebum production and sebaceous gland growth. Morphometric evaluation by light microscopy in the rat has shown that castration causes a large reduction in the volume of the glands (Sauter and Loud 1975). The administration of testosterone over several days produces an enlargement of the sebaceous glands. This effect is used for morphometric evaluation of topical anti-androgens.

The method is described in detail in Sect. P.9.1.

N.4.2.2.6 Anti-Androgenic Activity in the Hamster Flank Organ

PURPOSE AND RATIONALE

This is another bioassay preferably for topical anti-androgens. The flank organs of Syrian golden hamsters are located on each flank of the animal consisting mainly of sebaceous tissue. Like sebaceous glands in other species, these pigmented spots respond to androgens by an increase in size. This proliferation is inhibited by systemic or topical anti-androgens.

The method is described in detail in Sect. P.9.5.

N.4.2.2.7 Effect of 5α-Reductase Inhibitors on Plasma and Tissue Steroid Levels

PURPOSE AND RATIONALE

5α-Reductase inhibitors change the ratio of plasma testosterone to dihydrotestosterone (DHT) as well as the tissue concentrations particularly in the prostate tissue.

PROCEDURE

Treatment of Animals

Male Sprague-Dawley rats are treated subcutaneously with the 5α-reductase inhibitor or vehicle beginning on postnatal day 3 until the age of 4 or 7 weeks. After sacrifice, blood is withdrawn for testosterone and DHT determinations (George et al. 1989). Moreover, intraprostatic concentrations of testosterone and DHT are determined as an index of antiproliferative activity (di Salle et al. 1993).

Radioimmunoassay for Testosterone and Dihydrotestosterone

Serum testosterone and DHT are measured by radioimmunoassay (RIA) in serum or serum extracts using specific antisera without prior chromatography (Falvo and Nalbandov 1974). Serum samples of 0.5 ml may be extracted with 2 ml of freshly purified, peroxide-free diethyl ether by shaking for 60 s on a Vortex mixer. The aqueous phase is frozen at −70°C, then the ether phase containing steroids is transferred to conical test tubes, and evaporated under a stream of dry nitrogen. The dry residue is redissolved in BSA/phosphate buffer (1% BSA = bovine serum albumin) for RIA. [1,2,6,7-^{3}H]-Testosterone or [1,2,6,7-^{3}H]-dihydrotestosterone and specific antisera are added and tubes incubated over a period of 24 h at +4°C under nonequilibrium conditions. Bound hormone and free hormone are separated by adsorption on dextran-coated charcoal. The activity of each sample is determined by beta-spectrometry.

Commercially available RIA kits can be used with suitable validation.

EVALUATION

The hormone concentrations in the sample are calculated from a standard curve by a computer program (e. g., RIA-Calc, LKB), using appropriate control sera. The ratios of testosterone to DHT in rats treated with different doses of 5α-reductase inhibitors are compared with those of vehicle-treated intact control rats.

MODIFICATIONS OF THE METHOD

di Salle et al. (1998) measured prostatic concentrations of testosterone and 5α-dihydrotestosterone in rats by specific RIAs after treatment with a dual type I and II 5α-reductase inhibitor. Similar measurements of tissue testosterone:DHT ratios have been performed in dogs, in the context of pituitary down-regulation of androgen secretion by luteinizing-hormone-releasing hormone (LHRH) agonists.

N.5 Thyroid Hormones

N.5.0.1 General Considerations

The purpose of this section is twofold: to described the methods for determination of hormones secreted by the thyroid gland, and to described investigation of thyroid function in experimental models. For information on the hypothalamic–pituitary–thyroid system and its investigation, see the sections on anterior pituitary hormones (N.7) and hypothalamic hormones (N.9).

The thyroid gland secretes two types of hormones: the **thyroid hormones**, i. e., l-**thyroxine** (T_4), and **triiodothyronine** (T_3) which have metabolic functions and are involved in neuronal development, and the **calcitropic hormone**, **calcitonin**. The functional system for metabolic regulation subserved by the thyroid hormones is entirely different from the complex system for regulation of calcium and phosphate balance fulfilled by (thyro)calcitonin, parathormone from the parathyroid glands, and the calciferol hormones (formerly vitamin D) produced by the liver and kidneys and activated in the skin.

The main biological effects of $\mathbf{T_3}$ and $\mathbf{T_4}$ are on growth and development (e. g., maturation of tadpoles), their calorigenic effect (increase of basic metabolic rate), cardiovascular function (increased

sensitivity of the heart to catecholamines), and metabolic functions (lipid, carbohydrate, and collagen metabolism). The primary feedback effect is inhibition of thyroid-stimulating hormone (TSH) secretion. These effects can be used to test thyroid hormone analogs and metabolites. The thyroid hormones regulate iodine uptake and utilization in the thyroid, and their action can be inhibited by antithyroid drugs.

Historical bioassays rely on morphogenesis and neuronal development in **amphibia** (Biedl 1916; Pitt-Rivers and Tata 1959; Copp et al. 1962; Turner and Premachandra 1962). Thyroid hormones induce premature metamorphosis in amphibian tadpoles. Since the first observation by Gudernatsch (1913a, 1913b) this phenomenon has been studied by numerous workers with the purpose of adapting this response for the assay of thyroidal substances (Bomskov 1937). Within a short period of time, the treatment with thyroid hormones induces the transformation of the **tadpole** into a small frog with growth of limbs, lungs, and other terrestrial accoutrements, and stimulates the synthesis of enzymes mediating morphogenesis and transformation.

The **axolotl** (*Ambystoma mexicanum* or *tigrinum*) has been used as a test object to study metamorphosis induced by thyroid hormones. This animal loses the gills and forms lungs, changing the shape of its tail at the same time (Huxley and Hogben 1922; Zavadovsky and Zavadovsky 1926; Haffner 1927).

Another principle action of T_3 and T_4 is metabolic activation and increased energy expenditure. Kreitmair (1928) standardized thyroid preparations using the **weight loss of guinea pigs** after 1 week of treatment as a parameter. A guinea pig unit was defined as the dose which reduces the body weight of guinea pigs with an initial weight of 250–300 g within 7 days by at least 10%.

A different functional role is subserved by calcitonin. The **hypocalcemic hormone calcitonin** was discovered by Copp (Copp et al. 1962; Copp 1964). Calcitonin originates from parafollicular C-cells of the thyroid. Its functional antagonist is parathyroid hormone. The bioassay of calcitonin preparations is performed by assessing their ability to **lower the plasma calcium** in the rat. Assay of serum (thyro)calcitonin has a significant diagnostic role for thyroid carcinoma.

As with other hormones, research methods have progressed from bioassays of thyroid hormone action to direct measurement of the thyroid hormones (thyroxine and triiodothyronine) and their metabolites, to studies on enzymatic steps in thyroid hormone synthesis and inactivation, to the identification of thyroid hormone receptors as members of the super family of nuclear receptors, and to signaling induced by binding of thyroid hormones to their receptors.

Thyroid Hormone Receptors

Nuclear triiodothyronine binding proteins were purified and characterized by Torresanai and Anselmet (1978). Ichikawa and DeGroot (1987a, 1987b) described the purification and characterization of rat liver nuclear thyroid hormone receptors and thyroid hormone receptors in a human hepatoma cell line. Apriletti et al. (1988) reported large-scale purification of the nuclear thyroid hormone receptor from rat liver and sequence-specific binding of the receptor to DNA. Ichikawa et al. (1988) and Ichikawa and Hashizume (1991) published methods of an aqueous two-phase (dextran and polyethylene glycol) partitioning study of nuclear thyroid hormone receptors. Glucocorticoids, other steroid hormones, thyroid hormones and vitamin-derived hormones (including retinoids) all exert their effects by the regulation of hormone-responsive target genes within the cell nucleus. William and Franklyn (1994) reviewed the physiology of the steroid–thyroid hormone nuclear receptor superfamily. A nuclear hormone receptor-associated protein that inhibits transactivation by the thyroid hormone and retinoic acid receptors was described by Burris et al. (1995). Two different genes encode two different thyroid hormone receptors, thyroid hormone receptor-α and thyroid hormone receptor-β and these two thyroid hormone receptors are often co-expressed at different levels in different tissues. Chiellini et al. (1998) designed a high-affinity subtype-selective agonist ligand for the thyroid hormone receptor-β. The expression of thyroid hormone receptor isoforms in rat growth plate cartilage *in vivo* was described by Ballock et al. (1999). Yuan et al. (1998) described a component of a thyroid hormone receptor-associated protein (TRAP) co-activator complex which interacts directly with nuclear receptors in a ligand-dependent fashion. The sequence of the thyroid-hormone-response element and the recruitment of retinoid X receptors for thyroid hormone responsiveness was investigated by Wu et al. (2001).

N.5.0.2 Thyroidectomy

PURPOSE AND RATIONALE

Experiments for pharmacological evaluation of thyroid hormones and analogs were performed in thyroidectomized rats. Bomskov (1937) described the method of thyroidectomy in various animal species, such as tadpoles, frogs, birds, goats, dogs, cats, rabbits, guinea pigs, rats and mice, based on the clinical experience with thyroid resection in humans.

PROCEDURE

The thyroid in rats consists of three lobes (left, median, and right). The rat is anesthetized, e. g., with pentobarbital, and placed on a surgical table. The fur of the neck is removed with electric clippers and the area disinfected. A median skin incision of 2.0 cm length is made. On both sides large salivary glands and maxillary lymph nodes are found. They are pushed aside, making visible the musculus hyoideus covering the trachea. This muscle is split in the midline. The isthmus of the thyroid connecting both lobes is located below the thyroid cartilage. The lobes and the isthmus are separated with blunt forceps from the trachea and the blood vessels ligated. Alternatively, the thyroid can be removed by electrocauterization. In most cases, the parathyroid glands are severed by the operation, and postoperative substitution with calcium lactate 1% in drinking water is advised.

N.5.1
In Vivo Tests for Thyroid Hormones

N.5.1.1
Oxygen Consumption

PURPOSE AND RATIONALE

Basal metabolic rate, oxygen consumption and CO_2 production are increased by thyroid hormones. This has been used for diagnostic procedures in humans as well as for evaluation of thyroid hormones and their derivatives in animals (indirect calorimetry). The historical method based on survival time of mice placed individually into tightly closed glass jars (Smith et al. 1947; Basil et al. 1950; Gemmill 1953) was modified, measuring time until occurrence of convulsions. The method was based on the increase in oxygen consumption associated with the markedly increased metabolic rate at high doses of thyroid hormones.

PROCEDURE

This is a description of the now obsolete assay: mice are placed individually into 200-ml wide-necked bottles. The bottom of the bottles is covered with filter paper to soak up the urine. The bottles are tilted to an angle of 60° and rotated five times per minute in a special apparatus. The time until asphyctic seizures occur is noted. Immediately after observation of seizures, the mouse is released for recovery. Due to the defined muscle work, the time to seizures is shortened in controls to 20–30 min.

EVALUATION

Average time to seizures was calculated and dose–response curves were established.

MODIFICATIONS OF THE METHOD

Similar studies were reported by: Bomskov 1937; Lilienthal et al. 1949; MacLagan and Sheahan 1950; Reineke and Turner 1950; Anderson 1954; Heming 1964; Turner 1969

Several apparatuses have been designed to measure oxygen consumption in animals, e. g., by Holtkamp et al. (1955).

Stock (1975) described an automatic, **closed-circuit oxygen consumption apparatus** for small animals. A Perspex animal chamber is surrounded by a water jacket except for one end, which has a removable cover plate. This cover, as well as allowing access to the chamber interior, also holds the connections for the oxygen delivery line and the pressure line. For experiments involving injections, infusions, and blood sampling, catheters are passed through, and sealed into rubber bungs which are then forced into holes in the cover plate. A rubber gasket forms an airtight seal between the cover and the chamber. Within the chamber, the animal is supported on a wire grid over a layer of self-indicating soda lime and silica gel. A major determinant of sensitivity in this system is the dead space of the chamber. Chambers with internal dimensions of $20 \times 10 \times 10$ cm are suitable for animals such as mice and rats up to about 250 g body weight. Fixed volumes of oxygen are introduced into the chamber by an automatic syringe dispenser (Fisons Scientific) which draws pure oxygen from a spirometer through a drying tube filled with silica gel. When chamber pressure exceeds atmospheric by about 3 mmH_2O, the microdifferential pressure switch (KDG Instruments) inactivates the dispenser. The dispenser is reactivated when the pressure differential drops below this threshold value. The volume of oxygen dispensed is adjusted to the smallest volume that, with a single action of the syringe, will return chamber pressure to above the threshold value. The particular dispenser used in this system has the advantages of being (1) gas tight and (2) when activated will complete its pump cycle even if the chamber pressure exceeds the threshold value in midcycle. A discrete fixed volume of oxygen is delivered each time it is activated. To obtain the rate of oxygen consumption it is merely necessary to record the pump rate.

N.5.1.2 Inhibition of Iodine Release

PURPOSE AND RATIONALE

The thyroid gland has a high avidity for iodine, uptake of which may be measured by isotope-labeled iodine (^{131}I), in a dose-related and time-dependent manner. The release of ^{131}I from the thyroid in rats is inhibited by treatment with thyroxine (Wolff 1951), and the degree of inhibition is related to the dose administered (Perry 1951). This phenomenon was used to compare activity of thyroid hormone derivatives with the standard thyroxine.

For analytical and diagnostic purposes, direct quantitation of thyroid hormones is now achieved by methods such as radioimmunoassay and HPLC chromatography, and by measuring feedback inhibition of thyroid hormones directly via the decrease in serum TSH.

PROCEDURE

Male Sprague-Dawley rats weighing 180–240 g are fed a commercial laboratory chow without or with addition of 0.03% propylthiouracil (reference compound for thyroid peroxidase inhibition). Food is withheld 8 h before the injection of 25 μC ^{131}I or ^{125}I intraperitoneally. Radioactivity over the thyroid region of the neck is determined 40 h later (if necessary under sedation). This reading is taken as time zero and all further counts made at 24-h intervals may be expressed as a percentage of time-zero counts after correction for physical decay of the ^{131}I isotope. After the reading at time zero, the diet is changed to a feed containing 0.03% propylthiouracil, and several doses of the test preparation or the standard are injected subcutaneously at 24-h intervals up to a total of four doses. The daily loss of ^{131}I is inversely proportional to the dose of thyroid hormone.

EVALUATION

Percentage of time-zero counts after 96 h of ^{131}I remaining in the thyroid after the last of four doses is plotted against logarithm of dose. From these dose–response curves, potency ratios are calculated.

The method has been used by several authors: Reineke and Turner 1950; Anderson 1954; Turner and Premachandra 1962

CRITICAL ASSESSMENT OF THE METHOD

The assay described here was used for quantitative estimates and has now been replaced by analytical determination of thyroid hormone contents. For human drug formulations, bioequivalence studies are required when generic formulations are assessed This approach of measuring the uptake and release of labeled iodine may be modified for short-term uptake of ^{131}I or ^{125}I as a parameter of thyroid peroxidase inhibition by antithyroid drugs, and other drugs affecting thyroid function.

N.5.1.3 Anti-Goitrogenic Activity

PURPOSE AND RATIONALE

Thyroid weight and size are controlled by the action of thyroid-stimulating hormone (TSH) on thyroid tissue. In rats, increased secretion of TSH induces thyroid enlargement and weight increase within a few

days (addressed as goiter formation). In normal animals the secretion of TSH by the pituitary is regulated by feedback of thyroid hormones. The administration of goitrogenic compounds which block thyroid hormone synthesis and/or secretion reduces the concentrations of circulating thyroid hormones (T_4/T_3) and their pituitary effect (negative feedback inhibition of TSH secretion), releasing TSH from its feedback inhibition. The TSH rise induces hyperplasia of the thyroid follicles as indicated by the dose-related increase of thyroid weight. Hyperplasia is prevented by injection of thyroxine, triiodothyronine or thyroid hormone analogs.

PROCEDURE

Male Sprague-Dawley rats weighing 150–180 g are used in groups of eight to ten animals. During the treatment period, 0.1% propylthiouracil (PTU) is added to the food or to the drinking water, in order to achieve a stable baseline of thyroid weight. Over a period of 2 weeks, the rats are treated (preferably by gavage) with various doses of the test compound or the thyroxine standard (10–40 µg/kg). PTU controls are treated with the suspension medium or saline injections only. At autopsy on day 14, the thyroid glands are dissected out and weighed rapidly to avoid evaporation loss. Thyroids may also be lyophilized first to weigh dry matter. The two- to three-fold increase of thyroid weight by PTU is reversed dose-dependently to normal values by thyroid active substances.

EVALUATION

Dose–response curves are plotted and potency ratios with confidence limits may be calculated.

MODIFICATIONS OF THE METHOD

Similar studies were reported by: Reineke et al. 1945; Pitt-Rivers and Tata 1959; Turner and Premachandra 1962; Wiberg et al. 1964; Ortiz-Caro et al. 1983; Pisarev et al. 1994

The effect of PTU-induced baseline suppression is monitored and ascertained by measuring serum TSH, T_4 and T_3. The dose-related inhibition of the TSH rise by thyroid substances is used as the parameter to assess goiter prevention.

N.5.1.4 Tensile Strength of Connective Tissue in Rats, Modified for Thyroid Hormones

These studies are an example of evaluating the biological effect of high doses of thyroid hormones on tissues other than those involved in the increase of metabolic rate. Thyroid hormone secretion affects almost all tissues in the body, and high doses may exert unwanted effects on connective tissue.

PURPOSE AND RATIONALE

The decrease of tensile strength after a single high-dose injection of thyroid hormones is dose dependent and can be used for evaluation of thyroid hormone derivatives. Short-term treatment with corticosteroids increases the strength of connective tissue (Vogel 1969). This effect is antagonized by thyroid hormones (Ther et al. 1963; Vogel and Ther 1964). Thyroid hormones per se have a biphasic effect: short-term treatment decreases the dose-dependent tensile strength of epiphyseal cartilage, tail tendons and skin strips, whereas treatment over 10 days increases tensile strength, probably mediated by activation of endogenous adrenal secretion (similar to the effect of corticosteroid treatment).

PROCEDURE

Male Sprague-Dawley rats weighing 110 ± 10 g are injected subcutaneously with thyroid hormones (dose range of the standard L-triiodothyronine 0.1–1.0 mg/kg). After 24 h the animals are sacrificed and the tensile strength of distal femoral epiphyseal plates, tail tendons, or skin strips are tested as described in Sects. N.2.1.3.2, N.2.1.3.3, N.2.1.3.4, and P.11.2.1.1.

EVALUATION

Doses–response curves of test compounds and standard are established and potency ratios may be calculated. T_3 (L-triiodothyronine) is about 3 times more active than T_4 (levothyroxine), in accordance with its

metabolic activity. The mechanism of action of this short-term effect of thyroid hormones on connective tissue has not been explored.

N.5.2 Antithyroid Drugs

N.5.2.1 General Considerations

Antithyroid drugs interfere with synthesis, release, and/or the peripheral action of the thyroid hormone, lowering the basal metabolic rate. They are used in the treatment of thyroid disorders (hyperthyroidism). The suppression of T_4/T_3 secretion reduces thyroidal inhibition of the pituitary gland, increasing TSH secretion, and then induces the goitrogenic response. This response was used to detect antithyroid drugs and has been widely used for screening procedures. It is, however, nonspecific and may be caused by several different mechanisms, including enzyme induction of glucuronyltransferases. The goitrogenic response is of considerable interest in toxicology, because it may be produced by several compounds during early drug evaluation which modify the biosynthesis and/or inactivation of thyroid hormones in an unexpected manner.

N.5.2.2 Inhibition of Iodine Uptake in Rats

PURPOSE AND RATIONALE

Propylthiouracil (PTU) and a wide spectrum of drugs may inhibit thyroid hormone synthesis. Some of these drugs are used to treat thyrotoxicosis. As a consequence of thyroid peroxidase inhibition, the iodine uptake by and content in the thyroid is decreased. This phenomenon is dose dependent and may occur at lower doses than those increasing thyroid weight in rats (McGinty and Bywater 1945). The historical parameter of iodine content has been replaced by measuring the uptake and release of ^{131}I.

PROCEDURE

Groups of male Wistar rats age 26–28 days, weighing 40–45 g, are placed into metabolism cages. They are fed normal diet, and potassium iodide is added to the drinking water. In one modification of the method (for toxicology studies), the test compounds or the reference standard (several concentrations) may be added to the diet over a period of 10 days, and the amount of compound ingested by each rat is then calculated from the total food consumption over 10 days and expressed in milligram daily per kilogram of body weight. After 10 days of treatment, the rats are sacrificed and the thyroids dissected free from adjacent tissue and capsule. The thyroid is weighed and iodine content determined. In daily doses of between 0.1 and 10.0 mg/kg, thiouracil decreases the iodine content of the thyroid in a dose-dependent manner. Definitely higher doses are necessary to increase thyroid weight.

EVALUATION

Dose–response curves of test compounds and reference standard are plotted, and potency ratios with confidence limits may be calculated.

MODIFICATIONS OF THE METHOD

Walker and Levy (1989) used implantable pellets of propylthiouracil to induce thyroid dysfunction in rats. Uptake of labeled iodine is measured instead of iodine content. Release of labeled iodine may be stimulated by protirelin (TRH) injection in order to assess thyroid function, or as a quantitative bioassay for the effect of the hypothalamic hormone TRH.

N.5.2.3 Antithyroidal Effects in Animal Assays

The oxygen consumption in iodine-treated mice has been used as a bioassay, modified for antithyroid activity.

PURPOSE AND RATIONALE

The historical bioassay is based on oxygen consumption, which is increased in acutely potassium-iodide-treated mice, resulting in a decrease of asphyxiation time (thyroid activation). This effect is dose-dependently antagonized by antithyroidal compounds, and the time to convulsions is prolonged due to the reduced metabolic rate. The methods based on increased oxygen consumption after thyroid hormones (Sect. N.5.1.1) are applied.

MODIFICATIONS OF THE METHOD

Thyroid weight was an early parameter for the detection of antithyroid activity. Rabbits treated with goitrogenic compounds or fed exclusively with cabbage (Chesney et al. 1928; Marine et al. 1929) showed an up to tenfold increase of thyroid weight, histologically manifested as hyperplasia without colloid formation. These phenomena were reversed by iodine treatment (Bomskov 1937).

Goiter formation as a side-effect of non-steroidal anti-inflammatory drugs was studied by Müller et al. (1985).

N.5.3 Calcitonin

N.5.3.1 General Considerations

The calcitropic hormone (thyro)calcitonin was discovered in C-cells of the thyroid gland by Copp (Copp et al. 1962; Copp 1964, 1994). This hypocalcemic hypophosphatemic principle of the thyroid gland (Austin and Heath 1981) was designated thyrocalcitonin by Hirsch et al. (1964), Munson and Hirsch (1966), Raisz et al. (1967), and MacIntyre (1992). Its calcitropic effects on bone and kidney function are opposite to those of the parathyroid hormone. Calcitonin originates from parafollicular C-cells of the thyroid. Calcitonin secretion can be evaluated *in vitro* using the isolated perfused porcine thyroid (Pento 1985). Radioimmunoassays for calcitonin are available (Tashjian and Voelkel 1979), and species-specific methods for calcitonin determination need to be considered. Assays for calcitonin receptors have been described (Nissenson et al. 1985). Surveys on the effects of exogenous calcitonin was given by Deftos (1989); Braga (1994); Wallach et al. (1999). The biology and clinical relevance of calcitonin gene peptides has been reviewed (Reginster 1993; Silverman 2003; Zaidi et al. 1990).

N.5.3.2 Decrease of Serum Calcium in Rats

PURPOSE AND RATIONALE

The bioassay of calcitonin preparations is performed using their ability to lower the plasma calcium in the rat. This procedure has also been adopted by pharmacopoeias, using the International Reference Preparation for Calcitonin (porcine) consisting of freeze-dried purified pork calcitonin, and the International Reference Preparation for Calcitonin (salmon) consisting of freeze-dried purified synthetic salmon calcitonin. These assays for calcitonin quantitation, however, have now been replaced by a physicochemical method for pharmaceutical quality control. Either intravenous or subcutaneous administration can be chosen. International standards for salmon calcitonin, eel calcitonin, and the Asu^{1-7} analogue of eel calcitonin have been elaborated (Zanelli et al. 1990). A second international standard for porcine and human calcitonins has been established by an international collaborative study group based on the *in vivo* rat hypocalcemia bioassay (Zanelli et al. 1993).

PROCEDURE

Groups of at least five female Wistar rats, weighing 100–120 g, are used. Three doses of standard preparation (1, 3 and 9 mU per rat) and three doses of test preparation are injected intravenously. Then 1 h after injection, blood is withdrawn under light anesthesia. Plasma calcium is determined by flame photometry or by atomic absorption photometry.

EVALUATION

Dose–response curves of decreases in plasma calcium are established and potency ratios with confidence limits are calculated.

MODIFICATIONS OF THE METHOD

Similar studies were reported by: Kumar et.al. 1965; Munson et al. 1968; Rittel et al. 1976; Schwartz et al. 1981;Michelangeli et.al. 1983; Findlay et al. 1985; Buck and Maxl 1990; Deming et.al. 1994

Yates et al. (1990) assessed the acute hypocalcemic responses to single subcutaneous injections of calcitonin preparations in intact young male ICR Swiss mice weighing 12–20 g.

Calcitonin of the stingray and of the goldfish were characterized by Sasayama et al. (1992, 1993).

Kapurniotu and Taylor (1995) performed *in vitro* hypocalcemic assays in mice by analysis of serum calcium 1 h after subcutaneous injection of lactam-bridged analogs of human calcitonin.

N.5.3.3 Effect of Calcitonin on Osteoclasts in Vitro

PURPOSE AND RATIONALE

Calcitonin acts primarily by inhibition of osteoclastic bone resorption (Friedman and Raisz 1965; Aliapoulios et al. 1966). Zaidi et al. (1990, 1994) reported the development and validation of three microbioassays for calcitonin based on calcitonin-induced inhibition of the activity of isolated osteoclasts.

PROCEDURE

Femora and tibiae are removed from newborn Wistar rats. The bones are freed from adherent soft tissues and cut across their epiphyses in HEPES-buffered Medium 199 supplemented with heat-inactivated fetal calf serum, benzyl penicillin (100 µU/ml) and streptomycin (100 µg/ml). The osteoclasts are mechanically disaggregated by curetting the bones of each rat with a scalpel blade into 1 ml medium and agitating the suspension with a pipette. Larger fragments are allowed to settle for 10 s, before the supernatant is dropped onto appropriate substrate (bone slices, plastic Petri dishes or glass coverslips).

Motility-Based System

The morphological appearance of stained osteoclasts is used as an index to assess the state of cytoplasmic activity. Osteoclasts are settled on coverslips in microtiter wells and are incubated for 20 min at 37°C. The coverslips are removed, washed with Medium 199 and placed in separate wells, each containing 100 µl medium.

Following a further incubation for 30 min (37°C), serial dilutions (tenfold) of salmon or human calcitonin or test preparations or appropriate dilutions of plasma samples are added. The cells are finally incubated for 2 h, fixed in 10% glutaraldehyde and stained with toluidine blue. The state of motility of each osteoclast on each coverslip is scored by observing the characteristic shape change these cells undergo when motility is inhibited; a motile cell is characterized by a smooth outline with increased staining intensity over all or part of its periphery, whereas a immotile cell typically shows an irregular pale outline without ruffled edges. The number of immotile cells is counted on each coverslip and expressed as a percentage of the total number of cells counted.

Cytoplasmatic Spreading System

Osteoclasts are settled in tissue culture dishes (35 mm) and are incubated at 37°C for 20 min to allow sedimentation and attachment. The cells are then washed with Medium 199 and 2 ml of the same medium is placed in each well. The dishes are placed in the incubation chamber of an inverted phase-contrast microscope. Images of the osteoclasts are recorded on a time-lapse video recorder. A tracing of their outlines is transferred through a digitizing system into a computer, programmed to measure the area within each tracing.

The outlines of each osteoclast are recorded before or after the addition of calcitonin or vehicle to the cultures. For each variable, the outline of six osteoclasts is traced after a 60-min incubation in the chamber and again 40 min following the addition of the hormone. The mean surface area covered by six osteoclasts after incubation is expressed as a percentage of the mean surface area of the osteoclasts before the addition of hormone or vehicle.

Bone Resorption System

Specimens of human femoral cortical bone are obtained from donors (patients who died without evidence of bone disease). The adherent soft tissue is removed and the bone cortex cut longitudinally into slices (0.1 mm thick). The slices are then cut into pieces (approximately 3 mm^2). They are cleaned by ultrasonication (15 min, in sterile distilled water), dehydrated by immersion in 80% aqueous ethanol for 2 h, and stored to dry at room temperature. Osteoclasts isolated in Medium 199 are dropped onto 12–16 bone slices placed in a well of an 18-mm multiwell dish. Following incubation (37°C, 15 min), slices are removed, and washed gently in Minimal Essential Medium supplemented with 10% FCS and antibiotics as described above. They are placed in separate wells, each well containing five to six slices in 900 µl medium. After further incubation (37°C, 10% humidified CO_2, 10 min), 100 µl of medium containing the test concentration of the hormone or the test solution is added. Human $PTH_{(1–34)}$ (0.1 U/ml) is used to assess functional effects of contaminating osteoblasts.

The calcitonin analogs are tested at various concentrations (tenfold dilutions). Finally, bone slices

are incubated overnight (37°C, 10% humidified CO_2, 18 h). The cells are fixed in glutaraldehyde, stained with toluidine blue and examined by transmitted light microscopy. Osteoclasts and mononuclear cells are counted. The slices are then bleached by immersion in sodium hypochlorite solution for 30 min and dehydrated in 80% aqueous ethanol. Finally, they are sputter coated with gold, randomized and examined in a scanning electronic microscope. The numbers of osteoclastic excavations, each defined by a continuous border, are counted. The area of bone surface resorbed is calculated by tracing the outline of the concavities into a digitizing tablet, linked to a microcomputer. Resorption surface areas may be expressed as a percentage of the mean of the control response.

EVALUATION

Data of each assay are analyzed using classical methods for analysis of parallel line assays. Estimates of relative potencies are calculated from parallel log dose–response lines of test preparations and a reference preparation.

Osteoclasts are mechanically disaggregated from neonatal rat long bones and dispersed at low densities on slices of devitalized bovine cartilage bone. The resulting areas of bone excavation are quantified with micrometric precision by scanning electron microscopy together with computer-assisted image analysis. These findings are used to develop a formal bioassay for calcitonin.

N.5.3.4 Receptor Binding and cAMP Accumulation in Isolated Cells

PURPOSE AND RATIONALE

The human breast cancer cell line T47D responds to calcitonin and its analogs by receptor binding and accumulation of cAMP. This can be used as a biological assay (Findlay et al. 1980, 1983, 1985; Grauer et al. 1992; Sexton and Hilton 1992; Blind et al. 1993).

PROCEDURE

The human breast cancer cell line T47D was originally established from a pleural effusion from an infiltrating ductal breast cancer (Horwitz et al. 1978). For binding experiments, cell monolayers are washed with 0.02% EDTA before treatment with 0.125% trypsin in 0.02% EDTA for 2 min at 37°C, addition of complete medium before centrifugation at 200 *g*, and resuspension in complete medium.

Iodination of calcitonin is performed with ^{125}I using the chloramine-T method.

For binding experiments T47D cells suspended in isotonic buffer are added to ^{125}I-labeled salmon calcitonin mixed with varying concentrations of unlabeled calcitonin or analogs and incubated at 20°C for 1 h. Nonspecific binding is assessed as the binding of ^{125}I-labeled salmon calcitonin in the presence of excess (2 µg/ml) unlabeled salmon calcitonin.

Stimulation of adenylate cyclase in intact T47D cells by calcitonin analogs is assessed by measuring [^{3}H]cAMP production in cells prelabeled with [^{3}H]adenine. Cellular ATP pools are labeled by incubation with 2,8-[^{3}H]adenine (0.5–2 µCi/ml) for 2 h at 37°C in 12-well culture dishes in RPMI 1640 medium containing 0.1% BSA. Cells are then washed twice with serum-free medium and incubated for a further 20 min in medium containing 0.1% BSA and 1 mM isobutylmethylxanthine (IBMX) before treatment with calcitonin and its analogs for 10 min at 37°C in the same buffer. Incubations are terminated by removing medium and adding 100 µl 20% trichloroacetic acid at 4°C. This is followed by 800 µl of a 5 mM solution of ATP, ADP, AMP, cAMP, and adenine. The [^{3}H]cAMP is isolated by chromatography on Dowex and alumina. Radioactivity is counted in a scintillation counter.

EVALUATION

For both parameters full dose–response curves are generated and the concentrations required for half-maximal responses are calculated.

MODIFICATIONS OF THE METHOD

Yates et al. (1990) measured stimulation of adenylate cyclase activity by calcitonin analogs in primary cultures of mouse renal cortex which were prepared according to the methods of Fukase et al. (1982) from 4-week-old ICR Swiss mice and used at confluence after 4 days of culture.

A radioreceptor assay for potency determinations of formulations of salmon calcitonin was described by Sjödin et al. (1990).

Albrandt et al. (1993) cloned two receptors with high affinity for salmon calcitonin from the nucleus accumbens region of rat brain.

Likewise, Sexton et al. (1993) identified in rats two isoforms of the calcitonin receptor, designated C1a and C1b.

Functional aspects of the isoforms C1a and C1b were discussed by Martin et al. (1995).

The calcitonin receptor isoforms C1a and C1b were localized in rat brain using *in vitro* autoradiography by Hilton et al. (1995).

Keustner et al. (1994) cloned and characterized a second form of the human calcitonin receptor from T47D cells.

Sexton et al. (1994) assayed the cloned renal porcine calcitonin receptor cDNA expressed by transient transfection in COS-1 cells or stable transfection in HEK-293 cells for interaction with calcitonin, amylin and calcitonin gene-related peptide. The results suggested that amylin may act as a natural ligand for the renal porcine calcitonin receptor.

The various pathways in signal transduction by calcitonin were discussed by Horne et al. (1994).

Houssami et al. (1994) found that different structural requirements exist for calcitonin receptor binding specificity and adenylate cyclase activation.

Suva et al. (1997) synthesized benzophenone-containing calcitonin analogs and tested them for receptor binding and stimulation of cAMP accumulation.

Povzek et al. (1997) investigated the structure–function relationship of salmon calcitonin analogs as agonists, antagonists, or inverse agonists in heterologous calcitonin receptor expression systems using two calcitonin receptor cell clones, B8-H10 and G12-E12, which express about 5 million and 25,000 C1b receptors/cell, respectively.

The location of the phosphorylation of the human calcitonin receptor by multiple kinases was studied by Nygaard et al. (1997).

N.6 Parathyroid Hormone

N.6.0.1 General Considerations

The primary function of parathyroid hormone (PTH) is to maintain a constant concentration of Ca^{2+} in the extracellular fluid. Processes that are regulated include the absorption of Ca^{2+} from the gastrointestinal tract, the deposition and mobilization of bone Ca^{2+}, and the excretion of Ca^{2+} in urine, feces, sweat, and milk. PTH is the functional antagonist of calcitonin. The most prominent effect is to promote the mobilization of Ca^{2+} from bone. In the kidney, tubular reabsorption of Ca^{2+} is increased and tubular reabsorption of phosphate is inhibited. Clinically, idiopathic or postoperative hypoparathyroidism results in hypocalcemia followed by tetany.

PTH is used for treatment of hypoparathyroidism, and the symptoms of the disease can also be effectively antagonized by oral administration of dihydrotachysterol. A survey on the structure and function of the parathyroid gland in animals was published by Capen and Rosol (1989). The biologically active synthetic human parathyroid hormone 1–34 fragment (active sequence of PTH) is used for diagnostic testing (Mallette 1988).

An experimental model for secondary hyperparathyroidism with elevated levels of parathyroid hormone in rats has been described by Sancho et al. (1989).

Radioligand assays for parathyroid hormone receptors have been described (Habener and Potts 1976; Nissenson et al. 1985; Schneider et al. 1993).

Immunoassays for PTH are those measuring intact hormone (N-terminal, intact) and those measuring inactive fragments and partial sequences of the intact hormone (mid-region, C-terminal, polyvalent) (Endres et al. 1989). An immunochemiluminometric assay has been described by Klee et al. (1992).

Parathyroid hormone-related protein (PTHrP) was first identified and cloned from malignant tumor cells and tissues from patients with a syndrome called humoral hypercalcemia of malignancy (Moseley et al. 1987; Strewler et al. 1987; Suva et al. 1987). PTHrP-(1–34) and PTH-(1–34) act via a single species of cloned receptor (Abou-Samra et al. 1992; Schipani et al. 1993), although other studies have shown that specific receptors for each of these peptides exist (Usdin et al. 1995; Behar et al. 1996; Bergwitz et al. 1997; Yamamoto et al. 1997; Fukayama et al. 1998). PTHrP is an example of the widening array of sequences identified by molecular endocrinology, with functional characterization of their endocrine role often following after a considerable delay.

N.6.0.2 Receptor Binding Assay for PTH

PURPOSE AND RATIONALE

In many instances, the presence of receptors is explored as the counterpart of the presence of hormonally active substances in tissues and organs. However, the presence of binding sites does not immediately indicate functional activation of the respective tissue, and there are indeed circulating "free receptors" which have been identified as subunits of fragments of "whole receptors" located in cell membranes. Cloned receptors are frequently used for advanced research, to identify compounds which might interact with functional receptors in tissues, and acquire relevance as pharmacological tools for example for high-throughput screening. Furthermore, using radioligand assays to determine the receptor affinity of PTH analogs may provide helpful structure–activity information. Three receptors that are activated by PTH have been cloned. PTH and PTHrP bind to the PTH_1 receptor, for which many studies are published (Abou-Samra et al. 1992; Uneno et al. 1992; Schipani et al. 1993; Ureña et al. 1993; Kaufmann et al. 1994; Schermer et al. 1994; Orloff et al. 1995; Usdin et al. 1995; Bergwitz et al. 1996; Gardella et al. 1996; Yasuka et al. 1996; Bergwitz et al. 1997; Bisello et al. 1997; Guo et al. 1997; Yamamoto et al. 1997; Fukayama et al. 1998; Yaghoobian and Drueke 1998).

Behar et al. (1996b) reported ligand binding in stably transfected human embryonic kidney cells, HEK-293/C-21 cells that express the hPTH/PTRrP receptor, and HEK/BP16 cells that express the hPTH2 receptor.

The PTH_2 receptor has about 50% amino acid sequence identity with the PTH_1 receptor and is not activated by PTHrP, but by a peptide isolated from bovine hypothalamus, TIP39, which is only distantly related to PTH and PTHrP (Usdin 2000).

The PTH_3 receptor has been isolated from zebrafish (Rubin and Juppner 1999).

It is part of the problem of advanced research that cloning of receptors frequently precedes the validation of physiological relevance of receptor subclasses.

PROCEDURE

Stably transfected human embryonic kidney cells, HEK-293/C-21 cells that express the hPTH/PTRrP receptor (Pines et al. 1994), and HEK/BP16 cells that express the hPTH2 receptor (Behar et al. 1996a) are maintained in DMEM supplemented with 10% FBS.

The cells are incubated with [^{131}I]PTH-(1–34) (100,000 cpm/well) with or without competing unlabeled PTH-(1–34) or other ligands in binding buffer for 2 h at room temperature. Cells are washed twice with PBS, then solubilized in 0.5 ml of 0.1 M NaOH. Aliquots are taken for determination of bound radioactivity by γ-counting.

EVALUATION

Specific binding is expressed as counts per minute bound per well (raw data) and converted to the percentage specific binding of radioligand. Affinity constants and binding capacity of these receptors in tissue may be calculated, and dose–response curves of ligands are compared as a first step towards proof of signaling and biological activity.

MODIFICATIONS OF THE METHOD

McCuiag et al. (1994) reported the molecular cloning of the gene encoding the receptor for the parathyroid hormone/parathyroid hormone-related peptide in the mouse.

Inomata et al. (1995) characterized a PTH receptor with specificity for the carboxy-terminal region of PTH-(1–84).

N.6.0.3
PTH Assay by Serum Calcium Increase

PURPOSE AND RATIONALE

The classical method by Collip and Clark (1925) involves measurement of the rise in serum calcium after administration of parathyroid extracts to dogs. Hamilton and Schwartz (1932) use rabbits treated with oral loads of calcium chloride. The intact rat is very insensitive to injected parathyroid hormone; however, parathyroidectomy produces an increase in sensitivity (Holtz 1937; Davies and Gordon 1953; Davies et al. 1954; Thorp 1969; Zull and Malbon 1976).

PROCEDURE

Male Wistar rats weighing 200–250 g are anesthetized with pentobarbital sodium intraperitoneally. Parathy-

roidectomy is performed by cauterization. After a recovery period of 1 week, blood is withdrawn by retroorbital puncture (baseline). Various doses of the test preparation or standard are injected subcutaneously to groups of six to ten animals. Blood samples are obtained again 21 h later. Serum calcium is determined by flame photometry. The increase of calcium 21 h after PTH injection is calculated for each animal.

EVALUATION

Mean values of the increase in serum calcium are plotted versus logarithm of dose, and potency ratios versus PTH standard may be calculated for the test compounds.

MODIFICATIONS OF THE METHOD

An increase of whole-body calcium and skeletal mass after repeated-dose treatment with parathyroid hormone in normal rats and in rats with osteoporosis induced by pregnancy and lactation under a low-calcium diet was found by Hefti et al. (1981).

Parathyroid hormone prevented bone loss and augmented bone formation in ovariectomized rats (Kalu et al. 1990; Liu and Kalu 1990).

The active sequence of PTH has been used instead of the full secreted sequence.

N.6.0.4
Serum Phosphate Decrease After PTH

PURPOSE AND RATIONALE

Tepperman et al. (1947) developed a method using the fall in serum inorganic phosphorus in the rat after injection of parathyroid hormone (Thorp 1962).

PROCEDURE

Male Wistar rats weighing 150–200 g are fed Purina dog chow for at least 2 weeks prior to the experiment. During the experiment only water is allowed. Blood samples (baseline and PTH stimulated, 3 h after PTH) are taken from the tail and 0.6 ml is collected from each rat into tubes, centrifuged for 10 min and 0.2-ml samples of the serum are pipetted into 6 ml of 10% trichloroacetic acid; solutions are centrifuged and 5-ml aliquots of the protein-free solution are used for the estimation of inorganic phosphorus, by the method of Fiske and Subbarow (1925) for example. Serum phosphorus is measured before and 3 h after subcutaneous administration of various doses of test preparation or standard.

EVALUATION

Dose–response curves showing a linear relationship between log dose and response are suitable for the calculation of potency ratios.

N.6.0.5
cAMP Release in Isolated Perfused Rat Femur

PURPOSE AND RATIONALE

This is an *in vitro* assay. The effect of parathyroid hormone and analogs on release of cAMP from adult bone can be measured in a perfusion system of isolated rat femora (Sugimoto et al. 1985; Lopez-Hilker et al. 1992).

PROCEDURE

Five-week-old Wistar rats anesthetized with pentobarbital (45 mg/kg) are heparinized and used as donors, the femora are removed. Adhering muscles are stripped from the bone. A hole with about half of the depth of the cortex is made with a fine drill at the nutrient foramen below the femoral neck. Then a 21-gauge needle is inserted into this hole and fixed by dental cement to avoid leakage of the perfusate. The bone is then placed in an apparatus for liver perfusion and perfused at a flow rate of 1 ml/5 min by a pump with Krebs-Ringer-bicarbonate, continuously gassed with 95% O_2 and 5% CO_2 and containing 1 mg/ml glucose. Once the perfused bone is assembled, the bone is allowed to equilibrate for 45 min. Samples are collected into a chilled tube for the last 5 min for determination of basal cAMP levels. Then various doses of the test preparations or the standard are infused for 5 min and serial samples are collected every 5 min. In the perfusate, cAMP is measured by radioimmunoassay.

EVALUATION

Time–response curves and dose–response curves are established allowing the calculation of potency ratios with confidence limits.

MODIFICATIONS OF THE METHOD

Nissenson et al. (1981) measured the activation of canine renal cortical plasma membrane adenylate cyclase activity produced by parathyroid hormone standard and test sera from parathyroid venous effluent of patients with primary hyperparathyroidism, in the presence of the hydrolysis-resistant GTP analog 5′-guanylimidodiphosphate.

Gundberg et al. (1995) compared the effects of parathyroid hormone and parathyroid-hormone-related protein on osteocalcin release in the isolated rat hindlimb and in intact and thyro-parathyroidectomized rats.

Saito et al. (1987) established a new biological assay system for simultaneous measurement of bone resorption and bone mineralization in **organ cultures of chick embryonic femur**. Eleven-day-old chick embryonic femur was labeled with ^{45}Ca *in vitro*. $T_{1/2}$ of calcium efflux was calculated from the sequential release of the label into the medium. Parathyroid hormone increased calcium mobilization, indicating enhanced bone resorption, whereas hydrocortisone and sodium fluoride inhibited bone resorption. Calcitonin was ineffective.

Barling et al. (1989) measured the adenylate cyclase response to parathyroid hormone in cultured rabbit marrow fibroblast cells.

Docherty and Heath (1989) used osteosarcoma cells for an *in vitro* bioassay determining cAMP formation.

N.6.0.6 Renal and Metatarsal Cytochemical Bioassay

PURPOSE AND RATIONALE

Cytochemical bioassays using renal and metatarsal tissue are sensitive enough to detect plasma levels of parathyroid hormone and useful for determining the agonist and antagonist activities of fragments and analogs (Chambers et al. 1978; Goltzman et al. 1980; Bradbeer et al. 1988; Loveridge et al. 1991; Zaman et al. 1991; Bourdeau et al. 1990; Wood 1992).

PROCEDURE

For the **renal cytochemical assay**, kidney segments from vitamin-D-depleted guinea pigs are maintained in non-proliferative organ culture for 5 h using Trowell's T8 medium (GIBCO). The medium is then changed for 8 min before exposure to various doses of the parathyroid hormone standard, the parathyroid hormone fragment or the analog for an additional 8 min.

In the experiments for antagonistic activities, each segment is exposed to a single concentration of hPTH-(1–84) (106 fmol/l) or to hPTH-(1–34) (255 fmol/l) in the presence or absence of the antagonist to be tested. The segments are then shock-frozen to −70°C in *N*-hexane before being sectioned at 16 µm on a cryostat. The sections are examined for glucose-6-phosphate dehydrogenase activity using specific staining. The precipitated formazane is quantified in the cells of the distal convoluted tubules by means of a microdensitometer (wavelength 585 nm). Ten readings with each of two duplicate sections are made and the results presented as the mean integrated absorbance × 100 (±SEM).

For the **metatarsal cytochemical assay**, the metatarsals of young female Wistar rats weighing 50–100 g are removed and the growth plates are isolated. Only the four longest metatarsals have growth plates large enough to be of use. The metatarsals are maintained individually in nonproliferative organ culture in 5–10 ml Trowell's T8 medium buffered to pH 7.6 in an atmosphere of 95% O_2, 5% CO_2 at 37°C for 5 h. After the culture period, the medium is removed and each metatarsal exposed to fresh medium (buffered to pH 7.6 by bubbling with a 95% O_2, 5% CO_2 mixture) containing a low priming dose of PTH (0.5 fg/ml) for 8 min, followed by exposure to known concentrations of a standard PTH preparation or various concentrations of the analog or to dilutions of plasma for 8 min. The metatarsals are then briefly dipped in a 5% solution of polyvinyl alcohol and chilled immediately in *N*-hexane to −70°C.

Each bone is sectioned at 10 µm in a cryostat. The sections are reacted for glucose-6-phosphate dehydrogenase activity in a similar way as described for the renal cytochemical assay. The activity in hypertrophic chondrocytes is linear with respect to time from 10 min, at which time there is enough formazan to be measured, up to 40 min when the density of the formazan formed is too great for a reliable linear response. The enzyme activity in each section is measured in ten individual hypertrophic chondrocytes or osteoblasts lining the metaphyseal trabeculae by scanning and integrating microdensitometry at a wavelength of 585 nm. The results are presented as the mean integrated extinction × 100 (±SE) of ten measurements from each of two sections of each metatarsal.

EVALUATION

Dose–response curves are tested for linearity and parallelism and potency ratios are calculated.

CRITICAL ASSESSMENT OF THE METHOD

The cytochemical assays are sensitive but very time-consuming when compared with other analytical methods for the detection of PTH and PTH fragments.

N.6.0.7 cAMP Accumulation in Cultured Cells

PURPOSE AND RATIONALE

Parathyroid hormone and parathyroid hormone-related protein (PTHrP) stimulate intracellular cAMP accumulation in various cell types in a dose-dependent manner; for example, in PTHrP-overexpressing ROS cells, an osteoblast-like cell line Motomura et al. (1996); in UMR106 cells, a rat osteosarcoma cell line (Oldenburg et al. 1996); in the human osteosarcoma SaOS cell line (Rodan et al. 1987; Fukayama and Tashjian 1994); in COS-7 cells transfected with the human PTH-1 (PTH/PTHrP) receptor and the human PTH-2 receptor (Bergwitz et al. 1997); or in stably transfected human embryonic kidney cells (HEK-293/C-21 cells that express the hPTH/PTRrP receptor and HEK/BP16 cells that express the hPTH2 receptor) (Behar et al. 1996b).

PROCEDURE

Stably transfected human embryonic kidney cells, HEK-293/C-21 cells that express the hPTH/PTRrP receptor (Pines et al. 1994) and HEK/BP16 cells that

express the hPTH2 receptor (Behar et al. 1996a) are maintained in DMEM supplemented with 10%FBS. For cAMP determination, C-21 or BP-16 cells are incubated in 24-well tissue plates with various peptides for 10 min in DMEM in the presence of 1 mM 3-isobutyl-1-methylxanthine. The incubation is terminated by removal of the cell culture medium and addition of perchloric acid (final concentration 30%, vol/vol). Samples are neutralized with potassium bicarbonate and acetylated with acetic anhydrate. Total cAMP values (medium plus cells) are determined by RIA. Data are presented as the percentage stimulation, from the ratio of maximal accumulated cAMP levels obtained in the presence of the highest concentration of the agonist PTH-(1–34) compared to the basal cAMP level. The accumulated cAMP levels (picomoles) are calculated per 100,000 cells. Cell number is determined in a Coulter counter.

EVALUATION

Data are presented as the triplicate mean of $([cAMP]_c/[cAMP]_{PTHmax}) \times 100$ (±SEM) or sample stimulation vs. maximal PTH induced stimulation. $[cAMP]_c$ is the concentration of cAMP accumulated in response to a given concentration of a ligand, and $[cAMP]_{PTHmax}$ is the concentration of cAMP accumulated at the maximal dose (10^{-6} M) of PTH-(1–34).

N.6.0.8 Bone Anabolic Activitym in Ovariectomized, Osteopenic Rats

PURPOSE AND RATIONALE

This is an *in vivo* bioassay which may be used for the beneficial effect of PTH on bone. Vickery et al. (1996) tested an analog of human parathyroid hormone-related protein (1–43) (hPTHrP) in ovariectomized, osteopenic rats.

PROCEDURE

Groups of 3-month-old virgin female rats are subjected to bilateral ovariectomy or sham surgery. The ovariectomized animals are treated by daily subcutaneous injections of 0, 9, 29 or 80 µg/kg of test compound or human parathyroid hormone-related protein (1–43), starting on day 17 after surgery and continuing for 21 days. On day 12 and 19 following the first day of treatment, animals are dosed intraperitoneally with 6 mg/kg of a 3.75 mg/ml solution of calcein (Sigma) in 2% sodium bicarbonate saline. Body weights are recorded, following an 18-h fast, on the last day of treatment. The animals are sacrificed immediately following the last injection and the femurs, tibiae, and L2 vertebrae are excised.

The distal part of the right femur is cut in half longitudinally after removal of the epiphysis. The bone marrow is flushed out using a stream of water. The trabecular and cortical bone are separated using a dental drill. Calcium is extracted by immersion of the trabecular bone for 3 days and the cortical bone for 5 days in 5% trichloroacetic acid. The calcium content of the extracts is determined. Measurement are expressed as mean ±SEM in units of milligrams of Ca^{2+}/distal half femur per 100 g of body weight.

For histomorphometry, the left tibiae from sham, ovariectomized and high-dose-treated rats are removed and fixed in formalin. The tibiae are cut with a diamond disc into three pieces: the proximal 1 cm, 2 cm of the diaphysis, and the distal end. The proximal and diaphyseal portions are transferred to Villanueva stain for 72 h (Villanueva and Lundin 1989). The proximal specimen is then dehydrated through increasing con-

centrations of ethanol (70%–100%), defatted in acetone, and embedded in modified methyl methacrylate. Pairs of 5-µm-thick frontal sections are prepared from the anterior aspect with a microtome. The first section is stained with a modified Masson trichrome technique (Goldner 1938) and the second left unstained.

The diaphyseal portion is also dehydrated, defatted and embedded in methyl methacrylate. Five 150-µm-thick sections are prepared, ground to 100 µm thickness, and mounted unstained.

Growth cartilage thickness is measured by finding the distance between the proximal border of the epiphyseal growth cartilage and the metaphyseal junction at 12 places spaced 0.2 mm apart.

On each slide, a rectangular window is defined as the field for evaluation. The top line is drawn under the primary spongiosa, and the second line is drawn parallel to it and 3.5 mm distally. The side lines are drawn near to, but not touching, the endocortical surface.

Histomorphometric variables are calculated for mean trabecular volume and structure (trabecular thickness, number, spacing, mineralizing surface, individual osteoblast activity, and osteoclast surface). Surface-based, bone-volume-based, and total tissue-volume-based bone formation rates are also calculated.

In the cortical bone of the tibial diaphysis, the periosteal and endocortical surfaces are measured separately. Using transmitted light at 25 × magnification, the periosteal and endo-osteal perimeters are measured. The periosteal single-labeled and double-labeled surface and endo-osteal single-labeled and double-labeled surface are measured using 160 × magnification.

Vertebral processing and electron microscopy are performed in sham, ovariectomized and compound-treated groups. The second lumbar vertebra is removed, dissected from soft tissue, and split sagittally with a diamond saw. The two halves are fixed in a mixture of glutaraldehyde and formaldehyde for 24–48 h at 4°C. The tissue is decalcified in 10% EDTA in 0.1 M cacodylate, pH 7.2, postfixed for 1.5 h in OsO_4, stained in block with uranyl acetate, dehydrated and fixed in Epon. Then 50-nm sections are cut and examined in an electron microscope. Microphotographs are printed at a final magnification of 1300 ×. Each microphotograph is overlaid with a grid with a total test line length of 2.22×10^3 µm. Each intercept of the line with the trabecular surface is scored into one of four categories, depending on the cell type adjacent to the intercept: osteoblasts, osteoclasts, lining cells, no cells. The proportion of the trabecular bone surface area covered by each cell type is estimated by pooling the pictures from each rat and summing the grid points that intersect each cell type, then dividing by the total number of intersection, excluding the "no cell" counts.

EVALUATION

The treatment groups are compared by one-way analysis of variance (ANOVA) followed by Fisher's least-significance difference test to compare each treatment group with the ovariectomized vehicle control group. For the histomorphometric determinations, the Kruskal-Wallis test is applied to assess *r* group differences. For relative surface area cell coverage estimation, the treatments are compared overall as to the proportions of osteoblasts, osteoclasts, lining cells, and no cells using one-way ANOVA.

MODIFICATIONS OF THE METHOD

Anderson et al. (1990) proposed the ovariectomized, lactating Sprague-Dawley rat as an experimental model for the rapid development of osteopenia which may be used to test the effectiveness of bone-retentive drugs, potentially useful for treating osteoporotic women. Rats were ovariectomized on day 2 postpartum and were kept on a low-calcium diet. Measurements of serum total calcium, ionic calcium, albumin and parathyroid hormone were conducted between days 4 and 21 of lactation.

Anterior Pituitary Hormones

Much of the early research on anterior pituitary hormones was performed with extracts obtained from animal pituitary glands, and with animal models for the specific analytical determination of the concentrations of anterior pituitary hormones in serum, in pituitary tissue, and in some cases by measurement of

urinary excretion, for hormones which are excreted during pregnancy, for example. Biosynthetic hormone preparations are now available for human therapy, and species-specific hormone standards are also available for numerous animal species. For an understanding of the development of endocrine research, and the approach to understanding physiology that was necessary, helpful and effective, reference is made extensively to historical methods that are no longer required. As with other fields, the receptors for hypothalamic hormones and anterior pituitary hormones have been characterized and studied, for both a better understanding of regulation, and in several cases structure–activity studies. This approach has also been very helpful in understanding how the sensitivity of the pituitary gland is regulated by both negative feedback of gonadal steroids and the impact of hypothalamic hormones.

N.7.0.1 Hypophysectomy in Rats

PURPOSE AND RATIONALE

This is a classical technique for assessment of the biological effects of pituitary hormones (Collip et al. 1933b; Burn et al. 1952; Vogel 1965; Vogel 1969b). The pituitary gland is removed entirely (anterior and posterior pituitary), the functional deficiencies are identified, and hormone preparations are injected for substitution. Due to the presence of multiple deficiencies after the operation, results by this technique are limited. The approach is of considerable historical interest but has now been replaced by more specific investigation of single hormonal systems. Various techniques of hypophysectomy have been described by Biedl (1916), Thompson (1932), Collip et al. (1933b), Anselmino and Pecharz (1935), and Bomskov (1939) in several animal species, including dog, cat, rabbit, ferret, guinea pig, rat, mouse, chicken, and frog. For some time, hypophysectomy in the rat has been applied to biological standardization of anterior pituitary hormones.

Nowadays, hypophysectomized rats may be obtained from certified suppliers who are licensed to perform the required operation, and who are experienced in postoperative handling and maintenance.

PROCEDURE

In the rat, the parapharyngeal approach is less destructive than the transauricular approach, and is preferred for bioassay. Male Wistar or Sprague-Dawley rats weighing 110–150 g are anesthetized with modern anesthetics, and placed on a surgical table in a recumbent position. The head is tilted backwards to expose the operating field, the fur is removed with electric clippers, and the field of surgery is cleaned with alcohol. A median incision is made 2.5 cm in front of the sternum. The large salivary glands and the maxillary lymph nodes are retracted, the muscles over the trachea are divided at the midline, slightly below the thyroid a hole is made in the trachea ("tracheotomy"), and tracheal mucus is removed by vacuum aspiration. The insertion of a tracheal cannula is not necessary.

A deep blunt dissection is made directly medial to the tendon of the left or right digastric muscle. The ipsilateral glossopharyngeal nerve and the blood vessels are drawn to one side, and the pharynx and trachea are drawn to the other side, for an approach to the midline of the base of the skull. For the subsequent procedure, the use of an operating microscope is recommended (stereo microscope)

The base of the skull is cleaned using small pellets of cotton-wool. The spheno-occipital suture running between both mastoid processes is exposed. From behind, the crista occipitalis runs longitudinally up to the middle of this suture. Just at this point, a small hole is drilled at the base of the skull with a dental drill, taking care to leave the surrounding sinus blood vessels intact. The pituitary is now visible as a small, lens-shaped organ. With the tip of a fine glass tube, attached to a suction device, the pituitary gland is removed by aspiration. Occasional bleeding is stopped with a cotton-wool pellet. The trachea is now cleaned by suction pump and the wound closed. Animals are placed carefully in padded recovery cages, at an ambient temperature of 20–22°C for recovery. The removal of the posterior pituitary gland causes the animals to have experimentally induced diabetes insipidus and therefore they need access to sufficient quantities of drinking water.

MODIFICATIONS OF THE METHOD

Instead of a parapharyngeal approach, the **transauricular approach** may be used (S. Jung and H. G. Vogel unpublished data) to facilitate surgery. Male rats weighing 120–150 g are anesthetized and placed on their right side. The head is fixed between the thumb and the index finger of the left hand. In the perpendicular direction, a dental drill with a diameter of 2.2 mm is introduced into the meatus acusticus externus osseus. First, the fine lamellae of the middle ear are passed. Then, the drill is directed from the external ear to the contralateral orbita. In this way, the thin inner wall of

the bulla tympani is perforated. The junction of the bulla tympanica, os occipitale and os sphenoidale is located here. A small, straight forceps is introduced to remove bone fragments, and a blunt cannula diameter 1.6 mm is introduced to remove the pituitary gland by suction. The procedure needs much more technical skill than the current pharyngeal approach, and is more destructive.

N.7.1 Gonadotropins

N.7.1.0.1 General Considerations

Selection of assay methods depends on the study's objectives, i. e., whether it is the biological activity of gonadotropins or the quantitative response of elements in the signaling chain being assessed. The biological assays have been widely replaced by methods for receptor binding and receptor-induced response (signaling).

Follicle-stimulating hormone (FSH) and luteinizing hormone (LH) are glycoproteins which exist in multiple molecular isoforms (microheterogeneity) with different molecular weights and with different degrees of glycosylation (Ulloa-Aguirre et al. 1988; Dahl and Stone 1991). The fine differences identified by analytical methods are not relevant for the bioassay, which measures the sum of biological activities. The immunological methods provide limited information on biological activity and need to be validated for detection of the intact hormone or cross-reactivity with inactive subunits. *In vivo* animal bioassays are available (e. g., the Steelman–Pohley assay), and *in vitro* cell bioassays with a high degree of sensitivity and specific radioreceptor assays have been developed (Simoni and Nieschlag 1991). Striking differences in assay results were found when comparing estimates obtained by *in vivo* bioassays, *in vitro* cell assays, receptor-binding assays, and immunoassays with the International Standard for Pituitary FSH, when assayed in terms of the Second International Reference Preparation of Human Pituitary FSH and LH (Storring and Gaines Das 1989).

For binding assays, gonadotropin receptors of various animal species have been cloned (Poyner and Hanley 1992). Time-resolved fluoroimmunoassay for gonadotropins has been proposed by Iwasawa et al. (1994). Application of methods for detection and quantification depends on the research objective, which may be targeted to physiological functions, or to the biochemical identification of isoforms and subunits (Imse et al. 1992).

N.7.1.1
Follicle-Stimulating Hormone (FSH)

Some of the methods described here are used for quantal assay of biological FSH activity (in animals and *in vitro*); others are used for FSH activity in samples from nonclinical and clinical studies.

N.7.1.1.1
Ovarian Weight in hCG-Primed Rats

PURPOSE AND RATIONALE

Follicle-stimulating hormone (FSH) increases the weight of ovaries in immature rats by inducing follicular maturation in a dose-related manner. This effect is greatly enhanced by simultaneous administration of a constant dose of human chorionic gonadotropin (hCG) for luteinization of the follicles, allowing the detection of low amounts of FSH (Steelman and Pohley 1953).

PROCEDURE

Immature female Sprague-Dawley rats weighing 40–45 g are treated for 3 days by subcutaneous injections of FSH (twice per day), using three doses of the standard (e. g., ovine NIH-FSH-S-9, National Institute of Health, Bethesda, Md., USA) or the test preparation (at the same dose interval). A constant amount of 25 IU hCG (Primogonyl, Schering, Berlin) is added. Hormone preparations are injected in physiological saline containing 2% gelatin. Six to eight animals are used per group. Then, 18 h after the last injection, the animals are sacrificed, then the ovaries are dissected out and weighed to the nearest 0.1 mg.

EVALUATION

Dose–response curves for standard and test compounds are plotted and potency ratios with confidence limits are calculated.

CRITICAL ASSESSMENT OF THE METHOD

The Steelman–Pohley test is rather specific for FSH. The addition of luteinizing hormone (LH), thyroid-stimulating hormone (TSH), adrenocorticotropin (ACTH), human growth hormone (hGH), or prolactin did not influence the dose–response curves of FSH (Christiansen 1972b). The method has been adopted by pharmacopoeias (e. g., British Pharmacopoeia 1988).

MODIFICATIONS OF THE METHOD

Similar studies were reported by: Evans et al. 1939; Brown 1955; Segaloff 1962; Parlow and Reichert 1963; Christiansen 1972a; Storring and Gaines 1989

Igarashi and McCann (1964) reported a bioassay for FSH in mice using an added constant dose of hCG for augmentation, and uterine weight as the endpoint.

Brown and Wells (1966) described an assay of human urinary FSH with hCG augmentation, using ovarian weight in mice as the endpoint. The method has been used by Wide and Hobson (1986) to identify the effect of the assay method used to select the most active forms of FSH from human pituitary extracts.

Lamond and Bindon (1966) recommended the use of immature hypophysectomized mice for the assay of FSH with hCG augmentation, using uterine weight as endpoint.

Gans and van Rees (1966) studied a testicular augmentation assay method for FSH. Immature male rats were hypophysectomized and on the same day the right testis was removed and weighed. Treatment with various doses of FSH together with a constant dose of 20 IU hCG was started on the next day and continued for 6 days. On the 7th day, the animals were sacrificed and the remaining left testis was removed and weighed. The difference between weights of the right and left testis in each animal was used as the endpoint.

Uberoi and Meyer (1967) used the uterine weight of the immature rat as a pituitary gonadotropin assay, with augmentation by hCG.

Results obtained with the *in vivo* bioassay (Steelman and Pohley 1953) have been compared with an *in vitro* bioassay based on estradiol production by cultured Sertoli cells, and with an FSH immunoassay by Storring et al. (1981).

N.7.1.1.2 [^{3}H]Thymidine Uptake in Cultured Mouse Ovaries

PURPOSE AND RATIONALE

Follicle-stimulating hormone stimulates [^{3}H]thymidine uptake by cultured mouse ovaries in a dose-dependent manner, using the tissue-specific proliferation response of the follicles (Ryle 1971; Boggins and Ryle 1972).

PROCEDURE

Intact ovaries are obtained from 15-day-old mice. They are dissected carefully with the aid of a stereomicroscope and transferred to culture dishes. Each ovary is placed on a strip of lens tissue supported on a stainless steel mesh grid 4 mm above the floor of a plastic Petri dish and incubated in Eagle's medium supplemented with glucose and glutamine. The dishes are gassed with 5% CO_2 in air at 37°C. Three replicate dishes are used for each concentration of the standard (0.1 and 0.4 IU/ml) and of the test preparation. [^{3}H]Thymidine (0.02 µC) is added to each dish the day after the cultures are set up. Three days later the tissue is prepared for counting. Each grid is irrigated with about 5 ml saline solution. The ovary is then transferred to a counting vial and dissolved for counting the incorporated radioactivity in a liquid scintillation counter.

EVALUATION

Dose–response curves of [^{3}H]thymidine uptake are established for the standard and the test preparation, and potency ratios with confidence limits are calculated. Advantages over animal bioassays include increased specificity and a reduced requirement for a purified test preparation, which may be available only in small quantities.

CRITICAL ASSESSMENT OF THE METHOD

The [^{3}H]thymidine uptake by cultured mouse ovaries has found less acceptance than other *in vitro* methods described below.

MODIFICATIONS OF THE METHOD

Follicle cultures from mouse ovaries for the study of follicular metabolism have been described by Boland et al. (1993).

N.7.1.1.3 Granulosa Cell Aromatase Assay in Vitro

PURPOSE AND RATIONALE

The granulosa cell aromatase assay *in vitro* is based on the principle of the *in vivo* bioassay of Steelman and Pohley (1953), in which the ovarian weight response is the result of FSH-induced follicular maturation and induced estradiol production, which stimulates ovarian growth. The co-administration of human chorionic gonadotropin (hCG) at a standard amount enhances androgen production by theca cells, which in turn provides the androgen substrate for FSH-dependent aromatase activity in granulosa cells. Hsueh et al. (1983) and Jia and Hsueh (1985) developed a sensitive *in vitro* bioassay for FSH based on the stimulation of estrogen production by cultured granulosa cells in serum-free medium containing androstenedione.

PROCEDURE

Intact Sprague-Dawley rats (21–22 days old) are implanted with Silastic capsules containing diethylstilbestrol to stimulate granulosa cell proliferation. Four

days after implantation, the animals are sacrificed and ovaries are dissected for granulosa cell collection. The ovaries are decapsulated, follicles are punctured with 27-gauge hypodermic needles, and granulosa cells are carefully expressed into McCoy's 5a medium. An aliquot is diluted with trypan blue stain, and viable cells are counted with a hemocytometer. Cells are cultured in 16-mm, 24-well culture plates for 2–3 days at 37°C in a humidified, 95% air–5% CO_2 incubator. Each well contains 5×10^4 viable cells in 0.5 ml McCoy's 5a medium supplemented with 2 mM L-glutamine, 100 U/ml penicillin, 100 µg/ml streptomycin sulfate, 10^{-7} M diethylstilbestrol (DES), 10^{-6} M androstenedione (as aromatase substrate), 0.125 mM 1-methy-3-isobutylxanthine (MIX), 1 µg/ml insulin, and 30 ng/ml hCG.

For the measurement of FSH bioactivity in serum samples, each test is performed in triplicate at three dose levels (5, 10, and 20 µl). To ensure a constant volume of 20 µl serum in the total incubation volume of 500 µl, gonadotropin-free serum is added as required. For the FSH standard curve, 4% gonadotropin-free serum is added to the culture medium. The sensitivity is increased when the serum is pretreated with 12% polyethylene-glycol (PEG, mol. wt. 8000). After a culture period of 3 days, estradiol content in the medium is measured by radioimmunoassay (RIA).

EVALUATION

RIA data are analyzed using weighted logit-log regression analysis. Calculation of FSH bioactivity in serum samples or test preparations is performed using a standard curve fitted with a second-order polynomial.

MODIFICATIONS OF THE METHOD

Dorrington et al. 1975; Hsueh et al. 1984; Jia and Hsueh 1986; Dahl et al. 1989; Fauser et al. 1989; Storring and Gaines 1989; Matzkin et al. 1990; Simoni and Nieschlag 1991; YoungLai et al. 1992

Sensitivity may be improved by using a specific response of the follicles. Beers and Strickland (1978), Wang and Leung (1983), Combarnous et al. (1984), and Thakur et al. (1990) found that FSH led to a dose-dependent increase of plasminogen activator production in cultures of rat granulosa cells. This assay has been found to be extremely sensitive: as little as 10^{-15} mol of FSH could be detected.

Ax and Ryan (1979) found that FSH dose-dependently stimulates ^{3}H-glucosamine incorporation into proteoglycans by porcine granulosa cells *in vitro*.

Bhargava et al. (1989) used normal human ovarian cells for long-term cultures. These cells produced progesterone from cholesterol or pregnenolone and estrone from androstenedione when stimulated by FSH.

N.7.1.1.4 Sertoli Cell Aromatase Assay in Vitro

PURPOSE AND RATIONALE

The Sertoli cell aromatase assay was first described by Van Damme et al. (1979). This *in vitro* bioassay was developed following the observation by Dorrington et al. (1975) that FSH, but not LH, stimulates estradiol production by cultured Sertoli cells from immature rats. The assay has been further improved by Ritzén et al. (1982), Shah and Ritzén (1984), and Padmanabhan et al. (1987). These assays are used to determine bioactive FSH in serum for diagnostic use, and they are also applicable for measuring the activity of FSH preparations intended for therapy.

PROCEDURE

Sertoli cells are obtained from 7- to 10-day-old male Sprague-Dawley rats. Testes are decapsulated, the testicular tissue is chopped twice, at right angles, with a mechanical tissue slicer and incubated in culture medium containing 0.03% collagenase and 0.003% trypsin inhibitor for 5–10 min at 34°C. After the initial dispersal, seminiferous tubules settle to the bottom of the incubation flask, and the medium is decanted to remove interstitial cells. The tubules are washed several times; resuspended in medium that contains collagenase, trypsin inhibitor and 0.03% DNase (to prevent clumping of cells), and then incubated for 30 min at 34°C. During incubation, dispersion of Sertoli cells is hastened by repeated aspiration with a Pasteur pipette. The resulting cell suspension is washed three times; cell number and viability are determined by counting in trypan-blue-dye-containing medium. Cells are suspended in a density of 5×10^5 viable cells/ml. One milliliter of cell suspension is transferred to each well of Falcon multiwell culture dishes (16 mm diameter, Falcon Plastics, Oxnard, Calif., USA).

Sertoli cells are cultured in medium comprised of the following constituents: 1:1 (vol/vol) mixture of Ham's F-10 nutrient mixture and Dulbecco's Modified Eagle's Medium that contains 1.2 g/l sodium bicarbonate, 20 mg/l gentamicin, and 1 mg/l amphotericin. Also included in the medium are: 1 µg/ml insulin, 5 µg/ml transferrin, 10 ng/ml epidermal growth factor, 20 pg/ml T_4, 10^{-8} M hydrocortisone, and 10^{-6} M retinoic acid. The cell cultures are incubated in this medium in a water-saturated atmosphere that consists of 95% air and 5% CO_2 at 37°C.

After an initial incubation of the cell monolayers for 72 h, the medium is removed; the cells are washed once with the medium and re-incubated in the medium described above, which contains 2.5×10^{-6} M 19-hydroxyandrostenedione, FSH standard or unknown samples at various concentrations, and 0.1 mM methylisobutylxanthine (MIX). After a 24-h incubation, the medium is aspirated and centrifuged. The resultant supernatants are stored frozen until estradiol measurement by radioimmunoassay (England et al. 1974).

EVALUATION

The results are expressed as picograms of estradiol formed per milliliter culture medium. To evaluate changes in estradiol secretion with changes in FSH concentration, regression analyses are performed. From these data, activity ratios with confidence limits are calculated.

MODIFICATIONS OF THE METHOD

Similar studies were reported by: Dorrington and Armstrong 1975; Marana et al. 1974; Storring et al. 1981; Zaidi et al. 1981; Foulds and Robertson 1983; Wide and Hobsen 1983, 1986; Khna et al. 1984; Harlin et.al. 1988; Storring and Gaines 1989; Simoni and Nieschlag 1991;

Rao and Ramachandran (1975) used isolated rat seminiferous tubule cell preparations free of Leydig cells for determination of cyclic AMP production as an *in vitro* assay for FSH.

Sairam and Manjunath (1982) used rat seminiferous tubular suspensions containing Sertoli cells, incubated them with FSH preparations and measured cyclic AMP formation as the endpoint.

N.7.1.1.5 Receptor Binding Assay for FSH

PURPOSE AND RATIONALE

Significant differences between the receptor binding activity of FSH preparations and biological activity have been found by Marana et al. (1979), Zaidi et al. (1981), Foulds and Robertson (1983), and Burgon et al. (1993). This is attributed to measuring binding activity, which may differ from subsequent intracellular signaling. Several receptor binding assays have been described [Cheng (1975); Andersen et al. (1983) using bovine testes; Reichert (1976) using rat testes tubule tissue].

PROCEDURE

Membrane preparations from bovine testes are used according to the Cheng (1975) and Andersen et al. (1983). Fresh bovine testes or testes from rats weighing 220–280 g are decapsulated and rinsed with cold 0.025 M Tris-HCl buffer at pH 7.2, containing 0.3M sucrose, and then minced and homogenized with a Polytron homogenizer at maximum speed for 30 s at a concentration of 5 ml buffer per gram of tissue. The homogenate is first filtered through four layers, and the filtrate is again filtered through eight layers of cheesecloth. The filtrate is then centrifuged at 12,000 *g* for 30 min at 4°C. The pellet is discarded and the supernatant is further centrifuged at 100,000 *g* for 1 h at 4°C. The supernatant is discarded and the pellet resuspended in cold 0.025 M Tris-HCl buffer at pH 7.2, containing 10 mM $MgCl_2$, at a concentration of 1 ml buffer per gram of the original weight of the testis. The isolated membranes are stored at −70°C in aliquots of 10 ml per vial until use.

For assays, 12/75 mm glass disposable tubes are used. To each tube, 0.2 ml of 0.025 M Tris-HCl buffer at pH 7.2, containing 10 mM $MgCl_2$ and 0.1% BSA, 0.1 ml of standard FSH or unknown samples in the same buffer, 0.1 ml of ^{125}I-hFSH tracer labeled by the lactoperoxidase method (50,000 cpm, approximately 2 ng), and finally 0.1 ml of plasma membrane receptors of appropriate dilution (approximately 1–2 mg/ml) are added to reach a final volume of 500 µl per tube. All the above solutions are kept at 4°C before use. The tubes are then shaken vigorously and incubated at room temperature for 20 h. Following incubation, the reaction is stopped by adding 3.0 ml of cold 0.025 M Tris-HCl buffer containing 0.1% BSA. After centrifugation at 4000 rpm for 30 min, the supernatant is drained and the tip of each tube is dried. The pellet remaining at the bottom of the tube is counted in an automatic gamma counter.

EVALUATION

Specific binding (%) is defined as $(C_B - C_N) \times 100/C_T$, where C_B is the cpm bound to the testicular receptor (pellet), C_N is the nonspecific bound cpm (not

displaced by 1000-fold excess of unlabeled hFSH), and C_T is the total cpm added per tube. For standard curves, the specific binding of tracer ^{125}I-hFSH in the absence of cold hormone (6%–8% by 150–200 µg of receptor protein) is taken as 100% bound ^{125}I-hFSH, and the nonspecific bound ^{125}I-hFSH (1%–2% of the total cpm added) as the baseline. The specific binding of ^{125}I-hFSH over a range of hFSH concentrations is used for calculating a standard curve and sample concentrations.

MODIFICATIONS OF THE METHOD

The method has been used by several authors: Lee and Ryan 1973; Schwartz et al. 1973; Ketelslegers and Catt 1974; Reichert and Bhalla 1974; Calvo et. al 1986; Storring and Gaines 1989

Simoni et al. (1993a) analyzed the biological and immunological properties of the International Standard for FSH 83/575 by isoelectrofocusing and made a comparison with other FSH preparations. The results suggested that the international standard 83/575 is not fully representative of pituitary and serum FSH, and its use for calibration of immunometric methods based on monoclonal antibodies is unlikely to resolve problems of inaccuracy in the measurement of serum FSH.

Grasso et al. (1993) studied the effects of a testicular toxicant on FSH binding to membranes of cultured rat Sertoli cells, as a method in toxicology.

Wakabayashi et al. (1997) reported the cDNA cloning and transient expression of a chicken gene encoding an FSH receptor.

Simoni et al. (1993b) analyzed the molecular heterogeneity of two batches of commercially available urofollitropin by immunofluorometric assay, radioligand receptor assay and *in vitro* bioassay.

N.7.1.2 Luteinizing Hormone (LH) = Interstitial Cell Stimulating Hormone (ICSH)

Some of the methods described here are classical animal bioassays for LH/ICSH preparations, others are *in vitro* bioassays used in research and for clinical samples.

N.7.1.2.1 Prostate Weight in Hypophysectomized Rats

PURPOSE AND RATIONALE

The assay is based on a biological response. Injection of luteinizing hormone (ICSH) in hypophysectomized

male rats causes enlargement of the testes and the secondary sexual organs. The interstitial cells of the testes (Leydig cells) are stimulated by LH/ICSH and secrete androgens which in turn stimulate the accessory organs, such as the ventral prostate of the rat.

PROCEDURE

The method has been used by several authors: Greep et al. 1942; Segaloff et al. 1956; Segaloff 1962; British Pharmacopoeia 1988;

Immature male Sprague-Dawley rats aged 21 days are hypophysectomized. From the 2nd to the 5th day, they receive daily subcutaneous injections of two or more doses of the test preparation and the LH/ICSH standard. They are sacrificed on the 6th day. Both testes and the ventral prostate are prepared and weighed. LH/ICSH – but not FSH – induces a specific dose-dependent increase of prostate weight, whereas FSH also induces an increase of testis weight. A predominant LH activity in the test material mainly stimulates prostate weight, but not testis weight.

EVALUATION

Dose–response curves are plotted for the ventral prostate of each group of test preparation or standard allowing the calculation of activities and potency ratios with confidence limits.

N.7.1.2.2 Superovulation in Immature Rats

PURPOSE AND RATIONALE

An assay for evaluation of luteinizing hormone (LH) and the luteinizing component of human chorionic gonadotropin (hCG) was described by Zarrow et al. (1958). The sensitivity of the response is enhanced by priming with pregnant mares' serum gonadotropin (PMSG – mainly follicle-stimulating hormone activity) and by intravenous injection of the LH test preparation.

PROCEDURE

Groups of five immature female rats (Charles River strain, age 21 days) are treated with a priming dose of 30 IU of PMS to induce follicular development. Increasing doses of LH reference or test preparations are injected intravenously 56 h later, to induce ovulation. Then 24 h after the final injection, the animals are sacrificed, the fallopian tubes are removed and examined under a dissecting microscope (magnification of 40×) ϕ for the presence oocytes (ova). Ovulation is easily noted by an enlarged translucent segment of the tube, through which the ova can be seen. The segment is punctured with a dissecting needle and the entire cumulus clot containing the ova is expelled. The clump containing the oocytes is treated with hyaluronidase, and the number of ova is counted.

EVALUATION

Doses–response curves are obtained using three doses of standard/reference and test preparation for the calculation of potency ratios with confidence limits.

N.7.1.2.3 Ascorbic Acid Depletion of Ovaries in PMSG/hCG-Primed Rats

PURPOSE AND RATIONALE

Luteinizing hormone (LH, also known as interstitial cell stimulating hormone or ICSH) induces dose-dependent depletion of ascorbic acid in the ovaries of rats primed with pregnant mares' serum gonadotropin (PMSG) and human chorionic gonadotropin (hCG) (Parlow 1961; Parlow and Reichert 1963; Sandow et al. 1972.

PROCEDURE

Female Sprague-Dawley rats weighing 40 ± 5 g are injected with 50 IU PMSG (e. g., Anteron, Schering, Berlin) in 0.2 ml saline subcutaneously on day 1 at 3:00 p.m. On day 3, the rats receive 25 IU hCG (e. g., Primogonyl, Schering, Berlin) subcutaneously at 9:00 a.m. On day 7, three different doses of the standard (e. g., NIH LH-S-1, National Institute of Health, Bethesda, Md., USA) and the test substance are injected subcutaneously. Eight animals are used per group. Three hours later, the animals are sacrificed,

and both ovaries are removed, weighed, and homogenized for determination of ascorbic acid content.

EVALUATION

Dose–response curves for standard and test compound are plotted and activity ratios with confidence limits calculated.

N.7.1.2.4 Testosterone Production by Leydig Cells in Vitro Induced by LH

PURPOSE AND RATIONALE

Luteinizing hormone (LH) increases the biosynthesis and secretion of androgens in the Leydig cells of the testes. This can be used for an *in vitro* assay using isolated Leydig cells.

PROCEDURE

For Leydig cell isolation, male Wistar or Sprague-Dawley rats weighing 250–300 g are sacrificed, the testes removed and immediately decapsulated. Two testes are then digested with 7 ml of collagenase solution (1 mg collagenase/1 ml Gibco medium 199) at 37°C for 18 min. Plastic tubes of 40 ml capacity with tight-fitting caps are used, and are placed longitudinally in the water bath with constant shaking (75 cycles/min). After incubation, 15 ml of cold saline is added to each tube. The tubes are inverted a few times and then left at 4°C for 10 min. The supernatants are then carefully siphoned off from the top. The clear supernatant is mixed with an equal volume of 26% Ficoll/0.4% BSA/medium 199 at pH 6.5, and then centrifuged at 1500 *g* for 10 min at 4°C. The cell pellet obtained from the centrifugation is suspended in a known volume of incubation medium (Medium 199 containing 1% BSA and 0.01% lima bean trypsin inhibitor). An aliquot of the cell suspension is taken for counting in a Coulter counter, and the balance is diluted with the incubation medium giving a density of 4×10^6 cells/ml.

For each assay, 0.25 ml of the cell suspension is used. The assay is carried out in 12×75 mm plastic tubes incubated with graded doses of test compound at 37°C. Constant shaking (100 cycles/min) under a 95% O_2/5% CO_2 atmosphere for 3 h is required. At the end of the incubation, each tube is centrifuged, and the supernatant is assayed for testosterone by a radioimmunoassay (Dufau et al. 1972). The assay is carried out in triplicate and needs to be repeated at least once with different batches of donor animals.

EVALUATION

Dose–response curves are obtained with various doses of standard and test preparation to allow calculation of activities and potency ratios with confidence limits.

MODIFICATIONS OF THE METHOD

Similar studies were reported by: Van Damme et al. 1974; Dufau et al. 1976; Janszen et al. 1976; Dufau et al. 1977; Khan et al. 1984; Liu et al. 1984; Harlin et al. 1988; Stadler et al. 1989;Haavisto et al. 1990; Rodgers et al. 1992

N.7.1.2.5 Receptor Binding Assay for LH

PURPOSE AND RATIONALE

LH receptors are membrane receptors that mediate the initial hormone binding step; they are suitable for structure–activity studies and *ex vivo* analysis of receptor concentration changes. Luteinizing hormone is a glycoprotein composed of an α- and a β-subunit. Carbohydrate moieties are attached to both. Removal of the carbohydrate chains reduces bioactivity but enhances receptor binding.

PROCEDURE

For the preparation of Leydig cell receptors, the partially purified Leydig cells obtained from Ficoll gradient centrifugation as described above for the testosterone formation test are used. The cell pellet obtained from the Ficoll gradient centrifugation is first washed twice with unlabeled radioligand buffer (0.1 M Tris-HCl, pH 7.4, containing 5 mM $MgCl_2$, 0.1 M sucrose, and 0.1% BSA). The pellet is resuspended in a known volume of the same buffer. An aliquot of this suspension is taken for cell counting in a Coulter counter, and the balance is homogenized in a Polytron homogenizer for 10 s to break up the cells. This prevents internalization of the hormone molecule during the binding assay. The iodination of LH is carried out according to the chloramine-T method (Liu et al. 1977). After the addition of 2.5 ng of ^{125}I-labeled LH tracer, the binding assay is carried out at 37°C for 2 h with constant shaking. The hormone–receptor complex is then separated by centrifugation and bound radioactivity is counted in a Packard gamma-counter.

EVALUATION

Competitive–inhibition curves for specific binding are established and binding capacity is calculated.

MODIFICATIONS OF THE METHOD

Similar studies were reported by: Liu et al. 1974; Catt et al. 1976; Liu et al. 1984

Lee and Ryan (1972) described specific binding of human luteinizing hormone (LH) to homogenates of luteinized rat ovaries.

Storring and Gaines-Das (1993) described the second International Standard for Human Pituitary LH. Two new batches (coded as 80/552 and 81/535) were compared with the International Reference Preparation of Human Pituitary LH for Immunoassay (IRP 68/40) by 19 laboratories in 11 countries, using *in vivo* and *in vitro* bioassays, a receptor assay and immunoassays. An activity of 35 International Units of Human Pituitary LH was assigned to the contents of each ampoule coded 80/552.

Selvaraj and Moudgal (1993) used sheep luteal membranes for an LH receptor assay capable of measuring serum LH/chorionic gonadotropin (CG) in a wide variety of species.

Chen and Bahl (1993) reported a high expression of the hormone-binding active extracellular domain (1–294) of rat lutropin receptor in *Escherichia coli*.

Jia et al. (1993) developed a LH/CG bioassay using 293 cells permanently transfected with the human LH receptor cDNA and a luciferase reporter gene driven by a cAMP-dependent promoter.

Selvaraj et al. (1996) established a radioreceptor assay for LH/CG in human sera using immortalized granulosa cells transfected with LH/CG receptor.

N.7.1.3 Other Gonadotropins

GENERAL CONSIDERATIONS

The pituitary gonadotropins are species specific and exist in various isoforms containing different carbohydrate moieties. In the treatment of infertility, they were substituted by gonadotropin preparations from human urine purified by extraction (human menopausal gonadotropin, hMG, and human chorionic gonadotropin, hCG, from urine in pregnancy), containing variable proportions of follicle-stimulating and luteinizing activity. Pituitary gonadotropins for the treatment of infertility are now obtained by biosynthesis (recombinant DNA methods). Their structure closely resembles human FSH and LH.

Human chorionic gonadotropin (*hCG*) is excreted in the urine of pregnant women, and may also be excreted by tumors, such as hydatidiform mole and chorionepithelioma. hCG is measured as a tumor marker, and for the diagnosis of early pregnancy. hCG has mainly LH-like activity. Purified preparations of hCG and hMG are tested by bioassays.

Human menopausal gonadotropin (*hMG*) is excreted in the urine of postmenopausal women. hMG has predominantly FSH-like activity and was used to induce follicular maturation.

A gonadotropin preparation previously used in therapy is *pregnant mares' serum gonadotropin* (*PMSG*). Pregnant horses secrete large amounts of pituitary gonadotropin, which is not excreted in the urine and accumulates in serum. PMSG has predominantly FSH-like activity.

N.7.1.3.1 Corpus Luteum Formation in Immature Mice (Aschheim–Zondek Test)

PURPOSE AND RATIONALE

Aschheim and Zondek (1927, 1935) injected the urine of pregnant women (containing FSH and LH activity) into immature female mice and observed the ovulation and formation of corpora lutea. This procedure was widely used as a biological pregnancy test and later replaced the hCG assays. Further studies were performed by Hamburger and Pedersen-Bjergaard (1937).

PROCEDURE

Groups of 10–20 mice, 21 days of age, are treated with 5 equal subcutaneous injections of urinary extracts over the course of 48 h. The animals are sacrificed 96 h after the first injection. The ovaries are dissected and the formation of corpora lutea is observed by examination with a lens or a stereomicroscope. Rupture of follicles is indicated by blood spots.

EVALUATION

The number of ovaries showing the formation of corpora lutea was expressed as dose–response curves.

N.7.1.3.2 Biological Assay of hCG in Immature Male Rats

PURPOSE AND RATIONALE

The LH-like activity of hCG can be determined by measuring the weight increase of the prostate and seminal vesicles in immature male rats.

PROCEDURE

Immature male Sprague-Dawley rats at an age between 21 and 24 days are assigned at random to six groups of at least five animals. Three doses of standard (e. g., 4, 8, and 16 IU) and corresponding doses of the test preparation are dissolved in albumin-phosphate buffer, pH 7.2, and injected subcutaneously daily over a period of 4 days. On the 5th day, the animals are sacrificed and the seminal vesicles and prostate glands are prepared and weighed.

EVALUATION

Dose–response curves of the weights of seminal vesicles and ventral prostate glands are established for standard and test preparations allowing calculation of potency ratios with confidence limits.

MODIFICATIONS OF THE METHOD

The United States Pharmacopoeia USP 23 (1995) requests standardization of hCG in immature female rats at an age of 20–23 days. The animals are injected subcutaneously with three different doses of test preparation or standard daily on 3 days consecutively. They are sacrificed on the 5th day and the uteri are prepared and weighed.

N.7.1.3.3 Receptor Binding Assay for hCG

PURPOSE AND RATIONALE

The initial binding step to the luteinizing hormone (LH) receptor is used for quantification; the receptors may be obtained from superovulated rat ovaries, or from other tissues. Selvaraj et al. (1996) described an *in vitro* bioassay and radioreceptor assay for LH/chorionic gonadotropin (CG) in human sera using immortalized granulosa cells transfected with the LH/CG receptor.

PROCEDURE

Ovaries from pseudopregnant rats primed with pregnant mares' serum gonadotropin (PMSG) and hCG are homogenized. The homogenates are centrifuged at 2000 *g* for 15 min and the pellets are washed 3 times with 40 mM Tris buffer and resuspended in the same buffer. The suspension is filtered through four layers of cheesecloth prior to use. Fresh 2000-*g* fraction is prepared for each experiment. Purified hCG is labeled by the chloramine-T method resulting in a specific activity of approximately 60–70 μCi/μg.

For assessment of binding to receptors, a mixture consisting of the 2000-*g* fraction (equivalent to 2.5 or 5 mg of wet ovary or 45–90 μg of protein) and $(0.1–30) \times 10^{-10}$ M labeled gonadotropin or other test substances is incubated in a final volume of 1 ml of 40 mM Tris buffer (pH 7.4) containing 0.1% BSA at 25°C for 16 h. Then 1 ml ice-cold Tris buffer is added to the medium. This is immediately filtered, with suction, through Millipore EHWP filters (pore size 0.5 μm) previously wetted with 4% BSA to reduce nonspecific binding. The adsorbed material is washed with another 10 ml of ice-cold Tris buffer. The radioactivity on the filter is measured. Binding in the presence of a large excess of unlabeled hCG (200 IU/ml) is used to assess nonspecific binding.

EVALUATION

Specific binding is calculated and dose–response curves are obtained.

MODIFICATIONS OF THE METHOD

Similar studies were reported by: Catt et al. 1972,1976; Lee and Ryan 1973; Saxena 1976; Keutmann et al. 1983.

N.7.1.4
Human Menopausal Gonadotropin (hMG)

N.7.1.4.1
Biological Assay of hMG in Immature Rats

PURPOSE AND RATIONALE

The FSH-like activity of hMG can be measured by the ovarian weight response of immature rats. The LH-like activity of hMG can be determined in immature male rats by the increase of prostate and seminal vesicle weights.

PROCEDURE

Female Sprague-Dawley rats at an age between 21 and 24 days are assigned at random to six groups of at least five animals. Three doses of standard (e. g., a total dose of 1.5, 3, and 6 IU) and corresponding doses of the test preparation are dissolved in albumin-phosphate buffer, pH 7.2, and injected subcutaneously daily over a period of 3 days. On the 4th day, the animals are sacrificed and the ovaries are removed and weighed.

EVALUATION

Dose–response curves for FSH-like activity are established, and potency ratios with confidence limits may be calculated using hMG standard preparations.

N.7.1.6
Immunoassays of Gonadotropins

Immunoassays of gonadotropins are important in clinical diagnostics (RIA, ELISA and related methods). For pharmacological and biological experiments, they are measured in blood, urine, and pituitary tissue, e. g., for evaluation of gonadotropin releasing hormones (as described in Sects. N.9.2.5 and N.9.2.6). Many comparisons for results of *in vivo* and *in vitro* bioassays versus immunoassays showed significant discrepancies when expressed as the ratios of bioactive to immunoreactive LH (B/I ratio). However, there are numerous validated species-specific methods which are used for experimental endocrinology and clinical diagnosis.

Similar studies were reported by: Faiman and Ryan 1967; Wide and Hobson 1983; Ulloa-Aguire et al. 1988; Seth et al. 1989; Terouanne et al. 1989; Armbruster and Haws 1990; Wheeler 1991; Rosenfield an Helke 1992; Weiss et al. 1992; YoungLai et al. 1992; Haavisto et. al 1993.

N.7.1.7
Gonadotropin inhibition

N.7.1.7.1
General Considerations

Gonadotropin inhibition is suspected when, in early testing of compounds or in toxicology studies, weight reduction of gonads and the endocrine-dependent organs is found. Early tests used the physiological feedback effects of endogenous steroids in rats, e. g., the parabiosis experiment. This technique in rats was applied to the relationship between central and peripheral endocrine organs, the pituitary–gonadal axis. Basically, the deficit in gonadal steroid hormones after castration of one parabiotic partner induces increased secretion of gonadotropin which in turn stimulates hypertrophy of the gonads of the noncastrated partner. The procedure is described in detail by Byrnes and Meyer (1951); Shipley (1962). The parabiosis technique is now obsolete but was applied again a few years ago with remarkable success in the identification of the adipose tissue hormone leptin (see Sect. L.4.1).

N.7.1.7.2
Inhibition of Gonadotropin Secretion in Intact Animals

PURPOSE AND RATIONALE

The suppression of gonadotropin secretion by steroid compounds (as an example) can be detected in the endocrine survey test, described in Sect. N.1. Young rats, e. g., 80–100 g initial body weight, are treated with gonadal steroids or their derivatives to induce gonadotropin suppression by negative feedback of steroids (McGinty and Djerassi 1953; Saunders and Drill 1958; Shipley 1962). In intact rats, a reduction of gonadal weight indicates gonadotropin inhibition, whereas in castrated control groups (females or males), the weight increase of the sexual-hormone-dependent organs indicates the intrinsic estrogenic or androgenic property of the test compound.

PROCEDURE

Immature male and female Sprague-Dawley rats weighing 55–65 g or young rats 80–100 g are used. Groups of ten animals per sex and dosage group are treated daily over a period of 21 days with doses of the test compound usually by the oral or subcutaneous route. Controls receive the vehicle only. Testosterone may be used as reference compound (standard) in males and estradiol as the reference compound in females. Twenty-four hours after the last treatment, the animals are sacrificed and body weights recorded: in males, testes, seminal vesicles, ventral prostate and musculus levator ani; and in females, ovaries and uterus are dissected out and weighed. In addition, the gonadotropin content of the pituitary glands at autopsy may be determined to detect inhibition of gonadotropin synthesis.

EVALUATION

Organ weight averages are calculated for each treatment group and compared with controls. The reference steroids testosterone and estradiol suppress gonadal weight by pituitary gonadotropin inhibition (negative feedback) in intact animals, and increase gonadal weight in castrated animals by direct action. Dose–response curves can be established for the test compounds and the standard, and the relative potency of gonadotropin inhibition is calculated.

MODIFICATIONS OF THE METHOD

As an example of a classical bioassay, gonadotropin inhibition can be tested in semicastrated male rats (H. G. Vogel unpublished data, 1964). Male Sprague-Dawley rats weighing 50–60 g are orchiectomized on the left side. The testis is weighed (without epididymis and epididymal fat). Test compounds in various doses or the standard are administered subcutaneously once daily for a period of 10 days. Controls receive the vehicle only. Standard compounds may be medroxyprogesterone acetate 0.4, 2.0, and 10.0 mg per animal per day, or 17-ethinyl-19-nortestosterone acetate 0.1, 0.5, and 2.0 mg per animal per day subcutaneously.

On day 11, the animals are sacrificed and the remaining testis, the adrenals, the seminal vesicles, the ventral prostate and the musculus levator ani are dissected out and weighed. Gonadotropin suppression results in atrophy of the remaining (contralateral) testis as compared with testis weight of the untreated control. A decrease in adrenal weight indicates feedback inhibition of the pituitary–adrenal axis. The weight of seminal vesicles, the ventral prostate and the musculus levator ani indicates androgenic activity of the test

compound. Dose–response curves for the test compound and the standard as well as potency ratios are calculated.

N.7.1.7.3 Inhibition of Ovulation and Luteinization

PURPOSE AND RATIONALE

These methods were used frequently in research on contraception and selection of contraceptive steroids. Described here is an assay for progestational steroids. Progestagens inhibit pituitary gonadotropin secretion and synthesis. Progestional compounds, e. g., cyproterone acetate, inhibit ovulation and corpus lutea formation in young female rats by reducing luteinizing hormone secretion.

PROCEDURE

Female rats (35 days old) are treated once daily over a period of 7 days with increasing doses of gestagens, e. g., 0.125–2.0 mg progesterone or 0.025–0.40 mg 6α-methyl-17α-acetoxy-progesterone, subcutaneously. Controls receive the vehicle only. On the 8th day, the animals are sacrificed and body weight, ovarian weight, and number of corpora lutea are recorded. Progestogens inhibit follicular maturation, ovulation, and corpus lutea formation in this assay.

EVALUATION

Dose–response curves are established for average number of corpora lutea per animal and ovarian weight.

Similar studies were reported by: Junkmann 1957; Shipley 1962; Hebborn 1971; Phillips et al. 1987; Uilenbroek 1991

MODIFICATION OF THE METHOD

Ovum count can be performed in the oviduct of immature mice or rats after treatment with low doses of estradiol (Austin and Bruce 1956; May 1971). Immature rats or mice are injected with estradiol or stilbestrol at several dose levels to initiate estrus and ovulation. Then 72 h later the animals are sacrificed, and the oviducts are removed and examined under a stereomicroscope for the presence of ova. They can be seen through the swollen translucent walls of the oviduct. The swollen part of the oviduct is punctured with dissecting needles to release the ova and count the number of ova per animal. The rate of ovulation (number of ova) is related to the dose of estrogenic compound. In a modification of the method, inhibition of the rate of ovulation induced using a standard dose of estradiol by anti-ovulatory test compounds may be determined.

Hahn et al. (1977) treated rats in diestrus with test compounds administered orally in 0.5 ml sesame oil, and again on the following day when the animals were in proestrus. The animals were sacrificed on the next day, at which time they would normally have ova in the proximal segment of the fallopian tubes. Oviducts were separately flushed with saline onto a glass microscope slide, and the condition and number of ova were noted.

Inhibition of ovulation by gestagens can be studied in rabbits (Shipley 1965). Progesterone has a time-dependent effect on ovulation (stimulating or inhibiting secretion of pituitary gonadotropins). The timing of progesterone injection relative to the anticipated time of ovulation is important. Progesterone injected less than 4 h before ovulation in rabbits facilitates ovulation. In contrast, when injected more than 4 h before the anticipated time of ovulation (Sawyer 1952), progesterone inhibits ovulation. The rabbit ovulates within a few hours after mating, after mechanical stimulation of the vagina or after an intravenous injection of copper acetate (0.3 mg/kg). Progesterone injected 24 h before induction of ovulation will prevent ovulation.

Sexually mature female rabbits weighing 3–4 kg are treated with various doses of a standard progestogen or the test compound and 24 h later an ovulation-inducing stimulus is given. The rabbits are sacrificed and the ovaries are examined 18–24 h later. The total number of ovulation points on both of the ovaries is recorded for each animal. Dose–response curves for standard and test preparations are calculated.

N.7.1.7.4 Ovary–Spleen Transplantation

PURPOSE AND RATIONALE

This is a historical assay for gonadal steroids. Venous outflow from the spleen is exclusively to the liver. The steroids secreted by an ovary grafted to the spleen do not reach the peripheral circulation; they are degraded to inactive metabolites in the liver, and cannot exert their systemic feedback inhibition. The increasing gonadotropin secretion stimulates the growth of the transplanted ovary. This effect can be diminished or prevented by systemic application of gonadal steroids. Several studies were reported by: Mardones et.al. 1956; Shipley 1962; Biskind and Biskind 1990; D'Albora et al. 1992. The method by Mardones et al. (1956) for the guinea pig and by Desclin (1959) for the rat was modified by H. G. Vogel and S. Jung (unpublished data, 1962).

PROCEDURE

Female Sprague-Dawley rats weighing 100–120 g are anesthetized. The abdominal wall is opened by an incision lateral to the linea alba. Both ovaries are removed. One ovary is freed from the capsule and connective tissue and weighed to the nearest 0.1 mg. An incision is made at the cranial end of the spleen forming a deep pocket. The decapsulated ovary is pushed into this pocket. The incision is closed, and animals are treated with daily subcutaneous injection of an estrogen (e. g., 0.01, 0.1, 1.0, and 10 µg estradiol in 0.1 ml sesame oil) or a gestagen (e. g., 0.001, 0.01, 0.1, and 1.0 mg 6α-methyl-17α-acetoxyprogesterone) for a period of 5 weeks. Controls receive the vehicle only. In controls, the weight of the ovary may increase about eightfold, from an average weight at implantation of about 10.0 mg to values around 80.0 mg.

Estradiol at doses starting from 0.1 µg and 6α-methyl-17α-acetoxyprogesterone at a dose of 1.0 mg suppress ovarian growth completely by inhibition of LH secretion. The weight of the uterus is increased by direct action of estradiol too.

EVALUATION

Dose–response curves of test compounds and reference standards are calculated.

CRITICAL ASSESSMENT OF THE METHOD

The ovary–spleen transplantation method is similar to the parabiosis experiment, with much less stress to the animals.

N.7.1.7.5 Inhibition of Fertility

PURPOSE AND RATIONALE

Fertility in rats can be inhibited by treatment of females with steroids that inhibit pituitary gonadotropin secretion or compete at the progesterone receptor. The test was used for contraceptive steroids (Shipley 1962; Philibert et.al. 1985; Dhar et. al 1994).

PROCEDURE

A colony of about 100 adult female Sprague-Dawley rats weighing between 200 and 250 g is established. Daily vaginal smears are taken at noon for 5 days. Then 15 regularly cycling females in proestrus are selected and caged separately. The first drug dose is administered at 3:00 p.m. (day 1). At 5:00 p.m. two males are placed with each female. On day 2, vaginal smears are taken for sperm count at 8:00 a.m.. The sec-

ond drug dose is administered at 4:30 p.m. On day 3, vaginal smears are taken for sperm count at 8:00 a.m. again. The third drug dose is administered and sperm counts are taken at 4:30 p.m. The males are then removed. From the 4th to the 7th day the test drugs are administered in the morning. Controls receive the vehicle only. On day 9, the animals are sacrificed and the uterus examined for implantation sites.

EVALUATION

Compounds which prevent conception, as evidenced by the absence of implantation sites at autopsy, were given further consideration. Minimal effective doses preventing ovulation in all animals of a test group were determined.

N.7.2 Prolactin

There are considerable sequence homologies in the structures of growth hormone, prolactin and placental lactogen; however, their biological activities are rather different and each hormone exerts its specific pattern of activities on tissues, with growth hormone being an anabolic hormone, and prolactin predominantly a reproductive hormone.

N.7.2.1 General Considerations

The classical procedure for the bioassay of prolactin is based on the work of Riddle et al. (1939); namely, the increase in the weight of the crop sacs of doves and pigeons. Other methods are based on the induction of secretory changes in the mammary glands of rodents. Most of these methods can now be replaced by cell-based assays using suitable cell lines responding to prolactin.

The clinical measurements rely on immunoassays (Shiu and Friesen 1976; Jacobs 1979; Jeffcoate et al. 1986). Due to the species specificity of prolactin, a special radioimmunoassay for rats was developed.

Leroy-Martin et al. (1995) reported an immunocytochemical study of human prolactin receptors using antiidiotypic antibodies in human breast cancer.

N.7.2.2 Radioimmunoassay of Rat Prolactin

PURPOSE AND RATIONALE

Prolactin is a glycoprotein hormone exhibiting species specificity. For pharmacological experiments in rats, such as evaluation of gonadotropin releasing hormone activity or prolactin inhibiting factor activity, a homologous assay is necessary. The reagents for rat prolactin and guidance for the method are provided by National Pituitary Agency, USA (Jeffcoate et al. 1986).

PROCEDURE

Reagents

Standard: NIAMDD-rat-prolactin-RP-1

Antiserum: rabbit-anti-rat-prolactin (NIAMDD-S-6)

Tracer: ^{125}I-rat-prolactin (NIAMDD-I-3)

Second antibody: goat-anti-rabbit-gammaglobulin (Cat. No. OTP 14/15)

Buffer: 0.01 M-phosphate-saline/0.1% bovine serum albumin, pH 7.4

Assay Procedure

Standards: 0.03–1 ng/tube, 200 µl/tube

Antiserum: 1:4000 100 µl/tube

Tracer: specific activity 250 µCi/µg, 10,000 cpm in 100 µl/tube

Standards (or sample) are incubated with antiserum for 24 h at +4°C; the tracer is added and incubated for another 48 h. Then the second antibody (1:50), 200 µl/tube, is added, and incubated for 48 h at +4°C. Separation is performed with 1.0 ml ice-cold phosphate-buffered saline, pH 7.4, the vials spun at 1300 *g* for 15 min, the supernatant decanted, and the residue counted for 1 min in a gamma-counter.

Counting equipment required: gamma spectrometer.

EVALUATION

Data processing: standard curves and sample data are calculated by any suitable computer program, e. g., using a spline function.

N.7.2.3 Pigeon Crop Method

PURPOSE AND RATIONALE

This is again a historical bioassay no longer applied. Riddle and Bates (1939) showed that the secretion of "crop milk" by pigeons and doves is initiated and maintained by a factor from the anterior pituitary of these birds that is identical to the lactogenic hormone from mammals. Suitable assay methods have been developed on this basis (Meites and Turner 1950; Segaloff 1962; Cowie and Forsyth 1995). Pigeons are exquisitely sensitive to lactogenic hormone, and the assay can be done with considerably less material than the mammalian assays. The most sensitive assay is the so-called micromethod of local intracutaneous injections of the crop sac.

PROCEDURE

Pigeons of either sex (2–3 months old), but of uniform strain, e. g., White Carneaux, are injected intramuscularly (intrapectorally) with various doses of the test preparation or the standard once daily for 4 days. On the 5th day, the birds are sacrificed. A midventral incision is made through the skin and crop wall from keel to head. The contents of the crop and the adhering crop-milk are removed. The two lateral pouches are removed, the fat cleaned from the back of the glands and the wet weight of the glands determined. Thus, the unstimulated tissue in the dorsal midline and that around the proximal and distal opening of the crop are not weighed.

EVALUATION

Mean values of at least two doses of test preparation and standard are plotted versus logarithms of doses, and the potency ratios with confidence limits calculated.

MODIFICATIONS OF THE METHOD

The micromethod is based on the observation that only a small area directly over the site of injection is stimulated when lactogenic hormone is injected intradermally over the crop sac forming a "bleb" at the site of injection. A direct comparison of the potency of two different preparations can be made by a similar injection over the other crop sac. The birds are sacrificed on the 5th day and the entire crop sacs removed and examined by transmitted light (Lyons and Page 1935).

N.7.2.4 Lactation in Rabbits

PURPOSE AND RATIONALE

Only the rabbit and guinea pig have proven satisfactory for mammalian assays of lactogenic hormones. The assays are based on the prolactin-induced mammary growth and milk secretion of pseudopregnant animals.

PROCEDURE

Pseudopregnancy is induced in mature estrus rabbits by intravenous injection of 50 IU of human chorionic gonadotropin. On the 14th day, the rabbits are examined for the presence of well-developed mammary glands characteristic of pregnancy. Various doses of the test preparation or the standard of lactogenic hormone are injected subcutaneously once daily for 6 days. On the 7th day the animals are sacrificed and

the abdominal skin is incised in the midline and separated from the mammary gland underneath. The degree of enlargement of the glands with secretion is rated as follows:

– absence of response

+ all ducts are filled with milk

++ all ducts and most lobules are filled with milk though not greatly thickened

+++ entire gland is filled with milk

++++ mammary glands are greatly extended with milk throughout.

EVALUATION

The mean values for groups of six rabbits are compared with the values of the standard groups.

MODIFICATIONS OF THE METHOD

A more sensitive rabbit assay method is based on the ability of lactogenic hormone to act directly on mammary tissue (Lyons 1942). Small amounts of test compound are injected directly into one or more of the six milk ducts of a castrated, rabbit pretreated with estrone-progesterone. A localized lactation appears in the gland sector stimulated. A dose-dependent reaction was found. The assay is suitable for prolactin, placental lactogen and growth hormone.

N.7.3 Growth hormone (GH)

N.7.3.1 General Considerations

Growth hormone (GH) has been isolated from the pituitary glands of several species including humans and is species specific; for therapy it has been replaced by rDNA preparations. Several methods have been described for the detection and assay of GH activity (Russell 1955; Hughes 1985; Isaksson 1985; Rudd 1991).

Human GH consists of 190 amino acids with two disulfide bridges between cysteine residues. Human GH synthesis is controlled by two genes: hGH-N and hGH-V.

GH secretion is stimulated by growth-hormone-releasing hormone (see Sect. N.9.5). GH is released in a pulsatile fashion and has a half-life of about 10 min.

Receptors for GH are found in several organs, mainly in liver and muscle.

Receptor binding assays (Ilondo et al. 1991) and radioimmunoassays for GH in several animal species (Greenwood et al. 1963; Peake et al. 1978) and for somatomedins (Chochinov and Daughaday 1978) have been developed.

Amit et al. (1992) measured serum GH by radioimmunoassay and GH-binding protein by a binding assay with dextran-coated charcoal separation.

An immunoradiometric assay for Gh was described by Hofland et al. (1989).

Mertani et al. (1995) studied the cellular localization of the GH receptor/binding protein in the human anterior pituitary gland.

A high-performance receptor binding chromatography assay for GH was described by Roswell et al. (1996).

Strasburger et al. (1996) developed an immunofunctional assay for human GH (hGH). An anti-hGH monoclonal antibody recognizing binding site 2 of hGH is immobilized and used to capture hGH from the serum sample. Biotin-labeled recombinant GH-binding protein in a second incubation step forms a complex with those hGH molecular isoforms that have both binding sites for the receptor. The signal is detected after a short third incubation step with labeled streptavidin.

Functional characterization of monoclonal antibodies specific to GH receptor is described by Wang et al. (1996).

N.7.3.2 Weight Gain in Female Rats ("Growth Plateau Rats")

PURPOSE AND RATIONALE

Female rats 6 months of age, having reached maturity, gain weight at a very slow pace; the slowing down of the growth rate is described as "plateauing". Such rats can readily be induced by growth hormone to accelerate growth and weight gain (Greenspan et al. 1950; Papkoff and Li 1962).

PROCEDURE

Groups of ten adult female rats (Long-Evans or Wistar strain), 6 months old and weighing between 220 and 280 g, are used. Only animals which fail to gain more than 10 g in a 20-day period are used. At least two doses of the hormone preparation and the standard dissolved in saline are injected subcutaneously daily over a period of up to 20 days. During this time, weight gains between 10 and 40 g can be achieved. A straight line relationship exists between the logarithm of the daily dose and the growth response by body weight increase (Marx et al. 1942).

EVALUATION

The weight gains after administration of two doses of the test preparation and of the standard are used for 2+2-point assays, and potency ratios are calculated.

CRITICAL ASSESSMENT OF THE METHOD

The test needs a relatively large amount of test material. In spite of the species specificity of growth hormone, rats respond to growth hormone from many other species over a limited time period, before developing neutralizing antibodies.

MODIFICATIONS OF THE TEST

Immature female rats hypophysectomized at 26–28 days of age can be used (Li et al. 1945; Groesbeck and Parlow 1987). Smaller amounts of test substance are necessary for weight gain than in adult rats.

A cell proliferation assay using a stable clone of the myeloid cell line FDC-P1, transfected with the full-length growth hormone receptor (FDC-P1-hGRH), was described by Roswell et al. (1996) as an alternative to the classical hypophysectomized rat weight gain bioassay.

say for recombinant human growth hormone. Biologicals 24:25–39

N.7.3.3 Tibia Test in Hypophysectomized Rats

PURPOSE AND RATIONALE

Hypophysectomy is followed by cessation of epiphyseal growth due to growth hormone deficiency. The width of the epiphyseal cartilage is markedly reduced after hypophysectomy. Administration of growth hormone to hypophysectomized rats induces a remarkable increase in the width of the epiphyseal cartilage plate.

PROCEDURE

Female rats of the Long-Evans or Sprague-Dawley strains are hypophysectomized at the age of 26–28 days. They are used for the bioassay 12–14 days after the operation. The increase of body weight during this period of time has to be less than 0.5 g per day to indicate complete hypophysectomy. Six to ten animals are used for each group of two doses of test preparation and standard. The solutions are administered intraperitoneally twice daily for 4 days.

On the 5th day, the animals are sacrificed, both tibiae are dissected free of soft tissue, and the bones split in half with a sharp razor at the proximal end in the mid-sagittal plane. The halves are washed in water for 10 min, immersed in acetone for 6 min, and washed again in water for 3 min. They are then placed in 2% silver nitrate solution for 2 min and rinsed with water. During the water rinse, they are exposed to a strong light which turns the calcified portions of the bone dark brown. The stained tibiae are the transferred to a microscopic stage and the width of the uncalcified cartilage plate, which does not stain and remains white, is measured under low power with a calibrated micrometer eyepiece. Ten individual readings are made across the epiphysis.

EVALUATION

Mean values are obtained from a total of 20 readings for each bone specimen. They are averaged for each dose group. With a 2+2-point assay, the potency ratio with confidence limits versus the standard is calculated.

CRITICAL ASSESSMENT OF THE METHOD

The test has been firmly established as a standard method for assessing growth-promoting activity. For epiphyseal measurement, morphometry may be applied.

MODIFICATIONS OF THE METHOD

Bentham et al. (1993) described a double-staining technique for the detection of growth hormone and insulin-like growth factor-1 binding to rat tibial epiphyseal chondrocytes that were incubated with biotinylated ligands with or without an excess of unlabeled ligands, followed by incubation with Vectastain ABC complex, which was then reacted with diaminobenzidine. Double staining was accomplished by carrying out the first reaction with diaminobenzidine in the presence of nickel ammonium sulfate to give a black precipitate, followed by incubation with the second ligand, then the ABC complex and finally diaminobenzidine in the absence of nickel ammonium sulfate to give a brown stain.

N.7.3.4 ^{35}S Uptake

PURPOSE AND RATIONALE

Cartilage contains glucosaminoglycans, e. g., chondroitin sulfate. The uptake of labeled sulfate into cartilage is greatly reduced after hypophysectomy and restored after growth hormone application. This phenomenon can be used as the basis of a bioassay of growth hormone activity (Collins and Baker 1960; Papkoff and Li 1962).

PROCEDURE

Female Sprague-Dawley rats are hypophysectomized at 21 days of age and used for experimentation 3 weeks later. The animals are given intraperitoneal injections of growth hormone together with radioactively labeled sulfate once daily for 4 days. Eight to ten animals are

used for at least two doses of test preparations (growth hormone derivatives) and standard. The rats are sacrificed 24 h after the last injection and the amount of radiosulfate present in the seventh rib cartilage is determined. A linear relationship exists between the uptake of radiosulfate and the hormone given over a range of 3–20 µg per day for 4 days.

EVALUATION

Mean values for each group and the potency of the test preparation versus standard calculated with confidence limits are calculated in a 2+2-point assay.

N.7.3.5 Inhibition of Glucose Uptake in Adipocytes in Vitro

PURPOSE AND RATIONALE

The conversion of glucose to lipid in murine adipocytes is dose-dependently inhibited by human growth hormone (hGH). A sensitive *in vitro* bioassay was developed by Foster et al. (1993).

PROCEDURE

3T3-F442A embryonic murine fibroblasts (preadipocytes) are grown in Dulbecco's modified Eagle's medium (DMEM) containing 2 mM L-glutamine, 100 µg/ml streptomycin, 100 U/ml penicillin, and 0.1 µg/ml fungizone. The cells are plated in 60- or 100-mm plastic culture dishes at a density of 200 cells/cm^2 and grown to confluence at 37°C under a humidified atmosphere of 90% air/10% CO_2 in medium supplemented with 25 mM glucose and 10% calf serum. Medium is replaced every 2–3 days. Once confluent, the fibroblasts are converted to cells with the characteristics of adipocytes by incubation for 48 h in medium supplemented with 25 mM glucose, 10% fetal bovine serum, 0.5 mM methylisobutylxanthine, 2 µg/ml insulin, and 250 nM dexamethasone. This medium is then replaced with medium containing 10% fetal bovine serum and 2 µg/ml insulin with changes made every 2 days for 5–8 days until at least 70% of the cells have the characteristics of adipocytes as assessed by phase contrast microscopy.

For bioassays, the medium consists of DMEM containing 5.5 mM glucose, 2% BSA, 25 nM dexamethasone, 37 nM estradiol, 10 µg/l insulin, and 0.1 µCi/ml uniformly labeled [^{14}C]D-glucose. Cultures are co-incubated with increasing concentrations of 22-kDa human growth hormone (0.313–40 µg/l) as standard or test substance or medium (controls) for 24 h. For determination of hGH in patients, 100 µl or 200 µl serum is added. After incubation, the medium is removed and discarded. The cells are treated with Doles reagent (one part heptane, four parts isopropanol, 0.1 part 1 N H_2SO_4), the plates scraped, and the contents transferred to a glass tube. Lipids are extracted by the method of Dole and Meinertz (1969), and radioactivity of the lipid is determined by scintillation counting in a liquid scintillation spectrophotometer. Results are expressed as ^{14}C counts per minute per dish. Lipid accumulation in controls without hGH is taken as 100%. Logarithmic doses of 0.313–40 µg/l hGH result in a linear decrease of lipid accumulation. The assay is rather specific for 22-kDa hGH.

EVALUATION

From dose–response curves, activity ratios can be calculated.

MODIFICATIONS OF THE METHOD

Xu et al. (1995) studied the effects of GH antagonists on 3T3-F422A preadipocyte differentiation. The antagonists not only failed to induce adipose differentiation, including late marker gene expression (adipocyte protein 2), immediate early gene expression (c-fos), and tyrosine phosphorylation of intracellular proteins, but also antagonized GH-induced c-fos expression and phosphorylation of proteins of apparent molecular mass 95 kDa.

N.7.3.6 Eluted Stain Bioassay for Human Growth Hormone

PURPOSE AND RATIONALE

Ealey et al. (1988, 1995) and Dattani et al. (1993, 1995) developed an eluted stain bioassay

(ESTA) for human growth hormone (hGH). This assay is based on the production of MTT–formazan [MTT is 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium] by quiescent Nb2 cells under the influence of the hormone.

PROCEDURE

Rat Nb2 lymphoma cells are grown in suspension culture which consists of RPMI medium (Gibco) containing 50 U penicillin/ml, 50 µg streptomycin/ml, 2×10^{-3} M L-glutamine, 10% fetal calf serum and 10% horse serum. The cells are incubated in a humidified atmosphere of 5% CO_2/95% air at 37°C.

Prior to the bioassay of hGH, the cells are transferred to a quiescent medium, which is identical in composition to the growth medium described above except that the FCS is reduced from 10% to 1%. This slows down the rate of cell division and reduces the optical density of the unstimulated control in the subsequent ESTA bioassays by about 50%. Incubation is continued in a humidified atmosphere of 5% CO_2/95% air at 37°C for 24 h.

For the bioassay, the cells are transferred to the bioassay medium, which is the same as the growth medium but without FCS. The cells are plated out into 96-well microtiter plates, such that a final density of 2×10^5 cells/ml is obtained. Usually 50 µl of cell suspension at 4×10^4 cells/ml is added to each well. This is followed by the addition of 50 µl of various concentrations of test compound or standard (0.1–10 mU GH/l). The cells are incubated in a humidified atmosphere of 5% CO_2/95% air at 37°C for 96 h.

At the end of the bioassay incubation, the colorimetric endpoint is determined by the addition of 10 µl of MTT bromide solution (5 mg/ml in phosphate-buffered saline containing 0.1 mg/ml $CaCl_2$ and $MgCl_2 \cdot 6H_2O$, pH 7.3) to each well: incubation is continued for 40 min at 37°C in a dry incubator. During this time, activated cells reduce the yellow MTT salt to its purple formazan. After the 40-min incubation, 50 µl of 10% Triton X-100 in 0.1 M HCl is added to each well and the plate gently shaken for 30 min at room temperature. Bioassay responses of the 96 wells are quantified with a Biorad microtiter plate reader at optical densities at a test wavelength of 595 nm and a reference wavelength of 655 nm to correct for differential scattering.

EVALUATION

The determinations for all experiments are made from triplicate or quadruplicate microcultures and the results expressed as means and standard deviations. Dose–response curves for standard and test compounds are established.

MODIFICATIONS OF THE METHOD

The sensitivity of the assay can be increased by addition of ionic zinc (Dattani et al. 1993, 1995; Strasburger and Dattani 1997).

N.7.3.7 Reverse Hemolytic Plaque Assay for Growth Hormone

PURPOSE AND RATIONALE

The reverse hemolytic plaque assay as described by Neill and Frawley (1983), Luque et al. (1986), and Smith et al. (1986) can be used to determine growth hormone (GH) secretion by dispersed rat pituitary cells (Niimi 1994a, 1994b).

PROCEDURE

Anterior pituitary lobes of male Sprague-Dawley rats weighing 200–250 g are collected and minced into approximately 1-mm^3 fragments. The pituitary cells are dispersed and transferred to a siliconized flask containing 3 mg/ml trypsin in Dulbecco's phosphate-buffered saline containing 0.1% BSA and antibiotics, and incubated in a water bath for 5 min at 37°C. After gentle trituration by a siliconized pipette, the cells are separated by centrifugation and rinsed with phosphate-buffered saline containing 2 mg/ml DNase (type I; Sigma, St. Louis, Mo., USA). The dispersed cells are separated by centrifugation and rinsed once in phosphate-buffered saline with 1.5 mg/ml trypsin inhibitor (type II-L, Sigma). The cells are washed 5 times with Dulbecco's modified Eagle's medium (DMEM) containing 0.1% BSA and resuspended. Ovine erythrocytes are coupled with staphylococcal protein A

(Sigma) in the presence of 0.9% chromium chloride in normal saline. Pituitary cells (10^6 cells/ml) are combined with an equal volume of a 30% solution of protein-A-coupled erythrocytes in DMEM containing 0.1% BSA and antibiotics. The cell mixture is infused into a poly-L-lysine coated Cunningham slide chamber and preincubated at 37°C, 95% air/5% CO_2, for 50 min. After preincubation, the chamber is rinsed in DMEM-BSA and placed in Petri dishes containing DMEM and 10% horse serum containing 1% nonessential amino acids before performing the reverse hemolytic plaque assay.

After 24 h of co-incubation, the chambers are rinsed with DMEM-BSA. Monkey anti-rat GH serum diluted 1:150 in assay medium is then infused into the chambers alone or with different secretagogues and incubated for 2 h. Plaque development is initiated by infusion of guinea pig complement (Gibco) at a final dilution of 1:40. The reaction is terminated after 0.5 h by the infusion of B-5 fixative (6 g $HgCl_2$ and 1.25 g sodium acetate in 90 ml distilled water, add 10 ml 37% formaldehyde immediately before use). The pituitary cells are stained with 0.5% toluidine blue to facilitate observation of the hemolytic plaques.

EVALUATION

In each experiment, each concentration of secretagogue or vehicle is run in duplicate, and 150–200 cells/slide are counted. Two separate experiments have to be performed. The plaque area is measured by using a calibrated ocular reticule. The area of 50 plaques per slide is measured. Statistical analysis is performed by Student's *t*-test and one-way analysis of variance.

N.7.3.8 Determination of Growth Hormone Isoforms by 22-kDa GH Exclusion Assay

PURPOSE AND RATIONALE

Human growth hormone exists in variety of isoforms. In the pituitary, the most abundant isoform is 22-kDa GH, while other isoforms (non-22-kDa GH) are present in variable amounts. Boguszewski et al. (1996); Strasburger and Dattani (1997) described an analytical approach that focuses on the isoforms differing from monomeric and oligomeric 22-kDa GH.

PROCEDURE

Reagents

- Recombinant 22-kDa human GH (Genotropin, Pharmacia, Uppsala, Sweden)
- 22-kDa GH-specific monoclonal antibody (MCB), (Genentech, San Francisco, Calif., USA)
- magnetic polystyrene beads coated with rat anti-mouse IgG 1 (Dynabeads M-450), (Dynal, Oslo, Norway)
- polyclonal antibody-based IRMA (Pharmacia, Uppsala, Schweden)
- assay buffer containing phosphate-buffered saline, 5 g/l BSA, 5 ml/l Tween-20, 0.1 g/l thiomerosal.

Assay Procedure

A 100-µl aliquot of serum or test solution is mixed with either 10 µl of assay buffer containing MCB (final concentration 0.3 µmol/l) or 10 µl of assay buffer without MCB. The samples are incubated for 24 h at room temperature. A 160-µl aliquot of magnetic beads coated with rat anti-mouse IgG (concentration 4×10^5 beads/µl) is added to the samples. After further incubation for 2 h at room temperature with gentle agitation in a rotator, the tubes are put in contact with a magnetic device, Dynal MPC-E (Dynal, Oslo, Norway), for 1 min. The magnetic beads with the 22-kDa GH-MCB complexes are attracted by the magnet. While the tubes are in the magnetic device, 50-µl aliquots of the supernatant are transferred to new tubes for measurement of non-22-kDa GH levels in duplicate by the polyclonal antibody-based IRMA. The same procedure is performed for samples incubated with assay buffer (without addition of MCB) to determine total GH concentration.

EVALUATION

The amount of non-22-kDa GH isoforms is expressed as a percentage of total GH concentration. The Mann-

Whitney *U* test (two-tailed) is used to compare the percentage of non-22-kDa GH isoforms between the groups. The method is an example of the increasing use of physicochemical methods to characterize the heterogeneity of hormone preparations obtained by rDNA methods.

N.7.3.9 Steroid Regulation of Growth Hormone Receptor and GH-Binding Protein

PURPOSE AND RATIONALE

Gabrielsson et al. (1995) studied steroid regulation of growth hormone receptor (GHR) and GH-binding protein (GHPB) mRNAs in the rat. GHR and GHBP, arising from alternative splicing of the same gene, show a sexually dimorphic and GH-dependent expression pattern. Multiple alternative 5′-untranslated regions are present in GHR and GHBP transcripts in the rat, one of which, GHR_1, has been shown to be liver specific and found at higher levels in females.

PROCEDURE

Animal Treatment

For human GH treatment, groups of Wistar rats are implanted subcutaneously with osmotic minipumps delivering recombinant hGH at 200 µg/day for 7, 12, or 14 days. Steroid-treated animals are implanted subcutaneously with slow-release pellets delivering estradiol (E_2, 25 ng/day), testosterone propionate (12.5 µg/day) or corticosterone (3.5 µg/day) for up to 2 weeks. At the end of each study, animals are sacrificed and samples of blood and liver rapidly removed.

Protein Binding (GHBP) Assay

Plasma GHBP levels are measured by radioimmunoassay (RIA). Recombinant rat GHBP is used for iodination and reference preparation (Carmignac et al. 1992).

GH-Receptor-Based Assays

Liver samples are homogenized in 0.3 M sucrose containing 3 mM imidazole HCl, pH 7.4 (Carmignac et al. 1993). Samples of 100 µl (~2 mg protein) are incubated in duplicate at 22°C with radio-iodinated bovine GH (100 µl, 20,000 cpm) and 100 µl buffer (25 mM Tris-HCl, pH 7.4, containing 10 mM $CaCl_2$ and 0.1% BSA). After 2 h, 3 ml cold (4°C) buffer is added, the tubes centrifuged at 2700 *g* for 30 min, and the radioactivity in the pellets determined. Nonspecific binding is estimated in the presence of 1 µg unlabeled bovine GH and is subtracted from total binding to derive percentage specific bovine GH binding per milligram protein.

Generation of RNA Probes

Using an *in vitro* transcription kit, probes are labeled with [^{35}S]uridine triphosphate for solution hybridization assay and [^{32}P]uridine triphosphate for Northern blots and RNase protection assays. Total GHR coding region transcripts are measured using an antisense probe corresponding to a 423-nucleotide (nt) *Nco*I-*Kpn*I fragment (nt 989–1411) of the λ1 clone of the rGHR inserted into the pT7T318U vector. This sequence spans the transmembrane domain and part of the intracellular domain of the GHR and is not present in GHBP mRNA. Total GHBP transcripts are determined using a 46-nt oligonucleotide probe complementary to the alternate splice sequence encoding the GHBP hydrophilic tail. This probe does not detect GHR transcripts. GHR_1-containing transcripts are measured using a probe complementary to this 5′-UTR alternative exon sequence.

Northern Blots

Total RNA is prepared using the method of Chomczynski and Saachi (1987). RNA is run overnight on a 2.2 M formaldehyde/3-*N*-morpholine propanesulfonic acid agarose gel, transferred to a Nylon membrane and cross-linked using a Stratalinker (Strategene, La Jolla, Calif., USA). Membranes are prehybridized for 2–4 h at 60–65°C in 50% formamide, 5× SSC (1× SSC = 0.15 M NaCl, 0.015 M Na citrate, pH 7.0), 5× Denhardt's solution, 50 mM Na_2HPO_4, 0.2% sodium dodecyl sulfate (SDS), 250 µg/ml salmon sperm DNA, and 100 µg transfer RNA/ml, and incubated with ^{32}P-labeled probe [$(1–3)\times10^6$ cpm/ml] at the same temperature in 50% formaldehyde, 5× SSC, 1× Denhardt's solution, 20 mM Na_2HPO_4, 0.2% SDS, 10% dextran, 100 µg/ml salmon sperm DNA, and 100 µg tRNA/ml. After washing (60°C and 20 min/wash, starting at 3× SSC/0.1% SDS and reducing to 0.3× SSC/0.1% SDS) membranes are exposed to X-ray film with intensifying screens at −80°C or are detected by phosphorimaging.

Solution Hybridization Assays

Hepatic mRNAs are quantified by solution hybridization after the method of Möller et al. (1991). Liver is homogenized in 10 mM Tris-HCl, pH 7.5, containing 1% SDS and 5 mM EDTA, after proteinase K digestion. Total nucleic acids (TNAs) are extracted with phenol/chloroform, precipitated with ethanol, and the pellets dissolved in 0.2 × 10 mM Tris-HCl, pH 7.5, containing 1% SDS and 5 mM EDTA. For each assay, 10–100 µg TNAs is hybridized in duplicate with ^{35}S-labeled RNA probes (20,000–30,000 cpm) at 50°C overnight in 40 µl, 21 mM Tris-HCl buffer, pH 7.5, containing 600 mM NaCl, 4.5 mM EDTA, 7.5 mM dithiothreitol, 0.1% SDS, and 25% formamide. Standard tubes contain known quantities of target RNA, transcribed from the sense strand of the appropriate plasmid and quantified by absorption at 260 nm.

After digestion with RNase A (40 µg) and RNase T_1 (2 µg) protected fragments are precipitated with 10% trichloroacetic acid, are collected by filtration (GF/C paper, Whatman), detected by scintillation counting, and expressed as specific mRNA levels (attomoles per µg TNA).

RNase Protection Assay

Total RNA (20 µg) is hybridized under the same conditions as above, except that a ^{32}P-labeled probe (500,000 cpm) is used. After overnight incubation at 50°C, the samples are treated with 300 µl of a solution of 10 mM Tris, pH 7.5, 5 MM EDTA, and 300 mM NaCl, containing RNase A (40 µg/ml) and RNase T_1 (2 µg/ml), for 30 min at room temperature. After incubation with 50 µg proteinase K and 20 µl 10% SDS for 15 min at 37°C, samples are extracted with phenol/chloroform and ethanol precipitated with 10 µg tRNA as carrier. The pellets are dissolved in gel-loading buffer (10 mM EDTA and 1 mg/ml bromophenol blue in 80% formamide), denatured at 85°C for 4 min, and run on an 8 M urea/6% polyacrylamide gel. Detection is by autoradiography or phosphorimaging.

EVALUATION

Data are calculated as mean ±SEM. Differences between treatment groups are assessed using Student's *t*-test, or analysis of variance followed by Student-Newman-Keul's or Dunnett's tests.

MODIFICATIONS OF THE METHOD

Nilsson et al. (1995) described the expression of functional growth hormone receptors in cultured human osteoblast-like cells.

To measure the absolute number of mRNA molecules encoding the growth hormone receptor in human tissue, Martini et al. (1995) developed a quantitative polymerase chain reaction assay.

N.7.4
Adrenocorticotropin (ACTH)

N.7.4.1
Adrenal Ascorbic Acid Depletion

PURPOSE AND RATIONALE

This is now a historical assay, which however has been used extensively for standardization of ACTH preparations. The administration of pituitary adrenocorticotropic hormone (ACTH) is followed by a decrease in the amount of ascorbic acid present in the adrenals. The depletion of adrenal ascorbic acid is a function of the dose of ACTH administered. This relationship was used for a quantitative assay of ACTH by Sayers et al. (1948). The method has been selected for standardization of ACTH by several Pharmacopoeias, e. g. The United States Pharmacopeia USP 23 (1995), Deutsches Arzneibuch (1986) and British Pharmacopoeia (1988). Furthermore, the test has been used for evaluation of synthetic corticotropin analogs (Geiger et al. 1964; Vogel 1965, 1969a, 1969b). A similar test is used for luteinizing hormone action in the rat ovary.

PROCEDURE

Male Wistar rats weighing between 100 and 200 g are hypophysectomized 1 day prior to the test. The range of weights in any one test should not exceed 15 g. For one test with three doses of test preparation and standard, at least 36, preferably 60, hypophysectomized rats are necessary.

Solutions

Five units of the International Standard for corticotropin (Bangham et al. 1962) or an amount of test preparation supposed to contain about 5 units are dissolved in 0.25 ml of 0.5% phenol solution and diluted with 8.1 ml of 15% gelatin solution. In this way, 0.5 ml contains 300 mU ACTH. Then 3 ml of this solution is diluted with 6.0 ml gelatin solution (to prevent adsorption to glassware), resulting in 100 mU ACTH per 0.5 ml. Then 3 ml of this solution is again diluted with 6.0 ml gelatin solution, resulting in a content of 33 mU ACTH per 0.5 ml.

The hypophysectomized rats are randomly distributed to six groups. Each rat receives subcutaneously 0.5 ml of one of the various concentrations of test preparation or standard. Three hours after injection, the animals are anesthetized, both adrenals removed, freed from extraneous tissue and weighed. The rats are sacrificed and the skull opened to verify completeness of hypophysectomy.

The adrenals are homogenized in 4% trichloroacetic acid and the ascorbic acid determined according to the method of Roe and Kuether (1943). Other methods have been described.

ASCORBIC ACID DETERMINATION

Reagents

First 100 mg L-ascorbic acid is dissolved in 100 ml 4% trichloroacetic acid and 20 ml of this solution is diluted with 4% trichloroacetic acid to achieve a 0.2% ascorbic acid solution; 2 ml of this solution is diluted with 4% trichloroacetic acid to achieve a 0.02% ascorbic acid solution. Sulfuric acid (85%) is obtained by adding 900 ml concentrated sulfuric acid to 100 ml distilled water. Then 2 g dinitrophenylhydrazine is dissolved in 100 ml of 9 N H_2SO_4 (75 ml distilled water and 25 ml concentrated sulfuric acid), and 6 g thiourea is dissolved in 100 ml distilled water.

Calibration

Trichloroacetic acid (4%) is added to 0.0, 0.5, 1.0, 2.0, 3.0, 4.0, 6.0, and 8.0 ml of the 0.02% ascorbic acid solution and 1.0, 1.5, and 2.0 ml of the 0.2% ascorbic acid solution to reach a final volume of 8.0 ml. Then 100 mg charcoal is added to each sample and thoroughly mixed by shaking for 1 min. After 5 min the solutions are filtered. An aliquot of 0.1 ml of the 6% thiourea solution is added to 2.0 ml of the filtrate followed by 0.5 ml dinitrophenylhydrazine solution. The mixture is shaken and heated for 45 min at 57°C in a water bath. The solutions are placed in an ice-cold water bath and with further cooling 2.5 ml of the 85% sulfuric acid is added. The calibration curve is established at a wavelength of 540 µm using the solutions without ascorbic acid as blank.

Preparation of the Adrenals

Both adrenals are homogenized in glass tubes containing 200 mg purified sand and 8.0 ml of 4% trichloroacetic acid. The reagents are added as described for the calibration curve.

EVALUATION

The potency ratio including confidence limits is calculated with the 3+3-point assay.

MODIFICATIONS OF THE METHOD

The original method, as described by Sayers et al. (1948), used intravenous administration of ACTH and the difference of ascorbic acid in the left adrenal before injection and the right adrenal 1 h after injection as endpoint. Different values of the activity of synthetic peptides versus the International Standard resulted from different ways of administration (Vogel 1965).

The ascorbic acid depletion test can also be performed in dexamethasone-blocked rats. However, different potency ratios of synthetic corticotropin analogs have been found than in hypophysectomized rats (Vogel 1969a). The difference most likely depends on the dexamethasone blocking dose.

Other authors, including British Pharmacopoeia (1988) and Deutsches Arzneibuch (1986), use the 2,6-dichlorophenol-indophenol method for determination of ascorbic acid.

The glands are homogenized in 2.5% metaphosphoric acid with the addition of a small quantity of washed sand. With additional 2.5% metaphosphoric acid a final volume of 10 ml is reached. Then 5 ml of the filtrate is added to 5 ml indophenol acetate solution, and the absorbance of the mixture is read immediately in a photometer with a 520 µm filter. The indophenol acetate solution is prepared by dissolving 15 mg of 2,6-dichlorophenol-indophenol in 500 ml distilled water and dissolving 22.65 g sodium acetate·$3H_2O$ in 500 ml distilled water and mixing equal volumes.

A cytochemical bioassay of corticotropin was described by Chayen et al. (1976).

N.7.4.2 Corticosterone Blood Levels in Dexamethasone-Blocked Rats

PURPOSE AND RATIONALE

Corticotropin activity can be measured by the increase of corticosterone in venous blood of hypophysectomized rats (no longer required) or dexamethasone-blocked rats. The test can be used to measure time–response curves of corticotropin analogs or depot preparations (Vogel 1969a, 1969b). The sensitivity can be increased by determining corticosterone in adrenal venous blood after cannulation of the adrenal vein (Retiene et al. 1962).

PROCEDURE

Male Sprague-Dawley rats weighing 150–200 are injected subcutaneously 24 h and 1 h prior to subcutaneous injection of the ACTH preparation or the standard with 5 mg/kg dexamethasone in oily solution. Eight rats are used for each dose of test preparation or standard. At increasing time intervals after ACTH injection, the rats are anesthetized with 60 mg/kg pentobarbital i.p. and blood is withdrawn by venipuncture (alternatively by retro-orbital puncture). Next, 1 ml plasma is diluted with 2 ml distilled water and extracted (washed) with 5 ml petrol ether to remove the lipids. The petrol ether is discarded and 2 ml of the water layer is extracted twice with 5 ml methylene chloride by vigorous shaking for 15 min. The methylene chloride phase is separated by centrifugation. Both methylene chloride extracts are unified and shaken with 1 ml ice-cold 0.1 N NaOH. The water phase is immediately removed and the methylene chloride extracts dried by addition of dry sodium sulfate. A 5-ml aliquot of the methylene chloride extract is mixed with 5 ml of the fluorescence reagent (7 parts concentrated sulfuric acid, 3 parts 96% ethanol, v/v). After vigorous shaking, the methylene chloride phase is removed and fluorescence is measured with primary filters of 436 µm and secondary filters of 530–545 µm. For calibration, concentrations of 0, 20, 50, 100, and 250 µg/ml corticosterone are treated identically and measured in each assay.

EVALUATION

Using three doses of test compound and standard, potency ratios with confidence limits can be determined for each time interval with the 3+3-point assay giving evidence for the duration of action (Vogel 1969a, 1969b).

MODIFICATIONS OF THE METHOD

Pekkarinen (1965) used fluorometric corticosteroid determinations in guinea pigs resulting in highly deviating activity ratios of synthetic and commercial corticotrophins as compared with the international working standard of ACTH.

The contemporary method for the determination of the corticosterone concentration in serum is radioim-

munoassay, requiring much smaller blood samples and reducing the stress to the animals very markedly.

N.7.4.3 In Vitro Corticosteroid Release

PURPOSE AND RATIONALE

An *in vitro* assay of corticotropin was described by Saffran and Schally (1955). This test has been modified by Van der Vies (1957) and subsequently used by several authors (Staehelin et al. 1965; Vogel 1969a, 1969b).

PROCEDURE

Solutions

"Double Ringer" solution is prepared as follows:

4.50%	(w/v) sodium chloride	200.0 ml
5.75%	potassium chloride	8.0 ml
6.10%	calcium chloride	6.0 ml
10.55%	monopotassium phosphate	2.0 ml
19.10%	magnesium sulfate	2.0 ml
	double distilled water up to	545.0 ml

Final solution:

54.0 ml	double Ringer
26.0 ml	1% glucose solution (freshly prepared)
29.0 ml	double distilled water
21.0 ml	1.3% $NaHCO_3$ solution which has been gassed with carbon dioxide at room temperature for 1 h

The final solution is gassed with a mixture of 95% O_2 and 5% CO_2 for 10 min.

Preparation of Adrenals

Male Sprague-Dawley rats ($n = 20$) weighing 150–200 g are anesthetized with 50 mg/kg pentobarbital sodium i.p. applying as little handling stress as possible. The adrenals are removed and freed of connective tissue, taking care that the adrenals are not damaged. Each adrenal is carefully cut into four quarters with fine scissors. The eight quarters from each rat are randomly distributed to 20 preweighed incubation vessels filled with 1.5 ml of final solution. The flasks are mounted on Warburg manometers or placed into a suitable shaking water bath and are gassed under continuous shaking for 1 h with a mixture of 95% O_2 and 5% CO_2 at 38°C (= preincubation period).

The flasks are removed from the bath at the end of the preincubation period. The medium is aspirated as much as possible by means of a small tube attached via a collection bottle to the vacuum line. A 1.4-ml aliquot of fresh medium is added to each flask.

To five vessels each of the following solutions are added:

- 10.0 mU/0.1 ml ACTH standard
- 50.0 mU/0.1 ml ACTH standard
- 10.0 mU/0.1 ml test preparation
- 50.0 mU/0.1 ml test preparation
- 50.0 mU/0.1 ml medium (control)

The vessels are again incubated and gassed with a mixture of 95% O_2 and 5% CO_2 at 38°C under continuous shaking for 2 h. Then 1-ml aliquots of the medium in each vessel are transferred to carefully cleaned glass-stoppered tubes containing 2 ml methylene chloride. The tubes are vigorously shaken for 1 min and centrifuged for 5 min. The methylene chloride phase is transferred with a long needle and a syringe to a quartz micro-cuvette and readings are taken at 225, 240, and 255 µm.

Dry weight of the adrenals is determined by heating the incubations vessels to 150°C for 2 h.

EVALUATION

Extinction values are calculated for the maximum of absorption (Allen 1950) according to the formula:

$$E = E_{240} - \frac{E_{225} + E_{255}}{2}$$

The potency ratios are calculated with the 2+2-point assay.

MODIFICATIONS OF THE METHOD

Saffran et al. (1971) described a flow-through system for the study of adrenocortical function by rat tissue *in vitro*, in which the fluorometric measure of corticosterone is completely automated.

Corticosterone is now conveniently determined by RIA or by a high-performance liquid chromatography (HPLC) method.

N.7.4.4 Thymus Involution

PURPOSE AND RATIONALE

This is a classical indirect bioassay based on the steroid response of the target organ and its effect. Administration of corticotropin decreases thymus weight (due to inducing corticosterone secretion), followed by an increase of adrenal weight (Hayashida and Li 1952; Thing 1953; Thompson and Fisher 1953; Fischer 1962). Young rats respond with an involution of the thymus gland to graded doses of corticotropin (Rerup 1958). A similar assay is used for adrenal steroids.

PROCEDURE

Sprague-Dawley or Wistar rats of either sex, 7–10 days of age, weighing 10–15 g are used. Littermates are preferred. The animals are distributed at random to three groups of the standard and three to five groups of the unknown sample. The ACTH standard or test compounds are injected at different doses once daily subcutaneously for 3 days. Twenty-four hours after the last injection, the animals are sacrificed, the thymus dissected out and weighed to the nearest 0.1 mg. The response is expressed as the average of the individual values for each dose level.

EVALUATION

Dose–response curves are established and potency ratios calculated using a 3+3-point assay.

MODIFICATIONS OF THE METHOD

The numerical sensitivity of the assay can be increased using the quotient between the increase of the weight of the adrenals and the decrease of the weight of the thymus gland (Hohlweg et al. 1960) (ratio adrenal weight increase/thymus weight decrease).

Male Wistar rats at an age of about 3 weeks weighing 18–22 g are injected three times daily at 4-h intervals over 3 days with the test preparation or the standard dissolved in 10% gelatin solution. The animals are sacrificed 18 h after the last injection and the adrenals and the thymus gland removed and weighed.

The ratio of adrenal weight to thymus weight provides a steep dose–response curve.

N.7.4.5 Receptor Binding Assay for ACTH

PURPOSE AND RATIONALE

As for other hormones, receptors have been used as the test preparations for comparison of the binding affinities of adrenocorticotropin peptides using a cloned mouse adrenocorticotropin receptor expressed in a stably transfected HeLa cell line (Kapas et al. 1996). Such assays measure the initial membrane binding but not strictly the biological activation, e. g., of adrenal cells or melanocytes.

PROCEDURE

Hela cells are seeded into 12-well culture plates at a density of 10^6 cells/well. On the 2nd day of culture, the cells are washed as follows: 2 × in 1 ml of ice-cold 0.9% NaCl, 1 × in 1 ml of ice-cold glycine (50 mM glycine, 100 mM NaCl, pH 3.0) for 5 min, 2 × in 0.5 ml of ice-cold 0.9% NaCl. Cells are then incubated for 60 min at 20°C with increasing concentrations of nonradioactive ACTH or various ACTH analogs and the reactions initiated on the addition of [^{125}I-iodotyrosyl^{23}]ACTH[1-39] (2000 Ci/mmol; final concentration 0.1 pmol/l) in DMEM. At the end of the incubation, the medium is removed and the cells washed three times with 0.9% NaCl and then dissolved in 0.5 M NaOH/0.4% sodium deoxycholate. Each point is determined in triplicate, and the radioactivity is measured using a gamma-counter. Specific binding is determined by subtracting from the total binding the radioactivity associated with cells in the presence of 10^{-5} M nonradioactive ACTH.

EVALUATION

Binding parameters are determined using a computer-assisted calculation, e. g., the LIGAND program (Munson and Rodbard 1980).

MODIFICATIONS OF THE METHOD

Penhoat et al. (1993) reported the identification and characterization of corticotropin receptors in bovine and human adrenals by covalent cross-linking of radiolabeled ACTH with the bifunctional cross-linking agent disuccinimidyl suberate to cultured bovine adrenal fasciculata reticular cells and to crude plasma membrane fractions prepared from both human and bovine adrenals.

Lebrethon et al. (1994) and Penhoat et al. (1995) studied the regulation of ACTH receptor mRNA and binding sites by ACTH and angiotensin II in cultured human and bovine adrenal fasciculata cells.

Picard-Hagen et al. (1997) found that glucocorticoids enhance corticotropin receptor mRNA levels in ovine adrenocortical cells.

Zavyalov et al. (1995) described the receptor binding properties of peptides corresponding to the ACTH-like sequence of human pro-interleukin-1$_\alpha$.

Naville et al. (1996, 1997) developed a stable expression model in order to characterize the human ACTH receptor by binding studies and functional coupling to adenylate cyclase.

Schioth et al. (1996) described the pharmacological distinction of the ACTH receptor from other melanocortin receptors in the mouse adrenocortical cell line Y1.

Moreover, melanocortin receptors do not have a binding epitope for ACTH beyond the sequence of alpha-melanocyte-stimulating hormone (Schioth et al. 1997).

CRITICAL ASSESSMENT OF THE METHOD

Binding affinities are determined for structure–activity studies, and the results need to be assessed and confirmed for biological relevance using an assay for the biological response of tissues *in vitro*, and/or the biological effects in animals. These methods are also useful for assessing the sensitivity of hormone-responsive tissues from animals previously treated (adaptive response).

N.7.5
Thyrotropin (TSH)

N.7.5.1
General Considerations

The thyroid-stimulating hormone (TSH) can be determined by bioassays (effects on the thyroid gland and secretion of thyroid hormones) and its concentration can be measured by immunoassays, as with other polypeptide hormones (Utiger 1979; Meinhold et al. 1994; Spencer 1994). TSH receptors have been identified and their functional regulation has been described (Vassart and Dumontl 1992).

Large-scale synthesis of recombinant human thyrotropin has been reported (Cole et al. 1993; Hussain et al. 1996). The role of the thyrotropin receptor has been reviewed by Vassart and Dumont (1992). Castagiola et al. (1992) described a binding assay for thyrotropin receptor autoantibodies using the recombinant receptor protein. A brain-derived TSH receptor has been cloned and expressed (Bockmann et al. 1997), in accordance with the developmental effects of TSH in the fetus and newborn. Binding characteristics of antibodies to the TSH receptor were described by Oda et al. (1998).

N.7.5.2
Thyroid Histology

PURPOSE AND RATIONALE

Hypophysectomy results in atrophy of the thyroid gland, which is reversed by administration of thyrotropin. In the thyroid of normal young guinea pigs (Junkmann and Schoeller 1932; McGinty and McCullough 1936) or chicks (Jones 1939) characteristic histological changes are observed after administration of thyrotropin, associated with an increase of thyroid weight (goitrogenic response). In classical bioassays, these findings were the basis for standardizing by biological units (Turner 1950, 1969).

PROCEDURE

Male guinea pigs weighing 180–200 g are injected once daily on 4 days successively. Thyroids are re-

moved on the 6th day, weighed, and embedded for histological examination. Administration of thyrotropic hormone is followed by colloid resorption, increased vascularity, and increased epithelial cell height. Several regions of the thyroid are examined histologically. Alternatively, computer-assisted morphometry may be used. Rating scores are defined between +1 and +4.

EVALUATION

The rating scores are averaged and compared between test preparation and standard.

N.7.5.3 Iodine Uptake

PURPOSE AND RATIONALE

This is a bioassay for thyroid activation related to the initial step of thyroid-stimulating hormone (TSH) action (Turner 1950, 1962, 1969). The uptake of iodine (trapping) as well as the release of the newly formed iodinated thyroid hormones is under the control of thyrotropin (and in animal assays, under control of hypothalamic thyrotropin-releasing hormone, TRH). As a consequence, the uptake of ^{131}I and the release of ^{131}I-labeled thyroxin are increased after administration of TSH. A method using ^{131}I release in mice has been described by McKenzie (1958) and modified by Sakiz and Guillemin (1964).

PROCEDURE

Female mice weighing 10–15 g are kept in a temperature-controlled room and fed a low-iodine diet for 10 days. They are then injected intraperitoneally with 1.5 µC ^{131}I, followed 5 h later by 10 µg L-T_4 subcutaneously. After 24 h they receive a second injection of 5 µg L-T_4 and are used 48 h after the last injection. Under ether anesthesia 0.25 ml blood is withdrawn from the jugular vein into a heparinized syringe. Various doses of the test preparation or standard TSH are injected by the same route in 0.3 ml volume. Two hours later, again under ether anesthesia, a second 0.25-ml sample is taken, and the radioactivity measured. The increase of radioactivity in the blood samples is dependent on the dose of TSH.

EVALUATION

A 4-point assay technique is used with six observations for each of two doses of the standard and of the unknown preparation.

MODIFICATIONS OF THE METHOD

Depletion of ^{131}I from the thyroids of chicken was used as the endpoint for a TSH assay by Bates and Cornfield (1957).

N.7.5.4 TSH Bioassay Based on cAMP Accumulation in CHO Cells

PURPOSE AND RATIONALE

Indirect cell assays measure the activation of protein kinase A (PKA) through adenylcyclase. Several cell assays for thyrotropin using cultured FRTL-5 cells have been described (Vitti et al. 1986; Nissim et al. 1987; Horimoto et al. 1989). Persani et al. (1993) reported a cell assay for human thyrotropin using measurement of cAMP accumulation on Chinese hamster ovary (CHO) cells transfected with the recombinant TSH receptor.

PROCEDURE

Cells of the CHO-R strain JP-09 are cultured in Petri dishes in RPMI-1640 medium supplemented with 1 mM glutamine and 10% fetal calf serum. In these cells TSH biological activity is evaluated by measuring cAMP production. Cells are harvested from Petri dishes using a Trypsin-EGTA mixture and seeded in 96-well plates (10,000 cells/well). Cells are fed with fresh RPMI-1640 medium 24 h after seeding.

The assay is run after 48 h. After washing, 100 µl of TSH standard or samples diluted in hypotonic or isotonic medium containing 0.4% BSA, 10 mM HEPES, and 0.5 mM isobutylmethylxanthine, are incubated for 2 h at 37°C. Three different dilutions of immunoconcentrated TSH are bioassayed in triplicate, as are TSH preparations. cAMP is measured in nonacetylated samples by an RIA method using a commercial polyclonal anti-cAMP antibody (Vitti et al. 1986).

EVALUATION

Dose–response curves or single-point comparisons are used for potency or activity estimates.

N.7.6 Hormones Related to TSH

N.7.6.1 General Considerations

These hormonal factors are now characterized by molecular cloning. One of the characteristic symptoms of thyroid activation (Graves' or Basedow disease) is exophthalmos. A dissociation of the exophthalmos-producing activity from the TSH activity has been found (Dobyns and Steelman 1953). Moreover, time–response curves for TSH activity from the serum of patients with hyperthyroidism differed from those of the standard TSH, giving evidence for the presence of an abnormal factor, long-acting thyroid-stimulating factor (LATS). Bioassays for these factors have been developed (Ludgate 1999). TSH receptor stimulating antibodies have also been identified and suitable animal models have been investigated (diCerbo and Corda 1999; DeFelice et al. 2004).

N.7.6.2 Assay of Exophthalmos-Producing Substance (EPS) in Fishes

PURPOSE AND RATIONALE

Some TSH fractions were reported to produce more exophthalmos than others (Dobyns and Steelman 1953). A second fraction containing exophthalmos-producing substance (EPS) could be separated (Brunish et al. 1962). The activity of this substance was demonstrated in fishes.

PROCEDURE

Fundulus heteroclitus Linn., the common Atlantic minnow, has been found to be the suitable animal model (Albert 1945; Sobonya and Dobyns 1967; Turner 1969). Other fish species, such as *Carassius auratus* (the common gold fish; Haynie et al. 1962) and *Cyprinus carpio* (der Kinderen et al. 1960), were also used but gave less reliable results (Sobonya and Dobyns 1967). *Fundulus heteroclitus* Linn., common Atlantic minnows, 8–10 cm in length, are kept in a tank of running tap water at 10°C in winter and 18°C in summer. Before treatment the intercorneal distance is measured with Vernier calipers to the nearest of 0.1 mm. The test compound and the standard are injected intraperitoneally at various, but at least two, doses. To avoid loss of fluids by the intraperitoneal injection route, the needle is inserted into the cloaca, through the rectum, over the pelvic girdle, and into the peritoneal cavity for a distance of about 1.2 cm. The volume of fluid injected should be 0.1–0.5 ml. The effect of the hormone is to cause protrusion of the eyeballs. The intercorneal distance is measured again after 24, 48, and 72 h. The increase in proptosis is expressed

as a percentage of the intercorneal distance found at the beginning of the test.

EVALUATION

The increases of intercorneal distance after each dose are averaged and activity ratios with confidence limits calculated from the 2+2-points assay.

N.7.6.3 Assay of Long-Acting Thyroid-Stimulating Factor (LATS) in Mice

PURPOSE AND RATIONALE

This is a modification of the TSH assay to assess the late onset of action of LATS. In the assay of McKenzie (1958) (see N.7.5.3), mice previously injected with ^{131}I show a maximum increase in serum ^{131}I after an interval of 2–3 h when TSH is administered. In the assay of serum from thyrotoxic patients, Adams (1958) noted that the maximum response in guinea pigs did not occur until after 16 h. The abnormal responses to thyrotoxicosis sera suggested the presence of an additional factor different from TSH.

PROCEDURE

Mice maintained on a low-iodine diet for 10 days are injected with 15 µC ^{125}I and 10 µg Na L-T_4. Four days later, 0.1 ml of blood is obtained by retro-orbital puncture immediately before the injection of the test substance 2 and 9 h later. Radioactivity in the blood is then measured. By definition, radioactivity which is maximal after 2 h is indicative of TSH, whereas LATS causes a maximal increase at 9 h.

EVALUATION

The increases of radioactivity after 2 and 9 h are compared and evaluated by statistical methods.

MODIFICATIONS OF THE ASSAY

Ikeda and Nagataki (1983) and Ikeda et al. (1984) used male DDY mice weighing 15 g. They were fed a low-iodine diet for 14 days and then injected daily with 1 µg of 3,5,3′-triiodothyronine (T_3) s.c. and given T_3 (5 µg/ml) ad libitum in drinking water until sacrifice. From the 5th day of T_3 treatment they were injected i.p. with 0.25 ml of LATS-positive serum for 9 days. Groups of five mice were sacrificed before, 1, 3, 5, 7, and 9 days after the first injection of LATS. Then 1 µCi (0.5 ml) of Na [^{131}I] was administered i.p. 1 h before sacrifice. Thyroid lobes were excised, weighed, and radioactivity was measured by a gamma counter. Immediately before injection of Na [^{131}I], approximately 60 µl of blood was collected from the orbital plexus with heparinized capillary tubes and centrifuged at 12,000 rpm for 3 min. T_4 concentrations in serum were determined by radioimmunoassay.

Ealey et al. (1984, 1985) developed a sensitive cytochemical bioassay for thyroid stimulators, using reference preparations of thyrotropin and LATS. Thyroid stimulators cause changes in lysosomal membrane permeability within the thyroid follicular cells of guinea pigs, which can be monitored by measuring increased intralysosomal enzyme activity (in the case of this assay, naphthylamidase), with a chromogenic substrate leucine-2-naphthylamide, which itself does not readily permeate the lysosomal membrane in unstimulated cells.

N.8
Posterior Pituitary Hormones

N.8.0.1
General Considerations

Oxytocin and vasopressin were the first hormones isolated from the posterior pituitary lobe (Dale and Laidlaw 1912; Hogben et al. 1924; Fromherz 1926; Schaumann 1937). Vasopressin has antidiuretic activity and, at higher doses, hypertensive effects as well as endocrine functions (Hedge and Huffman 1987) and effects on the central nervous system (Gash et al. 1987), which are however outside the scope of this chapter. In terms of bioassays, the antidiuretic activity is the main parameter. Many analogs of vasopressin have been synthesized resulting in selective agonists and antagonists (Vogel and Hergott 1963; Allison et al. 1987; Mah and Hofbauer 1987; Manning et al. 1987). Different types of vasopressin receptors have been identified: V_1 (V_{1a}, V_{1b}) and V_2-receptors (Jard et al. 1976, 1986; Fahrenholz et al. 1988; Walker et al. 1988; Burnatowska-Hledin and Spielman 1989). Research on the vasopressin analogs has provided several compounds of clinical utility, and antagonists of vasopressin are now increasingly explored for several indications, including nonpeptide vasopressin antagonists (Mayinger and Hensen 1999; Serradeil-Le Gal et al. 2002; Greenberg and Verbalis 2007; Urban et al. 2007).

The use of bioassays in the evaluation of these vasopressin and oxytocin analogs has been reviewed (Liard 1988; Chan et al. 2000).

Oxytocin receptors have been described in several organs, such as uterus, mammary gland and CNS (Soloff 1976; Hruby and Chow 1990).

The synthesis and development of several orally active, nonpeptide oxytocin antagonists have been reported (Bell et al. 1998; Kuo et al. 1998).

Radioimmunoassays are available for both oxytocin (Kagan and Glick 1978) and vasopressin (Glick and Kagan 1978).

N.8.1 Oxytocin

N.8.1.1 Isolated Uterus

PURPOSE AND RATIONALE

Several authors, such as Dale and Laidlaw (1912), Fromherz (1926), Glaubach and Molitor (1932), Lipschitz and Klar (1933), and Simon (1933), used the isolated uterus of virgin guinea pigs as a sensitive test for determination of oxytocin activity. The isolated uterus of the rat (Holton 1948) is less sensitive but, in contrast to the guinea pig, the rat uterus shows no spontaneous contractions in solutions with low calcium and glucose concentrations. Historically, the method has been adopted by several pharmacopoeias, e. g., by the British Pharmacopoeia (1988). The United States Pharmacopeia 23 (1995) uses the isolated guinea pig uterus for determination of oxytocin activity in vasopressin preparations. Physicochemical assays are now used for standardizing drug content, instead of the biological responses.

PROCEDURE

Female Sprague-Dawley or Wistar rats weighing 120–200 g are used. At 18–20 h prior to the assay, the rat is injected i.m. with 100 µg of estradiol benzoate for priming (receptor induction). Immediately before the assay the rat is tested for estrogen-induced epithelial proliferation by vaginal smear. One horn of the uterus is suspended in an organ bath containing a solution of the following composition:

Sodium chloride	6.62 g/l
Potassium chloride	0.45 g/l
Calcium chloride	0.07 g/l
Sodium hydrogen carbonate	2.56 g/l
Disodium hydrogen orthophosphate	0.29 g/l
Sodium dihydrogen orthophosphate	0.03 g/l
Magnesium chloride	0.10 g/l
D-Glucose	0.50 g/l

The bath temperature is maintained at 32°C, a temperature at which spontaneous contractions of the uterus are abolished and the preparation maintains its sensitivity. The solution is bubbled with a mixture of 95% O_2 and 5% CO_2. The preparation is loaded with 1–2 g and the contractions recorded using a Statham transducer and a polygraph. Two doses of the standard preparation are added, ranging usually between 10 and 50 µU/ml organ bath. The preparation examined is diluted in such a way to obtain responses on the addition of two doses similar to those obtained with the standard preparation. The ratio between the two doses of the preparation being examined should be the same as that between the two doses of the standard preparation. The two doses of the standard preparation and the two doses of the preparation being examined are given according to a randomized block or a Latin square design and at least six to eight responses to each are recorded. The doses should be recorded at regular intervals of 3–5 min depending on the rate of recovery of the muscle.

EVALUATION

The activity and potency ratios with confidence limits are calculated from the 2+2-points assay.

MODIFICATIONS OF THE METHOD

The isolated rat uterus is also used to test spasmolytic activity of various drugs against oxytocin as spasmogen. Liebmann et al. (1993) used the rat uterus to test the pharmacological and molecular actions of the bradykinin B_2 receptor antagonist, Hoe 140.

The method described by Schübel and Gehlen (1933) using the **uterus of cats** 2–4 days after partum is of historical interest only.

In addition to the isolated rat uterus, Berde et al. (1957) used the **rat uterus *in situ***, the **cat uterus *in***

vitro, and the **cat uterus *in situ*** for evaluation of synthetic analogs of oxytocin.

Murray and Miller (1960) observed characteristic post-ural changes in rats following administration of oxytocin to unanesthetized rats described as "cramping" which was dose-dependent in estrogen-pretreated animals.

An *in vitro* **hen oxytocic assay** was designed by Munsick et al. (1960). Muscle strips of the uterine portion of the oviduct of laying hens are dissected and suspended in a van Dyke-Hastings solution containing 0.15 mM calcium, 0.5 mM magnesium and 100 mg% glucose. The strips are 2–3 cm long and 2–3 mm wide. The solution is gassed with oxygen containing 5% carbon dioxide and maintained at a temperature of 43°C. These conditions are necessary to prevent spontaneous contractions.

The **isolated uterus from immature guinea pigs** was used for evaluation of oxytocin activity by Fromherz (1926) and by Vogel and Hergott (1963).

Guissani et al. (1995) and Pettibone et al. (1996) reported the effect of oxytocin antagonists in **pregnant rhesus monkeys** *in vivo*.

N.8.1.2 Chicken Blood Pressure

PURPOSE AND RATIONALE

Oxytocin induces a transient fall in blood pressure in chicken and other birds. This effect can be used as an assay for oxytocin (Coon 1939). The method has been modified by Munsick et al. (1960) and accepted by pharmacopoeias; for example, the United States Pharmacopeia 23 (1995a, 1995b) uses the chicken blood pressure method for determination of oxytocin activity

with three doses of standard and test preparation and calculation of the activity ratio with confidence limits.

PROCEDURE

White Leghorn chickens weighing 1.2–2.0 kg are anesthetized by intravenous injection with 200 mg/kg sodium phenobarbital via the brachial vein. The ischiadic artery is exposed by removing the feathers from the outer surface of the left thigh, and an incision 7–8 cm long is made in the skin, parallel to and about 1.5 cm below the femur, exposing the gluteus primus muscle. The lower edge of this incision is retracted to expose the edge of the gluteus primus muscle overlying the semitendinosus muscle. The edge is then freed for the length of the incision, and when the free edge is lifted, the ischiadic artery, the ischiadic vein, and the crural vein can be seen lying along the edge of the semitendinosus muscle. The gluteus primus muscle is cut at right angles near the proximal end of the incision and the resulting flap deflected and secured to the upper thigh. A length of the ischiadic artery and the crural vein are dissected free and the artery is cannulated. The cannula is connected to a Statham pressure transducer. Blood pressure should be between 100 and 120 mmHg. The crural vein is cannulated for injections of the test preparations. Intravenous injection of oxytocin induces in chickens an immediate, transient fall in blood pressure. Doses of the standard are chosen which are followed by a decrease of blood pressure of between 20 and 40 mmHg. The required doses normally lie between 20 and 100 mU.

Two doses of the standard and two doses of the test preparations are injected according to a randomized block or to a Latin square design and at least six to eight responses to each should be recorded. The interval between injections should be constant and lies between 3 and 10 min, depending on the rate at which the blood pressure returns to normal.

EVALUATION

The responses to each dose are averaged and potency ratios with confidence limits calculated from the 2+2-points assay.

N.8.1.3 Milk Ejection in the Lactating Rabbit or Rat

PURPOSE AND RATIONALE

A sensitive bioassay for the estimation of oxytocin was described by van Dyke et al. (1955). This test makes use of the milk-ejecting properties of oxytocin.

PROCEDURE

A rabbit in the first or second week of lactation is anesthetized with urethane and pentobarbital. Usually, artificial respiration is not necessary. One jugular vein is cannulated for injections. One of the six ducts in a nipple of the rabbit is cannulated with a hypodermic needle and connected with a Statham strain gauge transducer. Two doses of the standard and the test preparation are injected according to a randomized block or to a Latin square design and at least six to eight responses to each should be recorded. The interval between injections should be constant at 3 min.

EVALUATION

The responses of each dose are averaged and potency ratios with confidence limits calculated from the 2+2-points assay.

MODIFICATIONS OF THE METHOD

The British Pharmacopoeia (1988) recommends the measurement of milk-ejection pressure in the lactating rat. A lactating rat weighing about 300 g in the 3rd to 21st day after parturition is anesthetized by pentobarbitone sodium. The trachea is cannulated. One jugular or femoral vein is cannulated for injection of the test preparations. The tip of one lower inguinal teat is excised and a polyethylene tube with an external diameter of 0.6 mm is inserted to a depth sufficient to ob-

tain appropriate measurement of pressure into the primary teat duct which opens onto the cut surface and is tied firmly in place with a ligature. The cannula is connected with a suitable strain gauge pressure transducer for recording on a polygraph.

Tindal and Yokoyama (1962) recommended the use of guinea pigs using essentially a similar procedure, but the injection is made into the internal saphenous artery after ligation of the main branches supplying the limb. In the guinea pig the mammary glands are supplied with blood from the external pudendal arteries, which branch from the internal saphenous artery just as they enter the legs.

N.8.1.4 Oxytocin Receptor Determination

The family of the vasopressin and oxytocin receptors has been studied very intensely (Peter et al. 1995) in order to obtain evidence for new indications, and to determine the specific regions in each receptor subtype and the associated effector systems for the G-protein-linked subtypes (Thibonnier et al. 1998).

PURPOSE AND RATIONALE

Premature labor and pre-term delivery is an important cause of death among infants and a major cause of newborn and child morbidity. Strong evidence exists that oxytocin and catecholamines are involved in the spontaneous uterine contractions which bring about premature delivery. Development of oxytocin antagonists is believed to be of therapeutic value for the prevention of pre-term labor (Manning et al. 1995; Chan et al. 1996).

In vitro binding to the oxytocin receptor is used as the first step in the characterization of potential oxytocin antagonists (Pettibone et al. 1990, 1991, 1993a, 1993b, 1996; Evans et al. 1993; Manning et al. 1995; Freidinger and Pettibone 1997; Pettibone and Freidinger 1997).

PROCEDURE

Uterine tissue is taken from nonpregnant adult Sprague-Dawley rats pretreated (18–24 h) with diethylstilbestrol (300 µg/kg, i.p.) and mammary tissue from lactating rats (4–14 days of lactation). The tissues are homogenized in 10 mM Tris containing 1 mM EDTA and 0.5 mM dithiothreitol, pH 7.4 and centrifuged at 48,000 *g* for 30 min at 4°C. The resulting pellets from mammary/uterine tissue are resuspended in 50 mM Tris/5 mM $MgCl_2$/0.1% BSA (pH 7.4) and centrifuged again to produce the final pellet. Competition studies are conducted at equilibrium for 60 min at 22°C using 1 nM [^{3}H]OT (30–60 Ci/mmol, New England Nuclear, Boston, Mass., USA) in the following buffer: 50 mM Tris/5 mM $MgCl_2$/0.1% BSA (pH 7.4). Nonspecific binding (5%–10% of total binding) is determined using 1 µM unlabeled oxytocin. IC_{50} values are calculated from the linear regression analysis of log concentration of inhibitor versus percentage inhibition of specific binding. Saturation binding studies are conducted at equilibrium using a 100-fold range of radioligand concentrations (i. e., 0.1–10 nM) and analyzed by a nonlinear regression program (McPherson 1985a, 1985b). The binding reactions are initiated by the addition of the tissue preparation (final protein concentrations, 100–200 µg protein/ml) and terminated by rapid filtration through Skatron glass fiber filters using a Skatron cell harvester system (Model 7019, Skatron, Sterling, Va., USA).

EVALUATION

Inhibition constants (K_i) are calculated for each compound from three to six separate IC_{50} determinations ($K_i = IC_{50} / [1 + c / K_d]$) using mean dissociation constants (K_d) obtained from saturation binding assays.

MODIFICATIONS OF THE METHOD

Maggi et al. (1994) used cultured Hs 805.Ut (corpus uteri, normal, human) cells or cells obtained from women in the early follicular or late luteal phase to study binding of antagonists at the human oxytocin receptor.

Pak et al. (1994) compared the binding affinity of oxytocin antagonists to human and rat oxytocin receptors and correlated the results with the rat oxytocic bioassay.

Species differences in central oxytocin receptor gene expression were investigated by Young et al. (1996).

Cloning and expression of the rhesus monkey oxytocin receptor was reported by Salvatore et al. (1998).

Molecular cloning and functional characterization of the oxytocin receptor from a rat pancreatic cell line (RINm5F) was reported by Jeng et al. (1996).

Elands et al. (1987) and Klein et al. (1995) recommended selective radioligands for the oxytocin receptor for the structure–activity research directed to receptor subtypes.

N.8.2 Vasopressin

N.8.2.1 Hereditary Vasopressin Deficiency in Rats (Brattleboro Strain)

This bioassay is based on an animal strain with genetic deficiency of vasopressin synthesis. Patients with diabetes insipidus excrete large amounts of very diluted urine and need a high fluid intake. This disorder is

due to a lack of vasopressin. A similar syndrome has been found in Brattleboro rats. In the rare nephrogenic form, the vasopressin receptors are defective (Sokol and Valtin 1982; Nyunt-Wai and Laycock 1990; Szot and Dorsa 1992). Vasopressin is also considered to be a modulator in the central nervous system in particular learning and memory processes. Therefore, many studies on learning and memory have been performed with this strain of rats. Valtin et al. (1965) found very little vasopressin in hypothalami and pituitaries of homozygous Brattleboro rats.

Schmale and Richter (1984) and Schmale et al. (1984) found a single base deletion in the vasopressin gene as the cause of diabetes insipidus in Brattleboro rats. The mutant vasopressin gene is transcribed but the message is not efficiently translated. Spontaneous hypertensive rats crossbred with Brattleboro rats inherit the mutated vasopressin gene (McCabe et al. 1988). The abnormal quinine drinking aversion in the Brattleboro rat with diabetes insipidus can be reversed by a vasopressin agonist (Laycock et al. 1994)

For testing aquaretic effects in Brattleboro rats see C.1.2.1.

MODIFICATIONS OF THE METHOD (OTHER DIABETES INSIPIDUS MODELS)

Similar studies werer reported by: Byrnes et al. 1953; Randall and Selitto 1958; Eviatar et al. 1961; Turner 1965; Dorfmann 1969; Neri et al. 1972; Neumann et al. 1977; Furr et al. 1987; Snyder et al. 1989; Christiansen et al. 1990; Shibata et al. 1992; Neubauer et al. 1993; Tagekawa et al. 1993

Several other animal models of diabetes insipidus have been developed and characterized (Herman et al. 1986; Grant 2000; Lloyd et al. 2005; Petersen 2006) for the understanding of pathophysiology, for explanation of genetic deficiencies, and to validate the animal models based on substitution of vasopressin deficiency.

N.8.2.2 Vasopressor Activity

PURPOSE AND RATIONALE

Vasopressin activity can be determined by the increase of blood pressure observed after surgical or pharmacological elimination of the central and peripheral nervous regulation of the cardiovascular system. Dekansky (1952) described a quantitative assay of vasopressin in anesthetized rats after blockade of other pressor substances by dibenamine (pithed rat).

PROCEDURE

A male Wistar rat weighing about 300 g is anesthetized by subcutaneous injection of 1.75 g/kg urethane. After 45–60 min, the trachea is cannulated with a polyethylene tube of 2.5 mm diameter. One femoral vein is cannulated for injections and the carotid artery for measuring blood pressure with a Statham transducer. The central and peripheral nervous systems, including both vagi and associated sympathetics, are left intact. No artificial respiration is necessary. Heparin (2000 U/kg) is injected through the venous cannula and washed through with saline. [Dibenamine *N*-(2-chloroethyl)dibenzylamine hydrochloride] is injected twice intravenously with an interval of 10 min at a dose of 1 mg/kg. The blood pressure stabilizes at a basal level of about 50 mmHg. Small doses of vasopressin induce an increase in blood pressure which is depen-

dent on the dose. Two doses of vasopressin standard (approximately 3–5 mU) and two doses of test preparation are injected repeatedly (usually 6 times) using a Latin square design. The doses are injected at intervals of 10–15 min.

EVALUATION

The responses of each dose are averaged and potency ratios calculated from the 2+2-points assay.

MODIFICATIONS OF THE METHOD

One of the first recommendations for standardizing posterior pituitary extract was by measuring blood pressure in anesthetized dogs (Hamilton 1912).

Vogel and Hergott (1963), studying the properties of a synthetic vasopressin analog, described a method in decerebrate rabbits previously used in this laboratory for standardization of posterior pituitary extracts. Rabbits weighing 2–3 kg were anesthetized by slow intravenous injection of butallylonal. The trachea is cannulated and the cannula connected with a respiration pump. One femoral vein is cannulated for injection of the test compounds. One carotid artery is cannulated for measurement of blood pressure with a Statham transducer. For chemical decapitation, the head of the anesthetized rabbit is bent forwards and a needle introduced into the foramen occipitale magnum, and then 0.5 ml of 30% trichloroacetic acid is injected. Artificial respiration is started immediately. Blood pressure is stabilized at a level of 30–40 mmHg. Two doses of standard and of test preparation are injected according to a Latin square design. The method has been proven to be very sensitive.

The British Pharmacopoeia (1988) recommends the intravenous injection of 10 mg/kg of the α-adrenoreceptor blocking agent phenoxybenzamine hydrochloride 18 h prior to the experiment to stabilize the blood pressure at a low level. USP 23 (1995a, 1995b) uses two doses of standard and test preparation in the phenoxybenzamine-blocked rat for calculation of vasopressin activity with confidence intervals in vasopressin and oxytocin preparations.

Knape and van Zwieten (1988) used the pithed rat to study vasoconstrictor activity of vasopressin after pretreatment with various drugs.

N.8.2.3 Antidiuretic Activity in the Conscious Rat

PURPOSE AND RATIONALE

For some period of time, it was uncertain whether vasopressin and adiuretin are the same or separate hormones. Special tests for antidiuretic activity in water-loaded rats were developed (Burn 1931) and adopted by pharmacopoeias. Vasopressin analogs show considerable dissociation of vasopressive and antidiuretic activities (Vogel and Hergott 1963).

PROCEDURE

Wistar or Sprague-Dawley rats weighing between 140 and 250 g of either sex are used. The range of weights in any one test should not exceed 50 g. Not less than 2 days before testing the preparation, the rats have to be accustomed to the metabolism cage by carrying out a preliminary test. All animals are injected with 0.1 ml saline solution per 100 g body weight instead of the test preparations given in the main test. Any rat that shows signs of stress or undue excitement or that has abnormally low or high rate of urine excretion should not be used in the main test. Food and water are withheld during each test but access is allowed between the tests. The rats are assigned at random to four groups,

each no less than four animals, and are weighed and marked for identification purposes. By stomach tube each rat receives a volume of water warmed to approximately 37°C and equivalent to 5% of the animal's body weight. Each rat is placed in a separate cage for collection of urine. Then 30 min later, the volume excreted by each rat is recorded and a second volume of tap water equal to the volume of urine together with a further volume equivalent to 3% of the animal's body weight is administered. This provides a total water load equivalent to 8% of the animal's body weight.

Using a different group of rats and two dilutions of the preparation to be examined and of the standard preparation, immediately after administration of the second dose of water, each rat is injected subcutaneously with a volume of the appropriate dilution equivalent to 0.1 ml per 100 g body weight. The urine passed during the first 5 min after injection is discarded and the volumes collected at intervals of 15 min are noted until a volume greater than 30% of the total water load is excreted.

EVALUATION

The responses of each dose are averaged and activity ratios with confidence limits are calculated from the 2+2-points assay.

MODIFICATIONS OF THE METHOD

Hydrated **conscious dogs** have been used to test the antidiuretic activity of vasopressin by van Dyke et al. (1955).

N.8.2.4 Antidiuretic Activity in the Rat in Ethanol Anesthesia

PURPOSE AND RATIONALE

This is a sensitive bioassay often reported for vasopressin analogs, which has been applied extensively but is no longer required due to the availability of other methods (e. g., Brattleboro rats). Ethanol suppresses the secretion of endogenous antidiuretic hormone (van Dyke and Ames 1951). Sensitive methods measuring urine output in ethanol-induced anesthesia were described (Dicker 1953; Dettelbach 1958; Munsick et al. 1960; Berde and Cerletti 1961), whereby the water load is automatically kept constant.

PROCEDURE

Female Sprague-Dawley rats weighing 200–250 g are spayed 7–10 days prior to use in order to eliminate the effect of gonadal steroids on the response to a water load. Each animal is given a 5-ml gavage of tepid tap water. At 3-day intervals thereafter, the water load is increased by 1-ml increments until a 10-ml level is reached. The day before an assay is to be performed, two or three animals are selected and given a 10-ml gavage of 2% ethanol. The animals are fasted overnight but are allowed free access to water. On the test day, they are placed into individual metabolism cages for water loading and anesthetizing. Each rat receives 5% of its body weight of warm 12%–15% ethanol by stomach tube. This induces anesthesia within a few minutes. After 45 min the same volume of 2% ethanol is again given by gavage. After 1 h the bladder is emptied by suprapubic pressure and the total urine output is measured.

The animal with the largest volume is selected and the water load calculated as the total volume administered less the volume excreted. The load on this animal is now increased to between 6% and 8% of its body weight with warm 2% ethanol. Then the urinary bladder is catheterized. Polyethylene tubing is inserted into the rat's stomach. A femoral vein is cannulated for injections. The hind legs are secured to the operation table, while the front legs are left free. Assays are started when urine flow reaches a steady level of at least 50 µl/min. The catheter from the bladder is connected to an apparatus consisting of two Woulff bottles. Urine is directed through the catheter into the first Woulff bottle, displacing fluid into the second Woulff bottle. The second bottle is filled with 0.5% NaCl solution in 50% ethanol to reduce the size of the drops. Each drop activates an impulse counter. The drops are collected in a small glass reservoir and led by means

of polyethylene tubing to the urine metering pipette. When the fluid level in this tube rises and makes contact with an adjustable needle electrode near the top, another pipette which is calibrated to the same volume empties a solution of 5% glucose in 2% ethanol through the gavage tube into the rat's stomach. By these means a constant water load is maintained.

The animals produce urine at a relatively steady rate for 3–5 h. Intravenous injections of vasopressin produce characteristic changes (decreased rate of urine flow), which begin usually within 2 min and subside in most instances within 15 min. The range in which the assay of antidiuretic activities is useful is between 2 and 64 μU/injection.

EVALUATION

Antidiuretic potency is calculated as the log ratio of the volume excreted in 5 min preceding injection to the volume excreted in the 5 min beginning 1 min after injection. Dose–response relationships are established for the standard and the test preparation and potency ratios are calculated.

MODIFICATIONS OF THE METHOD

Berde and Cerletti (1961) placed the rat anesthetized with ethanol on a balance. The water loss due to urine excretion and perspiratio insensibilis is replaced automatically using a solution of 5% glucose in 2% ethanol.

N.8.2.5 Spasmogenic Activity of Vasopressin in the Isolated Guinea Pig Ileum

PURPOSE AND RATIONALE

The ileum of the guinea pig has been found to be quite sensitive to vasopressin (Simon 1933; Schaumann 1937; Vogel and Hergott 1963). This is a direct effect on smooth muscle similar to the pressor effect. This test is not specific for vasopressin.

PROCEDURE

Pieces of guinea pig ileum are suspended in an organ bath according to the Magnus' technique (see J.4.3.1). Two different doses of the test preparation and of the standard are applied according to a Latin square design and the contractions measured using a strain gauge transducer. Four to six doses of each solution are measured.

EVALUATION

The responses of each dose are averaged and activity ratios with confidence limits are calculated from the 2+2-points assay.

N.8.2.6 Vasopressin Receptor Determination

PURPOSE AND RATIONALE

As in other areas of drug research, when specific receptor preparations became available for *in vitro* research, those identifying new vasopressin-like compounds (in structure–activity studies) turned to new methods with high specificity and capacity, replacing the cumbersome bioassays. Tests for receptor affinity are also used in "receptor screens" for the general pharmacology of new drug candidates, to predict their spectrum of activities.

Arginine vasopressin exerts its action through three membrane-bound G-protein-coupled receptor subtypes (V_{1a}, renal V_2 and V_3). The vasopressin-induced antidiuresis (via V_2 receptors coupled to aquaporins) helps maintain plasma osmolality and salt (NaCl) balances. The human V_1, V_2 and V_3 (V_{1b}) receptors and water-selective membrane proteins (aquaporins) in the kidney have been cloned, and receptor signaling has been characterized in detail (Thibonnier et al. 1998).

Pharmacological characterization of the human vasopressin receptor subtypes stably expressed in Chi-

nese hamster ovary cells was reported by Tahara et al. (1998).

Selective nonpeptide vasopressin antagonists (without agonistic activity) have been shown to be aquaretic agents in animals and humans. The development and therapeutic indications of orally active vasopressin receptor antagonists were reviewed by Thibonnier (1998), as were the postreceptor signaling mechanisms for the vasopressin receptor subtypes.

Serradeil-Le Gal et al. (1993, 1994a) studied the biochemical and pharmacological properties of a nonpeptide antagonist on rat and human vasopressin V_{1a} receptors, to explore the possibility of using centrally acting derivatives for indications in neuropharmacology.

PROCEDURE

Tissue samples from human uterus, adrenals, kidneys, and pituitaries are collected in conformity with national ethical rules. Uterus, adrenal, and kidney samples are immediately chilled in cold saline. Membranes are prepared within 3 h after collection. Pituitaries are collected within 6 h after death and immediately frozen in liquid nitrogen. Bovine kidneys can be obtained from a local slaughterhouse. Rat mammary tissue is taken from 19-day Sprague-Dawley pregnant rats.

For human adrenal membrane preparations, pieces of adrenal glomerulosa zone are suspended in a cold buffer (10 mM Tris-HCl, pH 7.4, 3 mM $MgCl_2$, 1 mM EDTA, 250 mM sucrose, 1 mM phenylmethylsulfonyl fluoride, PMSF) and fragmented using a glass/glass Dounce homogenizer. The homogenate is filtered through glass wool and centrifuged for 15 min at 1500 *g* at 4°C. The pellet is incubated for 15 min in ice-cold hypotonic buffer (10 mM Tris-HCl, pH 7.4, 3 mM $MgCl_2$, 1 mM EDTA, and 1 mM PMSF) and kept on ice to allow cell lysis. Lysed cells are recovered by centrifugation at 1500 *g* for 15 min at 4°C, homogenized using a loose-fitting Dounce homogenizer in hypotonic buffer supplemented with 40% glycerol, and stored at −20°C. Before experiments, glycerol is eliminated by washing the membranes in glycerol-free hypotonic buffer.

For preparation of hypophyseal membranes, frozen entire pituitary glands are rapidly thawed at 37°C in isotonic buffer supplemented with 0.1 mM PMSF, and the adenohypophyses are separated. Adenohypophyseal membranes are prepared as described above for adrenal membranes.

For rat mammary gland membrane preparations, tissues are minced and homogenized in 50 mM 10% (wt/vol) buffer A Tris-HCl, pH 7.4, 320 mM sucrose, and 0.5 mM dithiothreitol and centrifuged at 900 *g* for 15 min; the pellet is resuspended in buffer A and centrifuged as above. The two 900-*g* supernatants are filtered through cheesecloth and centrifuged at 70,000 *g* for 20 min. The pellet is washed with buffer B containing 50 mM Tris-HCl, pH 7.4, and 10 mM $MgCl_2$. Finally, the 70,000-*g* washed pellet is suspended in buffer B at a final concentration of ∼ 8 mg protein/ml and stored in aliquots in liquid nitrogen.

V_{1a} binding assays using ^{125}I linear AVP antagonist on human adrenal membranes, myometrial membranes from nonpregnant uterus, or platelet membranes are performed using an incubation medium (200 µl) containing 10 mM Tris-HCl, pH 7.4, 3 mM $MgCl_2$, 1 mg/ml bovine serum albumin (BSA), 0.05 mg/ml soy bean trypsin inhibitor, 0.5 mg/ml bacitracin, 0.1 mM PMSF, 0.5 mM EDTA, 10–60 pM ^{125}I-AVP linear antagonist, and increasing amounts of test compound. The reaction is started by the addition of membranes (10–40 µg/assay) that are incubated at 30°C for 45 min. The reaction is stopped by adding 3 ml of ice-cold filtration buffer (10 mM Tris HCl, pH 7.4, and 3 mM $MgCl_2$) followed by filtration through GF/C Whatman glass microfiber filters that have been soaked for at least 5 h in a solution containing 10 mg/ml BSA. Filters are washed five times with 3 ml of filtration buffer and counted for radioactivity by gamma spectroscopy. Nonspecific binding is determined in the presence of 0.3 µM unlabeled iodinated AVP linear antagonist or 1 µM AVP.

EVALUATION

The IC_{50} value is defined as the concentration of inhibitor required to obtain 50% inhibition of the specific binding. Inhibition constant (K_i) values are calculated from the IC_{50} values using the Cheng and Prusoff equation. Data for equilibrium binding (K_d, B_{max}), competition experiments (IC_{50} n_{Hill}), and kinetic constants (k_{obs}, k_1) are analyzed using an iterative nonlinear regression program (Munson and Rodbard 1980).

MODIFICATIONS OF THE METHOD

A receptor assay for arginine-vasopressin is described by Gopalakrishnan et al. (1986).

Pearlmutter et al. (1985) characterized a specific binding site for arginine-vasopressin in particulate membranes from rat aorta.

Pávó et al. (1993) reported the synthesis and binding characteristics of two sulfhydryl-reactive probes for vasopressin receptors.

Serradeil-Le Gal et al. (1994b) tested the effect of a nonpeptide vasopressin V_{1a} vasopressin antagonist on the binding and mitogenic activity of vasopressin in Swiss 3T3 cells.

Yatsu et al. (1997) tested the vasopressin antagonistic activities of a nonpeptide dual vasopressin V_{1a} and V_2 receptor antagonist on V_{1a} receptors in dog platelets and on V_2 receptors in dog kidney homogenates.

Ogawa et al. (1996) and Tahara et al. (1997a) tested V_{1a} receptor binding in homogenates of rat liver and V_2 receptor binding in rat kidney.

Barberis et al. (1995) characterized a linear radioiodinated vasopressin antagonist as an excellent radioligand for vasopressin V_{1a} receptors.

Radioligands for vasopressin V_1 receptors were described by Elands et al. (1988) and by Kelly et al. (1989).

Ala et al. (1997) reported the properties of a radioiodinated antagonist for human vasopressin V_2 and V_{1a} receptors and recommended this ligand for further studies on human vasopressin V_2 receptor localization and characterization, when used with a selective vasopressin V_{1a} ligand.

Howl and Wheatley (1995) found species heterogeneity in the characteristics of V_{1a} receptors and in the expression of hepatic V_{1a} receptors.

Thibonnier et al. (1994) reported molecular cloning, sequencing, and functional expression of a cDNA encoding the human V_{1a} vasopressin receptor.

Carnazzi et al. (1997) described photoaffinity labeling of the rat V_{1a} vasopressin receptor using a linear azidopeptidic antagonist.

Phalipou et al. (1997) studied the peptide-binding domains of the human V_{1a} vasopressin receptor with a photoactivatable linear peptide antagonist.

DDAVP (1-desamino-8-D-arginine vasopressin), which is considered to be a standard V_2 vasopressin receptor-selective agonist, was found to act also as an agonist at the V_{1b} vasopressin receptor (Saito et al. 1997).

Tahara et al. (1997b) investigated the effects of a nonpeptide V_{1a} and V_2 vasopressin receptor antagonist in binding and functional studies of rat vascular smooth muscle cells.

Tahara et al. (1998) expressed three subtypes of human arginine-vasopressin receptors, hV_{1a}, hV_{1b}, and hV_2, in Chinese hamster ovary cells and characterized them by [^{3}H]AVP binding. In addition, the coupling of the expressed receptor protein to a variety of signal transduction patterns was investigated.

N.9 Hypothalamic Hormones

N.9.1 Thyrotropin-Releasing Hormone (TRH)

N.9.1.1 General Considerations

Hypothalamic regulatory hormones are used in diagnostic procedures and for therapy, usually modified by chemical synthesis to enhance activities (Reichlin et al. 1976). The existence of regulators of anterior pituitary function, postulated many years ago (Bargmann 1949; Scharrer and Scharrer 1954), was experimentally demonstrated for the first time by Saffran and Schally (1955) in experiments utilizing hypothalamic and neurohypophyseal extracts. TRH was the first hypothalamic hormone whose chemical structure was elucidated (Bøler et al. 1969; Schally et al. 1970). Its main use is as a diagnostic instrument in thyroid disorders, pituitary tumors, and infertility.

Cloning, characterization, and transcriptional regulation of the TRH gene are reviewed by Wilber and Ai-Hua-Xu (1998).

Pekary (1998) discussed the physiological role of TRH-enhancing peptide (Ps4) which results from proteolytic processing of prepro-TRH.

Effects of TRH and its analogs in the CNS not related to the release of thyroid-stimulating hormone (TSH) (extrapituitary effects) have been found, indicating perhaps other therapeutic indications (Metcalf 1983; Flohé et al. 1983; Nemeroff et al. 1984; Horita et al. 1986; Horita 1998).

Radioimmunoassays for TRH are available (Bassiri et al. 1978).

Furukawa et al. (1980) reported the local effects of TRH on the isolated small intestine and tenia coli of the guinea pig. This effect could be related to the local release of catecholamines.

N.9.1.2 TRH Receptor Binding Assays

PURPOSE AND RATIONALE

Thyrotropin-releasing hormone (TRH) receptors from mouse (Straub et al. 1990; Jones et al. 1996), from rat (Sellar et al. 1993), and from men (Duthie et al. 1993; Matre et al. 1993; Yamada et al. 1993; Hinuma et al. 1994) have been expressed and characterized. Two isoforms have been identified (de la Peña et al. 1992; Lee et al. 1995). Constitutive activity of native TRH receptors has been demonstrated by Jinsi-Parimoo and Gershengorn (1997). Molecular and cellular biology of TRH receptors has been reviewed by Vassart and Dumont (1992) and by Gershengorn and Osman (1996).

TRH receptors have been localized in the pituitary gland (hypothalamic control of thyroid-stimulating hormone secretion), and in other brain regions (extrapituitary effects), which have been extensively explored but not resulted in therapeutic applications (Burt and Taylor 1983). TRH receptors can be determined by binding of [^{3}H]MeTRH (Taylor and Burt 1981; Sharif and Burt 1983; Jarowska-Feil et al. 1995; Yamada et al. 1995) or [^{3}H](3-Me-His^2)TRH (Simasko and Horita 1982).

TRH receptor affinity methods can be applied to the investigation of molecules which might interact with these receptors (Faden et al. 2005; Colson and Gershengorn 2006), and to the quantitate the description of receptor changes *ex vivo* after therapy.

PROCEDURE

Pooled tissue samples are homogenized in a sodium phosphate buffer (20 mM, pH 7.4) and centrifuged at 30,000 *g* for 30 min. The resultant pellets are washed twice by means of resuspension and centrifugation. The washed membranes are dispersed in fresh buffer and are used for the TRH receptor binding assay.

The membranes are incubated in 250 µl of the total volume with 0.5–8 nM of [^{3}H]MeTRH (NEN, sp. act. 62.8 Ci/mmol), in the presence or absence of 10 µM of TRH for 5–6 h at 0°C (in a water-ice bath). The receptor-bound and free [^{3}H]MeTRH are separated by rapid filtration through a glass fiber filter GF/B (Whatman) under reduced pressure (Harvester-Brandel). The trapped receptor-bound radioactivity is determined by liquid scintillation spectrometry (Beckman). The amount of specifically bound [^{3}H]MeTRH is expressed as fmoles per mg of protein.

EVALUATION

The data are subjected to the 6-point Scatchard analysis. The receptor density (B_{max}) and apparent dissociation constant (K_d) are determined.

MODIFICATIONS OF THE METHOD

Sun et al. (1998) described cloning and characterization of the chicken TRH receptor.

N.9.1.3 Release of ^{131}I from Thyroid Glands of Mice

PURPOSE AND RATIONALE

An animal bioassay method for TRH utilizes iodine-deficient mice, treated with ^{131}I, codeine, and 1 µg thyroxin (Redding et al. 1966; Bowers et al. 1967; Redding and Schally 1969). This is a historical test based on the effect of thyroid hormone release by TRH (indirect bioassay). The rise in radioactivity in blood 2 h after injection of the TRH preparations is proportional to the effect of TSH released by TRH. It needs to be assessed whether the extract being tested is free of TSH contamination.

PROCEDURE

Weanling mice of the Swiss-Webster strain weighing 15 g are fed a low-iodine diet and given distilled water for 10 days. At time zero, 4 µC Na^{131}I, 1 µg thyroxin, and 1 mg codeine phosphate are injected subcutaneously. Codeine is given again subcutaneously at 24, 30, and 48 h after time zero and then 2 h after the fourth injection of codeine, blood is taken from the orbital venous sinus. The test preparation or TRH standard is injected intravenously at increasing doses (0.01, 0.03, 0.09 µg/mouse), and 2 h later, a second blood sample is taken from the orbital venous sinus. The response is obtained by the increase of radioactivity from the first to the second blood sample (Δcpm).

EVALUATION

Dose–response curves are established for the test preparation and standard in order to calculate potency ratios with confidence limits.

MODIFICATIONS OF THE METHOD

TRH also stimulates release of TSH and subsequently of ^{131}I in rats pretreated with Na^{131}I and 5 µg thyroxin (Yamakazi et al. 1963).

TRH increases plasma TSH levels in thyroidectomized rats pretreated with 1 µg of T_3 (Bowers et al. 1965). This assay is based on enhanced TSH secretion after eliminating the feedback of thyroid hormones. The baseline is then lowered by T_3 pretreatment to provide a wider range for stimulation by TSH. Rats weighing 350–400 g are surgically thyroidectomized. After 1–3 months, 1 µg of L-triiodothyronine Na is given intraperitoneally; 2 h later urethane is given subcutaneously; approximately 1 h later 1.5 ml blood is removed from the jugular vein and the TRH preparation is administered intravenously. Another 1.5 ml blood is removed 15 min later. Heparin is added to the blood and TSH levels in plasma are assayed by release of ^{131}I from the mouse thyroid (McKenzie 1958) (see N.7.5.3). Results are recorded as mean change in blood ^{131}I levels in five mice.

TRH produces a significant depletion of pituitary TSH content in mice (Bowers et al. 1967). Swiss-Webster strain mice are treated as described for de-

termination of blood ^{131}I radioactivity. Two hours after administration of TRF, the animals are decapitated and the pituitaries immediately removed. Pituitaries of each group of five mice are combined and homogenized in 5 ml of 0.01 M acetic acid which contains 0.9% NaCl. TSH is determined according to McKenzie (1958) (see N.7.5.3). Today, this has been replaced by radioimmunoassay determination of pituitary TSH content.

N.9.1.4 Release of TSH from Rat Anterior Pituitary Glands in Vitro

PURPOSE AND RATIONALE

The *in vitro* bioassay method of Saffran and Schally (1955a, 1955b), developed for detecting corticotropin-releasing factor (CRF) activity, has been modified to measure TRH activity *in vitro* (Guillemin et al. 1963; Bowers et al. 1965; Schally and Redding 1967).

PROCEDURE

Male Sprague-Dawley rats weighing 150–200 g serve as donors. After removal, each pituitary is cut in half, transferred to a 15-ml beaker containing 1.5 ml Krebs-Ringer bicarbonate medium with 200 mg% glucose and incubated for three 60-min periods. The media used in the first two incubations are discarded. At the beginning of the third incubation period, various amounts of test preparation or TRH standard are added to individual beakers. At the end of the third incubation period the media from both control and experimental beakers are carefully freed of pituitary tissue. The media are then assayed by RIA for content of TSH.

EVALUATION

Dose–response curves are established for test preparation and standard allowing calculation of potency ratios with confidence limits.

MODIFICATIONS OF THE METHOD

For the assay of TRH analogs, cultures of enzymatically dispersed anterior pituitary cells from rats can be used instead of pituitary halves (Vale et al. 1972).

Barros et al. (1986) studied the effect of TRH on cultured GH3 rat anterior pituitary cells using the whole-cell voltage-clamp technique.

N.9.1.5
TSH and Prolactin Release by TRH in Rats

In bioassays for TRH activity based on the release of TSH measured by radioimmunoassay it was found in many species investigated, and also in clinical testing of humans, that the injection of TRH causes the dose-proportional release of prolactin. This test is suitable for biological activity of TRH, e. g., in domestic animals, and also for the clinical investigation of prolactin secretion in humans.

PROCEDURE

The TRH test in rats is performed in a minimally invasive manner, and when animals have been previously treated it is done 24 h after the last dosing on the following morning. The test dose is a subcutaneous injection of 1 µg/kg body weight synthetic TRH followed by blood sampling in unanesthetized rats 30 min later. Blood sampling may be performed by retro-orbital puncture.

For extended studies on pituitary responsiveness, it is also possible to use a very specific TRH test blocking basal TSH by injection of levothyronine (L-T_3, 1 µg/rat s.c.) 18 h before the test. The following morning, the TRH dose is injected intravenously followed by blood sampling at 15 min or (in anesthetized rats) after 15 and 30 min.

EVALUATION

The usual procedure for evaluation is to compare the TSH concentration in control animals and treated animals (drug treatment or physiological manipulation), to calculate group means, and to evaluate the significance of difference by appropriate statistical tests, where necessary by performing analysis of variance (ANOVA).

The individual response of the animals may be assessed by comparing the basal TSH concentration before the TRH test injection, and the TSH increments at increasing dose intervals after TRH stimulation.

MODIFICATIONS OF THE METHOD

The TRH test is useful in rats and in other animal species. The test dose may be administered by intravenous injection or preferably by subcutaneous injection; nasal application should also be considered (a considerably higher TRH dose is required, and this test can be performed in dogs).

Several analytical methods are available to determine the serum concentrations of TSH and prolactin, both from commercial suppliers and for research applications (Fraglia 1998; Markianos et al. 1996; Katznelson 1998; Fail et al. 1999; Hashizume et al. 2005; Koch et al. 2006). For human diagnostic applications, highly sensitive TSH tests based on measuring only the basal concentrations have replaced the diagnostic TRH test in many instances. Methods are increasingly sensitive, and, for a review, refer to the web site "thyroidmanager" (Spencer 2004).

N.9.2
Luteinizing Hormone Releasing Hormone (LH-RH)

N.9.2.1
General Considerations

Gonadotropin secretion is controlled by the hypothalamic peptide luteinizing hormone releasing hormone (LH-RH), which stimulates the release of FSH and LH.

The discovery of the structure of LH-RH then led to the synonym of gonadotropin releasing hormone (Gn-RH) and identification of its receptors followed (Conn et al. 1986). The search for a specific FSH-releasing factor has continued (McCann et al. 1993) but so far has remained elusive. LH-RH is secreted in a pulsatile fashion (Levine et al. 1991). This is not relevant to the bioassays, which use LH-RH injections as well as infusion for several hours. Radiolabeling and photoaffinity labeling of Gn-RH receptors have been described (Perrin et al. 1982; Hazum and Keinan 1983). LH-RH bioactivity is determined *in vitro* on pituitary cells and *in vivo* by its effects on ovulation, spermatogenesis, and other gonadal parameters (McCann 1970; Steelman 1970). Radioimmunoassays and radioreceptor assays are available (Nett and Niswender 1979). Many studies of rats and primates showed that prolonged administration of LH-RH agonists results in a decrease of LH and gonadal hormones to castrate levels (Sandow et al. 1978, 1980; Akhtar et al. 1983; Weinbauer et al. 1987, 1990).

Short- and long-term effects on pituitary–gonadal function in neonatal and adult female rats treated with gonadotropin-releasing hormones have been analyzed by Trimino et al. (1993).

The Food and Drug Administration (FDA) recommendations for preclinical testing of Gn-RH analogs, including pharmacology, pharmacokinetics and toxicology, are published by Raheja and Jordan (1994).

N.9.2.2 LH-RH Receptor Assays

PURPOSE AND RATIONALE

LH-RH (Gn-RH) interacts with a membrane receptor which belongs to the G-protein-coupled receptor family. The LH-RH-R is encoded by a single-copy gene consisting of three exons and two introns. Consistent with its site of action, LH-RH-R mRNA has been found in the brain, pituitary, gonads, placenta, as well as in tumor tissue and tumor cell lines (Jennes and Conn 1994). Binding to LH-RH receptors in rat pituitary membranes has been studied for LR-RH agonists and antagonists. Furthermore, the time course of downregulation of LH-RH receptors was followed (Halmos et al. 1996).

PROCEDURE

Receptor binding of LH-RH is determined using a sensitive *in vitro* ligand competition assay based on binding of radiolabeled buserelin or [D-Trp^6]LH-RH to rat anterior pituitary membrane homogenates (Halmos et al. 1993, 1996; Szöke et al. 1994). Membrane homogenates containing 40–80 µg of protein are incubated in triplicate with 60,000–75,000 cpm

(≈ 0.15 nM) [^{125}I][D-Trp^6]LH-RH as radioligand and with increasing concentrations (10^{-12}–10^{-6} M) of nonradioactive peptides in a total volume of 150 µl of binding buffer. At the end of the incubations, 125-µl aliquots of suspension are transferred to the top of 1 ml of ice-cold binding buffer containing 1.5% bovine serum albumin in siliconized polypropylene microcentrifuge tubes (Sigma). The tubes are centrifuged at 12,000 *g* for 3 min at 4°C. Supernatants are aspirated, and the bottoms of the tubes containing the pellet are cut off and assayed in a gamma-counter. Protein concentration is determined by the method of Bradford (1976) using a BioRad protein assay kit.

EVALUATION

Specific ligand-binding capacities and affinities are calculated by the computerized curve-fitting program of Munson and Rodbard (1980) as modified by McPherson (1985). To determine the types of receptor binding, dissociation constants (K_d values), and the maximal binding capacity (B_{max}), LH-RH binding data are also analyzed by the Scatchard method. Statistical significance is assessed by Duncan's new multiple range test.

MODIFICATIONS OF THE METHOD

Flanagan et al. (1998) recommended ^{125}I-[His^5,Tyr^6]-Gn-RH as the radioligand for analysis of mutant Gn-RH receptors.

Perrin et al. (1982) compared binding of radiolabeled antagonists and antagonists of gonadotropin-releasing hormone to rat anterior pituitary membrane homogenates.

Fekete et al. (1989) reviewed the role of receptors for LH-RH, somatostatin, prolactin, and epidermal growth factor in rat and human prostate cancers and in benign prostate hyperplasia.

Cloning, sequencing, and expression of the human gonadotropin-releasing hormone receptor are published by Kakar et al. (1992).

Marheineke et al. (1998) characterized the human gonadotropin-releasing hormone receptor heterologously produced using the baculovirus/insect cell and the semliki forest virus systems.

The binding kinetics of a long-acting gonadotropin-releasing hormone antagonist to rat LH-RH receptors were studied by Li et al. (1994).

Lovejoy et al. (1995) determined the receptor binding of gonadotropin-releasing hormone analogs in bovine pituitary membrane preparations.

The cDNA encoding the receptor for LH-RH was isolated from a human pituitary cDNA library and heterologously expressed in the murine fibroblast cell line LTK$^-$ by Beckers et al. (1995).

Tsutsumi et al. (1995) investigated the role of altered receptor biosynthesis in agonist-induced receptor downregulation in αT_3-1 cells, a mouse gonadotrope cell line.

Beckers et al. (1997) characterized gonadotropin-releasing hormone analogs by a cellular luciferase reporter gene assay. The assay is based on a fusion of the c-fos immediate-early gene promoter to *Photinus pyralis* luciferase (LUC) as reporter gene, stably transfected in murine LTK$^-$ cells expressing the human GnRH receptor. Transcription of endogenous c-fos and fos–Luc fusion gene are transiently induced quite similarly by fetal calf serum and a superagonistic Gn-RH analog. The reporter gene was used to monitor agonist-induced signaling via the human Gn-RH receptor. Whereas Luc activity was induced in a dose-dependent manner by Gn-RH or an agonistic analog, different antagonistic peptides completely inhibited this stimulation.

The current state of knowledge is reviewed by Cheng and Leung (2005), Kakar et al. (2004) and Millar et al. (2004) for domestic animals and for the human, including the description of two separate types of the gonadotropin-releasing hormone receptor (Gn-RH-I and II), and the increasing complexity of Gn-RH receptor-mediated signaling.

CRITICAL ASSESSMENT OF THE METHODS

There is an ever-increasing complexity of the extensive results of the application of LH-RH (Gn-RH) receptor methods, which may be to structure–activity studies with LHRH analogs, to elucidating species-specific regulation in domestic animals and in humans, or to the measurement of adaptive changes of the LH-RH receptor concentrations in physiology, in pharmacological experiments, and in the pathophysiology of human disease. Numerous approaches have been described based on ligand binding to receptors extracted from tissue, to cloned receptor proteins, and based on direct measurement of the receptor protein concentrations.

N.9.2.3 LH Release in the Ovariectomized Estrogen–Progesterone-Blocked Rat

PURPOSE AND RATIONALE

Ramirez and McCann (1963) recommended the ovariectomized, estrogen–progesterone-blocked rat (OEP rat) as a highly sensitive test model for LH-releasing activity. The gonadotropin content of the pituitary is increased after ovariectomy, due to reduced feedback inhibition through the absence of gonadal steroids. Basal secretion is then acutely lowered to a stable baseline by estrogen–progesterone blockade, whereas the amplitude for stimulation of LH secretion is augmented. The increase in plasma LH levels in donor rats after injection of LH-RH previously determined by bioassay in recipient rats is now conveniently measured by RIA. Since natural and synthetic LH-RH releases both gonadotropins (Schally et al. 1971b), merely stimulation of LH is necessary for routine LH-RH assay.

PROCEDURE

Female Sprague-Dawley rats weighing 150–200 are ovariectomized. They are kept in a light- and temperature-controlled animal room at 24°C and are fed commercial rat chow and tap water ad libitum. Tests are performed 1–3 months after ovariectomy. Three days prior to the assay, the rats receive 50 µg estradiolbenzoate and 25 mg progesterone in sesame oil by the transmuscular-subcutaneous route. For the assay, the rats are anesthetized by subcutaneous injection of 0.6 ml/100 g of 25% urethane solution. Changing to a new anesthetic will require validation of the effect of that anesthetic on sensitivity of the test. Various doses of the test compound or the standard

are injected intravenously into the jugular vein. After 10 min, 4–6 ml blood is withdrawn by cardiac puncture from each donor allowing the separation of 2 ml plasma.

In the original method, bioassayable LH was measured by the ovarian ascorbic acid depletion (OAAD) method according to Parlow and Reichert (1963) (see also N.7.1.2.3). Immature female Sprague-Dawley rats are injected on day 1 at 3:00 p.m. with 50 IU pregnant mares' serum gonadotropin (PMSG) in 0.2 ml saline subcutaneously. On day 3, the rats receive at 9:00 a.m. 25 IU human chorionic gonadotropin (hCG) subcutaneously. On day 7, three different doses of the standard (e. g., NIH LH-S-1, National Institute of Health, Bethesda, Md., USA) or the 2 ml of plasma from the OEP rats is injected intravenously. Eight animals are used per group. Three hours later, the animals are sacrificed, both ovaries are prepared, weighed, and homogenized for determination of ascorbic acid content. The LH activity in OEP plasma, as measure by OAAD, is expressed in terms of NIH-LH-S16 standard.

Furthermore, LH activity in the plasma of OEP rats is measured by radioimmunoassay. OEP rats are anesthetized with 25% urethane intraperitoneally. Blood is withdrawn by retro-orbital puncture. Then various doses of the test preparation or the standard are injected intravenously. After 10 min blood is withdrawn by cardiac puncture. Radioimmunoassays of LH are carried out by the double-antibody method of Niswender et al. (1968).

EVALUATION

Dose–response curves are established for the standard and the test preparation of LH-RH measured by bioassayable LH in OEP plasma as well as for RIA of the LH level in plasma, allowing the calculation of potency ratios with confidence limits. Furthermore, time–response curves can be established by RIA determination of plasma LH levels in OEP rats.

MODIFICATIONS OF THE METHOD

Instead of OEP rats, normal Male Sprague-Dawley rats can be used for measurement of the time course of release of LH after injection of LH-RH or LH-RH derivatives (Arimura et al. 1972). Male Sprague-Dawley rats weighing 120–150 g are anesthetized with 0.6 ml/100 g body weight of 25% urethane solution subcutaneously. After 30 min 0.8 ml blood is withdrawn from the jugular vein, and immediately substituted by the same volume of Haemaccel solution. The LH-RH preparation is injected subcutaneously in 1% gelatine-saline. Blood is withdrawn at hourly intervals up to 6 h, each time being substituted with Haemaccel solution. LH in plasma is determined by the double-antibody method of Niswender et al. (1968) and follicle-stimulating hormone according to the method of Daane and Parlow (1971).

N.9.2.4 Gonadotropin Release From Anterior Pituitary Cells

PURPOSE AND RATIONALE

Anterior pituitaries can be used directly, kept in culture or used for cell lines (Mittler and Meites 1964, 1966; Mittler et al. 1970; Sandow et al. 1972b) in order to study the synthesis and release of gonadotropins in response to LH-RH.

PROCEDURE

Female Sprague-Dawley rats weighing 100–150 g are used as donors. Each anterior pituitary is removed and cut into four to six pieces of approximately equal size. The cultures are performed in sterile disposable plastic Petri dishes each containing 3 ml medium consisting of 9 parts Difco medium 199 and 1 part of newborn calf serum; 25 U/ml penicillin and 25 µg/ml streptomycin are added. In each dish, the explants are supported at the gas interface. An atmosphere of 95% oxygen and 5% carbon dioxide and a temperature of 36°C are maintained. The opposite sides of the same pituitaries provide matched control and experimental preparations. The pituitaries are incubated for a total time of 5 days. After the first 2 days, the medium is removed and discarded. Fresh medium is then added with the LH-RH solutions. Approximately 12 h after the first change of medium and addition of LH-RH, media are removed and frozen. Fresh medium with LH-RH is again added; this procedure is repeated until six samples of medium representing the last 3 days of culture are obtained. Media are assayed for LH content by radioimmunoassay according to Niswender et al. (1968) and for FSH content according to Parlow and Reichert (1963).

EVALUATION

Using various concentrations of test preparation and LH-RH standard dose–response curves are obtained allowing the calculation of potency ratios with confidence limits.

CRITICAL ASSESSMENT OF THE METHOD

These methods do not reflect the time course of release found *in vivo* but are useful for potency estimates.

MODIFICATIONS OF THE METHOD

Instead of pituitary halves for the assay of LH-RH as well as for the assay of TRF and its analogs, cultures of enzymatically dispersed anterior pituitary cells from rats can be used (Vale et al. 1972; Martin and Sattler 1979).

Loughlin et al. (1981) used perifused pituitary cultures as a model for LH-RH regulation of LH secretion.

O'Connor and Lapp (1984) studied the effect of pulse frequency and duration of exposure to LH-RH in anterior pituitary cells attached to Cytodex I beads.

The functional integrity of anterior pituitary cells separated by a density gradient has been studied (Scheikl-Lenz et al. 1985).

The receptor binding ability of different agonists and antagonists of LH-RH to rat pituitary and human breast cancer membranes was studied by Fekete et al. (1989).

Vigh and Schally (1984) and Csernus and Schally (1991) described in detail a cell superfusion system consisting of a Sephadex column with dispersed pituitary cells. The LH response of anterior pituitary cells to a 3-min exposure to various concentrations of LH-RH at 30-min intervals as well as the growth hormone (GH) response to human GH-releasing hormone resulted in excellent dose–response curves. The effect of GH-releasing hormone was inhibited by somatostatin. Likewise, the effect of LH-RH was inhibited by pretreatment with LH-RH antagonists.

N.9.2.5 Radioimmunoassay of Rat LH

PURPOSE AND RATIONALE

Luteinizing hormone is a glycoprotein hormone exhibiting species specificity. For pharmacological experiments in rats, such as evaluation of gonadotropin-releasing hormone activity, a homologous assay is necessary. The reagents are provided by the National Pituitary Agency, Bethesda, Md. The assay procedure is similar to the standard operating procedure proposed by the National Pituitary Agency, USA.

PROCEDURE

Reagents

Standard:	NIH-rat-LH-RP 1
Antiserum:	rabbit-anti-rat-S 9
Tracer:	^{125}I-rat-LH-I 6
Second antibody:	Behring goat-anti-rabbit-gamma-globulin, (Behring, Cat. No. OTOP 14/15)
Buffer:	0.01 M phosphate-saline pH 7.4

Standard and samples are dissolved in 1% bovine serum albumin, tracer in 0.1% bovine serum albumin, and antiserum in EDTA-PBS (1:350 normal rabbit serum as carrier).

Assay

Standards:	0.25–62.5 ng/tube, 200 µl/tube
Antiserum:	1:20,000 100 µl/tube
Tracer:	specific activity 120 µCi/µg, 8000 cpm in 100 µl/tube

Standards (or sample) are incubated with antiserum and tracer for 48 h at +4°C, the second antibody 1:50 (200 µl/tube) is added, and incubated for 24 h at +4°C. Separation is performed with 1.0 ml ice-cold phosphate-buffered saline pH 7.4, the vial spun at 1300 *g* for 15 min, the supernatant decanted, and the residue counted for 1 min in a gamma-counter.

EVALUATION

Data processing: standard curves and sample data are calculated on a computer program using a spline function.

Quality control parameters

Limit of detection:	0.36 ng per tube
Standard curve (ED_{80}–ED_{50}–ED_{20}):	1.31-4.56-15.74 ng per tube
Inter-assay CV (15 assays):	20.9%
Intra-assay CV:	lt; 15%

N.9.2.6 Radioimmunoassay of Rat Follicle-Stimulating Hormone (FSH)

PURPOSE AND RATIONALE

Follicle-stimulating hormone (FSH) is a glycoprotein hormone exhibiting species specificity. For pharmaco-

logical experiments in rats, such as evaluation of gonadotropin-releasing hormone activity, a homologous assay is necessary. The reagents and the procedure are provided by the National Pituitary Agency, Bethesda, Md. The assay procedure is similar to the standard operating procedure proposed by the National Pituitary Agency, USA.

PROCEDURE

Reagents

Standard:	NIAMDD-rat-FSH-RP-1
Antiserum:	rabbit-anti-rat-FSH (NIAMDD-S-9)
Tracer:	^{125}I-rat-FSH (e. g. NIAMDD-I-4)
Second antibody:	Behring goat-anti-rabbit-gamma-globulin, (Behring, Cat. No. OTOP 14/15)
Buffer:	0.01 M-phosphate-saline/0.1% bovine serum albumin, pH 7.4

Assay

Standards:	6.25–1600 ng/tube, 200 µl/tube
Antiserum:	1:2000 100 µl/tube
Tracer:	specific activity 200 µCi/µg, 10,000 cpm in 100 µl/tube

Standards (or sample) are incubated with antiserum and tracer for 72 h at +4°C, the second antibody 1:50, 200 µl/tube, is added, and incubated for 48 h at +4°C. Separation is performed with 1.0 ml ice-cold phosphate-buffered saline pH 7.4, the vial spun at 1300 *g* for 15 min, the supernatant decanted, and the residue counted for 1 min in a gamma-counter.

EVALUATION

Data processing: standard curves and sample data are calculated on a computer program using a spline function.

N.9.2.7 Measurement of Ascorbic Acid Depletion in Ovaries of Pseudopregnant Rats

PURPOSE AND RATIONALE

The assay for LH-RH and LH-RH analogs can be performed in one step in pseudopregnant immature female rats using the biological response of the luteinized ovaries to gonadotropins released by the test compounds. Pseudopregnancy is induced in immature female Sprague-Dawley rats by treatment with gonadotropins. Numerous corpora lutea are formed after ovulation. On days 7–8 after the start of treatment the corpora lutea are very sensitive to endogenous or exogenous gonadotropins. Stimulation of steroid synthesis, mainly progesterone, is seen, associated with dose-dependent ascorbic acid depletion in the ovaries. The activity of LH-RH and LH-RH analogs can be determined by the decrease of ovarian ascorbic acid concentration, or the increase in progesterone secretion. Ascorbic acid depletion is a sensitive parameter for the endogenous gonadotropin release in the animals.

PROCEDURE

Immature female Sprague-Dawley rats weighing 35–45 g are pretreated with 50 IU pregnant mares' serum gonadotropin (PMSG) followed by an injection of 25 IU human chorionic gonadotropin (hCG) on the third day. On day 7 or 8, they are injected intramuscularly or subcutaneously with the test preparation or the LH-RH standard in 0.1 ml 1% gelatine-saline. Eight animals are used for each of three doses of the test preparation and standard. One hour later, the ovaries are dissected out, homogenized, and ascorbic acid is determined according to the method of Mindlin and Butler (1938) by photometry.

EVALUATION

Dose–response curves of ascorbic acid depletion are obtained for the test preparation and standard allowing the calculation of potency ratios with confidence limits.

MODIFICATION OF THE METHOD

The method has been adopted as a biological assay of gonadorelin with some modifications by pharmacopoeias, e. g., the British Pharmacopoeia (1988).

CRITICAL ASSESSMENT OF THE METHOD

Classical bioassays of the kind described here are now rarely applied for standardizing LH-RH (gonadorelin) due to the complexity of the biological method. They are being replaced by analytical methods of high specificity and sensitivity, e. g., high-performance liquid chromatography (HPLC) which has been compared with the biological assay and found to be suitable for standardization (see current versions of the British Pharmacopoeia). Standard preparations for gonadorelin (LH-RH, Gn-RH) and for LH-RH analogs

may be obtained from the suppliers (pharmaceutical companies); they are no longer prepared by the National Institute for Biological Standards and Control (NIBS, UK).

N.9.2.8 Progesterone Production in Pseudopregnant Rats

PURPOSE AND RATIONALE

Pseudopregnancy is induced in immature rats by pretreatment with gonadotropins. Numerous corpora lutea are formed after ovulation that are sensitive to endogenous gonadotropins released by LH-RH or LH-RH analogs on days 6–8 after treatment. By measurement of plasma progesterone, the steroidogenic activity of LH-RH analogs can be determined (Sandow et al. 1976).

PROCEDURE

Immature female Sprague-Dawley rats weighing 35–45 g are pretreated with 50 IU pregnant mares' serum gonadotropin (PMSG) followed by an injection of 25 IU human chorionic gonadotropin (hCG) on the third day. They are injected intramuscularly with LH-RH or the LH-RH analog on days 6, 7, or 9 between 8 and 10 a.m. Eight animals are used for each of three doses of test preparation and standard. Blood samples are collected 1 h after treatment. Plasma samples of equal volume are extracted with peroxide free diethylether. The ether phase containing progesterone is evaporated and the sample re-dissolved in BSA-phosphate buffer. Tritium-labeled progesterone and a specific antiserum against progesterone are added and incubated over a period of 24 h at 4°C. Bound hormone and free hormone are separated by absorption on Dextran-coated charcoal. The activity of the sample is determined in a scintillation cocktail containing Triton-X.

EVALUATION

Dose–response curves for progesterone concentrations are established for the test preparation and standard, allowing the calculation of potency ratios with confidence limits.

REFERENCES AND FURTHER READING

N.9.2.9 Induction of Ovulation in Rabbits

PURPOSE AND RATIONALE

Ovulation can be induced in mature rabbits by injection of LH-RH after initial priming. This is a modified assay for LH release, which was applied to hypothalamic extracts containing LH-RH activity (Sandow et al. 1972).

PROCEDURE

Six unmated, mature female rabbits (Himalayan strain) weighing 1.0–1.2 kg are used for each dose of standard or test preparation. Follicular maturation is induced by eight subsequent daily subcutaneous injections of LH-RH or the LH-RH analog to be tested in 0.2 ml 1% gelatine-saline. Then 48 h after the last injection, ovulation is induced by administering a fourfold to tenfold higher dose of the peptide in 0.2 ml subcutaneously. After 24 h, the animals are sacrificed, the ovaries weighed, and ovulation is determined by counting the numbers of follicles ovulated in the ovaries, as defined by local bleeding.

EVALUATION

At least two doses of test preparation and standard are used in order to establish dose–response curves, allowing the calculation of potency ratios with confidence limits.

MODIFICATIONS OF THE METHOD

Schröder et al. (1972) and Sandow and Hahn (1973) described changes in the ovary transplanted to the anterior eye chamber in the rabbit enabling the direct ob-

servation of ovulation. This method is also applicable to steroids and prostaglandins.

CRITICAL ASSESSMENT OF THE METHODS

Classical assays such as the eye–ovary transplant have provided excellent morphological information about changes of the ovary during drug treatment. They are however becoming increasingly obsolete because of other methods which are much less invasive, and their use should be considered only as an exception.

N.9.2.10 Induction of Superovulation in Immature Rats

PURPOSE AND RATIONALE

Immature female rats (24–26 days of age) do not show vaginal cycles before the onset of puberty. Treatment with pregnant mares' serum gonadotropin (PMSG) induces follicular maturation, followed by spontaneous ovulation 2 days later. Spontaneous ovulation can be blocked by barbiturates (e. g., phenobarbital) acting on the hypothalamus, and is overcome by exogenous LH-RH. The rats ovulate due to the release of endogenous gonadotropins. After hypophysectomy, no ovulatory activity is observed in the absence of the pituitary (Sandow et al. 1972).

PROCEDURE

Immature female Sprague-Dawley rats weighing 55–65 g are injected on day 1 with 10 IU PMSG subcutaneously. Following this pretreatment, the animals will ovulate spontaneously on day 3 between 2:00 and 4:00 p.m. Spontaneous ovulation is blocked by phenobarbital 4 mg/kg at 1:00 p.m. One hour later, the ovulatory peptide, dissolved in 1% gelatine/saline, is injected intravenously. Controls are treated with 1 or 2 IU human chorionic gonadotropin (hCG); negative controls, with gelatine-saline only. Eight rats are used for control groups and various doses of LH-RH or the LH-RH analog. On the next day, the rats are sacrificed at 11:00 a.m. and the oviducts are dissected and stained with Patent blue. The number of ova is counted under a microscope.

EVALUATION

A dose-dependent increase in the number of ova per rat is observed after LH-RH due to LH release and after hCG by direct action on the ovary. The effect of LH-RH analogs is compared with the effects of hCG. Minimal effective doses for LH release can be calculated.

N.9.2.11 Inhibition of Experimentally Induced Endometriosis

PURPOSE AND RATIONALE

This is an example of a disease model in animals designed to mimic treatment of an experimentally induced pathological condition. Endometriosis-like lesions can be induced in female rats by autotransplantation of endometrium under the renal capsule (Sakata et al. 1990; Mizutani et al. 1995). This method was used to compare the effect of steroid-induced suppression by a LH-RH analog after chronic administration (pituitary inhibition).

PROCEDURE

Under anesthesia laparotomy is performed in 9-week-old female Sprague-Dawley rats. The left uterine horn is resected and opened by a longitudinal incision. The endometrium is dissected from the myometrium. Then a 5×5 mm section of the endometrium is grafted under the capsule of the left kidney of the same animal. Two weeks later, the attachment and the viability of the endometrial explant are examined by a second laparotomy, the length, width, and height of the explant are measured, and the volume is then calculated. The criterion for a viable graft is fluid accumulation around the lesion. The rate of induction of endometriosis is more than 80%. Animals with endometriosis (with body weights of approximately 250 g) are randomly divided into treatment groups of ten animals each. Gonadotropin-releasing hormone agonists are injected at doses of 15 or 30 µg/kg subcutaneously daily for 3 weeks. A third laparotomy is performed 3 weeks after the beginning of the experiment. The presence of

fluid accumulation and the size of the endometrial explant are examined. The explant is excised and fixed in 10% formalin for histological evaluation.

EVALUATION

The evaluation of treatment on the regression of lesions in experimental endometriosis is analyzed statistically with the χ^2 test.

N.9.3 LH-RH Antagonistic Activity

N.9.3.1 Testosterone Suppression in Rats

PURPOSE AND RATIONALE

LH-RH antagonists suppress endogenous secretion of LH and testosterone in adult male rats after a single subcutaneous injection, and after repeated dosing (Loy 1994).

PROCEDURE

Groups of eight adult male Wistar rats weighing 200–250 g are injected subcutaneously with various doses of the test compound or a reference LH-RH antagonist dissolved in 5% mannitol solution. Four hours later, rats are decapitated and blood is collected from the trunk. Serum is separated in a refrigerated centrifuge (10 min at 3000 *g*), and stored frozen at −20°C until assay.

Radioimmunoassay for Testosterone

Serum testosterone is measured by radioimmunoassay in serum extracts using a specific antiserum without prior chromatography, or by direct assay in serum depending on the method. Serum samples of 0.5 ml are extracted with 2 ml of freshly purified, peroxide-free diethylether by shaking for 60 s on a Vortex-type mixer. The aqueous phase is frozen at −70°C, and the ether phase containing testosterone is transferred to conical test tubes, and evaporated under a stream of dry nitrogen. The dry residue is re-dissolved in BSA/phosphate buffer (BSA = 1% bovine serum albumin) for RIA. [1,2,6,7-^{3}H]Testosterone (New England Nuclear NET 367) and a specific antiserum (AS-781, Behringwerke, Marburg, Germany) are added and incubated over a period of 24 h at +4°C under nonequilibrium conditions. Bound hormone and free hormone are separated by adsorption on Dextran-coated charcoal by incubation for 30 min at +4°C and centrifugation at 3000 *g* for 15 min. Then 500 µl of supernatant is transferred into minivials and scintillation cocktail is added. Radioactivity is determined in a beta-counter (Falvo and Nalbandov 1974).

EVALUATION

The hormone levels in the sample are calculated from a standard curve by means of a computer program, using appropriate control sera. Using various doses of standard and test preparation dose–response curves can be established, allowing calculation of potency ratios with confidence limits. Alternatively, minimum effective doses can be calculated from comparisons with controls. Using different time intervals, e. g., 4, 8, and 24 h, the duration of the effect can be evaluated.

MODIFICATIONS OF THE METHOD

Testosterone suppression can be measured in several animal species, e. g., dogs and marmoset monkeys, or cynomolgus monkeys (Habenicht et al. 1990).

Ayalon et al. (1993) tested the potency of the LH-RH antagonist on the pituitary–gonadal system of female castrated and intact ovulating rats.

Reissmann et al. (1996) investigated the antitumor and hormone-suppressive effect of the LH-RH antagonist cetrorelix in the model of DMBA-induced mammary carcinoma (DMBA is 7,12-dimethylbenz[a]anthracene) in female rats and by testosterone determination in normal male rats.

Danz (1995) studied the effect of a gonadotropin-releasing hormone antagonist on androgen-binding protein production and its distribution among the epididymis, seminiferous tubule fluid, testicular interstitial fluid, and blood in rats.

Fallest et al. (1995) studied the transcriptional regulation of the rat luteinizing hormone β (rLHβ) gene through the use of **transgenic mice** bearing a region of the rLHβ gene linked to a luciferase (LUC) reporter gene. The postgonadectomy rise in pituitary rLHβLUC activity in females and males was blocked by daily administration of the Gn-RH antagonist antide.

Rivier et al. (1996) synthesized and evaluated many Gn-RH analogs and established a dose–response re-

lationship between Gn-RH antagonists and pituitary suppression.

CRITICAL ASSESSMENT OF THE METHOD

Structure–activity studies on LH-RH antagonists are based on screening for receptor affinity, and receptor-associated signaling for high-throughput assays. They need to be followed up by confirmation of biological activity, and for quantitation of structure–activity assessment, the assays described here have been eminently suitable for extended compound screening, although the estimates obtained need to be checked for their relevance against the results from intact animals. Suppression of testosterone secretion is one of the preferred methods of confirmation.

N.9.3.2 Antiovulatory Activity in Rats

PURPOSE AND RATIONALE

The rat antiovulatory assay (AOA) was widely used for LH-RH antagonists. Immature female rats (24–26 days of age) are primed with pregnant mares' serum gonadotropin (PMSG) to induce follicular maturation, followed by spontaneous ovulation 2 days later. The endogenous hypothalamic LH-RH discharge can be blocked by barbiturates (e. g., phenobarbital) to prevent spontaneous ovulation (see Sect. N.9.2.10). For antiovulatory activity, a test dose of 800 ng exogenous LH-RH is administered together with increasing doses of the LH-RH antagonist. The antagonist will then inhibit the LHRH-induced gonadotropin release. The test measures the dose of LH-RH antagonist required to inhibit the effect of a standard dose of LH-RH.

PROCEDURE

Immature female Wistar rats weighing 55–65 g are injected on day 1 at 9:00 a.m. with 10 IU PMSG subcutaneously. This priming induces follicular maturation and estradiol secretion. A spontaneous, endogenous LH discharge is observed on day 3 between 2:00 and 4:00 p.m.. The release of LH and spontaneous ovulation is blocked by intraperitoneal injection of phenobarbital 4 mg/kg on day 3 at 1:00 p.m.. The LH-RH antagonist is administered in various doses subcutaneously, intraperitoneally or intravenously 30 min before phenobarbital injection. Two hours later, a standard dose of 800 ng LH-RH is injected subcutaneously to induce ovulation. Control groups receive phenobarbital only (negative control) or phenobarbital and 800 ng LH-RH (positive control). Six to eight rats are used for control groups and various doses of the LH-RH antagonist. On the next day, the rats are sacrificed at 9:00 a.m. Both ovaries are prepared and weighed. The oviducts are dissected and stained with Patent blue. The number of ova is counted under a microscope. An effective dose of antagonist prevents LH-RH-induced ovulation.

EVALUATION

A dose-dependent suppression of induced ovulation is observed after the LH-RH antagonist. ID_{50} values can be calculated for various LH-RH antagonists according to the procedure of Litchfield-Wilcoxon. Minimal effective doses which fully suppress ovulation in each animal are calculated.

MODIFICATIONS OF THE METHOD

De la Cruz et al. (1975) described the blockade of the preovulatory LH surge in **hamsters** by an inhibitory analog of LH-RH.

Kovács et al. (1993) found that in ovariectomized and normally cycling rats antiovulatory doses of antagonists of LH-RH inhibit LH and progesterone but not follicle-stimulating hormone (FSH) and estradiol release.

Evaluation of biological activities of new LH-RH antagonists in male and female rats was reported by Pinski et al. (1993).

Rivier et al. (1995) tested a series of gonadotropin-releasing hormone antagonists in the rat antiovulatory assay.

Pinski et al. (1995) evaluated the optical isomers of the LH-RH antagonist Cetrorelix in ovulation inhibition in rats and in suppression of LH levels.

N.9.3.3 Effect of Repeated Administration of LH-RH Antagonists in Rats

PURPOSE AND RATIONALE

Repeated administration of LH-RH antagonists reduces the testosterone secretion in serum and the tissue content in the testes, and it also decreases the weight of testosterone-dependent organs, such as prostate and seminal vesicles. Moreover, pituitary LH content is decreased and the secretory capacity of the testes for testosterone is diminished. The effects are similar to those after supraphysiological doses of LH-RH agonists (paradoxical antifertility effects).

PROCEDURE

Male Wistar rats with an initial weight between 150 and 200 g are housed under standard conditions. They are treated with daily injections of the LH-RH antagonist for a period of 7 days up to 4 weeks. Alternatively, the LH-RH antagonist can be administered subcutaneously by infusion via minipumps or other routes of administration. Animals receiving the vehicle serve as controls, and rats castrated at the beginning of the experiment may be included for maximum inhibition. At the end of the treatment period, the animals are sacrificed 4 h after the last administration. Blood is collected for testosterone determination by radioimmunoassay. The androgen-dependent organs, testes, epididymides, ventral prostate, and seminal vesicles are dissected and weighed to the nearest 0.1 mg. The testes are decapsulated and incubated with 250 mU human chorionic gonadotropin (hCG) in order to determine the secretory capacity for testosterone. The testosterone tissue content is determined in the supernatant fraction of a testicular homogenate in the absence of hCG (unstimulated testis), and after 3 h of incubation of the contralateral testis with hCG (stimulated testis). Pituitary glands are dissected and the anterior lobe is frozen at −20°C for determination of LH by rat-specific radioimmunoassay (Sect. N.9.2.5). LH receptors in anterior pituitary homogenate are measured by binding of ^{125}I-buserelin *in vitro*.

EVALUATION

The effects of various doses of the LH-RH antagonist after various time intervals on the different parameters mentioned above are compared with values from intact controls and castrated animals. Significant differences compared to controls at the 95% level are calculated by Dunnett's test.

MODIFICATIONS OF THE METHOD

These are mainly models for contraceptive applications and tumor suppression using LH-RH antagonists.

Kangasniemi et al. (1996) used a combined treatment with a Gn-RH antagonist and an antiandrogen (flutamide) to suppress spermatogenesis in mice. Despite this effect, the treatment did not enhance recovery from spermatogenesis produced by a 10-Gy dose of radiation.

Sinha-Hikim and Swerdloff (1993, 1994) examined the time course of suppression and recovery of spermatogenesis and its relationship to the temporal changes in circulating levels of gonadotropin and testosterone and intratesticular testosterone levels after cessation of treatment with a potent Gn-RH antagonist.

N.9.3.4 Inhibition of Gonadotropin Release From Anterior Pituitary Cultures

PURPOSE AND RATIONALE

The same methods as described for studying the stimulation of gonadotropin release by LH-RH agonists (Sect. N.9.2.3, N.9.2.4) can be used for assessment of LH-RH antagonists.

PROCEDURE

Anterior pituitaries of young adult Sprague-Dawley rats are digested with collagenase for 1 h followed by a mechanical dispersion. The resulting cell suspension from 1.5 pituitaries, containing mostly small clusters of cells, is then sedimented together with a suspension of Sephadex G-10 (Sigma) and packed into 6.6-mm columns. Tissue culture medium 199 (Sigma) with supplements, equilibrated with 95% air/5% carbon dioxide, is perfused through the columns at a flow rate of 0.33 ml/min. After an overnight recovery period, during which the baseline stabilizes and the cells regain their full responsiveness, the samples to be tested are introduced through a four-way valve. During a 9-h experimental period, 180 1-ml fractions are collected. The system is standardized with 3-min exposures to 100 mM potassium chloride or 3 nM LH-RH. The compounds are introduced in various concentrations, generally for 3–9 min (time of one to three fractions), at 30-min intervals. Rat LH levels are measured from aliquots (50 µl) of the collected medium effluent by radioimmunoassay. As a standard, rat LH-RP2 reference standard is used. Repeated stimulation with 3 nM LH-RH for 3 min at 30-min intervals results in a pulsatile LH release.

EVALUATION

The suppression of pulsatile LH release due to repeated administration of LH-RH by antagonists is evaluated.

MODIFICATIONS OF THE METHOD

Krummen et al. (1991) assessed the direct effects of testosterone in primary cultures of pituitary cells.

A special long-term superfusion system was developed by Rékási et al. (1993) in order to evaluate the effects of cytotoxic compounds linked to LH-RH analogs on different types of rat pituitary cells. LH, growth hormone and prolactin were determined simultaneously in the effluent.

N.9.3.5 Anti-Tumor Effect of LH-RH Antagonists

PURPOSE AND RATIONALE

LR-RH antagonists were found to inhibit experimental tumors in rats and mice.

PROCEDURE

To induce mammary carcinomas, female rats are each given a single dose of DMBA (dimethylbenzanthracene) at the age of 50 days. The first mammary tumors can be detected 20–30 days later. The tumor weight is determined by palpation, comparing the volume of each tumor to that of preformed Plasticine models. The tumor weight is calculated by multiplication of the model weight by a factor which takes account of the specific weights of Plasticine and tumor tissue. After the total tumor mass per animal has reached about 1 g, the animals are randomly divided into treatment groups. At least eight animals are used per group. The rats are treated for 3 weeks with different subcutaneous doses of LH-RH antagonists or vehicle. The experiment is terminated at the end of the 3rd week from the initiation of the experiment. Histological examination of the tumors is performed.

EVALUATION

The change in tumor volume is calculated on the basis of individual responses. For determination of the mitotic index, 4000 cells are considered in each tumor.

MODIFICATIONS OF THE METHOD

Reduction of tumor weight in female BDF_1 mice bearing MXT mammary adenocarcinomas after treatment for 3 weeks with a LH-RH antagonist was reported by Szende et al. (1990).

Inhibition of MIA PaCa-2 human pancreatic xenografts in nude mice by a LH-RH antagonist was reported by Radulovic et al. (1993).

The involvement of insulin-like growth factors in growth regulation of the Ishikawa endometrial tumor cell line and the possible interference by LH-RH analogs was evaluated by Kleinman et al. (1993).

Pinski et al. (1994) investigated the effects of treatment with a LH-RH antagonist and a LH-RH agonist in Copenhagen rats bearing the anaplastic androgen-independent Dunning R-3327-AT-1 prostatic adenocarcinoma implanted orthotopically into the ventral lobes of prostate glands.

Vincze et al. (1994) tested the anti-tumor effect of the gonadotropin-releasing hormone antagonist MI-1544 *in vitro* on human breast cancer lines and *in vivo* on xenografts in immunosuppressed mice.

Manetta et al. (1995) reported the *in vitro* and *in vivo* inhibitory effects of a LH-RH antagonist against a panel of human ovarian carcinomas.

The effects of LH-RH and a LH-RH antagonist on cell growth and production of hCG and cAMP in JAR human chorioncarcinoma cells were examined *in vitro* by Horváth et al. (1995).

CRITICAL ASSESSMENT OF THE METHOD

In many instances, research is now based on assessing and confirming the anti-apoptotic activity of tumor-inhibiting compounds, e. g., methods based on thymidine incorporation to assess tissue proliferation may be considered. In the case of LH-RH antagonists the use of biological systems based on transplanted tumors in animals reflects the suppression of pituitary hormone release followed by reduced secretion of gonadal steroids. Testing the effect on experimental tumors in animals is a recommended procedure for obtaining confirmation of the clinical potential of application.

N.9.4 Corticotropin-Releasing Hormone (CRH)

N.9.4.1 General Considerations

A hypothalamic factor inducing release of corticotropin (ACTH) from pituitaries was the first of the hypothalamic releasing hormones identified using *in vitro* bioassays (Saffran and Schally 1955; Guillemin and Rosenberg 1955). A common pre-pro-hormone, opiomelanocortin, was identified as the source of corticotropins and endorphins. Much later, the structure of a 41-residue ovine hypothalamic peptide stimulating the secretion of corticotropin and β-endorphin was identified (Vale et al. 1981), followed by elucidation of the structure of human CRH (Shibahara et al. 1983) and of other species, such as porcine corticotropin-releasing factor (CRF; Patthy et al. 1985) and equine CRF (Livesey et al. 1991). Reviews are given by Brodish (1979), Rivier and Plotsky (1986), and Taylor and Fishman (1988), Vigh et al. (1982), Koob (1999). Conformational differences between ovine and human CRH were detected using circular dichroism, Fourier transform infrared spectroscopy, nuclear magnetic resonance (NMR) and dynamic light scattering (Dahte et al. 1996).

The binding sites of immunoreactive CRH in the rat ovary and its potential physiological role were studied by Mastorakos et al. (1993).

Studies on CRF receptors in the pituitary have been performed (Wynn et al. 1983; Millan et al. 1987). Investigations into the general pharmacological properties of human CRH did not reveal any considerable side-effects (Andoh et al. 1994).

Derivatives with agonistic and antagonistic properties have been synthesized and tested (Rivier et al. 1984; Kornreich et al. 1992; Chen et al. 1996; Schulz et al. 1996; Webster et al. 1996; Arai et al. 1998).

The role of CRH in inflammatory processes was investigated by Webster et al. (1998).

Non-mammalian peptides sauvagine (from frog) and **urotensin** 1 (from fish) have approximately 50% sequence homology with CRF and share *in vitro* and physiological actions characteristic of CRF (Rivier et al. 1983). A mammalian urotensin-like peptide (named **urocortin**) with partial sequence identity with urotensin 1 and CRF has been identified in rat (Vaughn et al. 1995) and human (Donaldson et al. 1995) tissues. The mouse and human urocortin genes have been isolated and characterized (Zhao et al. 1998).

A **corticotropin-releasing factor binding** *protein (CRFBP)* was isolated and is thought to be an important modulator of CRF in both the CNS and the periphery (Behan et al. 1995; Petraglia et al. 1996; Cortright et al. 1997; Hobel et al. 1999). CRFBP levels rise at 30–35 weeks of pregnancy and dramatically decrease at 38–40 weeks. *In vitro*, CRFBP inhibits the ACTH-releasing properties of CRF.

Cortright et al. (1995) described a mouse brain CRH-binding protein (CRHBP) highly homologous to human and rat CRHBPs, but distinct from the CRH receptor.

Stenzel-Poore et al. (1996) described **transgenic mice** with CRH overproduction that induces behavioral changes that parallel the stress syndrome. Van Gaalen et al. (2002, 2003) reported anxiety-like behavior and reduced attention in mice overproducing CRH in an operant five-choice serial task, which taxes sustained and divided attention.

Bale et al. (2002) found that mice deficient for both CRF receptor 1 (CRFR1) and CRFR2 have an impaired stress response and display sexually dichotomous anxiety-like behavior.

N.9.4.1.1 Central Effects and Actions of CRH

In some contrast to the initial conception of a hypothalamic factor regulating adrenocortical function, research on CRH, related CRF peptides and nonpeptidic compounds interacting with the CRH receptors, has established for CRH both a central role and important peripheral effects. In keeping with knowledge about the effects of neurohypophyseal hormones and steroids on brain functions, memory and learning, a similar role has been established for CRH (Croiset et al. 2000). In the process of establishing these functions, the presence of CRF receptors in the central nervous system and other tissues has been a starting point for investigations (reviewed by De Souza 1995; Perrin and Vale 1999; Eckard et al. 2002). As in other areas, specific animal models are now focusing on mutant mice for the prediction and confirmation of function (Contarino et al. 1999). Bruijnzeel and Gold (2005) have reviewed the role of CRF-like peptides in various forms of drug dependence, both to elucidate mechanisms and to explore potential therapies (Chatzaki et al. 2006). In keeping with the functional effect on the pituitary–adrenal system, involvement of CRH in the stress response has been addressed by Smith and Vale (2006), and the synthesis of CRF receptor antagonists may offer therapeutic potential in central disorders related to anxiety, psychiatric disorders, stress, and drug dependence (Valdez 2006).

Effects on the gastrointestinal tract of CRH have been described by several groups (Martinez and Tache 2006, 2007; Tache and Bonaz 2007).

Vergoni and Bertolini (2000) and Doyon et al. (2004) have suggested a functional role in the central regulation of appetite and body weight, by interaction with the melanocortin system.

Based on its interaction with CRH receptors, indications for modulation of synaptic transmission have also been found with CRH (Orozco-Cabal et al. 2006), which has parallels with the newly discovered functional role of LH-RH (GnRH),. Cardiovascular effects have been described and assigned to CRH receptors (Nazarloo et al. 2006). The existence of a CRH-like placental corticotropin-releasing factor has been confirmed even though the functional role remains elusive (Fadalti et al. 2000).

N.9.4.2 In Vitro Assay for CRH Activity

PURPOSE AND RATIONALE

The first *in vitro* assay procedures to detect CRF activity (Saffran and Schally 1955; Saffran et al. 1955) were based on incubation of rat anterior pituitary halves with the test substances in bicarbonate-buffered, oxygenated medium at 38°C for 1 h in the presence of 0.0004 M DL-arterenol and 0.004 M ascorbate followed by measurement of ACTH release into the medium by incubation with adrenal tissue and determination of corticosterone (a two-stage bioassay where a biological product of CRH action is determined by a quantitative biological response). Guillemin and Rosenberg (1955) used pituitary tissue culture from rat and dog and determined ACTH activity in the medium by the *in vivo* ascorbic acid depletion method in the rat according to Sayers (1954) (see Sect. N.7.4.1). The assay was later considerably simplified by using ACTH radioimmunoassay (RIA). Several modifications of these procedures have been used (Schally et al. 1968; Yasuda et al. 1982). Most investigators used rat pituitary cell cultures (Giguère and Labrie 1982; Giguère et al. 1982; Aguilera et al. 1983; Bilezikjan and Vale 1983; Vale et al. 1983a, 1983b; Patthy et al. 1985), while pituitary segments have been used by Antoni et al. (1983) and by Widmaier and Dallman (1984).

PROCEDURE

Anterior pituitaries are obtained from adult Sprague-Dawley rats, cut into small pieces and incubated in a Dubnoff incubator for 45 min at 37°C in 10 ml of oxygenated Medium 199 (GIBCO) containing 0.5% collagenase, 0.25% BSA, and 50 µg/ml gentamicin. The fragments can be easily dispersed mechanically into single cells by repeated suction and expulsion from a pipette. The cell suspension is centrifuged at room temperature for 10 min at 100 *g*. The cell pellet is then resuspended in 1.0 ml of medium and divided into four equal volumes. Each volume (containing about 5×10^6 cells) is mixed with 0.5 ml Sephadex G-15 which has been equilibrated previously with oxygenated medium. The mixture of pituitary cells and Sephadex is transferred into four chambers of a superfusion apparatus (Vigh and Schally 1984; Evans et al. 1988; Czernus and Schally 1991) consisting of a number of 1-ml plastic syringe barrels (modified by cutting off their distal end) mounted vertically in a Plexiglas holder which is kept at 37°C by circulating water. Each barrel is fitted with plungers at both ends. Holes are drilled in the plungers to accommodate plastic tubing. The lower plunger is covered with a small piece of 30-µm-pore nylon net to keep the Sephadex beads from escaping. The "pores" between the beads are small enough to prevent the pituitary cells from escaping and large enough to allow unrestricted flow of medium through the column. The upper plunger tubing is used for directing the flow through the chamber from the medium reservoir. The flow through the system is controlled by a multichannel peristaltic pump which is placed after the superfusion chamber. Thus, the system is operated by suction with negative pressure.

The cells are perfused overnight with Medium 199 (Gibco) at a flow rate of 20 ml/h. The samples are administered every 30 min for 3 min and 1-ml fractions are collected at 3-min intervals. Synthetic CRF at 0.2 and 2 mM is used as standard. The corticotropin released into the medium is measured by a specific RIA for corticotropin.

EVALUATION

Dose–response curves are established for test preparation and standard allowing the calculation of potency ratios with confidence limits.

N.9.4.3 In Vivo Bioassay of CRH Activity

PURPOSE AND RATIONALE

Munson and Briggs (1955) described an assay using rats pretreated with morphine and pentobarbital. Many modifications for a reliable *in vivo* bioassay of CRH activity have been tested including rats with hypothalamic lesions (Schally et al. 1968; Yasuda et al. 1982). Arimura et al. (1967) described an assay for corticotropin-releasing factor (CRF) using rats treated with morphine, chlorpromazine, dexamethasone and pentobarbital. This assay has been further improved by Graf et al. (1985).

PROCEDURE

Male Sprague-Dawley rats weighing about 200 g are maintained on a 12:12 h light:dark cycle at constant temperature for at least 5 days before use. On the day of the experiment, the rats are prepared with an initial single subcutaneous injection of a mixture of chlorpromazine (10 mg/kg) and morphine sulfate (20 mg/kg) followed after 75 min by pentobarbital (25 mg/kg) intraperitoneally. Then 60 min after the injection of pentobarbital, various doses of test substances or standard or vehicle (0.9% NaCl, 1% BSA, 0.1% ascorbic acid) are injected into an exposed jugular vein. Blood samples (0.5 ml) are collected in heparinized syringes immediately before and 30 min after injection of test substances. The blood is transferred to chilled polypropylene tubes containing EDTA (1.0 mg) and aprotinin (Trasylol, 50 µl) and centrifuged (2000 *g*, 15 min 4°C). Plasma samples are stored at −20°C for corticosterone assay using a cross-reacting cortisol RIA that also measures corticosterone, the main corticoid secreted by rats, or a corticosterone RIA.

EVALUATION

Data for CRH activity of experimental groups are evaluated by analysis of variance or covariance followed by Duncan's multiple range test.

N.9.4.4 Collection of Hypophyseal Portal Blood in Rats

PURPOSE AND RATIONALE

Worthington (1966), Porter and Smith (1967), Gibbs (1984), and Sarkar and Minami (1991) described methods to collect hypophyseal portal blood in rats. These methods can be used to measure the changes in secretion of several hypothalamic hormones under the influence of various factors.

Gibbs and Vale (1982), Gibbs (1985a), and Plotsky and Sawchenko (1987) studied the effect of various conditions on hypophyseal portal plasma levels of corticotropin-releasing factor (CRF) and arginine vasopressin.

Luteinizing hormone-releasing hormone (LHRH) was determined by Ching (1982), Sarkar (1987), Petraglia et al. (1987); thyrotropin releasing hormone (TRH) by Fink et al. (1982); growth-hormone-releas-

ing hormone (GH-RH) by Plotsky and Vale (1985); β-endorphin by Sarkar and Yen (1985); neuropeptide Y by Sutton et al. (1988); vasoactive intestinal peptide by Sarkar (1989); vasopressin and oxytocin by Gibbs (1984); and dopamine and epinephrine by Ben-Jonathan et al. (1977), and Gibbs (1985b).

PROCEDURE

Pentobarbital-anesthetized rats are placed on an isothermal heating pad in a stereotactic instrument. After cannulation of the trachea, the animals are mechanically ventilated. The base of the skull is exposed by a transpharyngeal approach, and the basisphenoid bone is drilled away. The dura is cut and deflected, the rat is heparinized, and, after the stalk is cut, a polyethylene cannula filled with saline is placed over the hypophyseal stalk for collection of blood. The cannula leads to an ice bath, and the distal end of the tubing ends in a fraction collector where portal blood is collected by gravity flow at a rate of about 10 µl/min.

EVALUATION

Portal plasma concentrations of CRH, LHRH, TRH, GH-RH, β-endorphin, neuropeptide Y, vasoactive intestinal peptide, vasopressin and oxytocin, and catecholamines were determined after various treatments and compared with control periods of spontaneous secretion.

MODIFICATIONS OF THE METHOD

Cowell et al. (1991) described *in vitro* models for examination of the mechanisms controlling the secretion of hypothalamic hormones.

N.9.4.5 CRH Receptor Determination

PURPOSE AND RATIONALE

CRH mediates its effects through high-affinity receptors identified and characterized by radioreceptor studies. Cellular signaling was measured by stimulation of adenyl cyclase in membrane fractions of rat brain, pituitary, and spleen (Grigoriadis et al. 1993; Hauger and Aguliera 1993). Cloning studies indicate the existence of at least two types of mammalian receptor (De Souza et al. 1998; Steckler and Holsboer 1999; Dautzenberg and Hauger 2002). The CRF_1 receptor has been cloned from several species including human (Chen et al. 1993; Castro et al. 1996; Di Blasio et al. 1997; Grammatopoulos and Hillhouse 1998), mouse

(Vita et al. 1993), and rat (Perrin et al. 1993). Species homologies are 98% identical over the full length of 415 amino acids.

There are three isoforms of the CRF_2 receptor: the $CRF_{2(a)}$ receptor, which has been cloned from both rat (Lovenberg et al. 1995) and human (Liaw et al. 1996), is a 411-amino-acid protein which shares approximately 70% identity with the CRF_1 receptor; the $CRF_{2(b)}$ receptor isoform has been cloned from rat (Lovenberg et al. 1995), mouse (Stenzel et al. 1995), and human (Kostich et al. 1996) and is 431 amino acids in length, differing from the $CRF_{2(a)}$ receptor in that the first 34 amino acids in the N-terminus are replaced by 54 different amino acids; the $CRF_{2(c)}$ receptor has been identified in human brain (Sperle et al. 1997; Kostich et al. 1998).

[^{125}I]Sauvagine binding to CRH_2 receptors was characterized by Rominger et al. (1998).

CRH in plasma is mostly bound to the corticotropin-releasing hormone-binding protein (CRH-BP) and is therefore inactive except for the free fraction. CRH-BP is predominantly produced by the liver and distributed and expressed differently from the CRH receptors (Cortright et al. 1995; Zhao et al. 1997).

Rhode et al. (1996) used whole brains of Wistar rats for the CRH receptor assay.

PROCEDURE

Whole brains of male Wistar rats weighing 220–250*g* are homogenized with a Teflon-glass homogenizer (10 strokes at 800 rpm) in 0.32 M sucrose, 50 mM Tris/HCl (pH 7.2), 10 mM $MgCl_2$, 2 mM EGTA, and 0.15 mM bacitracin at 50 mg wet weight per milliliter. After centrifugation at 1000 *g* for 5 min, the supernatant is centrifuged at 26,000 *g* for 20 min. The pellet is resuspended in 50 mM Tris/HCl (pH 7.2), 10 mM $MgCl_2$, 2 mM EGTA, adding 0.15 mM bacitracin and 0.0015% aprotinin (assay buffer), and again centrifuged. The pellet is suspended in assay buffer containing 0.32 M sucrose and stored at −20°C. All steps are carried out at 4°C. Protein concentrations are determined by the method of Bradford (1976) using BSA as standard.

Then, 100 µg of membrane preparation in 300 µl assay buffer is incubated in quadruplicate with 0.1 nM [^{125}I]Tyr-oCRH in the absence and presence of 12 different concentrations (0.2 nM up to 1 µM) of unlabeled peptides at 25°C for 2 h. Nonspecific tracer binding is determined in the presence of 1 µM ovine CRH (oCRH). At the end of incubation, 3 ml of ice-cold assay buffer without inhibitors (containing 0.01% Triton X-100) is added to the assay tube and the samples are immediately filtered through GF/C filter discs (Whatman), presoaked for 2 h in 0.1% polyethylenimine using a Brandel-Harvester. The incubation tubes and filters are then washed with 3 ml cold washing buffer. Triton X-100 in this buffer strongly reduces nonspecific tracer binding. Radioactivity retained on the filter is measured by gamma-counting.

EVALUATION

Receptor affinities (K_{ass}, $K_d = 1/K_{ass}$) and capacities (B_{max}) are estimated using the nonlinear least-squares curve fitting program RADLIG (BIOSOFT, Cambridge, UK) and a K_d of 0.48 nM for the binding of the tracer peptide as determined from tracer saturation curves.

MODIFICATIONS OF THE METHOD

Schulz et al. (1996) used P2 membranes from human neuroblastoma IMR32 cells to test receptor binding of a selective nonpeptide antagonist of corticotropin-releasing factor (CRF).

Webster et al. (1996) used rat frontal cortex, pituitary, cerebellum, and heart tissue for *in vitro* characterization of antalarmin, a nonpeptide CRH receptor antagonist.

Grigoriadis et al. (1996) recommended ^{125}I-tyro-sauvagine as a high-affinity radioligand for the pharmacological and biochemical study of human CRF 2α receptors.

Differences between normal and adenomatous pituitary corticotrophs in the labeling characteristics of CRH receptors were reported by Abs et al. (1997).

Rabadan-Diehl et al. (1997) studied the role of glucocorticoids and hypothalamic factors in the regulation of pituitary CRH receptor mRNA and CRH during adrenalectomy in rats.

The differential regulation of hypothalamic pituitary CRH receptors during the development of adjuvant-induced arthritis in rats was reported by Aguilera et al. (1997).

Grammatopoulos and Hillhouse (1998) reported the solubilization and biochemical characterization of the human myometrial CRH receptor.

The interaction between glucocorticoids and CRH in the regulation of the pituitary CRH receptor has been studied in rats by Ochedalski et al. (1998).

The multiple actions of CRF on neuroendocrine and behavioral functions were examined using high-affinity, nonpeptide antagonists (Lundkvist et al. 1996).

Wei et al. (1998) described analogs of CRH and urocortin with selective activity at CRH_1 and $CRH_{2\beta}$ receptors.

Perrin et al. (1999) used an agonist, urocortin, and an antagonist, astressin, as radioligands for characterization of CRF receptors.

N.9.4.6 CRF Receptor Antagonists

PURPOSE AND RATIONALE

Studies with CRF antagonists indicate a role for CRF in certain psychiatric diseases and drug addiction (Koob 1999). This is in line with the known clinical psychotropic effects of corticotropin and glucocorticoids at elevated doses.

Various truncations of agonist peptides with deletions of the first 8–11 amino-terminal amino acid residues have resulted in potent peptide antagonists (Rivier et al. 1984; Hernandez et al. 1993; Miranda et al. 1994; Schulz et al. 1996). Several nonpeptide CRF receptor antagonists have been described (Griebel et al. 1998; Okuyama et al. 1999; Habib et al. 2000; Gully et al. 2002; Griebel et al. 2002; Heinrichs et al. 2002; Grigoriadis 2003; Gutman et al. 2003). Receptor autoradiography was performed in treated rats by Heinrichs et al. (2002) and Gutman et al. (2003).

PROCEDURE

Brains from treated rats are sectioned at the level of the prefrontal cortex and lateral septum to determine CRF_1 and CRF_2 receptor binding, respectively. The prefrontal cortex has been shown via *in situ* hybridization to express predominantly CRF_1 receptors, whereas the lateral septum expresses CRF_2 receptors in rodents (Van Pett et al. 2000). After the behavior experiments, 15-µm-thick rat brain sections containing the prefrontal cortex and the lateral septum are sectioned at approximately −20°C, mounted on Superfrost Plus Slides and stored at −80°C until the assay. *Ex vivo* CRF receptor autoradiography is performed on 15-µm-thick rat brain sections. Sections are removed from the −80°C freezer and allowed to warm up to room temperature in a desiccator. Brain sections are fixed for 2 min in 0.1% paraformaldehyde, pH 7.5, followed by a 15-min incubation in assay buffer (50 mM Tris, 10 mM $MgCl_2$, 2 mM EGTA, 0.1% bovine serum albumin, 0.1 mM bacitracin, and 0.1% aprotinin, pH 7.5). Triplicate slides containing adjacent brain sections are incubated in one of three conditions:

1. 0.1 nM radiolabeled ^{125}I-sauvagine to determine total binding at both the CRF_1 and CRF_2 receptor subtypes;
2. 0.1 nM radiolabeled ^{125}I-sauvagine + 1 µM of a specific CRF_1 receptor antagonist to be tested, to determine CRF_2 receptor-specific binding; or
3. 0.1 nM radiolabeled ^{125}I-sauvagine + 1 µM unlabeled sauvagine to determine nonspecific binding.

After a 2-h incubation, unbound radioligand is removed by two 5-min rinses in ice-cold phosphate-buffered saline + 1% bovine serum albumin on a rotating platform at 60 rpm, followed by two brief dips in ice-cold distilled, deionized H_2O. Slides are then rapidly dried using a cold air blow dryer and exposed to Kodak Biomax MR film with ^{125}I-microscale standards (Amersham Biosciences) for 80–90 h.

Images from the receptor autoradiography films are digitized with a CCD-72 (Dage-MTI, Michigan City, Ind., USA) image analysis system equipped with a Nikon camera. Semiquantitative analysis is performed using AIS software (version 4.0, Imaging Research, St. Catherines, ON, Canada). Optical densities are calibrated against co-exposed ^{125}I-microscale standards and expressed in terms of nanocuries per gram of tissue equivalent.

EVALUATION

CRF_1-receptor-specific binding is calculated as total binding minus CRF_2 receptor binding, and CRF_2 receptor-specific binding is calculated as CRF_2 receptor binding minus nonspecific binding. Receptor binding data are expressed as a percentage of the control values. The percentage of binding is subtracted from 100 to estimate percentage of occupancy by the antagonist relative to vehicle-treated rats. In all cases, three to four sections are matched at the rostrocaudal level and used to produce a single value for each animal. Significant differences are evaluated by one- or two-tailed *t* tests or one-way ANOVA followed by Student-Newman-Keuls post hoc analysis.

N.9.5 Growth-Hormone-Releasing Hormone (GH-RH)

N.9.5.1 General Considerations

The discovery of the growth-hormone-releasing hormone (GH-RH) by physiological experiments, and the isolation and purification of the hormonal principle are reviewed elsewhere (Reichlin et al. 1976; Krulich and Fawcett 1977; Ling et al. 1985; Frohman and Jansson 1986; Gelato and Merriam 1986; Grossman et al. 1986; Thorner et al. 1986; Frohman et al. 1986; Muller 1987; Vance 1990). The initial studies on analogs of GH-RH raised expectations that therapy by GH injections might be replaced by GH-RH therapy (Dean and Friesen 1986). It was however found that infusions and high-dose treatment with GH-RH reduced to the response of GH release, in a similar manner as described for the gonadotropin receptors, due to receptor adaptation (Catt et al. 1980).

The comparative endocrinology of hypothalamic control of GH secretion by GH-RH, and the presence of GH-RH receptors in animal species have been explored for mammalian and nonmammalian animal species (Ukena et al. 2006; Lee et al. 2007).

N.9.5.2 Radioreceptor Assay of Growth Hormone-Releasing Hormone

PURPOSE AND RATIONALE

As for other polypeptide hormones, GH-RH receptors may be used for quantification and potency estimates of relative binding affinities. Several agonistic and antagonistic analogs of human GH-RH (hGH-RH) have been synthesized by various groups of investigators. The clinical and basic aspects of GH-releasing peptides are reviewed by Argente et al. (1996).

In vitro assays with pituitary cells have been used for screening the biological activity of hGH-RH analogs prior to their evaluation *in vivo* (Heiman et al. 1985; Kovacs et al. 1988; Campbell et al. 1991). A careful determination of binding activities of the peptides to specific GH-RH receptors provides important data for the design of more active analogs. Several studies demonstrated that the radioligand, [His^1-, ^{125}I-Tyr^{10},Nle^{27}]-hGH-RH(1-32)NH_2, binds specifically to a single class of receptors in rat pituitary cells and homogenates, and can be used for radioreceptor assay (Campbell et al. 1991; Seifert et al. 1985a, 1985b; Struthers et al. 1989). The use of a radioreceptor assay for *in vitro* screening of analogs of GH-RH was described by Halmos et al. (1993).

PROCEDURE

Pituitaries from male Sprague-Dawley rats (250–300 g) are used to prepare crude membranes. Immediately after decapitation, anterior pituitaries are removed, rinsed with cold saline, and homogenized in 5 times their volume of homogenization buffer (50 mM Tris-HCl, 5 mM EDTA, 5 mM $MgCl_2$, 30 µg/ml bacitracin, pH 7.4) on ice using an Ultra-Turrax homogenizer at maximal speed. The homogenate is centrifuged at 500 *g* for 10 min at 4°C. The supernatant containing the crude membrane fraction is again centrifuged at 70,000 *g* for 50 min at 4°C. The pellet is washed twice by resuspending in ice-cold homogenization buffer and spinning. The final pellet is resuspended in homogenization buffer and stored at −70°C until used for the receptor binding studies. Protein concentration is determined by the method of Bradford (1976) using a commercially available protein assay kit.

[His^1,^{125}I-Tyr^{10},Nle^{27}]hGH-RH(1-32)NH_2 is iodinated by the chloramine-T method (Greenwood et al. 1963). The receptor binding assay is carried out for 60 min in GH-RH binding buffer (50 mM Tris-HCl, 5 mM EDTA, 5 mM $MgCl_2$, 1% BSA, 30 µg/ml bacitracin, pH 7.4) at 24°C. For saturation binding analyses, 50–150 µg membrane homogenates are incubated in duplicate with a least six concentrations of radioligand, ranging from 0.005 to 0.35 nM in the presence or absence of excess unlabeled peptide (1 µM) in a final volume of 300 µl. Incubation is terminated by immersing siliconized borosilicate tubes in ice water, transferring 270 µl of the suspension into cold siliconized polypropylene microfuge tubes, and centrifuging at 12,000 *g* for 2 min at 4°C, and aspirating the supernatants. To reduce the nonspecific binding, 500 µl/tube of GH-RH binding buffer is added and the tubes recentrifuged. The washing step is repeated and the supernatant again aspirated. Finally, the bottoms of the tubes, containing the pellet, are cut off and counted for radioactivity in a gamma-counter.

In the competition experiments, which also include the specificity experiments, 50–100 µg of membrane homogenates are incubated in duplicate with 0.10–0.15 nM radioligand plus various concentrations of nonradioactive analogs and other peptides (10^{-12}–10^{-6} M).

EVALUATION

Percent specific binding is plotted against the log concentration of competitors. The curves are compared at the 50% specific binding levels (IC_{50}). The ligand-PC and McPherson computerized curve fitting pro-

grams of Munson and Rodbard (1980) are used to analyze competition and saturation data. To determine the types of receptor binding, dissociation constants (K_d) and the maximal binding capacity of receptors (B_{max}), and the saturation binding data are also analyzed by the Scatchard method.

MODIFICATIONS OF THE METHOD

Carrick et al. (1995) described a rapid and sensitive binding assay for GH releasing factor (GRF). Human embryonic kidney (HEK293) cells and rat pituitary tumor (GH_4C_1) cells were transfected with the porcine GRF receptor cDNA. Stably expressing cell lines are referred to as 293-P2 and GH_4-P1, respectively. GH_4C_1 cells transfected with somatostatin receptor subtype 2 are called GH_4-R2.20 and HEK293 cells transfected with somatostatin receptor subtype 5 are called 293-R5.2. GH_4-P1 and 293-R5.2 were derived by the calcium phosphate method of transfection and 293-P2 and GH_4-R2.20 using lipofectamine. For binding assays, cells were removed from culture dishes by the addition of phosphate-buffered saline containing 1 mM EDTA and cell membrane fractions prepared. Membrane pellets were suspended in 25 mM Tris, pH 7.4, plus protease inhibitors, aliquoted and stored at −80°C. The binding assay consisted of approximately 25 pM radiolabeled ligand in the presence or absence of unlabeled ligand in assay buffer (50 mM HEPES, pH 7.4, 5 mM $MgCl_2$, 2 mM EGTA) and cell membranes (2–10 µg). The total assay volume of 200 µl included wheat-germ-agglutinin-coated SPA beads at a concentration of 1 mg/assay, and for GRF binding, 0.05 mg/ml alamethicin (Sigma St. Louis, Mo., USA); 96-well plates were used for most assays. Assays were agitated on a plate shaker for 3 h. Samples were counted on a Wallac Microbeta Counter for 1 min per sample. The conventional binding assay was performed (Mayo 1992), except that following binding and centrifugation the membranes were washed in 0.5 ml binding buffer, centrifuged, and counted.

Abribat et al. (1990) and Gaudreau et al. (1992) developed a binding assay for GH-RH in rat pituitaries. Using this technique, Lefrancois and Gaudreau (1994) tried to identify the receptor-binding pharmacophores of GH-RH in rat pituitaries.

Hassan et al. (1995) developed a competitive binding assay using cloned porcine GH-RH receptors in order to study structure–activity relationships.

Kaijkowsi et al. (1997) investigated GH-RH receptor structure and activity using yeast expression technologies.

Muccioli et al. (1998) characterized specific binding sites for synthetic GH secretagogs (sGHS) on membranes from pituitary gland and different human brain regions using a peptidyl sGHS (Tyr-Ala-hexarelin) which has been radio-iodinated to high specific activity at the Tyr residue.

N.9.5.2.1 Growth Hormone Release from Rat Pituitaries in Vitro

PURPOSE AND RATIONALE

For testing of pituitary cell stimulation, isolated pituitary glands or cell cultures may be used. Antagonism by adding somatostatin, for example, is tested in the presence of a standard concentration of GH-RH. Human GH-RH has the structure of a 44-amino-acid amide, which was isolated from human endocrine tumors and later confirmed as a hypothalamic hormone. The effect of GH-RH analogs can be tested on isolated rat pituitaries measuring GH release. This test system avoids the interference of counter-regulatory somatostatin secretion, which limits the duration of GH release *in vivo*.

PROCEDURE

The pituitaries of male Sprague-Dawley rats weighing about 100 g are quickly removed after decapitation. The posterior lobe is discarded and the anterior lobe is divided into two halves by a midsagittal cut. Five bisected hemipituitaries are incubated in plastic vials containing 4 ml TCM 199 with 0.1% BSA, 15 µg/ml penicillin, and 25 µg/ml streptomycin. The vials are gassed with 95% O_2 and 5% CO_2. After 30 min of control incubation, the medium is changed and various doses of standard and test substances are added for an incubation of 90 min. GH content in the medium and in the pituitaries is determined by a specific radioimmunoassay (Schalch and Reichlin 1966).

EVALUATION

Dose–response curves are established for standard and test compounds measuring GH release into the medium and GH depletion from the pituitaries allowing calculation of potencies ratios with confidence limits.

MODIFICATIONS OF THE METHOD

Superfused pituitary cells may be used measuring activity and duration of effect, as well as interaction of stimulatory and inhibitory factors. Growth-hormone-releasing factor from tumors in human pancreas and from rat hypothalami as well as analogs of GH-RH were evaluated in a superfused pituitary cell system (Vigh and Schally 1984; Czernus and Schally 1991; Halmos et al. 1993), see also Sect. N.9.4.2, *in vitro* assay for CRH activity. Anterior pituitaries of two young adult male Sprague-Dawley rats were digested with 0.5% collagenase CLS2 (Worthington) for 50 min. After incubation, the fragments were digested into cell clusters (5–40 cells) by mechanical dispersion, and then transferred onto two columns and allowed to sediment simultaneously with 0.8 ml Sephadex G-10. The dead volume of the system was set to 1 ml. Medium 199 containing BSA (2.5 g/l), $NaHCO_3$ (2.2 g/l) and gentamicin sulfate (85 µg/ml) was equilibrated with a mixture of 95% air and 5% CO_2 and used as the culture medium. The medium was pumped at a flow rate of 0.33 ml/min. During an overnight recovery period, the baseline stabilized and the cells regained their full responsiveness. The samples were then infused through a four-way valve at 5×10^{-10} M concentration for 3 min (1 fraction) at 45-min intervals. Rat GH was determined by double-antibody radioimmunoassay.

The same system was used by Rekasi and Schally (1993) and Kovács et al. (1996a) to evaluate the activity of GH-RH antagonists. For determination of the antagonistic activity, the cells were exposed to 10^{-8}, 10^{-7}, and 10^{-6} M GH-RH antagonist simultaneously with 10^{-9} M GH-RH or to 10^{-6} M GH-RH antagonist combined with 100 mM KCl (controls for potassium-stimulated GH secretion) for 3 min. After 30 min, the duration of the inhibitory effect of GH-RH antagonist was also tested by repeated 3-min infusions of 10^{-9} M GH-RH.

Using this system with pituitaries of **transgenic mice** overexpressing the human GH-RH gene, Kovacs et al. (1997) evaluated the effects of GH-RH antagonists.

In addition to growth hormone release, Horváth et al. (1995) determined cAMP release from superfused rat pituitary cells stimulated by GH-RH.

GH release was determined using cultured rat pituitary cells (Brazeau et al. 1982; Perkins et al. 1983; Scheikl-Lenz et al. 1985). Pituitary cells were prepared by enzyme dispersion with collagenase, DNase and pancreatin. The cells were cultured for 3 days in microbiological Petri dishes in Dulbecco's modified essential medium with 20 mM HEPES, 15% fetal calf serum, 100 mU/ml penicillin-G and 100 µg/ml streptomycin at 37°C and 10% CO_2.

Cheng et al. (1993) tested time- and dose-dependent GH release by a nonpeptidyl GH secretagogue in rat pituitary cells.

Sanchez-Hormigo et al. (1998) tested GH-releasing hexapeptide, one of several synthetic GH secretagogues, on GH secretion from cultured porcine somatotropes.

Kovács et al. (1996b) measured the effects of chronic administration of a GH-RH agonist on body weight, tibia length and tail length in growth-hormone-deficient (monosodium-glutamate-lesioned) rats.

Jacks et al. (1996) evaluated an orally active GH secretagogue in dogs. Serum GH levels were dose-dependently increased after oral and intravenous administration. Moreover, an increase of insulin-like growth factor and serum cortisol was found.

N.9.5.2.2 Long-Term Pituitary Cell Culture

Long-term-cultured pituitary cells have been used extensively to study the response of GH secretion and synthesis. Roh et al. (2006) applied this principle to the investigation of priming by GH-RH and by synthetic secretagogues derived from ghrelin. They found that low doses of GHRP-2 and GH-RH were suitable for priming somatotrope cells in culture for subsequent stimulation by GH-RH and ghrelin.

Studies *in vitro* using long-term cell cultures have shown that priming with low doses of GH-RH enhances the subsequent response to the stimulation with GH-RH analogs. Fintini et al. (2005) have used a new animal model for the assessment of GH secretion, the GH-deficient GH-RH-knockout (GH-RH-KO) mouse model. The found that priming with the non-GH-RH secretagogue derived from the gastrointestinal peptide ghrelin augmented the subsequent response to a GH-RH analog.

N.9.5.3 GH-RH Bioassay by Growth Hormone Release in Rats

PURPOSE AND RATIONALE

Releasing activity can be determined by plasma GH stimulation after intravenous or subcutaneous injection of GH-RH in rats.

PROCEDURE

Male Sprague-Dawley rats weighing about 100 g are anesthetized by fractionated subcutaneous injections of 0.7 ml/kg of 25% urethane solution. The jugular vein is cannulated. Various doses of GH-RH test preparations or standard are injected intravenously in 0.2 ml 1% gelatin/saline. After 15 min blood samples are collected for determination of GH by a specific radioimmunoassay (Schalch and Reichlin 1966). The plasma concentration is expressed in terms of NIAMD-rat-GH-RP-1.

As a modification also suitable for testing other releasing hormones, e. g., by subcutaneous application, a double-barreled polyethylene catheter is implanted into the jugular vein, with one lumen being used for blood sampling and the second small lumen being used to keep the catheter open by heparin infusion into the tip of the collection catheter. Blood is continuously withdrawn by a peristaltic pump and fractions of 500 µl heparinized blood are collected at intervals of 10 min. To compensate for blood losses, the erythrocyte fraction of four to eight consecutive plasma samples is reinfused in a plasma expander (Haemaccel 3.5%) via a femoral vein. Before treatment, two 2-min samples are collected, and, after injection, two 2-min samples are collected again, followed by sampling intervals of 10 min for up to 3 h. GH is determined by a specific radioimmunoassay (Schalch and Reichlin 1966).

EVALUATION

Using several doses of standard and test preparation dose–response curves are established, allowing calculation of the potency ratio with confidence limits. Time–concentration curves after subcutaneous or, for example, intranasal application allow the duration of action to be evaluated.

MODIFICATIONS OF THE METHOD

Wehrenberg and Ling (1983) and Wehrenberg et al. (1985) determined the *in vivo* biological potency of rat and human GH-releasing factor and fragments of human GH-releasing factor in swivel-cannulated, conscious, freely moving rats and in cannulated anesthetized rats.

N.9.5.4 GH-RH Analogs

Many studies have been performed with synthetic GH-RH analogs, starting with the active sequence GHH (1–29), and proceeding to more powerful compounds, which were explored in domestic animals (Bhatti et al. 2006), and tested for their therapeutic potential in clinical studies (Doi et al. 2004; Furuta et al. 2004; Veldhuis et al. 2005).

Other Peptide Hormones

N.10.1
Melatonin

N.10.1.1
General Considerations

The role of melatonin as a neurotransmitter, a hormone, and a possible therapeutic agent has been a matter of controversy (Brainard 1978; Reiter 1991; Hajak et al. 1996; Huether 1996; Jansen et al. 2006) ever since melatonin was isolated and identified as *N*-acetyl-5-methoxytryptamine by Lerner et al. (1958) and characterized by Axelrod and Wurtman (1966). Melatonin is synthesized and released by the pineal gland and has been shown to play a key role in the regulation of mammalian circadian rhythms and reproductive functions (Reiter 1991; Arendt et al. 1995; DiBella and Gualano 2006). Melatonin is also produced in extrapineal sites, such as the retina (Lundmark et al. 2006), the Harderian glands, and the gut (Huether 1993, 1994; Messner et al. 2001). It should however be noted that methods for the identification of peptides and neurotransmitters have reached extremely high levels of sensitivity; as a consequence, their presence in a tissue does not necessarily indicate that a relevant physiological function is subserved in that organ or tissue. Melatonin is synthesized from 5-hydroxytryptamine (5-HT) by a two-step biochemical pathway (Reiter 1991). Initially, 5-HT is acetylated to produce *N*-acetylserotonin, which is subsequently *O*-methylated to form melatonin.

N.10.1.2
Melatonin Receptor Binding

PURPOSE AND RATIONALE

The activity of melatonin is mediated through high-affinity G-protein-coupled receptors. Two human melatonin receptor subtypes, hMT1 and hMT2, have been cloned (Reppert et al. 1994, 1995; Browning et al. 2000; Dubocovich et al. 2001). A third melatonin-binding site named MT_3 has been described as the human homolog of cytoplasmatic quinone reductase 2 (Nosjean et al. 2000, 2001).

Audinot et al. (2003) described the evaluation of selective ligands of human cloned MT_1 and MT_2 receptors. Binding affinities were determined using [2-^{125}I]-melatonin. Methods for the measurement of melatonin and melatonin derivatives (Middleton 2006) and for the melatonin receptor ligands (Zlotos 2005) have been reviewed

PROCEDURE

Membrane Preparations

HEK.293 and CHO-K1 cell lines stably expressing the hMT_1 or hMT_2 receptor are grown to confluence, harvested in phosphate buffer containing 2 mM EDTA and centrifuged at 1000 *g* for 5 min (4°C). The resulting pellet is suspended in 5 ml Tris/HCl, pH 7.4, containing 2 mM EDTA and homogenized using a Kinematica polytron. The homogenate is then centrifuged (20,000 *g*, 30 min, 4°C), and the resulting pellet is suspended in 75 mM Tris/HCl, pH 7.4, containing 2 mM EDTA and 12.5 mM $MgCl_2$. Aliquots of membrane preparations are stored in binding buffer (Tris/HCl 50 mM, pH 7.4, 5 mM $MgCl_2$) at −80°C until use.

[2-^{125}I]Melatonin Binding Assay

Membranes are incubated for 2 h at 37°C in binding buffer (Tris/HCl 50 mM, pH 7.4, 5 mM $MgCl_2$) in

a final volume of 250 µl containing [2-^{125}I]melatonin (200 pM) for competition experiments using CHO cells and 25 or 200 pM, respectively, for MT_1 and MT_2 receptors expressed in HEK cells. Nonspecific binding is defined with 10 µM melatonin. The reaction is stopped by rapid filtration through GF/B unifilters, followed by three successive washes with ice-cold buffer.

EVALUATION

Data are analyzed using the program PRISM (GraphPad Software, San Diego, Calif., USA). For saturation assays, the density of binding sites (B_{max}) and the dissociation constant of the radioligand (K_D) are calculated according to the method of Scatchard. For competition experiments, inhibition constants are calculated according to the Cheng-Prusoff equation. For the correlation analysis of pK_i values, the Pearson product moment correlation coefficient is employed.

MODIFICATIONS OF THE METHOD

Receptor binding assays have been used to evaluate new melatonin receptor ligands (Depreux et al. 1994; Dubocovich et al. 1997a; Charton et al. 2000a, 2000b; Nonno et al. 2000).

Dubocovich et al. (1997b) used **rabbit retina membranes** for binding studies with [2-^{125}I]melatonin.

Nonno et al. (2000) and Audinot et al. (2003) used the **[^{35}S]GTPγS binding assay** to evaluate the functional activity of agonists and antagonists. Membranes were prepared as for the [2-^{125}I]melatonin binding assay. Together with test drugs, they were diluted in binding buffer (20 mM HEPES, pH 7.4, 100 mM NaCl, 3 mM $MgCl_2$, 3 µM GDP) in the presence of 20 µg/ml saponin in order to enhance the agonist-induced stimulation level. For agonist tests, incubation was started by the addition of 0.1 nM [^{35}S]GTPγS to membranes and ligands, and carried on for 60 min at room temperature in a final volume of 250 µl. To test for antagonistic activity, membranes were preincubated for 30 min with melatonin (30 nM or 3 nM for hMT_1 and hMT_2 receptors, respectively) and several concentrations of the tested compound. The reaction was started by the addition of 0.1 nM [^{35}S]GTPγS and followed by a 60-min incubation. Nonspecific binding was assessed using nonradiolabeled GTPγS (10 µM). All reactions were stopped by rapid filtration through GF/B unifilters presoaked with distilled water, followed by three successive washes with ice-cold buffer.

Data were analyzed using the program PRISM to yield EC_{50} and E_{max} values for agonists. Antagonist potencies were expressed as K_B with $K_B = IC_{50}/1+([ago]/EC_{50}ago)$, where IC_{50} is the inhibitory concentration of antagonist that gives 50% inhibition of [^{35}S]GTPγS binding in the presence of a fixed concentration of agonist ([ago]) and the EC_{50}ago is the EC_{50} of the agonist when tested alone. I_{max} (maximal inhibitory effect) was expressed as a percentage of that observed with melatonin, 30 nM and 3 nM ([ago]) for hMT_1 and hMT_2 receptors, respectively.

N.10.1.3 In Vitro Assay of Melatonin: Inhibition of Forskolin-Stimulated cAMP Accumulation

PURPOSE AND RATIONALE

Reppert et al. (1995), Browning et al. (2000), and Charton et al. (2000a, 2000b) used the inhibition of forskolin-stimulated cAMP accumulation for characterization of melatonin receptors and evaluation of synthetic derivatives.

PROCEDURE

Generation of CHO-mt_1 and CHO-MT_2 Cells

Clones representing the sequence of the human mt1 receptor are amplified using degenerate primers based on the sequence of the *Xenopus laevis* melatonin receptor (Ebisawa et al. 1994). Cloning was in pBluescript (Strategene, La Jolla, Calif., USA). The human MT_2 sequence is cloned in a similar manner using the sequence described by Reppert et al. (1995). The sequences encoding the receptor are cloned into the mammalian vector pcDNA3 (Invitrogen) and introduced into CHO cells by conventional calcium phosphate precipitation techniques, which are then placed under G418 selection (1 mg/ml). Cell lines, which give the greatest melatonin-induced inhibition of cAMP accumulation, are chosen for further studies.

cAMP Assays

The assay is performed using 96-well plates in a final assay volume of 200 µl. Confluent CHO-mt_1 and CHO-MT_2 cells are incubated at 37°C with DMEM-F12, containing 300 µM isobutylmethylxanthine to inhibit phosphodiesterase activity. Following a 60-min incubation, agonist (0.01 pM to 100 µM) is added. After 60 min, forskolin (30 µM) is added and cells are incubated for a further 15 min. For antagonist experiments, melatonin is co-incubated with luzindole (0.1–100 µM) for 60 min prior to the addition of forskolin. The reaction is terminated by removal of media and addition of ice-cold ethanol (100 µl) for 30 min at 4°C. Ethanol samples are evaporated and cAMP concentrations determined by [^{125}I]cAMP scintillation proximity assay (Amersham).

EVALUATION

cAMP data are fitted with a four-parameter logistic equation to determine pIC_{50} values and Hill coefficients. Drug responses are expressed as percentage inhibition of forskolin-stimulated cAMP. The potency ratio is defined as the ratio of the EC_{50} of the drug relative to that of melatonin determined in the same experiment.

MODIFICATIONS OF THE METHOD

Morgan et al. (1989) and Conway et al. (2000) studied inhibition of cAMP production in cultures of ovine pars tuberalis cells by melatonin.

Furthermore, Conway et al. (2000) characterized the human melatonin mt_1 and MT_2 receptors using the **CRE-luciferase reporter assay**. HEK293 cells expressing human melatonin mt_1 and MT_2 receptors were cultured to ~ 80% confluence at which time they were co-transfected with the plasmids pGL3 (CRE2-TK) and pcDOR8 (Barrett et al. 1994) using the lipid transfection reagent FuGENE™ 6 (Boehringer Mannheim). Cells were cultured for 24 h post-transfection before being washed with phosphate-buffered saline (pH 7.4), recovered in phenol-red-free Dulbecco's modified Eagle medium (supplemented with 10% fetal calf serum) and seeded as 50-µl aliquots (5×10^4 cells) into white 96-well tissue culture plates. Following a further 24-h incubation, drug treatments were added in a 5.6 µl volume to triplet wells, and plates were left to incubate overnight (16 h). The level of expressed luciferase was measured by the addition of 50 µl of Constant Light Signal Reagent (Boehringer Mannheim) to each well, and plates were briefly placed in the dark (30 min, room temperature) before being quantified an a Packard LumiCount™ Reader (1 s per well). Where experiments were designed to measure drug-mediated dose–response effects, a control melatonin dose–response study was always included. Data from the triplet wells were averaged and the control data normalized from a value of 100 (no melatonin) to a value of 0 (maximum response, 10^{-5} M melatonin). Data obtained from other drug treatments were normalized relative to the control values determined in that experiment. All experiments were performed on three or more separate occasions, and mean values ± SEM determined.

IC_{50} values and apparent efficacies were calculated by fitting a four-parameter logistic curve through the

mean normalized data. For antagonists, pA_2 values were determined by performing Schild analysis.

N.10.1.4 Dopamine Release from Rabbit Retina

PURPOSE AND RATIONALE

Dubocovich et al. (1997) compared the pharmacological profile of the rabbit retina ML_1 presynaptic heteroreceptor that mediates the calcium-dependent release of dopamine to that of the human Mel_{1a} and Mel_{1b} recombinant melatonin receptors, and determined potencies of melatonin receptor agonists and antagonists.

PROCEDURE

Albino rabbits (2.5–3.5 kg) maintained on a 14-h/10-h light/dark cycle are sacrificed by decapitation during the light cycle. Retinal pieces are incubated in Krebs solution gassed with 95%O_2 and 5%CO_2 for 20 min at 37°C in the presence of 0.1 μM [^{3}H]dopamine (specific activity 55 Ci/mol). The pieces of retina are washed in Krebs solution at 37°C and placed in glass superfusion chambers between a pair of platinum electrodes 30 mm apart. Retinal tissue is superfused at 1 ml/min with Krebs solution (37°C) containing (*S*−*R*)-sulpiride (0.1 μM) to block D_2 dopamine autoreceptors, beginning 60 min after the onset of superfusion, i. e., when the spontaneous outflow of radioactivity has leveled off. Samples of the superfusate are collected by means of a fraction collector at 4-min intervals. Tritium release from retinal tissue is elicited by field stimulation using 2-min-duration (3 Hz, 20 mA, 2 ms) pulses that are delivered from platinum electrodes by a Grass stimulator. During stimulation, pulses are monitored on an oscilloscope. In each experiment two periods of field stimulation are applied at 60 min and 100 min after the incubation with [^{3}H]dopamine. Samples of the superfusate are collected before, during, and after the period of stimulation. Drugs are added to the perfusion medium either 40 min before the first or 20 min before the second stimulation period. At the end of the experiment, the retinal tissue contained in each chamber is solubilized in 0.5 ml TS-1 (Research Products Int., Elk Grove, Ill., USA) and the tritium content is determined by liquid scintillation counting.

EVALUATION

The outflow of radioactivity in each sample is expressed as the percentage of total tissue radioactivity determined to be present at the beginning of each sample collection period: total tritium released per sample divided by total tritium present in the tissue all multiplied by 100 (Dubocovich 1985). Results are expressed as the ratio of the overflow during the second and first periods of field stimulation within the same experiments.

N.10.1.5 Effect on Xenopus Melanophores

PURPOSE AND RATIONALE

TeckTeh and Sugden (1998) examined the potency of melatonin receptor ligands using the pigment aggregation response in a clonal line of *Xenopus laevis* melanophores.

PROCEDURE

Culture of Xenopus laevis melanophores

A clonal line of *Xenopus laevis* melanophores (M. Lerner, University of Texas) is grown in diluted (0.7 ×) L-15 medium (Sigma) containing 20% heat-inactivated fetal calf serum, penicillin (100 IU/ml) and streptomycin (100 µg/ml). The medium is first conditioned by *Xenopus laevis* fibroblasts (Daniolos et al. 1990).

Microtiter plate assays

Melanophores are seeded into flat-bottomed 96-well microtiter plates and grown in conditioned L-15 medium at 24°C for 2–4 days until cell density is $(6–8) \times 10^4$ cells/well. For the 4–18 h before using melanophores, condition medium is replaced with 0.7 × L-15 medium; pigmented granules remain fully dispersed in this medium. Agonist potency is determined by measuring the redistribution of pigment granules within the melanophores by quantitating the change in absorbance of the cells at 630 nm on a Biotek microtiter plate reader. The fractional change in absorbance $(1 - [A_f/A_i]$, where A_i is the initial absorbance before drug addition and A_f is the final absorbance 1 h after drug treatment) is calculated for each concentration of drug tested.

EVALUATION

Concentration–response data are plotted and EC_{50} values are determined using the ALLFIT program (De Lean et al. 1978) with the four-parameter logistic equation:

$$Y = [A - D]/[1 + (X/C)B] + D$$

where X is the concentration of the analog, Y is the fractional change in absorbance, A is the maximal absorbance in the absence of the analog, B is the slope factor, C is the concentration of the analog producing half of the maximal response (EC_{50}) and D is the minimal absorbance. The response to each drug is measured in six independent experiments. Antagonistic potency (pA_2) is determined by constructing concentration–response curves to melatonin in the absence or presence of varying concentrations (1–100 µM) of each antagonist.

N.10.1.6 Vasoconstrictor Activity of Melatonin

PURPOSE AND RATIONALE

Evans et al. (1992), Ting et al. (1997), and Delagrange et al. (1999) used the vasoconstrictor action of melatonin in the tail artery of juvenile Wistar rats to evaluate melatonin agonists and antagonists. Two different recording systems, the Halpern pressure myograph (Halpern et al. 1984) and the Halpern–Mulvany wire myograph, were compared.

PROCEDURE

Male juvenile (3–4 weeks old, weighing 55–100 g) Wistar rats are housed in a 12-h light/dark cycle. They are sacrificed 1–2 h after lights on by decapitation. The ventral artery of the tail is dissected and placed onto a dissecting disc in gassed, modified Krebs-Henseleit solution. The blood vessel is carefully cleaned from fat and connective tissues with the aid of a dissecting microscope and divided into ring segments of 2–3 mm length. Ring segments are suspended between two supporting jaws in a stainless steel chamber of a Mulvany–Halpern wire myograph and allowed to equilibrate for 30 min. The preparations are bathed in Krebs-Henseleit solution maintained at 34 ± 1°C and gassed with 95% O_2/5% CO_2. Tension is applied by adjusting the micrometer connected to one of the supporting jaws, while an isometric transducer connected to the other jaw measures force. An initial tension of 0.2–0.5 g is applied. Then the preparations are allowed to relax to 0.1–0.4 g weight. Vessels are contracted with 60 mM KCl to assess tissue viability and provide a reference contracture for subsequent data analysis. A stimulator is used to deliver 5-s trains of electrical pulses (10–20 V, 3 ms pulse width) at a frequency of 2–3 Hz every 4–5 min. The voltage and the frequency of the field stimulation are adjusted at the beginning of each experiment to obtain 20%–35% of the KCl response. Concentration–responses curves are constructed for melatonin and test compounds. For experiments with putative antagonists, these agents are added 20 min before the construction of a dose–response curve for melatonin.

EVALUATION

Isometric tension responses are expressed as a percentage of the enhancement in response to the predrug of

neurogenic contractions. The sensitivity of the preparations is assessed as the negative logarithm of the concentration required to produce 50% of the maximum response (pEC_{50}) after the agonist concentration–effect ($E/[A]$) data are fitted to the formula:

$$E = \alpha[A]^n/([A]^n + [A_{50}]^n)\,,$$

where E is the response, α is the asymptote, $[A]$ is the agonist concentration, n is the gradient of the $E/[A]$ curve and $[A_{50}]$ is the midpoint of the $E/[A]$ curve (Black et al. 1985). $[A_{50}]$ values represent agonist concentration giving 50% of the maximum responses and are shown as the negative logarithm (pEC_{50}). The maximum response of each analog is expressed as a ratio of the maximum response to melatonin (E_{max}) obtained in segments from the same animal. For the antagonistic experiments, the agonist concentration ratio (CR) is determined in each experiment. The CR is the ratio of EC_{50}values in the presence and absence of antagonist. Differences between mean values are compared using either paired or unpaired Student's t-test (two tailed) and are considered statistically significant if $P < 0.05$.

MODIFICATIONS OF THE METHOD

Viswatanan et al. (1997) reported that melatonin receptors mediate **contraction of rat cerebral artery**. Male Sprague-Dawley rats (7–8 weeks old) were sacrificed by decapitation and their brains quickly removed and kept in ice-cold Krebs-Ringer buffer aerated with 95% O_2/5% CO_2. The posterior communicating artery, between the point at which the internal carotid artery joins and the middle cerebral artery originates, is dissected from the base of the brain, kept in ice-cold Krebs-Ringer buffer, cleaned of excess connective tissue, and transmitted to a vessel chamber filled with cold Krebs-Ringer buffer. Both ends of the artery are mounted on glass cannulas (100 µm diameter) and secured using 10–0 surgical silk sutures. The cannulas at the proximal and distal ends of the artery are connected to pressure transducers. The artery is perfused with oxygenated Krebs-Ringer buffer using a servo system. The intraluminal pressure of the artery is gradually increased to 60 mmHg by increasing the flow rate of the Krebs-Ringer buffer. The transmural pressure within the artery segment is maintained at 60–65 mmHg, a pressure chosen because it approximates the non-neurogenic pressure exerted on arterial blood vessels in rats. The chamber is superfused with oxygenated Krebs-Ringer buffer maintained at 37°C. The lumen diameter of the artery is continuously measured using a video electronic analyzer. The preparation is equilibrated for 45–60 min and during this interval it develops the myogenic tone.

Increasing concentrations (10^{-12}–10^{-6} M) of melatonin are administered through the perfusion buffer, without washout, at regular intervals of 5 min, and the lumen diameter is recorded continuously. Changes in lumen diameter are measured and expressed as percentage contraction.

N.10.1.7 Melatonin's Effect on Firing Rate of Suprachiasmatic Nucleus Cells

PURPOSE AND RATIONALE

Ying et al. (1996) studied the effects of drugs related to melatonin on neuronal firing activity in the suprachiasmatic nucleus, intergeniculate leaflet, and other brain areas in anesthetized Syrian hamsters. The suprachiasmatic nucleus of the hypothalamus functions as the dominant pacemaker for behavioral and physiological circadian rhythms in mammals (Moore 1983; Meijer and Reitveld 1989). Photic information required for entrainment to lighting cycles reaches the suprachiasmatic nucleus through a direct projection from the retina, and, via an indirect pathway, the geniculohypothalamic tract, originating in the retinorecipient intergeniculate leaflet of the geniculate nuclei (Zhang and Rusak 1989). The firing rates are suppressed by melatonin and its analogs, whereas antagonists reverse this effect (Ying et al. 1996; Liu et al. 1997).

PROCEDURE

Male Syrian hamsters weighing 100–140 g are kept in a photoperiod with 14 h of light beginning at 05:00 a.m. for at least 2 weeks before being used. The animals are anesthetized with 25% urethane (2 g/kg i.p.) and given subcutaneous injections of Robinul (3-hydroxy-1,1-dimethylpyrrolidinium bromide α-cyclopentylmandelate, A.H. Robins; 2%, 0.1–0.2 ml/animal) to reduce congestion of the respiratory tract during anesthesia. Hamsters are mounted in a stereotaxic apparatus and body temperature is maintained at 37°C throughout the experiment. A hole is drilled in the skull overlying the suprachiasmatic nucleus or intergeniculate leaflet region, with the aid of a magnifier. Special care is taken to avoid bleeding caused by damage to the superior sagittal sinus. The eyelids contralateral to the recording site are retracted with sutures and the eye is covered with mineral oil to prevent dehydration after the pupils are dilated with a topical application of 1% atropine sulfate. Electrodes are aimed at the suprachiasmatic nucleus using stereotaxic coordinates (0.2–0.6 mm anterior to the bregma, 0.2–0.35 mm lateral to the midline, and 7.6–7.8 mm ventral to the cortical surface), with the upper incisor bar 2 mm below the interaural line. Electrodes aimed at the hippocampus, dorsal lateral geniculate nucleus and intergeniculate leaflet are inserted 1.4–1.6 mm posterior to the bregma, 3.3–3.8 mm lateral to the midline, and 2.0–4.5 mm ventral to the cortical surface. The animal is maintained in a darkened room except during light pulses or while repositioning the electrodes.

Five-barrel glass micropipettes are prepared (Ying et al. 1993) with the recording barrel filled with fast green (Sigma) at a sub-saturated concentration in 2 M NaCl. One barrel is filled with 2 M NaCl for automatic current balancing. The other barrels are filled with melatonin hydrochloride, or metergoline, or test compound.

For intraperitoneal injections of doses between 0.5 and 10 mg/kg, melatonin and test compounds are dissolved in dimethylsulfoxide (DMSO) and further diluted with saline. For iontophoretic studies, test compounds are used in 5 mM concentrations.

Single-unit extracellular recordings are made from 15:00 to 20:00 hours, overlapping both projected light and dark phases of the daily illumination cycle in the colony room. Contralateral whole-retinal illumination is conveyed to the eye from a tungsten-halogen lamp using fiber optics and a computer-controlled shutter. Photically responsive neurons are identified and recorded during sustained light presentations (typically 1–2 min). Cells are identified as photically responsive or light sensitive if their firing rates are consistently increased or suppressed by >30% by sustained, whole-retinal illumination.

EVALUATION

A computer program controls data acquisition, light exposures and iontophoretic applications of drugs. Agonist effects are defined as repeatable changes relative to predrug firing rates of >20% at some dose of the drug. In order to compare the effects of melatonin and test compounds, agonist potencies are expressed as ED_{50}values, the doses required to produce half-maximal effects. The impact of an agonist is expressed as the proportion of the effect of an agonist that is reversed by the co-application of the antagonist; i. e., the difference between the agonist effects in the absence and the presence of the antagonist, divided by the agonist effect alone, and expressed as a percentage.

N.10.1.8 Melatonin's Effect on Circadian Rhythm

PURPOSE AND RATIONALE

Melatonin induces phase shifts of circadian rhythms through an action within the suprachiasmatic nucleus of the hypothalamus (Benloucif and Dubocovich 1996; MacArthur et al. 1997; Dubocovich et al. 1998; Delagrange et al. 1999). Competitive melatonin receptor antagonists block phase shifts of circadian rhythms of electrical activity and neuronal firing within the suprachiasmatic nucleus, suggesting that these phys-

iological responses are mediated through activation of melatonin receptors. Dubocovich et al. (1998) tested phase shifts of running activity in C3H/HeN mice induced by melatonin and antagonists. From these data, the authors concluded that selective MT_2 melatonin receptor antagonism is necessary to block melatonin-mediated phase advances of circadian rhythms.

PROCEDURE

Male C3H/HeN mice (5–6 weeks old) are housed in groups of five and maintained in temperature- and humidity-controlled rooms. Food and water are provided at libitum. Animals are maintained for 2 weeks on a 12-h/12-h light/dark cycle (300 lux at the level of the cage) and are then transferred to constant and complete darkness in individual cages ($18 \times 30 \times 12$ cm) equipped with activity wheels. Mice are kept under constant darkness for 3 weeks to stabilize the free-running activity rhythm (TAU = mean duration of the free running circadian period). The animals are treated on 3 days consecutively at circadian time 10 (CT10). (CT12 = onset of activity). CT10 is estimated from the TAU value for each day. Each mouse is treated with vehicle, or melatonin (0.3, 0.9, 3.0, 9.0, or 30 µg melatonin per animal) or the antagonist to be tested at various dosages. Each mouse receives one treatment every 3 weeks and a total of four treatments. All treatments are performed under a dim red light (15 W, Kodak 1A filter) with illuminance of less than 3 lux.

Rhythms of wheel-running activity are measured with a magnetic microswitch, which detects revolutions of the running wheel and is on line with a computer (Benloucif and Dubocovich 1996). Data are collected using the Dataquest III hardware and software package and analyzed with the assistance of TAU software (Mini-mitter, Sunriver, Ore., USA) The exact circadian time of the pulse is determined after treatment from the onset of steady-state activity on the day of the pulse. Aligning the TAU guide by eye over the steady-state activity onsets of free-running activity for 7–10 days before the pulse and from day 4 to 14 after the pulse assesses phase shifts.

EVALUATION

Phase shifts induced by treatment are measured in hours as the difference between the steady-state pre- and post-pulse activity onsets, using the TAU program ruler. Differences between vehicle/melatonin and antagonist/melatonin-treated groups are assessed for each melatonin dose by analysis of variance, followed by pairwise comparison when indicated.

N.10.1.9 Melatonin's Effect on Neophobia in Mice

PURPOSE AND RATIONALE

Kopp et al. (1999a) studied the effects of melatonin on neophobic responses in different strains of mice. Melatonin counteracted avoidance responses to an unfamiliar environment in BALB/c and C3H/He mice, but not in C5BL/6 mice. In this experimental situation, animals can move freely in simultaneously presented familiar and unfamiliar places (Hughes 1968).

Delagrange et al. (1999) and Kopp et al. (1999b) tested the effects of a melatonin antagonist on the neophobia-reducing properties of melatonin in BALB/c mice.

PROCEDURE

Male BALB/c mice at an age of 10 weeks are housed in groups of five in standard cages with food and water available ad libitum under controlled conditions at a 12-h light:12-h dark cycle with lights on at 01:00 hours, so that the animals can observed under dim red light in their active period.

The observation apparatus consists of a rectangular polyvinylchloride box ($30 \times 20 \times 20$ cm), covered with Plexiglas and subdivided into six equal square units ($10 \times 10 \times 20$ cm), which are all interconnected by small holes located at the floor level. It can be divided in half lengthwise by closing a temporary partition. The apparatus is kept in the mouse room. The experimenter always stands next to the box at the same place. Approximately 24 h before testing each animal is randomly placed in one-half of the apparatus with the temporary partition in place, to be familiarized with it. The floor of this half only is covered with sawdust, and the animal has unlimited access to food and water during 24 h of the familiarization period. At

the end of this period, the temporary partition between the familiar and unfamiliar compartment is removed and the animal then observed for 10 min. Measures are taken of the number of approach responses followed by avoidance reaction toward the unfamiliar places (attempts), the time spent in the unfamiliar compartment (time), the total number of square units entered (locomotion), and the total number of rears made by the animals (rears).

Mice are treated either with saline (controls) or with 1 mg/kg melatonin, or with various doses of the antagonist, or combinations thereof.

EVALUATION

Data are treated with either an analysis of variance (ANOVA) followed by Newman-Keuls a posteriori *t*-test, if groups come from a population with homogeneous standard deviations, or with a Kruskal-Wallis nonparametric ANOVA test followed by Mann-Whitney tests if groups come from a population with heterogeneous standard deviations.

N.10.2
Melanophore Stimulating Hormone

The early investigations of the pigmentary effects of corticotropin, melanotropin and related peptides derived from the pro-opiomelanocortin family were focused on the control of pigmentary and adrenocortical function (Slominski and Wortsman 2000; Millington 2006). With increasing knowledge and more sophisticated methodology, this role has now been considerably extended (Boehm et al. 2006), including actions on energy balance (Fehm et al. 2004; Butler 2006; Nargund et al. 2006), actions on the cardiovascular system and kidney function (Humphreys 2007), erectile dysfunction (Hadley and Dorr 2006), and even antimicrobial properties (Catania et al. 2006). The pigmentary action of MSH analogs is being commercialized (Hadley and Dorr 2006).

The early studies on synthetic MSH-derived peptide analogs have been considerably extended, with therapeutic applications in view for the control of appetite, and anti-obesic compounds of the future.

N.10.2.1
Skin Darkening in Whole Amphibia

PURPOSE AND RATIONALE

MSH (melanocyte-stimulating hormone or melanotropin) is also called melanophore expanding hormone, based on the microscopical observation of expansion of melanocytes in amphibia (Landgrebe and Waring 1950, 1962; Sandow et al. 1977; Inouye and Ozsuka 1987). Several amphibia species can be used, such as *Xenopus laevis*, *Rana temporaria* or *R. esculenta*, or *Hyla arborea*. Hypophysectomized animals are more sensitive than intact ones. Numerous corticotropin analogs have MSH activity based on a common peptide core shared with MSH. The structure of two melanocyte-stimulating hormones has been elucidated: α-MSH containing 13 amino acids, and β-MSH containing 18 amino acids.

Hunt (1995) reviewed the role of MSH as a regulator of human melanocyte physiology.

PROCEDURE

The pretest conditions require adaptation for blanching of the skin, e. g., by keeping the animals on a white background prior to the assay. *Xenopus laevis* or *Rana temporaria* are kept in single cages at 16°C under humid conditions. Injections of various doses of the test preparation or the standard are given into the dorsal lymph sac. After 1 h, the webs between the digits of the hind limbs are investigated under a stereomicroscope, the eyepiece of which is fitted with a photoelectric cell, the other being available for microscopic examination. The state of melanophore expansion can be assessed by direct visual examination and recorded in terms of an arbitrary melanophore index, or by modern methods of morphometry.

EVALUATION

For test preparation and standard, dose–response curves can be established and potency ratios calculated.

N.10.2.2 Assay in Isolated Amphibian Skin

PURPOSE AND RATIONALE

Melanophores in isolated pieces of pale amphibian skin (from background-adapted animals or those maintained in MSH-free medium) expand within a short period of time after immersion in a MSH-containing buffer. Subsequent immersion of the skin in fresh saline results in contraction of the melanophores (Trendelenburg 1926; Jores 1933; Landgrebe and Waring 1950). Several methods using isolated amphibian skin have been described using either light absorption or light reflection (Landgrebe and Waring 1962). These methods are historical and have been replaced by using cell cultures of melanocytes.

PROCEDURE

For studies on light absorption, the skin of *Rana temporaria* or *R. esculenta* is used. Before sacrificing the donor animal and dissecting the isolated skin, it is important to submit the living animal to varying white and black backgrounds under overhead illumination of a light source of 100 W, so that the melanophores can expand and contract before operation. The areas most suitable for use in this technique are from the thighs. Before using the skin for an actual assay, each piece should be immersed in a sufficiently concentrated MSH solution to expand the melanophores almost but not quite fully. The skin is then washed with saline until the melanophores are fully contracted again and in a suitable condition for the test. This usually takes about 45 min. A piece of skin is mounted in a cell which holds the skin stretched and enables it to be immersed in saline or test solution. It is placed in position on the stage of a binocular microscope. An eyepiece is used for visual observation and a photoelectric cell is attached to the other connected directly to a sensitive galvanometer. Various concentrations of the test preparation or the standard are added. At least six skin pieces are used for each concentration of test preparation or standard. Galvanometer readings and readings of the melanophore index are taken simultaneously every 10–15 min until the maximum response is elicited, usually in 30–45 min.

EVALUATION

Assessment of potency is made from the readings of the melanophore index and from the light absorbed, which is recorded as a percentage of the light originally passing through the skin, and is plotted against the log concentration.

CRITICAL ASSESSMENT OF THE METHOD

The methods were originally developed to standardize extracts with (pigmentary) MSH activity by the use of a bioassay. They are still necessary for evaluating compounds for biological MSH activity since not only natural ACTH but also synthetic peptides, such as $\beta^{1\text{-}24}$-corticotropin (Schuler et al. 1963) or $\beta^{1\text{-}23}$-corticotropin-23-amide (Vogel 1965, 1969), possess MSH activity.

MODIFICATIONS OF THE METHOD

Measurement of light reflection by skin pieces, instead of light absorption, was used by Shizume et al. (1954).

In **cell-based assays**, Siegrist and Eberle (1986), Bagutti and Eberle (1993), and Sahm et al. (1993, 1996) used cultured mouse B16 melanoma cells in

a sensitive *in situ* melanoma assay to study the structure–activity relationship of melanocyte-stimulating hormone peptides. B16 cells were seeded at a density of 2500 cells per well in 96-well microtest culture plates. After 24 h the cells were incubated in the presence of serial dilutions of MSH peptides for 3–5 days. The melanin released into the medium of each well was then determined spectrophotometrically at a wavelength of 405 nm using an automatic microplate reader calibrated against synthetic melanin.

Sahm et al. (1994, 1996) measured release of ^3H_2O into the medium from [3′,5′-^{3}H]L-tyrosine by tyrosinase in B16 mouse melanoma cells after incubation with α-MSH analogs.

MSH assays have also been used to study the factors regulating the release of MSH (**MRF**) or inhibiting the release of MSH (**MIF**) (Kastin et al. 1969; Celis et al. 1971).

N.10.2.3 Binding to the Melanocortin Receptor

PURPOSE AND RATIONALE

Much of the initial work on the biological effects of hormones has been expanded by using cloned subclasses of receptors for identification of more specific ligand compounds. A family of five MSH receptor subclasses for the melanocortic peptides has been identified (Chhajlani and Wikberg 1992; Chhajlani et al. 1993; Gantz et al. 1993b; Schiöth et al. 1997a, 1988a; Strand 1999). The melanocortin MC_1 receptor is expressed in melanocytes and melanoma cells and binds α-MSH with high affinity. The MC_1 receptor plays an important role in skin and fur pigmentation in a variety of vertebrates (Cone et al. 1996). The melanocortin MC_2 receptor (i. e., the ACTH receptor) has a well-defined function in steroid production in the adrenal gland (Schiöth et al. 1996a). The melanocortin MC_3 receptor is found in the hypothalamus, the brain, and in the placenta, gut tissues and the heart (Gantz et al. 1993a; Desarnaud et al. 1994; Sahm et al. 1994). The melanocortin MC_4receptor (Schiöth et al. 1996b, 1998b) has been found to affect feeding in rodents and may be important for weight homeostasis (Fan et al. 1997; Huszar et al. 1997). The melanocortin MC_5 receptor is primarily located in various peripheral tissues but has also been found in the brain (Labbé et al. 1994; Fathi et al. 1995).

Schiöth et al. (1997b, 1998a) described binding of synthetic MSH analogs to the human melanocortin receptor subtypes.

Melanocortin-4 receptor antagonists increase food uptake in rats (Kask et al. 1998a, 1998b; Skuladottir et al. 1999).

PROCEDURE

Expression of Receptor Clones

The human melanocortin MC_1 and human melanocortin MC_5 receptors are cloned into the expression vector pRc/CMV (Invitrogen). The human melanocortin MC_3 and human melanocortin MC_4 receptors were cloned into the expression vector

pCMV/neo. For receptor expression COS-1 cells are grown in Dulbecco's modified Eagle's medium with 10% fetal calf serum. Eighty percent confluent cultures are transfected with the DNA mixed with liposomes in serum-free medium. After transfection, the serum-free medium is replaced by serum-containing medium and the cells are cultivated for 48 h. Cells are then scraped off, centrifuged and used for radioligand binding.

Binding Studies

The transfected cells are washed with binding buffer (Schiöth et al. 1995) and distributed into 96-well non-culture-coated plates, which are centrifuged and the binding buffer is removed. The cells are then immediately incubated in the well plates for 2 h at 37°C with 0.05 ml binding buffer in each well containing a constant concentration of [125I]NDP (= [Nle^4-D-Phe^7]α-MSH) and appropriate concentrations of the competing unlabeled ligand. After incubation the cells are washed with 0.2 ml of ice-cold binding buffer and detached from the plates with 0.2 ml of 0.1 M NaOH. Radioactivity is counted by a gamma-counter.

EVALUATION

Data are analyzed by fitting to formulas derived from the law of mass action. The method is generally referred to as computer modeling. K_d values for [125I]NDP are calculated (Schiöth et al. 1995, 1996a). The binding assays are performed in duplicate and repeated three times.

MODIFICATIONS OF THE METHOD

Adan et al. (1994) compared the behavioral effects of melanocortins with binding data on MC_3 and MC_4 receptors.

Sahm et al. (1996) studied receptor binding affinities and biological activities of linear and cyclic melanocortins in B16 murine melanoma cells expressing the native MC_1 receptor.

Quillan and Sadée (1996) searched for peptide ligands that cross-react with melanocortin receptors and found several peptides with previously unrecognized agonistic or antagonistic activity on amphibian and human melanocortin receptors.

Peng et al. (1997) compared the actions of C-terminally modified melanocortin peptides at rodent MC_1 and MC_3 receptors.

Bagutti et al. (1993) recommended [^{111}In]DTPA-labeled (where DTPA is diethylenetriaminopentaacetic acid) analogs of α-MSH as ligands for the detection of MSH receptors *in vitro* and *in vivo*.

Erskine-Grout et al. (1996) described functional photoaffinity-labeled, biotinylated and fluorescent probes for the melanoma MC_1 receptor.

N.10.3 Melanocortin Peptides

The melanocortin system refers to a set of hormonal, neuropeptidergic, and paracrine signaling pathways that are defined by components that include the five G-protein-coupled melanocortin receptors; peptide agonists derived from the pro-opiomelanocortin preprohormone precursor; and the endogenous antagonists, agouti and agouti-related protein (Gantz and Fong 2003; Cone 2006). This group of regulatory peptides was explored in the context of understanding regulation of body weight development, and finding specific anti-obesic compounds (Bjorbaek and Hollenberg 2002; Della-Fera and Baile 2005; Padwal and Majumdar 2007). As with the leptin research, there are also indications for the central regulation of thermogenesis by melanotropin peptides (Myers 2004; Fan et al. 2005). The subclasses of melanocortin receptors involved in these several functions have been characterized, and the MC4 receptor is of particular interest (Garcia-Borron et al. 2005; Adan and van Dijk 2006; Adan et al. 2006; Getting 2006). Structure–activity studies on the melanocortin agonists and antagonists have provided further tools for detailed investigation (Cai et al. 2005) by modification of the natural ligands, and by the search for small molecule ligands (Todorovic and Haskell-Luevano 2005). Not surprisingly, the research on body weight regulation has also provided indications for the pathophysiology of cachexia (DeBoer and Marks 2006a, 2006b).

Interactions of the hypothalamic–pituitary–thyroid axis with the central melanocortin system have been investigated and reviewed (Martin et al. 2006).

There has also been considerable interest in the regulation of immune responses and inflammation by melanocortin peptides (Maaser et al. 2006), based on the established relationship of α-MSH and inflammation (Eves et al. 2006; Lin and Fisher 2007).

N.10.4 Relaxin

N.10.4.1 General Considerations

Relaxin is a peptide hormone originally prepared from sow ovaries. The hormone acts on collagen and induces increased flexibility of the pelvic girdle of guinea pigs. In mice, the length of the interpubic ligament is increased. Moreover, relaxin inhibits spontaneous uterine motility. In addition to its effects on the reproductive tract, relaxin exerts hemodynamic effects (Coulson et al. 1996). The actions of relaxin as a pleiotropic hormone were reviewed by Bani (1997).

The therapeutic relevance of relaxin in humans is still open to debate (Schwabe and Büllesbach 1994; Goldsmith et al. 1995).

The primary structure of relaxin is highly homologous to insulin. Unlike insulin, the structure of which is remarkably well conserved among the vertebrates, relaxin sequences can vary by more than 50% between different species (Evans et al. 1993; Layden and Tregear 1996). Despite these large variations, most relaxins have very similar biological activities in animal test systems, probably because the receptor binding region of the B chain, in contrast to the rest of the molecule, is highly conserved between species.

Relaxin of various species has been synthesized (Büllesbach and Schwabe 1993; Wade et al. 1994).

Synthetic human relaxin has been characterized by high-performance liquid chromatography (Canova-Davis et al. 1990).

Klonisch et al. (1999) determined the nucleic acid sequence of canine **preprorelaxin** using reverse transcription polymerase chain reaction (PCR) and rapid amplification of cDNA ends-PCR. Canine preprorelaxin consists of 534 base pairs encoding a protein of 177 amino acids with a signal peptide of 25 amino acids, a B domain of 35 amino acids, a C domain of 93 amino acids, and an A domain of 24 amino acids.

The **relaxin-like factor (RLF)** is described as a member of the insulin/relaxin/insulin-like growth factor family that is expressed predominantly in the reproductive system, with greatest expression in the Leydig cells of the testis (Pusch et al. 1996; Zarreh-Hoshyari-Khah et al. 1999).

Several **bioassays** have been used for relaxin, such as the pubic symphysis method in guinea pigs and mice, inhibition of uterine motility in rats, and stimulation of interstitial collagenase activity in cultured uterine cervical cells from guinea pigs (see below).

Taylor and Clark (1989, 1992a, 1992b) developed a **reverse hemolytic plaque assay** which allows the quantitative analysis of relaxin secreted by single porcine luteal cells.

Radioimmunoassays for relaxin were described by Sherwood (1979), Jockenhövel et al. (1991), and Steinetz et al. (1996). Lucas et al. (1989) developed an enzyme-linked immunoassay to study human relaxin in human pregnancy and in pregnant rhesus monkeys.

N.10.4.2 Relaxin Bioassay by Pubic Symphysis Method in Guinea Pigs

PURPOSE AND RATIONALE

Experimental relaxation of the pubic symphysis of the spayed guinea pig was described as early as 1929 by Hisaw. The relaxation of the symphysis after relaxin administration is determined by manual palpation.

PROCEDURE

Virgin female guinea pigs of mixed strains weighing 300–400 g are used. Prior to the assay, the animals have to be primed with estrogen and relaxin. Estrogen priming consists of one subcutaneous injection per week of 5 µg of estradiol cyclopentylpropionate in 0.1 ml of sesame oil. Relaxin priming is accomplished by administering 20 µg of relaxin standard in 1 ml saline subcutaneously once a week on day 5 after the estrogen injection.

Six hours after relaxin administration the symphysis of the animal is palpated. The animal is held head down, ventral side away, between the thighs of the seated observer. The sciatic crests and symphysis pubis are firmly grasped between the thumbs and forefingers so that the two halves of the pelvis may be moved back and forth alternately. If the pubic symphysis is rigid at this time, the estrogen and relaxin priming are continued weekly until marked mobility of the symphysis is observed. The increased flexibility is transient: the peak response occurs at 6 h and subsides 12–24 h after injection. Mobility responses are estimated subjectively and scored on an arbitrary scale of 0–6. "Zero" indicates no detectable flexibility of the pubic symphysis, whereas "6" represents extreme softening. Scoring should be performed by the same investigator throughout a study.

One week after an animal has responded positively to 20 µg of relaxin standard, it is added to the assay colony. Before assay time, all eligible animals are mixed and divided into groups of 10–20 each. On the day of the experiment, all animals are palpated before injection. Only those with no symphyseal movement are used. Two doses of test preparation and two doses of standard are injected subcutaneously to different groups. Six hours later, two operators palpate and score each animal.

EVALUATION

The scores are averaged and a median score calculated. The activity of an unknown preparation is determined by comparison with the dose–response curve of concomitantly administered relaxin standard.

MODIFICATIONS OF THE METHOD

Steinetz and Lust (1994) reported that the relaxin-induced pubic symphyseal relaxation in guinea pigs is inhibited by treatment with glycosaminoglycan polysulfates or pentosan polysulfate. The authors recommended the guinea pig symphysis assay for relaxin as a novel rapid screening test for compounds with potential chrondroprotective activity.

N.10.4.3 Relaxin Bioassay in Mice

PURPOSE AND RATIONALE

An increase in length of the interpubic ligament in mice can be used as a bioassay for relaxin. Other methods used include X-ray measurement of pubic separation (Hall 1948; Dorfman et al. 1953) and direct measurement of interpubic ligament (Kroc et al. 1959; Steinetz et al. 1960, 1969a, 1969b).

PROCEDURE

Virgin female mice (e. g., NMRI strain) weighing 18–20 g are used for the assay. Twenty mice are employed for each of three dose levels of standard and test preparation. On day zero each mouse is primed with a single subcutaneous injection of 5 µg estradiol cyclopentylpropionate in 0.1 ml sesame oil. On day 7, the test preparation and the standard are injected subcutaneously. At 18–24 h later, the mice are sacrificed, the abdominal cavities are opened, and uteri are examined for evidence of estrogen priming. Mice exhibiting threadlike uteri are discarded. The anal and vulval areas are then cut away with scissors, and the upper half of the body is cut off to prevent subsequent bleeding at the pubic symphysis. The bony birth canal is freed of skin, vagina, and rectum, and fascia are cleaned off the symphysis pubis. The pelvis is placed on a binocular microscope fitted with a calibrated ocular micrometer. A transilluminating device consisting of a U-shaped lucite rod is affixed to the microscope. The tip of the rod is beveled to direct light vertically through the exposed pubic ligament. The feet of the carcass are grasped between the thumb and index finger, applying a slight lateral traction.

The shortest distance between the edges of the pubes is measured, using the ocular micrometer. Micrometer readings are then converted to millimeters.

EVALUATION

Mean values of length of interpubic ligament, expressed in millimeters, are plotted versus logarithm of dose. From dose–response curves activity ratios with confidence limits versus the standard are calculated.

MODIFICATIONS OF THE METHOD

Bullesbach and Schwabe (1996) tested rat relaxin and synthetic analogs in the mouse symphysis pubis assay for structure–activity relationships.

Samuel et al. (1998) studied the effects of relaxin, pregnancy and parturition on collagen metabolism in the **rat** pubic symphysis. During pregnancy and particularly during birth, there was a significant reduction of tissue wet and dry weight, which coincided with an increase in water content and a significant reduction of overall collagen content.

N.10.4.4 Inhibition of Uterine Motility

PURPOSE AND RATIONALE

This is one of the historical assays based on a nonspecific biological response. Its application and reliability depend on the state of purification of relaxin preparations. Relaxin specifically inhibits the spontaneous motility of estrogen-dominated uterus *in vivo* and *in*

vitro (Downing and Hollingsworth 1993). Wiqvist and Paul (1958) proposed a relaxin assay based on inhibition of motility of the rat uterus *in vitro* (Steinetz et al. 1969).

PROCEDURE

The donors (female Sprague-Dawley or Wistar rats weighing 150–180 g) are ovariectomized and primed with 2 µg estradiol daily for 3 days. On day 4, uterine horns are removed, bisected, and suspended in Locke's solution gassed with 1% CO_2 in O_2 at a temperature of 37.5 ± 0.5°C. The contractions are recorded using a Statham transducer and a polygraph. A symmetrical 4-point assay is adopted with twofold dose increments of standard and test preparation. Responses consisting of slowing down the contraction frequency up to total suppression of the contractions are classified visually and assigned score values of 1–3. All four test doses (two doses each of standard and test preparation) are run simultaneously on the four uterine segments obtained from each rat.

EVALUATION

Mean values of scores are calculated for each dose. Potency ratios with confidence limits are calculated from the 2+2-point assay.

MODIFICATIONS OF THE METHOD

Felton et al. (1953) described a test for relaxin activity using the inhibition of uterine contraction in anesthetized guinea pigs *in vivo*.

Inhibition of spontaneous and prostaglandin-driven myometrial activity by relaxin in anesthetized rats was reported by Porter et al. (1979).

Downing and Sherwood (1985) studied the influence of relaxin on uterus contractility and on cervical distensibility in different stages of pregnancy in the rat.

Del Angel Meza et al. (1991) measured the effect of relaxin on uterine and ileum tissue of rats *in vivo* and *in vitro*.

Vu et al. (1993) tested the activity of a recombinant prorelaxin in an *in vitro* bioassay in CHO cells. Human uterine endometrial cells were treated with various dilutions of conditioned medium and the amounts of intracellular cAMP produced were determined by radioimmunoassay.

N.10.4.5 Relaxin Assay by Interstitial Collagenase Activity in Cultured Uterine Cervical Cells

PURPOSE AND RATIONALE

As an example of the changing approach in assay methods, Mushayandebvu and Rajabi (1995) provided evidence for a biological response suitable for *in vitro* assay. Relaxin is involved in cervical dilatation by stimulating interstitial collagenase, a key enzyme involved in this process. Human recombinant relaxin induces a dose-dependent increase of collagenase activity in cultured guinea pig cervical cells.

PROCEDURE

Abdominal hysterectomy is performed in anesthetized female Hartley guinea pigs under aseptic conditions. The cervix is excised and washed three times in Hank's balanced salt solution (HBSS) containing penicillin G sodium (100 U/ml), streptomycin sulfate 100 µg/ml), and amphotericin B (1.25 µg/ml). The cervix is cut into 2- to 4-mm pieces and digested in Dulbecco's modified Eagle's medium (DMEM) containing bacterial collagenase type A1 (0.5 mg/ml) and DNase type 1 (0.05 mg/ml) at 37°C. The digested mixture is filtered once every 15–30 min through a nylon monofilament with a pore size of 400 µm. Following each filtration, separated cells are collected by centrifugation at 365 *g* for 10 min at room temperature followed by a resuspension in DMEM containing 10% heat-inactivated fetal calf serum (FCS). Cells are washed twice with HBSS; this is followed by resuspension in DMEM containing 10%

penicillin G sodium (100 U/ml), streptomycin sulfate 100 µg/ml), and amphotericin B (1.25 µg/ml). The unfiltered material is redigested and the process is repeated until the cervical tissue is completely digested.

Cells are plated in 24-well plates at 1×10^5 cells per well in 500 µl of medium containing 10% FCS and antibiotics and then are incubated in a humidified atmosphere of 5% CO_2 in air at 37°C. After 4 days all viable cells are adhered. Culture medium and unattached cells are removed and fresh medium is added. At confluency (5–7 days), culture medium is removed, cells are washed once with HBSS, and serum-free DMEM containing antibiotics is added. The cells are treated with recombinant human relaxin (1–1000 ng/ml) at 0, 24, and 48 h. Culture media are collected at 96 h from initial treatment with the appropriate controls and frozen immediately at −20°C until assayed for collagenase activity (Dean and Woessner 1985; Rajabi et al. 1988, 1991).

Enzyme samples [up to 100 µl in assay buffer: 50 mM Tris HCl (pH 7.5), 0.2 M NaCl, 10 mM $CaCl_2$, 0.02% sodium azide, 0.035% Brij-35] are incubated with 10 µl of [^{3}H]telopeptide-free collagen substrate [specific activity 3.1×10^6 cpm/mg collagen at 2.24 mg/ml, in 50 mM Tris HCl (pH 7.6), 0.3 M NaCl] in 1.5-ml microfuge tubes. Aminophenylmercuric acetate (0.5 mM) is used to activate procollagenase; 1,10-phenanthroline (1 mM) is added to inhibit collagenase and serves as blank control for nonspecific collagenolysis. After 18–48 h of incubation at 29°C, the reaction is terminated by addition of EDTA to a final concentration of 40 mM. Collagenase cleavage products are further digested by trypsin and chymotrypsin in the presence of BSA (10 mg/ml assay buffer) for 2 h at 29°C. The undigested [^{3}H]telopeptide-free substrate is precipitated in 10% trichloroacetic acid at 0°C for 30 min followed by centrifugation at 18,000 *g* at 4°C for 30 min. A 100-µl aliquot of the supernatant is mixed in 5 ml Aquasol scintillation fluid and counted in a liquid scintillation counter.

EVALUATION

The percentage digestion is calculated as the total cpm in the supernatant minus cpm in the 1,10-phenanthroline blanks divided by original counts in the [^{3}H]telopeptide-free substrate (in 100 µl of 10% trichloroacetic acid in assay buffer) × 100. One milliunit of collagenase is defined as the amount of collagenase that digests 1 ng of collagen in 1 min at 29°C.

All results are presented as the mean ±SEM of three separate experiments. Statistical analysis is performed by Student's *t*-test for paired observations and by one-way ANOVA for multiple observations.

N.10.4.6 Relaxin Receptor Binding

PURPOSE AND RATIONALE

Using a monocomponent, high specific activity, carrier-free porcine relaxin tracer [^{125}I], Yang et al. (1992) demonstrated relaxin receptors in the symphysis pubis, uterus, and ovary of mice. A linear Scatchard plot suggested the presence of only one kind of receptor and a dissociation constant of 5×10^{-10} M.

PROCEDURE

Crude membranes are prepared from uterine horns of estrogen-primed mice. The tissues are homogenized three times for 10 s with a Polytron homogenizer. The homogenate is centrifuged at 700 *g* for 10 min, and the supernatants are recovered and recentrifuged twice at the same speed. Thereafter, the supernatants are centrifuged at 10,000 *g* for 30 min. The crude membrane pellets are washed with HEPES buffer, centrifuged again, the resuspended in 200–500 µl water, and aliquots are removed for Lowry protein estimates.

The crude membrane suspension is diluted to 3 mg/ml protein with binding buffer (25 mM HEPES, 0.14 M NaCl, 5.7 mM KCl, 1.6 mM $CaCl_2$, 0.025 mM $MgCl_2$, 1.5 mM $MnCl_2$, 1% BSA, 2.8 mM glucose, 0.2 mM phenylmethylsulfonylfluoride, 80 mg/l soybean trypsin inhibitor, pH 7.5). The assay is initiated by adding this to 120 µl crude membranes (300 µg protein) with and without 0.2 µg unlabeled relaxin. At the end of the incubation period, 1 ml HEPES buffer, containing 1% BSA, is added, and bound and free relaxin are separated by three successive washings and centrifugations.

EVALUATION

The tubes are analyzed for radioactivity in a Minigamma 400 (LKB, Rockville, Md., USA). Duplicates are run for each experimental point, and experiments are repeated several times.

MODIFICATIONS OF THE METHOD

The control of relaxin secretion and relaxin receptors by relaxin was studied by Bryant-Greenwood et al. (1982).

Relaxin receptors in the myometrium of rats and pigs were studied by Mercado-Simmen et al. (1982a, 1982b).

Fluoresceinylthiocarbamyl relaxin was prepared by Segaloff and Gabbard (1982) for the demonstration of relaxin receptors.

Experiments by Büllesbach and Schwabe (1988) suggested a unique site for the interaction of relaxin with its uterine and symphyseal receptors.

Using a ^{32}P-labeled human relaxin, Osheroff and Phillips (1991) localized relaxin binding sites in rat uterus, cervix, and brain.

The receptor binding site of human relaxin II was studied by Büllesbach et al. (1992).

Min and Sherwood (1996) identified specific cell types that contain relaxin receptors in various organs of pregnant pigs.

N.10.5 Calcitonin Gene-Related Peptide

N.10.5.1 General Considerations

In relation to the established traditional hormone definition, many new polypeptides have been identified by molecular biology and characterized by receptor binding and *in vitro* systems, while their definitive function is not yet assigned. Calcitonin-gene-related peptide (CGRP) is an example of this rapid development and change in approach by applying new methods. CGRP is a 37-amino-acid neuropeptide which was first identified as a product of the calcitonin gene by alternative splicing (Amara et al. 1982). This original peptide is referred to as α-CGRP; a second gene, unrelated to calcitonin, produces β-CGRP (Amara et al. 1985). These two forms are closely related in both rat and humans, and are widely distributed throughout most parts of the nervous system. CGRP shares about 50% identity with another 37-amino-acid peptide, amylin (Rink et al. 1993). CGRP shows weak but significant homology with adrenomedullin, a 52-amino-acid peptide (Kitamura et al. 1993). Several forms of CGRP have been sequenced: α- and β-CGRP from rat and humans, and single variants from sheep, pig, chick, salmon, and the laughing frog, *Rana ridibunda* (Poyner 1997). The calcitonin/CGRP gene is expressed in specific cell types of both the endocrine and nervous systems. The gene is alternatively spliced to yield mRNA encoding calcitonin in thyroid C-cells or the neuropeptide CGRP in a subset of central and peripheral neurons (Amara et al. 1982; Morris et al. 1984; Born and Fischer 1993). The rat as well as the human calcitonin/CGRP gene consists of six exons. The calcitonin mRNA contains exons 1–4 with a poly(A) tail at exon 4 whereas CGRPα includes exons 1, 2, 3, 5, and 6 with a poly(A) tail at exon 6 (Van Rossum et al. 1997).

α- and β-CGRP display several biological activities, including peripheral and cerebral vasodilatation, a blood-pressure-lowering effect, cardiac acceleration, regulation of calcium metabolism, reduction of intestinal motility, regulation of glucose metabolism, stimulation of pancreatic enzyme secretion, diminution of appetite, reduction of growth hormone release, influence on inflammation and nociception, and inhibition of interleukin-2 production (Poyner 1992, 1997; Wang et al. 1992; Wimalawansa 1996).

Nuki et al. (1994) compared the vasodilatory activity of chicken calcitonin gene-related peptide with human α-CGRP and rat CGRP in the precontracted mesenteric vascular bed of rats (see Sect. A.8.2.5).

Wisskirchen et al. (1998) tested agonists of calcitonin gene-related peptide, homologs, and antagonists in rat isolated pulmonary artery (see Sect. A.1.2.1) and rat deferens (see Sect. A.1.2.3).

Tomobe et al. (1998) found that the vasodilatation in isolated superior mesenteric arteries by calcitonin gene-related peptide was significantly larger in spontaneously hypertensive rats than in normal Wistar–Kyoto rats.

In order to elucidate the mechanism of endogenous CGRP release in peripheral vasodilatation, Brain et al. (1993) used a multiple site ^{133}Xe clearance technique.

Raddino et al. (1997) studied the mechanism of action of human calcitonin gene-related peptide in rabbit heart and human mammary arteries.

Champion et al. (1997) analyzed the responses of human synthetic adrenomedullin and calcitonin gene-related peptides in the hindlimb vascular bed of the cat (see Sect. A.8.2.1).

Castellucci et al. (1993) investigated the vasodilator activity of CGRP in the rat isolated and perfused kidney.

McMurdo et al. (1997) investigated the effect of the calcitonin gene-related peptide receptor antagonist $CGRP^{8-37}$ on blood flow in the knee joint of anesthetized rats. Synovial blood flow was measured in both exposed and intact skin-covered knees by Laser Doppler perfusion imaging.

Sakai et al. (1998) found a synergism of calcitonin gene-related peptide with the blood-pressure-lowering effect of adenosine.

Preibisz (1993) reported beneficial effects of CGRP infusions in patients with congestive heart failure and in subjects with neurological deficits after surgical treatment of subarachnoid hemorrhage.

Cadieux et al. (1999) described bronchoprotector properties of calcitonin gene-related peptide in guinea pig and human airways. Calcitonin gene-related peptide inhibited substance-P-induced bronchoconstriction *in vivo* and *in vitro*.

Smith et al. (1993) tested the ability of C-terminally truncated fragments of human α-calcitonin gene-related peptide to stimulate amylase secretion from guinea pig pancreatic acini and to relax precontracted mesenteric arteries (see Sect. A.1.2.9).

Meini et al. (1995) investigated the propagation of impulses in the guinea pig ureter and its blockade by calcitonin gene-related peptide. Furthermore, Maggi et al. (1995) studied the mechanisms of the inhibitory effect exerted by calcitonin gene-related peptide on the spontaneous activity of the guinea pig isolated renal pelvis.

Protective effects of calcitonin gene-related peptide in different experimental models of gastric ulcers (reserpine-induced gastric lesions, ethanol-induced gastric lesions, gastric damage and acid secretion in pylorus-ligated rats) were reported by Clementi et al. (1993).

The role of nitric oxide in the anti-ulcer activity of calcitonin gene-related peptide was investigated by Clementi et al. (1994a).

Evangelista and Renzi (1997) investigated the protective role of endogenous and exogenous calcitonin gene-related peptide in water immersion stress-induced gastric ulcers in rats.

Li et al. (1997) determined the ability of analogs of human α-calcitonin gene-related peptide to stimulate amylase secretion from guinea pig pancreatic acini (see Sect. J.7.0.10) and to relax isolated porcine coronary arteries precontracted with 20 mM KCl (see Sect. A.3.1.3).

Calcitonin gene-related peptide acutely augments the contractile response of skeletal muscle to both direct and indirect stimulation as studied in the isolated rat diaphragm by Fleming et al. (1993).

Dumont et al. (1997) used the isolated guinea pig heart (see Sect. A.3.1.2) and the isolated rat vas deferens (see Sect. A.1.2.3) for *in vitro* bioassays of CGRP agonists and antagonists.

Poyner et al. (1999) found a concentration-dependent inhibition of the electrically stimulated twitch response of guinea pig vas deferens by calcitonin gene-rated peptide, amylin and adrenomedullin (see Sect. A.1.2.3).

The role of calcitonin gene-related peptide in the protection of capsaicin-induced gastric mucosal hyperemia in rats was studied by Merchant et al. (1994).

Clementi et al. (1994b) studied the anti-inflammatory activity of calcitonin gene-related peptide in cutaneous inflammation induced by Croton oil, arachidonic acid, tetradecanoylphorbol acetate or cantharidin.

Schaible (1996) investigated the role of tachykinins and calcitonin gene-related peptide in the spinal mechanisms of nociception and in the induction and maintenance of inflammation-evoked hyperexcitability in spinal cord neurons.

The development of tolerance to spinal morphine analgesia in rats was prevented by a calcitonin gene-related peptide receptor antagonist (Menard et al. 1996).

Lutz et al. (1997) investigated the anorectic effects of CGRP and amylin in rats chronically cannulated in the lateral brain ventricle.

Specific calcitonin gene-related peptide receptors were characterized in hamster pancreatic cells (Barakat et al. 1993).

In doses of 25–200 µg/kg i.p., CGRP decreased food intake in mice, suggesting a role for CGRP as a satiety factor (Morley et al. 1996).

CGRP inhibits insulin-stimulated glycogen synthesis in rat skeletal muscle (Leighton and Cooper 1988).

Chatzipantelli et al. (1996) described the lipolytic actions of calcitonin gene-related peptide.

Howitt and Poyner (1997) determined the effects of a series of agonists and antagonists on the calcitonin gene-related peptide receptor of cultured rat L6 skeletal myocytes.

Kurz et al. (1995) studied the receptors of calcitonin gene-related peptide in the rat thymus and suggested that CGRP is a paracrine thymic mediator that may influence the differentiation, maturation, and proliferation of thymocytes.

N.10.5.2 Receptor Binding of CGRP

PURPOSE AND RATIONALE

Calcitonin gene-related peptide receptors are localized in many tissues, such as brain, heart, spleen, blood vessels, liver, lung, and kidney (Born and Fischer 1993; Muff et al. 1995). They are abundant in the brain, and the pattern is similar in the rat, pig, cow, sheep, and humans (Wimalawansa and El-Kholy 1993, 1996).

Multiple CGRP receptors (subclasses) have been observed: based on pharmacological properties they are divided into at least two subtypes and denoted as $CGRP_1$ and $CGRP_2$ (Dennis et al. 1989, 1991; Quirion 1992; Poyner 1997). CGRP-(8-37), which lacks seven terminal amino acid residues, is a selective antagonist of $CGRP_1$ receptors, whereas the linear analog of CGRP, diacetoamidomethyl cysteine CGRP (Cys[ACM2,7]CGRP), is a selective agonist of $CGRP_2$ receptors.

An atypical CGRP subtype has been reported (Dennis et al. 1991; Van Rossum 1997).

A sensitive and specific radioreceptor assay for calcitonin gene-related peptide was described by Wimalawansa (1989).

PROCEDURE

For membrane preparation, tissue samples, e. g., dissected brain areas from rats, are placed in 10 vols of ice-cold 50 mM Tris-HCl buffer (pH 7.4) containing 0.32 M sucrose, 0.5 mM dithiothreitol, and 5 mM EDTA. After centrifugation of the homogenate at 100 *g* for 10 min, the resultant pellet is rehomogenized with 5 vols of fresh buffer and recentrifuged. The pellet is discarded and the supernatants are pooled and recentrifuged at 30,000 *g* for 45 min at 4°C. The resulting crude membrane pellet is resuspended in 5 vols of assay buffer (50 mM Tris-HCl, 10 mM KCl, 3 mM sodium azide, and 200 IU/ml aprotinin) and recentrifuged at 30,000 *g* for a further 45 min. This procedure is repeated twice with fresh assay buffer. Protein concentrations are determined and adjusted to 1–2 mg/ml. The samples are frozen on dry ice and stored at −70°C until radioligand binding studies.

For radioligand binding studies, [^{125}I]CGRP (25 pM, ~5 fmol containing ~20,000 cpm/tube) is incubated with various membrane preparations (150–200 µg/ml membrane protein in an incubation medium of 200 µl) in the presence of 200 IU/ml aprotinin and 0.2% heat-inactivated BSA at 4°C for 120 min in polypropylene microcentrifuge tubes in a shaking water bath. At the end of the incubation period, 700 µl of chilled assay buffer is added and immediately centrifuged at 11,000 *g* for 2 min in a refrigerated microcentrifuge. The supernatant is discarded and the resulting membrane pellet is rewashed and the radioactivity remaining in the pellet is counted.

EVALUATION

Specific binding is calculated by subtracting the [^{125}I]CGRP binding in the presence of unlabeled

CGRP. Results are expressed as fmol of [^{125}I]CGRP bound/mg membrane protein.

MODIFICATIONS OF THE METHOD

Van Rossum et al. (1994) described the binding profile of a selective calcitonin gene-related peptide receptor antagonist ligand, [^{125}I-Tyr]hCGRP$_{8-37}$, in rat brain and peripheral tissues.

Muff et al. (1992) reported that the calcitonin gene-related peptide receptor in a human neuroblastoma cell line (SK-N-MC) is clearly different from the calcitonin receptor in a human breast carcinoma cell line (T47D).

Aiyar et al. (1996) described a cDNA encoding the calcitonin gene-related peptide type 1 receptor. Stable expression in human embryonic kidney 293 (HEK 293) cells produced specific high-affinity binding sites for CGRP that displayed pharmacological and functional properties very similar to those of the native human CGRP$_1$ receptor.

Poyner et al. (1999) characterized the receptors for calcitonin gene-related peptide and adrenomedullin on the guinea pig vas deferens.

Juaneda et al. (2000) reviewed the molecular pharmacology of CGRP and related peptide receptor subtypes.

Schindler and Doods (2002) described binding properties of the nonpeptide CGRP receptor antagonist radioligand, [^{3}H]BIBN4096BS.

N.10.6 Inhibin

N.10.6.1 General Considerations

Inhibin is a gonadal dimeric glycoprotein that has an inhibitory effect on the secretion of follicle-stimulating hormone by the pituitary gland. The existence of a nonsteroidal gonadal hormone was described by McGullagh as early as 1932. The hormone was isolated and purified from human seminal plasma, ram rete testis fluid, and from bovine follicular fluid (Franchimont et al. 1979, 1989; Robertson et al. 1986; Vale et al. 1986; De Kretser and Robertson 1989). After the determination of the full structure of bovine (Forage et al. 1986) and human (Mason et al. 1986; Stewart et al. 1986; Tierney et al. 1990) inhibin, it was found that inhibin shares structural homology with a family of glycoproteins which includes Mullarian inhibiting substance, transforming growth factor-β, follistatin, activin, and bone morphogenic proteins (Robertson 1991; Moore et al. 1994). Inhibin is a disulfide-linked dimer of an α-subunit and a structurally related β-subunit, either β_A or β_B (Robertson et al. 1992). Inhibin A and inhibin B are related dimeric

protein hormones and endocrine regulators of the reproductive axis which show differing patterns during the period of follicular development (Woodruff et al. 1996).

Clinically, inhibin determination may have uses in reproductive medicine and oncology; the diagnosis of some forms of cancer including granulosa cell tumors, cystadenocarcinoma of the ovary and hydatidiform mole and in the physiology and pathology of pregnancy including placental function (Halvorson and DeCherney 1996).

An International Standard for Porcine Inhibin was described by Gaines Das et al. (1992). An International Standard for human recombinant inhibin was established by Rose and Gaines Das (1996).

Tio et al. (1994) purified gonadotropin surge-inhibiting factor (GnSIF), a monomeric polypeptide that shares some biological activities with inhibin, from Sertoli cell-enriched medium.

N.10.6.2 In Vitro Bioassay for Inhibin

PURPOSE AND RATIONALE

Several modifications of *in vitro* bioassays for inhibin have been used to establish the International Standard for porcine inhibin (Gaines Das et al. 1992) and for human recombinant inhibin (Rose and Gaines Das 1996). Mason et al. (1996) used rat anterior pituitary cells for characterization and determination of the biological activities of noncleavable high-molecular-weight forms of inhibin A and activin A.

PROCEDURE

Anterior pituitary cells are prepared from adult male rats and added to 48-well cluster plates at an initial density of 75,000 cell per 0.4 ml of medium per well. Cultures are preincubated in DMEM-Ham's F12 (1:1) medium with bicarbonate supplemented with nonessential amino acids, antibiotics (100 U/ml penicillin, 100 pg/ml streptomycin, and 250 ng/ml fungizone), and 10% charcoal-stripped FBS. Two days later, the cells are washed, and the medium is replaced with serum-free medium supplemented with antibiotics and recombinant human inhibin A (20–100 pM) as standard. Cultures are incubated with test samples for 65–72 h, after which the samples of medium are collected and stored at −20°C until assayed for follicle-stimulating hormone (FSH) by radioimmunoassay (RIA) using goat second antibody precipitation with

the following reagents (NIDDK): rat FSH-RP-2, rat FSH-I-8 iodinated using Iodogen, and anti-rat FSH-S-11 primary antiserum. Each sample for bioassay is tested at least twice in independent cell cultures to confirm the observations.

EVALUATION

Characteristics of the concentration–response curve, including the maximum effect and medium inhibitory concentration (IC_{50}), are computed using the Allfit program (Munson and Rodbard 1980).

MODIFICATIONS OF THE METHOD

Robertson et al. (1991) studied *in vivo* the FSH-suppressing activity of human recombinant inhibin A in the serum of male and female rats.

Wreford et al. (1994) studied the age dependence of gonadotropin-suppressing activity of human recombinant inhibin in the serum of male rats.

Simpson et al. (1992) induced bilateral cryptorchism in adult male Sprague Dawley rats under ether anesthesia by cutting the gubernaculum of both testes, translocating the testes to the abdominal cavity and ligating the inguinal canal to prevent redescent of the testes into the scrotum. After 28 days, Sertoli cell cultures from these rats were prepared and inhibin secretion in response to follicle-stimulating hormone (FSH) was measured.

Brown et al. (1991) investigated the effects of inhibin-rich porcine follicular fluid administration on serum bioactive and immunoreactive FSH concentrations and compensatory testosterone secretion in hemicastrated adult rats.

Hertan et al. (1999) used primary cultures of ovine anterior pituitary cells for bioassays of inhibin and identified high-affinity binding sites for inhibin using iodinated recombinant human 31-kDa inhibin.

Jakubowiak et al. (1989) found similar effects of inhibin and cycloheximide on gonadotropin release in superfused rat pituitary cell cultures.

Demura et al. (1996) studied the levels of inhibin α, β_A and β_B subunit mRNAs by a quantitative reverse transcription-polymerase chain reaction and the changes in their levels caused by adding inhibin α, β_A and β_B subunit mRNA antisense oligonucleotides and inhibin A, activin A or gonadotropin-releasing hormone (GnRH) to cultured rat anterior pituitary cells.

Robertson et al. (1996) investigated the specificity of several immunoassay methods in terms of their ability to detect the range of inhibin forms found in plasma and their relationship to bioactivity.

A commercially available enzyme-linked immunosorbent assay (ELISA) for inhibin A (Serotec, Oxford) was used by several authors (Wenstrom et al. 1997; Blumenfeld et al. 1998; Wallace et al. 1998). Magoffin and Jakimiuk (1998) used specific and sensitive two-site enzyme-linked immunosorbent assays for determination of inhibin A, inhibin B, and activin A.

An *in vitro* method has been developed by Allenby et al. (1991) for culturing isolated seminiferous tubules from adult rats for 1–3 days and optimized on the basis of the secretion of immunoactive inhibin under basal conditions and after maximal stimulation with rat FSH or dibutyryl cAMP. Inhibin was measured using a double-antibody radioimmunoassay based on an antibody generated in a sheep to the 1–26 sequence (plus gycine^{27}tyrosine^{28}) of the N-terminus of the α-subunit of porcine 32-kDa inhibin. The effect of three known testicular toxicants (meta-dinitrobenzene, nitrobenzene, and methoxy acetic acid) on these cultures was assessed.

Knight et al. (1991) described the development of a two-site immunoradiometric assay for dimeric inhibin using antibodies against chemically synthesized fragments of the α and β subunit. Knight and Muttukrishna (1994) described the measurement of dimeric inhibin using a modified two-site immunoradiometric assay specific for oxidized (Met O) inhibin.

N.10.7 Activin

N.10.7.1 General Considerations

Activin is a pluripotent growth factor that was originally isolated based on its ability to stimulate follicle-stimulating hormone (FSH), but is now known to have other important roles during development, erythropoiesis, inflammation, and wound healing (De Paolo 1997). Three types of activin, formed by dimerization of two inhibin-β subunits β_A and β_B, are termed activin A ($\beta_A\beta_A$), activin AB ($\beta_A\beta_B$) and activin B ($\beta_B\beta_B$) (Ling et al. 1986; Vale et al. 1986; Mason et al. 1989; Nakamura et al. 1992). In addition, a third β-subunit (β_C) has been identified (Hötten et al. 1995; Loveland et al. 1996). Lee et al. (1989) suggested that, in the testis, the Leydig cells secrete activin and the Sertoli cells produce inhibin, or a combination of both. As members of the transforming growth factor beta (TGF-β) family, the activins are involved in a diverse range of physiological processes, including the regulation of FSH biosynthesis and secretion (Mason 1988; MacConnell et al. 1999), steps in embryonic development (Thomsen et al. 1990), spermatogonial mitosis (Mather et al. 1990) and erythroid differentiation (Eto et al. 1987). Activin acts via a family of activin receptor subunits that includes one type I (Act RI or ALK-2) and two homologous type II (IIA and IIB) subunits (Dalkin et al. 1996; Hashimoto et al. 1998).

N.10.7.2 In Vitro Bioassay for Activin

PURPOSE AND RATIONALE

In vitro bioassays for activin have been developed using the production of follicle-stimulating homone (FSH) from cultured pituitary cells (Robertson et al. 1992), the accumulation of hemoglobin in K562 erythroleukaemia cells (Schwall and Lai 1991), and the ability to induce mesoderm tissue in animal cap explants of *Xenopus* (De Winter et al. 1992). One of the sites of production of activin A is the bone marrow (Shao et al. 1992; Yamashita et al. 1992; Uchimaru et al. 1995). Brosh et al. (1995) found that the mouse plasmacytoma cell line MPC-11 (Laskov and Scharff 1970) was exquisitely sensitive to inhibition by activin A without being influenced by a variety of other cytokines and growth factors. On this basis, Phillips et al. (1999) evaluated the MPC-11 cell line as the basis for an *in vitro* bioassay for activin.

PROCEDURE

MPC-11 plasmacytoma cells are cultured in Dulbecco's modified Eagle's medium supplemented with 10% fetal calf serum, 24 mM bicarbonate, L-glutamine, nonessential amino acids and Pen-strep in a 95% air/5% CO_2atmosphere at 37°C, and passaged at 1×10^6 cells/25 cm^2 flask every second day. For experiments, 100 µl cell suspension is added to 96-well plates at a density of 1000 viable cells/well in culture medium containing 25 µM β-mercaptoethanol. Activin, other test reagents and sera (100 µl/well) are added to the cultures diluted in phosphate buffer (pH 7.4) containing 6.5 mM Na_2HPO_4, 1.5 mM KH_2PO_4, 0.14 M NaCl, 0.01% BSA and Pen-strep. Cells are cultured in the presence of test reagents for 2 days; on the third day 25 µl [^{3}H]thymidine (0.25 µCi/25 µl, 6.7 Ci/mmol) is added to each well and 24 h later the cells harvested and thymidine incorporation assessed. Proliferation of MCP-11 cells, as measured by thymidine incorporation, is inhibited by increasing doses of activin A or activin B, whereas follistatin, inhibin A, LH, and interleukin-1β are ineffective.

EVALUATION

All test preparations, including activin standards and sera, are assayed in quadruplicate, and experiments are repeated at least twice. Relative bioactivity and parallelism are assessed using parallel-line bioassay statistics.

MODIFICATIONS OF THE METHOD

Mesoderm induction assays in *Xenopus* were used by Wuytens et al. (1999). *Xenopus* embryos were obtained by *in vitro* fertilization. They were maintained in 10% Normal Amphibian Medium and staged according to Nieuwkoop and Faber (1967). Animal pole regions were dissected from mid-blastula (stage 8) embryos and cultured in 75% Normal Amphibian Medium containing 0.1% bovine serum albumin and wild-type or mutant activin (2.5 ng/ml). A preliminary assessment of mesoderm induction was based on the elongation of the animal caps. Animal pole regions were then frozen on dry ice, and expression of the mesoderm-specific gene Brachyury (Xbra) was assessed by RNase protection analysis.

LaPolt et al. (1989) examined the effects of purified porcine activin on inhibin secretion and messenger RNA levels in cultured granulosa cells obtained from immature, estrogen-treated rats. Western blot analyses performed with affinity-purified antisera to inhibin α- and β_A-subunits revealed that treatment with either FSH or activin increased the secretion of inhibin $\alpha\beta$ dimer, with a further increase after co-treatment.

Attardi and Miklos (1990) examined the effect of purified recombinant human activin A on steady-state levels of mRNAs for the gonadotropin subunits in pituitary cell cultures prepared from adult male rats.

Carroll et al. (1991) used rat anterior pituitary cells *in vitro* and determined the apparent half-life of FSHb mRNA in the presence and absence of recombinant human activin A after addition of actinomycin D.

Demura et al. (1993) measured follistatin-free activin and inhibin in the culture medium of porcine granulosa cells by a competitive protein binding assay and N-fragment RIA, respectively. Both activin and inhibin were secreted under the control of FSH and LH.

Miyamoto et al. (1999) investigated the effect of activin A on secretion of LH, FSH, and prolactin by fe-

male cultured rat pituitary cells at the single-cell level by means of the cell immunoblot assay. Anterior pituitary cells were preincubated with or without activin A for 24 h, after which they were monodispersed and immediately used for cell immunoblot assay.

Peng et al. (1999) examined the expression of activin receptor mRNAs in human ovary and placenta. Primers specific for two type-I and two type-II receptors (ActR-I, Act-RI_B, ActR-II, and Act-RII_B) were used in polymerase chain reaction to amplify cDNAs prepared from granulosa-luteal cells, placental tissues, and trophoblast cells.

Liu et al. (1996) measured release of immunoreactive activin A from cultured rat anterior pituitary cells by a specific radioimmunoassay.

Shintani et al. (1991) developed a radioimmunoassay for the measurement of activin A, which is identical to erythroid differentiation factor.

For measurement of activin in biological fluids by radioimmunoassay, McFarlane et al. (1996) added sodium deoxycholate, Tween 20 and sodium dodecyl sulphate as dissociating agents in order to remove interference by follistatin.

Knight et al. (1996) developed a two-site enzyme immunoassay for the determination of total activin A concentrations in serum and follicular fluid.

Saito et al. (1991) developed an assay method for activin-binding protein, which exploits its high affinity for sulfated polysaccharides, and used this method to investigate the production of activin-binding protein by rat ovarian granulosa cells *in vitro*.

N.10.8
Follistatin

N.10.8.1
General Considerations

Follistatin is a monomeric glycosylated polypeptide chain which was identified from bovine and porcine follicular fluids on the basis of its inhibition of pituitary follicle-stimulating hormone secretion (Robertson et al. 1987; Ueno et al. 1987; Ying et al. 1987; Bohnsack et al. 2000). Follistatin exerts its inhibitory effect on FSH secretion by neutralizing activin activity (Namakura et al. 1990; Shimonaka et al. 1991; De Winter et al. 1996). Follistatin is able to bind and neutralize the actions of many members of the transforming growth factor-β family of proteins and plays a significant role during organogenesis (Patel 1998). There are two main forms of mature mammalian follistatin which occur as a result of alternative modes of precursor mRNA splicing, giving core proteins of 315 amino acids and the carboxy-truncated variant of 288 amino acids. Further variants in the molecular weight of mature follistatin occur as a result of varying degrees of glycosylation (Inouye et al. 1991; Sugino et al. 1993).

N.10.8.2
Immunoassay for Follistatin

PURPOSE AND RATIONALE

Evans et al. (1998) developed an ultra-sensitive two-site enzyme immunoassay for human follistatin.

PROCEDURE

Female Balb/c mice are immunized subcutaneously with 20 µg recombinant human follistatin rh-FS288 in an emulsion with complete Freund's adjuvant. The immunization is repeated on two further occasions at monthly intervals in complete Freund's adjuvant, before finally boosting intravenously with rh-FS288 (total 100 µg in saline). The spleen is removed and the splenocytes are fused to Sp2/0 myeloma cells using polyethylene glycol following a standard fusion protocol (Galfre and Milstein 1981). Hybridoma supernatants are screened on a 96-well plate coated with rh-FS288 (0.2 µg/ml in sodium bicarbonate buffer, pH 9.4). Positive clones are expanded and recloned in methyl cellulose. The supernatants from these clones are titrated against rh-FS288 (0.2 µg/ml) under a standard ELISA protocol (Groome et al. 1995). On the basis of these experiments, clones are selected (29/9 and 17/2) and isotoped with a commercial kit. The clones are grown to produce ascitic fluid in pristane-primed BALB/c mice. Purification of IgG is carried out using protein-G affinity chromatography.

Antibody to a selected clone (29/9) diluted in 0.2 M sodium bicarbonate buffer, pH 9.4, is coated by simple absorption onto 96-well ELISA plates overnight at room temperature (10 µg/ml). The following day, the plates are banged to dryness on paper toweling, then 100 µl of dry coat reagent per well is added to the plates. After a 1-h incubation at room temperature the plates are banged to dryness and stored in a sealed box.

Both standard (rh-FS288) and samples are diluted in dissociation solution (84 mmol/l sodium deoxycholate, 3.4% Tween 20, 1% BSA, 5% mouse serum in PBS). Standards are prepared by serially diluting the stock rh-FS288 to give a high standard of 2500 pg/ml and a low standard of 19.53 pg/ml.

Duplicate 50-µl amounts of standard or test samples are added to wells on the plate, which is then sealed

and incubated overnight stationary at room temperature in a sealed moist box. The following day, the plate is washed and to each well is added 50 µl of approximately 1 µg/ml of Fab fragment of clone 17/2, which has previously been coupled to alkaline phosphatase by heterobifunctional chemistry (Ishikawa et al. 1983). This is diluted in Tris conjugate buffer: 1% BSA in 25 mM Tris-HCl, pH 7.5, containing 0.15 M NaCl and 0.5% Tween 20. After a 2-h incubation in a moist chamber at room temperature, the plate is washed thoroughly, and banged to dryness on paper toweling. Alkaline phosphate substrate (50 µl) is added to each well and the plate incubated for 2 h stationary at room temperature. Amplifier solution (50 µl) is then added to each well and the ensuing chromogenic reaction is stopped by adding 0.4 M HCl (50 µl/well) once color begins to develop in the zero analyte wells and the top standard has an absorbance of approximately 1.8. The well absorbencies are read at 490 nm with a reference wavelength set at 620 nm using a microplate reader.

EVALUATION

To determine whether dose–response relationships of serially diluted standard and test samples are identical (parallel), the slope values (± 95% confidence intervals) of log-transformed data for each response curve are compared by linear regression. The curves are deemed to be parallel if the slopes (± 95% confidence intervals) are found to overlap.

MODIFICATIONS OF THE METHOD

Nakamura et al. (1992) investigated the effect of follistatin on activin-induced granulosa cell differentiation in freshly harvested granulosa cells from diethylstilbestrol-treated rats. Activin induced a remarkable change in granulosa cellular morphology from elongated fibroblast-like to round cells, which was prevented by follistatin.

Xiao et al. (1992) studied the effects of activin and follistatin on FSH receptors and differentiation of cultured rat granulosa cells *in vitro*.

DePaolo et al. (1991) determined FSH and LH levels by RIA in the serum of ovariectomized rats and compared *in vivo* the FSH-suppressing activity of follistatin and inhibin.

Ophthalmologic Activity[1]

[1] Review and contributions by B. Schultz and W.H. Vogel.

O.1 Introduction

Ocular pharmacology shares many methods with other indications and treatment of other organs. Therefore, in many instances, the reader has to be referred to other sections, such as:

- neovasculrization of the cornea to Sect. A.8.3.4,
- topical anesthesia of the cornea to Sect. G.1.3.1,
- influence on α- and β-adrenoreceptors in the mouse iris to Sect. A.1.3.24,
- *in vitro* determination of carbonic anhydrase inhibition to Sect. C.1.1.1,
- electroretinogram in diabetic hyperglycemia and galactosemia to Sect. K.8.1.5,
- effect of streptomycin induced cataract to Sect. K.8.1.6,
- effect on galactose feeding-induced cataract to Sect. K.8.1.7,
- effect on naphthalene induced cataract to Sect. K.8.1.8,
- immunological methods to Sect. I.2.2.16.

Nevertheless, ocular pharmacology is a special issue, which justifies a special chapter in this book.

O.2 Intraocular Pressure

O.2.1 Acute Measurement of Intraocular Pressure

PURPOSE AND RATIONALE

For evaluation of drugs, intraocular pressure is measured in normal animals or in animals with experimental glaucoma.

PROCEDURE

New Zealand white rabbits, weighing 2.0–2.5 kg, are acclimated to the laboratory environment at least

one day prior to experimentation. Intraocular pressure (IOP) measurements consist of topically administering one drop (approximately 50 µl) of a short-acting local anesthetic (Ophthaine 0.5%) directly on the eyes of an unrestrained rabbit. Approximately 40–45 s following local anesthetic administration, an IOP reading for each eye is taken for 10 s and recorded as mm Hg. IOP is determined by applanation pneumotonometry using an Alcon pneumotonograph modified for the rabbit eye (Vareilles et al. 1977).

On the day of the experiment, two baseline IOP measurements are determined and designated as $P_1$and P_2, respectively. The P_1 measurement is recorded 30 min prior to drug administration while the P_2 measurement occurs just prior drug or placebo administration. The P_2 measurement is designated as IOP at zero time and is used as the baseline control value for determination of percent reduction in pressure. Thus, a baseline is determined for each rabbit studied.

Immediately following the P_2 measurement, the appropriate concentration of drug or vehicle is administered topically to the right eye of 5 rabbits. This is done by placing three successive 20 µl additions directly onto the eye at two- or three-minute intervals. In addition, during drug application, the lower eyelid is held so that excess fluid is collected in the exposed conjunctival sac. Simultaneously, the left eye receives vehicle with the same regimen as the drug-treated right eye. The vehicle (control) treatment is to monitor potential contralateral ocular effects. Following drug or vehicle treatment, IOP measurement are taken at the following time periods: 0.5; 1.0; 1.5; 2.0; 3.0; 4.0; 5.0 and 6.0 h.

EVALUATION

The *IOP* of each rabbit eye for each time period is initially recorded in mm Hg. However, to account for initial *IOP* differences among rabbits, the changes in mm Hg are normalized by converting to percent reduction in outflow pressure (*ROP*).The *ROP* is calculated according to an equation proposed by Mishima (1981):

$$\%\,ROP = (Po - Pe/Po - Ep) \times 100$$

where *Po* is the *IOP* reading in mm Hg at zero time, *Pe* is the experimental *IOP* reading at the appropriate time following drug or vehicle administration and *Ep* is the episcleral venous pressure taken as a constant of 10 mm Hg. The percent *ROP* for each rabbit at each time period is recorded and grouped to determine a mean percent *ROP* for each time period as well as the duration of action. The overall activity of the drug based on the mean percent *ROP* for five rabbits is categorized as follows:

% reduction in outflow pressure	activity
10.1–20.0	slight
20.1–40.0	moderate
>40	marked

MODIFICATIONS OF THE METHOD

Rowland et al. (1981) studied circadian rhythm in intraocular pressure using repeated tonometry in **rabbits**.

Santafé et al. (1997) studied the hypotensive effects of topically applied calcium-antagonists on intraocular pressure in conscious rabbits using a manual applanation tonometer calibrated by direct manometry.

Okada et al. (1995) studied the *IOP* response to different doses of intravitreally injected endothelin-1 in rabbits using a pneumatotonometer.

Drago et al. (1997) studied the effect of repeated administration of combinations of beta-blockers with pilocarpine on *IOP* and heart rate in conscious rabbits.

Chidlow et al. (1999) investigated the effect of topical application of a HT_{1A} receptor agonist on *IOP* in normotensive rabbits using an applanation tonometer.

Goldblum et al. (2000) studied the effect of an acetylcholinesterase inhibitor on *IOP* in normotensive rabbits using a TonoPen XL.

The effect of various carbonic anhydrase inhibitors on *IOP* pressure was measured by several authors, such as Supuran et al. 1999; Briganti et al. (2000).

Burke and Potter (1986) studied the ocular effects of a relatively selective $\alpha 2$ agonist in cats, rabbits and monkeys. Intraocular pressure was measured using an Alcon pneumatonometer, and pupil diameter under constant illumination using a pupillometer. Furthermore, cat nictitating membrane responses were recorded after injections via the lingual artery into the right external artery supplying the nictitating membrane.

Moore et al. (1995) described long-term non-invasive measurement of *IOP* in the **rat** eye. Rats were anesthetized with short-acting isoflurane inhalant and *IOP* was determined by averaging 15 valid individual readings with a TonoPen 2 tonometer.

Krishna et al. (1995) studied the circadian rhythm of *IOP* in Lewis rats using a TonoPen 1 tonometer.

Diurnal variations of *IOP* in the eyes of awake male brown Norway rats were measured by Moore et al. (1996) using a TonoPen XL tonometer.

Cabrera et al. (1999) found no significant difference of *IOP* in four strains of rats using conscious, unsedated animals.

Jia et al. (2000) determined the diurnal *IOP* response of Brown Norway rat eyes after sclerosis of the aqueous humor outflow pathways and its relationship to optic nerve damage. Hypertonic saline was injected into a single episcleral vein and *IOP* measured in both the light and dark phases of the circadian cycle in awake animals.

John et al. (1997) developed a method to measure *IOP* in living **mice** of genetically different mouse strains. Eyes of anesthetized mice were cannulated with a very fine fluid-filled glass micro-needle. The micro-needle was connected to a pressure transducer and the pressure signal was analyzed with a computer system.

Miller and Rhaesa (1996) evaluated the effect of a topical α_2-agonist on *IOP*, pupil size and heart rate in normal **cats**.

Bhattacherjee et al. (1999) trained domestic adult cats to accept topical ocular drug administration and pneumotonometry. Cats received either various corticosteroids or vehicle topically to both eyes three times a day for approximately 28 days. The increase of *IOP* was found to depend on the concentration and structure of the corticosteroid.

Gelatt et al. (1997) evaluated the effects of locally applied pilocarpine preparations on *IOP* and pupil size in glaucomatous Beagle **dogs**.

Peterson et al. (1996) compared readings with the Tono-Pen, a handheld applanation tonometer based on the Mackay-Mark principle, with *IOP* measured manometrically after anterior chamber cannulation through the peripheral cornea with a 26-gauge needle connected to a vertically adjustable reservoir and a pressure transducer in cynomolgus **monkeys**.

For *in vitro* determination of carbonic anhydrase inhibition see C.1.1.1.

0.2.2 Measurement of Intraocular Pressure by Telemetry

PURPOSE AND RATIONALE

McLaren et al. (1996), Pericot et al. (1996), Schnell et al. (1996) published methods to measure intraocular pressure by telemetry in conscious, unrestrained rabbits.

PROCEDURE

Telemetric Pressure Transducers

The implantable pressure monitors (Model TA11PA-C40; Data Sciences International, St. Paul, MN) are cylindrical, measure 25 mm in length and 15 mm in diameter, and weigh approximately 9 g. They contain a pressure transducer, a short-range amplitude modulation radiotransmitter, and a battery in a biocompatible case. Pressure is conducted to the transducer through a fluid-filled polyurethane catheter that is 15 cm long and 0.7 mm in diameter. The 3-mm distal tip of the catheter couples the transducer to the surrounding fluid; it is modified with a thin flexible wall, and the end is filled with a biocompatible gel. The thin wall conducts transient pressure changes, whereas the gel prevents mixing of the fluid in the catheter with the surrounding biological fluid and conducts slow pressure changes.

The transmitter broadcasts an amplitude modulation signal to two antenna and receiver assemblies mounted inside the animal's cage.

Implant Surgery

The transducers are implanted in rabbits weighing 2 to 3.5 kg by using aseptic conditions under anesthesia with intramuscular injections of 50 mg/kg ketamine and 5 mg/kg xylazine. A 4-cm midline incision is made on the dorsal neck and connective tissue and muscle layer over the vertebral column and between the scapulae are blunt dissected to form a pocket to contain the transducer capsule. This area is covered with moist gauze while the eye is prepared to receive the catheter.

The right eye is used in all experiments. Eyelids are retracted with an infant lid speculum, and a 7-0 silk suture is placed through the mid-corneal stroma approximately 3 mm from the superior limbus. The two ends are weighted to maintain downward rotation of the globe. The conjunctiva is opened 2 to 3 mm temporal to the superior rectus muscle and gently dissected free of the sclera back to the supertemporal orbital rim.

A 10 cm, 17-gauge catheter needle is inserted through the conjunctival opening, advanced to the orbital rim, and pushed through the orbital fascia into the subcutaneous space just behind the orbital rim. It is advanced carefully under the skin to the top of the skull and back between the ears until the tip emerges from the opening at the back of the neck. The needle is flushed with sterile saline to remove any tissue or blood it has collected.

The transducer is dipped in an antibiotic solution (1000 U/ml bacitracin and 10 mg/ml neomycin in Ringer's solution) and is placed in the pocket formed earlier in the neck. The tip of the cannula is then inserted into the bore of the 17-gauge needle and advanced carefully as far as possible. The needle is withdrawn and removed from the conjunctival opening, leaving the transducer catheter along its path. Approximately 2 cm of the catheter is left extending through the conjunctival opening.

The anterior edge of the conjunctival flap is reflected forward, and the sclera over the trabecular meshwork is scraped with a sharp, rounded blade until the trabecular meshwork is visible as a dark streak. A 21-gauge needle is inserted through this thinned tissue into the anterior chamber and withdrawn, and the anterior chamber is refilled through the same opening with Healon. The catheter is grasped with a tube forceps and is inserted through the opening into the anterior chamber. The tip is advanced to approximately mid pupil. Care is taken not to touch the corneal endothelium.

The catheter is secured to the sclera with three 9-0 or 10-0 nylon sutures. Each is tied securely around the catheter three times and its ends passed through the sclera before they are tied together. One 8-0 silk suture is also tied tightly three times around the catheter to promote formation of granulation tissue. The catheter is pulled gently back toward the transducer to remove the excess loop in the orbit.

The capsule is anchored in the pocket on the neck. Again, care is taken, not to nick or make any sharp bends in the catheter. The muscle layer and the skin are closed so that the entire transducer and the catheter assembly are located internally.

For measurement of intraocular pressure lowering drugs, ocular hypertension caused by injection of 5% glucose is used. The rabbits are left undisturbed for 30 min before the beginning of telemetric intraocular pressure measurements. One measurement is recorded every 15 s for 5 s with a sampling rate of 250 Hz. Fifty µl of test solution or saline are instilled into the conjunctival sac of the implanted eye and intraocu-

lar pressure is recorded for the next 60 min. A sterile 5% glucose solution (20 ml/kg) is then injected into the marginal vein of the ear. Intraocular pressure is recorded for the next 40 min. All studies are performed using a cross-over protocol. A wash-out period of 5 days is allowed between experiments.

EVALUATION

For statistical analysis, the average values of data collected over the time period of interest are calculated for individual animals. For comparisons within groups, statistical analysis is performed on averaged date using two-tailed Student's *t*-test for paired data or unpaired test for unpaired data.

MODIFICATIONS OF THE METHOD

Pericot et al. (1996) induced chronic ocular hypertension by a single injection of α-chymotrypsin into the posterior ocular chamber of rabbits anesthetized by an intramuscular injection of 35 mg/kg ketamine and 4 mg/kg xylazine. Continuous intraocular pressure was measured by telemetry and the effects of timolol, dorzolamide, and epinephrine. The transmitter of a miniaturized radiotelemetry system was implanted into rabbits, and its catheter was tunneled subcutaneously to the superior conjunctival sac and inserted into the midvitreous.

Dinslage et al. (1998) recorded the effects of tonometry, handling, water drinking, and instillation of topical ophthalmic medications on *IOP* by telemetry in rabbits for several months during each 24-h day/night cycle.

McLaren et al. (1999) measured the effects of topical ibopramine and epinephrine on the circadian rhythm of *IOP* in undisturbed rabbits by telemetry.

0.3 Aqueous Humor Flow Rate

PURPOSE AND RATIONALE

Aqueous humor flow rate can be determined by ocular fluorophotometry (Ogidigben et al. 1993, 1994).

PROCEDURE

New Zealand White rabbits weighing 2.5–4 kg of either sex are used. For unilateral sympathectomy, the animals are anesthetized with a dose of ketamine/xylazine (44/8 mg/kg i.v.). Through a midline incision in the neck, the cervical sympathetic nerve trunk is isolated from both the vagus and the common carotid artery by blunt dissection. To be sure that the isolated nerve is the sympathetic trunk, it is electrically stimulated with a square-wave pulse of 4 Hz (0.7-ms duration, 5-s train) at 4 V with a bipolar electrode connected to a Grass SD9 stimulator; dilatation of the rabbit's pupil is satisfactory confirmation of nerve isolation. The preganglionic sympathetic trunk and superior cervical ganglion are severed and removed. During 1–2 weeks post surgery, sympathetically denervated eyes of rabbits are examined for persistent miosis and ptosis.

The corneas of adult rabbits are treated bilaterally by instilling 2% fluorescein topically, 1 drop every 5 min for a period of 30 min (Brubaker 1989). Subsequently, fluorescein concentrations in the cornea and anterior chamber are measured using a Fluorotron Master (Coherent Medical Inc., Palo Alto, CA). Basal aqueous humor flow rates are established both in sympathetically denervated and normal eyes. In the following week, groups of rabbits are treated bilaterally with the test drug or with vehicle. Fluorometry recordings are started 30 min after drug or vehicle administration, and subsequent recordings are made every hour for a total of 5 h.

EVALUATION

Student's *t*-tests for paired data are used to evaluate drug-induced changes.

CRITICAL ASSESSMENT OF THE METHOD

The study in hemi-sympathectomized animals allows the separation of direct drug effects from effects exerted via the sympathetic nervous system

MODIFICATIONS OF THE METHOD

According to Yablonski et al. (1978), the acute decrease in intraocular pressure caused by timolol can be explained entirely by its effect on the aqueous humor flow.

The effect of various compounds on aqueous humor inflow into the posterior chamber of the **rabbit** eye can be used to determine the mechanism of action and to compare the potency of *IOP* lowering compounds. Aqueous humor production is indirectly quantified in the New Zealand white rabbit by means of the *IOP* recovery rate assay of Vareilles and Lotti (1981). After a control pneumotonographic *IOP* measurement, a 20% NaCl solution is infused i.v. into the marginal ear vein of a rabbit at a rate of 1 ml/min for 10 min using an infusion pump. The hypertonic saline infusion causes a rapid and marked fall in *IOP* with a peak reduction occurring 15 min after the start of infusion. Thereafter, the pressure gradually returns to normal over the ensuing 120 min in normal rabbits. Compounds under study are solubilized in a suitable vehicle. Sixty min prior to NaCl infusion, the drugs are instilled directly onto both eyes as three successive 20 µl drops with each drop separated by two or three min. Following the NaCl infusion, the intraocular pressures of both eyes are measured at 5, 10, 15, 30, 60, 90 and 120 min and then every 30 min until *IOP* recovers to preperfusion values. The mean of the *IOP* for the 2 eyes is recorded and plotted against time. The *IOP* recovery rate is then expressed as the slope of the *IOP* recovery line calculated from the points 15 min from the start of NaCl infusion to the ensuing 120 min by means of the least squares method. The difference in slope and percentage change between control and that produced by experimental compounds are analyzed using an unpaired Student's *t*-test. A compound which lowers *IOP* by reducing aqueous humor flow will exhibit a prolonged *IOP* recovery rate as evidenced by a shallow slope compared to that produced by vehicle.

Taarnhøj et al. (1990) reported calibration of measurements *in vivo* of fluorescein in the rabbit cornea. The quenching was measured by four different techniques: (1) by elution of fluorescein, (2) by elution of albumin, (3) by polarization of fluorescence, and (4) by spectrofluorometry. Quenching of fluorescence of fluorescein in the rabbit cornea can be explained by the interaction of fluorescein and albumin in the cornea.

Burke and Schwartz (1996) surveyed the preclinical data on aqueous humor flow and intraocular pressure of brimonidine.

Beilin et al. (2000) characterized the *IOP* lowering activity and possible mechanism of action of a synthetic, non-psychotropic cannabinoid after i.v. administration in rabbits measuring *IOP* by pneumatonometry, aqueous humor inflow rate by fluorophotometry, blood pressure and heart rate by a computerized physiograph system connected to the central ear artery.

Mermoud et al. (1996) established methods to determine normal outflow facility using anterior chamber infusion with constant pressure and aqueous humor production by a technique of dilution with FITC-albumin in Lewis **rats**.

Tian et al. (1997) determined the effects of adenosine agonists on intraocular pressure with an minified Goldmann applanation tonometer and aqueous humor dynamics by fluorophotometry in cynomolgus **monkeys**.

0.4 Experimental Glaucoma

0.4.1 Alpha-Chymotrypsin Induced Glaucoma in Rabbits

PURPOSE AND RATIONALE

Sears and Sears (1974) induced glaucoma in rabbits by intraocular injection of alpha-chymotrypsin. Several other animal models resembling glaucoma in human beings have been reviewed (Gelatt 1977).

PROCEDURE

Male New Zealand rabbits weighing about 2 kg are pretreated with 10 mg/kg i.p. indomethacin to prevent the otherwise immediate onset of inflammation and

then slightly anesthetized with pentobarbital to eliminate any nystagmus. The right eye is anesthetized topically with 2% lidocaine. The anterior chamber is cannulated with a 30-gauge needle attached to a reservoir set at a pressure of 25 mm Hg. Then a second cannula, 32-gauge, is introduced into the anterior chamber near the limbus and directed to the posterior chamber through the pupil. A sterile isotonic saline solution (0.5 ml) containing 150 units of alpha-chymotrypsin is irrigated through the cannula into the posterior chamber. Care is taken to avoid the injection of any enzyme into the corneal stroma. Both cannulae are then removed without significant loss of aqueous humor. The eyes are examined at daily intervals for the first week, then on alternate days for the second week, and then weekly for the duration of the experiments. Intraocular pressure is measured with a tonometer adapted for rabbit eyes.

Treatment with drugs is performed before and after surgery.

EVALUATION

Intraocular pressure of animals treated with alpha-chymotrypsin and those treated additionally with drugs is expressed as mean ± SEM and compared statistically with untreated controls using ANOVA followed by Student's *t*-test.

MODIFICATIONS OF THE METHOD

Melena et al. (1998a) measured the effect of topical dihydroergocristine on *IOP* in alpha-chymotrypsin-induced ocular hypertensive **rabbits** with a pneumatonometer.

Drago et al. (1997) measured the effects of beta-blockers combined with pilocarpine on rabbit intraocular pressure. Experimental increase of intraocular pressure was induced by a subconjunctival injection of betamethasone-21-phosphate (4 mg/ml) in both eyes every week for 4 weeks. The intraocular pressure was measured in conscious rabbits using an electronic pneumotonometer after surface anesthesia with one drop of 0.4% benoxinate solution.

Melena et al. (1997) induced ocular hypertension in rabbits by weekly subconjunctival injection of a betamethasone suspension into the left eye and measured *IOP* with a manometrically calibrated pneumatonograph.

With the same method, Melena et al. (1998b) measured the effect of topical diltiazem on the rise of *IOP* and the effect on established ocular hypertension.

Santafe et al. (1999) induced ocular hypertension in rabbits by oral administration of 60 ml/kg tap water and measured the effect of topical diltiazem on *IOP*.

Balaban et al. (1997) studied the mechanisms of vasopressin effects on intraocular pressure in anesthetized **rats** after cannulation of the anterior chamber of the eye and infusions of artificial cerebrospinal fluid or arginine vasopressin solutions.

Mermoud et al. (1994) described an animal model of uveitic glaucoma. Uveitis was induced in Lewis rats by injection of S-antigen.

Morrison et al. (1998) produced scarring of the aqueous humor outflow pathways by unilateral episcleral vein injections of hypertonic saline in Brown Norway rats and measured *IOP* and optical nerve damage after topical treatment with artificial tears, 0.5% betaxolol, or 0.5% apraclonidine.

Ueda et al. (1998) described an experimental glaucoma model in the rat induced by laser trabecular photo-coagulation after an intracameral injection of India ink.

Gu et al. (2000) induced experimental glaucoma in the right eyes of Wistar albino rats by intracameral injection of India ink followed by laser trabecular photocoagulation 4 days later. The left eye served as control. Drugs were injected intraperitoneally just before trabecular photocoagulation. Five days later, 3% fast blue was injected into both superior colliculi. The eyes were enucleated another 3 days later and flat mounts of the retinas were prepared. Labeled ganglion cells were counted in the area 1 mm away from the optical disc.

Wang et al. (1997) induced glaucoma in one eye of cynomolgus **monkeys** by repeated argon laser photocoagulation or diode photocoagulation of the mid-trabecular meshwork to study the effects of 5-methylurapidil.

Schmidt et al. (1998) induced glaucoma in rhesus monkeys by 2–3 laser treatments of one eye and measured *IOP*, ocular pulse amplitude and peak pulse blood volume after treatment with anti-glaucoma drugs.

Serle et al. (1998) studied the effect of prostanoid derivates on *IOP* and aqueous humor flow rates in cynomolgus monkeys with unilateral laser-induced glaucoma.

0.4.2 Episcleral Venous Occlusion Induced Glaucoma in Rats

PURPOSE AND RATIONALE

The importance of trabecular and uvosceral outflow for the treatment of glaucoma has been underlined by Woodward and Gil (2004). Shareef et al. (1995), Sawada & Neufeld (1999), Neufeld et al. (1999) described a rat model of chronic elevated intraocular pressure.

PROCEDURE

Male Wistar rats weighing about 250 g are anesthetized with a mixture of 80 mg/kg ketamine and 12 mg/kg xylazine given intraperitoneally. All ocular surgical manipulations are unilateral, the contralateral eye serving as control. A 2-mm-long incision through the conjunctiva and Tenon's capsule is made on the limbal periphery of the eye. Two radial relaxing incisions are made at the edges of the initial incision. The tissue is recessed posteriorly exposing the underlying extraocular muscle, which is isolated and anchored by a suture to expose the underlying episcleral vein. The episcleral veins are identified by their location (slightly deeper than the ocular muscles), relative immobility, larger caliber, branching pattern, the darker blood contained and their communication with a limbal venous plexus. In contrast, the arteries travel a relatively straight course and communicate with a single perilimbal artery. In most cases, four episcleral veins are noted. By manipulating the anchored muscles, a hand-held cautery is applied to the veins. After ocular surgery, the eyes are treated with an antibiotic ointment.

Immediately after surgery, intraocular pressure rises from 12 mm Hg up to at least 20 mm Hg, remaining at this level for months.

This model is used more recently to study biochemical changes during elevated intraocular pressure and/or to study effects of drugs for antiglaucoma effects. Neufeld et al. (1999) treated a group of rats with aminoguanidine, a relatively selective inhibitor of nitric-oxide synthase 2 in the drinking water for 6 months. Tsai (2005) studied the effects of erythropoietin and the preservation of ganglion cells during glaucoma. Sarup (2005) reported on the effects of dorzolamide and timolol on glaucomatous eyes. Guo (2006) studied the effects of glutamate on glaucoma.

EVALUATION

Once a week, each animal is anesthetized (xylazine/ketamine) and intraocular pressure is determined bilaterally using a pneumotonometer. On any given eye, three to five tonometer readings are taken and averaged. On a given day, mean ± SD is derived for all control and surgical eyes. Significant differences between surgical and control eyes are determined by χ^2 analysis with Student's t test for independent means

for each day on which measurements are performed. Furthermore, IOP between treated and non-treated animals is compared.

MODIFICATIONS OF THE METHOD

WoldeMussie et al. (2001, 2002) induced chronic ocular hypertension in rats using laser photocoagulation with a blue-green argon laser.

0.4.3 Photocoagulation Induced Glaucoma in Monkeys

PURPOSE AND RATIONALE

Lee et al. (1985), Woodward et al. (2003) used a method originally described by Gaasterland and Kupfer (1974) for the production of sustained, elevated intraocular pressure in the rhesus monkey by repeated, circumferential argon laser photocoagulation of the mid-trabecular meshwork.

PROCEDURE

Cynomolgus or rhesus monkeys are anesthetized with systemic pentobarbital and placed at the slit lamp delivery system of the argon laser. Both eyes are treated with topical proparacaine 0.5% and photocoagulated using a modified Koeppe-type gonioscopy lens with hydroxypropylmethylcellulose as the filling fluid. Approximately 200 laser applications are made to each eye, aimed at the middle of the trabecular meshwork, using a 50 µbeam diameter, 0.2 to 0.5 second duration and 0.4 to 0.8 watts of power. Slit lamp and fundus examination are repeated every 5 to 8 days.

Drugs are applied locally as solutions with a drop size of 50 µl. Intraocular pressure is recorded in 6-h diurnal curves at 9:30 a.m., 10:00 a.m., 10:30 a.m., 11:30 a.m., 12:30 p.m., 1:30 p.m., 2:30 p.m., and 3:30 p.m. The baseline diurnal curve serves as control and is made 1 or 2 days before the experimental diurnal curve. On the experimental day, baseline intraocular pressure is measured at 9:30 a.m. The test drugs are administered to both eyes of the monkey immediately after the 9:30 a.m. measurement.

This procedure has also been applied by Kielczewski et al. (2005).

EVALUATION

The intraocular pressures on the treated day are compared to that of the control day. Alternatively, the differences in intraocular pressures at intervals after therapy between the treated and control day measurements are compared to the initial (0 hour) differences between the treated and control day values.

0.5 Local Anesthesia of the Cornea

PURPOSE AND RATIONALE

Surface anesthesia of the cornea is a prerequisite for ophthalmic surgery. Sigmund Freund studied the phar-

macological actions of cocaine and Carl Koller introduced cocaine in 1884 into clinical practice as a topical anesthetic. In pharmacology, following the pioneering work of Sollmann (1918), block of the rabbit corneal reflex as described by Régnier (1923) has become a standard test method for evaluating local anesthetics (Quevauviller 1971; Muschaweck et al. 1986). A detailed description of methods to evaluate the activity of compounds for surface anesthesia is given in Sect. G.1.3.1.

0.6 Experimental Cataract Formation

PURPOSE AND RATIONALE

Cataract formation can be induced experimentally by various procedures, such as

- **streptomycin** treatment (see Sect. K.8.1.6),
- **galactose feeding** (see Sect. K.8.1.7),
- **naphthalene** treatment (see Sect. K.8.1.8).

Another procedure to induce experimental cataract is treatment of young rats with **selenite**. A review of this model was given by Shearer et al. (1997). Oštádalová et al. (1978) induced cataract by administration of a single dose of sodium selenite to suckling rats.

PROCEDURE

Male Wistar rats are used. On the 2nd day of life, the sucklings are divided in such a way that 8 males were kept with one mother. On the 10th day of life (i. e., when they are in absolute nutritive dependence of the mother) a single dose of 0.02 M solution of Na_2SeO_3 is administered s.c. to 5 experimental groups receiving 5, 10, 20, 40 and 60 µmoles/kg, respectively. The first control group receives s.c. a 0.02 M solution of a sulphur compound (Na_2SO_3), i. e., an element homologous with selenium, at a dose of 60 µmoles/kg. As reference group, 2-months-old male rats are used to which a 0.02 M solution of Na_2SeO_3 is administered s.c. in an amount of 20 µmoles/kg. Mothers of the sucklings as well as the group of adult males, are fed on a standard laboratory diet with water ad libitum. All animals are checked daily and the experiment is terminated 20 days after the treatment.

Cataracts in the sucklings are visible by the naked eye after the opening of their eyes, i. e., on the 14–16th day of life. The opacity is yellowish-white, localized in the center of the lens (nuclear cataract). Two forms are observed: permanent cataracts, persisting through the whole experimental period, and intermittent cataracts, which disappear after some time and reappear after a certain delay. Doses of 40 and 20 µmoles/kg are mostly associated with permanent cataract, the dose of 10 µM/kg causes an uneven distribution of both types of cataracts. The cataractogenic effect is not found in adult animals.

EVALUATION

Dose-dependence of the incidence of cataracts is evaluated using the χ^2-test.

MODIFICATIONS OF THE METHOD

Anderson et al. (1988) observed massive cortical cataract 15–30 days after a single injection of an overdose of sodium selenite into 14-day-old rats.

Watanabe and Shearer (1989) studied the release of crystallins from the lens into aqueous an vitreous humor in rats with a selenite overdose cataract.

Huang et al. (1991) studied DNA damage, repair, and replication in selenite-induced cataract in rat lens.

Huang et al. (1992) observed cataract formation in lenses from rat receiving multiple, low doses of sodium selenite.

Kelley et al. (1993) demonstrated a marked reduction in alpha-crystallin chaperone activity by calpain II in selenite cataract induced in young rats.

Zhao and Shichi (1998) tested the prevention of cataract and other ocular tissue damage induced by injection of 350 mg/kg **acetaminophen** and induction of cytochrome P450 in C57BL/6 mice.

Kojima et al. (1996), Shui et al. (1997) studied cataract formation in Brown Norway rats treated with X-ray irradiation and **corticosteroids** using slit lamp microscopy, photography with a Scheimpflug camera and scanning electron microscopy.

Hatano and Kojima (1996) induced cataract in Brown Norway rats by **UV-B irradiation** and pretreatment with **l-buthionine sulfoximine**.

Ishida et al. (1997) treated adult rats with oral doses of 0.2, 1 or 5 mg/kf **FK506 (tacrolimus)** over 13 weeks. In the highest dose, cataract development was observed.

Cataract formation in **transgenic mice** was studied by Mitton et al. (1996) and by Cammarata et al. (1999).

0.6.1 N-Methyl-N-Nitrosourea Cataract Induction Sprague-Dawley Rats

PURPOSE AND RATIONALE

Cataracts can be induced in rats by injection of N-methyl-N-nitrosourea (MNU). Yoshizawa et al. (2000) utilized a direct acting alkylating agent to induce cataractous lesions in neonatal stage of critical development. Longstanding evidence of lenticular tissue susceptibility to N-methyl-N-nitrosourea (Murthy et al. 1972, 1979, Roy et al., 1989, and Smith et al. 1988) and retinal tissue susceptibility to N-methyl-N-nitrosourea (Nakajima et al. 1996, Nambu et al. 1997, Taomoto et al. 1998, Yuge et al. 1996) has been documented.

PROCEDURE

Chemical and dose formulation were prepared as follows. N-Methyl-N-nitrosourea(MNU) was purchased from Nacalai Tesque (Kyoto) and kept at −20°C in the dark. Just before use, MNU solution was dissolved in physiological saline containing 0.05% acetic acid. A total of 254 rats (male: 120, female 134) received a single IP injection of 100 mg/kg body weight of MNU at 0 (day of birth), 5, 10, 15, or 20 days of age. For sequential observation the rats treated on days 0 and 5 (groups 1 and 2, respectively were killed 1, 2, 3, 5, 7, or 14 days after dosing. Those treated on days 10, 15, and 20 (groups 3, 4, and 5, respectively) were euthanized 3, 7, 14, and 30 days after dosing. The rats were observed daily for clinical signs and 8 (group 1) or 4 (groups 2–5) randomly selected rats were weighed on each examination day and euthanized. At each time point, 4 untreated rats were euthanized for comparison.

At necropsy, bilateral eyeballs were macroscopically examined and quickly removed using an operation microscope K-280 (Konan, Tokyo and complete necropsy was done on all animals.

Acquired tissue was fixed and processed. At each time point 1 eye was fixed overnight in 10% neutral buffered formalin, and the other was fixed either in Davidson solution (2 eyes of each group, in methacarn methanol:chloroform:acetic acid, 6:3:1, 2 or 4 eyes of each group), or in 2.5% glutaraldehyde solution (2 eyes of group 1). The formalin-, Davidson-, and methacarn-fixed tissues were routinely processed for paraffin embedding and stained with hematoxylin and eosin (HE), and selective sections were used for TUNEL staining. Lenses from day 0 MNU-treated rats (group 1) as well as age-matched untreated rats, prefixed in 2.5% glutaraldehyde solution, were postfixed

in 2% OsO_4 and processed for Luveak-812 embedding. One-micrometer thick sections stained with toluidine blue were used to locate areas for electron microscopy. Ultrathin sections stained with uranyl acetate and lead citrate were examined with uranyl acetate and lead citrate were examined with a Hitachi H-600 electron microscope (Hitachi, Tokyo).

EVALUATION

Cataractous lesions are examined by immunohistochemical analysis, in situ detection of apoptosis, DNA fragmentation and Western blotting of Bcl-2 and Bax Proteins, Caspase – 3/CPP 32 Protease activity assay, and cataract index. Immunohistochemical detection of 7-Methyldeoxyguanosine (7-mdGua) adducts was performed to detect DNA methylamine adducts. Per methods from Sato et al. (1986) eyes from sacrificed rats were fixed in acetone methylbenzoate xylene (Amex) and processed for paraffin embedding. Per methods by Ozaki et al. (1993), deparaffinized sections treated with 0.05 N sodium hydroxide in 40% ethanol for 15 seconds, and 1% nonfat milk in phosphate-buffered saline for 1 hour and then exposed to primary antibody (× 1,000) at 4°C overnight. Immunohistochemistry was carried out using a labeled streptavidin biotin kit (Dako, Carpineteria, CA). 3,3′-Diaminobenzidine tetrahydrochloride (DAB, Wako Pure Chemicals, Osaka) was used for antigen visualization.

In situ detection of apoptosis by TUNEL was carried out using an apoptosis detection kit (Apop-Tag, Oncor, Gaithersburg, MD). Cells with fragmented nuclei in HE-stained sections correlated well with the TUNEL-positive cells. The apoptotic index (number of fragmentation nuclei per whole nuclei × 100) was determined in HE-stained sections and compared among groups. A total of approximately 300 lens epithelial cells located in the germinative zone were counted.

DNA fragmentation was compared with apoptotic methods. The genomic DNA was isolated from the excised lenses (each sample contained 8 whole rat lens with the use of a SepaGene kit (Sanko, Tokyo) based on the guanidine thiocyanate extraction procedure. Per methods from Nambu et al. (1998) an equal amount of DNA sample (10 µg/lane) was subjected to electrophoresis on a horizontal 0.8% agarose gel containing ethidium bromide and visualized under ultraviolet illuminations.

Western Blotting of Bcl-2 and Bax proteins was performed to detect downregulation and upregulation, respectively as a downstream expression within the apoptotic cascade. Lenses were minced and homogenized in PBS (-). The homogenate was sonicated 3 times and centrifuged at 14,000 × *g* for 30 minutes. Per methods by Laemmli (1970) the supernatant was diluted with lysis buffer, and tissue extracts containing 50 µg of total protein were subjected to 12% SDS-PAGE. Proteins were blotted to nitrocellulose membrane (Bio-Rad, Hercules, CA). After the nonspecific protein binding had been blocked with 5% nonfat dry milk in PBS for 30 minutes, blots were incubated at 4°C overnight in antimous/rat Bax (PharMingen, CA. × 200 dilution in PBS with 1% BSA) or anti-Bcl-2 (PharMingen, CA, × 200) antibody. After being washed 3 times in buffer containing 1% Triton × 100, blots were incubated for 30 minutes in EnVision + (× 20, Dako Glostrup) and treated with DAB for color development. The density of each band was evaluated by computer-associated scanner densitometry (NIH image).

Caspase-3/CPP 32 Protease activity assay was used to examine for CPP-32 activation after lens epithelial cells and to differentiate a-nucleated lens fibers (Ishizaki et al. 1998). Caspase 3 activity of lenses was assayed using caspase 3/CPP32 colorimetric protease assay kit (MBL, Nagoya). Same protein samples used for western blotting were homogenized in 500 µl of lysis buffer, and homogenates were centrifuged at 10,000 × *g* for 1 minute. Supernatants were prepared to 100 µg protein/50 µl lysis buffer, and 50 µl were added to reaction buffer and incubated for 2 hours at 37°C with 200 µM DEVD (Asp-Glu-Val-Asp)-p NA substrate (MBL, Nagoya). Reactions were monitored in a microplate reader at an excitation wave length of 405 nm.

Cataract index was assigned to determine severity of cataract. In routinely prepared HE-stained tissue sections, bilateral eye specimens were evaluated based on the presence of the following 7 items: 1) lens epithelial apoptosis, 2) lens epithelial desquamation 3) multilayered spindle epithelium, 4) lens fiber swelling, 5) liquefaction/vacuolar change, 6) calcification and 7) bizarre nuclei of lens fiber cells. Each item was arbitrarily scored as absent (point 0), slight (point 1), moderate (point 2), severe (point 3), and very severe (point 4). The cataract index was the sum of each score.

MODIFICATIONS OF THE METHOD

Kiuchi et al. (2002) altered the age at injection and confirmed presence of cataracts by histological methods. Cataract was induced by single intraperitoneal injection of N-methyl-N-nitrosourea in 15-day-old Sprague-Dawley (Jcl:SD) rats. Threshold dose

of MNU required for cataract induction in a 3–4 week time period was 70 mg/kg. Males and females were both equally affected. Mature cataract was confirmed histologically by degeneration, swelling, vacuolation, liquefaction of the lens fibers and formation of Morgagni-like water vacuoles.

Miki et al. (2006) used the model to compare the effects of differences in gender and gonadal status on the occurrence of N-methyl-N-nitrosourea induced cataract and retinopathy in Lewis rats. Ovary-intact, ovariectomized, testis-intact and testectomized rats were used for the study. Castration was performed at 36 days of age, 50 mg/kg MNU was administered intraperitoneally at 50 days of age and lens and retinal changes were evaluated at 260 days of age (210 days after MNU injection). Results were assessed by cataract index and retinal damage ratio.

Kiuchi et al. (2003) adapted cataract model to examine retinal degeneration following single injection of 60 mg/kg body weight of N-methyl-N-nitrosourea into Sprague-Dawley rats. Retinal degeneration was confirmed by electroretinogram (ERG) recordings and morphometric analysis of retinal thickness and damaged retinal area. For ERG, animals were dark-adapted for 12 hours and prepared under dim red light. ERGs were recorded with a gold wire loop on the cornea using 1% tetracaine topical anesthesia and a drop of 1% methylcellulose. A gold wire electrode was placed on the sclera 1 mm from the temporal limbus. Ground electrode was placed on the ear. Signals were bandpass amplified using a computer-assisted signal averaging system. Scotopic ERG responses averaged with a stimulus interval of 3 to 60 seconds and 20–30 scotopic responses were averaged with a stimulus interval of 1 second. Strobe flash stimuli were presented in a Ganzfeld bowl (Model GS2000; LACE Electronica sel via marmiccilo, Pisa, Italy). Immediately after ERG animals were sacrificed and morphometric analysis was completed. Tissues were fixed and processed as above. Then, color images of stained sections were obtained as PICT files with a Fujix HC-2000 high-resolution digital camera (Fujifilm, Tokyo, Japan). Brightness and contrast of each image file were uniformly enhanced using Adobe Photoshop version 4.0 and images were analyzed using NIH imaging freeware. Total retinal thickness (from the internal limiting membrane to the pigment epithelium) and photoreceptor cell thickness (thickness of the outer nuclear layer and photoreceptor layer were measured and the photoreceptor ratio (photoreceptor cell thickness/total retinal thickness × 100) was calculated as described by Yoshizawa et al. (2000). Measurements were taken at the posterior pole (approximately 200 µm on either side of the optic nerve). Area of retinal damage was determined from sections prepared at megaloscopic magnification and color images obtained as PICT files using high- resolution digital slide scanner (Dimage Scan Multi: Minolta, Tokyo, Japan. Entire length of retinal and length of damaged area were measured on brightness and contrast enhanced images. Damaged area was defined as the presence of fewer than 4 photoreceptor cells in the outer nuclear layer and the retinal damage ratio was defined as length of damaged retina/length of whole retina × 100.

CRITICAL ASSESSMENT OF THE METHOD

Most animal models cause more or less complete opacification whereas human cataracts start as many focal points in different lens layers. Human lens layers include: anterior capsule, cortex, nucleus, and posterior capsule. Age related human lenticular cataractous changes are localizable in these layers and termed capsular opacities, anterior cortical cataracts, nuclear sclerosis and posterior subcapsular cataracts respectively.

0.6.2 TGFβ Cataract Induction in Wistar Rats

PURPOSE AND RATIONALE

Hales et al. (1999) used TGFβ normally secreted by transforming cells to stimulate growth of normal cells for cataract induction. Previous studies by Lui et al. (1994) and Hales et al. (1994) reported that TGFβ specifically stimulates growth of lens epithelial cells evidenced by aberrant morphologic and molecular changes that mimic those documented in some forms of human cataract.

PROCEDURE

Male Wistar rats were killed at 15 weeks, one at 6 weeks and one at 12 weeks. Per methods by Schulz et al. (1996), following euthanizing, eyes were removed and placed in culture dishes containing Medium 199 (Trace Biosciences, Sydney, Australia) with BSA and antibiotics.

EVALUATION

Both eyes from four rats were fixed whole for routine histology to determine the influence of TGFβ on all ocular tissues. Lenses removed from remaining eyes as whole lens cultures then examined for the presence of opacities and photographed. Representative lenses and whole eyes were fixed in Carnoy's (1:3 acetic acid: ethanol) and processed for routine histology and immunolocalization. Briefly, entire lenses and whole eyes were serially sectioned and collected onto subbed glass slides. Every fifth slide was stained with hematoxylin-eosin (HE)and sections were examined for evidence of plaque formation and/or fiber deterioration. Sections corresponding to those that displayed histological changes were used for immunolocalization of β-crystallin and the extra cellular matrix proteins laminin and type I collagen. Nuclei were counterstained (Hoechst 33258; Boehringer-Mannheim, La Jolla, CA).

Photographed lenses were examined for displaying loss of clarity and changes in cellular architecture. Cell rupture of fibers if evident would be a result of needle tip penetration of capsule rather than an alteration induced by TGFβ.

Micrographs of lenses were assessed for transparency. Lack of transparency was detectable as the presence of distinct subcapsular opacities toward the anterior and/or posterior poles of the lens, or a generalized more diffuse clouding involving the cortical fiber cells.

Histological examination of serial sections compared controls vs. TGFβ eyes. Control eyes maintained a normal lens equator and bow zone and eyes injected with TGFβ revealed the characteristic appearance of lens equator and bow zone disruption histologically. An abnormal finding in eyes injected with TGFβ may also be evidenced by nucleated fiber cells in the lens cortex and extending toward the posterior pole. Mikuni (1980) and Vrensen (1995) have recognized that severe disruption of the ordered arrangement of nuclei at the rat lens equator and in the bow region as well as rat lenses that atypically retain their nuclei beyond the bow region resemble the changes in lenses associated with human cortical cataract. Finally, cataractous growth from TGFβ injected eyes was viewed for their tendency to lose their uniform curvature, as depicted by an undulating capsule.

HE stained sections were observed for plaque formation. Positive plaque formation is demonstrated in slides containing subscapsular plaques with cells appearing rounded and containing large, dense nuclei or others present with matrix deposits where cells appear flattened and slightly elongated except for a layer of epithelial-like cells beneath the matrix deposits.

Immunolocalization following previous methods established by Hales et al. (1995) was performed on HE stained sections that were histologically positive for abnormalities. Sections were assessed immunologically for deposits of laminin and type I collagen by reactivity with laminin.

MODIFICATIONS OF THE METHOD

Fujinaga (1990) conducted long-term observations on 180 Wistar male rats to demonstrate similarities between the senile Wistar rat cataract and the human senile cataract. Other variables under study included agents thought to slow the progression of cataracts. Rats were initially classified into six groups (control, vitamin E diet, ARI, EPC eye drops, catalin eye drops and reduced catalin eye drops) to study the effects of the agents on the cataract. Effects of anti-cataract agents were investigated using cultured lens epithelial cells.

0.6.3 Diabetic Cataract Formation in Sprague Dawley Rats

PURPOSE AND RATIONALE

Diabetic cataract formation was induced in rats by injection of streptozocin. Takamura et al. (2001) employed the diabetic cataract model to study apoptosis in lens epithelial cells.

PROCEDURE

Sprague-Dawley rats that were three weeks old were intraperitonealy injected with 0.1 mg/g bodyweight of streptozotocin (Sigma, St. Louis, MO, USA) to prepare a rat diabetes model. All rats weighed 50 g. Every other week between 4 and 12 weeks of age the lens anterior capsule was excised for subsequent epithelial proliferation studies. A total of 60 rats were used; twelve rats were used each time. Diabetic inclusion criteria were defined as a blood glucose level of 200 mg/dL or higher, which was measured twice: One week after streptozotocin administration and prior to excision of the anterior capsules. Rats were sacrificed with ether anesthesia and the eyeballs were immediately extracted, incised at the posterior lens capsular side, and the anterior capsules with lens epithelial cells were obtained.

Once the rat diabetes model was established, immunostaining of proliferating cell nuclear antigen (PCNA)was performed. This is an index of nuclear DNA synthesis. Each sample was fixed in 0.1M phosphate buffer (pH 7.4) containing methanol for anti-PCNA immunohistochemical analysis.

To perform immunohistochemical staining of PCNA the avidin-biotin complex method (ABC method) was applied. ABC method utilizes a Histofine SAB-PO(M) kit (Nichirei, Tokyo) and anti-PCNA monoclonal antibody (mouse monoclonal antibody NC012; Novocastra Lab, Newcastle, UK) as the primary antibody. Samples without treatment with anti-PCNA monoclonal antibody represented the negative control in each staining. Light microscopy via a differential interference prism (Olympus, Tokyo) was completed to observe fragments.

EVALUATION

Diabetic cataracts of the anterior lens capsules are examined by immunohistochemical analysis. Sprague-Dawley rats injected with streptozotocin can serve as a model for the formation of diabetic cataracts and studying lens epithelial apoptosis. In the absence of high glucose levels the non-diabetic lens epithelial cells survive independently of signals from other cells and produce a factor that inhibits cell death or apoptosis (Ishizaki et al. (1993), Raff et al. (1993).

MODIFICATIONS OF THE METHOD

Gavrieli et al. (1992) observed lens epithelial proliferation and detected an amount of fragmented DNA rep-

resenting apoptotic cell bodies by using the TUNEL method. In this method, diabetic cataracts are induced as above and the anterior capsule is excised as above. Then each sample was fixed in 0.1M phosphate buffer (pH 7.4) containing 4% paraformaldehyde for the Terminal deoxynucleotidyl transferase (TdT-mediated dUTP-biotin nick end labeling (TUNEL) method for immunohistochemical analysis. Specimens of anterior capsule were then extended on glass slides and treated with 10-fold diluted proteinase K (DAKO, Glostrup, Denmark). ApopDETEK (DAKO) was used for TdT reaction, and Horseradish Peroxidase-DAB in situ Detection System (DAKO) was used for reaction of biotin-labeled dUTP with peroxidase-avidin complex. Samples without treatment with TdT represented the negative control in each staining.

Umemura et al. (1996) extended the duration of sample fixation and concentration of proteolytic enzymes. This may increase the ratio of TUNEL-positive cells to whole fragments which would improve the relationship between the types of cataract and diabetes. The results show that DNA is fragmented over time in fixed preparations so that an increased duration may be necessary.

Hegde et al. (2003) investigated the suitability of using CD-1 mice, a species known to have low lens aldose reductase activity as a streptozotocin diabetic cataract induced model. The mice were injected with streptozotocin and blood glucose evaluated seven days post injection. Diabetic inclusion criteria were defined as a blood glucose level of 300–400 mg/dL or higher. Animals were examined by direct ophthalmoscopy, slit lamp examination and Scheimpflug photography. Additionally morphological studies were performed to view multilayered and numerous nucleated cells in the superficial anterior cortex.

Lee et al. (1994, 1999) compared diabetic cataract formation in transgenic mice that overexpress aldose reductase. The entire 1.4-kb cDNA from a human AR (hAR) clone with 36-bp 5′ and 325-bp 3′ untranslated regions (16) was released from the Bluescript vector by Xba 1 and EcoRV digests and inserted into the Xba I and Msc I site of the pCAT-Basic vector (Promega) that contains the simian virus 40 splice site and poly (A) sequence. A single intraperitoneal injection of streptozotocin at a dose of 200 mg/kg of body weight induced hyperglycemia. Lenses were examined through a dilated pupil. The study showed that these transgenic mice that overexpress aldose reductase in their lens epithelial cells were found to become susceptible to the development of diabetic and galactose cataracts.

0.6.4 Cataract Formation in Knock Out Mice

PURPOSE AND RATIONALE

Cataract formation was studied in genetically altered mice to detect factors influencing cataract origination and progression. Brady et al. (1997) studied the influence of αA-crystallin (αA), a dominant protein in the lens, on cataract initiation and development.

PROCEDURE

αA Gene knockout mice were generated as follows. A λ phage clone spanning 16 kb of the αA locus was isolated from a 129Sv mouse genomic library (Stratagene). A targeting vector was constructed by placing the following pieces of DNA, in the given order, into the plasmid pBluescript (Pro-mega): a 9-kb NotI/AatII restriction fragment encompassing the 5′ flanking region and first nine nucleotides of the αA coding region, the phosphoglycerate kinase neomycin phosphotransferase (PGK/neo) expression cassette from the vector pPNT (24) in opposite transcriptional orientation to the αA gene, a 1.3-kb XhoI/XmnI restriction fragment containing most of the first intron and part of the second exon of the αA gene in the same orientation as the αA promoter fragment, and the PGK/herpes simplex virus thymidine kinase expression cassette of pPNT in the same orientation as the aA sequences. In addition, to ensure that no protein-encoding transcripts

could be produced by the disrupted allele, a double-stranded oligonucleotide containing translation termination codons in all three reading frames as well as a copy of the αA polyadenylylation signal was inserted between the 5′ αA sequence and the PGK/neo cassette. Linearized knockout plasmid DNA (30 mg) was electroporated into 4×10^7 J1 embryonic stem cells derived from 129Sv mice. Cell lines established from 192 colonies surviving double selection with the neomycin analogue G418 and ganciclovir were analyzed by PCR for homologous recombination at the αA locus. Correctly targeted embryonic stem cells, confirmed by Southern blot analysis, were injected into C57BL/6 blastocysts and then implanted into pseudopregnant CD1 female mice. Chimeric males were mated to 129Sv or B6D2F1 females, and heterozygous offspring identified by PCR were interbred to produce mice homozygous for the αA knockout allele.

Mice that were homozygous for the disrupted allele produced no detectable αA in their lenses. Initially, the αA-deficient lenses appeared structurally normal, but they were smaller than the lenses of wild-type littermates. Later on, the lenses developed an opacification that started in the nucleus and progressed to a general opacification with age.

EVALUATION

Eyes were examined by slit lamp, histo-and immunochemistry and protein analyses. It is suggested that such knock-out mice can serve as a model for studying the formation and drug treatment of cataracts.

0.7 Models of Eye Inflammation

0.7.1 Allergic Conjunctivitis

PURPOSE AND RATIONALE

Allergic conjunctivitis is a common clinical condition that resembles immediate hypersensitivity reactions in the nose, airways, and skin in many aspects. Allergic conjunctivitis is regarded as a mast cell-mediated disease: a similar array of inflammatory mediators, mostly histamine, is released, and the conjunctiva is responsive to many of these inflammatory mediators.

Trocme et al. (1986), Fukushima et al. (1997), Iwamoto et al. (1999) induced allergic blepharoconjunctivitis in rats by immunization with ovalbumin. Keane-Myers et al. (1999) sensitized and challenged mice by local application of a cat dander extract. Ragweed pollen was used for sensitization of mice by Merayo-Lloves et al. (1996), Hu et al. (1998), Magone et al. (1998, 2000).

PROCEDURE

An extract of ragweed pollen is prepared. Ragweed is defatted with acetone and extracted with 50 mM Tris buffer overnight. The extract is then dialyzed against PBS for 48 h, filtered, and stored at 4°C until use. Protein concentration is determined with Coomassie plus protein assay. The ragweed extract is biotinylated. An $Al(OH)_3$ gel (alum) is prepared, centrifuged for 15 min at 1000 rpm and stored at 4°C. Ragweed and alum are mixed at a concentration of 50 µg ragweed in 5 mg of alum 40 min before immunization. On day 0 mice are anesthetized with methoxyflurane during the injection of ragweed and alum in one hind footpad. On day 10, conjunctivitis is induced by topical application of 1.5 mg ragweed suspended in 10 ml phosphate buffered saline, pH 7.2, into each eye. Two groups of control mice are either not immunized or immunized with alum alone; both groups are challenged with the same dose of ragweed on day 10. The animals are sacrificed 20 min and 3, 6, 12, 24, 48, and 72 h after topical ragweed administration.

Animals are examined clinically for signs of immediate hypersensitivity response 20 min after the topical application of ragweed. Chemosis, conjunctival redness, lid edema, and tearing were each graded on a 0–3+ scale. The total score consists of the sum of scores in each of these four categories.

For histology, the eyes are enucleated with the attached lids and intact conjunctiva and immediately fixed in 4% glutaraldehyde for 30 min and then transferred to 4% formaldehyde for at least 24 h before processing. The tissue is embedded in methyl acrylate, serially sectioned and stained. The numbers of infiltrating neutrophils, eosinophils, goblet cells, and mast cells in one section are counted. Immunohistochemical staining is performed with rat primary antibodies using an avidin-biotin-peroxidase complex technique. Macrophages and lymphocytes in one section of the conjunctiva are assessed.

EVALUATION

All results are presented as mean ±SE. Comparisons between immunized mice, drug treated mice

and controls are made with the two-sided Student's *t*-test.

MODIFICATIONS OF THE METHOD

Hu S et al. (1998) compared effectiveness and molecular pharmacological mechanisms of antiallergic agents on experimental conjunctivitis induced by ragweed in SWR/J mice. Allergic conjunctivitis was evaluated by scoring of the clinical signs and histopathology. mRNA expression of interleukin 1β, IL-6 and tumor necrosis factor α was analyzed by reverse transcription polymerase chain reaction techniques.

Woodward et al. (1995) studied the pruritogenic and inflammatory effects of prostanoids in the conjunctiva in **guinea pigs** and counted the scratching episodes by the hind limb.

Reichel et al. (1998) established a simple model of **conjunctival wound healing** in the mouse eye. Four week old BABL/c mouse eyes were studied over a 14 day period. Surgical procedure under general anesthesia involved a blunt dissection of the conjunctiva performed by injection of 25 µl of phosphate buffered saline via a 27 gauge needle into one eye, while the was used as control.

0.7.2 Corneal Inflammation

PURPOSE AND RATIONALE

Unlike the conjunctiva, the cornea is an avascular tissue. The cornea serves three major functions: protection, refraction and light transmission. Corneal inflammatory diseases usually result from injury and infection rather than from allergic disorders. Models involving chemical or mechanical injury, therefore, directly mimic clinically encountered situations.

Leibowitz and Kupferman (1974) induced inflammatory response by the injection of clove oil directly into the corneal stroma, resulting in the chemotactic attraction of large numbers of polymorphonuclear leukocytes.

PROCEDURE

New Zealand albino rabbits of either sex are anesthetized with 15 mg/kg i.v. sodium thiamylal. A corneal inflammatory response is produced in both eyes by the interlaminar inoculation 0.03 ml of laboratory grade clove oil centrally with a 30-gauge needle attached to a tuberculin syringe. All animals receive two intravenous injections of 0.05 mCi/kg of tritiated thymidine (0.7 Ci/mM) 24 h apart. The second thymidine injection is given 24 h prior to the induction of the corneal inflammatory response. Therapy is initiated immediately after the intracorneal injection of clove oil consisting of one drop (0.05 ml) of test compound or standard every hour for a total of 6 doses. One h later, the animals are sacrificed under anesthesia and a 10 mm penetrating corneal button is removed by

trephination. The tissue samples are solubilized with a commercially available solubilizing agent (Soluene, Packard Instruments Corp.). The samples are counted in a scintillation counter for 10 min and the amount of radioactivity in each cornea documented.

EVALUATION

The data from individually treated eyes are expressed as percent change in radioactivity relative to their own untreated control eyes. These differences are averaged to determine a mean value for each treatment group. Statistical comparisons are performed by standard methods including random block analysis.

MODIFICATIONS OF THE METHOD

Neovascularization of the rabbit cornea has been used by several authors to study inhibition of angiogenesis (see Sect. A.8.3.4).

Alio et al. (1994, 1995) studied the relative effectiveness of nonsteroidal anti-inflammatory drugs versus corticosteroids and of antioxidants in the topical treatment of experimental acute corneal inflammation induced by corneal alkali burn in rabbits. The corneal inflammatory response was evaluated by Luminol-enhanced chemiluminescence, ultrasonic pachymetry, and computer-assisted analysis of the area of corneal ulceration.

Laria et al. (1997) evaluated combined non-steroidal therapy in experimental corneal injury. A corneal alkali burn was induced in New Zealand white rabbits by applying 1-N NaOH filter paper on the central axis of the right cornea for 30 s. The inflammatory index, area and perimeter of the wounded corneal zone, and corneal transparency were evaluated after 5 days treatment.

A similar method was used by Ozturk et al. (2000).

Sonoda et al. (1998) studied inhibition of corneal inflammation by the topical use of Ras farnesyltransferase inhibitors. The central corneas of BALB/c **mice** were cauterized with silver nitrate. Clinical signs and neovascularization were evaluated.

0.7.3 Auto-Immune Uveitis in Rats

PURPOSE AND RATIONALE

The mechanisms of certain types of uveitis have been studied in animals involving autoimmunity. Uveitis has been produced in guinea pigs following injections with homologous uveal tissue.

PROCEDURE

Hartley strain guinea pigs, weighing 400–500 g, are injected at 0, 1, 2, 5, and 8 weeks with a 10% suspension of homologous retina emulsified in Freund's complete adjuvant. The retinas are obtained by dissection of freshly removed eyes of either normal albino or pigmented guinea pigs and stored frozen at –50°C. Each animal receives 0.2 ml of this emulsion at a time, the first injection being administered intradermally into both hind foot-paws, and the remainder of the series given intramuscularly. Groups of 6 animals receive the test drug or the vehicle orally. Control animals receive similar injections of saline. The severity of the uveal inflammation can be clinically evaluated by slit lamp examination. The animals are sacrificed and the eyes are examined histologically.

EVALUATION

The incidence of uveitis is recorded by histological means as percentage of treated animals.

MODIFICATIONS OF THE METHOD

Highly purified bovine retinal S antigen in complete Freund's adjuvant was injected subcutaneously in **guinea pigs** to induce experimental autoimmune uveitis (Liversidge et al. 1987; Mahlberg et al. 1987).

Cultured retinal pigment epithelial cells from guinea pigs were used by Liversidge et al. (1988).

Experimental autoimmune uveitis has been induced in **rats** (Nussenblatt et al. 1981; Chan et al. 1984, 1987; Mochizuki et al. 1985; Fujino et al. 1988).

Experimental autoimmune uveoretinitis was in-

duced in Lewis rats by injection of very high doses of bovine opsin (Brockhuyse et al. 1987).

Melanin-associated antigen from the iris and ciliar body was used to induce experimental autoimmune anterior uveitis in male Lewis rats by Bora et al. (1995).

Ramanathan et al. (1996) found that recombinant IL-4 aggravates experimental autoimmune uveoretinitis in Lewis rats.

Hanashiro et al. (1997) injected various doses of either lipopolysaccharide or the lipid A region of the lipopolysaccharide into the foot pad of an inbred strain of Lewis rats and compared the inflammation patterns by assessing the protein concentrations and the inflammatory cell content in the aqueous humor.

Merino et al. (1998) reported that lipoteichoic acid from *Staphylococcus aureus* injected into the foot pad of Lewis rats induced a strong ocular inflammation between 24 and 30 h after injection.

Hikita et al. (1995) evaluated the effects of topical FK506 on endotoxin-induced uveitis in the Lewis rat.

Tsuji et al. (1997) investigated the effects of systemically and topically applied betamethasone derivatives on endotoxin-induced uveitis in female Lewis rats.

McMenamin and Crewe (1995) studied kinetics and phenotype of the inflammatory cell infiltrate and the response of the resident tissue macrophages and dendritic cells in the iris and ciliary body in endotoxin-induced uveitis in Lewis rats.

Uchio et al. (1997) achieved suppression of actively induced experimental autoimmune uveoretinitis in rats by $CD4^+$ T cells.

Egwuagu et al. (1999) found in transgenic Lewis rats that expression of interferon-gamma in the lens exacerbates anterior uveitis and induces degenerative changes in the retina.

Immunogenic uveitis in **rabbits** was studied by Kaswan and Kaplan (1988).

Jamieson et al. (1989) sensitized rabbits to bovine serum proteins and then challenged intravitreally to induce an uveitis. They recommended this procedure as a model for anti-inflammatory drug screening.

Whitcup et al. (1996) produced endotoxin-induced uveitis in **mice** by injecting 200 µg *Salmonella typhimurium* endotoxin diluted in 0.1 ml sterile saline into one hindpad.

Geiger et al. (1994) reported that transgenic mice expressing IFN-gamma in the retina develop inflammation in the eye and photoreceptor loss.

0.7.4 Ocular Inflammation Induced by Paracentesis

PURPOSE AND RATIONALE

Paracentesis stimulates prostaglandin PGE_2 and $PGF_{2\alpha}$ release into the anterior chamber of the eye which can be inhibited by antiinflammatory agents (Miller et al. 1973; Kulkarni and Srinivasan 1985).

PROCEDURE

New Zealand white rabbits (2.0 to 2.5 kg) are anesthetized with a 50:50 mixture of xylazine (20 mg/kg) and ketamine (100 mg/kg) i.m. Test compounds are topically administered by placing three drops (about 60 µl) on each eye. The eyes are then taped shut to prevent drying. One hour after compound or vehicle administration, inflammation is induced by paracentesis. For each rabbit, the aqueous humor from both eyes is combined to form the "Pre" sample. Three more drops of compound or vehicle are again administered to each eye and the eyes taped shut. Another one-hour period is allowed to elapse, enough time for the aqueous humor to build back up in the eye. Paracentesis is performed a second time and the aqueous humor from both eyes is combined to form the "Post" sample. Prior to this second paracentesis, the general appearance of the eye is rated on a scale of 1 to 3, based on the following criteria: 1 = clear, relatively normal appearance; 2 = opaque, some protein accumulation in the anterior chamber; 3 = very cloudy, protein accumulates in clumps in the anterior chamber, hyperemia, swelling. This rating gives some indication of the extent of inflammation and correlates with the amount of prostaglandin accumulation. Prostaglandins are measured in 10 µl of aqueous humor from the "Pre" and "Post" samples by RIA.

EVALUATION

The amount of prostaglandin present is determined according to the standard curve supplied with each RIA kit. The extent of inflammation is determined by the magnitude of increase in prostaglandin levels in the "Post" versus the "Pre" sample. Dose-response curves for inhibition by test drug and standard are established.

MODIFICATIONS OF THE METHOD

Struck et al. (1995) studied the effects of non-steroidal anti-inflammatory drugs on inflammatory reactions. The right eye of rabbits was burned with alkali (0.25 M sodium hydroxide). The animal were treated with eye drops containing a cyclooxygenase inhibitor and a leukotriene antagonist. Hyperemia of the limbal vessels, corneal vascularization, the number of PMNLs in the cornea and the prostacyclin level in the anterior chamber of the eye served as criteria.

0.7.5 Ocular Inflammation by Lens Proteins

PURPOSE AND RATIONALE

Ocular inflammation can be induced by lens proteins which can be prevented by lipoxygenase inhibitors (Miyano and Chiou 1984; Chiou and Chiou 1985; Chang and Chiou 1989).

PROCEDURE

New Zealand albino rabbits are anesthetized by i.m. injection of 25 mg/kg ketamine hydrochloride and 5 mg/kg xylazine. The anesthesia is maintained by injection of 12.25 mg/kg ketamine and 2.5 mg/kg xylazine every hour throughout the experiment. After the animals are deeply anesthetized, 50 µl of the drug is topically applied to one eye and the other eye receives 50 µl of the solvent. One hour after the application of the drug, 25 µl of lens protein (30 mg/ml, prepared according to Miyano and Chiou 1984) is injected intracamerally with a 27 1/2 gauge needle; extreme care is taken to avoid contact with the iris. Fifteen min after injection of lens proteins, 14 mg/kg of fluorescein is infused through the marginal ear vein at a rate of 1 ml/min. The inflammation which occurs in the eyes of the rabbits is measured by quantifying the amount of fluorescein leakage into the anterior chamber using a fluorophotometer. Measurements are taken at various intervals after injection of lens proteins. At the end of experiments, the animals are sacrificed by an overdose of pentobarbital sodium. Fluorescence measurements are done at 30, 60, 90, 120, 180, 240 and 300 min intervals.

EVALUATION

The concentration of fluorescein in the anterior chamber is determined by taking the average of three values in each of the fluorometric measurements. The results are analyzed by using a paired *t*-test with *P*-values of less than 0.05 as statistically significant.

MODIFICATIONS OF THE METHOD

Augustin et al. (1996) evaluated the effects of allopurinol in lens induced uveitis by morphological methods and compared these effects with those of steroids and a combination of both drugs biochemically and morphologically.

0.7.6 Proliferative Vitreoretinopathy in Rabbits

PURPOSE AND RATIONALE

Injection of cultured fibroblast cells into the rabbit vitreous results in a condition that mimics the features of proliferative vitreoretinopathy in man (Algvere and Kock 1976; Sugita et al. 1980; Ophir 1982). Proliferative vitreoretinopathy is a complication of severe eye injury or retinal detachment and is a major cause of failure in retinal reattachment surgery. Because of its simplicity and reproducibility, Wiedemann et al. (1984) proposed this model in rabbits as screening model for antiproliferative drugs.

PROCEDURE

Dermal fibroblasts are obtained from skin explants of young rabbits which are prepared by excising a 1 × 1 cm area of dorsal skin and scraping it thoroughly with a scalpel blade to remove hair and subcutaneous fat. The explants are rinsed in sterile PBS, minced finely, and placed in 35-mm Petri dishes containing 200 µl of Dulbecco's medium supplemented with 20% heat-inactivated fetal calf serum, 50 µg/ml garamycin, and 5 µg/ml fungizone. When cells begin to grow, tissue pieces and medium are removed and 2 ml of fresh medium is added. When cells have grown to confluence, they are passaged into 75-cc flasks by rinsing with 1 ml of PBS and incubating with 1 ml of 0.25% trypsin/0.02% EDTA for 5–10 min at room temperature. Subsequent to the initial passage, cells are split at a 1:4 ratio upon reaching confluence. For injection into the vitreous, confluent cells from the third to tenth passage are trypsinized with 0.25% trypsin/0.02% EDTA, centrifuged at 500–600 g, washed twice with the medium, then resuspended in the medium and allowed to stand for 10–15 min to let cell clumps settle. The number of cells in suspension is determined using a Coulter counter. Tuberculin syringes are filled with 600 µl of cell suspension, which allows five injections in 0.01 ml steps.

Pigmented rabbits of either sex weighing 2–3 kg are anesthetized with 2.0–2.5 ml of a 1:1 Rompun-ketamine mixture. The eyes are dilated using one drop of 10% Neo-Synephrine, 1% Mydriacyl, and 1% atropine. Only one eye of each animal in injected using an operating microscope. Fifty thousand, 100000 or 250,000 cells in a total volume of 0.1 ml medium are injected into the posterior portion of the midvitreous through a 27-gauge needle 5 mm from the corneoscleral limbus at the superonasal quadrant. The test drug or the vehicle is injected as a second injection through the same entrance site and is delivered to the same place in the vitreous. Both injections have to be done slowly to prevent posterior retinal holes or deformation of the injected cells by shearing forces. The needle is withdrawn slowly to prevent leakage of vitreous from the wound. A paracentesis is performed to equilibrate the intraocular pressure after the second injection. An ointment containing antibiotics and atropine is applied at the end of the procedure.

EVALUATION

The development of proliferative vitreoretinopathy in the injected eyes is followed by indirect ophthalmoscopy; the appearance of membranes and detachment is documented by fundus photography.

MODIFICATIONS OF THE METHOD

A survey of eye models of inflammation including conjunctivitis, corneal responses to injurious stimuli, uveitis models, and retinal diseases has been presented by Woodward et al. (1989).

Retinopathy in **rats** resembling lesions seen in human retinopathy of prematurity could be provoked in newborn rats by exposure to 80% O_2 for the first 5 days of life (Ricci et al. 1995, 2000).

Hikchi et al. (1996) described an experimental model of ocular inflammation induced by intravitreal injection of interleukin 1 beta in rabbits.

Chapter P
Pharmacological Models in Dermatology

P.1 Skin Sensitization Testing

P.1.1 Guinea Pig Maximization Assay

PURPOSE AND RATIONALE

A variety of methods are available for the prospective identification of skin sensitizing chemicals. The methods that have been used are the Draize rabbit irritancy test (Draize et al. 1944; Phillips et al. 1972), the occluded guinea pig patch test (Buehler 1965), and the guinea pig maximization test (Magnusson and Kligman 1969; Magnusson 1980). The guinea pig maximization test is an adjuvant sensitization test requiring intradermal injections of the test substance, in combination with Freund's complete adjuvant, which stimulates non-specifically the immune system of treated animals, enhancing their ability to respond to sensitizing chemicals.

PROCEDURE

Groups of 15–20 guinea pigs (Hartley strain) are used. On day 0 an area of 4 × 6 cm over the shoulder region is clipped short with an electric clipper. Three pairs of intradermal injections are made simultaneously, so that on each side of the midline there are two rows of injections each. The injection sites are just within the boundaries of the 2 × 4 cm patch, which is applied one week later. Injections are (1) 0.1 ml Freund's adjuvant alone, (2) 0.1 ml test material, and (3) 0.1 ml test material in Freund's adjuvant. Control animals are given the same injections but without the test agent, i. e. Freund's adjuvant and vehicle.

On day 7, the same area over the shoulder region is again clipped and shaved with an electric razor. The test agent in petrolatum is spread over a 2 × 4 cm filter paper in an even, rather thick layer or, if liquid, to saturation. The patch is covered by an overlapping, impermeable plastic adhesive tape. This in turn is firmly secured by an elastic adhesive bandage, which is wound

around the torso of the animal. The dressing is left in place for 48 h. Control animals are exposed to the vehicle without the test agent in the same way as the experimental group.

On day 21, in experimental and control animals the flanks are shaved on both sides on an area of 5 × 5 cm each. Filter paper pieces, 2 × 2 cm, are sealed to the flanks for 24 h with the same occlusive bandage as for topical induction: (1) left side: patch with the test agent in the highest non-irritant concentration. The same vehicle as for topical induction is used; (2) right side: path with the vehicle.

On day 23, reading is made 24 h after removing of the patches. By then, skin irritation due to the occlusive dressing has usually faded.

EVALUATION

If the challenge reactions in the experimental group clearly outweigh those in the control group, the agent is regarded to be a sensitizer. To grade the substances according to the percentage of animals sensitized, the substances are divided into 5 classes, ranging from weak (grade I) to extreme (grade V) sensitizers (Kligman 1966).

MODIFICATIONS OF THE METHOD

Improvement of the classical guinea pig maximization test was proposed by several authors: Maurer et al. (1980a), Shillaker et al. (1989), Botham (1992), Kashima et al. (1993), Basketter et al. (1995), Frankild et al. (1996), Vohr et al. (2000), Steiling et al. (2001).

Maurer et al. (1980b) developed a model for the evaluation of the photocontact allergenic potential in the guinea pig. Four days before the induction period, Pirbright white guinea pigs were shaved on the back skin and chemically depilated. During the 3-week initial induction period, the animals were treated epicutaneously four times a week with the test drug. Four days before the challenge at week 6 the skin was again chemically depilated. During the challenge periods at weeks 6 and 9, the animals were treated for 3 days consecutively with the test drug. To stimulate the immunological reactivity, the guinea pigs received four intradermal injections of Freud adjuvant/saline 1:1. After each application, the animals were irradiated for 15 min with a Osram Xenon 6000 W UV lamp. The intensity of erythematous reactions was evaluated according to the Draize scoring scale.

A predictive assay for contact allergens using human skin explant cultures has been described by Pistoor et al. (1996).

Use of **transgenic animals** to investigate drug hypersensitivity has been proposed by Moser et al. (2001).

P.1.2 Popliteal Lymph Node Hyperplasia Assay

PURPOSE AND RATIONALE

The popliteal lymph node assay in mice or rats has been recommended as a tool for predicting allergies (Kammuller et al. 1989; Bloksma et al. 1995; Koch et al. 2000; Pieters 2001). Moreover, the inhibition of popliteal lymph node hyperplasia can be measured (Schorlemmer et al. 1998; Mollison et al. 1999). The test can be used to study compounds potentially effective in allergic eczema

PROCEDURE

Spleens from Brown-Norway rats are harvested aseptically, splenocytes expressed by compression with a hemostat in Dulbecco's phosphate buffered saline (DPBS), red blood cells lysed with Tris (0.16 M) buffered in ammonium chloride (0.17 M) buffer, washed twice (400 *g*), irradiated (20 Gy), washed in DPBS, and suspended in DPBS at 5×10^7 cells per ml. On day 0, recipient Lewis rats are injected subcutaneously into the plantar surface of the right hindpaw with 0.1 ml of the splenocyte suspension. Compounds are dissolved in an appropriate vehicle and dosed daily, 2 ml/kg, on days 0–3. Recipients are sacrificed on day 4 and popliteal lymph nodes (PLN) from both hind limbs from vehicle control rats, or the right popliteal lymph node from drug-treated rats, are dissected free and weighed individually on a microbalance (Mollison et al. 1993). The average weight of PLN from the left leg of vehicle-treated animals is used as background.

EVALUATION

Percent inhibition is calculated using the following formula:

$$100 - \frac{PLN_{\text{exp.}} - PLN_{\text{mean left}}}{PLN_{\text{mean right}} - PLN_{\text{mean left}}} \times 100$$

$PLN_{\text{exp.}}$ = experimental PLN weight

$PLN_{\text{mean left}}$ = mean vehicle control left PLN weight

$PLN_{\text{mean right}}$ = mean vehicle control right PLN weight

ED_{50} values are derived by simultaneous least square regressive analysis.

P.1.3 Local Lymph Node Assay

PURPOSE AND RATIONALE

More recently, the local lymph node assay in mice has been recommended for measurement of allergenic potency (Kimber and Weisenberger 1989; Kimber et al. 1995; Kimber 2001; Basketter and Scholes 1992; Basketter et al. 2001).

PROCEDURE

Groups of mice (CBA strain), weighing 20–25 g, receive topical applications of the test chemical on the dorsum of both ears, once a day for three consecutive days. In standard analyses, three concentrations of the test material are evaluated together with the relevant vehicle control. Five days after the initiation of exposure, all mice receive an intravenous injection of [^{3}H]-labeled thymidine into their tail vein. Five hours later, animals are sacrificed and draining auricular lymph nodes excised. A single cell suspension of lymph node cells is prepared by gentle mechanical disaggregation and the cells are washed and resuspended in trichloroacetic acid for at least 12 h at 4°C. Precipitates are resuspended in trichloroacetic acid and transferred to an appropriate scintillation fluid. The incorporation by draining lymph node cells of [^{3}H]-labeled thymidine is measured by ß-scintillation counting and recorded as mean disintegrations per min (dpm).

EVALUATION

For each concentration of the test material a stimulation index (*SI*) is derived relative to the concurrent vehicle control. Those chemicals that at one or more test concentrations induce a *SI* of three or greater are classified as skin sensitizers.

Dose-response curves are plotted in order to provide information on the relative potencies of skin sensitizers. The concentration of the test chemical required to produce a stimulation index (*SI*) of three (named *EC3* value) is calculated using the formula:

$$EC3 = c + [(3 - d)/(b - d) \times (a - c)]$$

where the data points lying immediately above and below the *SI* value of three on the dose-response plot have the coordinates (a,b) and (c,d), respectively.

MODIFICATIONS OF THE METHOD

On the basis of a modified local lymph node assay, Homey et al. (1997) analyzed immunosuppressive effects of topically applied drugs. On four consecutive days, NMRI mice were treated on the dorsal surfaces of both ears with increasing concentrations of test compound. During the last three days, the mice received in addition the contact sensitizer, oxazolone (1%). On day 5, draining auricular lymph nodes were removed in order to assess lymph node cell counts and perform flow cytometric analysis of lymph cell subpopulations.

Hariya et al. (1998) developed a non-radioactive endpoint in a modified local lymph node assay.

P.2 Experimental Dermatitis

Several methods involving skin reactions are discussed in other chapters, such as:

- Ultraviolet erythema in guinea pigs (H.3.2.2.1),
- Vascular permeability (H.3.2.2.2),
- Oxazolone-induced ear edema (H.3.2.2.4),
- Croton-oil ear edema in rats and mice (H.3.2.2.5),
- Spontaneous autoimmune diseases in animals (I.2.2.1),
- Passive cutaneous anaphylaxis (I.2.2.4),
- Arthus type immediate hypersensitivity (I.2.2.5),
- Delayed type hypersensitivity (I.2.2.6),
- Reversed passive Arthus reaction (I.2.2.7),
- Acute graft versus host disease (I.2.2.15),
- SLE-like disorder in MRL/lpr mice (I.2.2.16),
- Inhibition of allogenic transplant rejection (I.2.2.20).

P.2.1 Spontaneous Dermatitis

P.2.1.1 NC/Nga Mouse as Model for Atopic Dermatitis

The NC/Nga mouse has been recommended as a model for atopic dermatitis (Matsuda et al. 1997; Tsudzuki et al. 1997; Suto et al. 1999; Vestergaard et al. 1999, 2000; Kotani et al. 2000; Aioi et al. 2001; Kohara et al. 2001). When kept in specific pathogen free conditions, it remains healthy, but when kept in non-sterile conditions, it spontaneously develops a disease resembling atopic dermatitis at the age of 6–7 weeks. The level of IgE in the blood gradually increases to very high levels, and peaks at the age of 16–18 weeks (Matsuda et al. 1997). This enhanced IgE production has been attributed to an increased sensitivity of the B cell to the CD40 ligand and to IL-4, which is the result of enhanced phosphorylation of Janus kinase 3, a feature found also in atopic dermatitis (Matsumoto et al. 1999). At 16–18 weeks, the mice develop dry skin, and, gradually, nodular lesions, which in turn become crusted wounds. The lesions are pruritic and they are located on the back, the neck, the ears and the face. Biophysical parameters show impairment of water retention and barrier function. The amount of ceramide in the skin decreases significantly (Aioi et al. 2001).

Histologically, the skin lesions in the NC/Nga mice are characterized by hyperkeratosis and parakeratosis, which resemble the lichenified lesions observed in atopic dermatitis patients. In the dermis, an infiltration is found, similar to that seen in atopic dermatitis patients, containing lymphocytes, eosinophils, mast cells and macrophages, in addition to a large population of dendritic cells (Vestergaard et al. 1999).

The lesions in the NC/Nga mouse improve after treatment with tacrolimus hydrate (FK506) ointment (Hiroi et al. 1998) and also with topical steroids (Vestergaard et al. 1999). Both treatments reverse the changes in the skin, block the expression of inflammatory cytokines and decrease the serum levels of IgE.

FURTHER DERMATITIS MODELS

Iwasaki et al. (2001) recommended atopic NC/Nga mice as a model for allergic asthma: after immunization with ovalbumin, severe allergic responses were elicited by a single intranasal challenge.

Arai et al. (2004) showed that a prostanoid DP_1 receptor agonist inhibits the pruritic activity in NC/Nga mice with atopic dermatitis.

Mihara et al. (2004) described the vital role of the itch-scratch response in development of spontaneous dermatitis in NC/Nga mice. Capsaicin-sensitive sensory nerves of these mice were ablated by neonatal capsaicin treatment. Scratching behavior was almost completely prevented in these mice and the development of dermatitis and elevation of the serum IgE level were significantly suppressed.

Ohmura et al. (2004) studied the involvement of substance P in scratching behavior in a picrylchloride-induced dermatitis model in NC/Nga mice.

Takano et al. (2004) evaluated the antipruritic effects of several agents on scratching behavior by NC/Nga mice.

Takaoka et al. (2005, 2006) tested the expression of IL-31 gene transcripts in NC/Nga mice with atopic dermatitis. The expression of IL-31 mRNA in the skin of NC/Nga mice with scratching behavior was significantly higher than that in NC/Nga mice without scratching behavior.

Further animal models for atopic dermatitis were described, such as the NOA (Naruto Research Institute Otsuka Atrichia) mouse (Natori et al. 1999; Watanabe et al. 1999). The mice develop ulcerative skin lesions with accumulation of mast cells and increased serum IgE.

A spontaneous mutation characterized by chronic proliferative dermatitis in C57BL mice was described by HogenEsch et al. (1993).

Barton et al. (2000) reported that mice lacking the transcription factor ReIB develop T cell-dependent skin lesions similar to human atopic dermatitis.

Herz et al. (1998) developed a human-SCID mouse model to analyze the possible role of bacterial superantigens in human allergic immune responses under *in vivo* conditions.

Hossen et al. (2005) described the effect of loratadine on atopic-dermatitis-associated pruritus in ICR and hairless mice.

Sonkoly et al. (2006) described IL-31 as a new link between T cells and pruritus in atopic skin inflammation.

Chan et al. (2001) reported that the expression of IL-4 in the epidermis of **transgenic mice** results in a pruritic inflammatory skin disease. The mice spontaneously develop a skin disease reproducing all key features of human atopic dermatitis, including xerosis, conjunctivitis, inflammatory skin lesions, *Staphylococcus aureus* infection, histopathology of chronic dermatitis with T cell, mast cell, macrophage-like mononuclear cell, and eosinophil infiltration, and elevation of total serum IgE and IgG1.

Konishi et al. (2002) demonstrated in IL-18-transgenic mice that IL-18 contributes to the spontaneous development of atopic dermatitis-like inflammatory skin lesion independently of IgE/stat6 under specific pathogen-free conditions.

P.2.1.2 Motheaten Mice

Mice homozygous for the autosomal recessive motheaten (me) or the allelic viable motheaten (me^v) mutations develop severe and early-age onset of systemic autoimmune and inflammatory disease (Green and Shultz 1975; Shultz et al. 1984; Shultz 1988; Kovarik et al. 1994; Su et al. 1998). These mice show arthritis, patchy dermatitis and hemorrhagic pneumonitis; the latter is considered to be the cause of the early death of me and me^v mice at the age of 3 and 9 weeks, respectively.

Homozygous me^v mice are identified first at the age of 3–4 days by focal depigmentation of the skin, followed by patchy absence of hair and by necrotic lesions on paws, tail and ears.

P.2.1.3 Spontaneous Erythema in Hairless Rats

The hairless rat (WBN/Kob-*Ht*) is a dominant mutant derived from the Wistar strain. With an incidence rate of about 4% in both male and female animals, at an age of 20 weeks an erythema appears spontaneously

on the dorsal skin, gradually becoming widespread and progressive in nature (Iwamoto et al. 1997; Tani et al. 1998). Histopathologically, erythema is characterized by dermatitis induced by an immunological reaction. Areas of erythema in the skin were decreased by treatment with dexamethasone (1 mg/kg) or cyclosporine (25 or 50 mg/kg) injected subcutaneously every other day for 2 weeks. The results suggested that erythema on the hairless rat could be used as an animal model of spontaneous dermatitis.

MODIFICATIONS OF THE METHOD

Atopic dermatitis-like symptoms were reported in hypomagnesaemic hairless rats by Chavaz et al. (1984) and Neckermann et al. (2000).

P.2.1.4 Spontaneous Atopic Dermatitis in Dogs

PURPOSE AND RATIONALE

Atopic dermatitis is a known chronic inflammatory skin disease in dogs (Scott et al. 2001).

Olivry et al. (2001) characterized the inflammatory infiltrate during IgE-mediated late phase reactions in the skin of normal and atopic dogs with *Dermatophagoides farinae*-induced allergy.

Nuttall et al. (2002) studied the expression of Th1, Th2 and immunosuppressive gene transcripts in canine atopic dermatitis and found over-production of IL-4. Canine atopic dermatitis was proposed as a possible animal model of human atopic dermatitis.

P.2.2 Contact Dermatitis

P.2.2.1 Contact Hypersensitivity in Animals

PURPOSE AND RATIONALE

The phenomenon of contact hypersensitivity in animals is thought to mirror atopic dermatitis or eczema in patients (Corsini et al. 1979; Cooper 1994; Leung 1997).

P.2.2.1.1 Contact Hypersensitivity in Mice

PROCEDURE

CD1 mice are sensitized on the shaved abdomen with 20 µl of 0.5% 2,4-dinitrofluorobenzene (DNFB) in a vehicle consisting of 95% acetone/5% olive oil on days 0 and 1. On day 5, groups of 10 mice are challenged with 0.2% DNFB with or without co-dissolved drug, 10 µl on both the internal and external surface of both ears. Mice are sacrificed 24 h post-challenge, and a 7 mm diameter circle punched from each ear is weighed immediately on a microbalance.

EVALUATION

The mean earplug weight from naïve mice challenged with 0.2% DNFB are used as background control.

Percent inhibition is calculated using the following formula:

$$100 - \frac{\text{plug}_{\text{exp.}} - \text{plug}_{\text{mean naïve}}}{\text{plug}_{\text{mean sens.}} - \text{plug}_{\text{mean naïve}}} \times 100$$

$\text{plug}_{\text{exp.}}$ = experimental ear plug weight

$\text{plug}_{\text{mean naïve}}$ = mean naïve ear plug weight

$\text{plug}_{\text{mean sens.}}$ = mean sensitized vehicle control plug weight

ED_{50} values are derived by simultaneous least square regressive analysis.

MODIFICATIONS OF THE METHOD

Lowe et al. (1977) used oxazolone-sensitized Swiss Webster **mice** to evaluate anti-inflammatory properties

of a prostaglandin antagonist, a corticosteroid and indomethacin in experimental contact dermatitis.

Studies in mice on allergic contact dermatitis were performed by Ek and Theodorsson (1990), Fraginals et al. (1990), Katayama et al. (1990), Lavaud et al. (1991), Trenam et al. (1991), Stanley et al. (1991), Maguire (1996), and Corsini and Galli (1998).

Grabbe et al. (1995) showed that removal of the majority of epidermal Langerhans cells by topical or systemic steroid application enhances the effector phase of contact hypersensitivity in BALB/c mice.

Koyama et al. (1998) used tenascin-C knockout mice and studied the effect on dinitrofluorobenzene-induced dermatitis.

Meingassner et al. (1997) sensitized female NMRI mice on the shaved abdomen with 50 µl of oxazolone (2% in acetone). After 7 days, they were challenged with 10 µl of 2% (for topical testing) or 0.5% (for systemic testing) oxazolone on the inner surface of the right ear. Compounds were tested topically by a single application of 10 µl ethanolic solution to the challenge site, 30 min after challenge. Compounds were tested for systemic activity by administration of a single subcutaneous injection immediately after challenge or by two oral doses (2 h before and immediately after challenge). The unchallenged left ears served as normal controls. Dermatitis was evaluated from the difference in pinnal weight, which was taken as a measure of inflammatory edema 24 h after challenge.

Traidl et al. (1999) reported inhibition of allergic contact dermatitis to dinitrochlorobenzene (DNCB) but not to oxazolone in interleukin-4-deficient mice.

Morita et al. (1999) reported that fur mites induce dermatitis associated with IgE hyperproduction in NC/Kuj mice. Four-week-old NC/Kuj mice were kept together with NC mice infected with fur mite (*Myocoptes musculinus*) for 2 weeks in isolated clean rooms and thereafter separated. Serum IgE levels were determined and the skin examined histologically.

Matsuoka et al. (2001) described a mouse model of the atopic eczema/dermatitis syndrome by repeated application of a crude extract of house-dust mite *Dermatophagoides farinae*. The mites were cultured in a mixture of mouse diet and dried yeast in culture flasks. A crude extract in PBS was applied to the shaved back of NC/Nga mice or BALB/c mice three times a week for 8 weeks. In the NC/Nga group, dryness and scaling appeared on the skin, and scratching behavior increased at the second week in the treated group. Skin erosion and hemorrhage occurred in the fourth week. The epidermis thickened and deepened into the upper dermis, in which mast cells were highly accumulated, corresponding with the skin lesions of atopic eczema/dermatitis syndrome in patients.

Matsui and Nishikawa (2002) used female specific-pathogen-free BALB/c mice at an age of 6–8 weeks. The animals were barrier-disrupted by repeated applications of adhesive cellophane tape prior to percutaneous sensitization by topical administration of 100 µl of a solution of house dust mite antigen. Seven days after the sensitization, the mice were challenged on the shaved dorsal skin near the ear by subcutaneous injection of 10 µl of mite antigen or lipoteichoic acid from *Staphylococcus aureus* for elicitation of localized skin inflammation. The cytokine response in the dorsal skin was investigated by reverse transcription-polymerase chain reaction and immunohistological analysis.

Spergel et al. (1998) reported that epicutaneous sensitization with ovalbumin induced localized allergic dermatitis and hyper-responsiveness to methacholine after single exposure to aerosolized antigen in mice.

Spergel et al. (1999) used mice with targeted deletions of IL-4, IL-5, and interferon-γ cytokine genes to assess the role of these cytokines in a murine model of allergic dermatitis elicited by epicutaneous sensitization with ovalbumin.

Laouini et al. (2003) used IL-$10^{-/-}$ mice to examine the role of IL-10 in a mouse model of allergic dermatitis induced by epicutaneous sensitization with ovalbumin on tape-stripped skin.

Takeshita et al. (2004) underlined the essential role of MHC II-independent $CD4^+$ T cells, IL-4 and STAT6 in contact hypersensitivity induced by fluorescein isothiocyanate in the mouse and recommended fluorescein-isothiocyanate-induced contact hypersensitivity as a suitable animal model for atopic dermatitis.

Sasakawa et al. (2001) induced atopic dermatitis-like lesions by topical application of mite antigens in NC/Nga mice. Extracts of mite antigen were injected repeatedly at the ventral side of the ear. Clinical symptoms and thickness of the ear were measured. On day 18, blood and submandibular lymph nodes were collected to measure plasma immunoglobulins and to perform histochemical analysis.

Heishi et al. (2003) performed gene expression analysis of atopic dermatitis-like skin lesions induced in NC/Nga mice by mite antigen stimulation under specific pathogen-free conditions. Mite Extract-Dp (LSL Japan) was injected intradermally into the right and left pinnae and into the skin of NC/Nga of BALB/c mice in two places once per 3 days, and the clinical symptoms and the ear thickness were measured. On day 14 or 28, plasma IgE was determined. Further-

more, mRNA transcripts in pinnae were analyzed using real-time quantitative PCR.

Food hypersensitivity plays a pathogenic role in patients with atopic dermatitis (Sicherer and Sampson 1999).

Li et al. (2001) reported a murine model of atopic dermatitis associated with food hypersensitivity. Female C3H/HeJ mice were sensitized orally to cow's milk or peanut with cholera toxin adjuvant and then subjected to low-grade allergen exposure. Histologic examination of skin lesions, allergen-specific Ig levels, and allergen-induced T-cell proliferation were studied. Treatment of the eruption with topical corticosteroids led to decreased pruritus and resolution of the cutaneous eruption.

P.2.2.1.2 Contact Hypersensitivity in Rats

Meingassner et al. (1997) sensitized female Sprague Dawley rats by application of 80 µl of 2% 2,4-dinitrofluorobenzene (DNFB, dissolved in acetone, DMSO and olive oil 50:10:38 v/v/v), applied in 20 µl volumes to the inner surface of both ear lobes and to both shaved inguinal regions on day 1. Allergic contact dermatitis was elicited with 30 µl of 0.5% DNFB applied to the test sites of ≈15 mm in diameter on both shaved flanks on day 12. Animals were treated twice by gavage 2 h before and immediately after challenge. Dermatitis was evaluated by measuring the thickness of the lifted skin fold at the test sites with a spring-loaded micrometer (Schnelltaster, Kröplin, Germany) before challenge and 24 h after challenge.

P.2.2.1.3 Contact Hypersensitivity in Guinea Pigs

Guinea pigs, six per group, are sensitized on the dorsal surface of one ear pinna with 50 µl of 10% DBFB in 50% acetone: 50% olive oil on day 0, and then on the opposing ear on day 1. On day 5, animals are shaved and challenged with 0.5% 1-chloro-2,4-dinitrochlorobenzene (DNCB) with or without co-dissolved drug, 15 µl per site, 4.8 µl per cm^2, on the dorsolateral surface (Hsieh et al. 1996). Naïve animals are challenged with DNCB and serve as non-specific controls. The response is scored visually in a blinded fashion 24 h after challenge (0: no change; 0.5: questionable erythema; 1: faint or scattered erythema; 2: mild, confluent erythema; 3: moderate erythema without edema or induration; 4: strong erythema with uniform induration or edema; 5: severe erythema with induration or edema, plus ulceration). Data are calculated as for mouse contact hypersensitivity.

Rosenqvist et al. (1991) studied the effects of cilazaprilat and enalaprilat on experimental dermatitis in guinea pigs.

Boyera et al. (1992) tested repeated application of dinitrochlorobenzene to the ears of sensitized guinea pigs as an animal model for contact eczema in humans.

The effect of a topical preparation of mycophenolic acid on experimental allergic contact dermatitis of guinea pigs induced by dinitrofluorobenzene was described by Shoji et al. (1994).

P.2.2.1.4 Contact Hypersensitivity in Pigs

Groups of 6–12 pigs are sensitized with 10% DNFB in acetone/DMSO/olive oil (45:5:50 by volume) to the shaved outer aspect of both ears and bilateral sites of the lower abdomen, 100 µl per site, on day 0, with a second application of 5% DNFB to the internal pinna and the lower thorax on day 3. On day 9, pigs are restrained on a webbed canvas cart and the test area carefully shaved with an electric clipper. A pilot challenge with 0.1, 0.15, and 0.2% DNCB in acetone/olive oil (95:5 by volume), 3.8 µl per cm^2, is used to determine conditions for obtaining submaximal average response in each animal cohort. Pigs are scored by a blinded observer, 24 h post-challenge on a scale from 0 to 4 (0: no change; 0.5: questionable erythema; 1: faint or scattered erythema; 2: moderate erythema without induration or edema; 3: strong erythema with focal areas of edema or induration: 4: extreme erythema with uniform induration or edema). Pigs having a mean DNCB control score <1.5 are excluded (Hsieh et al. 1997). Based on their pilot response on day 10, animals are stratified into two groups having comparable mean scores, challenged on duplicate sites with DNCB in 95:5, with or without co-dissolved drug, and scored on day 11. Scores for each challenge site are compared with the average of the control spots treated with DNCB alone on the same pig, and expressed as percentage inhibition.

Bilski and Thomson (1984) recommended allergic contact dermatitis in the domestic pig as a model for evaluating the topical anti-inflammatory activity of drugs and their formulations.

Meingassner and Stütz (1992) sensitized female domestic pigs with a 10% solution of DNFB dissolved in 50% acetone, 10% dimethylsulfoxide (DMSO) and 30% olive oil applied in volumes of 100 µl onto both auricles (medial aspects) and groins on day 1. The ani-

mals were exposed again on the lateral aspects of both auricles to 100 µl of 2% DNFB on day 4. Challenge was performed with a 1% DNFB solution (without DMSO) on day 12 by applying 20 µl epicutaneously to each of 24 test sites (2 cm diameter) arranged in four craniocaudal lines on the dorsolateral back of each animal. The test sites were treated twice (0.5 and 6 h after challenge) with 20 µl of solutions of active compound or drug vehicle. Evaluation of the treatment-related effects was performed at the peak inflammatory response which was 24 h after challenge. Each test site was evaluated visually for (1) intensity, (2) extent of erythema, and (3) consistency using arbitrary scores from 0 to 4. In addition, skin changes were biophysically characterized by measuring microvascular perfusion (PeriFlux PF3 Laser Doppler Perfusion Monitor) and reflective color measurement (Minolta Chroma Meter CR 200).

Vana and Meingassner (2000) described morphologic and immunohistochemical features of experimentally induced contact dermatitis in **Göttingen minipigs**.

P.2.2.2 Non-Immunologic Contact Urticaria

PURPOSE AND RATIONALE

Contact urticaria is defined as a wheal-and flare reaction, appearing shortly after certain substances contact intact skin and disappearing within some hours, leaving normal appearing skin. Contact urticaria is divided into two main types, immunologic and non-immunologic (Maibach and Johnson 1975). Immunologic contact urticaria is mediated at least partially by specific IgE antibodies attached to mast cell membranes. Vasoactive substances, released from mast cells, elicit erythema and edema of the skin. Non-immunologic contact urticaria appears only on the contact area without previous sensitization. Specific antibodies against the causative substance are not found in serum. Lahti and Maibach (1984) investigated the suitability of the guinea pig for studies on non-immunologic contact urticaria.

PROCEDURE

Female Hartley strain guinea pigs weighing 350–500 g are used. Fifty µl of test substances is applied with a micropipette to both sides of the earlobe. One ear of the animal is challenged with the contact urticant, while the other ear serves as control with ethyl alcohol. Earlobe thickness is measured three times on four different sites using a string micrometer with round touching plates, 6 mm in diameter. The string of the instrument is adjusted so that the moving plate does not squeeze the tissue, but stops at once when it reaches the surface of the ear. The mean of 12 measurements is recorded as the pre-application thickness. All measurements after application of the test substance are performed once on the same four sites, and the mean is recorded as the post-application thickness.

The thickness of the ear is measured 5 min after application, and then every 10 min during the first h, every 15 min during the second, and every 30 min during the third h.

EVALUATION

The differences between post-application and pre-application values are recorded and plotted as time-response and dose-response curves.

MODIFICATIONS OF THE METHOD

Lauerma et al. (1997) used the trimellitic anhydride-sensitive mouse as an animal model for contact urticaria. BALB/c mice were sensitized with trimellitic anhydride by topical applications and treated with glucocorticosteroids, antihistaminics, or non-steroidal anti-inflammatory drugs. Ears were challenged with trimellitic anhydride and ear thickness was measured at baseline and 1, 2, 4, 8, and 24 h after challenge. Trimellitic anhydride caused a biphasic ear swelling response. However, there was also an early swelling by trimellitic anhydride in non-sensitized mice, suggesting that non-immunological as well as immunological mechanisms contribute to early swelling by trimellitic anhydride.

Irritant contact dermatitis was induced in mice by the application of 20 µl 0.01% A23187 (calcium ionophore) or 0.005% PMA (phenyl mercuric acetate) to both aspects of the right pinnae which were treated simultaneously (A23187) or after 30 min (PMA) with the test compound or vehicle (Meingassner and Stütz 1992). Topical efficacy was assessed by determination of the differences in weight of both auricles of treated and untreated mice 7.5 h (A23187) or 6 h (PMA) after application of the irritants.

P.2.3
Immunological Models of Atopic Dermatitis

P.2.3.1
Mononuclear Cells from Atopic Dermatitis Donors

PURPOSE AND RATIONALE

Rühl et al. (2003) studied the effects of PPAR-α and PPAR-β ligands on immunoglobulin synthesis and cytokine production by peripheral blood mononuclear cells from normal donors and patients with atopic dermatitis.

PROCEDURE

Peripheral blood mononuclear cells were isolated from buffy coats of non-allergic healthy donors and atopic dermatitis patients by Ficoll Hypaque (D = 1.077) separation (350 *g*, 30 min, room temperature). B cells were purified by magnetic cell sorting using anti-CD19-coupled magnetic beads. Then 4×10^8 peripheral blood mononuclear cells in 800 µl PBS + 20 nM ethylenediaminetetraacetic acid + 0.2% bovine serum albumin + 15 µl Beriglobin (Chinon Bering, Marburg, Germany) were incubated for 10 min in ice, followed by addition of 200 µl conjugated beads (1.5 ratio) and 10 min of incubation at 4°C. After several washings, CD19-positive B cells were selected by magnetic positive selection with LS^+ column, and the cells were then resuspended in medium and counted. The same procedure was done for the purification of T cells and monocytes, respectively, using anti-CD3 and anti-CD14 coupled magnetic beads.

Peripheral blood mononuclear cells and purified B cells (10^6 cells per ml) were cultured in RPMI 1640 culture medium supplemented with L-glutamine (2 mM), penicillin (100 U per ml), streptomycin (100 µg/ml) and 10% heat inactivated fetal calf serum. All cell cultures were carried out at 37°C in humidified air and 5% CO_2 atmosphere.

For the immunoglobulin assays, immunoplates (Nunc, Wiesbaden, Germany) were coated overnight at 4°C with the isotope-specific anti-human Ig-Fc antibodies diluted in 0.1 M bicarbonate buffer. Blocking was performed by adding 2% bovine serum albumin/Tris-buffered saline for 1 h, followed by several washings. Supernatants and internal standard were then added to the wells and incubated in duplicate for 2 h. After several washes, the alkaline phosphatase-conjugated antibodies (IgA, IgG and IgM) or biotinylated anti-IgE MoAb was added. For IgE, plates were incubated for another hour with alkaline-phosphatase-conjugated streptavidin. Following the final reaction with phosphatase substrate (Sigma, Dreieich, Germany), plates were read in a microplate ELISA reader at 405 nm, and the amount of immunoglobulin was calculated according to the standard curve. Cytokines were determined by ELISA assays.

EVALUATION

Wilcoxon's signed rank test for matched pairs was performed to compare the results within the donor groups.

MODIFICATIONS OF THE METHOD

Furthermore, Rühl et al. (2003) performed *in vivo* experiments in ovalbumin-sensitized female NMRI mice confirming the *in vitro* findings and showing that the IL-4-mediated immune response was inhibited in PPAR-activator-treated mice.

Sperhake et al. (1998) studied the effects of recombinant human soluble interleukin-4 receptor on interleukin-4/staphylococcal enterotoxin B-stimulated peripheral mononuclear cells from patients with atopic eczema.

Hong et al. (2003) demonstrated the PPARγ-dependent anti-inflammatory action of rosiglitazone in human monocytes. Furthermore, it was shown that the suppression of tumor necrosis factor α (TNFα) secretion is not mediated by phosphatase and tensin homolog (PTEN) regulation.

P.2.3.2
The SCID-hu Skin Mouse as Model for Atopic Dermatitis

PURPOSE AND RATIONALE

Severe combined immunodeficiency (SCID) mice have a defect in the antigen recombinant system that prevents the development of mature B and T lymphocytes (Bosma et al. 1983) and therefore renders these mice tolerant to xenografts of human cells and tissues.

Carballido et al. (2000, 2003), Biedermann et al. (2002, 2004), Igney et al. (2004) and Lametschwandtner et al. (2004) reported the establishment of an *in vivo* mouse model that allows monitoring of human T cell migration into human skin. This model is based on the use of SCID mice transplanted with human skin (SCID-hu Skin mice). Adoptively transferred human T helper (Th)2 cells obtained from atopic dermatitis skin lesions or peripheral blood T cells selectively migrate to the human skin grafts of these SCID mice in response to defined chemokines locally injected in the human skin grafts. Homing of human T cells into the human skin on SCID-hu Skin mice is a specific process since it only occurs in response to chemokine ligands that are specific for the chemokine receptors expressed on the migrating T cells.

PROCEDURE

Generation of SCID-hu Skin Mice

Human adult skin is obtained from breast or abdominal reduction surgery. The skin is perfused with cell culture media containing penicillin and streptomycin and fat tissues are removed. Subsequently, full thickness skin is trimmed at the dermal side to obtain skin biopsy samples containing the full epidermis, the papillary dermis, and part of the reticular dermis. This skin tissue is cut into pieces of approximately 10×10 mm and kept at 4°C in cell culture media until use. C.B-17/GbmsTac-*Prkdc*^{scid} *Lyst*^{bg} mice (M&B, Ry, Denmark, herein referred to as SCID mice) are anesthetized by i.p. injection of a solution containing ketamine and xylazine and their backs shaved. Subsequently, two pieces of skin of the same size as the human grafts are removed from the back of the mice and replaced by human skin pieces, which are fixed at their edges using surgical glue. At the end of the procedure, the human grafts are covered with a polyvinyl bandage to prevent scratching and to facilitate tissue engraftment. After transplantation, the human grafts undergo a period of human keratinocyte hyperproliferation resulting in the formation of hyperkeratotic crusts. During this process, human skin grafts fuse with the adjacent mouse skin. About 5 weeks after transplantation, the crusts fall off and reveal a skin tissue containing all the characteristic structures of normal human skin including a network of newly grown vessels connecting the graft with the underlying mouse tissues.

Generation and characterization of human T cells for skin homing studies in vivo

Th lymphocytes selected for *in vivo* migration studies in SCID-hu Skin mice are isolated from human atopic skin lesions in order to obtain Th cells with optimal skin homing potential. Human Th cell lines are grown from biopsies of **atopic dermatitis** patients challenged with house dust mite (HDM) antigens (Carballido et al. 1997). Th cell clones are isolated from the HDM-specific lines by limiting dilution and maintained by repeated stimulation with irradiated allogenic human peripheral blood mononuclear cells (PBMC) and phytohaem agglutinin (PHA), followed by expansion with human IL-2.

Atopic dermatitis is an inflammatory skin disease in which skin-infiltrating allergen-specific Th2 cells play a crucial role (Robert and Kupper 1999). Accordingly, the majority of the human Th cell clones isolated from atopic skin biopsy samples are of the polarized Th2 phenotype. These cells produce large amounts of IL-4, IL-5 and IL-13 but low or undetectable levels of IL-2 and IFN-γ. All Th cells express CLA LFA-1 and CCR4. Based on these results and the observation that CCL22 (macrophage-derived chemokine, MDC) is abundantly produced in atopic dermatitis skin lesions, CCL22 is selected as a relevant ligand for the evaluation of skin-specific migration of human Th cells in the SCID-hu Skin mouse model. In order to demonstrate that CCL22 induces Th2 cell activation, Th2 clones are loaded with Fluo-4acetoxymethyl ester (Fluo-4/AM, Molecular Probes, Eugene, Ore., USA). Following the addition of CCL22 (300 ng/ml), changes in fluorescence intensity are analyzed every 5 s using a FACScan FL-1 channel (Becton Dickinson, San Jose, Calif., USA) (Biedermann et al. 2002). Comparable results were obtained with CCL17 (thymus-activation-regulated chemokine, TARC), which is the other ligand for CCR4 and is also abundantly expressed in atopic dermatitis lesions. These results demonstrate the relevance of CCL17 and CCL22 interactions with CCR4 for activation of Th2 cells derived from atopic dermatitis skin lesions. In addition, human peripheral T cells are analyzed for their skin homing capacity in SCID-hu Skin mice. PBMC are isolated from healthy volunteers.

Recruitment of Human Th Cells to Human Skin Grafts in SCID-hu Skin Mice

To evaluate the potential of selected chemokines to recruit atopic-dermatitis-derived human Th2 cells and peripheral blood T cells to human skin *in vivo*, 1.5×10^8 Th2 cells or PBMC are adoptively transferred (i.p.) into SCID mice which have been previously transplanted (6–8 weeks) with two pieces of human skin (SCID-hu Skin mice). Following Th cell transfer, 300 ng of CCL22, CXCL10 (IFN-γ-inducible

protein of 10 kDa, IP-10), or vehicle control is injected intradermally (i.d.) in the human skin grafts of the SCID-hu Skin mice. On day 8, mice are sacrificed and human skin grafts are harvested and processed into single-cell suspensions using a mechanical tissue disaggregator. These cell suspensions are stained with human anti-CD3, anti-CD4 or anti-CD45 mAb conjugated to FITC and PE (Becton Dickinson) and analyzed in the FACScan. CCL22 effectively recruits human Th2 cells into human skin grafts of SCID-hu Skin mice, whereas CXCL10 is ineffective. These data are consistent with the expression of CCR4 on atopic-dermatitis-derived Th2 cells, whereas CXCR3, which is the receptor for CXCL10, is not expressed on these cells. Furthermore, treatment of Th2 cells prior transfer into SCID mice with *Bordetella pertussis* toxin, an inhibitor of G-protein-coupled receptors, completely abolishes the migratory capacity of these Th2 cells indicating the requirement of an intact chemokine receptor signaling pathway (Biedermann et al. 2002). It has to be noted that CCR4-mediated human skin homing of Th2 cells is not restricted to CCL22 since the alternative CCR4-ligand, CCL17, also induces Th2 migration to human skin grafts, although to a lesser degree than CCL22.

Similarly to Th2 cells, T cells present in human PBMC can also be recruited into human skin grafts of SCID-hu Skin mice. These T cells migrate in response to both CCL22 and CXCL10 chemokines (300 ng injected i.d. into human skin), which is consistent with CCR4 and CXCR3 expression on these cells. Peripheral blood T cells also express functional CCR2, since the T cells migrate into human skin in response to the CCR2 ligand CCL2. From these data it can be concluded that both skin-derived Th2 cells and peripheral blood T cells can be recruited into human skin grafts provided that these T cells express the chemokine receptors specific for the recruiting chemokine.

Inhibition of Human T Cell Migration into Human Skin of SCID-hu Skin Mice

The present SCID-hu Skin mouse model has been validated for measuring various inhibitors of human T cell rolling, extravasation and migration *in vivo*. It was shown that inhibition of CLA/E-Selectin interactions using an E-Selectin-specific mAb or a low molecular weight (LMW) E-Selectin-specific antagonist strongly inhibited CCL22-mediated Th2 cell migration into the skin (Biedermann et al. 2002). Similarly, anti-LFA-1 mAbs administered at 5 mg/kg at day 1 prior to Th2 cell transfer and on day 4 strongly inhibits Th2 cell migration into the human skin. Th2 cell migration in response to CCL22 is also inhibited in a dose-dependent fashion by LMW LFA-1 inhibitors, given daily p.o. starting on the day of T cell transfer.

CRITICAL ASSESSMENT OF THE METHOD

This mechanistic model allows analysis of the relevant steps involved in human T-lymphocyte migration into inflamed skin. In addition, it can be used for preclinical testing of drug candidates that are highly selective for human target molecules associated with the different steps of T cell migration in an environment that resembles the physiologic or pathologic conditions occurring in humans. The model allows the study of chemotactic responses of human cells toward specific, intracutaneously administered chemokines and testing of specific antagonists of human Th cell migration *in vivo*.

P.3 Pruritus Models

P.3.1 Pruritus and Scratching Behavior in Mice

PURPOSE AND RATIONALE

Pruritus is a common feature of many skin disorders. Since its pathogenesis in largely unknown, proper treatment is not available. The development of new treatments is hampered by the lack of animal models for studying pruritus (Woodward et al. 1985). Kuraishi et al. (1995) have proposed that pruritogenic but not algesiogenic agents stimulate the scratching activity in mice. Scratching is usually registered by counting the number of scratches from direct visual observation or from a video recording (Gmerek and Cowan 1983; Larsen et al. 1994; Thomas et al. 1994). Elliott et al. (2000) developed a method, which allows the automated registration of the scratching activity of the hind legs of mice for periods longer than 24 h.

PROCEDURE

Mice with chronic proliferative dermatitis (cpdm/cpdm mice), a spontaneous mutation of C57BL/Ka mice showing a skin disorder accompanied by severe scratching (Gijbels et al. 1996, 2000), at an age of 6–12 weeks or normal C57BL/Ka mice treated subcutaneously with 100 µg/mouse compound 48/80 or 3 mg/mouse histamine hydrochloride, are used.

Metal rings made of soft 1-mm-diameter aluminum wire are placed around both hind legs of the animal just above the ankle. The ring has to be of sufficient diameter that it is just free enough to rotate around the limb. Mice are housed individually in cages (12 × 18 × 13 cm), which are placed on a scratch detection unit consisting of a plastic outer casing containing the circuit board, and, inset into the top, four ferrite rods with copper coils.

As the mouse scratches, the movement of the metal rings (fitted around its hind legs) in the field generated by the coils elicits a signal that can be transformed into peaks of different frequencies using fast Fourier transformation. Data are downloaded to memory every 3 s, filtered and a power spectrum constructed. The power spectrum is analyzed for a scratch pattern every 1.5 s. Scratching is routinely classified as a signal that gives rise to peaks with maximal amplitudes of around 200 mV and frequencies greater than 15 Hz. The amplitude of general motor activity peaks (movement from bedding using hind limbs, drinking from water bottle) is usually greater than 500 mV and at frequencies of less than 10 Hz. In order to obtain the best discrimination between scratching and general motor activity, any contribution to the scratch frequencies of high energy/low frequency peaks is filtered out by setting the upper detection limit at 0.5 mV for scratching.

EVALUATION

Data are expressed as mean ± SEM Statistical analysis is performed by one-way analysis of variance followed by Student's *t*-test.

MODIFICATIONS OF THE METHOD

Inagaki et al. (2002, 2003) used new apparatus, MicroAct, to study mechanisms in the induction of scratching behavior in BALB/c mice by compound 48/80. A small magnet (1 mm in diameter, 3 mm long) was inserted subcutaneously in both hind paws under ether anesthesia. The mouse with magnets was placed in an observation chamber (11 cm in diameter, 18 cm high), which was surrounded by a round coil. The electric current induced in the coil by the movement of magnets attached to the hind paws was amplified and recorded. Characteristic waves reflecting scratching behavior were detected by a computer.

Brash et al. (2005) designed a repetitive movement detector used for automatic monitoring and quantification of scratching in mice. The system is based on a sensitive force transducer positioned below a recording platform holding a lightweight recording box in which the animal is placed. A programmed microcontroller is used to discriminate between non-specific movement, grooming behavior, and scratching movements made by the animal's hind limb. Following subdermal injections of histamine receptor agonists into the neck of a mouse, dose-related scratching occurred which was detected and quantified.

Larsen et al. (1994) studied the influence of ultraviolet irradiation on scratching behavior in hairless mice. Especially the wavelengths 315–330 nm were more itch provoking than erythemogenic.

Several authors used the model of **compound 48/80-induced scratching behavior** in mice. Sugimoto et al. (1998) studied the effects of histamine H_1 receptor antagonists on compound 48/80-induced scratching behavior in mice. Rojavin et al. (1998) investigated the antipruritic effect of millimeter waves in mice treated with compound 48/80. Inagaki et al. (2002) studied the mechanisms of induction of scratching behavior in BALB/c mice by compound 48/80. Shinmei et al. (2004) studied the effect of Brazilian propolis on scratching behavior induced by compound 48/80 and histamine in mice. Oliveira et al. (2004) re-

ported suppression of the scratching behavior induced by dextran 40 and compound 48/80 by treatment with pentacyclic triterpenoids. Inagaki et al. (1999, 2000) studied the participation of histamine H_1 and H_2 receptors in passive cutaneous anaphylaxis-induced scratching behavior in ICR mice and evaluated anti-scratch properties of drugs in BBLB/c, ICR, and ddY mice treated with dinitrofluorobenzene painting.

Hossen et al. (2003) reported involvement of histamine H_3 receptors in scratching behavior in mast-cell-deficient mice.

The involvement of the μ- and κ-opioid system in scratching behavior was investigated by Tohda et al. (1997), Kamei and Nagase (2001), and Umeuchi et al. (2003, 2005).

Tan-No et al. (2000) reported that intrathecally administered spermine produces scratching, biting, and licking behavior in mice.

Hansson et al. (2002) described a model of chronic itchy dermatitis in transgenic mice with epidermal overexpression of stratum corneum chymotryptic enzyme.

Andoh and Kuraishi (2002) described inhibitory effects of azelastine on the substance P-induced itch-associated response in mice.

Umeuchi et al. (2005) tested spontaneous scratching behavior in MRL/*lpr* mice, a possible model for pruritus in autoimmune diseases, and antipruritic activity of a κ-opioid receptor agonist and recommended MRL/*lpr* mice scratching behavior as a suitable model of pruritus that occurs in autoimmune diseases.

P.3.2 Pruritic Dermatitis in Other Species

Gmerek and Cowan (1983) described an animal model for preclinical screening of systemic antipruritic agents in **rats**. Bombesin induces dose-related excessive scratching when administered intracerebroventricularly (i.c.v.) to rats. Scratching elicited by 0.10μg bombesin i.c.v. was monitored with the help of a microcomputer.

Thomas and Hammond (1995) found that microinjections of morphine into the rat medullary dorsal horn produces a dose-dependent increase in facial scratching in Sprague Dawley rats.

Thomsen et al. (2001) proposed scratch induction in the rat by intradermal serotonin as a model of pruritus. Several compounds (histamine, compound 48/80, kallikrein, trypsin, papain, substance P and PAF) were injected into the rostral back of rats. Only serotonin induced excessive scratching at the site of injection. The model was recommended for research and development of antipruritics of the non-histaminic type.

De Castro Costa (1987) tested scratching behavior in arthritic rats; Thomsen et al. (2002), in hairless rats; Ozaki et al. (2005), in beige rats with IgE hyperproduction.

Hayashi et al. (2001) studied the effects of a histamine H_1 antagonist on cutaneous hyperpermeability and scratching behavior induced by poly-L-arginine in rats.

Noshima and Carstens (2003) described quantitative assessment of directed hind limb scratching behavior in Sprague Dawley rats after intradermal injection of serotonin into the nape of the neck.

Gingold and Bergasa (2003) found that a cannabinoid agonist increases nociception threshold in rats with cholestasis secondary to bile duct resection. The model was recommended when testing compounds for treatment of pruritus due to cholestasis.

Minami and Kamei (2004) published a chronic model for evaluating the itching associated with allergic conjunctivitis in rats. After subcutaneous and local sensitization with egg albumin, scratching behavior was observed after instillation of egg albumin into the eyes.

Butler et al. (1983) described pruritic dermatitis in asthmatic basenji-greyhound **dogs**, which was manifested as lichenified plaques and as inflammatory nodules and papules. The authors recommended this disease as a model for human atopic dermatitis.

Osifo (1991) used a dog model to study structure–activity relationships in the pruritogenicity of chloroquine and amodiaquine metabolites.

Patterson and Harris (1981) reported chronic pruritic dermatitis in asthmatic **rhesus monkeys**.

Ko and Naughton (2000) described an experimental itch model in rhesus monkeys.

Holden et al. (2003) found in this model that activation of κ-opioid receptors inhibits pruritus evoked by subcutaneous or intrathecal administration of morphine.

P.4 Psoriasis Models

P.4.1 General Considerations

Several authors reviewed the experimental models for psoriasis (Krueger and Jorgensen 1990; Boehncke 1997; Nickoloff 1999; Rosenberg et al. 1999; Schön 1999; Mizutani et al. 2003). In addition to studies in animals, various *in vitro* investigations were carried out with autopsy material from human psoriatic lesions. Several studies were devoted to the T-cell hypothesis of psoriasis (Bos and de Rie 1999). Lymphocytes may change epidermal growth homeostasis, leading to increased keratinocyte proliferation and abnormal differentiation of these apoptotic cells that end their life cycle as corneocytes.

P.4.2 In Vitro Studies with Isolated Cells

P.4.2.1 Cultured Keratinocytes

PURPOSE AND RATIONALE

Cultured keratinocytes have been used to study the pathogenesis of psoriasis (Mils et al. 1994; Bata-Csörgö et al. 1993, 1995a, b; Ockenfels et al. 1996; Nylander-Lundqvist and Egelrud 1997a, b; Nylander-Lundqvist et al. 1998; Konger et al. 1998; Szabo et al. 1998; Dimon-Gadal et al. 2000; Karvonen et al. 2000; Segaert et al. 2000; Ting et al. 2000) and to evaluate antipsoriatic drugs (Chapman et al. 1990; Ockenfels et al. 1995; Medalie et al. 1996; Lin et al. 1999; Diaz et al. 2000; Farkas et al. 2001). Sampson et al. (2001) tested the *in vitro* keratinocyte antiproliferant effect of *Centella asiatica* extract and triterpenoid saponins.

PROCEDURE

The medium (FDMEM) consists of Dulbecco's Modified Eagle Medium supplemented with 10% fetal bovine serum (FBS), 1% penicillin and 2% streptomycin.

SVK-14 keratinocytes (Taylor-Papadimitriou et al. 1982) are cultured in FDMEM medium in flasks at 10% CO_2 and 37°C. When confluent, cells are washed with magnesium- and calcium-free phosphate buffered saline (PBS). PBS is decanted and cells detached by adding 5 ml of trypsin (0.05%) in EDTA (0.02%). PBS is added to a volume of 50 ml. The cell pellet obtained by centrifugation (1000 *g*, 5 min) is re-suspended in 10 ml of FDMEM. Cell counts in the final suspension are determined using a haemocytometer, and the cell density is adjusted to 25000/ml with FDMEM.

For microtiter assays, cells (5000 in 200 µl medium) are inoculated into the inner wells of 96-well plates. The outer edge wells of the plate contain 200 µl of 10% fetal bovine serum in PBS. After 24 h at 37°C, 10% CO_2, plating medium is replaced with FDMEM containing test material or standard in 200 µl. Standard substances are: madecassoside (50 nM–5 mM), asiaticoside (100 nM–10 mM), dissolved in methanol, and dithranol (0.33–170 µM) dissolved on DMSO. Each sample concentration is tested with 6 replicates on each of three separate plates. Cells exposed to FDMEM alone provide 100% growth control. Cells are incubated for 7 days at 37°C, 10% CO_2 prior to carrying out the sulphorhodamine B assay.

For the sulphorhodamine B (SRB) assay (Skehan et al. 1990), cells are fixed by layering 100 µl of ice-cold 50% trichloroacetic acid on top of the growth medium. Cells are incubated at 4°C for 1 h, after which plates are washed 5 times with cold water, excess water drained off and the plates left to dry in air. SRB stain (50 µl; 0.4% in 1% acetic acid) (Sigma) is added to each well and left in contact with the cells for 10 to 30 min after which they are washed with 1% acetic acid, rinsing 4 times until only the dye adhering to the cells is left. The plates are dried and 100 µl of 10 mM Tris buffer added to each well to solubilize the dye. The plates are shaken gently for 5 in on a plate reader

and the absorbance is read at 550 nm using a Titertek Multiscan MCC/340 II plate reader.

EVALUATION

Mean optical density (OD ± SD) is calculated for each concentration from the six replicate wells in a single plate. The data is used to plot a dose response curve from which IC_{50} values ± SD are obtained.

MODIFICATIONS OF THE METHOD

Fogh et al. (1993) described an *ex vivo* skin model. Keratomized psoriatic skin samples were incubated in the presence of the calcium ionophore a23187 and arachidonic acid for 45 min at 37°C. After extraction of lipids, eicosanoids were determined by reversed-phase high-performance liquid chromatography in combination with specific radioimmunoassays.

Hager et al. (1999) described long-term culture of murine epidermal keratinocytes.

Hanley et al. (1998) found that the differentiation of keratinocytes in cultures from human foreskin was stimulated by activators of the nuclear hormone receptor peroxisome proliferator-activated receptor α (PPARα).

Rivier et al. (1998) reported differential expression of PPAR subtypes during the differentiation of human keratinocytes. When normal human keratinocytes were induced to differentiate by shifting the culture medium to a high Ca^{2+} concentration, the expression of PPARα and PPARγ mRNA was increased, whereas that of PPARδ remained unchanged. In lesional compared with unlesional psoriatic epidermis, the expression of PPARα and PPARγ was reduced, indicating that these two subtypes are tightly linked in the epidermal differentiation process.

Naik et al. (1999) found that human keratinocytes constitutively express interleukin-18 and secrete biologically active interleukin-18 after treatment with pro-inflammatory mediators and dinitrochlorobenzene.

Muga et al. (2000) reported that 8S-lipoxygenase products activate PPARα and induce differentiation in murine keratinocytes. Transgenic mice with 8S-lipoxygenase targeted to keratinocytes were generated through the use of a loricrin promoter. In cultured keratinocytes, PPARα was identified as a crucial component of keratin-1 induction through transient transfection with expression vectors for PPARα, PPARγ, and a dominant negative PPAR as well as through the use of known PPAR agonists.

Ellis et al. (2000) found that ligands for PPARγ inhibit keratinocyte proliferation. Troglitazone improved psoriasis and showed normalization in these models of proliferative skin disease.

Kömüves et al. (2000) studied keratinocyte differentiation in hyperproliferative epidermis and found that topical application of PPARα activators restores tissue homeostasis.

Rosenfield et al. (2000) reviewed PPARs and skin development.

Sakamoto et al. (2000) described activation of human PPAR subtypes by pioglitazone.

Tan et al. (2001) studied the roles of PPARβ/δ in the keratinocyte's response to inflammation. The authors showed by the use of cultures of primary keratinocytes from wild-type and PPAR$\beta/\delta^{-/-}$ mice that inflammatory signals, such as tumor necrosis factor α (TNFα) and interferon β (INFβ), induce keratinocyte differentiation. The proinflammatory cytokines initiate the production of endogenous PPARβ/δ ligands, which are essential for PPARβ/δ activation and action.

Thuillier et al. (2002) found inhibition of PPAR-mediated murine keratinocyte differentiation by lipoxygenase inhibitors. The effect was mediated primarily through PPARα and PPARγ.

Zhou et al. (2002) performed genetic analysis of four novel PPARγ splice variants in monkey macrophages.

Hong et al. (2003) described PPARγ-dependent anti-inflammatory action of rosiglitazone in human monocytes, whereby the suppression of TNFα secretion is not mediated by Lipid phsophatase PTEN regulation.

Kojo et al. (2003) evaluated human PPAR subtype selectivity of a variety of anti-inflammatory drugs based on a novel assay for PPARδ (β).

Kuenzli and Saurat (2003) reviewed the role of PPARs in cutaneous biology.

Westergaard et al. (2003) studied expression and localization of PPARs and nuclear factor κB in normal and lesional psoriatic skin.

Gosh et al. (2004) found disruption of transformation growth factor signaling and profibrotic responses in normal skin fibroblasts by PPARγ.

P.4.2.2 Effect on T Lymphocytes

PURPOSE AND RATIONALE

Psoriasis vulgaris is considered as an inflammatory cell-mediated autoimmune disorder (Uyemura et al. 1993; Gottlieb et al. 1994; Bata-Csörgö et al. 1995; Austin et al. 1999). Lesional skin T cells contribute pro-inflammatory/type 1 (T1) cytokines to initiate and maintain the cell-mediated keratinocyte hyperplasia in inflammatory lesions. Atopic dermatitis is characterized by the presence of Th2 cell and their respective cytokines (Cooper 1994; Leung 1997). A therapeutic agent down-regulating both Th1 and Th2 cytokine production would be desirable (Mollison et al. 1999; Santamaria et al. 1999).

PROCEDURE

Human Mixed Leukocyte Reaction (MLR) Assay

Fifty milliliters of sodium heparinized blood, obtained from normal, unrelated donors, is mixed with an equal volume of Dulbecco's phosphate buffered saline (DPBS). Peripheral blood mononuclear cells (PBMC) are isolated by density centrifugation at 400 *g* over Histopaque-1077. A sufficient number of PBMC are washed three times in RPMI-1640 medium and used as responder cells. The remaining PBMC (stimulator cells) are washed as above and treated with 25 µg/ml mitomycin C for 30 min at 37°C in an atmosphere of 5% CO_2 and 100% humidity and then washed three times with RPMI-1640 medium. The stimulator cells are pooled at $0.5–1.0 \times 10^6$ cells per ml per donor in RPMI-1640 medium. Cells are cultured in medium consisting of RPMI-1640 supplemented with 4 mM L-glutamine, 500 µM 2-mercaptoethanol, 10% fetal bovine serum, 25 units/ml penicillin, and 25 µg/ml streptomycin. Mixed leukocyte reactions are performed in 96 well flat-bottom plates (Corning, Acton MA) in a final volume of 220 µl, containing 20 µl of culture medium with or without test compound or standard (ascomycin, purified from a fermentation of *Streptomyces hygroscopicus* ssp. *ascomyceticus* ATCC 14891 and characterized according to Or et al. 1993), 100 µl of responder cells (1×10^6 cells per ml) and 100 µl of stimulator cells ($2–4 \times 10^6$ cells per ml). Cultures are incubated at 37°C in an atmosphere of 5% CO_2 and 100% humidity for 4 days. On day 4, 0.5 µCi of [^{3}H]thymidine is added to each well during the last 6 h of culture. Cultures are harvested onto glass-fiber mats using a 96 well harvester. [^{3}H]Thymidine uptake is measured by direct β-counting using a Matrix 9600 β-counter (Packard, Meriden, CT).

Inhibition of IL-2 Production in Human Whole Blood and PBMC

Fifty milliliters of venous blood from normal donors is drawn into tubes containing sodium heparin. Twenty-five milliliters of blood is used directly. PBMC are isolated from the remaining sample as described above and cultured at 1×10^6 cells per ml with supplemented RPMI-1640. Whole blood or PBMC are induced to secrete IL-2 with 50 ng PMA per ml plus 1 µg ionomycin per ml. Immunosuppressive potency of test compound vs. standard is determined by measuring the inhibition of IL-2 secretion. Assays are performed in 96 well flat-bottom plates in a volume of 210 µl, which includes 190 µl of whole blood or PBMC (1×10^6 cells per ml), 10 µl of PMA (1 µg/ml) and ionomycin (20 µg/ml) mixture and 10 µl of serially diluted test compound. Plasma or tissue culture supernatants are collected 24 h later and IL-2 concentrations determined by ELISA.

Porcine MLR Assay

Fifty milliliters of sodium heparinized venous blood is drawn from pigs and diluted with an equal volume of 0.9% saline. PBMC are isolated by density centrifugation for preparation of responder and stimulator cells as described above. MLR are performed as described for human MLR using 100 µl of responder

cells (2×10^6 cells per ml) and 100 µl of stimulator cells ($0.5–4 \times 10^6$ cells per ml).

Rat MLR Assay

Popliteal, inguinal, and mesenteric lymph nodes from newly sacrificed Lewis rats and spleens from Brown Norway rats are aseptically removed. Single cell suspensions of splenocytes and lymphocytes are prepared using forceps and a hemostat to macerate the tissues. Red blood cells in the splenocyte suspension are lysed by 2 min incubation at ambient temperature in red blood cell lysis buffer containing 0.14 M NH_4Cl in 0.0167 M Tris-HCl, pH 7.2. Responder cells from Lewis rat lymph nodes and stimulator cells from Brown Norway rat spleens are washed three times in RPMI-1640 medium and then sedimented at 400 *g* for 10 min. Stimulator cells are prepared as for human, and the assay is conducted in serum-free AIM-V medium supplemented with 1% Antibiotic-Antimycotic solution and 50 µM 2-mercaptoethanol, using an optimized cell ratio of 100 µl of responder cells (2×10^6 cells per ml) and 100 µl of stimulator cells ($1–2 \times 10^6$ cells per ml) and an incubation period of 4 days.

Mouse MLR Assay

Spleens are aseptically removed from newly sacrificed C_3H(C_3H/HeNCrIBR) and BALB/c mice. Splenocytes are prepared and the assay conducted as for rat, using an optimized cell ratio of 100 µl of responder cells (4×10^6 cells per ml) and 100 µl of stimulator cells (1×10^6 cells per ml).

Concanavalin A-Induced Guinea Pig Lymphocyte Proliferation Assay

Spleens are aseptically removed from newly sacrificed guinea pigs. Single cell suspensions of splenocytes are prepared as for rat using 4 min incubation in lysis buffer to remove red blood cells. Splenocytes are washed three times in RPMI-1640 medium and adjusted to 6.25×10^5 cells per ml in culture medium consisting of RPMI-1640 supplemented as described for human MLR. Concanavallin A-induced proliferation reactions are performed in a volume of 200 µl, containing 20 µl of culture medium with or without test compound or standard, 160 µl of guinea pig splenocytes and 20 µl concanavallin A (20 µg/ml). Cultures are incubated for 3 days, pulse labeled on the last day with [^{3}H]thymidine, harvested and counted as described.

Inhibition of Cytokine Secretion

Serially diluted test compound or standard is added to 96 well plates with PBMC in RPMI-1640 medium at 1×10^6 cells per ml. PMA and ionomycin are added to effect 10 ng per ml and 500 ng per ml concentrations, respectively. Supernatants from these cultures are collected 24 h later after centrifugation and stored at –80°C until use. Concentrations of IL-2 and IFN-γ in the supernatants are determined by ELISA. For assessing inhibition of IL-4 and IL-5 secretion in T cells by the test compound, $CD4^+$ cells are isolated from PBMC using a T cell subset enrichment column (RandD Systems, Minneapolis, MN). Purified $CD4^+$ cells are cultured with serially diluted test compound and PMA at 10 ng per ml in plates previously coated with 100 ng per ml solution of anti CD3 antibody (Immunotech, Westbrook, ME). Supernatants are collected after centrifugation 40 h later. IL-4 and IL-5 concentrations in the supernatants are determined by ELISA.

EVALUATION

Dose response curves for test compound and standard are established and IC_{50} values for inhibition calculated.

MODIFICATIONS OF THE METHOD

Gillitzer et al. (1996) studied neutrophil migration in psoriatic lesions as a model for neutrophil chemotaxis.

Kunstfeld et al. (1997) investigated the migration of inflammatory T cells from psoriasis through superficial vascular plexus and through deep vascular plexus endothelium. Superficial and deep plexus human skin was placed separately into SCID mice.

P.4.3
Psoriasis Models in Normal Animals

P.4.3.1
Mouse Tail Model for Psoriasis

PURPOSE AND RATIONALE

The mouse-tail test was introduced by Jarrett and Spearman (1964). The model is based on the induction of orthokeratosis in those parts of the adult mouse-tail, which have normally a parakeratotic differentiation. Quantification of orthokeratosis was achieved by morphometric evaluation of the scales with the aid of a semiautomatic evaluation unit (Bosman et al. 1992; Bosman 1994; Sebök et al. 1996).

PROCEDURE

Male albino NMRI mice weighing 25–27 g are used.

The tails are treated locally with 0.1 ml ointment applied to the proximal part of the tail. For the contact time of 2 h a plastic cylinder is slipped over the tail and fixed with adhesive tape. At the end of contact time the cylinders are removed and the tails washed. Animals are treated once daily, 5 times a week, for 2 weeks. Five to 8 animals are used per dosage group. Two hours after the last treatment the animals are sacrificed and the tails prepared histologically (fixation in 4% formalin, paraplastic embedding). Longitudinal sections of about 5 µm thickness are prepared and stained with hematoxylin-eosin.

The epidermal thickness is measured as the distance between the dermo-epidermal borderline and the beginning of the horny layer. Five measurements per animal are made in each of 10 scales. Out of these 50 measurements the mean for the individual animals is calculated.

The sections are examined for the presence of a granular layer or isolated granular cells induced in the previously parakeratotic skin areas (10 sequential scales per animal). The measurements are carried out at the border of the scale with a semiautomatic image evaluation unit (VIDS III, AI TEKTRON). The distances are obtained in pixels (1 pixel = 1.2120 µm).

Quantitative values of orthokeratosis are obtained by measuring the length of the granular layer per scale (A) and the whole scale length (B). The whole scale length is defined as the length of the scale lying between two adjacent hair follicles, beginning and ending at the turning point between hair follicle and scale. Percent keratosis is calculated by the formula:

$$(A/B) \times 100\,.$$

EVALUATION

Ten sequential scales per animal are measured and the results given in % orthokeratosis per scale. Five to 8 animals are taken for one drug concentration or control group. Thus 50–80 individual orthokeratosis values are obtained per test group. Mean and standard error of the mean are calculated per animal and per group. From the individual orthokeratosis values per dosage group (50–80 scales) a frequency distribution is constructed. Therefore the values (ranging from 0 to 100% orthokeratosis) are grouped into classes with a constant class interval of 10% (class 1: 0–10%; class 2: 10.1–20%; class 10: 90.1–100% orthokeratosis). The frequency per class is calculated in %:

$$\text{class frequency} = \frac{\text{no. of scales in the class}}{\text{total no. of scales}} \times 100\,.$$

For every class the cumulative frequency is constructed by adding the frequencies of all foregoing classes.

Due to a non-Gaussian distribution of the orthokeratotic values (100% is the maximal effect), the Mann-Whitney U-test is used.

The efficacy of test compounds on epidermal differentiation is calculated from the mean length of orthokeratosis after treatment with the substrate (Ok_s) and with salicylic acid as control (Ok_c) using the formula:

$$(Ok_s - Ok_c)/(100 - Ok_c) \times 100\,.$$

MODIFICATIONS OF THE METHOD

Nagano et al. (1990) studied the effect of tumor necrosis factor in the mouse-tail model of psoriasis.

Beyaert et al. (1992) induced a psoriasiform inflammatory reaction in mice by subcutaneous injection of a combination of tumor necrosis factor and lithium chloride.

Sebök et al. (2000) used the mouse tail test to compare tazarotene, a receptor-specific retinoid, with the classical topical antipsoriatic compound dithranol.

Worm et al. (2001) studied the effects of retinoids on *in vitro* and *in vivo* IgE production in ovalbumin-sensitized BALB/c mice.

Several studies were performed in **guinea pigs** (Miller and Ziboh 1990; Kumar et al. 1992; Maini et al. 1999). Tuzun et al. (1993) reported psoriasis lesions in guinea pigs receiving propranolol; however, their results could not be confirmed by Wolf et al. (1994).

P.4.3.2 Rat Ultraviolet Ray B Photodermatitis Model for Psoriasis

PURPOSE AND RATIONALE

Rat ultraviolet ray B photodermatitis has been proposed as an experimental model of psoriasis vulgaris by Nagakuma et al. (1995).

PROCEDURE

Male Wistar rats weighing around 300 g are used. Hair on the dorsal skin is clipped and carefully shaved. An area (1.5 × 2.5 cm) on one side of the flank is irradiated for 15 min (1.5 J/cm^2) at a vertical distance of 20 cm with UV-B lamps. A biphasic erythema is observed. Immediately after irradiation, initial faint erythema appears, disappearing within 30 min. The second phase of erythema starts 6 h after the irradiation and gradually increases, peaking between 24 and 48 h. The color is brownish-red, and the reaction is confined to the exposed area with a sharp boundary. By 48–72 h after irradiation, dark-brown scale is formed on the erythematous lesion. Pieces of the scale are relatively thick. The scale separates and the erythema decreases daily. The skin sites return to normal about 10 days after irradiation.

The irradiated rats are sacrificed after various time intervals by decapitation under ether anesthesia. Skin biopsies are taken immediately, fixed in 10% formalin and embedded in paraffin. Tissue sections (4 µm thick) are stained with hematoxylin and eosin. The numbers of the keratinocyte layers, including the basal layer, are counted by direct microscopy.

For DNA labeling (Morimoto et al. 1991), 20 mg/kg 5-bromo-2-deoxyuridine (BrdU) is administered i.p. 8 h before decapitation. Frozen tissue sections (8 µm) are prepared with a cryostat. The sections are then fixed in acetone for 10 min, 4% paraformaldehyde containing 1% $CaCl_2$ (pH 7.0) for 10 min and 1% glutaraldehyde for 5 min. After fixation, sections are digested with 0.006% pepsin in 10 mM HCl for 10 min at 37°C, and incubated in 4 M HCl for 30 min at ambient temperature to denature DNA. They are then incubated with anti-BrdU mouse monoclonal antibody and then

with alkaline phosphatase-conjugated anti-mouse IgG sheep IgG antibody. Antibody-binding sites are visualized with naphthol and fast red at pH 9 in the dark. The number of labeled as well as unlabeled cells at the epidermal basal layer or outer root sheath cell layers of the hair follicles are counted in five high-power fields to a total of at least 100 cells. The intensity of BrdU incorporation is demonstrated as a labeling index (%) with the following formula:

$$\text{labeling index} = \frac{\text{no. of labelled cells}}{\text{total cell no. counted}} \times 100$$

EVALUATION

Chronological changes of thickness of keratinocytes at the epidermis and the hair follicles as well as of DNA labeling indices are plotted as time-response curves.

MODIFICATIONS OF THE METHOD

Kippenberger et al. (2001) found that activators of peroxisome proliferator-activated receptors (PPARs) protect human skin from ultraviolet-B-light induced inflammation. In an *in vitro* model with human keratinocytes inflammation was mimicked by irradiation with ultraviolet light. Activators of PPARα were shown to reverse ultraviolet-B-light-mediated expression of inflammatory cytokines.

P.4.4 Hyperproliferative Epidermis in Hairless Mice

PURPOSE AND RATIONALE

Epidermal differentiation and barrier development *in vivo* are influenced by nuclear hormone receptors (Hanley et al. 1997, 1998, 1999; Kömüves et al. 1998; Rosenfield et al. 2000; Smith et al. 2001a, 2001b; Kuenzli and Saurat 2003a, 2003b). Kömüves et al. (2000) studied the effect of PPARα activators on keratinocyte differentiation in hyperproliferative epidermis in hairless mice.

PROCEDURE

Subacute epidermal hyperproliferation is induced by repeated barrier abrogation with acetone treatment (Denda et al. 1996). Animals are treated twice a day with acetone until the transepidermal water loss reaches 8–10 mg per cm^2 per h (measured on four to five different spots) as determined by an electrolyte water analyzer.

Chronic epidermal hyperproliferation due to essential fatty acids deficiency is achieved by feeding an isocaloric diet free of essential fatty acids after weaning for 2–3 months (Man et al. 1993).

To test the effect of PPARα activators, mice are treated on one flank side with solutions of the drug dissolved in propylene glycol/ethanol (3/7) twice a day for 3 days. After sacrifice, tissues are collected for histology, *in situ* hybridization, or immunohistochemistry.

EVALUATION

Data are presented as mean ± SEM. Statistical differences are determined using Student's *t*-test.

P.4.5 Psoriatiform Skin Diseases in Spontaneous Mice Mutations

PURPOSE AND RATIONALE

Nearly 100 mouse mutations have been described as causing some type of abnormality of the skin or hair. These include "asebia", a mildly hyperkeratotic disorder with sebaceous gland hyperplasia, "ichthyosis", an example of abnormal hair growth associated with hyperkeratosis, "rhino" and "hairless", two related examples of congenital follicular malformations, and "flaky skin", a potential animal model of eruptive psoriasis.

P.4.5.1 Flaky Skin (*fsn*) Mouse

PURPOSE AND RATIONALE

Flaky skin (*fsn*) is an autosomal recessive mouse mutation that causes pathologic changes in the skin, yielding a papulosquamous disease resembling human psoriasis (Sundberg et al. 1993). In addition, this mutation, assigned to distal chromosome 17, causes anemia and gastric forestomach hyperplasia (Beamer et al. 1995).

The *fsn* mutation arose spontaneously in the A/J inbred strain at The Jackson Laboratory (Beamer et al. 1986). Psoriasiform skin lesions are first evident as focal epidermal hyperplasia and inflammation at 2 weeks of age. These lesions become confluent and diffuse by 3–4 weeks of age and are associated with marked dermal infiltration of lymphocytes and small numbers of neutrophils and macrophages. Mast cell numbers increase significantly in the dermis from 2 weeks of age onward. Diffuse dermal neovascularization accompanies these cutaneous changes (Sundberg et al. 1997). Systemic lesions include progressive and massive papillomatosis of the stratified squamous epithelium of the forestomach, hyperplasia and dysplasia of the glandular stomach, increased apoptosis of cecal enterocytes, renal glomerulopathy associated with inflammatory cell infiltrates and fibrosis around the portal triads in the liver, splenomegaly due to massive erythropoiesis, and granulomatous lymphadenitis.

Scanning microscope examination (Morita et al. 1995) reveals a greatly thickened epidermis, and sparsity of hairs and scale accumulations in the epidermal surface. Hair shafts have conspicuous pits, striations, and exophytic protrusions. Nails are bent at a 90-degree angle with surface irregularities and accumulation of scale at the nail base. Transmission electron microscopic examination shows increased epidermal thickness, mitochondrial aberrations, and intraepidermal invasion by neutrophils. Keratin abnormalities are detected using immunocytochemical staining for profilaggrin. At the dermal-epidermal junction, numerous macrophages and mast cells are seen in close proximity to focal dissolutions of the basement membrane. A high density of collagen fibers and cellular infiltrates are evident in the papillary dermis.

Besides lymphadenopathy and mast cell accumulation, elevated serum IgE levels (>7000 fold increase compared with normal littermates), autoimmunity (evidenced by glomerulonephritis with immune complex deposition in the kidneys), are observed in flaky skin mutant mice (Pelsue et al. 1998).

Peripheral lymph nodes of adult mutant (*fsn/fsn*) mice were found to contain almost 10-fold more leukocytes than peripheral lymph nodes from phenotypically normal littermates. Analysis of peripheral lymph node cells using mAbs and flow cytometry revealed that this predominantly lymphoid hyperplasia is characterized by approximately equivalent increases of $CD3^+$ T cells and $C19^+$ B cells (Abernethy et al. 2000a). A dysregulated expression of CD69 and IL-2 receptor alpha and beta chains was found on $CD8^+$ T lymphocytes (Abernethy et al. 2000b). Expression and function of IL-1 beta is increased in psoriasiform skin lesions of flaky skin (*fsn/fsn*) mice (Schön et al. 2001).

However, neutrophils also played a critical role of for the generation of psoriasiform skin lesions in flaky skin mice (Schön et al. 2000). Intraperitoneal injection of the neutrophil-depleting RB6–85C monoclonal antibody resulted in a dramatic reduction of the epidermal thickness.

Similar to active human psoriatic lesions, an increase of epidermal growth factor receptors was observed in *fsn/fsn* mice (Nanney et al. 1996).

Sundberg et al. (1994a) transplanted full-thickness skin grafts from flaky skin mice on the dorsal skin

of genetically athymic nude (*nu/nu*) mice. The grafts maintained the psoriatiform phenotype of the donors.

Backcrosses to different mouse strains suggested several modifier genes affecting the *fsn* phenotype (Sundberg et al. 1994b). As cyclosporine A, in contrast to glucocorticoids, was not effective when used for topical or systemic treatment of *fsn* lesions, it seems that there is no immunologic basis for these lesions. Therefore, it remains uncertain whether the flaky skin mouse can be used to test potential therapeutic compounds.

P.4.5.2 Asebia (*ab/ab*) Mouse

PURPOSE AND RATIONALE

The asebia mouse was first described by Gates and Kasarek (1965) as hereditary absence of sebaceous glands. The asebia mouse represents a spontaneous mutation in BALB/c mice leading to hyperplasia of the epidermis and chronic inflammatory dermal changes, including enhanced cellularity, edema and elevated mast cell numbers (Josefowicz and Hardy 1978; Brown and Hardy 1988). The circadian rhythms in cell proliferation are suppressed in the chronically hyperproliferative epidermis of the asebia mouse (Brown et al. 1988a). UVB radiation as well as anthralin and tar with UVB further stimulate proliferation in the already hyperproliferative epidermis of the asebia mouse (Brown et al. 1988b, 1989). The gene for the enzyme stearyl-CoA desaturase 1, which is expressed in sebaceous glands, is disrupted in the asebia mouse (Parimoo et al. 1999; Zheng et al. 1999; Miyazaki et al. 2000). Besides Sdc1 and Sdc2, Zheng et al. (2001) identified Scd3 – a novel gene of the stearoyl-CoA desaturase family with restricted expression in the skin. Since T cell and neutrophil infiltrates are not observed in asebia mice, a pathogenesis distinct from psoriasis has been suggested (Schön 1999).

Asebia-2J (Scd1(ab2J)): a new allele and a model for scarring alopecia was described by Sundberg et al. (2000).

P.4.6 Psoriasiform Skin Diseases in Genetically Modified Animals

PURPOSE AND RATIONALE

Based on expression in inflammatory skin disorders, several factors, such as cytokines, are considered to play a crucial role in the pathogenesis of psoriasis and other skin diseases. Transgenic animals are tools to analyze these factors (Meyer 1990; Rothnagel et al. 1990; Sellheyer 1996; Rosenberg et al. 1999).

Bullard et al. (1996) described a polygenic mouse model of psoriasiform skin disease in **CD18-deficient mice**. CD18 deficiency in patients results in recurrent microbial infections, leukocytosis, impaired wound healing, failure of granulocyte emigration, and lack of pus formation (Anderson et al. 1995). A hypomorphic mutation for CD18 was introduced by Wilson et al. (1993) into mice with homocygotes displaying mild leukocytosis, an impaired response to chemically induced peritonitis, and delays in transplantation rejection. When this CD18 mutation was crossed back onto PL/J strain of mice, the development of an inflammatory skin disorder was observed (Bullard et al. 1996). The disease is characterized by erythema, hair loss, and the development of crusts. The histopathology reveals hyperplasia of the epidermis, subcorneal microabscesses, orthohyperkeratosis, parakeratosis, and lymphocyte exocytosis similar to human psoriasis and other hyperproliferative skin disorders. The dermatitis rapidly resolved after subcutaneous administration of dexamethasone.

Dermal infiltrates of macrophages/monocytes within the dermis of clinically uninvolved skin were seen in transgenic mice with epidermal overexpression of K14/IL-1α, suggesting a role of IL-1α for macrophage attraction (Groves et al. 1995). In severely affected animals, inflammation reactions occur that are characterized by a mixed inflammatory infiltrate, and by acanthosis and parakeratosis. **IL-1α transgenic mice** support a primary role of IL-1α as an inducer of cutaneous inflammation, which may be helpful for clarifying pathogenesis of psoriasis.

Wilson et al. (1990) reported that expression of the **BNLF-1 oncogene** of Epstein-Barr virus in the skin of transgenic mice induces hyperplasia and aberrant expression of keratin 6.

Cook et al. (1997, 1999) found that overexpression of the heparin-binding EGF-related ligand amphiregulin in the epidermis of transgenic mice induces a psoriasis-like cutaneous phenotype. **Transgenic mice with a K14 enhancer/promoter-driven amphiregulin gene** targeted to the epidermis displayed a macroscopic phenotype that included extensive areas of scaling and erythematous skin with marked alopecia. Histological examination revealed hyperkeratosis, focal parakeratosis, acanthosis, mixed leukocytic infiltration that included both CD3-positive T cells in the dermis and epidermis, and a tortuous vasculature.

Two completely opposite phenotypes were observed in **mice expressing K10/BMP-6** (bone morphogenetic protein-6, a member of the TGF-β superfamily) within the epidermis (Blessing et al. 1996). Whereas keratinocyte proliferation was severely reduced in animals with strong and homogenous expression of the transgene, weaker and patchy expression led to marked hyperproliferation.

Rodriguez-Villanueva et al. (1998) reported that **human keratin-1.bcl-2 mice** aberrantly express keratin 6, exhibit reduced sensitivity to keratinocyte cell death induction, and are sensible to skin tumor formation.

The concept of vascular endothelial growth factor (VEGF) being an important angiogenic factor in psoriatic skin (Detmar et al. 1994) was supported by **transgenic mice with constitutive epidermal K14/VEGF expression**. These animals exhibited dilated and contorted dermal microvessels (Detmar et al. 1998). There was also an increased number of dermal mast cells, and leukocyte adhesion and extravasation was enhanced in VEGF transgenic mice. The transgenic delivery of VEGF to mouse skin results in a profound inflammatory condition with many of the cellular and molecular features of psoriasis, including the characteristic vascular changes, epidermal alterations, and inflammatory infiltrates. These symptoms can be effectively reversed by the addition of VEGF Trap, a potent VEGF antagonist (Xia et al. 2003). VEGF-A also promoted lym-

phatic vessel proliferation and enlargement. Combined systemic treatment with blocking antibodies against VEGF receptor-1 (VEGFR-1) and VEGFR-2 potently inhibited inflammation and also decreased lymphatic vessel size (Kunstfeld et al. 2004).

Klement et al. (1996) found that **IκBα deficiency** results in a sustained NF-κB response and widespread dermatitis in mice.

Seitz et al. (1998) reported that alterations on NF-κB function in transgenic epithelial tissue demonstrate a growth inhibitory role for **NF-κB**.

To determine the role of κB-α deficient immunocytes in the pathogenesis of skin disease in adult mice, Chen et al. (2000) utilized the RAG2-deficient blastocyst complementation system to generate **RAG2–/–, IκB-α–/– chimeras**. These animals display a psoriasiform dermatitis characterized by hyperplastic epidermal keratinocytes and dermal infiltration of immunocytes, including lymphocytes. Skin grafts transferred from diseased chimeras to recipient nude mice produce hyperproliferative epidermal keratinocytes in response to stimulation.

Transgenic mice overexpressing suprabasal integrins α_2, α_5, and β_1 demonstrate a phenotype similar to psoriasis with cycles of flaking and inflamed skin, suggesting that disrupted keratinocyte integrin-ligand interactions may play a role in hyperproliferative states (Carroll et al. 1995).

Robles et al. (1996) found that **expression of cyclin D1 in epithelial tissue** of transgenic mice results in epidermal hyperproliferation and severe thymic hyperplasia.

Carroll et al. (1997) used the **involucrin promoter to overexpress** IFN$_\gamma$ in the suprabasal layers of transgenic mouse epidermis. The mice exhibited striking hypopigmentation of the hair due to reduction of DOPA-positive melanocytes. Severely affected mice had reddened skin, growth retardation, hair loss, and flaky skin lesions. The skin was characterized by a dermal infiltrate of T lymphocytes and macrophages/monocytes.

When **scid/scid mice were reconstituted with MHC-matched, but minor histocompatibility mismatched CD4$^+$/CD45RB^{hi}T lymphocytes**, almost all of the animals developed skin lesions similar to human psoriasis within 4–8 weeks after transfer (Schön et al. 1997). The psoriatiform skin lesions did not develop in recipients of unfractionated splenocytes or CD4$^+$/CD45RB^{lo} T cells, indicating that T cell dysregulation is the primary pathogenic factor in this model. When recipients of CD4$^+$/CD45RB^{hi} T cells were treated with either cyclosporine A or UVB irradiation, the psoriasiform lesions were dramatically improved demonstrating that immunosuppressive therapies are efficacious. The model was proposed as a T cell initiated murine model of inflammatory skin lesions (Schön and Parker 1997).

Mann et al. (1993) found that mice with a **null mutation of the TGF-a gene** have abnormal skin architecture, wavy hair, and curly whiskers and often develop corneal inflammation.

Turksen et al. (1992) described psoriasiform changes in the skin of transgenic mice with **overexpression of interleukin 6**.

Guo et al. (1993) reported that targeting expression of **keratinocyte growth factor** to keratinocytes elicits striking changes in epithelial differentiation in transgenic mice.

Hong et al. (1999) showed that IL-12, independently of IFN-gamma, plays a crucial role in the pathogenesis of a murine psoriasis-like disorder. Only a few *scid/scid* mice develop skin lesions when CD4$^+$/CD45RB^{hi} are transferred alone. Coadministration of LPS plus IL-12 or staphylococcal enterotoxin B in *scid/scid* mice one day after **CD4$^+$/CD45RB^{hi}cell transfer** greatly enhances disease penetrance and severity.

Schön et al. (2000) reported a cutaneous inflammatory disorder in **integrin alpha E (CD103)-deficient mice**. Skin inflammation correlated with alpha E deficiency in mice with a mixed 129/Sv × BALB/c background.

Transgenic rats expressing human HLA-B27 and β_2-microglobulin develop psoriasiform skin changes as part of a multi-organ inflammatory disease (Hammer et al. 1990). In the most severely affected lines, psoriasiform lesions first occurred at about 20 weeks of life and were observed in 10% to 80% of animals. Male appeared to be more prone to skin changes than females (Taurog et al. 1993, 1994, 1999). Similar to human pathogenesis, T cells seem to be the most important factor in HLA-B27 transgenic rats (Breban et al. 1996).

Xenotransplantation of Human Psoriatic Skin

PURPOSE AND RATIONALE

Xenotransplantation models for psoriasis involve the transfer of human psoriatic skin to animals. First stud-

ies were performed by transplantation of involved psoriatic and non-psoriatic human skin onto congenitally athymic (nude) mice (Krueger et al. 1975, 1985; Baker et al. 1992). More recently, human psoriatic skin grafts were transplanted onto SCID mice (Nickoloff et al. 1995; Boehncke et al. 1994, 1997, 1999; Gilhar et al. 1997; Sugai et al. 1998; Dam et al. 1999; Raychaudhuri et al. 2001) allowing screening of anti-psoriatic drugs.

PROCEDURE

Keratome biopsies ($7 \times 2 \times 0.05$ cm containing both dermis and epidermis) are obtained from clinically symptomless skin of patients with psoriasis or from psoriatic plaques. Prior to the procedure, the skin is defined and infiltrated with 1% lidocaine and epinephrine 1:200. The full-thickness skin biopsy is dissected into 12 grafts. CB-17 SCID mice at an age of 6–8 weeks are anesthetized with an i.p. injection of 1.56 mg phenobarbital before transplantation of the human xenografts on the flank area. The grafts are sutured with absorbable 6–0 Vicryl Rapid suture and covered with Xeroform dressings for one week. Animals transplanted with the psoriatic plaque are then randomized into groups receiving PBS as negative controls or 0.15 mg cyclosporine A or the test compound intradermally into the xenografts. Within 4 weeks, the animals are sacrificed by CO_2 asphyxiation and 4 mm punch biopsies are obtained from each xenograft. Biopsies are fixed in 10% neutral-buffered formalin for paraffin embedding.

EVALUATION

A semiquantitative scale is used to indicate the extent of new vessel formation (angiogenesis) that can be seen between the xenograft and the underlying fascia muscularis. A calibrated eyepiece microscope is used for estimating the epidermal thickness in the vertical sections. Statistical differences are calculated using Student's *t*-test for multiple comparisons.

MODIFICATIONS OF THE METHOD

Using this model, Raychaudhuri et al. (2004) found that a high-affinity nerve growth factor receptor blocker improves psoriasis.

Nickoloff et al. (1995) studied severe combined immunodeficiency mouse and human psoriatic skin chimeras. Autologous blood-derived $CD4^+$ cells injected into symptomless transplanted psoriatic skin engrafted onto SCID mice produced full-fledged psoriatic lesions (Wrone-Smith and Nickoloff 1996; Sugai et al. 1998; Nickoloff and Wrone-Smith 1999; Nickoloff et al. 1999; Nickoloff 2000).

Yamamoto et al. (1998) studied the effects of superantigen-driven peripheral blood mononuclear cells on the persistence of psoriasiform epidermis and on the cytokine gene expression of grafted psoriatic skin. Staphylococcal enterotoxin B-stimulated peripheral blood mononuclear cells from psoriatic patients were repeatedly injected under the grafted full-thickness involved psoriatic skin onto severe combined immunodeficient mice. A persistence of the psoriasiform epidermis was found after 5 weeks. E-selectin expression was observed on endothelial cells in the upper epidermis of the mice.

Tissue specificity of E- and P-selectin ligands in Th1-mediated chronic inflammation was studied by Chu et al. (1999).

Zeigler et al. (2001) used the human psoriatic skin-SCID mouse transplant model to compare the effect of antibody to CD11a with ciclosporin and clobetasol propionate.

Zollner et al. (2002) used a SCID-hu model and found that proteosome inhibition reduces superantigen-mediated T cell activation and the severity of psoriasis.

Boyman et al. (2004) presented an animal model in which skin lesions developed spontaneously when symptomless prepsoriatic human skin was engrafted onto AGR129 mice, deficient in type I and type II interferon receptors, and for the recombination activating gene 2. Upon engraftment, resident human T cells in prepsoriatic skin underwent local proliferation.

P.5
Scleroderma Models

P.5.1
Scleroderma Models in Chicken

Scleroderma is an autoimmune disorder which occurs in the severe systemic form, a localized scleroderma (morphoea) and as lichen sclerosus et atrophicus. Chickens of the University of California line 200 (**UCD-200 chickens**) developed an inherited inflammatory fibrotic disease, closely resembling human progressive systemic sclerosis (scleroderma) (Gershwin et al. 1981; Van de Water et al. 1984; Boyd et al. 1991; Gruschwitz et al. 1991, 1993; Herold et al. 1992; Needleman 1992; Brezinscheck et al. 1993; Ausserlechner et al. 1997; Nguyen et al. 2000). An acute inflammatory stage started at an age of about 60 days after hatching, leading to fibrosis with fast progression with severe lymphocytic infiltration and excessive accumulation of collagen in skin and internal organs. A sequential increase of type VI, type I and type II procollagen transcripts and a progressive increase of autoantibodies to histone, to ssDNA and to dsDNA was found.

A further strain of chickens with progressive systemic sclerosis (UCD 206) has been identified (Duncan et al. 1995; Sgonc et al. 1995).

Worda et al. (2003) analyzed the apoptosis-inducing effect of anti-endothelial cell antibodies in systemic sclerosis by the chorionallantoic membrane assay.

P.5.2 Scleroderma Models in Mice

Jimenez and Christner (2002) gave a survey on murine animal models of systemic sclerosis.

The **tight-skin mouse** is regarded as an experimental model for scleroderma (Walker et al. 1990; Muryoi et al. 1992; Delany and Brinkerhoff 1993; Kasturi et al. 1993, 1994; Wallace et al. 1994; Pablos et al. 1995; Frondoza et al. 1996). This mutant mouse develops autoantigens specific for scleroderma target tissues. The tight-skin disease was first discovered in 1967 at the Jackson Laboratory in the B10.D2(58N)/Sn mouse strain. The disease occurred spontaneously. Green et al. (1976) have identified the tsk locus and shown it to be linked to pallid locus. The tight skin character is transmitted as an autosomal dominant trait and homozygous tsk/tsk mice die *in utero*. The striking feature of the disease is the presence of thickened skin, firmly bound to subcutaneous and deep muscular tissue, with excessive accumulation of collagen in skin and internal organs (Menton et al. 1978; Osborn et al. 1983). Synthesis and accumulation of type I collagen is markedly increased (Jimenez et al. 1986; Ong et al. 1998). Biochemical studies have shown that the prolyl hydroxylase and glycosaminoglycan content of the affected tissue is increased (Ross et al. 1987).

Dermal fibrosis in the tight-skin mouse was reduced after local application of halofuginone, an inhibitor of collagen type I synthesis (Pines et al. 2001).

Additionally, the **tight skin 2 mouse** has been described as an animal model of scleroderma displaying cutaneous fibrosis and mononuclear cell infiltration (Christner et al. 1995, 1996; Wooley et al. 1998; Sgonc et al. 1999).

Bleomycin-induced scleroderma in genetically mast cell deficient **WBB6F1-W/W^V mice** was described as an animal model of sclerotic skin (Yamamoto et al. 1999a–d, 2000; Yamamoto and Nishioka 2001, 2002; Yamamoto 2002).

Murine sclerodermatous graft-versus-host disease is considered as a model for human scleroderma (Claman 1990; Schiltz et al. 1994; McCormick et al. 1999; Zhang et al. 2002, 2003; Atamas and White 2003). Fibrosis in sclerodermatous graft-versus-host disease is driven by infiltrating TGF-β_1-producing mononuclear cells. Zhang et al. (2002) characterized the origin and types of cutaneous effector cells, the cytokine and chemokine environments, and the effects of anti-TGF-β antibodies on skin fibrosis, immune cell activation markers, and collagen and cytokine synthesis.

Dong et al. (2002) transplanted skin from scleroderma patients to SCID mice and investigated the skin xenografts for factors downstream of TGF-β. Deficient expression of Smad7 was found as a putative molecular defect in scleroderma.

A syndrome resembling human systemic sclerosis (scleroderma) in **MRL/lpr mice lacking interferon-receptor** was described by Le Hir et al. (1999).

P.6 Pemphigus Models

P.6.1 Experimentally Induced Pemphigus in Mice

PURPOSE AND RATIONALE

Pemphigus is defined as a group of spontaneously occurring disorders of skin and mucosae in which blisters and erosions form within the epidermis due to loss of intercellular contact (Marks 1987). Pemphigus occurs also spontaneously in domestic animals, such as dogs, cats, and horses (Hurvitz 1980; Scott et al. 1983; Sueki et al. 1997). Various attempts were made to study experimentally induced pemphigus in mice (Buschard et al. 1981; Takahashi et al. 1985; Anhalt et al. 1986a, b; Rock et al. 1990; Juhasz et al. 1993; Allbritton et al. 1997; Koch et al. 1997; Fan et al. 1999;

Mahoney et al. 1999; Amagai et al. 2000; Zillikens et al. 2001, Rädisch et al. 2002; Hashimoto 2003).

Fan et al. (1999) screened four strains of female mice (BALB/c, DBA/1, SJL/J, and HRS/J) for their ability to produce pathogenic anti-desmoglein 3 antibodies. Only BLB/c mice immunized with full length desmoglein 3 can produce pathogenic antibodies capable of causing acantholysis in human foreskin in culture and blistering in neonatal mice.

PROCEDURE

Six- to 8-week-old female BALB/c, DBA/1, SJL/J, and HRS/J are immunized four times with 20 µg/mouse of purified desmoglein 3 protein in CFA (on days 1, 10, 20, and 30), four times with 20 µg/mouse of extracellular domain of desmoglein 3 (on days 40, 50, 60, and 70), and twice with 20 µg/mouse of refolded desmoglein 3 (on days 80 and 90), then they are boosted twice more with 20 µg/mouse of extracellular domain of desmoglein 3 in IFA by i.p. inoculation (on days 97 and 104). Control groups of mice are similarly immunized with BSA.

IGs from 10 ml of pooled serum from mice immunized with desmoglein 3 are precipitated with 40% ammonium sulfate, dialyzed against PBS twice, lyophilized, and reconstituted in water to 1 ml. One hundred µl of the reconstituted antibodies/mouse is injected into neonatal BALB/c mice.

EVALUATION

Mice are examined 18–24 h post injection for blister formation. Cross sections containing the blister and comparable areas in control animals are biopsied and frozen sections are prepared for routine histological examination.

MODIFICATIONS OF THE METHOD

Amagai et al. (2000) and Ohyama et al. (2002) developed an active autoimmune disease model for pemphigus using autoantigen knockout mice.

Xu et al. (2001) characterized BALB/c mice B lymphocyte autoimmune responses to skin basement membrane component type XVII collagen, the target antigen of the autoimmune skin disease bullous pemphigoid. The mice were immunized with peptides of the human and/or the murine-equivalent BPAg2 pathogenic NC16A domain.

Using keratinocytes from plakoglobin knockout mice, Caldelari et al. (2001) studied the role of the Armadillo protein plakoglobin in pemphigus vulgaris.

Nguyen et al. (2004) reported that pemphigus vulgaris IgG and methylprednisolone exhibit reciprocal effects on keratinocytes. The therapeutic effects of methylprednisolone may be due to both the upregulated synthesis and the post-translational modifications of keratinocyte adhesion molecules.

P.7
Ichthyosis Vulgaris Models

P.7.1
Experimentally Induced Ichthyosis in Mice

PURPOSE AND RATIONALE

Ichthyosis vulgaris is a heterogeneous autosomal skin disease characterized by dry, scaly skin, mild hyperkeratosis, and a decreased or absent granular layer that either lacks, or contains morphologically abnormal, keratohyalin granula (Anton-Lamprecht and Hofbauer 1972). Both the skin of ichthyosis vulgaris patients and keratinocytes cultured from affected individuals exhibit reduced or absent profilaggrin mRNA and protein levels (Sybert et al. 1985). The symptoms and the genetics of the ichthyotic (*ic/ic*) mouse were described by Spearman (1960), Green et al. (1974), Jensen and Esterly (1977), Holbrook (1989). Presland et al. (2000) demonstrated loss of normal profilaggrin and filaggrin in flaky tail (*ft/ft*) mice and proposed this as an animal model for the filaggrin-deficient skin disease ichthyosis vulgaris.

Elias et al. (1983) and Chung et al. (1984) induced ichthyosis in the hairless mouse by treatment with diazacholesterol and used this as an assay for comparative potency of topical retinoids.

PROCEDURE

Male hairless mice, 2–3 months old, are fed either a normal laboratory diet supplemented with 60 mg/kg/day of 20,25-diazacholesterol or normal laboratory diet. Diazacholesterol blocks the conversion of Δ^{24}-reduction of desmosterol to cholesterol (Anderson and Martt 1965), and as a result desmosterol accumulates in stratum corneum lipids rather than cholesterol. Ichthyotic changes generally become apparent after 8–12 weeks and are most pronounced over the back and tail. With the exception of some reduction in body weight in comparison with controls, the animals appear healthy. Since the tail manifests the most exaggerated scaling, this site is used for topical drug applications. As the animals become ichthyotic, the daily dose of diazacholesterol can be lowered to 30 mg/kg and maintained at that level.

The test substances (retinoids) are first solubilized in a small volume of dimethyl sulfoxide and then dissolved in Cremophore EL. A volume of ~100 µl of each test substance is applied once daily to circumscribed areas of the tail. Treatment groups consist of 3 animals each, and each animal serves as its own control. The drop is first placed on an investigator's gloved index fingers and then spread evenly around a designated band of the tail. Each animal is treated with two concentrations of the test drug. The most proximal and most distal portions of the tail are left untreated as control regions. Applications are continued for 2 weeks. At three- or four-day intervals, and at the termination of the experiment, the clinical response is graded from 0 to 4+, with 0 indicating no response and 4+ indicating removal of all visible scale, leaving a glistening surface.

Prior to biopsy, the skin surface is coated with a thin film of flexible collodion to prevent fragmentation during frozen sectioning. Perpendicular sections of biopsy samples are stained with aqueous 8-anilino-2-naphthalene sulfonic acid, which on fluorescence microscopy depict selectively stratum corneum hydrophobic membrane domains.

EVALUATION

Both control and drug-treated sections are measured in a double-blind manner. The mean and SE from a minimum of five separate regions are tabulated. Significant differences are determined by Student's *t*-test.

MODIFICATIONS OF THE METHOD

Harlequin ichthyosis (ichq): a juvenile lethal mouse mutation with ichthyosiform dermatitis was described by Sundberg et al. (1997).

Shultz et al. (2003) described mutations at the mouse ichthyosis locus within the lamin B receptor gene as a single gene model for human Pelger-Huet anomaly.

Knox and Lister-Rosenoer (1998) described an infantile ichthyosis in **rats** and proposed this as a new model of hyperkeratotic skin disease.

P.8 Xeroderma Models

P.8.1 Experimentally Induced Xeroderma in Mice

PURPOSE AND RATIONALE

Xeroderma pigmentosum is an autosomal recessive disorder characterized by hyperphotosensitivity and multiple cancers in association with abnormal DNA repair (Robbins et al. 1974; Satokata et al. 1992). Xeroderma pigmentosum group A (XPA) gene-deficient mice cannot repair UV-induced DNA damage and easily develop skin cancers by UV-irradiation (Nakane et al. 1995; Miyauchi-Hashimoto et al. 1996, 1999). Kuwamoto et al. (2000) tested the involvement of enhanced prostaglandin E_2 production in the photosensitivity in Xeroderma pigmentosum group A model mice and the influence of a prostaglandin synthesis inhibitor.

PROCEDURE

XPA gene-deficient homogeneous mice, age 8–12 weeks, are used (Nakane at al 1995). The UVB source consists of a bank of fluorescent sunlamps with an emission spectrum from 270 to 375 nm, peaking at 305 nm. The mice are anesthetized by i.p. injection of phenobarbital to keep them immobile during exposure. The ears are irradiated with 250 mJ per cm^2 of UVB. Immediately after irradiation, the test drug (20 µl of 1% solution of the prostaglandin synthesis inhibitor indomethacin) is applied to the ears. Ear thickness is measured with a dial thickness gauge immediately before irradiation and 1–4 days after irradiation. The amounts of PGD_2, PGE_2, and PGF_{2a} in mouse ears at 0, 24, 48, and 72 after UVB irradiation are determined by enzyme immunoassay.

EVALUATION

Student's *t*-test is employed to determine the statistical difference between means.

MODIFICATIONS OF THE METHOD

De Boer et al. (1999) described a mouse model for the DNA repair/basal transcription disorder trichothiodystrophy, revealing cancer predisposition.

Sun et al. (2003) described a genetic mouse model carrying the nonfunctional xeroderma pigmentosum group G gene. A disrupted XPG allele was generated by insertion of neo cassette sequences into exon 3 of the XPG gene by using embryonic stem dell techniques.

P.9 Vitiligo Models

P.9.1 Vitiligo in Mice

PURPOSE AND RATIONALE

A **mouse model for vitiligo** was described by Lerner et al. (1986), designated C57BL/6J-vit/vit. The vitiligo mouse has congenital dorsal and ventral white spots as well as progressive replacement of pigmented hairs with each spontaneous molt or after plucking.

Sidman et al. (1996) described pigment epithelial and retinal phenotypes in the vitiligo mivit, mutant mouse.

Tang et al. (1997) studied abnormalities of the electroretinogram in relation to histopathological findings in vitiligo mutant mice.

Iwamoto et al. (1991) established a mouse model for melanoma in which metallothionein/ret transgenic mice express the ret oncogene fused to the metallothionein promoter. Lengagne et al. (2004) reported the occurrence of spontaneous vitiligo in this animal model for human melanoma.

P.9.2 Smyth Line Chickens

PURPOSE AND RATIONALE

Smyth et al. (1981) developed a mutant line of chickens (DAM line) that is charactereized by a high incidence of spontaneous, postnatal, cutaneous amelanosis as a result of an autoimmune phenomenon (Smyth 1989). An intrinsic melanocyte defect, characterized by melanosomes with abnormal irregular surfaces, predisposes these chickens to the pigment disorder (Boissy et al. 1986). Both B cell and T cell compartments of the immune system are involved in the pathology of the disease (Lamont et al. 1982; Erf et al. 1995). Melanocyte-specific antibodies have been detected in the serum of Smyth line chickens (Austin et al. 1992). These autoantibodies cross-react with mouse and human melanocytes and are able to bind pigment within tissues (Searle et al. 1993). Mammalian tyrosinase-related protein-1 is recognized by autoantibodies from vitiligous Smyth chickens (Austin and Boissy 1995). The Smyth chicken model for spontaneous autoimmune vitiligo shows various incidences and degrees of alopecia ranging from alopecia areata-like to universalis-like integumental changes (Smyth and McNeil 1999). Sreekumar et al. (2000) analyzed

the effect of endogenous viral genes in the Smyth line chicken model for autoimmune vitiligo. Erf et al. (2001) reported a strong connection between herpes virus infection and the expression of autoimmune vitiligo in Smyth line chickens. Sreekumar et al. (2001) performed molecular characterization of the Smyth chicken sublines and their parental controls by restriction fragment length analysis and DNA fingerprint analysis. Wang and Erf (2003, 2004) investigated the melanocyte-specific cell-mediated immune response in vitiliginous Smyth line chickens and studied apoptosis in feathers of Smyth line chickens with autoimmune vitiligo.

P.10 Erythropoietic Protoporphyria

P.10.1 General Considerations

PURPOSE AND RATIONALE

Erythropoietic protoporphyria (EPP) is an inherited disease that is associated with deficiency of the last enzyme of heme biosynthesis, ferrochelatase, which catalyzes the insertion of ferrous iron into protoporphyrin. Ferrochelatase deficiency is accompanied by photosensitivity syndrome (Bottomley et al. 1975; Cox 1997; Lim and Cohen 1999). It is characteristically manifested by a severe burning pain associated with edema and erythema within a few minutes of exposure to visible light (Cox 1997). Some of these symptoms are related to the extravasation of intravascular contents, such as blood plasma, caused by pronounced damage to endothelial cells (Brun and Sandberg 1991). The defect in ferrochelatase results in accumulation of protoporphyrin (Bottomley et al. 1975; Cox 1997; Lim and Cohen 1999), which may be produced in immature red blood cells, released into the plasma, and accumulate in the cell membranes of endothelial cells due to its hydrophobicity (Brun and Sandberg 1991).

P.10.2 Animal Models for Erythropoietic Protoporphyria

PURPOSE AND RATIONALE

Many animal models on erythropoietic protoporphyria are published. Berenson et al. (1992) described a new model of protoporphyric hepatopathy using protoporphyrin overload in unrestrained rats.

Most studies have been performed using mice (Gschnait et al. 1975; Konrad et al. 1975; Cantoni et al. 1983; Tanaka et al. 1993; Libbrecht et al. 2003; Bellingham et al. 1995) described experimental murine protoporphyria induced by griseofulvin. Smith et al. (1997) induced protoporphyria by the orally active iron chelator 1,2-diethyl-3-hydroxypyridin-4-one in C57BL/10ScSn mice.

Many authors (Boulechfar et al. 1993; De Verneul et al. 1995; Meerman et al. 1999; Fontanellas et al. 2001; Abitbol et al. 2005; Han et al. 2005; Navarro et al. 2005) have used genetically altered mice with a recessive inherited ferrochelatase deficiency, originally described by Tutois et al. (1991). Magness et al. (1998) analyzed the human ferrochelatase promoter in transgenic mice.

Pawliuk et al. (2005) reported prevention of murine erythropoietic protoporphyria-associated skin photosensitivity and liver disease by dermal and hepatic ferrochelatase.

Takeshita et al. (2004) performed an L-band electron spin resonance (ESR) study to investigate *in vivo* oxygen radical generation in the skin of the protoporphyria mouse model with visible light exposure.

PROCEDURE

Chemiluminescence techniques have been used to detect $^1O_2$ and O_2^{*-} using the emission of $^1O_2$ itself or a chemiluminescent probe (Khan 1981; Nakano et al. 1986). As the luminescence arising from reactive oxygen species is usually very weak compared with the irradiating light, it is technically hard to evaluate reactive oxygen species generation during photodynamic reactions using this method. *In vivo* generation of reactive oxygen species was detected in the skin in erythropoietic protoporphyria disease during irradiation with light, using a technique other than chemiluminescence.

In vivo electron spin resonance (ESR) spectroscopy was used operating at low microwave frequencies as an alternative to chemiluminescence techniques. This technique has enabled the non-invasive measurement of durable free radicals, including a nitroxyl radical, in living experimental animals (Subczynski et al. 1986; Bacic et al, 1989; Ishida et al. 1989; Ferrari et al, 1990; Utsumi et al. 1993). The nitroxyl radical loses its ESR signal on reaction with transient free radicals, such as $^*OH$ and O_2^{*-} (Takeshita et al. 2004). Free radical reactions were evaluated in various animal models, including hyperoxia (Miura et al. 1992), ischemia–reperfusion (Utsumi et al. 1993), X-ray irradiation (Miura et al. 1997), and streptozotocin-induced diabetes (Sano et al. 1998) using L-band (1–1.2 GHz) and 300 MHz ESR spectrometers with a nitroxyl radical probe (a spin probe). In these experiments, the disease model animal was set in the loop-gap resonator of the ESR spectrometer. Loop-gap type resonators are unsuitable for measuring radicals in the skin of experimental animals, because they detect radicals distributed throughout the body. By contrast, a surface-coil-type resonator (surface resonator) has been used to measure radicals in limited positions, such as the skin (Bacic et al. 1989; Swartz et al. 1994; Kuppusamy et al. 1998; He et al. 2001; Fuchs et al. 1997). Furthermore, ESR measurement with a surface resonator does not interfere with light irradiation, since only the single-turn coil portion of the resonator is attached to the skin.

This study used ESR with a surface resonator to detect *in vivo* ROS generation with light exposure in the skin of griseofulvin-induced protoporphyria model mice, a standard model for EPP (Gschnait et al. 1975; Konrad et al. 1975; Wolff et al. 1975; Plosch et al. 2002).

P.11 Acne Models

P.11.1 Activity on Sebaceous Glands of Rats

PURPOSE AND RATIONALE

Bioassays for topical antiandrogens are based on inhibition of sebum secretion. Sebum production is increased by endogenous or exogenous androgens in many species including humans. In the mouse (Lapière and Chèvremont 1953; Neumann and Elger 1966), the Mongolian gerbil (Mitchell 1965), and the golden hamster (Hamilton and Montagna 1950), the male sex hormone stimulates sebum production and sebaceous gland growth. Morphometric evaluation by light microscopy in the rat has shown that castration causes a large reduction in the volume of the glands (Sauter and Loud 1975). The administration of testosterone over several days produces an enlargement of the sebaceous glands. Early transformations, which take place in the morphology of the organelles in sebaceous cells, can be observed by electron microscopy. In the cyto-

plasm of intermediate cells a large number of vesicular elements derived from the smooth endoplasmic reticulum is formed, participating in the synthesis of lipids which appear as droplets of varying size (Karasek 1968; Morohashi 1968). Following an increase of lipid droplets, the cells increase in size, become totally differentiated and are pushed towards the apex of the gland where they break up and release their content (sebum) into the infundibulum. This effect is used for morphometric evaluation of topical anti-androgens.

PROCEDURE

Groups of 5 adult male Sprague-Dawley rats weighing 180–220 g are shaved in the interscapular area. Twenty-four hours later, the test preparation or the standard (cyproterone acetate) is applied locally to the shaved area at increasing doses (0.05, 0.5, and 5 mg/cm^2) in 20 µl ethanol. The treatment is continued for three weeks. Controls receive ethanol only. The animals are sacrificed 24 h after the last administration. Pieces of skin from the interscapular region are excised and processed for evaluation by electron microscopy. The volume density of the smooth endoplasmic reticulum vesicles is measured.

EVALUATION

Dose-response curves are established for volume density of vesicles of the smooth endoplasmic reticulum after various doses of antiandrogen and testosterone standard in order to calculate activity ratios. Statistical comparison with untreated controls allows calculation of threshold doses.

MODIFICATIONS OF THE METHOD

Ebling and Petrow (1993) tested 19-Aldehydo-4-androstene-3,17-dione, an estrogen precursor that inhibits sebaceous secretion in ovariectomized testosterone-treated rats.

De Young et al. (1984, 1985) described intradermal injection of *Propionibacterium acnes* as a model of inflammation relevant to acne. Intradermal injection of killed *P. acnes* into the rat ear induces a chronic acne-like inflammation characterized by edema and cell infiltration of several months' duration, formation of comedones, hypersensitization, and transepithelial elimination.

Shamoto et al. (1999) investigated the dermal histology and the regional draining superficial lymph node of a new mutant strain of hairless rats (ISh). The homocygote ISh rat was characterized as having naked and wrinkled skin. The comedo-like casts in the skin resembled human acne.

P.11.2 Activity on Sebaceous Glands of the Fuzzy Rat

PURPOSE AND RATIONALE

Fuzzy rats, a genetic mutant between hairless and haired albino rats, exhibit sexual dimorphism in the skin (Ferguson et al. 1979). A brown-colored, thick seborrhoeic coating on the entire back is characteristic of male rats while the female rats show clear skin with white fuzzy hairs. In male rats the hair follicles resemble human sebaceous follicles associated with hyperplastic glandular lobules, dilatation and micro-comedo (Plewig and Kligman 1975). Castration caused a reduction in size of the sebaceous glands and ducts, and a testosterone implant in castrated rats resurrected glandular hyperplasia and ductal dilatation (Uno et al. 1990).

This rodent model for androgen-dependent hyperplasia of the sebaceous glands is useful for the study of many pharmacological aspects, comprising the rate of percutaneous absorption, stability, and affinity to target organs of the testing compounds and selection of adequate vehicles for topical application (Ye et al. 1997).

PROCEDURE

Peripubertal male fuzzy rats at an age of 25 days weighing about 40 g are kept in single cages at a temperature of 24°C and a 12-h light-and-dark cycle. They are divided into several groups for local treatment with 5α-reductase inhibitors or androgen receptor antagonists. One group serving as control is castrated at an age of 25 days in anesthesia. Approximately 0.5 ml of a 1% solution of test compounds dissolved in 30% propylene glycol, 50% alcohol and 20% water are applied to the other groups in a 4 × 4 cm area on the lower back once per day 5 days per week. Vehicle solution alone is applied to the control and castrate groups. After 8 weeks of treatment, the animals are euthanized by anesthesia with ketamine HCl, 100 g/ml, xylazine HCl, 120 g/ml, acepromazine, 5 g/ml, 1 ml/kg intramuscularly.

Photographs of the backs are taken pre-treatment and every 2 weeks after the start of treatment.

Eight weeks after starting treatment, the animals in all groups are given an intraperitoneal injection of 200 mg/kg bromodeoxyuridine 2 h before euthanasia. A blood sample is then collected from the right ventricle of the heart under anesthesia with the ketamine-xylazine-acepromazine mixture. After euthanasia with an overdose of the same anesthesia solution, fresh skin tissues are taken by a punch (4 mm diameter) from the marked area of the back and immediately incubated with EDTA solution for the split-skin preparation. The rest of the skin in the marked area is cut and fixed with 10% neutral buffered formalin solution for morphometric analysis of the sebaceous glandular lobules. The ventral lobes of the prostate are dissected and the weight is measured.

For morphometric analysis of the sebaceous glands, the size of sebaceous glandular lobules is first determined. Using formalin-fixed skin, small skin samples are taken by punch (4 mm diameter) and serial frozen sections (40 µm thick), horizontal to the epidermal surface, are cut and collected in water-filled wells. Four to five free-floating sections containing sebaceous glandular lobules are selected and stained with 1% osmium and 2.5% potassium dichromate solution for 2–3 min. The sections are washed with distilled water and mounted on a glass slide with aqua mount. Darkly stained globular lobules are distinctively seen under the microscope or on microvideo images. The largest lobular area in each glandular image is measured by a computer-assisted microimage apparatus, using a program of image analysis.

Split preparations of the pilosebaceous organ are used to measure the size of the sebaceous lobule and duct, and the number of DNA synthesis sebocytes. Fresh skin samples, 4 mm punched, are incubated with 17 mM EDTA in phosphate buffer (0.1 M, pH 7.4) for 2 h at 27°C. The pilosebaceous organs attached to the epidermis are manually split from the dermis. Following fixation with 10% buffered formalin, free-floating split tissues are stained by the immunocytochemical method, using a monoclonal antibody against bromodeoxyuridine with the avidin-biotin complex method.

On viewing the split tissue under a stereomicroscope, the sebaceous glandular lobules with a duct attached to the follicular shaft are clearly visible. After mounting on a slide glass, these *in situ* images of the sebaceous glands are observed on a computer monitor with a microvideo apparatus, and the area of the lobes, the diameter of the duct and number of bromodeoxyuridine-stained nuclei in the sebocytes are measured.

EVALUATION

Group data are expressed as means ± standard error. The results are analyzed using the *t*-test.

MODIFICATIONS OF THE METHOD

Marit et al. (1995) presented anatomical and physiological parameters of the fuzzy rat, collected for each sex at five ages, including histological and clinical biochemical profiles, organ and body weights, and a characterization of gross and histopathological findings.

Yourick and Bronaugh (2000) studied percutaneous penetration and metabolism of 2-nitro-*p*-phenylendiamine in human and fuzzy rat skin.

Salcido et al. (1995) described an animal model and computer-controlled surface pressure delivery system for the production of pressure ulcers. A method for inducing dermal pressure lesions on the fuzzy rat was developed using a computer-controlled displacement column, which produced a constant tissue interface pressure.

P.11.3 Activity on Ear Sebaceous Glands of Syrian Hamsters

PURPOSE AND RATIONALE

The ear sebaceous glands of the Syrian hamster have been proposed as a model system for human sebaceous glands because of the similarities in morphology and in turnover time (Hamilton and Montagna 1950; Plewig and Luderschmidt 1977). As an androgen-sensitive structure, the ear sebaceous glands have been used to determine the effect of antiandrogenic compounds by the use of histoplanimetry on projections of sagittal sections of the ear (Luderschmidt and Plewig 1977). Matias and Orentreich (1983) developed a stripped skin planimetric method to measure the ear sebaceous gland areas in Syrian golden hamsters.

Seki et al. (1995) determined the effects of topically applied spironolactone on androgen stimulated sebaceous glands in the hamster pinna.

PROCEDURE

Adult female Syrian golden hamsters, 9–10 weeks of age and 110–120 g in weight, are kept at constant temperature and humidity and fed commercially prepared hamster food and water. The hamsters are divided at random into three groups. Testosterone propionate (80 µg dissolved in 1 ml sesame oil) is administered to two groups every other day over a two weeks period to stimulate androgen responses. Hamsters in the third group are injected with 1 ml sesame oil only as controls. The hamsters receive once daily applications of 0.1 g of a colorless clear hydrophilic gel preparation of 5% spironolactone, containing ethanol and isopropyl alcohol on the ventral side of the right pinna for two weeks. The left side is left untreated as control. On day 15, 4 mm punch biopsy specimens from each hamster are obtained from the central region of the bilateral pinnae where sebaceous glands are most developed.

The sebaceous gland size is measured by the whole mount technique (Motoyoshi 1988). After the biopsy specimens are immersed in physiological saline at 4°C for 18 h, cartilages are removed. Then, each specimen is immersed in 2 N NaBr at 37°C for one hour, and the epidermis is peeled off with fine forceps. The obtained dermis sheet containing sebaceous glands is stained with Susan III and mounted on a glass slide.

EVALUATION

An area of five or more sebaceous glands, including all the sebaceous acini attached to one pilosebaceous unit in each biopsy specimen, is measured with a computerized image analyzer (Olympus CIA-102) and shown as a mean value ± standard deviation ($mm^2/100$). The values are compared using Student's paired *t*-test.

MODIFICATIONS OF THE METHOD

Gollnick (1990, 1992) evaluated azelaic acid proposed for acne treatment, using comedo formation in the hamster ear model and recommended it as a new substance in the spectrum of antiacne agents.

Matias and Gaillard (1995) studied the local inhibition of sebaceous gland growth in the ventral ear pinna of sexually mature male Syrian hamsters by topically applied androgen receptor inhibitors.

Seki and Morohashi (1993) investigated the effect of some alkaloids, flavonoids and triterpenoids on the lipogenesis of sebaceous glands of the hamster ear. Lipogenesis was assayed by determining ^{14}C incorporation into sebaceous lipids extracted from the sebaceous glands, which were incubated with ^{14}C-acetate.

Morgan et al. (1993) studied the occurrence of zinc-induced synthesis of metallothionein in skin after topical application of the anti-acne drug Zineryt lotion in hamster ears. The dinitrophenyl hapten-sandwich immunohistochemical method involving a monoclonal anti-metallothionein antibody was used to detect and localize zinc-binding metallothionein in the treated and untreated hamster skin.

Burkhart et al. (2000) studied the effects of benzoyl peroxide on lipogenesis in sebaceous glands using the flank organs of female golden Syrian hamsters.

P.11.4
Activity on Ear Sebaceous Glands of Rabbits

PURPOSE AND RATIONALE

Several authors used the rabbit ear model to study comedo formation (Weirich and Longauer 1974; Mills and Kligman 1975; Motoyoshi 1983a; Kligman 1989; Ito et al. 1985, 1991; Maeda 1991) in order to assess the comedogenicity of cosmetics, toiletries and drugs and to evaluate potential anti-acne drugs. Sebaceous follicles in the inner surface of rabbit ears are sensitive to many substances called comedogenes, which, when applied topically, induce comedo formation. This comedo induction takes place after about 2 weeks of repeated topical application of a chemical comedogen such as 1% coal tar, 50% oleic acid, or 50% tetradecane.

PROCEDURE

Male rabbits weighing 2.5–3.5 kg are used. Tetradecane, testosterone, and dimethyl sulfoxide are separately inuncted on rabbit pinnas once a day for 4 weeks. The pinnas are biopsied on days 1, 3, 7, and 28. Untreated pinnas and squalene-treated pinnas serve as controls. Three-dimensional images of sebaceous glands are reconstructed from their serial histological sections using a computer-image analysis system.

EVALUATION

The volumes of the sebaceous glands, the number of acini, and the volume of individual acini are compared between groups.

MODIFICATIONS OF THE METHOD

Motoyoshi (1983b) studied the correlation between surface microscopy and dermal histology in tetradecane-induced comedones in rabbit ear skin.

Kligman and Kligman (1994) used the rabbit ear to assay the comedogenic potentialities of an array of known tumorigens. Complete carcinogens and some tumor promoters were invariably strongly comedogenic at concentrations of 1.0% and below. The rabbit ear model was recommended to be an easy and reliable way to screen for carcinogenicity.

P.11.5
Activity on the Hamster Flank Organ

PURPOSE AND RATIONALE

The flank organs of Syrian golden hamsters are located on each flank of the animal consisting mainly of sebaceous tissue. Like sebaceous glands in other species,

these pigmented spots respond to androgens by an increase in size. This proliferation is inhibited by systemical or topical anti-androgens.

PROCEDURE

Female Syrian golden hamsters (*Mesocricetus auratus*), weighing 80–110 g are kept at constant temperature on a commercial diet and water ad libitum. They are castrated 24 h prior to the experiment. The costovertebral region is shaved; the horny layer is stripped the day prior to the tes and then every 3 days. For stimulation, animals receive a subcutaneous dose of 250 µg testosterone propionate in 25 µl peanut oil in the dorsal neck fold, for three weeks (weekdays only or continually). On the same days, the anti-androgen dissolved in water/ethanol (1:4, v/v) is applied locally to the left flank organ at increasing doses, using a micropipette under a continuous air stream to enhance the evaporation of the solvent. At least 5 animals are used per group. Controls receive vehicle only, and another group, testosterone propionate only. After treatment the animals are sacrificed under ether anesthesia. The 2 major perpendicular axes of the pigmented spot overlying each flank organ are measured and multiplied to obtain the surface area index. The flank organs are excised and divided into two halves along the major axis, immediately fixed in 10% formalin and embedded in paraffin. The 5 µm-thick sections are stained with haematoxylin-eosin. Sebaceous glands and hairs are measured in the first 2 sections of each half of the specimen, using a semiautomatic computerized image analyzer. The sebaceous gland area in each field is quantified in square millimeters. The diameter of all the hair under each flank organ is measured in micrometers.

EVALUATION

The local (topical) anti-androgenic activity of the test compound is estimated by the ability to inhibit the effects in the ipsilateral treated flank organ whereas the systemic activity is evaluated by the inhibition on the untreated contralateral flank organ. The values for surface area index, sebaceous gland area, and average of diameter of the hairs on the flank organ of the treated left and the untreated right side are compared for anti-androgen-treated animals with controls using two-way analysis of variance and *t*-test.

MODIFICATIONS OF THE METHOD

Wuest and Lucky (1989) studied the differential effect of testosterone on pigmented spot, sebaceous glands and hair follicles in the Syrian hamster flank organ.

Noto et al. (1991) quantified the antiandrogenic activity of topically applied canrenoic acid in the hamster flank organ. The flank organs of female Syrian hamsters were stimulated by subcutaneous administration of testosterone propionate. Sebaceous glands and hair follicles were measured by a computerized image analyzer. Using this method, the same authors (Noto et al. 1992) compared the activity of some topical antiandrogens.

Aricò et al. (1993) found no antiandrogenic effects of topical bifonazole on sebaceous glands and hair in the hamster flank organ.

Lucky et al. (1995) studied the autoradiographic localization of tritiated dihydrotestosterone in the flank organ of the albino hamster.

Foreman et al. (1984) found that in the hairless hamster, progesterone can antagonize dihydrotestosterone-mediated hypertrophy of the sebaceous gland.

CRITICAL ASSESSMENT OF THE METHOD

The relevance of the hamster flank organ model to man has been challenged by Franz et al. (1989).

P.11.6
Activity on the Skin of the Rhino Mouse

PURPOSE AND RATIONALE

The Rhino mouse has been widely used as an experimental acne model to evaluate topically active comedolytic and anti-keratinizing agents (Kligman and Kligman 1979; Ashton et al. 1984; Mezick et al. 1984; Chatelus et al. 1989; Bernerd et al. 1991; Bouclier et al. 1991; Tramposch et al. 1992; Zheng et al. 1993; Sundberg 1994; Fort-Lacoste et al. 1999).

Rhino mice are hairless mutants with a rhinoceros-like appearance, which carry the rhino gene, a recessive allele of the hairless gene ($hr^{rh}hr^{rh}$) (Howard 1941). This recessive mutation on chromosome 14 results in a mouse with wrinkled skin devoid of body hair by age of 25 days. At that time, the end of the first hair cycle, the follicular papillae fail to follow the regressing hair follicles and become isolated in the dermis. The papillae do not re-associate with the follicular epithelium to initiate a new hair follicle cycle. The upper remnants of the hair follicles are filled with sloughed, cornified cells and form utriculi with a small sebaceous gland at their base, resembling an open comedone. The Rhino skin becomes progressively loose, forming folds and ridges, due to the expansion of the surface, secondary to abortive hair follicles filling with cornified debris. The utriculi progressively enlarge, forming pillory cysts (pseudocomedones), which are dilated follicular infundibula filled with cornified debris (Mann 1971). The dermal cysts of the rhino mouse develop into unopened sebaceous glands (Bernerd et al. 1996).

Seiberg et al. (1997) studied the effects of trypsin on apoptosis, utriculi size and skin elasticity in the rhino mouse. González et al. (2000) measured the effect of graduated local doses of all-*trans* retinoic acid applied to the skin of rhino mice with fluorescence excitation spectroscopy and compared the data with histological findings.

PROCEDURE

Seven-weeks old female rhino mice ($hr^{rh}hr^{rh}$) obtained from Charles River Laboratories are divided into groups receiving graduated doses of test compound (all-*trans* retinoic acid) dissolved in an ethanol/propylene glycol mixture (70:30) or the solvent as controls. The solution is applied once per day in doses of 100 µl on the entire dorsal skin, for 5 consecutive days each week, for a total period of 2 weeks. Animals in all groups are sacrificed 24 h after the last treatment and biopsies are obtained immediately following sacrifice. Fluorescence excitation spectra are collected from dorsal skin on a daily basis during treatment. During the measurements, the animals are sedated with inhalation of methoxyflurane.

Fluorescence excitation spectra are obtained *in vivo* with a fluorescence spectrophotometer (SkinSkan, SPEX, Edison NJ) equipped with a 450 W Xenon lamp, double monochromators on the excitation and emission, a photomultiplier detector (R928P, Hamamatsu, Japan) connected to a single photon counting system and a bifurcated quartz fiber bundle (Model 1950; SPEX Ind., Edison, NJ) for light delivery and collection. The individual fibers are 100 µm in diameter and are randomly arranged to form a bundle 6 mm in diameter. The resolution is 4 nm, the intensity of the excitation radiation is in the range of 1–20 mW/cm^2, and the total delivered radiation dose is below the erythema threshold. Each fluorescence measurement consists of a set of eight serial excitation spectra collected by positioning the emission monochromator from 340 to 480 nm in increments of 20 nm and scanning the excitation monochromator from 260 to within 20 nm of the emission monochromator setting. Light from the excitation monochromator is focused into one leg of the bifurcated fiber bundle. The other leg of the fiber bundle is focused into the input of the emission monochromator. The joined end of the fiber bundle is brought into direct contact with the skin site measured. Care is taken to clean properly the fiber bundle end with an alcohol swab between measurements on different animals and that gentle pressure is applied to the animals during measurement.

Significant changes are observed in the fluorescence spectra as a result of the application of comedolytic agents. The first peak, located approximately at

295 nm, which is related to tryptophan, increases significantly, whereas the second peak at 340–370 nm, which is attributed to collagen links, exhibits a dramatic decrease.

For histology, skin samples approximately 5 mm in diameter are obtained from the skin of each animal following sacrifice, from the mid-line of the anterior portion of the skin. All specimens are fixed in 10% buffered formaldehyde for 24 h, and later embedded in paraffin. Tissue sections 5 µm thick are cut perpendicularly to the epidermal surface and stained with hematoxylin and eosin for light microscopic examination. For each animal, the epidermal and dermal thickness, utriculi diameter, and number of capillaries containing more than 5 erythrocytes are assessed with a micrometer eyepiece adapted to a microscope (Leitz SM-LUX, Ernst Leitz, Wetzlar, Germany) using a 40× objective for the measurement of epidermal and dermal thickness, and utriculi diameter, and a 20× objective for the count of dilated capillaries.

EVALUATION

Time-response curves and dose-response curves of the changes of fluorescence spectra are established compared with the changes of histological data.

MODIFICATIONS OF THE METHOD

In addition to image analysis, Seiberg et al. (1997) tested the effects of trypsin on skin elasticity and elastin expression in the Rhino mouse.

Beehler et al. (1995) studied gene expression of retinoic acid receptors and cellular retinoic acid-binding proteins in rhino and hairless mouse skin.

Imakado et al. (1995) found that targeting expression of a dominant-negative retinoic acid receptor (RAR) mutant in the epidermis of transgenic mice results in loss of barrier function.

Feng et al. (1997) reported that suprabasal expression of a dominant-negative RXR alpha mutant in transgenic mouse epidermis impairs regulation of gene transcription and basal keratinocyte proliferation by RAR-selective retinoids.

González et al. (1997) investigated DNA ploidy changes in rhino mouse skin after treatment with all-*trans* retinoic acid and retinol.

Petersen et al. (1984) developed an animal model using human face skin onto the nude mouse to study human sebaceous glands. The effects of androgens were evaluated.

Lesnik et al. (1992) reviewed agents that cause enlargement of sebaceous glands in hairless mice.

P.11.7 Activity on the Skin of the Mexican Hairless Dog

PURPOSE AND RATIONALE

The Mexican hairless dog has been recommended as a model for the comedolytic and morphogenic activity of retinoids and other anti-acne agents (Loux et al. 1974; Schwartzman et al. 1996; Kimura and Doi 1996). A semilethal mutation of an autosomal dominant 'L' gene produces an animal with multiple developmental defects, including poor dentition, early degeneration of the thymus, hairlessness and numerous comedones (Yankell et al. 1970a; González-Diddi et al. 1971; Goto et al. 1987; Fukuda et al. 1991). The Mexican hairless dog is nearly bald, with sparse, flimsy hair most abundant on the limbs and head. In most hairy species, the primary hair is surrounded by 7 to 10 accessory hairs. In this species, the follicles are mainly single and not in clusters. The skin is tan-colored. A brownish, waxy material unevenly coats the surface; this can be removed easily by soap and lipid solvents. A great number of comedones cover the surface, and these are nearly all of the open variety. The majority is rather small (a few millimeters in diameter), and may be viewed as horn-filled shallow invaginations. Scattered among these, especially on the face, neck and thighs, are larger, black-tipped open comedones. These are hard, deep, horny impactions, which are expelled with difficulty. A few small, closed comedones occur on the neck and lateral aspect of the chest.

Papulopustules are rare, and are found mainly on the metacarpus and metatarsus. They apparently do not develop from the rupture of comedones as in humans. Thus, this animal mimics human acne only with regard to comedones. These, unlike the human variety, do not originate from pre-existing sebaceous follicles. They arise de novo, and completely lack sebaceous glands.

PROCEDURE

About 1-year-old female animals are used. Areas of 4–5 cm^2 on the dorsolateral aspects of the trunk are treated once daily (5 working days) for 14 weeks with test formulations or tretinoin formulations (0.025–0.1%) as standard.

Biopsies are taken from each site under local anesthesia at 5 weeks and again at 14 weeks.

EVALUATION

The clinical picture and the histology of biopsies are compared before, during, and after treatment.

MODIFICATIONS OF THE METHOD

Yankell et al. (1970b) used the Mexican hairless dog for sunscreen recovery studies.

Hunziker et al. (1978) compared percutaneous penetration of benzoic acid, progesterone and testosterone between Mexican hairless dogs and man.

Matsumura et al. (1992) described a burn wound-healing model in the hairless descendant of the Mexican hairless dog.

P.11.8 In Vitro Sebocyte Model

PURPOSE AND RATIONALE

Cultured human sebocytes have been used by several authors to study sebum formation and to evaluate po-

tential anti-acne drugs (Zouboulis et al. 1991a, b, 1993, 1994, 1998; Rosenfield 1989; Doran and Shapiro 1990; Doran et al. 1991; Akamatsu et al. 1993; Guy et al. 1996a, b; Rosenfield et al. 1998; Wauben-Penris et al. 1998; Tsukada et al. 2000; Fritsch et al. 2001).

PROCEDURE

Human sebaceous glands are isolated from facial skin and seeded on monolayer 3T3 cells (Xia et al. 1989). Primary sebocyte cultures are derived from the periphery of the gland lobules and are maintained to confluence before subcultivation. All experiments are performed using secondary sebocyte cultures, which consist of cells undergoing sebocytic differentiation.

Human sebocytes are seeded in 96-well culture plates at a concentration of 10^4 cells/well and are left to attach for 2 days at 37°C with 5% CO_2 in culture medium consisting of Dulbecco's modified Eagle's medium and Ham's F12 medium (1:1) supplemented with 8% fetal calf serum, 2% human serum, 10 ng/ml epidermal growth factor, 10^{-9} M cholera toxin, 3.4 mM L-glutamine, 100 IU/ml penicillin, and 100 µg/ml streptomycin. The medium is then aspirated, and serum-free keratinocyte basal medium (KBM) (Clonetics, San Diego, CA) without additives, supplemented with steroids, e. g., testosterone (10^{-8}–10^{-5} M), 5a-dihydrotestosterone (10^{-8}–10^{-5} M), or spironolactone (10^{-12}–10^{-7} M) or their combinations are added to 6 wells at each concentration. KBM is concomitantly added to another 6 wells serving as controls. The plates are incubated at 37°C for 10 days before evaluation. KBM with and without compounds is changed every 2 days.

Cell numbers of treated human sebocytes in 96-well culture plates are assessed over 9 days by counting single-cell suspensions in Neubauer chambers and compared with the absolute fluorescence units (AUF) of parallel wells obtained using the 4-methylumbelliferyl heptanoate (MUH)-fluorescence assay (Stadler et al. 1989). This assay is based on the hydrolysis of the fluorogenic substrate MUH by esterases of proliferating cells. A stock solution of 10 mg/ml MUH is prepared in DMSO and kept frozen at –20°C until use. On the day of assessment, KBM is removed, and the cells are washed twice with phosphate-buffered saline without Ca^{2+} and Mg^{2+} (pH 7.2). The MUH stock solution is diluted in phosphate-buffered saline up to 100 µg/ml, and 100 µl of the final solution is added to each well. The plates are then incubated for 30 min at 37°C and read automatically on a Titertek Fluoroscan II (Flow, Meckenheim, Germany).

EVALUATION

The results are given as absolute fluorescence units using 355-nm excitation and 460-nm emission filters. Statistical significance of the differences between the means is assessed by Student's *t*-test.

P.12 Skin Mycosis

P.12.1 General Considerations

PURPOSE AND RATIONALE

Fungal infections of the skin account for a large number of consultations to general practitioners and dermatologists. They are caused by dermatophytes, such as Trichophyton rubrum, Trichophyton tonsurans, Trichophyton mentagrophytes, Microsporum canis, Epidermophyton floccosum, Microsporum gypseum, and Trichophyton verrucosum. (Sinski and Kelley 1991).

Most fungal skin infections, such as tinea pedis and tinea cruris, respond to topical therapy, although widespread or chronic infections that do not respond to local measures may require systemic treatment, for example with griseofulvin, ketoconazole or terbinafine. Traditional topical products such as compound benzoic acid ointment (Whitfield's ointment) and tolnaftate preparations have largely been superseded by other topical-active antifungal agents, such as the imidazoles (e. g. clotrimazole, miconazole or econazole) or hydroxypyridones (e. g. ciclopirox), which are well tolerated and rapidly effective (Gupta et al. 1994). Fungal infections also affect the appendices, such as hair and nails. To evaluate antifungal agents not only the antimicrobial spectrum, but also the penetration plays a decisive role.

P.12.2 In Vitro Inhibitory Activity

PURPOSE AND RATIONALE

In vitro tests are performed to investigate whether the test compound in comparison to standards covers the most relevant pathogens of dermal mycoses. The test conditions are rendered more difficult by addition of protein since the main infection site for fungi is the horny layer of the epidermis, which has a high protein content.

PROCEDURE

The studies are performed by means of conventional serial dilution procedures in test medium without and with addition of 4% bovine albumin. The test medium is Sabouraud dextrose broth containing 1% Neopeptone Difco (Difco Laboratories, Detroit, Mich., USA) and 2% glucose. The basic medium is sterilized in an autoclave at 121°C for 15 min. The pH is adjusted to 6.5 with 1 N NaOH. The medium containing albumin is sterilized by filtration through a membrane filter. For preparation of the test series, the inhibiting substances are dissolved in methanol and then rapidly diluted with slightly warmed test medium, so that series with a continuous dilution factor of 2 are obtained: 125–0.03 µg/ml in medium without protein, 500–1 µg/ml in medium with protein. Each test tube contains 3 ml. The test organisms are various strains of dermatophytes (*Trichophytum mentagrophytes*, *T. rubrum*, *T. verrucosum*, *T. equinum*, *T. gallinum*, *Microsporum canis*, *Microsporum gypseum*) and yeasts (*Candida albicans*, *Ca. tropicalis*, *Ca. pseudotropicalis*, *Ca. krusei*, *Ca. parapsilosis*, *Ca. lipolytica*, *Ca. brumpti*, *Ca. utilis*, *Torulopsis glabrata*). The organisms are pre-cultured on a modified Grütz agar at 28°C for periods of 1–4 weeks. The suspensions are adjusted by photometry that about 10^5 microconidia of dermatophytes and 10^4 yeast cells per ml are obtained in each inoculated test tube. The minimal inhibitory concentrations are measured after 14 days incubation at 28°C.

EVALUATION

The percentage of strains of *Trichophytum mentagrophytes*, *Trichophytum rubrum*, and *Candida albicans* is plotted against dilution steps for each test compound with and without albumin and IC_{50} values are calculated.

P.12.3 In Vivo Activity in the Guinea Pig Trichophytosis Model

PURPOSE AND RATIONALE

The guinea pig trichophytosis model has been used by several authors to evaluate antimycotic compounds (Millberger and Gillert 1973; Dittmar et al. 1981; Plempel et al. 1983; Petranyi et al. 1987; Schaude et al. 1990; Garcia Rafanell et al. 1992; Arika et al. 1993).

PROCEDURE

Male albino guinea pigs (Pirbright White), bred mycosis-free, weighing 450–550 g are fed Altromin pellets and tap water ad libitum. On both sides of the back, areas of 5 × 12 cm are shorn to a fur length of 1 mm. Three areas with a diameter of 3 mm are inoculated with a pipette on either side. Per injection site, 10^4 spores of *Trichophyton mentagrophytes* 2114 in 0.05 ml suspension in physiological saline solution are inoculated. Three days after inoculation, infections with redding and scale formations are observed. From days 3–7 after the infection, 1 ml of the test preparation or standard is applied onto the right animal sides and rubbed in once daily. The diameters (mm) of all alopecias are measured with a ruler 3.5 weeks after the infection.

EVALUATION

The values of alopecias, separated according to the treated group and animal side, are determined and statistically evaluated using Duncan's new multiple range test.

P.12.4 Skin Penetration

PURPOSE AND RATIONALE

Cutaneous pathogenic fungi like dermatophytes or Candida ssp. present a particular affinity for the stratum corneum. Therefore the bioavailability of antimycotic drugs in the thick horny layer of the skin is an important element of treatment success. These studies can be performed in human cadaver skin (Dittmar 1981; Kligmann et al. 1987; Hänel et al. 1988)

PROCEDURE

Skin pieces, measuring 10 × 12 cm are removed from the back of corpses not later than 24 h after death. The subcutis is removed and the skin piece divided 3 to 5 parts. The edges (4 mm) of each individual piece are then taped with Tesa-film (adhesive tape) and the remaining surface is treated with the antimycotic compound. 0.05 ml of compound preparation or solution is rubbed into the skin for 10 s. For a period of one h, the pieces are placed on water agar, allowing for free admission of air. After this time, the compound is carefully wiped off with filter paper and water.

The skin area treated with the antimycotic is then stripped with Tesa-film tape as follows: (A) one third of the area remains unstripped; (B) one third of the area is stripped three times; (C) one third of the area is stripped six times. Then each piece of skin is placed into a Petri dish, which is heated in a water bath to 52°C for 15 min. The epidermis is removed from all the skin pieces, which are then placed on slides (with the base turned upwards) and put into the upper parts of plastic Petri dishes. Each of the epidermis pieces is inoculated in 20 sites with a microconidia suspension of the dermatophyte Trichophyton mentagrophytes 109-FHM 1a. The spores had been rinsed off from three-week-old slant cultures, using distilled water. Approximately 50–100 viable spores are deposited at each inoculation site.

The upper parts of the Petri dishes (containing the slides with the epidermis pieces) are then covered with the bottom parts of Petri dishes, which contain 2% aqueous agar for producing a wet chamber. Holes in the covers serve to avoid excess humidity in the chamber. The chambers are incubated at 28°C for 5 days. The fungal growth is recorded daily according to a three points score system.

EVALUATION

Growth is evaluated by visual scoring from days 2–5 after inoculation and calculation of AUCs from growth curves.

Inhibition values (%) are calculated according to the formula:

$$\text{inhibition} = \frac{\text{growth on controls} - \text{growth after treatment}}{\text{growth on contols} \times 100}$$

MODIFICATIONS OF THE METHOD

Ceschin-Roques et al. (1991) performed penetration studies on excised skin from the back of slaughtered pigs.

P.13 Biomechanics of Skin

P.13.1 General Considerations

Several attempts were made to describe the mechanical properties of skin by mathematical models (Ridge and Wright 1965; Harkness 1971; Hirsch and Sonnerup 1968; Jamison et al. 1968; Viidik 1968, 1969, 1973, 1979; Frisén et al. 1969a, b; Veronda and Westman 1970; Danielson 1973; Soong and Huang 1973; Wilkes et al. 1973; Jenkins and Little 1974; Lanir and Fung 1974; Vogel 1976, 1986; Barbanel and Evans 1981; Barbanel et al. 1978; Lanir 1979; Barbanel and Payne 1980; Burlin 1980, 1981; Fung 1981; Sanjeevi 1982; Potts and Breuer 1983).

Most of these authors used models derived from studies in polymers (Ferry 1970). The simplest mechanical model analogous to a viscoelastic system is a spring combined with a dashpot, either in series (**Maxwell element**) or in parallel (**Voigt or Kelvin element**). Combinations of these elements were used to explain the mechanical phenomena in connective tissue, such as stress-strain behavior, relaxation and mechanical recovery, hysteresis and creep phenomena (Jamison et al. 1968; Frisén et al. 1969a, b; Hirsch and Sonnerup 1968; Vogel 1976, 1993; Riedl and Nemetscheck 1977; Vogel and Hilgner 1979; Viidik 1968, 1969, 1973, 1977, 1979). Larrabee (1986), Larrabee and Sutton (1986).

Larrabee and Galt (1986) reviewed the theoretical and experimental mechanics of skin and soft tissue and proposed a mathematical model of skin deformation based on the finite element method. A finite element based method to determine the properties of planar soft tissue was also described by Flynn et al. (1998).

Unfortunately none of these models has been found to be sufficient to describe all properties of human and animal skin including the mechanical history before measurement and the time-dependence during measurement. There is no comprehensive and unequivocally accepted model to describe completely the biorheology of skin. Therefore, several methods are used in order to get insight into the physical properties of skin.

P.13.2
In Vitro (ex Vivo) Experiments

P.13.2.1
Stress-Strain Behavior

P.13.2.1.1
Measurement of Skin Thickness, Ultimate Load, Tensile Strength, Ultimate Strain and Modulus of Elasticity

PURPOSE AND RATIONALE

Animal experiments are preferable when studying the biomechanical properties of the dermis, since only in animals can the values at higher extension degrees be studied, *ex vivo* or *in vivo* under anesthesia, whereas studies in humans are limited by pain threshold or to tests in cadaver skin. Skin thickness, ultimate load, tensile strength, ultimate strain and ultimate modulus of elasticity are the most informative parameters, which describe the mechanical properties of the dermis.

PROCEDURE

Groups of at least 10 male Sprague-Dawley rats with an initial weight of 120 ± 5 g are treated subcutaneously or orally with test drugs or saline. The duration of treatment is usually 5 days; however, for special studies treatment can be prolonged up to 3 months. The animals are sacrificed under anesthesia. The back skin is shaved and a flap of 5×5 cm removed. Subcutaneous fat is removed from the skin flaps. The sample is placed between two pieces of plastic material with known thickness. In this way, **skin thickness** can be measured reliably by calipers with an accuracy of 0.1 mm. Perpendicular to the body axis two dumbbell shaped specimens with a width of 4 mm in the middle of the sample are punched out (Vogel 1969, 1970, 1989, 1993a). The samples are kept in Peteri dishes until testing at room temperature on filter paper soaked with saline solution. The specimens are fixed between the clamps of an INSTRON instrument a at gauge length of 30 mm. All measurements are carried out within at least 1 h. For long lasting test procedures, such as relaxation or cyclic loading, the samples are wrapped with saline soaked filter paper (Vogel 1976a, b 1989, 1993a, b).

Stress-strain curves are registered at an extension rate of 5 cm/min, showing a characteristic shape. During low strain values, there is a gradual increase of load; the curve has a concave part. The stress-strain curve ascends according to an exponential func-

tion (Vogel and Hilgner 1977). Afterwards an almost straight part is reached indicating the dependence on Hook's law. At this part the **ultimate modulus of elasticity** (Young's modulus) can be calculated (increase of load divided by the cross sectional area). Then some yielding of the curve occurs which ends in a sudden break of the specimen. This point indicates **ultimate strain** and **ultimate load**.

EVALUATION

From ultimate load divided by the cross sectional area (specimen width times original skin thickness measured at the beginning of the experiment), **tensile strength** can be calculated. The mean values of skin thickness, ultimate strain, ultimate load, tensile strength, and modulus of elasticity of treated animals are compared with controls using ANOVA and Student's *t*-test.

CRITICAL ASSESSMENT OF THE METHOD

The parameters: **skin thickness, ultimate strain, ultimate load, tensile strength, and modulus of elasticity** are influenced by many factors, such as hormones and desmotropic drugs. The most pronounced changes are seen after glucocorticosteroids, both after systemic and local application (Vogel 1969, 1970, 1974a). Several studies were performed on age dependence of mechanical parameters in rat skin. Ultimate load, tensile strength and modulus of elasticity show a very sharp increase during puberty, a maximum at 12 months and a slight decrease thereafter (Vogel et al. 1970; Vogel 1976b, 1978, 1983, 1988, 1989, 1993a). Studies on age dependence show a similar pattern for skin thickness, ultimate load, tensile strength, ultimate extension, modulus of elasticity, hysteresis, relaxation, creep behavior and biochemical data both in animals and men (Holzmann et al. 1971; Vogel 1987a, b).

Therefore, extrapolations from animal studies to behavior of human skin are justified.

However, due to the anatomical conditions (haired skin in animals) the biomechanics of the epidermis can be studied better in human experiments than in animals.

MODIFICATIONS OF THE METHOD

Measurement of skin thickness, ultimate strain, ultimate load, tensile strength, and modulus of elasticity can be used in the evaluation of topical corticosteroids (Schröder et al. 1974; Alpermann et al. 1982; Vogel and Petri 1985).

Similarly, Töpert et al. (1990) measured skin atrophy and tensile strength of skin after 30 days local administration of corticosteroids in rats.

Oxlund and Manthorpe (1982) found an increase of strength and a decrease of extensibility of skin strips after long-term glucocorticoid treatment of rats. In agreement with studies by Vogel (1974b, 1978), these results were explained by a change in collagen cross-linking pattern.

Jørgensen et al. (1989) found a dose-dependent increase of mechanical strength in intact rat skin after treatment with biosynthetic human growth hormone.

Andreassen et al. (1981) studied the biomechanical properties of skin in rats with streptozotocin-induced diabetes. An increased stiffness and strength was found: maximal stiffness was increased by 20% and the strain rate at maximum stress was decreased by 10%.

Oxlund et al. (1980) found that the stiffness of rat skin was increased in the early postpartum period. This increase was also found in adrenalectomized animals.

Foutz et al. (1992) studied the effects of freezing on mechanical properties of rat skin.

Among desmotropic drugs, *lathyrogenic* compounds, such as amino-acetonitrile, and *D-penicillamine* decrease ultimate load, tensile strength without major influence on skin thickness (Vogel 1971a, b, 1974a). A decrease of the strength of skin strips in rats after treatment with D-penicillamine was also found by Fiedrich et al. (1975) and by Oxlund et al. (1984).

A dose-dependent increase of tensile strength in skin after treatment with was found with **non-steroidal anti-inflammatory drugs** (Vogel 1977).

Strain rate influences the values of ultimate load, tensile strength and modulus of elasticity, but not the effect of age and of corticosteroids (Vogel 1972b). Changes in tensile strength are correlated with the content of insoluble collagen (Vogel 1974b).

Fry et al. (1964) prepared skin rings from the lower part of the leg in rats and studied the age-dependence of the mechanical properties.

Nimni et al. (1966) measured tensile strength of excised skin samples in rabbits during aging.

Pan et al. (1998) studied ultrasound, viscoelastic and mechanical properties in rabbit skin, including stress relaxation, creep and Young's modulus as a function of strain.

Lofstrom et al. (1973) described circadian variations of tensile strength in the skin of two inbred strains of mice.

The effect of radiation therapy on mechanical properties of skin was studied in mice by Hutton et al. (1977) and by Spittle et al. (1980).

Schneider et al. (1988) measured tensiometric properties in guinea pig skin from flaps of normal dor-

sal skin and after implantation of an ovoid **tissue expander** filled for four days with saline.

Belkoff et al. (1995) studied the mechanical properties of skin in pigs after subcutaneous implantation and inflation of silicone tissue expanders.

Mustoe et al. (1989) compared the effects of a conventional tissue expansion regimen of 6 weeks with an accelerated regimen of 2 weeks in a model in dogs and measured skin thickness, elasticity, creep and stress relaxation.

P.13.2.1.2 Measurement of Mechanical Properties at Low Extension Degrees

PURPOSE AND RATIONALE

At low strain values, stress-strain curves of skin samples show a gradual increase of load, the curve has a concave part. The stress-strain curve ascends according to an exponential function (Vogel and Hilgner 1977).

PROCEDURE

Groups of at least 10 male Sprague-Dawley rats with an initial weight of 120 ± 5 g are treated subcutaneously or orally with test drugs or saline. The animals are sacrificed under anesthesia; the back skin is shaved and a flap of 5×5 cm removed. Subcutaneous fat is removed from the skin flaps. The sample is placed between two pieces of plastic material with known thickness to measure skin thickness by calipers. Perpendicular to the body axis two dumb-bell shaped specimens with a width of 4 mm in the middle of the sample are punched out (Vogel 1969, 1970, 1981, 1989, 1993). The specimens are fixed between the clamps of an INSTRON instrument at a gauge length of 30 mm. An extension rate of 5 cm/min is chosen. Tension is registered at 2, 5, 10, 20, 30, 40, 50, 60, 70, 80 and eventually 90% elongation. The registration is started with high sensitivity and switched to one tenth of the sensitivity in order to register the steep end of the curve.

EVALUATION

During registration with high sensitivity, the curve reaches an almost straight part. At this part, a tangent is drawn which is used for calculation of E_2. The distance from the start to the cross-point of this tangent with the baseline is measured and denominated as extension until the first rise (D). The angle between the tangent and the baseline is halved. At the cross-point with the stress-strain curve another tangent is drawn and used for calculation of E_1. At the second part of the curve registered with low sensitivity a further tangent is drawn for calculation of E_3, which is identical to the ultimate modulus of elasticity.

Mean values for $\boldsymbol{E_1}$, $\boldsymbol{E_2}$, $\boldsymbol{E_3}$, and ultimate stress of skin strips from treated animals are compared with controls using Student's t-test.

MODIFICATIONS OF THE METHOD

Belkoff and Haut (1991) developed a structural model to evaluate the changing microstructure of maturing rat skin.

Foutz et al. (1994) developed a phenomenological model to characterize the non-linear portion of stress-strain curves of rat skin.

P.13.2.1.3 Step Phenomenon

PURPOSE AND RATIONALE

Analysis of the low parts of the stress-strain curve revealed a "step"-phenomenon (Vogel and Hilgner 1977, 1979a, b; Vogel 1988). If samples obtained perpendicular to the body axis are extended, a gradual increase of load is observed at low degrees of extension,

which is suddenly interrupted by a decrease of the registered curve. Then the curve increases again, being interrupted by a second or third step.

PROCEDURE

Groups of 10 male Sprague-Dawley rats with an initial weight of 120 ± 10 g are treated subcutaneously or orally with test drugs or saline. The animals are sacrificed under anesthesia, the back skin is shaved and a flap of 5 × 5 cm removed. Subcutaneous fat is removed from the skin flaps. The sample is placed between two pieces of plastic material with known thickness to measure skin thickness by calipers. Perpendicular to the body axis two dumb-bell shaped specimens with a width of 4 mm in the middle of the sample are punched out. The ends of the skin strips are fixed in the clamps of an INSTRON instrument resulting in a gauge length of 30 mm. The specimen is stretched with a strain rate of 50 mm/min. The first part of the stress-strain curve is registered with 10 times higher amplification than the second part. The steps are evaluated as follows.

EVALUATION

Tangents to the curves are drawn before and after each step. Then a vertical line is drawn in the middle of the step. The distance between the cross-points of this line with the tangents is measured and calculated as stress loss (ΔS). Furthermore, in the middle of each vertical line a horizontal line is drawn. The distance between the cross-point with the curves is measured and calculated as elongation due to the step (ΔE). Total stress loss is calculated by adding all values of ΔS and dividing by the number of specimens.

If this parameter is considered not only by itself but also in connection with tensile strength it can be calculated as percentage of ultimate stress (= % of breaking strength). In addition, the stress value, which would have been achieved without the step (= value *S*) and the elongation at which the step occurred (= value *E*) is registered. If stress loss at one step is multiplied with the elongation at this point, an indication of work loss is achieved (value ΔS times *E*). Taking into account the corresponding parameters indicating total work input (ultimate stress times ultimate strain), the relative work loss can be calculated.

Furthermore, elongation gain due to the steps is calculated by adding all values of ΔE and by dividing by the number of specimens.

Mean values of these parameters from treated animals are compared with controls using Student's *t*-test.

CRITICAL ASSESSMENT OF THE METHOD

The step phenomenon can be explained by the different orientation of collagen fibers in the dermis and by the presence of a muscular layer in rat skin. The muscular fibers are in a direction longitudinal to the body axis. If samples are obtained perpendicular to the body axis, the muscle bundles are cut transversally. In further studies the muscle layer was removed in one specimen and compared with a control still having the muscle layer. Investigation of the directional variation showed that the step phenomenon is mainly due to the muscular layer oriented longitudinal to the body axis and the connective tissue between the muscle bundles, whereas the anisotropic behavior of extensibility and ultimate strain is caused by the directional variation of the collagenous bundles in the dermis.

MODIFICATIONS OF THE METHOD

The step phenomenon could also be found in creep experiments (Vogel and Hilgner 1979b).

P.13.2.1.4 Anisotropy of Skin

PURPOSE AND RATIONALE

As is the case with human skin indicated by Langer's lines (Langer 1861; Gibson et al. 1969; Wright 1971; Stark et al. 1977; Daly 1982), the skin of rats exhibits **directional differences** (Hussein 1972, 1973; Vogel and Hilgner 1979a, b; Vogel 1981, 1983a, 1985a, b, 1988; Belkoff and Haut 1991). Stress-strain curves of rat skin showed a different shape if excised perpendicularly or longitudinally to the body axis. Directional variations of mechanical parameters in rat skin were studied depending on maturation and age (Vogel 1981).

PROCEDURE

Male Sprague-Dawley rats are used at different age groups from 1 week up to 24 months. Young animals (1, 2 and 3 weeks) are delivered with their mothers from the breeder. Each age group is randomly divided

into 2 blocks which are assigned as "perpendicular to body axis" or "longitudinal to body axis". The animals are sacrificed under anesthesia, the back skin is shaved and a flap of 5×5 cm removed. Subcutaneous fat is removed from the skin flaps. The sample is placed between two pieces of plastic material of known thickness to measure skin thickness by calipers. From each rat two dumb-bell shaped specimens with a width of 4 mm in the middle of the sample are punched out either perpendicular or longitudinal to the body axis, allowing a gauge length between the clamps of an INSTRON instrument of 30 mm. Stress-strain curves are measured at a strain rate of 50 mm/min, whereby the first part of the curve is registered with 10-fold amplification. Besides ultimate values, the extension is measured at given load interval for each curve:

0. 05, 0. 1, 0. 2, 0. 5, 1, 2, 10, 20, and 50 N

and at given stresses:

0. 01, 0. 02, 0. 05, 0. 1, 0. 5, 1, 2, 5, and 10 N/cm^2.

EVALUATION

Each parameter is measured longitudinal and perpendicular to the body axis. The mean values are statistically compared within each age group using Student's *t*-test.

At low loads, extension is higher in the longitudinal than in the perpendicular direction. The situation is reversed at medium and high stress values. Ultimate extension shows remarkable differences between longitudinal and perpendicular samples. Specimens obtained perpendicular to the body axis showed an increase during maturation, a maximum at 4 months of age and a decrease during further aging. The behavior of samples obtained longitudinal to the body axis was quite different. After an initial rise a maximum was found at 3 weeks. Afterwards a slight decrease was noted. Between 1 and 4 weeks all values of ultimate extension were significantly higher in samples punched out longitudinally to the body axis; between 4 and 12 months they were considerably lower (Vogel 1981).

CRITICAL ASSESSMENT OF THE METHOD

The data indicate the importance of directional variations in all studies of biomechanics of skin.

MODIFICATIONS OF THE METHOD

Directional variations of rat skin were also found in hysteresis experiments (Vogel 1983a) and in relaxation experiments (Vogel 1985a).

Directional variations of the stress-strain curves were also described in the skin of tight-skin mutant mice (Menton et al. 1978).

P.13.2.1.5 Relaxation Phenomenon

PURPOSE AND RATIONALE

In the relaxation experiment the viscous properties of rat skin are measured (Vogel 1973, 1976a, b, 1983, 1985, 1993a, b).

PROCEDURE

Groups of 10 male Sprague-Dawley rats with an initial weight of 120 ± 10 g are treated subcutaneously

or orally with test drugs or saline. The animals are sacrificed in anesthesia, the back skin is shaved and a flap of 5 × 5 cm removed. Subcutaneous fat is removed from the skin flaps. The sample is placed between two pieces of plastic material with known thickness to measure skin thickness by calipers. Perpendicular to the body axis two dumb-bell shaped specimens with a width of 4 mm in the middle of the sample are punched out.

Skin strips are fastened between the clamps of an INSTRON instrument and extended with the high strain rate of 1000 mm/min up to 20% extension. This extension is kept constant for 5 min. The chart speed is initially 1000 mm/min, then 10 mm/min. In this way, the **initial tension** and the **stress values at 0.001, 0.01, 0.1, 1, and 5 min** can be measured. Due to relaxation, the stress values drop down roughly with the logarithm of time.

Furthermore, the **residual stress** after 5 min relaxation period is measured and calculated as percentage of the original stress. After 5 min the sample is returned to 90% of the original strain, for example, from 20% to 18%. The stress following such unloading is recorded and again calculated as percentage of the original stress. Immediately after unloading, the measured stress values rise again spontaneously, which is called **mechanical recovery**. Mechanical recovery is calculated as percentage of initial tension and as percentage of stress after unloading. The relaxation experiment is repeated with increasing degrees of extension of 40%, 60%, 80% and eventually 100% until the specimen breaks.

EVALUATION

For each sample, the relaxation is calculated according to the formula

$$\sigma(t) = A_1 + A_2 \times \log t$$

resulting in two constants (A_1 and A_2) for each sample whereby A_1 is the stress at $t = 0$, and A_2 the slope of the relaxation curve.

The **ratio between the constants A_1 and A_2** has to be considered as the most characteristic parameter of the relaxation experiment.

The means of these parameters are compared between treated animals and controls using Student's *t*-test.

MODIFICATIONS OF THE METHOD

In studies of age dependence in rats skin, a definitive decrease of the **ratio A_2/A_1** was found at 40% and 60% extension degrees indicating a decrease of plasticity with age. Mechanical recovery, as an indicator of secondary elasticity, was better in old animals at medium extension degrees than in young individuals. Stress relaxation was decreased after corticosteroids and increased after thyroid hormones and D-penicillamine (Vogel 1973, 1993a, b).

Purslow et al. (1998) suggested that relaxation processes within the collagen fibers or at the fiber-matrix interface might be responsible for the viscoelastic behavior of skin.

Vogel HG (1993b) Strength and viscoelastic properties of anisotropic rat skin after treatment with desmotropic drugs. Skin Pharmacol 6:92–102

P.13.2.1.6 Hysteresis Experiments

PURPOSE AND RATIONALE

In the hysteresis experiment not only the elastic but also the viscous properties of skin are measured (Vogel 1978, 1983).

PROCEDURE

Groups of 10 male Sprague-Dawley rats with an initial weight of 120 ± 10 g are treated for 10 days subcutaneously or orally with test drugs or saline. The animals are sacrificed under anesthesia, the back skin is shaved and a flap of 5 × 5 cm removed. Subcutaneous fat is removed from the skin flaps. The sample is placed between two pieces of plastic material of known thickness to measure skin thickness by calipers. Perpendicular to the body axis two dumb-bell shaped specimens

with a width of 4 mm in the middle of the sample are punched out.

Using the INSTRON instrument, the samples are stretched up to a given extension degree (e. g., 20%) with an extension rate of 20 mm/min. When the given extension is achieved the crosshead is immediately moved back to the starting position with the same velocity. From the upward curve the stress and the modulus of elasticity at the end of the loading phase at the given strain indicating the elastic properties can be measured. When the sample is unstretched the unloading curve shows a different pattern reaching the baseline much earlier than the curve left it during the upward phase. From this point the **residual extension** can be measured. Immediately after the first hysteresis cycle, the experiment is repeated up to an extension degree of 30%, than to 40% and 50% and finally up to 60%.

EVALUATION

By planimetry of the area below the upward curve the **energy input** and of the area between the hysteresis loop the **energy dissipation** can be calculated as well as the **ratio between energy dissipation and energy input** at each hysteresis cycle indicating the viscous properties. Stress and modulus of elasticity at the end of the hysteresis loop, energy input, energy dissipation and the ratio between energy dissipation and energy input at each hysteresis cycle are compared between treated animals and controls using Student's *t*-test.

MODIFICATIONS OF THE METHOD

In rat skin, a maximum of the ratio between energy dissipation and energy input was found at 30% to 40% extension. This ratio is influenced by age. At low extension degrees there was an increase with age, whereas at high extension degrees an age-dependent decrease was noted. The ratio dissipation/input was slightly decreased by prednisolone, but definitively increased by D-penicillamine (Vogel 1993b).

P.13.2.1.7 Isorheological Point

PURPOSE AND RATIONALE

Buss et al. (1976) demonstrated the determination of the isorheological point to be a valuable parameter for the mechanics of connective tissue. This method has been modified and elaborated for the skin strips of rats (Vogel 1984, 1985, 1987).

PROCEDURE

Groups of 20 male Sprague-Dawley rats with an initial weight of 120 ± 10 g are treated subcutaneously or orally with test drugs or saline. The groups are divided randomly into groups of 10 animals for examination of skin samples either perpendicular or longitudinal to the body axis. The animals are sacrificed under anesthesia, the back skin is shaved and a flap of 5×5 cm removed. Subcutaneous fat is removed from the skin flaps. The sample is placed between two pieces of plastic material with known thickness to measure skin thickness by calipers. Two dumb-bell shaped specimens with a width of 4 mm in the middle of the sample are punched out.

Being fastened between the clamps of an INSTRON instrument, the specimen is expanded rapidly up to 2 N and the corresponding strain is measured. Keeping this strain constant, the load decay (relaxation) is measured for 5 min. Then the sample is again loaded up to 2 N and a second relaxation period of 5 min is evaluated. In the third cycle, the sample is unloaded to 50% of the load observed after the 5-min relaxation period in the second cycle. The phenomenon of **mechanical recovery** is observed. With the crosshead driven up and down, the point is sought where neither immediate relaxation nor mechanical recovery can be observed. The load and strain at this point define the **isorheological point**, which is characterized by the fact that under isometric conditions, the measured load is constant for several minutes. Increasing and decreasing the load by 10% produces a saw-tooth-shaped curve from which the **modulus of elasticity at the isorheological point** can be calculated. The same procedure is performed at higher initial loads such as 10 N and 50 N. The product of percentage of strain multiplied by stress at the isorheological point indicates energy density.

EVALUATION

The means of these parameters are compared between treated animals and controls using Student's *t*-test.

The values showed a decrease during maturation, a minimum at 12 months and an increase during senescence. In studies with desmotropic compounds, the decreased viscosity after treatment with prednisolone acetate was more evident at the isorheological points than at the ultimate values. Likewise, the higher extensibility after treatment with D-penicillamine was indicated more clearly by the isorheological points than by the ultimate strain.

P.13.2.1.8 Creep Experiments

PURPOSE AND RATIONALE

In creep experiments, viscous behavior of skin is studied. The strain under constant load is also denominated as retardation behavior. (Vogel 1977, 1987).

PROCEDURE

Groups of 10 male Sprague-Dawley rats with an initial weight of 120 ± 10 g are treated for 10 days subcutaneously or orally with test drugs or saline. The animals are sacrificed under anesthesia, the back skin is shaved and a flap of 5×5 cm removed. The sample is placed between two pieces of plastic material with known thickness to measure skin thickness by calipers. Perpendicular to the body axis three dumb-bell shaped specimens with a width of 4 mm in the middle of the sample are punched out.

In a special apparatus, skin specimens are suddenly loaded with 100, 200 or 500 g and the extension degree measured. An immediate extension occurs which is followed by a slow and almost continuous creep being measured as **ultimate extension rate**. Furthermore, **extension achieved after 1 h** is registered.

EVALUATION

The means of these parameters are compared between treated animals and controls using Student's *t*-test.

An age-dependent decrease of these parameters was found in rat and human specimens indicating a decrease of viscosity or plasticity with maturation and age. Ultimate extension rate was decreased by prednisolone and increased by D-penicillamine.

P.13.2.1.9 Repeated Strain

PURPOSE AND RATIONALE

By the method of using repeated strain, mainly the viscous properties of skin are measured (Vogel and Hilgner 1978; Vogel 1987).

PROCEDURE

Groups of 10 male Sprague-Dawley rats with an initial weight of 120 ± 10 g are treated for 10 days subcutaneously or orally with test drugs or saline. The animals are sacrificed under anesthesia, the back skin is shaved and a flap of 5×5 cm removed. The sample is placed between two pieces of plastic material with known thickness to measure skin thickness by calipers. Perpendicular to the body axis two dumb-bell shaped specimens with a width of 4 mm in the middle of the sample are punched out.

Skin specimens are fastened between the clamps of an INSTRON instrument, extended with a strain rate of 100 mm/min up to 20% extension and immediately unloaded followed by further cycles with the same strain rate and extension degree. The peak of the second cycle is considerably lower than the first, followed by a further decrease in the next cycles. The number of cycles is counted until the stress value is only one half of that of the first cycle. Immediately afterwards, the degree of extension is increased to 30%. Again the number of cycles is counted until the stress value was only one half of that of the first cycle. In this way, the **number of cycles indicating the half-life of tension** due to relaxation is counted at each step of 20%, 30%, 40%, 50%, 50%, 70%, 80%, 90% and eventually 100% extension. The number of cycles decreased from the first step (20%) to the third step (40%) and increased continuously until the last step. This increase was almost an exponential function of the number of steps.

EVALUATION

The means of the number of cycles indicating the half-life of tension due to relaxation at each step are compared between treated animals and controls using Student's *t*-test.

The parameters measured with this method are influenced by several factors: An increase was noted from an age of 1 month up to 24 months. The values were decreased by D-penicillamine and increased by prednisolone treatment. Again this method showed that plasticity of skin is decreased by age and by corticosteroids and increased by D-penicillamine.

MODIFICATIONS OF THE METHOD

Lafrance et al. (1998) tested mechanical properties of human skin equivalents submitted to cyclic forces. The *in vitro* production of disk-shaped (25.4 mm diameter) skin equivalents was based on the culture, under submerged conditions, of keratinocytes seeded on anchorage-based dermal equivalents, a human type I+III collagen gel supplemented with elastin and glycosaminoglycans. The specimens were submitted to quasi-static ramp-deflection cycles induced by means of an actuated hemispherical head. The effects of repeated loading were studied by monitoring the indentation load versus deflection and the relaxation of load over 1000 s.

P.13.2.1.10 Correlation Between Biomechanical and Biochemical Parameters

PURPOSE AND RATIONALE

Mechanical parameters of skin, such as skin thickness, ultimate load, tensile strength, ultimate strain and ultimate load of elasticity as well as hysteresis, relaxation, isorheological point, creep behavior and values after repeated strain are clearly dependent on maturation and age. They are also influenced by drugs, such as corticosteroids and desmotropic compounds. Therefore, it was of interest to elucidate the correlations of these parameters with biochemical values such as collagen content, collagen fraction, glycosaminoglycans, and elastin (Vogel 1973, 1976, 1980, 1987, 1988).

PROCEDURE

Mechanical Parameters

Male Sprague Dawley rats are sacrificed under anesthesia; the back skin is shaved and a flap of 5 × 5 cm removed. Subcutaneous fat is removed from the skin flaps. The sample is placed between two pieces of plastic material with known thickness to measure skin thickness by calipers. Perpendicular to the body axis two dumbbell-shaped specimens with a width of 4 mm in the middle of the sample are punched out. The specimens are fixed between the clamps of an INSTRON instrument at a gauge length of 30 mm. An extension rate of 5 cm/min is chosen. Tension is recorded at 2, 5, 10, 20, 30, 40, 50, 60, 70, 80 and eventually 90% elongation. The recording starts with high sensitivity and is switched to one-tenth of the sensitivity in order to record the steep end of the curve. Stress-strain curves are determined at an extension rate of 5 cm/min, showing a characteristic shape. During low strain values, there is a gradual increase of load; the curve has a concave part. The stress-strain curve ascends according to an exponential function (Vogel and Hilgner 1977). Afterwards an almost straight part is reached indicating the dependence on Hook's law. At this part the ultimate modulus of elasticity (Young's modulus) can be calculated (increase of load divided by the cross-sectional area). Then some yielding of the curve occurs, which ends in a sudden break of the specimen. This point indicates ultimate strain and ultimate load.

Biochemical Parameters

Total collagen content was measured as mg hydroxyproline/g wet weight of skin according to the method of Stegemann (1958). Collagen was further analyzed according to solubility at 4°C.

Fraction I	soluble in 0.15 mol NaCl solution
Fraction II	soluble in 0.5 mol NaCl solution
Fraction II	soluble in citrate buffer solution
Fraction IV	insoluble.

Glycosaminoglycan content and the fractions hyaluronic acid, chondroitin sulfates and heparan sulfate were determined by column chromatography. The results were expressed as glucuronic acid per g wet weight. Glucuronic acid was determined according to Bitter and Muir (1960).

Elastin was determined according to Naum and Morgan (1973). The specimen was homogenized in deep-frozen state. A sample of 50 mg was extracted with 0.15 M NaCl solution, later on twice by 5 M guanidine hydrochloride solution at 25°C. After hydrolyzation in an autoclave at 1 atm excess pressure for 45 min, the residue was digested with 0.01% elastase solution (Elastase, Merck, Darmstadt) at 37°C for 2 h. Bovine ligamentum nuchae was used as standard. Elastin was determined in the supernatant as protein according to Lowry et al. (1951). Results were expressed as mg elastin per g wet weight.

EVALUATION

A clear correlation between tensile strength and the content of insoluble collagen was found in all studies for age dependence and the effect of corticosteroids and desmotropic compounds such as D-penicillamine (correlation coefficient 0.9901; Vogel 1974). The values of glycosaminoglycans and of elastin showed age-related dependence and changes after drug treatment, but no significant correlation with the mechanical parameters.

MODIFICATIONS OF THE METHOD

Oxlund et al. (1988) studied the role of elastin in the mechanical properties of rat skin. They concluded that elastin plays a role in the mechanical behavior of rat skin at small stress values and small deformations.

P.13.2.2 Thermocontraction

PURPOSE AND RATIONALE

If collagenous material such as skin or tendon is heated in a water bath, thermocontraction occurs. This phenomenon was already described by Wöhlisch (Wöhlisch and du Mesnil de Rochemont 1927; Wöhlisch 1932). Verzár and other authors used the phenomenon of thermocontraction of tendons and skin strips extensively to study the ageing process (Verzár 1955, 1957; Lerch 1951; Rasmussen et al. 1964; Boros-Farkas and Everitt 1967; Viidik 1969, 1977, 1979; Vogel 1969). With increasing temperature, a sudden increase of isometric force is found, which is followed by a decrease. To evaluate this phenomenon, either the **shrinkage temperature** or the **stress at and above the shrinkage temperature** can be measured. Furthermore, the decrease of sample strength can be measured.

PROCEDURE

Groups of 10 male Sprague-Dawley rats with an initial weight of 120 ± 10 g are treated for 10 days subcutaneously or orally with test drugs or saline. The animals are sacrificed under anesthesia, the back skin is shaved and a flap of 5×5 cm removed. The sample is placed between two pieces of plastic material with known thickness to measure skin thickness by calipers. Perpendicular to the body axis two dumb-bell shaped specimens with a width of 4 mm in the middle of the sample are punched out.

The samples are attached to the clamps of a specifically modified INSTRON instrument which allows the submersion of the test specimen into a beaker filled with 0.9% saline solution. This solution is kept at 58°C or 60°C by a thermostat. Immediately after immersion, the exerted tension is measured and the **maximum of tension** and **time until maximal tension** are recorded.

EVALUATION

The means of these parameters are compared between treated animals and controls using Student's *t*-test.

MODIFICATIONS OF THE METHOD

Joseph and Bose (1962) tested the shrinkage temperature of skin in newborn rats, at 10 months and 2 years and found an increase from 51.2°C to 61.1°C.

Alain et al. (1977, 1980) tested pieces of dorsal skin of rats. Temperature of maximum tension was decreased from birth to 1 month, and then very slowly increased with age. A rapid relaxation was observed in young rats and in non-senescent adult rats.

Rundgren (1976) found changes of thermal contractility in skin of young and old female rats, and also changes due to repeated pregnancies.

Blackett and Hall (1980) found an increase of thermal shrinkage temperature in two strains of mice during the aging period.

Danielsen (1981) determined thermal stability measured as area shrinkage without tension during heating for membranes of collagen fibrils, reconstituted from solutions of highly purified rat skin collagen.

Allain et al. (1980) built a device, which measured not only hydrothermal shrinking but also swelling in rat skin.

Le Lous et al. (1982a, b, 1983), Flandin et al. (1984) applied the technique of differential scanning calorimetry to evaluate the denaturation process of collagen in rat skin.

P.13.3 In Vivo Experiments

P.13.3.1 Stress-Strain Curves in Vivo

PURPOSE AND RATIONALE

In contrast to studies in human beings, animal experiments allow measurement of mechanical properties both *in vivo* under anesthesia and later on *in vitro* (*ex vivo*) at the same site. For this purpose, special methods had to be developed (Barbanel and Payne 1981; Vogel 1981a, b, 1982; Vogel and Denkel 1982, 1985; Denkel 1983).

PROCEDURE

Groups of 10 male Sprague-Dawley rats with an initial weight of 120 ± 10 g are treated for 10 days subcutaneously or orally with test drugs or saline.

The rats are anesthetized with 60 mg/kg Nembutal i.p. The back skin is shaved mechanically. Skin thick-

ness is measured by use of calipers on an elevated skin fold. Four small (14 × 14 mm) metal plates bearing a hook are used as tabs and are glued on the skin in both longitudinal and perpendicular direction at a distance of 25 mm with a cyanoacrylate preparation. An operation table is mounted on the crosshead of an INSTRON instrument. The table can be turned to allow stretching of the skin in both perpendicular and longitudinal directions relative to the body axis. The anesthetized animals are fastened by their legs to the operation table. A triangle is attached to the load cell. At the end of the triangle, threads are fastened which are conducted by reels and hooked to the tabs. The cross head is moved down manually until the threads are stretched, however, no tension is measured yet. Then the crosshead is driven downwards with a rate of 50 cm/min, what means that the actual extension rate is 100 cm/min. The load is measured only to limited values in order to prevent damage of the skin. In each rat the stress-strain curve is recorded in both directions whereby the order (first longitudinal or first perpendicular) is changed from animal to animal. In this way, the influence of the first extension on the results of the second extension is eliminated. Stress-strain curves are recorded up to an elongation of 80%. Modulus of elasticity is calculated from the almost straight part of the curve.

EVALUATION

Average stress-strain curves with standard deviations are plotted for each treatment group perpendicular and longitudinal to the body axis. The stress values and the values for modulus of elasticity of the treated groups are compared with controls using Student's *t*-test.

CRITICAL ASSESSMENT OF THE METHOD

In spite of similar conditions, differences between the stress-strain curves from *in vitro* and *in vivo* experiments were found. These findings confirmed the statements of other authors (Barbanel and Payne 1981; Wijn 1980) of the importance of tab distance and tab geometry (Vogel 1981b). Analysis of the data showed that the higher the ratio of distance between the tabs to the area below the tabs, the higher were the stress values. These findings can be explained by the fact that skin consists of several layers. Only the upper layer (epidermis) is fastened to the tabs in the *in vivo* experiment. The forces transmitted to the lower layers are transmitted by a larger area if the area under the tabs is larger. The lower layer can slide over a larger area and is therefore less extended resulting in lower stress values. No sliding is possible if the sample is fastened from both sides as it is performed in the *in vitro* experiments. Taking into account all experimental conditions including the strain rate, the *in vivo* results are comparable with those obtained *in vitro*. This holds true for the age-dependence as well as for the influence of desmotropic compounds (Vogel and Denkel 1985).

MODIFICATIONS OF THE METHOD

Cook et al. (1977) compared tension/extension ratio curves *in vivo* and *in vitro* in **rats** using the suction-cup method. Baker et al. (1988) described an apparatus for testing mechanical properties of normal and irradiated **pig** skin *in vivo.* In this system, the pads were attached to the skin of the pig rump with double-sided tape. They were moved apart at a predetermined rate using a motorized unit. Force was assessed using a S-shaped, center point, double beam load cell mounted on a movable crosshead. Displacement of the pads was measured using a floating core linear variable displacement transducer. Using this system, Baker et al. (1989) studied the effect of single doses of X-rays on the mechanical properties of pig skin *in vivo*.

Zeng et al. (2001) studied the biorheological characteristics of skin after expansion in **dogs**.

P.13.3.2 Repeated Strain in Vivo

PURPOSE AND RATIONALE

A special method has been developed to study the mechanical properties of rat skin after repeated strain *in vivo* and the course of recovery during different time intervals (Denkel 1983; Vogel and Denkel 1985; Vogel 1988).

PROCEDURE

Male Sprague-Dawley rats with an initial weight of 120 ± 10 g are treated for 10 days subcutaneously or orally with test drugs or saline. Groups of 10 animals are used for each time interval tested and for the two directions of testing.

Tabs are fastened on the shaved back skin of anesthetized rats with a distance of 25 mm either perpendicular or longitudinal to the body axis with a cyanoacrylate preparation. With an extension rate of 100 mm/min, the skin is extended 30 times for a 50% strain under anesthesia. Load is recorded and stress calculated by dividing load by skin thickness measured from a skin fold obtained with calipers. The 1st, 5th, 10th, 20th, 25th and 30th cycles are recorded with faster paper speed in order to facilitate the evaluation of modulus of elasticity and stress values. Modulus of elasticity is calculated from the upper part of the stress-strain curve. The area under the curve of 30 cycles is evaluated by computerized calculation according to Simpson's formula (Hütte 1915; Denkel 1983; Vogel 1988).

EVALUATION

Average curves of stress vs. number of cycles with standard deviations are plotted for each treatment group perpendicular and longitudinal to the body axis. The stress values and the values for modulus of elasticity of the treated groups are compared with controls using Student's *t*-test.

CRITICAL ASSESSMENT OF THE METHOD

Stress values decreased after repeated loading approximately with the logarithm of number of cycles. Stress values and the area under the curve were higher perpendicular than longitudinal to the body axis, as found in other *in vivo* experiments (Vogel and Denkel 1985). During the experiment, modulus of elasticity increased in both directions from the first to the fifth cycle. This may be explained by the so-called "conditioning" of connective tissue (Nemetscheck et al. 1980). From the 5th to the 30th cycle, a decay of modulus of elasticity approximately with the logarithm of number of cycles was noted. The area under the curve calculated from stress values resembled closely the pattern of initial stress, indicating that this value dominates for the area under the curve and that the decay is only of secondary importance.

P.13.3.3 In Vivo Recovery After Repeated Strain

PURPOSE AND RATIONALE

A method was developed to study the *in vivo* recovery of mechanical properties of rat skin after repeated strain (Denkel 1983; Vogel and Denkel 1985; Vogel 1988, 1990, 1993a, b). Full recovery, i. e., ***restitutio ad integrum***, can be observed only by doing *in vivo* experiments but not by *in vitro* experiments.

PROCEDURE

Male Sprague-Dawley rats with an initial weight of 120 ± 10 g are treated for 10 days subcutaneously or orally with test drugs or saline. Groups of 10 animals are used for each time interval tested and for the two directions of testing.

As in the experiment of repeated strain, tabs are fastened on the shaved back skin of anesthetized rats with a distance of 25 mm either perpendicular or longitudinal to the body axis with a cyanoacrylate preparation. With an extension rate of 100 mm/min, the skin is extended 30 times for a 40% strain under anesthesia. Load is recorded and stress calculated by dividing load by skin thickness measured from a skin fold obtained with calipers. The 1st, 5th, and 30th cycles are recorded with faster paper speed in order to facilitate

the evaluation of modulus of elasticity and stress values. Modulus of elasticity is calculated from the upper part of the stress-strain curve. The area under the curve of 30 cycles is evaluated by computerized calculation according to Simpson's formula (Hütte 1915; Denkel 1983; Vogel 1988).

After the first run the animals are returned to their cages with the tabs still in position. A second run of repeated strain is applied after different time intervals at 1, 6, and 16 h. The stress values in the second run are definitively lower than in the first run.

When calculated as percentage of the first run, the differences diminish with extended time intervals. By this *in vivo* method not only the mechanical recovery, which can also be observed *in vitro*, but also the biological recovery, i. e., the restitutio ad integrum, can be measured. Almost full recovery is found after 16 h.

EVALUATION

Average curves of stress vs. number of cycles with standard deviations are plotted for each treatment group perpendicular and longitudinal to the body axis. The stress values and the values for modulus of elasticity of the treated groups are compared with controls using Student's *t*-test. Stress of the first and 30th cycle as well as the area under the curve at the second run are expressed as percentage of the first run after the 1, 6, or 16 h interval. Furthermore, the hours to reach certain percent levels up to 100% are calculated for the stress values during the first cycle and the area under the curve both longitudinally and perpendicularly to the body axis.

CRITICAL ASSESSMENT OF THE METHOD

In the late phase of recovery, an even better restitutio ad integrum was found in animals treated with 300 mg/kg p.o. D-penicillamine or 10 mg/kg s.c. prednisolone acetate. In contrast to other biomechanical parameters, the restoration process was found to be barely influenced by treatment with desmotropic compounds.

Surprisingly, in studies on age dependence restitutio ad integrum was the fastened in old animals. The ability of the dermis to reconstitute the fibrous structure is apparently not influenced negatively by age.

P.13.4 Healing of Skin Wounds

PURPOSE AND RATIONALE

Healing of skin wounds is a multiphasic process. The effect of drugs on the healing process was studied by measuring the mechanical strength at various time intervals after incision of the skin (Vogel 1970).

PROCEDURE

Groups of 10 to 20 male Sprague-Dawley rats weighing 120 ± 5 g are used for each dosage or control and for each test interval. Under anesthesia the dorsal skin is shaved and an approximately 3 cm long incision is made down to the fascia in a cranio-caudal direction in the dorso-lumbar region. Immediately afterwards, the wound is closed with wound clips. The rats are treated subcutaneously with test drugs beginning on the day of surgery. The clips are removed the day before the tensile strength is tested or on the 10th post-operative day at the latest.

For the measurement of wound tensile strength, the rats are sacrificed under anesthesia on days 3, 6, 9, or 12 after surgery. Wound clips are fastened *in situ* on each side of the incision and connected by means of threads with the load cell and the crosshead of an INSTRON-Instrument. Stress-strain curves are recorded at an extension rate of 5 cm/min. **Dehiscence of the wound** results in a sudden drop of the registered load. For experiments up to 3 weeks, bell-shaped skin strips are punched and tensile strength is tested, as described for evaluation of tensile strength in normal skin.

EVALUATION

Mean values of tensile strength of skin wounds in drug treated groups at each time interval are compared with controls using Student's *t*-test. To visualize the influ-

ence of drugs on the healing process, the changes following treatment with drugs are expressed as percentage of vehicle treated controls.

A dose-dependent decrease following treatment with corticosteroids is found after immediate postoperative treatment and a dose-dependent increase in prolonged experiments. This data serve as comparative parameters for new test compounds

MODIFICATIONS OF THE METHOD

Many authors measured tensile strength of skin wound to follow the course of wound healing under various conditions. Most experiments were performed in **rats** (Struck et al. 1967; Corps 1969; Holm-Pedersen and Zederfeldt 1971; Holm-Pedersen and Viidik 1972a, b; Andreassen et al. 1977; Andreassen and Oxlund 1987; Greenwald et al. 1993; Seyer-Hansen et al. 1993; Jyung et al. 1994; Adamson et al. 1996; Brunius and Ahren 1996; Oxlund et al. 1996; Paul et al. 1997; Taylor et al. 1997; Quirinia and Viidik 1991, 1998; Canturk et al. 1999; Gupta et al. 1999), with some of them also using the INSTRON-Instrument (Phillips et al. 1993; Maxwell et al. 1998; Jimenez and Rampy 1999; Kim and Pomeranz 1999).

A biphasic effect of corticosteroids on wound healing in rats was also found by Oxlund et al. (1979).

Forslund et al. (2006) published a comparative dose–response study of cartilage-derived morphogenetic protein (CDMP)-1, -2 and -3 for tendon healing in rats.

Furthermore, **mice** (Butler et al. 1991; Celebi et al. 1994; Kashyap et al. 1995; Vegesna et al. 1995; Gonul et al. 1998; Matsuda et al. 1998), **guinea pigs** (Bernstein et al. 1991; Drucker et al. 1998; Silverstein and Landsman 1999), **rabbits** (Sandblom 1957; Wu and Mustoe 1995; Pandit et al. 1998, 1999; Knabl et al. 1999; Xia et al. 1999), **dogs** (Howes et al. 1929; Al Sadi and Gourley 1977; Scardino et al. 1999), **pigs** (Langrana et al. 1983; Higashiyama et al. 1992; Chang et al. 1998; Fung et al. 1999) or **Yukatan miniature pigs** (Van Dorp et al. 1998) were used.

Using PPARα, β and γ mutant mice, Michalik et al. (2001) demonstrated that PPARα and β are important for the rapid epithelialization of a skin wound and that each of them plays a specific role in this process. PPARα is mainly involved in the early inflammatory phase of the healing, whereas PPARβ is implicated in the control of keratinocyte proliferation.

PPARβ is discussed as a target for wound healing drugs (Tan et al. 2003).

Smith et al. (2001a, 2001b) discussed the role of peroxisomes in dermatology.

In some studies simultaneously polyvinyl alcohol sponges were implanted in which collagen accumulation was determined (Albina et al. 1993; Schaffer et al. 1996; Koshizuka et al. 1997; Bitar 1998; DaCosta et al. 1998; Witte et al. 1998).

Ågren and Mertz (1994) found excessive granulation tissue formation and retarded wound contraction in wounds in tight-skin mice.

Kyriakides et al. (1999) reported accelerated wound healing in mice with a disruption of the thrombospondin 2 gene.

P.14 Protection Against UV Light

PURPOSE AND RATIONALE

The mechanical parameters' skin thickness, ultimate strain, ultimate load, tensile strength and modulus of elasticity were used to evaluate the effects of UV-irradiation and the prevention of skin damage in hairless mice (Alpermann and Vogel 1978; Vogel et al. 1981).

PROCEDURE

Female hairless mice (strain mutant h/h) with an initial weight of 20 ± 2 g are used. Groups of 20 animals are treated topically with 0.025 ml of the sunscreen product or the base. One other group is not treated topically, but irradiated. A further group is neither treated nor exposed to UV-B.

A special light source (Osram Ultra-Vitalux No. 2) is used. This light source is almost free from UV-C. For UV exposure groups of 5, mice are immobilized under a fine wire net of 14×14 cm at a distance of from the lamp, resulting in an irradiation energy of 14 mW/cm^2 for UV-B and 33 mW/cm^2 for UV-A. Irradiation is performed once a day except Saturday and Sunday during 4 weeks. Exposure time is 45 s in the first week, 60 s in the second, 90 s in the third, and 120 s in the fourth week. The animals are sacrificed umder anesthesia 72 h after the last irradiation. A flap of back skin is removed, skin thickness measured by use of calipers and two dumb-bell shaped samples punched with a width of 4 mm in the middle of the specimen. Stress-strain curves are recorded with an INSTRON-instrument at a strain rate of 5 cm/min. Ultimate load and ultimate strain are recorded and tensile strength as well as ultimate modulus of elasticity are calculated.

Furthermore, samples of skin are deep-frozen for chemical analysis of collagen and soluble collagen fractions as well as of elastin (Vogel 1978).

EVALUATION

The mean data from animals treated with sunscreen products are compared with those of animals treated with ointment base, irradiated and non irradiated controls using ANOVA and Student's *t*-test.

MODIFICATIONS OF THE METHOD

The effect of UV-irradiation on skin has been studied by several authors both in man and in animals.

Wolska (1974) recommended the hairless mouse as an experimental model for evaluating the effectiveness of sunscreen preparations.

Cook et al. (1979) investigated the changes in the mechanical properties of intact **guinea pig** skin resulting from ultra-violet irradiation.

Lowe and Breeding (1986) evaluated several sunscreen preparations by UVB irradiation of mice. Sunscreen solutions were applied to the back of 5–8 weeks old female skh/HR-1 mice one h before irradiation with FS40 sunlamps. Epidermal DNA synthesis assay was used to measure sunscreen efficacy. The amount of UVB required to achieve a 50% suppression of radiolabelled thymidine incorporation in treated and untreated mice was compared as a ratio to determine the protective factor. Furthermore, epidermal ornithine decarboxylase activity was determined by measuring the release of $^{14}CO_2$ from L-[1-^{14}C]ornithine 24 h after a single UVB exposure. Edema was estimated by the increase in double skin fold thickness measured by a caliper at 24 h post irradiation.

Benrath et al. (1995) reported that substance P and nitric oxide mediate wound healing of ultraviolet photodamaged skin in **rats**.

Muizzudim et al. (1998) studied the effect of topical application of antioxidants and free radical scavengers on protection of hairless mouse skin, exposed to

suberythemal doses of ultraviolet B three times a week, and measured epidermal thickness by microscopy.

Fullerton and Keiding (1997) quantified UV-B induced erythema in depilated Hartley-strain albino male guinea pigs and compared the results with a tristimulus colorimeter (Minolta ChromaMeter CR-200) and two spectrophotometers (Minolta Spectrophotometer CM-508i and CM-2002). With the tristimulus colorimeter the color is expressed in a three-dimensional color space, which simulates the perception of color by the human eye.

Nishimori et al. (2001) described degenerative alterations of dermal collage fiber bundles in photodamaged human skin and UV-irradiated hairless mouse skin and the effects on decreasing skin mechanical properties and appearance of wrinkles.

Oba and Edwards (2006) studied the relationships between changes in mechanical parameters of the skin, wrinkling, and destruction of dermal fiber bundles caused by photoaging on hairless mice irradiated with UVB light.

Further description of ultraviolet erythema in animals see Sect. H. 3.2.2.1.

P.15 Transepidermal Water Loss (TEWL)

PURPOSE AND RATIONALE

The physical basis for the measurement of transepidermal water loss (TEWL) is the diffusion law discovered by A. Fick in 1855.

$$dm/dt = -D \times A \times dp/dx$$

where:

A = surface (m^2),

m = water transported (g),

t = time (h),

D = diffusion constant ($= 0.0877\ g/m \times h \times mm\ Hg$),

p = vapor pressure of the atmosphere (mm Hg),

x = distance from skin surface to point of measurement.

Most of the recent studies are performed with commercially available instruments, such as Tewameter TM 210, Courage and Khazaka, Cologne, Germany, Evaporimeter EP1, Servo Med AB, Vallingby, Sweden, primarily designed for the used in human beings.

Several studies were performed in **rats**, e. g., in hairless rats (Doucet et al. 1991; Vanbever et al. 1998), neonatal rats (Wickett et al. 1995), in rats with experimentally induced condition of essential fatty acid deficiency (Basnayake and Sinclair 1956; Prottey et al. 1976; Hartop et al. 1976, 1978; Penneys 1992; Yamaguchi et al. 1998; Meguro et al. 2000), **hairless mice** (Grubauer et al. 1989; Mortz et al. 1997; Sato et al. 1998), essential fatty acid deficient hairless mice (Menton 1968; Lowe and Stoughton 1977), platelet-type 12-lipoxygenase deficient mice (Johnson et al. 1999), keratin 10 deficient mice (Jensen et al. 2000), **guinea pigs** (Frosch et al. 1993; Fuchs et al. 1998; Sagiv et al. 2000), **pigs** (Zhao and Singh (1999) **Yucatan micro-swine** (Gendimenico et al. 1995).

Löffler et al. (2001) evaluated irritant skin reaction in mice by measurement of auricular transepithelial water loss.

PROCEDURE

BALB/c mice aged 10–16 weeks are sensitized on day 0 by applying 50 µl 2,4-dinitro-flurobenzene (DNFB) solution (0.5% diluted in acetone/olive oil 4:1) to the shaved dorsal neck region. On day 5, the dorsal surface of one ear is challenged by applying 10 µl DNFB 0.3%; the other side is treated by acetone/olive oil alone.

Transepithelial water loss is measured with an evaporimeter (Tewameter TM 210, Courage and Khazaka, Cologne, Germany) with a measuring cylinder into which the whole ear of the mouse can be placed. The measurements are performed under isofluoran inhalation anesthesia. Measurements are performed before and 24 h after challenge.

EVALUATION

The comparison between the treated and untreated ears is calculated by the Wilcoxon test. The comparison between the tested groups is calculated by the Kruskal-Wallis *H*-test, after the Mann-Whitney *U*-test.

P.16 Skin Hydration

PURPOSE AND RATIONALE

Techniques to characterize the barrier function of the skin include a number of noninvasive methods to measure moisture content and loss through the skin surface. One of these measurements is the determination of skin hydration using a method known as corneometry (Bilchmann and Serup 1988). This technique determines the capacitance of the skin due to its behavior as a dielectric medium and assesses a 10- to

20-µm thickness of the stratum corneum. The method has been compared with other techniques (Van Neste 1991; Fluhr et al. 2001) and applied to evaluate dermatological and cosmetic products in human volunteers (Zuang et al. 1997; Singh et al. 2001; Yilmaz and Borchert 2006).

Jensen et al. (2000) studied skin hydration in keratin-10-deficient mice. Kappes et al. (2004) used this method to investigate the quality of human xenografts on SCID mice. Hester et al. (2004) evaluated this method in dogs.

PROCEDURE

Normal adult dogs (female Beagle and male houndcross dogs) were used. Hair was clipped from the left inguinal region of each dog 1 week before measurements to minimize any effects of recent hair clipping. Because hair grows sparsely in the inguinal region, only a minimal amount of clipping was necessary. To measure skin hydration, a Corneometer 825 meter (Courage Khazaka Electronics) was used. Animals were gently restrained in a right-lateral recumbency on a padded floor and were given time to relax so that movements could be minimized during data collection. The probes were held in place manually, and readings were taken for 20 s each. The data were stored electronically using a laptop computer and appropriate software. Values representing an average of at least ten determinations were used to calculate average values.

EVALUATION

Statistical analyses were conducted by repeated-measures ANOVA for main time-and-breed effects and time × breed interactions with Tukey' multiple comparisons performed at P values <0.05.

Influence on Hair Growth

PURPOSE AND RATIONALE

Several mutations affecting hair growth or quality have been reported in the laboratory mouse (Holland 1988), among them "alopecia" (Dicke 1955); "alopecia periodica" (Tutikawa 1952); "crinkled" (Falconer et al. 1951); "frizzy" (Falconer and Snell 1952); "fuzzy" (Mann 1964); "rhino" (Mann 1971); "naked" (Raphael et al. 1982); "nude" (Flenagen 1966; Buhl et al. 1990; Militzer 2001); "ragged" (Slee 1962); androchronogenetic alopecia (AGA) mouse (Matias et al. 1989); aging C3H/HeJ mice (Sundberg et al. 1994); SPF-ASH mice (Shimada et al. 1994); "nackt" (Benavides et al. 1998); transgenic mice overexpressing homeobox gene MSX-2 (Jiang et al. 1999). Kligman (1988, 1998) used the Skh-hairless mouse as a model for evaluating promoters of hair growth.

PROCEDURE

Six litters of Skh-hairless-1 albino mice with 5–8 animals are housed, with their mothers, in individual plastic cages. Food and water are supplied ad libitum. Beginning at 1 week of age, topical treatment is applied: two litters dorsal application of low dose (e. g., 0.2% minoxidil), two litters dorsal application of high dose, two litters abdominal application of high dose. Application is performed once daily five times a week at a rate of 20 µl/cm^2 of skin using a digital micropipette. Two control litters receive no treatment. All treatment continue for up to 17 weeks, after which mice are sacrificed and grossly examined for signs of toxicity.

Mice are observed daily for hair growth and weighed each week. Photographs are taken when hair growth appears to be maximum. At the time of maxi-

mal hair growth, two or three representative neonates from the treated and untreated groups are sacrificed for skin biopsies; all remaining mice continue on treatment to asses the extent of a third pelage. Biopsy specimens are fixed in formalin and stained with hematoxylin and eosin.

EVALUATION

In transverse sections, all active hair matrices or viable follicles, which contain keratin zed hairs located in the subcutis, are counted. Fourteen to 16 contiguous fields are examined over a surface distance of 1 cm at 250× magnification. Mean values of the groups are compared using Student's *t*-test.

MODIFICATIONS OF THE METHOD

De Brouwer et al. (1997) studied the effects of a nonsteroidal anti-androgen on human hair production by balding scalp grafts maintained in testosterone-conditioned **nude mice**. Samples of balding human scalp were grafted on to the left flank of nude mice (bal/c, nu/nu). All mice received a topical application of 300 µg/10 µl testosterone propionate on the non-grafted flank. Testosterone conditioning started 5–7 weeks after grafting and went on until the end of the experiment, once daily 5 days a week. Anti-androgen/placebo treatment was started before hair production was visible. Hair production potential was assessed according the number and diameter of the hairs.

A hair loss mutation on mouse chromosome 19, called **scraggly**, was described by Herron et al. (1999).

Several authors studied **chemotherapy-induced alopecia in mice, rats and rabbits** (Powis and Kooistra 1987; Paus et al. 1994a, b; Cece et al. 1996; Sredni et al. 1996).

The **Dundee experimental bald rat (DEBR)** was used as model for alopecia areata (Oliver and Lowe 1995; McElwee et al. 1997).

Kimura (1996) underlined the usefulness of studies in **hairless descendants of Mexican hairless dogs** in dermatological science.

The **balding stumptail macaque** is recommended as a model for androgenetic alopecia (Brigham et al. 1988; Diani et al. 1995; Pan et al. 1998).

The stimulating effect of drugs on hair growth has been studied using *in vitro methods.*

Kurata et al. (1996) investigated the effect of hypertrichotic agents on follicular from macaque and human skin and nonfollicular cells (normal keratinocytes and dermal fibroblasts) *in vitro*. Minoxidil induced a significant increase in all follicular cells in a dose-specific manner, whereas nonfollicular cells showed no response.

Lachgar et al. (1996) found inhibitory effects of bFGF, VEGF and minoxidil on collagen synthesis by cultured hair dermal papilla cells from rat vibrissa follicles.

Boyera et al. (1997) described biphasic effects of minoxidil on the proliferation and differentiation of normal human keratinocytes obtained form microdissected hairs of from plucked hairs. Minoxidil stimulated human keratinocyte proliferation at micromolar doses, while antiproliferative, pro-differentiative and partially cytotoxic effects were observed with millimolar concentrations.

Sato et al. (1999) reported that minoxidil increases 17β-hydroxysteroid dehydrogenase and 5a-reductase of cultured human dermal papilla cells from balding scalp.

Cutaneous Microcirculation

P.18.1
General Considerations

PURPOSE AND RATIONALE

Various techniques are used to determine cutaneous blood flow, such as radioactive microspheres, xenon clearances, plethysmography, laser Doppler velocimetry (Flagrell 1986; Guy et al. 1985), reflectance spectrophotometry (Kimura et al. 1988; Kakizoe et al. 1992).

P.18.2
Laser Doppler Velocimetry

PURPOSE AND RATIONALE

Laser Doppler velocimetry and laser Doppler flowmetry are essentially identical procedures. With these methods, light is transmitted from a helium-neon laser source in the instrument to the skin via an optical fiber. The laser provides light of single frequency (wave-

length 632.9 nm) and allows the Doppler effect to be exploited. The incident radiation enters the skin tissue and is multiply scattered and reflected by non-moving components and by the mobile red blood cells that are encountered as the radiation penetrates to a depth of 1–1.5 mm. A portion of scattered/reflected incident radiation exits the skin and is collected by second or third optical fibers that carry the light back to the instrument. The returning radiation falls on a photodetector and is converted to an electrical signal. Stationary skin tissue reflects and backscatters light at the same frequency as the incident source. Erythrocytes moving with certain velocity, however, reflect radiation that is slightly frequency-shifted, the shift increasing with increasing velocity.

Hirkaler and Rosenberger (1989) described simultaneous two-probe laser Doppler velocimetric assessment of topically applied drugs as a simple, noninvasive method for the determination of cutaneous blood flow in anesthetized rats.

PROCEDURE

Male Sprague-Dawley rats (400–500 g) are anesthetized with urethane (1.6 g/kg), the abdominal region carefully clipped and the remaining hair removed with a commercially available depilatory. Phthalate buffer (pH 4.0) is gently applied to neutralize the effects of the depilatory cream. The rat is placed on its back and allowed to stabilize for approximately 15 min. Cutaneous blood flow is measured using two standard Medpacific LD 5000 capillary perfusion monitors and probes (1.9 cm diameter). The probes are modified to allow application of the drug without removal of the probe. This is achieved by enlarging the center opening of the adhesive pad to 1 cm, which creates a drug well of approximately 5 µl vol. The drug is introduced through a short length of polyethylene tubing (PE10) held in place by the adhesive pad and placed slightly off center to avoid interference with the sensing device.

The modified probes are attached to the lower abdominal region of the rat, approximately 1–2 cm from the midline. Cutaneous blood flow is recorded continuously from 30 min prior to drug application and for 5 h post-dosing. Various doses of standard (0.015 to 0.75 mg/kg minoxidil) or test compound or control vehicle (propylene glycol 15%, ethyl alcohol 65%, water 20%) are applied. At the end of the experiment, the animals are sacrificed.

EVALUATION

Post-dosing values are expressed as % change from control and analyzed using Student's paired *t*-test.

MODIFICATIONS OF THE METHOD

Knight et al. (1987) measured microvascular blood flow by a laser Doppler flow meter in **rabbit** epigastric island flaps made ischemic for various intervals of time.

P.18.3 Measurement of Skin Microcirculation by Reflectance Spectroscopy

PURPOSE AND RATIONALE

Kimura et al. (1988), Kakizoe (1992) developed reflectance spectrophotometric measurement to analyze the microcirculation of the skin in real time. The light reflected from the skin tissue containing information about hemoglobin, the injected dye, and other data, is continuously analyzed into the relative absorption spectrum and the changes in relative absorption values at specific wavelengths are used as indices of oxyhemoglobin content and capillary permeation.

PROCEDURE

Male Wistar rats weighing 300–400 g are anesthetized with pentobarbital (40 mg/kg i.p.). The skin of the back is shaved and the hair removed by a commercial hair remover. A polyethylene catheter (PE10) is inserted into the femoral artery to measure blood pressure on a polygraph. An other catheter is inserted into the femoral vein for injection of drugs or Evans blue.

To obtain the relative absorption spectra, a spectro-multi-channel-photodetector system (MCPD 110; Otsuka Electronics Co., Ltd., Osaka, Japan) is used. White light (halogen lamp 150 W) is projected onto the skin through an optical fiber. The light reflected from the skin is transmitted to the detector system via another optical fiber. The positions of the optical fibers are fixed independently. Each fiber is attached to a steel arm on the stand, and the height of the arms is adjusted so that the top of the fibers can be in gentle contact with surface of the skin. The angles of the fibers are adjusted so that the relative absorbance spectrum with the best peaks of oxyhemoglobin can be obtained. The reflected light is passed through a slit and illuminated

on the grating surface to obtain the spectrum. Following amplification by an image intensifier, the component wavelengths are sampled by photodiode array in a short time interval. The relative absorbance spectra from the skin against the spectra for the white light are obtained at wavelengths ranging from 450 to 643 nm, arranging the initial relative absorbance at 640 nm to zero. The sampling time is 50 ms. The average of 10 measurements is indicated at 1-s intervals on the output unit. The spectrum at a point of time and time-dependent changes in relative absorbance values at selected wavelength are shown on the display and registered by an X-Y recorder.

After achieving a steady state under anesthesia, the relative absorbance spectrum is obtained from the skin, and two peaks ate wavelength of about 540 and 577 nm, corresponding to those of oxyhemoglobin, are observed. The relative absorbance spectrum is measured at the posterior part of the back near the backbone because the shape is relatively flat in this region and it is easy to fix the optical fibers.

To standardize the changes in oxyhemoglobin content in skin tissue, graduated doses of noradrenaline are injected intravenously and the effect on relative absorbance is measured.

To measure the content of oxyhemoglobin and permeation of the capillaries at the same time, 1.5 ml/kg 0.05% Evans blue solution is injected intravenously 10 min before measurement. Histamine (0.3–100 µg/50 µl/site) is injected intradermally into the skin of the back, and measurement is started 1 min after the injection. The changes in the relative absorbance values at 540 nm, an absorption peak in the oxyhemoglobin spectrum, and at 610 nm, an absorption peak in the Evans blue spectrum, are measured for 15 min, and the absorption values at baseline and the point of maximum change are compared.

EVALUATION

Results are expressed as mean ± SEM. Comparisons are made using the Student's *t*-test or Mann-Whitney's *U*-test.

MODIFICATIONS OF THE METHOD

Hertel (1986, 1992) measured cutaneous microcirculation in the pinnal of conscious rats. Erythrocyte flow velocities were measured by the 'flying spot technique' (Tyml and Ellis 1982) and the diameters of the capillaries were measured from a monitor with a ruler.

Da Costa et al. (1992) measured the fluctuations in the diameter of selected arterioles in the cutaneous microcirculation of **Syrian golden hamster** dorsal skin flap chambers. These ranged in size between 10 and 70 µm at different branching order sites, before burn, at the same site after burn and after injection of drugs.

P.19
Isolated Perfused Skin Flap

PURPOSE AND RATIONALE

Riviere et al. (1986) and Riviere and Monteiro-Riviere (1991) described the isolated perfused porcine skin flap as an *in vitro* model for percutaneous absorption and cutaneous toxicology studies. This group has used the model for various purposes (Riviere et al. 1995; Vaden et al. 1996; Baynes et al. 1997; Inman et al. 2003; Monteiro–Riviere et al. 2003).

PROCEDURE

Weanling female Yorkshire pigs weighing 20–30 kg are acclimated for 1 week prior to the study. The pigs are housed on elevated floors and provided water and 15% protein pig and sow pellets ad libitum.

The isolated perfused porcine skin flap is a single, axial pattern tubed skin flap obtained from the ventral abdomen of female weanling swine. Two flaps per pig, each lateral of the ventral midline, may be obtained in a single surgical procedure. The surgery involves two steps: creation of the flap in stage I and harvest in stage II. Pigs weighing approximately 20–30 kg are pre-medicated with atropine sulfate and xylazine hydrochloride, induced with ketamine hydrochloride, and inhalation anesthesia is maintained with halothane. Each pig is prepared for routine

surgery in the caudal abdominal and inguinal region and a 4 × 12 cm area of skin is demarcated. Following incision and scalpel dissection of the subcutaneous tissue, the caudal incision is apposed, sutured, and the tubed skin flap edges trimmed of fat and closed. Two days later, a second surgical procedure is used to cannulate the artery and harvest each of these skin flaps. The isolated perfused porcine skin flap is then transferred to a custom-designed temperature- and humidity-regulated perfusion chamber. A computer monitors perfusion pressure, flow, pH, and temperature. The flaps are perfused for 1 h prior to dosing with a modified Krebs/Ringer bicarbonate buffer (pH 7.4) containing bovine serum albumin, glucose, penicillin G amikacin, and heparan, during which 1.0-ml arterial and 3.0-ml venous samples are collected to assess glucose utilization. Once flap viability is confirmed, the perfusion is interrupted and each flap is removed from the chamber. Flap perfusion is resumed, with the venous perfusate sampled every 15 min for the first 2 h and every 30 min thereafter for the 8-h duration. Absorption is defined as the total amount of radioactivity detected in the perfusate over an 8-h perfusion period and expressed in units of % of applied radioactivity or mass absorbed. Penetration is defined as the sum of total radioactivity found in the perfusate (absorption), stratum corneum, fat and dosed skin samples. Penetration is the maximum amount of test compound that could be absorbed into the systemic circulation if all test compounds within the skin ultimately were absorbed over a prolonged period of time. Penetration is also relevant to the direct toxic effect within the skin.

EVALUATION

Total recovery is calculated as the sum of penetration plus the amount of radioactivity found in the washing samples. All data are expressed as mean ± standard error of the mean (SEM). The significant differences ($P < 0.05$) across each set of treatments are determined by ANOVA in PC SAS (SAS Institute, Cary, N.C., USA; version 8.01). Significant differences ($P < 0.05$) between each mean and paired nonaqueous counterpart are determined using a Student's *t*-test.

MODIFICATIONS OF THE METHOD

Pickens et al. (1994) studied the effect of extended perioperative pentoxifylline on random skin flap survival in Yorkshire pigs.

Skin flap models have been described for several animal species, mostly in **rats** (Hahn et al. 1993; Stadelmann et al. 1998; Yenidunya et al. 1998; Cottler et al. 1999; Yang and Morris 1999; Jones et al. 2001; Oksar et al. 2001; Lay et al. 2003; Mittermayer et al. 2003; Ozkan et al. 2004; Agaoglu and Siemionow 2005; Ulusal et al. 2005; Hosnuter et al. 2006). Lineaweaver et al. (2004) described the influence of vascular endothelium growth factor and surgical delay on survival of the transverse rectus abdominis myocutaneous flap in rats. The model is based on the right abdominis rectus muscle as carrier and inferior epigastric vessels as vascular pedicle. Following induction of general anesthesia, the abdominal regions were shaved, and a rectangle measuring 3 × 8 cm was drawn onto the upper abdominal area of the rats. The borders of the skin paddle of the proposed transverse rectus abdominis myocutaneous flap were cut down to deep fascia. The branches of both superficial epigastric vessels joining the flap were ligated and cut. Both rectus abdominis muscles were divided at the superior border of the skin paddle. The superior deep epigastric vessels of both rectus abdominis muscles were divided. The skin incision was then closed using 4–0 nylon sutures.

Barker et al. (1989) and Minh et al. (2002) described skin flap models in **mice**.

Degner et al. (1996) described a medial saphenous fasciocutaneous free flap in **dogs**.

Teunissen et al. (2004) evaluated the primary critical ischemia time for the deep circumflex iliac cutaneous flap in **cats**.

Bristol et al. (1991) reported preparation and metabolic parameters of an isolated perfused skin flap in **horses**.

Q.1 Regulations for the Care and Use of Laboratory Animals in Various Countries

See Table Q.1 on the following page.

Q.2 Techniques of Blood Collection in Laboratory Animals

Q.2.1 Introduction

Blood is collected from laboratory animals for various scientific purposes, for example, to study the effects of a test drug on various constituents, such as hormones, substrates, or blood cells. In the field of pharmacokinetics and drug metabolism, blood samples are necessary for analytical determination of the drug and its metabolites. Blood is also needed for some *in vitro* assays using blood cells or defined plasma protein fractions.

The techniques for blood collection depend on specific factors which differ from one experiment to the other. There is a difference between terminal and non-terminal blood collection techniques. The conditions of blood collection at the end of an experiment which includes death of the animal (terminal experiment) are completely different (anesthesia, volume of blood)

from those of single or repeated blood collections from a conscious animal. Terminal blood collection under anesthesia allows the use of techniques which are not acceptable for non-terminal blood collections.

Q.2.2 Aspects of Animal Welfare

Minimizing any pain and distress in laboratory animals during the procedure have to be as important as achieving the desired experimental results. This is important not only for humanitarian reasons but also as part of good scientific practice. Blood collection may be stressful to the animal due to the handling and the discomfort associated with a particular technique. Many biochemical and physiological changes are associated with stress which affect the results, e. g. increases in the blood levels of catecholamines, prolactin and glucocorticosteroids can influence certain metabolic parameters, such as glucose, as well as the counts of erythrocytes, white cells, and packed cell volume. Therefore, stress should be reduced to an absolute minimum if it is not possible to avoid it at all, this is not only in the interest of animal welfare but also in the interest of good science to obtain representative data. To minimize stress during blood collection, e. g. from dogs or cats, it may be helpful for the animal as well as for the operator first to do some dummy runs and provide rewards to the animal.

During non-terminal blood collection it is important not to withdraw too much blood which could reduce total blood volume and lead to false results. A reduced total blood volume is accompanied by a reduced hemoglobin content and oxygen transport capacity (Gainer et al. 1955) as well as by a fall in blood pressure, and an increase in the concentrations of stress-related hormones. It may be further accompanied by other factors such as necrosis of the gastric mucosa.

The welfare of the individual animal should not be endangered by removal of too large a volume of blood or by too frequent collections. This may be the case more often when small laboratory animals, e. g. mice, gerbils, rats or hamsters are used. In these cases the study protocol should be adapted to use more animals to minimize distress for the individual animal.

Q.2.3 Total Blood Volume

The total blood volume is very difficult to determine (McGuill et al. 1989) and depends on species, sex, age and health as well as nutritional condition. Total blood volume is smaller in larger animals than in smaller animals of the same species in relation to body weight. It is also smaller in older and obese animals compared to normal weight and young animals. Total circulating blood volume is in the range of 55–70 ml/kg body weight.

Q.2.4 Terminal Blood Collection

Terminal blood collection represents (i) exsanguination as a single process of blood removal to collect as much blood as possible and (ii) multiple blood sampling during a terminal experiment under general anesthesia. Basically, exsanguination should only be performed after the animal has been rendered unconsciuos by another method, e. g. physical stunning or general anesthesia. This is due to the fact that stress occurs

with extreme hypovolemia and accessing deeper blood vessels causes pain. Due to the anesthetized condition of the animal and the terminal nature of the experiment, methods can be used for exsanguination which can never be recommended for non-terminal blood collections with recovery of the animal. These include

- blood withdrawal from the V. cava caudalis or the aorta after laparatomy when as much blood as possible should be removed in a sterile manner,
- exsanguination after decapitation, incision of the jugular vein or carotid artery or techniques in the slaughterhouse, when a non-sterile collection is possible,
- retro-orbital bleeding of smaller laboratory animals like mice, gerbils, hamsters and rats which can also be a method of exsanguination.

Q.2.5 Non-terminal Blood Collection

Non-terminal blood collections can be differentiated into single and multiple blood withdrawals. Possible peripheral veins for blood withdrawal are listed in Table Q.2.

Q.2.5.1 Single Blood Removal

A single withdrawal of up to 15% of total blood volume does not influence the well-being of the animal. However, the removal of 15 to 20% might be accompanied by side effects such as fall in cardiac output or blood pressure. Haemorrhagic shock can be induced by the withdrawal of 30–40% of total blood volume and the loss of 40% causes mortality in up to 50% of pigs and rats (McGuill et al. 1989).

A single removal of up to 15% of total blood volume may be repeated after 3–4 weeks from normal and healthy animals with no detectable adverse effects. This does not mean that the animal does not experience any adverse effects, but it does not show any.

Symptoms of hypovolaemic shock are fast pulse, pale mucous membranes, hyperventilation and a subnormal body temperature including cold skin and extremities. In these animals therapeutic intervention consists of volume substitution with warm isotonic intravenous infusion.

Q.2.5.2 Multiple Blood Removal

Multiple withdrawal of blood samples should not exceed 1% of total blood volume every 24 h (0.6 ml/kg/d). More frequent withdrawals and/or removal of larger volumes of blood causes anemia.

Symptoms of anemia are pale mucous membranes of the conjunctiva or inside the mouth, intolerance to exercise and an increased respiratory rate in cases of severe anemia. Anemia can be easily detected by de-

termination of erythrocyte cell count and packed cell volume (haematocrit), hemoglobin level as well as reticulocyte count in a blood sample. In case of anemia the animal should be treated with iron and vitamin B12 and should be monitored for the above mentioned blood parameters during therapy until normal values are reached again.

Q.2.6
Technical Aspects of Blood Removal

A common method in mice and rats for collecting up to 0.1 ml capillary blood is to remove the tip of the tail. For repeated blood sampling the blood clot on the tail has to be removed to get fresh capillary blood. This method is sufficient for multiple blood collections to determine, e. g. blood glucose or total radioactivity after the administration of radiolabeled drugs. In tailless animals such as guinea pigs and hamsters, cardiac puncture under general anesthesia may be the preferred technique.

Blood collections from larger animals will preferably be performed from a superficial vein. The person holding the animal and raising the vein plays a key role in collecting blood without undue stress to the animal by talking to and stroking the animal. Some animals, e. g. dogs and some primates, may be trained to present a limb for blood removal without the use of any physical restraint.

It is important to locate the vessel accurately before insertion of the needle or the catheter. In most cases obstruction of the venous return is necessary for distension of the vessel and to successfully insert the needle. The bore of the needle should be as large as possible to ensure rapid blood withdrawal with minimal risk of blood clotting within the needle. When the sample is taken too quickly by a syringe, the vein will collapse. After the needle has been withdrawn, continuous pressure should be applied immediately to the puncture site and maintained for at least 30 s. The animal should be monitored 15 min later to check for after-bleeding.

Q.2.6.1
Permanent Venous Cannulation

For multiple blood collections a permanent venous access by chronic cannulation is often recommended. In most cases, particularly in rats, it is necessary to restrain the animal in harnesses or jackets to prevent it from damaging or removing the cannula. In these cases the signs of stress are often apparent by an increase in serum levels of stress hormones. However, a few days after implantation of catheters, hormone levels are normal in restrained rats (Tsukamoto et al. 1984; Wiersma and Kastelijn 1985). Such animals are usually housed alone and the tethering restricts normal movements such as lying on the back and rolling over. Such restrictions may be considered as potential sources of stress. This can be prevented by having the catheter exit the back of the animal for only 2 cm and capping it with a steel needle. At the time of the experiment, a longer catheter is attached for blood collections.

A simple device for serial blood collection has been described by Sir-Petermann et al. (1995).

One has to balance very carefully the distress and discomfort of the individual animal with a permanent cannulation under restraint conditions for a longer period with multiple blood samplings without permanent cannulation. In the first case, multiple values from the same animal can be obtained showing perhaps individual differences among a group of animals. In the latter case it may be necessary to use a larger number of animals but there is less discomfort for the individual animal.

Short-term cannulation (less than a day) of a peripheral blood vessel in larger animals is easy to perform. A butterfly needle can be inserted under aseptic conditions and multiple blood samples can readily be collected. Long-term cannulation (longer than two days) in larger and smaller animals often presents complications such as blockage of the cannula by thrombi. The infusion and administration of substances via the permanent cannula are much easier than the removal of blood. Thrombi attached to the end of the cannula function as a one-way valve. Clotting can be prevented by repeatedly filling the catheter with saline containing heparin.

Q.2.6.2
Retro-Orbital Bleeding

Blood sampling by orbital puncture is a controversial technique. The puncture of the orbital venous plexus is often performed in tailless animals, e. g. hamsters. This technique is also used in rats and mice, when larger volumes are required which cannot be obtained from the tail vein. Basically, retro-orbital bleeding should always be performed under anesthesia. Pasteur pipettes, micropipettes or microcapillary tubes are used and pushed with a rotating movement through the conjunctiva laterally, dorsally or medially of the eye to the back wall of the orbit. In general, inflammatory reactions can be seen histologically in the puncture

track four days after punction. After 4 weeks the lesions have healed without detectable scars (van Herck et al. 1992). However severe side-effects such as retro-orbital haematoma with subsequent pressure on the eye cannot be completely excluded. This pressure can damage the optical nerve. The animal may be unable to close its eye. Bleeding from the orbital venous plexus should only be performed with recovery of the animal in exceptional circumstances when there is no other method available. The technique should be performed only by a well-trained staff and only one eye should be used.

Q.2.6.3
Cardiac Puncture

The collection of blood by cardiac puncture has been performed in guinea pigs, gerbils and hamsters. In these species it is difficult to collect blood by alternative methods except retro-orbital bleeding. In general, cardiac puncture should be performed under general anesthesia with atropine as premedication to prevent cardiac arrhythmia. If cardiac puncture is used for a non-terminal blood withdrawal with recovery, the animal has to be separated from other animals until it is fully conscious. It should be carefully watched for adverse effects and sacrificed if found in distress due to complications like bleeding into the pericardium or into the thorax.

Q.3
Anesthesia of Experimental Animals[2]

Q.3.1
Introduction

In biomedical research, experiments should only be done with a conscious animal if it is not possible to do the study in an anesthetized one. Anesthetic conditions should always be chosen to exclude stress, discomfort and pain for the animal which could have negative influences on the pharmacological results and reproducibility of the data. Therefore, an experimental design causing minimal discomfort to the animal is always preferable. This is important not only for humanitarian reasons but also for good scientific practice.

Many pharmacological experiments are performed under anesthesia:

- terminal experiments under anesthesia followed by euthanasia,
- experiments under anesthesia with recovery at the end of the study, and
- experiments in which an animal is surgically prepared under anesthesia and continuation of the experiment occurs with the conscious animal after recovery.

Generally, two possibilities exist for immobilization of aggressive animals and to prevent escape: (i) physical restraint (e. g. immobilization cages or immobilization tubes) and (ii) chemical restraint with anesthetic compounds. As a rule of thumb it is recommended to use physical restraint for animal studies in which no anesthesia would be used in comparable studies in man. Physical restraint can be used for short and painless interventions like administration of substances or blood sampling from a vein.

In general, physical restraint produces fear, distress and anxiety in experimental animals with the result of stress symptoms which could affect the results of the study. To minimize pain for the animals, to obtain correct and reproducible results and to protect the handlers from aggression by the animals, it is often necessary to use chemical restraint. However, the chemical used can affect the biochemistry or physiology of the animal.

It is possible to anesthetize special areas of the animal (local anesthesia) or the whole animal (general anesthesia). Local anesthesia plays only a minor role

[2] By J. Maas, A.W. Herling, K. Seeger (first edition), revised by U. Albus (2nd and 3rd edition).

for experimental animals as compared to general anesthesia.

Q.3.2 Local Anesthesia

Local anesthesia is the regional and reversible elimination of pain with chemical compounds. Circulatory, pulmonary and renal functions are not disturbed and the animals are conscious. Surface anesthesia has to be distinguished from the anesthesia produced after a local injection. The most common compounds for surface anesthesia are tetracaine and proparacaine. Procaine, butanilicaine, lidocaine, mepivacaine and etidocaine are commonly used injectable local anesthetics. Local anesthesia is only recommended for gentle and calm animals (cattle, sheep). For most laboratory animals, general anesthesia is the method of choice.

Q.3.3 General Anesthesia

Q.3.3.1 Preparation

It is very important to check the general condition of the animal prior to anesthesia. This check should include a clinical examination (inspection, auscultation, palpation) of the animal concerned. Sometimes it could be useful to perform a few laboratory tests, e. g. hematocrit, hemoglobin, pH-value of blood and acid/base parameters.

Those animals with a vomiting reflex should be fasted prior to anesthesia. Most animal species should be fasted for a period of at least 12 h but pigs and cattle for at least 24 h. Water can be offered during the fasting period ad libitum.

Q.3.3.2 Premedication

Premedication is recommended prior to anesthesia for easier administration of the anesthetic and for elimination of side effects of the anesthetic used, such as disturbing autonomic reflexes.

Q.3.3.2.1 Hydration and Base Excess

Based on hematocrit, hemoglobin and erythrocyte values, the hydration of the animal should be normalized prior to anesthesia. Infusions of glucose or Ringer solution can be used for this purpose. To check the success of the treatment repeated determinations of the above mentioned values are necessary.

In cases of acidosis (pH of blood < 7.36), treatment of the animals with $NaHCO_3$ is recommended. If measurement of base excess is possible, the amount of $NaHCO_3$ can be determined from the following formula:

$$\text{Dose } NaHCO_3 \text{ (ml)} = \text{g body weight} \times \text{base excess}/0.6$$

Q.3.3.2.2 Atropine

To avoid cardiopulmonary problems and to decrease saliva production, atropine should be administered intramuscularly prior to general anesthesia. The recommended dose varies considerably and is usually between 0.05 and 0.1 mg/kg body weight. Cats and rodents have a higher activity of atropine-esterase in the liver, and these species need higher amounts of atropine (up to 0.25 mg/kg).

Q.3.3.2.3 Sedation and Pain Elimination

Indications for sedation and elimination of pain are to calm the animals and to stabilize the autonomic nervous system.

For sedation the following compounds are used:

- minor tranquilizers without autonomic effects:
- meprobamate, diazepam,
- major tranquilizers with autonomic side effects:
- propionyl-promazine, acetylpromazine, azaperone, dehydrobenzperidol, xylazine, detamidone.

Anaesthesia does not necessarily lead to analgesia (elimination of pain). Although general anaesthesia produces loss of consciousness and pain isnot perceived, the noxious stimuli will be transmitted to the CNS and will develop central hypersensitivity, leading to a postoperative heightened perception. To reduce the degree of central hypersensitivity analgesics have to be administered before noxious stimulation begins (preemptive analgesia). Analgesia should also reduce or eliminate peripheral inflammation, which aggravates central hypersensitivity.

For analgesia, the opioids used are mainly:

- methadone, meperidine, fentanyl.

In most species (dog, rabbit, guinea pig) a sedative effect is to be observed after administration of these compounds. In other species (pig, cat) an excitatory effect can occur.

Minor tranquilizers, major tranquilizers and analgesic compounds are often used in common with anes-

Table 3 Anesthesia of experimental animals (values are in mg/kg)

Species	Premedication	Sedation	Short anaesthesia	Medium anaesthesia	Long anaesthesia
Rat	Atropine (0.2 s.c.)	Diazepam (2.5 i.m.)	Alfentanyle + Etomidate (0.03 + 2 i.m.) or Inhalation (Isoflurane)	Xylazine + Ketamine (5 + 100 i.m.) or Pentobarbitone (50 i.p.)	Xylazine + Ketamine (16 + 100 i.m.) or Urethane (1500 i.m.)
Mouse	Atropine (0.1–0.25 s.c.)	Diazepam (5 i.p.)	Alfentanyle + Etomidate (0.03 + 2 i.m.) or Inhalation (Isoflurane)	Xylazine + Ketamine (5 + 100 i.m.) or Pentobarbitone (50 i.p.)	Xylazine + Ketamine (16 + 100 i.m.)
Hamster	Atropine (0.1–0.2 s.c.)	Diazepam (5 i.p.)	Inhalation (Isoflurane)	Xylazine + Ketamine (5 + 50 i.m.) or Pentobarbitone (35 i.p.)	Xylazine + Ketamine (10 + 200 i.m.)
Guinea pig	Atropine (0.1–0.2 s.c.)	Diazepam (2.5–5 i.m.)	Inhalation (Isoflurane)	Xylazine + Ketamine (2 + 80 i.m.)	Xylazine + Ketamine (4 + 100 i.m.) or Pentobarbitone + Chloralhydrate (30 i.p. + 300 i.v.)
Rabbit	Atropine (0.1–0.2 s.c.)	Diazepam (1–5 i.m.)	Inhalation (Isoflurane)	Xylazine + Ketamine (5 + 25–80 i.m.)	Xylazine + Ketamine (5 + 100 i.m.) or Pentobarbitone + Chloralhydrate (30 i.p. + 300 i.v.)
Cat	Atropine (0.05–0.2 s.c.)	Diazepam (0.2–1 i.m.)	Acetylpromazine (0.5–1 i.v./i.m.) or Propionylpromazine (0.5–1 i.v.) or Xylazine (2 i.m.)	Xylazine + Ketamine (2 + 10 i.m.) or Ketamine (5 i.v.) or Inhalation (Isoflurane)	Pentobarbitone (35 i.v./i.p.)
Dog	Atropine (0.05 s.c.)	Xylazine (3 i.m.) or Acetylpromazine (0.5 i.m.) or Propionylpromazine (0.5 i.m.) or Droperidol (1 i.m.) or Diazepam (1 i.m.)	Thiopental (17 i.v.) or Metomidate + Fentanyl (4 + 0.005 i.m.) or Alfentanil + Etomidat (0.03 + 1 i.m.) or Inhalation/Intubation (Isoflurane)	Xylazine + Methadone (2 + 1 i.m.) or Xylazine + Ketamine (2 + 10 i.m.) or comb. with Diazepam (0.6 i.m.) or Propionylpromazine + Methadone (0.5 + 1 i.v.) or Acetylpromazine + Methadone (0.5 + 0.5–1 i.v.)	Pentobarbitone (30 i.v.) or Xylazine + Ketamine (2 + 15 i.m.) or Intubation (Isoflurane)
Pig		Azaperone (1–2 i.m.) or Chlorpromazine (1–2 i.m.)	Thiopental (10 i.v; 5% solution)	Azaperone + Metomidate (0.05–5 + 2.5–5 i.m. + i.v./i.p.) or Tiletamine + Zolazepam + Xylazine (2 + 2 + 0.5–1 i.m.)	Pentobarbitone (10–25 i.v.)
Sheep Goat		Xylazine (0.05–0.1 i.m.) or Diazepam (2 i.m.)	Xylazine + Ketamine (1–2 + 5–10 i.m.) or Thiopental (7.5–10 i.v.)	Pentobarbitone (20–30 i.m.)	Ketamine after pretreatment with Xylazine/ketamine 3–4 h or Intubation (Isoflurane)
Monkey[a]	Atropine (0.05–0.1 s.c.)	Diazepam (1.0 i.m.) or Xylazine (1–2 i.m.) or Ketamine (10–30 i.m.)	Inhalation/Intubation (Isoflurane)	Xylazine + Ketamine (2 + 10 i.m.)	Pentobarbitone (20–30 i.v./i.p.) or Intubation (Isoflurane)

[a] Anaesthesia of monkeys depends very much on the monkey species.

thetics. A compilation of such combinations is summarized in Table Q.3.

Q.3.3.3
Course of Anesthesia

The animal has always to be observed very carefully during anesthesia. Various systems can be checked with technical equipment, e. g. circulatory system (heart rate, pulse, blood pressure, ECG, peripheral perfusion, temperature) or pulmonary system (respiratory rate).

A very important procedure during anesthesia is the determination of the depth of anesthesia. There are four stages of anesthesia:

I. Stage of analgesia (from the first effect to unconsciousness):
   - heart and respiratory rate increase, normal dilation of pupils.

II. Stage of excitation (from the beginning of unconsciousness to the start of regular respiration): respiration irregular, dilated pupils, increased motor reflexes, nystagmus, opisthotonus.

III. Stage of tolerance (from the beginning of regular respiration to the termination of spontaneous respiration):
   This stage is divided into four steps:
   A) regular respiration, narrow pupils, most reflexes present
   B) skeletal muscles relaxed, narrow pupils, no eyelid reflex, corneal reflex present, flat respiration, good analgesia.
      This is the optimal stage of anesthesia for surgery
   C) only corneal reflex present, respiration very flat, pupils dilated
   D) no reflexes, respiration very flat, pupils very dilated

IV. Stage of asphyxia (after termination of the spontaneous diaphragmatic respiration):

V. no reflexes, no respiration: danger of death, immediate use of antidotes is necessary to prevent death.

By using combinations of different anesthetics – mainly by using combinations with muscle relaxing agents – the reactions of animals will differ from this scheme.

Q.3.3.4
Routes of General Anesthesia

In general, there are two different routes to induce general anesthesia: (i) injection and (ii) inhalation anesthesia. Sometimes combinations of both routes are used. The decision for one or the other route depends on the animal species, the purpose of the study and the necessity of control during anesthesia.

Q.3.3.4.1
Injection

By using this route of anesthesia the narcotic compound is dissolved in a liquid. The route of administration can be intravenous, intramuscular, subcutaneous or intraperitoneal. The mostly frequently used compounds are mentioned below:

Barbiturates

There are three groups of barbiturates: long acting, short acting and very short acting barbiturates. For laboratory animals short and very short acting barbiturates are used predominantly (sodium pentobarbitone, thiopental, hexobarbital).

Barbiturates are metabolized in the liver and mainly excreted via the bile. They are very fat soluble.Their short duration of action is caused by a distribution into adipose tissue. Fat represents a large compartment for these compounds with a relatively slow excretion. This can lead to prolongation of the narcotic effects after repeated dosing. The dosing of barbiturates should be adjusted according to the observed reactions of the individual animal as there are individual differences due to age, body weight, size, fat content and general condition of the animal. Barbiturates are not analgesic and should not be given without opioids.

Chloralhydrate

Chloralhydrate is a relatively old soporific compound. By using it for anesthesia cardiovascular side effects are often observed. The range of dosing is very narrow. Its use for laboratory animals is therefore limited. Intraperitoneal injections in rats can lead to paralysis of the ileus.

Combinations of Analgesic with Neuroleptic Compounds

This method is often used for dogs and rodents. Strong analgesics (morphine, methadone, meperidine, fentanyl) are combined with neuroleptics like phenothiazine, acetylpromazine or butyrophenone. The anaesthesia can be rapidly terminated by available antagonists.

Ketamine

Ketamine is a neuroleptic compound with a very fast onset of action following intramuscular administration. It can be used for nearly all species. A side effect of this compound is an increased tonus of skeletal

muscles but this can be prevented by the simultaneous administration of xylazine or diazepam.

Hypnotic Agents

Hypnotics are compounds which produce a very deep sleep without analgesia (metomidate). Therefore combination with neuroleptic compounds is recommended (e. g. combination azaperone with metomidate for pigs). As a single compound, metomidate can only cause anesthesia in birds.

Xylazine

Xylazine is frequently used for anesthesia in combination with other substances (Table Q.3). As a single compound it is only used to produce anesthesia in cattle.

Urethane

Urethane was formerly used as a hypnotic agent, It can, at the appropriate dose, produce a long acting (about 10 h) anesthesia in rats. Urethane is liver toxic and therefore its use is limited to some pharmacological models in which liver metabolism is of no importance. Due to its carcinogenic properties it should not be used anymore.

The important criteria of anesthesia are sedation, unconsciousness, analgesia and relaxation. These cannot be achieved with a single compound. Therefore, a combination of different compounds is necessary. The most common combinations for different species are listed in Table Q.3 with respect to the duration of anesthesia: short (up to 30 min), medium (up to 120 min) and long anesthesia (longer than 120 min).

Q.3.3.4.2 Inhalation

Inhalation anesthesia is more common for the bigger laboratory animals such as dogs, cats, sheep, goats and monkeys. However, it has gained an increased importance in small laboratory animals like rodents. The advantages of this form of anesthesia are the possibilities of controlling exactly the depth of anesthesia and of fast management of complications.

The parts of an inhalation system include:

- Bottle with oxygen (blue bottles)
- Valve to regulate pressure (reduces the pressure of the oxygen-bottle)
- Flowmeter (monitors the gas flow to the animal)
- Evaporator (evaporation of liquid anesthetic compounds)
- Oxygen-bypass (fast supply of oxygen to the animal in case of need)
- Tube to the system

Different techniques are used for laboratory animals:

Technique of Insufflation

Administration of anesthetic compounds is performed via a mask. Expiration occurs into the air of the room. Advantages are the simple procedure without valves and CO_2-absorber, and the very small dead volume of the system. Disadvantages are the waste of compounds, drying of the trachea of the animals, the impossibility of checking the respiration volume and the expiration of narcotic compounds into the room air (jeopardy to the staff).

Open System

Inspired and expired gases are separated by a valve. The inspired air consists of the fresh mixture of gases. The expiration reaches completely the atmosphere. The "Stephen slater" is the most used system of this group. It is recommended for smaller animals.

Half-Closed and Closed Systems

In closed systems all of the expired air passes to a CO_2 absorber. The CO_2 is removed chemically and the air is inspired again with newly evaporated anesthetic compounds mixed with oxygen. In a half-closed system, part of the expired air reaches the atmosphere. Advantages of closed systems include the economic benefit, the decrease of fluid and body heat loss from the animal and no risk to the laboratory staff. Disadvantages are the necessity to change the absorber every 8–10 h during anesthesia, the production of heat and the increase of resistance to breathing.

Summary

If it is possible inhalation should be done by intubating the animal. The risk of aspiration of stomach contents with the danger of an aspiration pneumonia can then be minimized. It is very important to use a tube with the correct diameter and length. An animal should be unconscious for intubation (see Table Q.3). In order to avoid gulp or cough reflexes it is recommended to administer succinylcholine, a muscle relaxant. Atropine can also be administered to decrease saliva production. Generally, all methods of injection anesthesia mentioned (Table Q.3) can be combined with an inhalation method. Such a "balanced anesthesia" is recommended for long and highly sophisticated operations.

Compound	Conc. with N_2O/O_2 (%)	Conc. without N_2O/O_2 (%)	MAC
Methoxyflurane	0.4–1	3.5	0.23
Isoflurane	1.0–2.5	1.5–3.5	1.4
Enflurane	0.5–1.5	2	2.2

MAC: minimal alveolar concentration for an anesthetic effect.

Table 4 Inhalation compounds and their characteristics

Q.3.3.4.3 Inhalation Compounds

The inhalation mixture has to include 21% oxygen. Sometimes it is better to administer 33% oxygen. Isoflurane, methoxyflurane and enflurane are widely used compounds for inhalation anesthesia. Ether is not longer recommended for anesthesia, due to the hazard of explosion and fire and because it is highly irritating to the respiratory tract. By using a mixture of N_2O and O_2 the amount of the evaporated compounds can be reduced drastically (Table Q.4).

Q.3.3.5 Termination of Anesthesia

Inhalation anesthesia can be stopped by removing the supply of evaporated compounds. To hasten the elimination of anesthetic compounds, the concentration of oxygen in the system can be increased for a period of five min.

The elimination of injected compounds is difficult to influence. It may be possible to accelerate metabolism of the anesthetic by using agents which stimulate metabolism in the liver and excretion by the kidney.

It is very important to check the body temperature of the animal during and after anesthesia. In cases of low body temperature the use of heating lamps or pads is necessary. After termination of anesthesia the animals go through the same phases as mentioned above but in the reverse order (tolerance, excitation, analgesia).

During anesthesia it might be necessary to stimulate respiration or circulation. Stimulatory agents for respiration are doxapram, pentamethylentetrazole, nikethamide, methetarimide, lobeline or micoren. Stimulatory agents for circulation are adrenaline, effortil, dopamine and ephedrine. The application of pure oxygen via a mask is also recommended during an injection anesthesia. Antidotes to morphine and its derivatives are morphine-antagonists like naloxone. Yohimbine is an antagonist of xylazine. The antidote for diazepam is flumazenil. There are no direct antagonists for ketamine and barbiturates.

Q.3.4 Postoperative Analgesia

To effectively reduce pain in animals a pain assessment has to be made using behavior, stress response etc. Pain assessment will be facilitated by

- a good knowledge of the species specific behaviors of the animal being assessed
- a knowledge and comparison of the individual animal's behaviour before and after the onset of pain (eg pre- and post-operatively)
- the use of palpation or manipulation of the affected area and assessment of the responses obtained
- examination of the level of function of the affected area: e. g. leg use following injury or limb surgery, together with a knowledge of any mechanical interference with function
- the use of analgesic regimens or dose rates that have been shown to be effective in controlled clinical studies, and evaluation of the change in behaviour this brings about
- a knowledge of the non-specific effects of any analgesic, anaesthetic or other drugs that have been administered

Analgesics can be broadly divided into two groups, the opioids or narcotic analgesics and the non-steroidal anti-inflammatory drugs (NSAID). Clinical pain involves several pathways, mechanisms and transmitter systems. To provide the most effective pain relief, drugs of different classes should be applied, acting on different parts of the pain system, for example combining opioids and NSAIDs.

Q.4 Euthanasia of Experimental Animals[3]

Q.4.1 Introduction

Biomedical research needs animals. This is most obvious in case of *in vivo* animal experiments. However, for other scientific purposes, e. g. *in vitro* studies, biological material is also necessary to study enzymes, membranes, receptors, cells, tissues, or organs which are obtained from dead animals. Therefore, animals have to be sacrificed in biomedical laboratories (i) at the end of an *in vivo* experiment, (ii) during experiments where sacrifice of the animals is not part of the study but must be done when pain, distress and suffering exceed acceptable levels or if it is likely for the animal to remain in pain or distress after cessation of the experiment, and (iii) to provide biological material for *in vitro* studies.

The following remarks are a summary of the*Recommendations for Euthanasia of Experimental Animals* of the *Commission of the European Communities* (1993) and the *Guidelines for Skillful and Human Euthanasia of Laboratory Animals* (1993) of Switzerland.

Q.4.2 Euthanasia

Euthanasia means a gentle death and should be regarded as an act of a human method of sacrificing an animal with a minimum of physical and mental suffering. The method of euthanasia should be appropriate for the species and the age of the animals. The method should be painless, avoid excitement and achieve rapid unconsciousness and death. Additionally, the method should be reliable, reproducible and irreversible.

Prior to euthanasia, it is important to recognize symptoms of fear, distress and anxiety; these symptoms are species specific. Depending on the species these symptoms may include distress vocalisation, attempts to escape, aggression, freezing, salivation, urination and defecation. Distress vocalization and release of certain odors or pheromones by a frightened animal may cause anxiety in other animals housed nearby. In this context it has to be stressed that many vocalisations of animals are in a range of frequencies which are out of the human hearing range. Therefore, animals should not be present during euthanasia of other animals, especially of their own species. If possible, an animal should not be killed in a room where other animals are housed, in particular in case of a bloody method of euthanasia, e. g. decapitation.

Euthanasia usually requires some physical control over the animals. Suitable control minimizes pain, distress, fear and anxiety in the animal and depends on animal species, size, state of domestication and method of euthanasia. Gentle handling, stroking and talking to the animal during euthanasia often have a calming effect on many animals. The use of sedating and immobilising drugs may be necessary in those cases, where capture or restraint may cause pain, injury or anxiety to the animal.

The person performing euthanasia is the most relevant factor during sacrificing an animal in order to cause a minimum of pain, fear and distress. A suitable method of euthanasia can be extremely harmful to the animal if it is badly performed. All persons performing euthanasia should be well trained, demonstrate professionalism and be sensitive to the value of animal life.

After euthanasia it is essential to confirm death. Signs of death are cessation of heartbeat and respiration, and absence of reflexes. Death must be guaranteed by exsanguination or removal of the heart, destruction of the brain, decapitation, evisceration or the presence of rigor mortis.

Methods for euthanasia of laboratory animals can be separated into physical and chemical methods.

Q.4.2.1 Physical Methods Recommended for Euthanasia of Laboratory Animals

Physical methods are stunning (concussion, electrical stunning, and stunning with a captive bolt), cervical dislocation, decapitation, and microwave irradiation. The different methods of stunning as well as cervical dislocation cause a rapid loss of consciousness which must be followed immediately by a method to force and guarantee death of the animal.

Concussion may be sufficient in smaller animals, e. g. rodents, to achieve unconsciousness and is performed by a blow to the head. Electrical stunning is a common method in the slaughterhouse predominantly for pigs. Only specific equipment must be used for this method either in the slaughterhouse or in laboratory. Stunning with a captive bolt is also a common and an effective method for larger animals in the slaughterhouse to achieve unconsciousness. Adapted equipment can also be used for larger rabbits in biomedical labo-

[3] By A.W. Herling (1st edition), revised by U. Albus (2nd and 3rd edition).

ratories. The correct localisation of the captive bolt is important in order to achieve immediate destruction of the brain. Cervical dislocation destroys the brainstem but the large vessels to the brain are often intact. All these methods have to be followed immediately by an act to force and guarantee death, e. g. exsanguination, removal of the heart or destruction of the brain.

During the decapitation process the head is separated from the neck which causes an immediate interruption of the blood circulation to the brain and a fall in blood pressure in the brain with subsequent loss of consciousness. This is valid only for warm-blooded animals. In cold-blooded vertebrates it is recommended to stun the animals prior to decapitation due to their higher resistance against anoxia. For decapitation of smaller laboratory animals specific guillotines have been developed.

Euthanasia by microwave irradiation is used by neurobiologists for fixation of brain metabolites without destruction of brain anatomy. Only specific equipment developed for this purpose must be used (no domestic microwave ovens). It is essential to localize correctly the microwave beam onto the brain of the animal.

Q.4.2.2 Chemical Agents Recommended for Euthanasia of Laboratory Animals

Many chemicals can cause death due to their toxicity, but only a few are recommended for euthanasia. The most suitable chemicals for euthanasia are certain anesthetics in overdose. In this case, the anaesthetic agent causes unconsciousness, followed by death.

Volatile anesthetics such as halothane, enflurane, isoflurane and methoxyflurane should only be used in a gas scavenging apparatus. Carbon dioxide at high concentrations of 80 to 100% causes unconsciousness within a few seconds.

Injectable anesthetics, predominantly barbiturates such as sodium pentobarbitone, are the most widely used and the most appropriate agents for euthanasia for most animals. Three times the anesthetic dose causes generally rapid unconsciousness and death. Intravenous injection is the most reliable and rapid route. Intraperitoneal injection may also be used in smaller rodents but it needs more time for death to occur. The intracardial and intrapulmonal administration can only be recommended in unconscious animals, because it is painful and, in the case of intracardial injection, difficult to perform successfully on the first attempt.

The agent T61 is a mixture of a local anesthetic, a hypnotic and a curariform component. It is used only intravenously. Due to the curareform component it is not allowed in some countries but it has been demonstrated that unconsciousness and neuromuscular blockade occur simultaneously in dogs and rabbits. Nevertheless, prior sedation should be performed if possible.

Q.4.2.3 Methods and Agents Not to Be Used for Euthanasia of Laboratory Animals

Physical methods not to be used for euthanasia are exsanguination, rapid freezing, pithing, decompression, hyperthermia, hypothermia, asphyxia, drowning and strangulation. Chemicals not to be used are carbon monoxide, nitrogen, nitrous oxide, cyclopropane, chloroform, trichloethylene, hydrogen cyanide, magnesium sulfate, potassium chloride, nicotine, strychnine, chloral hydrate, and ethanol. Some of the above mentioned chemicals are not recommended for euthanasia because they are extremely noxious and dangerous to the experimenter.

Neuromuscular blocking agents such as curare, succinylcholine or suxamethonium which do not cause rapid unconsciousness prior to death should also not be used. Ketamine is a very good anesthetic with a wide therapeutic safety margin for most animal species. Therefore, it is unsuitable for euthanasia.

However, non-acceptable methods of euthanasia can be used if animals are anaesthetized or rendered insensible and unconscious by a recommended method. This is used for, e. g. exsanguination, rapid freezing, and pithing. Exsanguination must not be performed in sight or smell of other animals. Rapid freezing is important to minimize enzymatic processes prior to subsequent biochemical determinations in tissues and organs. Pithing is a quick method of brain destruction achieved by insertion of a needle through the foramen magnum.

Q.4.2.4 Recommended Methods for Euthanasia for Specific Animal Species

Mouse

- Decapitation
- Cervical dislocation with subsequent exsanguination
- Euthanasia within a 80% carbon dioxide atmosphere
- Euthanasia within an atmosphere of suitable volatile anesthetics
- Sodium pentobarbitone at a dose of 150 mg/kg i.p.

Rat

- Concussion, cervical dislocation (both with subsequent exsanguination), and decapitation, conducted only by well trained persons
- Euthanasia within a 80% carbon dioxide atmosphere
- Euthanasia within an atmosphere of suitable volatile anesthetics
- Sodium pentobarbitone at a dose of 100 mg/kg i.v. or 150 mg/kg i.p.
- Microwave irradiation

Hamster

- Decapitation; conducted only by well trained persons
- Euthanasia within a 80% carbon dioxide atmosphere
- Euthanasia within an atmosphere of suitable volatile anesthetics
- Sodium pentobarbitone at a dose of 300 mg/kg i.p.

Guinea Pig

- Concussion (with subsequent exsanguination), and decapitation; conducted only by well trained persons
- Euthanasia within a 80% carbon dioxide atmosphere
- Euthanasia within an atmosphere of suitable volatile anesthetics
- Sodium pentobarbitone at a dose of 150 mg/kg i.p.

Rabbit

- Stunning with captive bolt
- Concussion (with subsequent exsanguination); conducted only by well trained persons
- Sodium pentobarbitone at a dose of 120 mg/kg i.v.
- T61 at a dose of 0.3 ml/kg strictly i.v. via a catheter

Cat

- Sodium pentobarbitone at a dose of 100 mg/kg i.v. or 200 mg/kg i.p.
- T61 at a dose of 0.3 ml/kg strictly i.v. via a catheter; it is recommended to anesthetize the animal beforehand with 20–30 mg/kg ketamine i.m. or 1–2 mg/kg xylazine plus 10 mg/kg ketamine i.m.

Dog

- Sodium pentobarbitone at a dose of 100 mg/kg i.v.
- T61 at a dose of 0.3 ml/kg strictly i.v., it is recommended to anesthetize the animal beforehand with 1–2 mg/kg xylazine plus 10 mg/kg ketamine i.m.

Ferret

- Sodium pentobarbitone at a dose of 120 mg/kg i.p.

Cattle, Sheep, Goat, Horse, Pig

- Sodium pentobarbitone at a dose of 100 mg/kg i.v.; for larger animals prior sedation is recommended (Xylazin).
- All other acceptable methods which are used for slaughtering

Primate

- Sodium pentobarbitone at a dose of 100 mg/kg i.v.; it is recommended to anaesthetize the animal beforehand with 1–2 mg/kg xylazine plus 10 mg/kg ketamine i.m.
- T61 at a dose of 0.3 ml/kg strictly i.v., it is recommended to anesthetize the animal beforehand with xylazine/ketamine i.m.
