The multienzyme, multistep process of fatty acid oxidation also occurs inside the mitochondria. Deficiencies of any of the enzymes involved, including carnitine palmitoyltransferase types I and II, may present in the newborn period (121). The infantile type of carnitine palmitoyltransferase II deficiency presents as severe attacks of hypoketotic hypoglycemia, sometimes associated with cardiac damage, culminating in sudden death. A deficiency in carnitine acylcarnitine translocase also may produce seizures, apnea, and bradycardia in the neonatal period. Seizures may infrequently occur in other defects of fatty acid oxidation, though they are not their most prevalent feature. When they occur, they are often due to associated hypoglycemia or hepatic dysfunction.

Peroxisomal Disorders

Peroxisomes play an important role in the body's ability to break down very-long-chain-fatty acids (VLCFA) including pristanic acid via beta-oxidation and phytanic acid via alpha-oxidation. They are also involved in the biosynthesis of bile acids, plasmalogens, and pipecolic acid (122).

Disorders of the peroxisome have been divided into three categories: (i) disorders of peroxisomal biogenesis (Zellweger syndrome spectrum [ZSS]), (ii) disorders of a single peroxisomal enzyme (X-linked adrenoleukodystrophy [XALD], acyl-coenzyme A [acyl-CoA] oxidase deficiency); and (iii) disorders with deficiencies of multiple peroxisomal enzymes (rhizomelic chondrodysplasia punctata). The discussion that follows is limited to ZSS and acyl-CoA oxidase deficiency. XALD is discussed with the later-onset conditions (1).

Zellweger Syndrome Spectrum

The ZSS is the most common peroxisomal disorder in early infancy, with an estimated incidence of 1:50,000. This disorder was previously categorized as three distinct diseases (ZS, neonatal adrenoleukodystrophy, and infantile Refsum disease), but is now known to be a single condition with a varying spectrum of phenotypic severity. The ZSS phenotype is caused by mutations in any of several different PEX genes involved in peroxisome biogenesis, of which at least 12 have been identified. PEX1 mutations are the most common cause of ZSS (123).

Diagnosis is made via sending a peroxisomal enzyme or VLCFA panel that measures plasma levels of VLCFA, phytanic and pristanic acid, and plasmalogens. VLCFA alone can be the initial screening test, though one must keep in mind that the degree of elevation may vary and that false negatives can occur (124). Confirmatory molecular genetic testing is available as well.

Dysmorphic features may be noted shortly after birth. Within the first week to several months of life, the affected child develops encephalopathy, hypotonia, and hyporeflexia. Seizures occur in 80% of patients, including partial, generalized tonic–clonic (rare), and myoclonic seizures, and atypical flexor spasms. Multisystem abnormalities of the brain, kidneys, liver, skeletal system, and eyes may occur. Eye abnormalities include cataracts, glaucoma, corneal clouding, optic nerve hypoplasia, pigmentary retinal degeneration, and Brushfield spots. The presence of the latter, along with hypotonia and a dysmorphic appearance, may cause confusion in the diagnosis of Down syndrome versus ZSS. Findings on neuroimaging can include pachygyria or polymicrogyria localized to the opercular region and cerebellar heterotopias (125).

Patients with ZSS have partial motor seizures originating in the arms, legs, or face. The seizures do not culminate in generalized seizures and are easily controlled with medication. The interictal EEG of patients with ZS shows infrequent bilateral independent multifocal spikes, predominantly in the frontal motor cortex and surrounding regions. Less frequently, hypsarrhythmia is observed (126).

Presently, only symptomatic treatment is available for this condition.

Acyl-Coenzyme A Oxidase Deficiency

Acyl-CoA oxidase deficiency was initially described in two siblings by Poll-The et al. (127). Clinical features included hypotonia, pigmentary retinopathy, hearing loss, developmental delay, adrenocortical insufficiency, absence of dysmorphic features, and onset of seizures shortly after birth. A deficiency in acyl-CoA oxidase was identified, resulting from a deletion in its coding gene (17q25). In children with acyl-CoA oxidase deficiency, serum VLCFA levels are elevated, whereas pipecolic acid levels are normal. Cortical malformations are generally absent, and the interictal EEG may show continuous diffuse high-voltage theta activity (128).

Tay–Sachs and Sandhoff Disease

GM2 gangliosidosis is an autosomal recessive lysosomal disorder that invariably includes seizures as a prominent feature. The infantile forms of GM2 gangliosidosis include Tay–Sachs disease, caused by a deficiency in hexosaminidase A (Hex A), and Sandhoff disease, caused by a deficiency in Hex A and B. The enzymatic defect leads to intraneuronal accumulation of GM2 ganglioside. Tay–Sachs disease does not have any extraneural involvement, and the clinical presentation is that of a progressive encephalopathy (1).

The HEXA gene is localized to chromosome 15 (15q23–q24), and mutations are found more

commonly in the Ashkenazi Jewish population of Eastern or Central European descent. The overall incidence of 1 in 112,000 live births in the general population increases to 1 in 3900 in this defined group (129).

Development appears to be normal until 4 to 6 months of age, when hypotonia and loss of motor skills are evident. Within the next several months to years, spasticity, blindness, and macrocephaly develop. The classic cherry-red spot is present in the ocular fundi of more than 90% of patients. Seizures become prominent, with frequent partial motor, complex partial, and atypical absence seizures that respond poorly to medication. Myoclonic jerks are frequent and are often triggered by an exaggerated startle response to noise (1).

The EEG is normal early in the course of disease. Gradually, background activity slows, with bursts of high-voltage delta activity and very fast central spikes. Diffuse spike and sharp-wave activity may be noted with acoustically induced myoclonic seizures. EEG amplitude declines as the disease progresses (130).

Enzymatic studies in leukocytes and skin fibroblasts reveal an isolated absence or deficiency in hexosaminidase A activity. Clinical genetic testing is available. Prenatal diagnosis and carrier detection for high-risk populations are also available (1).

Sandhoff disease is associated with a mutation of the β-subunit of hexosaminidase, (HEXB) located on chromosome 5 (5q13) (131). Unlike Tay–Sachs disease, there is no association with a particular ethnic group. Clinical presentation is similar to that of Tay–Sachs; however, distinguishing features in some patients include hepatosplenomegaly and skeletal involvement. Enzymatic testing demonstrates the diminished activity of hexosaminidase A and B. Detection of N-acetylglucosamine-containing oligosaccharides in the urine and foam cells in the bone marrow is also diagnostic. As with Tay–Sachs disease, no treatment is immediately available (1).

Krabbe Disease (Globoid Cell Leukodystrophy)

Globoid cell leukodystrophy (Krabbe disease) is another lysosomal disorder occurring in this age group and is due to a deficiency of galactocerebrosidase (GALC) enzyme activity. The GALC gene is located at chromosome 14q31 (132).

Depending on the severity of the enzyme deficiency, there are four phenotypic presentations of the disorder: (i) infantile onset, before the age of 6 months; (ii) late infantile onset, between ages 6 months and 3 years; (iii) juvenile onset, between ages 3 and 7 years; and (iv) adult onset, beginning after 7 years of age. The majority of cases begin within the first 3 to 6 months of life with irritability, poor feeding, emesis, and rigidity. Muscular spasms induced by stimulation are prominent. Blindness and optic atrophy ensue. Initially, increased tendon reflexes are present and then gradually diminish as breakdown of peripheral myelin occurs (133).

Partial or generalized clonic or tonic seizures, as well as infantile spasms, are seen, which may be difficult to distinguish from muscular spasms (134). In contrast to what is observed in many classic white matter diseases, seizures occur early in the course of Krabbe disease in 50% to 75% of infants with the disorder. EEG characteristics include a hypsarrhythmia-like pattern with irregular slow activity and multifocal discharges of lower amplitude than that typically seen with West syndrome. In a 1969 study of seven infants by Kliemann et al., six children had prominent β activity occurring independently in the posterior temporal regions and vertex that was superimposed over slower, high-amplitude waves. This activity was observed to be state dependent and to occur in long runs without any apparent clinical manifestations. In the terminal stages of the disease, little electrical

activity is detected (135).

Diagnosis is made by measuring GALC enzyme activity in leukocytes or skin fibroblasts, followed by confirmatory gene sequencing. The disease is relentlessly progressive, with death by 1 to 2 years of age (133).

GM1 Gangliosidosis Types I and II

GM1 gangliosidosis occurs due to lysosomal β-galactosidase (GLB) deficiency, and mutations in the GLB1 gene localized to chromosome 3 (3p21.33). GLB deficiency leads to the accumulation of GM1 ganglioside and degradation products in nerve cells and other tissues. In the infantile form, the affected child is initially developing typically and then has a regression in development by 3 to 6 months of age, with rapid neurologic deterioration following. Seizures develop by 2 years of age. Clinical features may include coarse facial features, hepatomegaly, bone deformities (dysostosis multiplex), visual abnormalities, hypotonia, progressive microcephaly, and hematologic abnormalities. A macular cherry-red spot can be seen. Diagnosis is determined by findings of reduced GLB enzyme activity in leukocytes or skin fibroblasts, urine galactose-containing oligosaccharides in association with elevated keratan sulfate, vacuolization in blood lymphocytes or bone marrow, and distinctive findings on long bone and spine radiographs. Definitive testing is via molecular genetics (136).

The juvenile form of the condition typically has a slower neurologic progression. Cerebral manifestations with regression of developmental milestones and visual symptoms are typically present by 2 to 4 years of age (136).

EEG features of both forms include background slowing, with increasing, irregular slow activity as the disease progresses. In type II, a fluctuating 4- to 5-cycle temporal rhythmic discharge has been observed (137).

Progressive Encephalopathy with Edema, Hypsarrhythmia, and Optic Atrophy

Progressive encephalopathy with edema, hypsarrhythmia, and optic atrophy (PEHO) syndrome, described by Salonen et al. (138) in 1991, is characterized by infantile spasms, arrest of psychomotor development, hypotonia, hypsarrhythmia, edema, and optic atrophy. Characteristic features include epicanthal folds, midfacial hypoplasia, protruding ears, gingival hypertrophy, micrognathia, and tapering fingers. Edema develops over the limbs and face. The progressive decline seen with this disease suggests a metabolic defect, although no biochemical marker has been identified. Based on the pattern of inheritance associated with the disease, it is presumed to be an autosomal recessive disorder. Neuroimaging shows progressive brain atrophy and abnormal myelination. Hypoplasia of the corpus callosum has been reported. Seizures generally begin as infantile spasms with associated hypsarrhythmia on the EEG. Later, other seizure types may be seen, including tonic, tonic–clonic, and absence seizures. The EEG may evolve to a slow spike–wave pattern. Prognosis is poor in children with this disorder, with survival only into adolescence (139).

METABOLIC DISORDERS OF LATE INFANCY, CHILDHOOD, AND ADOLESCENCE

While many of the previously discussed disorders can have a later onset of symptoms, there are

several disorders that typically begin outside of the newborn and early infancy period. A few of these disorders are discussed below.

Neuronal Ceroid Lipofuscinoses

The neuronal ceroid lipofuscinoses (NCLs) are a group of diseases that result in storage of lipopigments in the brain and other tissues. At least five clinical subtypes have been reported, as well as rare, atypical forms, and most are transmitted as autosomal recessive traits. The disorder can present at any age, from infancy through adulthood.

The condition occurs due to a genetic defect leading to impaired lysosomal function and intra- and extralysosomal storage. Thus far at least fourteen genes (CLN 1–14) have been identified, leading to the various phenotypes, though depending on the type of mutation, there is significant overlap between age of onset and symptoms (140).

Evaluation for this condition begins with quantification of palmitoyl-protein thioesterase (PPT1) and tripeptidyl-peptidase (TPP1) enzyme levels in leukocytes. Based on the enzyme deficiency found and age of onset, targeted gene sequencing is performed. If these levels are normal or the patient has an adult onset of symptoms, electron microscopy of skin for characteristic abnormalities and/or lymphocytes for vacuoles is recommended. This approach has evolved from the previous one of obtaining a skin biopsy as the diagnostic test in all patients. In rare instances, storage product identification in cells from a rectal suction or conjunctival biopsy is necessary. With advances in genetic knowledge, this type of testing is now infrequent. A next-generation sequencing panel of the various NCL genes is available (141,142).

Visual loss is a feature of almost all except the adult form of NCL either as the presenting symptom or occurring months to years after disease onset. The infantile form typically presents between 6 and 24 months of age with developmental regression, myoclonus, ataxia, and visual failure. Other features include incoordination of limb movements, acquired microcephaly, and optic atrophy. Seizures are prominent, including myoclonic jerks and astatic, atonic, or generalized seizures. EEG features aid in the diagnosis, with an early attenuation and progressive loss of the background. Neuroimaging may show progressive cerebral and cerebellar atrophy (143).

Epilepsy begins between the ages of 2 and 4 years in the late infantile form, followed by cognitive decline, ataxia, and eventually visual failure with optic atrophy. Early development is normal or mildly delayed. Multiple seizure types develop as well, with staring, generalized tonic–clonic, myoclonic, and atonic components. As the disease progresses, irregular myoclonus evoked by proprioceptive stimuli, voluntary movement, or emotional fluctuations become prominent. A characteristic EEG pattern of occipital spikes on low-frequency photic stimulation is observed. Giant visual evoked responses and somatosensory evoked potentials are seen as well. Juvenile-onset disease presents with visual loss between the ages of 4 and 10 years. Epilepsy begins a year to several years later, with multiple seizure types. The treatment of these conditions is symptomatic. Life span varies from several years to adulthood depending on the severity of the enzyme defect (143).

Metachromatic Leukodystrophy

Metachromatic leukodystrophy is the result of a deficiency of arylsulfatase A (ASA), leading to an accumulation of lipid sulfatide. Late infantile, juvenile, and adult-onset subtypes occur with about half of patients presenting between the ages of 1 and 2 years. Hypotonia, weakness, and unsteady gait

suggestive of a neuropathy or myopathy are the most common presenting symptoms with the late-infantile form. These symptoms are followed by a progressive decline in mental and motor skills (144).

Partial seizures develop late in the clinical course in 25% of patients with the late-infantile form of metachromatic leukodystrophy and in 50% to 60% of patients with the juvenile-onset form (145,146). A progression from normal EEG features to diffuse slowing with epileptiform discharges correlates well with clinical decline (147). Bone marrow transplantation, especially if performed prior to the onset of neurologic symptoms, may be beneficial in some patients and may be accompanied by improvements in clinical neurophysiologic studies (148).

Diagnosis is initially made by quantifying ASA enzyme activity in leukocytes or cultured skin fibroblasts. Urine sulfatide activity can be measured. Molecular genetic testing of the ARSA gene (22q13.3–qter) is clinically available. Treatment is symptomatic (149).

Mucopolysaccharidoses

The mucopolysaccharidoses are a family of lysosomal storage disorders caused by a deficiency in several enzymes involved in the degradation of glycosaminoglycans. The various mucopolysaccharidoses share many clinical features, including a progressive course, multisystem involvement, organ enlargement, dysostosis multiplex, and abnormal facial features (150).

A subtype with a primarily neurologic phenotype is Sanfilippo syndrome (mucopolysaccharidosis type III), in which only heparan sulfate is excreted in the urine; four different forms have been described, each associated with a different enzymatic defect. The gene locus is 17q25.3 (151).

Generalized seizures develop in about 40% of patients with Sanfilippo syndrome, but these are often easily controlled with AEDs. Progressive dementia and severe behavioral disorders are other features. In a meticulous study of one patient, the EEG showed lack of normal sleep staging, absence of vertex waves and sleep spindles, and an unusual alteration of low-amplitude fast activity (12 to 15 Hz) with generalized slowing (152). Bone marrow transplantation was successful in several cases but not useful in others. Enzyme replacement therapy is available for some of these conditions (153).

Sialidosis Type I

Sialidosis type I, an autosomal recessive disorder of late childhood to adolescence, is characterized by progressive visual loss, polymyoclonus, and seizures. The myoclonus can be debilitating and is stimulated by voluntary movement, sensory stimulation, or excitement. Increased myoclonus with cigarette smoking and menstruation has been reported. As the disease progresses, cognitive decline, cerebellar ataxia, and blindness with optic atrophy occur. Dysmorphic features, bony abnormalities, and hepatosplenomegaly are absent. The EEG contains rhythmic spiking over the vertex, with a positive polarity overlying a low-voltage background (154). Neuroimaging shows diffuse cerebral and cerebellar atrophy. Diagnosis can be made by detection of an increase in sialic acid—containing oligosaccharides in the urine, vacuolated lymphocytes in the peripheral blood, and foamy histiocytes in bone marrow smears. Enzyme assays for deficiency of α-neuraminidase, the structural components of which are encoded on chromosome 10, offer definitive diagnosis. The gene defect has been localized to 6p21.3 (155).

Sialidosis Type II (Galactosialidosis)

Sialidosis type II, the juvenile form of this group of disorders, has features similar to those of sialidosis type I. Distinguishing characteristics are the less prominent myoclonic activity and the additional clinical features of coarse facies, corneal clouding, dysostosis multiplex, and hearing loss. Inheritance is autosomal recessive, and a higher incidence of this form of the disease is found in Japan. In the majority of cases, a partial deficiency of GLB can be seen in addition to neuraminidase deficiency (galactosialidosis), which may be the result of a defect in protective protein; the gene locus coding for this protein is 20q13.1. The EEG contains moderate-voltage generalized 4 to 6 per second paroxysms (156).

Gaucher Disease Type III

Three types of Gaucher diseases are known: type I, a chronic form with adult onset; type II, a rare form associated with infantile demise; and type III, a chronic form with neurologic involvement. These disorders result from a mutation in the gene encoding acid β-glucosidase (1q21), which leads to accumulation of glucosylceramide in the lysosomes of cells in the reticuloendothelial system (157). In the rare type III form, hepatosplenomegaly may be present from birth or early infancy, which may cause type III to be confused with the more common type I form of Gaucher disease. When neurologic symptoms develop in childhood to early adulthood, type III can be clearly distinguished from type I, in which cerebral features are absent. Frequent myoclonic jerks and tonic–clonic seizures ultimately develop. A supranuclear palsy of horizontal gaze is present in the majority of cases and is an important diagnostic sign. Generalized rigidity, progressive cognitive decline, and facial grimacing may be present. Paroxysmal EEG abnormalities may be seen prior to the onset of convulsions, with worsening as the disease progresses; diffuse polyspikes and spike–wave discharges are also seen. The most characteristic EEG findings are rhythmic trains of spike or sharp waves at 6 to 10 per second (158). The diagnosis can be made by the clinical findings in combination with Gaucher cells detected in the bone marrow. Another laboratory abnormality is an elevated serum acid phosphatase. Unlike type I disease, which is prevalent in the Ashkenazi Jewish population, type III is reported predominantly in Sweden. A multimodal approach is suggested with enzyme replacement therapy and deoxynojirimycin analogs aimed at blocking the synthesis of glucocerebroside to lessen the systemic manifestations. Therapeutic trials with bone marrow transplantation have shown some success in improving CNS manifestations of Gaucher disease type III (159).

Neuroaxonal Dystrophies

Axonal dystrophies include infantile neuroaxonal dystrophy, pantothenate kinase–associated neurodegeneration (formerly Hallervorden–Spatz disease), and Schindler disease. Pantothenate kinase-associated neurodegeneration is not discussed here, as seizures are not a prominent feature.

Infantile neuroaxonal dystrophy (Seitelberger disease) is an autosomal recessive disorder affecting both the central and the peripheral nervous systems. Characteristic pathologic features of axonal spheroids within the peripheral and central nervous systems are seen. Clinical features begin between 1 and 2 years of age with psychomotor regression, hypotonia, and development of a progressive motor sensory neuropathy. Seizures occur in one-third of patients, with onset of convulsions after 3 years of age. The EEG finding of high-amplitude fast activity (16 to 24 Hz), unaltered by eye opening or closure, is characteristic of all children with this disorder, regardless of the occurrence of seizures. During sleep, the fast activity may persist, and K complexes are typically

absent (160). Seizure types described with infantile neuroaxonal dystrophy include myoclonic and tonic (161,162). A video–EEG case report by Wakai et al. (163) described tonic spasms and an electrographic correlate of a diffuse, one-second, high-voltage slow complex, followed by desynchronization suggestive of infantile spasms.

Schindler disease results from a deficiency in α-N-acetylgalactosaminidase (22q11). Affected patients appear normal at birth, but progressive neurologic decline becomes evident in the second year. Manifestations include spasticity, cerebellar signs, and extrapyramidal dysfunction. Generalized tonic–clonic seizures and myoclonic jerks are common. EEG abnormalities include diffuse and multifocal spikes and spike–wave complexes (164).

Mitochondrial Diseases in Older Infants and Children

An overview of mitochondrial disease in infants is outlined in an earlier portion of this chapter.

POLG1 Disease, Including Childhood-Onset Epilepsia Partialis Continua, and Alpers Disease

The mtDNA polymerase gamma (POLG) is a nuclear gene required for mtDNA replication. Over the recent past, mutations of this gene have been linked to a wide array of growing phenotypes. While many of these phenotypes do not have seizures as their primary or only feature, a phenotype with EPC as the initial and often only manifestation is known as is a form with progressive myoclonic epilepsy (165).

POLG mutations are also the principal cause of Alpers disease (166).

Alpers and Alpers–Huttenlocher diseases are characterized by a rapidly progressive encephalopathy with intractable seizures and diffuse neuronal degeneration. Seizures are often partial complex or myoclonic though they can evolve to include multiple types. The EEG may show rhythmic slowing, predominating either in the posterior or anterior derivations, sometimes admixed with periodic brush-like patterns (167). Varying amounts of liver disease is also present. Symptoms may begin at any age, and liver disease may not be present for years. Encephalopathy and liver disease can stabilize with partial resolution of symptoms. Disease onset after exposure to valproate and valproate-related worsening of existing symptoms is characteristic of this condition (168,169). There is recent debate about whether patients with encephalopathy and epilepsy of undetermined etiology need to receive POLG testing prior to initiating valproate therapy (170).

MERRF and MELAS

While we now understand that many patients with primary mitochondrial disease may not present syndromically or with maternally inherited disease, the initially described conditions designated by acronyms remain an important cause of mitochondrial disease and epilepsy. Two of these syndromic presentations of mitochondrial disease are described below.

Onset of MERRF occurs before 20 years of age, with ataxia and predominantly myoclonic seizures. Affected individuals may have short stature, neurosensory hearing loss, optic atrophy, myopathy, or encephalopathy. EEG findings may include background slowing, focal epileptiform discharges, and atypical spike or sharp and slow-wave discharges that have a variable association with the myoclonic jerks. Suppression of these discharges during sleep is characteristic. As with many of the progressive myoclonus epilepsies, giant somatosensory evoked potentials are observed.

Lactic acidosis and the presence of ragged-red fibers on muscle biopsy are common features of the diagnosis. The inheritance pattern is compatible with maternal transmission. In the majority of cases, a point mutation at position 8344 of the mitochondrial gene for transfer ribonucleic acid (tRNA)-lysine has been identified (171). Other mtDNA point mutations are also known to lead to this phenotype.

Classically, mitochondrial encephalopathy with lactic acidosis and stroke-like episodes (MELAS) presents in childhood with the sudden onset of stroke-like episodes. Migraine-like headaches, progressive deafness, seizures, cognitive decline, and myopathic features may accompany these symptoms. EPC can be seen, and seizures often evolve into partial or generalized status epilepticus. Myoclonic seizures are prominent in individuals with MELAS. Strokes are often occipital in location, and seizures may present with visual auras and migraine. Lactic acid is elevated in the blood, and ragged-red fibers can be present on muscle biopsy. Four-point mutations are predominantly seen with MELAS. Three of these (3243, 3250, and 3271) affect the mtDNA gene of tRNA-leucine. The other mutation involves a coding region of complex I of the respiratory chain (172). Intravenous L-arginine has been used to prevent the morbidity of acute metabolic strokes in these patients, and its regular use has become more routine (173).

Dentatorubral–Pallidoluysian Atrophy

Dentatorubral–pallidoluysian atrophy (DRPLA) is a rare autosomal dominant disease due to a trinucleotide (CAG) expansion of the ATN1 gene on chromosome 12p (12p13.31). Clinical manifestations are dependent on the length of the unstable trinucleotide repeats and vary from a presentation of juvenile-onset progressive myoclonic epilepsy to an adult-onset syndrome with ataxia, dementia, and choreoathetosis. The juvenile form can also be variable in its presentation. In general, symptoms begin in infancy to early childhood with myoclonus, ataxia, dementia, opsoclonus, or seizures that can be generalized tonic–clonic, atypical absence, or atonic. Pathologic features are striking, with neuronal loss and gliosis in the dentatorubral and pallidoluysian structures (174).

The EEG characteristically shows bursts of slowing, irregular spike–wave discharges, and multifocal paroxysmal discharges. A photoparoxysmal response is seen, and myoclonic seizures can often be triggered by photic stimulation (175).

Congenital Disorders of Glycosylation

Congenital disorders of glycosylation (CDG) are multisystemic diseases characterized by a defect in the synthesis of N-linked glycoproteins and glycolipids. Over 50 disorders of glycosylation have now been identified leading to altered protein folding and stability (176).

CDG type Ia, phosphomannomutase-2 deficiency, is the best characterized of these syndromes (gene PMM2, 16p13.3–p13.2). The most common symptoms include infant-onset failure to thrive and hepatopathy. Developmental delays, cerebellar hypoplasia, ataxia, progressive neuropathy involving the legs, retinal degeneration, and skeletal deformities are also common. Subcutaneous tissue changes with an odd distribution of fat, retracted nipples, and odd facies, including almond-shaped eyes, have been described. Imaging studies reveal cerebellar hypoplasia. A unique pattern of coagulation changes is associated with the syndrome, including depression of factor XI, antithrombin III, protein C, and, to a lesser extent, protein S and heparin cofactor II. These changes may account for stroke-like episodes observed in affected children. Clinical neurophysiologic studies demonstrate interictal

epileptiform discharges and giant somatosensory evoked potentials. Screening for this condition involves initially assessing transferrin glycosylation status via mass spectroscopy; more sensitive testing of a variety of glycosylated proteins via a mass spectroscopy N-glycan panel is also available (177). Mass spectroscopy testing is preferred in detecting less common disorders of glycosylation.

Disorders of Peroxisome Metabolism: X-linked Adrenoleukodystrophy

XALD is an X-linked genetic defect in one of the peroxisomal membrane transport proteins. The condition occurs due to mutations in the ABCD gene (Xq28) and leads to three varied phenotypes. The childhood onset form begins in early school age with attention deficit and cognitive regression.

Partial motor seizures, often with secondary generalization, and generalized tonic–clonic seizures can occur. Status epilepticus has been the initial presenting symptom, and EPC has also been reported. Diagnosis is made by quantifying VLCFA levels in plasma, followed by gene sequencing and confirmation (178). The EEG is characteristic, with high-voltage polymorphic delta activity and loss of faster frequencies over the posterior regions (179).

Adrenomyeloneuropathy and isolated Addison disease presentations account for the other phenotypes and are typically not associated with epilepsy.

Progressive Myoclonic Epilepsies

The progressive myoclonic epilepsies are a collection of disorders presenting with the triad of myoclonic seizures, tonic–clonic seizures, and neurologic dysfunction that often manifests as dementia and ataxia. Onset generally begins in childhood through adolescence, though they may begin later in life. If myoclonic features are not prominent, children with this syndrome may be erroneously diagnosed with Lennox–Gastaut syndrome. For this reason, a careful history to detect myoclonic features is important in children with intellectual deterioration and frequent seizures (180).

Previously discussed disorders that can lead to this phenotype include mitochondrial cytopathies (especially POLG mutations, MERRF, and MELAS), sialidoses, some of the other lysosomal diseases, DRPLA, and NCL. The two disorders below are listed separately since they are atypical storage diseases and are routinely tested for via direct molecular genetic testing.

Lafora Body Disease

Lafora body disease is an autosomal recessive disease that occurs due to mutations in either the EPM2A (6q24) or EPM2B (6p22.3) genes, encoding for the proteins laforin and malin (181). Laforin prevents the accumulation of phosphate on glycogen while malin is a ubiquitin ligase that regulates laforin. Defects in these genes lead to phosphate accumulation on glycogen and glycogen precipitation. Accumulation of this unbound glycogen leads to the formation of Lafora bodies and neuronal dysfunction (182).

Symptoms typically begin in the teen years, with focal, multiregional, or generalized myoclonus. The myoclonus is brought out by action, touch, light, and stress. Generalized tonic–clonic seizures may also occur. A prior childhood history of an isolated febrile or afebrile seizure may exist. Cognitive symptoms may lag by months or years and initially include visual hallucinations, personality changes, confusion, and ataxia. The visual hallucinations frequently represent occipital

seizures (183).

Generalized bursts of spikes and polyspikes superimposed on a normal background may be seen initially on the EEG. The presence of spikes in the posterior quadrant is a distinguishing feature that suggests the diagnosis with the appropriate clinical scenario (184). As the disease progresses, the EEG becomes increasingly disorganized. A photoconvulsive response can be seen with photic stimulation.

On neuroimaging, cerebellar atrophy is occasionally observed. Intracytoplasmic inclusion bodies (Lafora bodies) are seen on electron microscopy of a skin, liver, or muscle biopsy. A negative biopsy does not exclude the diagnosis. Molecular genetic testing is the preferred route of diagnosis. There is no effective treatment for this disorder, and the average life span after onset is 2 to 10 years (183).

Unverricht–Lundborg Disease (Baltic Myoclonus)

This autosomal recessive progressive encephalopathy is characterized by relentless myoclonus and generalized seizures due to defective function of the cystatin B protein and mutations in the CSTB gene (21q22.3). Testing for a common dodecamer repeat (that leads to over 90% of cases) and gene sequencing is clinically available (185).

Onset is in childhood or adolescence with seizures that are predominantly myoclonic and frequently occur after awakening. Absence and atonic seizures are also observed. Myoclonus can become quite disabling, interfering with speech and swallowing, and is often provoked by voluntary movement and excitement. Cognition is generally retained, although a mild decline may be observed later in the disease course. A labile affect and depression are commonly seen. Cerebellar ataxia, tremors, hyporeflexia, wasting of the distal musculature, and signs of chronic denervation on electromyography may be seen as the disease progresses (186).

The EEG reveals progressive slowing, with generalized 3-to-5-per-second spike–wave-like bursts that are frontally predominant. Paroxysmal flicker responses and generalized spikes and polyspikes are seen with photic stimulation (187,188). Although this disorder occurs worldwide, it has an especially high incidence in Finland, Estonia, and areas of the Mediterranean.

Phenytoin and AEDs predominantly affecting sodium channels can worsen symptoms (189). Death occurs in the third to fourth decade of life.

Disorders of Amino Acid Metabolism: Homocystinuria

Disorders of transsulfuration include cystathionine β-synthase deficiency, the most frequent cause of homocystinuria; the gene locus is 21q22.3 (190). The condition is screened for by extended newborn testing in many states and thus treated presymptomatically. When untreated, mental retardation, behavioral disturbances, and seizures are manifestations of CNS involvement; ectopia lentis, osteoporosis, marfanoid habitus, and scoliosis are other common clinical findings (191). Some patients respond to pyridoxine therapy. Generalized seizures occur in about 20% of patients with pyridoxine-nonresponsive homocystinuria and in 16% of patients with the pyridoxine-responsive form. EEG features are relatively nonspecific, with slowing and focal interictal epileptiform discharges that may ameliorate with treatment (192). Thromboembolism, malar flushing, and livedo reticularis reflect vascular system involvement. Biochemical abnormalities include homocystinemia, methioninemia, decreased cystine concentration, and homocystinuria.

DIAGNOSTIC INVESTIGATION IN METABOLIC AND MITOCHONDRIAL DISORDERS

The diagnosis of genetically determined metabolic diseases can be complicated for many reasons. We suggest that a metabolic basis be considered for all unexplained epileptic conditions of infancy or childhood until proven otherwise. Routine interrogation of blood, urine, and CSF samples as discussed in this chapter will be informative in a significant subset of patients, and alternative treatment options may emerge. Before obtaining appropriate metabolic, biochemical, or tissue specimens, the physician should try to formulate a differential diagnosis. Age at onset, type of epilepsy, associated clinical findings, family history, ethnicity, and neurologic examination continue to be the most important considerations in initial diagnostic possibilities. Neurologists experienced in metabolic disorders can often narrow the list of possible disorders at the first clinical encounter. Therefore, a consultation with a metabolic specialist is useful before or after initial screening tests are performed.

The presence of macular cherry-red spots, abnormal appearance of the hair, or a peculiar distribution of fat over the posterior flanks or thighs immediately suggests a diagnosis of Tay–Sachs disease, Menkes disease, or CDG, respectively. Deceleration of head growth during infancy, with consequent acquired microcephaly, may imply Glut-1 transporter deficiency, another defect of energy metabolism, the infantile form of neuronal ceroid lipofuscinosis, or Rett syndrome, among other possibilities. Dislocated lenses and a seizure followed by a stroke are characteristic of homocystinuria and MOCOD. Seizures with stroke-like episodes also suggest CDG, mitochondrial disorders or OTC deficiency. Genetically determined metabolic diseases often have a saltatory historical pattern in contrast to neurodegenerative diseases, which are inexorably progressive.

Evaluation in the Absence of Overt Clinical Clues

In certain circumstances, the underlying problem will not be intuitively obvious and the patient's disorder may masquerade as a form of cryptogenic epilepsy.

Certain screening tests can be used to help narrow the differential diagnosis. A complete blood cell count with differential and platelet count should be obtained in every case. Bone marrow depression occurs in the organic acidemias, and the peripheral smear may reveal important clues such as a macrocytic anemia or vacuolated lymphocytes. A complete serum chemistry profile will uncover acidosis, and electrolyte disturbances or specific organ dysfunction. A low blood urea nitrogen may suggest a defect involving the urea cycle. Calcium and magnesium concentrations should be determined in every case. A low uric acid concentration raises the possibility of MOCOD. Ammonia elevations point toward amino and organic acidopathies when mild, and urea cycle defects when marked. Quantitative measurement of plasma amino acids and urine organic acids provide diagnostic clues about disorders of amino and organic metabolism, mitochondrial disease, UCDs and disorders of vitamin metabolism.

When faced with refractory epilepsy without an etiology at any age, spinal fluid analysis is mandatory to exclude certain treatable causes of the epilepsy. An elevated CSF protein concentration is characteristic of demyelinating and inflammatory conditions, including certain mitochondrial disorders, metachromatic leukodystrophy and globoid cell leukodystrophy. A low CSF glucose concentration is consistent with hypoglycemia caused by a defect of gluconeogenesis or Glut-1 transporter defects. Lactate and pyruvate values are elevated in CSF disorders of cerebral energy

metabolism, including PDH deficiency, pyruvate carboxylase deficiency, numerous disturbances of the respiratory chain, certain defects of neurotransmitter synthesis and Menkes disease. A low CSF lactate value may be seen in Glut-1 transporter defects. CSF amino acids can provide additional information in disorders of ammonia, amino acid, organic acid, and mitochondrial metabolism. Elevations in threonine can be seen in pyridoxal 5-phosphate-dependent seizures. Elevations in glycine may point toward glycine encephalopathy (NKHG). Abnormally low serine concentrations point to PHGD deficiency.

Spinal fluid neurotransmitter analysis should also be routine in these circumstances. This testing includes measuring the neurotransmitter amines, biopterin, neopterin, and 5-MTHF levels. A low CSF 5-MTHF concentration suggests a defect involving folate metabolism, whether due to systemic disease, another inborn error of metabolism or primary cerebral folate deficiency. Abnormal CSF dopamine, and serotonin metabolites, along with biopterin and neopterin help diagnose disorders of neurotransmitter synthesis. In addition, if a special peak of a yet unknown compound appears on high-performance liquid chromatograms (routinely performed as part of spinal fluid neurotransmitter testing), the finding is diagnostic of pyridoxine- and folinic acid–responsive epilepsy due to ALDH7A1 mutations.

More focused testing for specific disorders may also be needed. These include transferrin and glycan analysis via mass spectroscopy for disorders of N-glycosylation, urine S-sulfocysteine for sulfite oxidase or MOCOD, lysosomal enzyme analysis in leukocytes for various storage disorders or PPT1 or TPP1 levels in leukocytes for the NCLs. A peroxisomal panel in blood or at least VLCFA levels will help diagnose ZSS and XALD. In addition, urine oligosaccharides, sialic acid levels, and glycosaminoglycans help better elucidate the cause of certain storage disorders. Urine guanidinoacetate and creatine levels are sent for diagnosing disorders of creatine synthesis. Urine and spinal fluid pipecolic acid and α-AASA levels are elevated at times in pyridoxine-dependent epilepsy.

Tissue biopsy specimens also provide important information in establishing a diagnosis. Specimens of skin, peripheral nerve, and skeletal muscle may provide useful clues as well. These tissues can be sent for electron microscopy, histopathologic staining, and selective biochemical analysis. Only rarely are a liver or brain biopsy necessary. Rectal and conjunctival biopsies are infrequently performed.

At times, but less frequently, the EEG features may be sufficiently distinctive to suggest the diagnosis of a limited number of conditions (Table 31.2). In other disorders, the EEG features can help narrow the differential diagnosis. For example, a burst-suppression pattern is seen in patients with NKH, PKU, MSUD, and molybdenum cofactor/sulfite oxidase deficiency, in addition to other disorders. Some distinctive EEG features include a comb-like rhythm with 7- to 9-Hz central activity, which is seen in patients with MSUD and propionic acidemia; vertex-positive polyspikes, seen in sialidosis type I; bioccipital polymorphic delta activity, seen in XALD; and 16- to 24-Hz invariant activity, seen in those with infantile neuroaxonal dystrophy.

Table 31.2 Electroencephalographic Patterns and Their Associated Disorders

Electroencephalogram pattern	Disorder
Comb-like rhythm	MSUD, propionic acidemia
Fast central spikes	Tay–Sachs disease
Rhythmic vertex-positive spikes	Sialidosis type I
Vanishing electroencephalogram	Infantile neuronal ceroid lipofuscinosis type I
High-amplitude 16- to 24-Hz activity	Infantile neuroaxonal dystrophy
Diminished spikes during sleep	Progressive myoclonus epilepsy
Giant somatosensory evoked potentials	Progressive myoclonus epilepsy
Marked photosensitivity	Progressive myoclonus epilepsy and neuronal ceroid lipofuscinosis, particularly type II
Burst-suppression pattern	Neonatal citrullinemia, NKH, propionic acidemia, Leigh syndrome, D-glycine acidemia, MOCOD, Menkes disease, HLCS deficiency, neonatal adrenoleukodystrophy
Hypsarrhythmia	Zellweger syndrome, neonatal adrenoleukodystrophy, neuroaxonal dystrophy, NKH, PKU, congenital defect of glycosylation type III

Brain imaging provides important information, although findings are rarely specific. Progressive atrophy is associated with neuronal ceroid lipofuscinosis, mitochondrial diseases, and certain storage disorders. White matter signal abnormalities are characteristic of peroxisomal disease (especially XALD), storage disorders, some mitochondrial diseases, disorders of neurotransmitter synthesis, MOCOD, disorders of creatine transport and synthesis, and some organic acidurias. Calcification of the cerebral cortex and basal ganglia is seen with select inherited metabolic diseases. Brain MRA may show abnormal dilatation and tortuosity of intracranial blood vessels in patients with Menkes disease. Brain MRS may demonstrate elevated lactate levels in those with various mitochondrial diseases, elevated N-acetylaspartic acid in patients with Canavan disease, or depressed creatine levels in those with inborn errors of creatine metabolism.

When the clinician is asked to evaluate a child with a progressive encephalopathy manifesting with seizures and no overt clinical clues, a screening paradigm must be used. There is seemingly no limit to the number of tests that can be performed, and the financial burden of these investigations can quickly become considerable. Accordingly, we propose the following screening tests, which should be tailored to the age and symptoms at presentation.

To some extent, the differential diagnosis can be pared down by calling to mind a discrete list of diseases for each of the different epilepsy syndromes (see Table 31.1). Nevertheless, it is likely that screening evaluations will need to be performed. Table 31.3 presents metabolic diseases associated with seizures and common biochemical abnormalities. Table 31.4 presents treatable or modifiable metabolic disorders that should not be overlooked.

Table 31.3 Metabolic Diseases and Biochemical Abnormalities

Seizures and metabolic acidosis
- Pyruvate dehydrogenase complex deficiency
- Pyruvate carboxylase deficiency
- Mitochondrial encephalomyopathies
- Amino and organic acidurias
- Multiple carboxylase deficiency disorders

Seizures and hypoglycemia
- Glycogen storage diseases
- Fructose 1,6-bisphosphatase deficiency
- Hereditary fructose intolerance
- Galactosemia
- Organic acidemias
- Disorders of N-glycosylation

Seizures and hyperammonemia
- Urea cycle defects, including hyperammonemia–hyperornithinemia–homocitrullinuria disorder
- Biotinidase deficiency
- Organic acidurias
- Fatty acid oxidation disorders
- Carnitine palmitoyltransferase type I deficiency
- Mitochondrial cytopathies

Table 31.4 Treatable or Modifiable Metabolic Disorders

Category	Disorder	Screening Test(s)	Notes
Common disorders	Amino and organic acidopathies	Amino acids, plasma	Fasting or preprandial specimens preferred; urine amino acids and urine acylcarnitines should be obtained selectively
	Mitochondrial cytopathies	Organic acids, urine	
	Fatty acid oxidation disorders	Lactate/pyruvate	
	Urea cycle disorder	Acylcarnitines, plasma	
	Biotinidase deficiency	Ammonia	
		Biotinidase activity	
Require spinal fluid for diagnosis	Glut-1 transporter defects	CSF glucose	Obtain pre-LP plasma glucose for comparison
	Glycine encephalopathy (NKHG)	CSF amino acids	Obtain pre-LP plasma amino acids for comparison
	Serine deficiency (PHGDH deficiency)	CSF amino acids	Obtain pre-LP plasma amino acids for comparison
	Pyridoxine- and folinic acid–responsive epilepsy	Identification of an unknown compound peak when CSF neurotransmitter amines are tested	CSF and urine pipecolic acid, α-AASA, and CSF threonine may also be elevated
	Defects of neurotransmitter synthesis	CSF neurotransmitter amines, biopterin, and neopterin	
	Cerebral folate deficiency	CSF methyltetrahydrofolate	Need plasma folate for comparison
	Pyridoxal phosphate responsive epilepsy	CSF pyridoxal phosphate level	CSF threonine may also be elevated
Less common disorders	Disorders of creatine synthesis	Urine guanidinoacetate	Plasma levels may also be obtained
		Brain MRS	
	Sulfite oxidase/molybdenum cofactor deficiency	Uric acid, plasma	Uric acid is normal in sulfite oxidase deficiency
		Urine *S*-sulfocysteine	
	Disorders of copper metabolism	Plasma copper and ceruloplasmin	24-h urine collections may be needed
	Thyroid transporter defects	T3, free T4 and TSH	TSH alone is not an accurate screening tool

General Studies

- Complete blood cell count with differential
- Electrolytes, CO_2, BUN/creatinine, and liver enzymes (Chem-20)
- Uric acid levels in blood and urine
- Blood ammonia
- Blood lactate/pyruvate
- Plasma amino acids
- Plasma acylcarnitines
- Urine organic acids
- Electroencephalography
- MRI and MRS

Additional Tests to Consider

- VLCFA and/or peroxisomal panel (which also checks phytanic and pristanic acid levels)
- Lysosomal enzyme analysis in leukocytes
- Biotinidase level, followed by biotin administration
- CSF for

    - Routine studies, especially glucose, lactate, and pyruvate; a concomitant pre-LP plasma glucose sample is needed for comparison to accurately evaluate for GLUT1 disease, CSF and plasma glucose should be obtained on fasting specimens with the patient not receiving dextrose-containing IV fluids.
    - Amino acids; a concomitant pre-LP plasma amino acid sample is needed for comparison
    - Neurotransmitter levels including biogenic amines (dopamine and serotonin metabolites), neopterin, and biopterin. This testing automatically screens for the peak of an unknown compound seen in cases of pyridoxine-dependent/folinic acid–responsive epilepsy (this testing can even be obtained after performing a therapeutic trial of pyridoxine, folinic acid, or pyridoxal 5-phosphate)
    - 5-MTHF for cerebral folate deficiency
    - Pyridoxal 5-phosphate for PNPO deficiency
    - α-AASA levels
    - Succinyladenosine for adenylosuccinase deficiency (a disorder of purine/pyrimidine metabolism)
- PPT1/TPP1 levels for neuronal ceroid lipofuscinosis (recommended prior to obtaining skin biopsies)
- An N-glycan panel for disorders of glycosylation
- Serum copper/ceruloplasmin
- Urine guanidinoacetate and creatine for disorders of creatine synthesis or transport
- Urine S-sulfocysteine for sulfite oxidase and/or MOCOD
- Urine oligosaccharides and/or mucopolysaccharides
- Urine purine/pyrimidine analysis
- Urine α-AASA levels

Selective

- Skin biopsy for
    - Electron microscopy
    - Fibroblast culture with fibroblasts sent for enzymatic assays (mitochondrial disorders, NCLs, PDH and PC deficiencies, lysosomal storage disease)
- Muscle biopsy (mitochondrial disorders)
- Nerve biopsy (neuroaxonal dystrophy)
- MRS (mitochondrial disorders and disorders of creatine synthesis and transport)
- Bone marrow for Gaucher cells

Focused Genetic Testing

- Chromosome oligo- or SNP-array analysis (comparative genomic hybridization)
- Methylation studies of chromosome 15q12 for Prader–Willi/Angelman syndrome followed by UBE3A gene sequencing if Angelman syndrome is suspected
- Rett/MECP2 and CDKL5 gene sequencing and deletion analysis
- EPM1 (Unverricht–Lundborg/Baltic myoclonus) and EPM2A/B (Lafora body disease) testing for PME

- Select nDNA and mtDNA gene analysis for mitochondrial disease; a variety of next-generation sequencing gene panels are available
- POLG1 gene sequencing for brain–liver disease (Alpers phenotype) or EPC
- Consideration of next-generation sequencing epilepsy gene panels. The clinician needs to be aware of the genes tested and whether deletions/duplications for those genes are also assessed. This testing now routinely includes genes for many treatable or modifiable epilepsy conditions, and diagnostic results may allow one to avoid invasive testing.
- Consideration of exome sequencing

TREATMENT OF METABOLIC AND MITOCHONDRIAL DISORDERS

The treatment of seizures associated with inherited metabolic and mitochondrial diseases should focus on the metabolic disturbance. Seizures associated with hypoglycemia, hyponatremia, hypocalcemia, and hypomagnesemia respond best to correction of these disturbances and should be treated with appropriate replacement therapy. Dietary treatment is beneficial for many inherited metabolic diseases, including defects of the urea cycle, defects of fatty acid oxidation, gluconeogenic defects, aminoacidopathies, organic acidurias, and the Glut-1 deficiency syndrome and can lead to a better neurologic outcome if started early.

In particular, the ketogenic diet is effective in controlling seizures in patients with the Glut-1 deficiency syndrome, and it improves cognitive outcome in patients with PDH deficiency. Blood ketones should be monitored directly, and every effort should be made to maintain a significant ketonemia with blood B-hydroxybutyrate values around 5 mM. Urine ketone measures can be misleading and falsely reassuring.

PKU can be well treated with a diet low in phenylalanine. Protein restriction is recommended for defects of the urea cycle and most amino acidopathies, and fat restriction is advised for defects involving fatty acid oxidation. Pyridoxine-dependent epilepsy and other vitamin-responsive syndromes often respond to prompt administration of the specific vitamin or cofactor. A lactose-free diet may aid those with primary cerebral folate deficiency. Enzyme protein replacement has proved effective in patients with Gaucher disease. Bone marrow transplantation has been used to treat patients with select lysosomal disorders, mucopolysaccharidoses, and adrenoleukodystrophy. Some patients with urea cycle defects, gangliosidoses, or leukodystrophies have improved with liver transplantation.

A general rule of thumb in regards to acute treatment when any metabolic disorder leading to epilepsy is suspected as follows:

- Make the patient NPO; this prevents the intake of any potentially harmful compound in the diet.
- Begin dextrose-containing IV fluids; dextrose is used here as a dietary substrate and not just to prevent hypoglycemia. It is also a metabolic signal to the cells to end catabolism. A high glucose delivery (D10 or D20) can also be used with insulin if needed. Insulin also serves as a metabolic signal to the body to end catabolism and helps maintain normoglycemia.
- Correct any electrolyte disturbances.
- Prevent fasting and dehydration by administering IV fluids.
- Avoid medications that may worsen acidosis including lactated Ringer's, and valproic acid

(when possible).
- Begin empiric trials of pyridoxine, pyridoxal 5-phosphate, biotinidase, and folinic acid while awaiting test results.
- Consider beginning IV levocarnitine while awaiting test results.

Conventional AEDs may be useful adjuncts to the specific treatment of a metabolic disorder but are often ineffective when used alone. In some circumstances, patients with metabolic derangements or neurodegenerative disorders may worsen with AED treatment that may be contraindicated—for example, phenytoin in patients with Unverricht–Lundborg disease; corticotropin and ketogenic diet in those with pyruvate carboxylase deficiency; ketogenic diet in patients with organic acidurias; and valproate in individuals with urea cycle, fatty acid oxidation, and mitochondrial defects. Metabolites of valproate interfere with β-oxidation, and valproate use depletes carnitine stores. Valproate is also an inhibitor of mitochondrial complex 1 and 4 and can lead to a fatal hepatopathy in patients with mitochondrial POLG gene mutations. Valproate, topiramate, zonisamide, and acetazolamide are relatively contraindicated with the ketogenic diet. Kidney stones are a complication associated with the ketogenic diet, as well as with acetazolamide, zonisamide, and topiramate use. Carnitine should be considered as a supplement in patients with any metabolic disorder that presents with seizures, particularly when valproate is used. An experimental report of inhibited glucose transport with phenobarbital raises concern for its use in patients with Glut-1 deficiency syndrome.

Conclusions

Seizures are often part of the clinical picture of inherited metabolic disorders, particularly when these conditions first appear during the neonatal period or infancy. Unfortunately, the clinical presentation of seizures is seldom distinctive enough to allow immediate diagnosis. Nevertheless, the timing of onset, certain characteristic clinical features, family history, and EEG findings may facilitate recognition of the more common diagnoses (see Table 31.1). Why seizures commonly accompany some metabolic diseases and infrequently occur in others is only partially understood, but certain correlations are intuitively obvious. Defects in energy metabolism are commonly associated with seizures—for example, the Glut-1 deficiency syndrome, other hypoglycemic syndromes, and defects of pyruvate metabolism; the Krebs cycle; and the respiratory chain. Also, seizures frequently accompany inherited metabolic disorders that affect neurotransmission, such as glycine encephalopathy, pyridoxine-dependent epilepsy, and GABA transaminase deficiency. A more fundamental common mechanism may be operative in many of these conditions. For example, an alteration in the ratio of glutamic acid to GABA may exist in disorders associated with cerebral energy failure and in conditions affecting the GABA shunt. Any inherited metabolic condition in which the extracellular glutamate concentration is elevated and the extracellular GABA concentration is lowered would lower the seizure threshold. Recent studies have confirmed this speculation in patients with symptomatic hypoglycemia, NKH, and pyridoxine-dependent epilepsy.

In contrast, defects of fatty acid oxidation are less likely to be associated with epilepsy. Fatty acids do not serve as oxidizable fuels for brain metabolism. Brain function is compromised mainly when the patient is subjected to fasting and hypoketotic hypoglycemia develops. Under these conditions, the brain is deprived of its two primary fuels, glucose and ketone bodies, and disturbed consciousness and seizures may occur. An exception is short-chain acyl-CoA dehydrogenase

deficiency, which is frequently associated with seizures in the absence of hypoglycemia.

Metabolic diseases provide some important insights into the neurochemical determinants of the epileptic state. Alterations of neurotransmission and ion channels are common themes in the pathophysiology of these diverse metabolic conditions. All infants and young children seen with unexplained seizure disorders (cryptogenic epilepsy), and adolescents and adults with unexplained epilepsy that began in childhood should be evaluated for an inherited metabolic disorder. Careful study of patients will continue to identify novel inherited metabolic disorders and lead to more direct and effective treatments of these conditions.

CHAPTER 32 CENTRAL NERVOUS SYSTEM INFECTIONS AND EPILEPSY

GAGANDEEP SINGH AND J.M.K. MURTHY

The association between central nervous system (CNS) infections and seizures and epilepsy has received little attention in the recent past as many infectious disorders have been controlled to a considerable extent in high-income countries. However, these disorders continue to pose significant health problems in resource-poor countries of the world. Moreover, infectious disorders sporadically engender interest in high-income countries owing to travel to and immigration from endemic resource-poor countries, thereby leading to imported cases.

The list of CNS infectious disorders is long, but few are noteworthy in consideration of their association with epilepsy. Meningitis (pyogenic, tubercular, and aseptic), encephalitis, cerebral malaria, neurocysticercosis (NCC), and toxocariasis are discussed herein. Human immunodeficiency virus infection is beyond the scope of this chapter.

SELECTED CNS INFECTIONS

Bacterial Meningitis

Meningitis is characterized by inflammation of the meninges, often involving the cerebrum via vasculitic infarctions or abscesses. The three most common organisms responsible for bacterial meningitis are Streptococcus pneumoniae, Neisseria meningitidis, and Hemophilus influenzae. Notwithstanding a dramatic drop in its incidence owing to the routine vaccination programs in childhood, H. influenzae type 1b remains the most common organism responsible for bacterial meningitis in the western world. In rest of the world, S. pneumoniae and N. meningitides are the commonly responsible organisms. Seizures occur in nearly a third of patients during the acute phase of infection in bacterial meningitis.

Viral Encephalitis

Encephalitis, which refers to inflammation of cerebral parenchyma, manifests with seizures, altered consciousness, behavior, and cognition, and focal neurologic deficits. Over 100 different viruses cause endemic, epidemic, or sporadic forms of encephalitis (1). The endemic forms exhibit specific geographic predilections, for example, West Nile virus, La Crosse, St. Louis, eastern and western equine encephalitis viruses in the United States, tick-borne encephalitis in Eastern Europe, Japanese B encephalitis and Nipah viruses in Asia and Murray Valley encephalitis virus in Australia. In addition, up to 60% of suspected viral encephalitis episodes remain etiologically undiagnosed (1).

Herpes viruses, including Herpes simplex type 1 (HSV-1), are the commonest cause of sporadic encephalitis worldwide (2–4). These viruses (including Varicella zoster virus, Human herpesvirus 6,

and Human herpesvirus 7) are uniquely neurotropic and can remain latent in the nervous system, particularly the trigeminal sensory ganglion for long periods of time following acute infection. HSV-1 has an affinity for involvement of inferior frontal and mesial temporal cortices. Interesting in this context is the demonstration of HSV-1 genome by polymerase chain reaction techniques in resected temporal lobe specimens from patients with intractable mesial temporal lobe epilepsy who otherwise had no prior encephalitic episodes (5). These findings have not been replicated in other studies, though (6). Similarly, genomes of another herpes virus, HHV-6, have been demonstrated in resected human epileptic tissue (7,8). The virus, HHV-6, is causally associated with rare cases of limbic encephalitis in immunocompromised individuals. In immunocompetent individuals, however, the virus remains dormant in the nervous tissue without any pathogenic repercussions. Thus, while these findings are of interest, the role of herpes virus infection in medically refractory mesial temporal lobe epilepsy apart from cases with antecedent HSV-1 encephalitis remains speculative.

Cerebral Malaria

The microparasite, Plasmodium, of which four species are known (P. vivax, P. falciparum, P. malariae, and P. ovale) is responsible for malaria. Cerebral malaria, one of its most serious forms, is associated with P. falciparum infestation. The parasite is transmitted to humans by the bite of the female Anopheles mosquito. The bite releases P. falciparum sporozoites, which undergo a series of transformations to eventually parasitize human red blood cells. The parasitized red blood cells get sequestered in the cerebral microcirculation. During this process, various inflammatory mediators, such as intracellular adhesion molecule-1 and interleukins are released, which in turn lead to microvascular occlusion, microinfarcts, and damage to the blood–brain barrier (9).

Cerebral malaria presents with fever, coma, and seizures. Seizures might occur in both cerebral malaria and uncomplicated malaria. Since malaria typically presents as an acute febrile illness in children <5 years of age, many of the seizures particularly in uncomplicated malaria may actually be febrile seizures. Moreover, seizures in cerebral malaria differ from febrile seizures of uncomplicated malaria in being prolonged, complex, and at times occurring at rectal temperatures below 38°C. The seizures are believed to be the result of sequestration of parasitized red blood cells in the cerebral microcirculation and possibly related to an up-regulation of several interleukins. Other factors associated with seizures in cerebral malaria include hypoglycemia, raised intracranial pressure, and electrolyte imbalance. The incidence of seizures in cerebral malaria varies geographically as the reported incidence in series of patients from Southeast Asia was 20% but amounted to nearly 80% in African reports (10,11). It is unclear whether these differences are true or the result of an ascertainment bias.

Neurocysticercosis

Infestation of the brain with the larval stage (cysticercus) of the macroparasite, Taenia solium, is known as NCC (12). Human beings are definitive hosts and harbor the adult tapeworm/s in their intestines, while pigs, the intermediate hosts, carry the larval stage. Humans get infested by the larval stage accidentally by ingesting Taenia eggs through fecal–oral contamination. The eggs develop into embryos, which penetrate the intestinal wall to enter the blood stream and get lodged in various organs, including brain, muscles, subcutaneous tissue, and eyes. In the brain, the larvae (cysticerci) might lodge in the cerebral parenchyma, subarachnoid space, or the ventricles. Here, they pass

through a series of pathologically distinct evolutionary stages (Fig. 32.1A– I) (13). Correspondingly in imaging studies, the cysticerci appear to pass from a live or active stage (vesicular stage on pathologic studies), that is, without any breakdown of the blood–brain barrier and little host inflammatory response in the surrounding brain parenchyma (see Fig. 32.1B and C) eventually to a dead or inactive (fibrocalcified) parasite (see Fig. 32.1H) (14,15). The intervening stage is known as the "degenerating," "transitional," or "encephalitic" stage (colloidal and granulonodular stages on pathologic studies) characterized by breakdown of the blood–brain barrier and consequent development of surrounding host inflammatory response (see Fig. 32.1D–F).

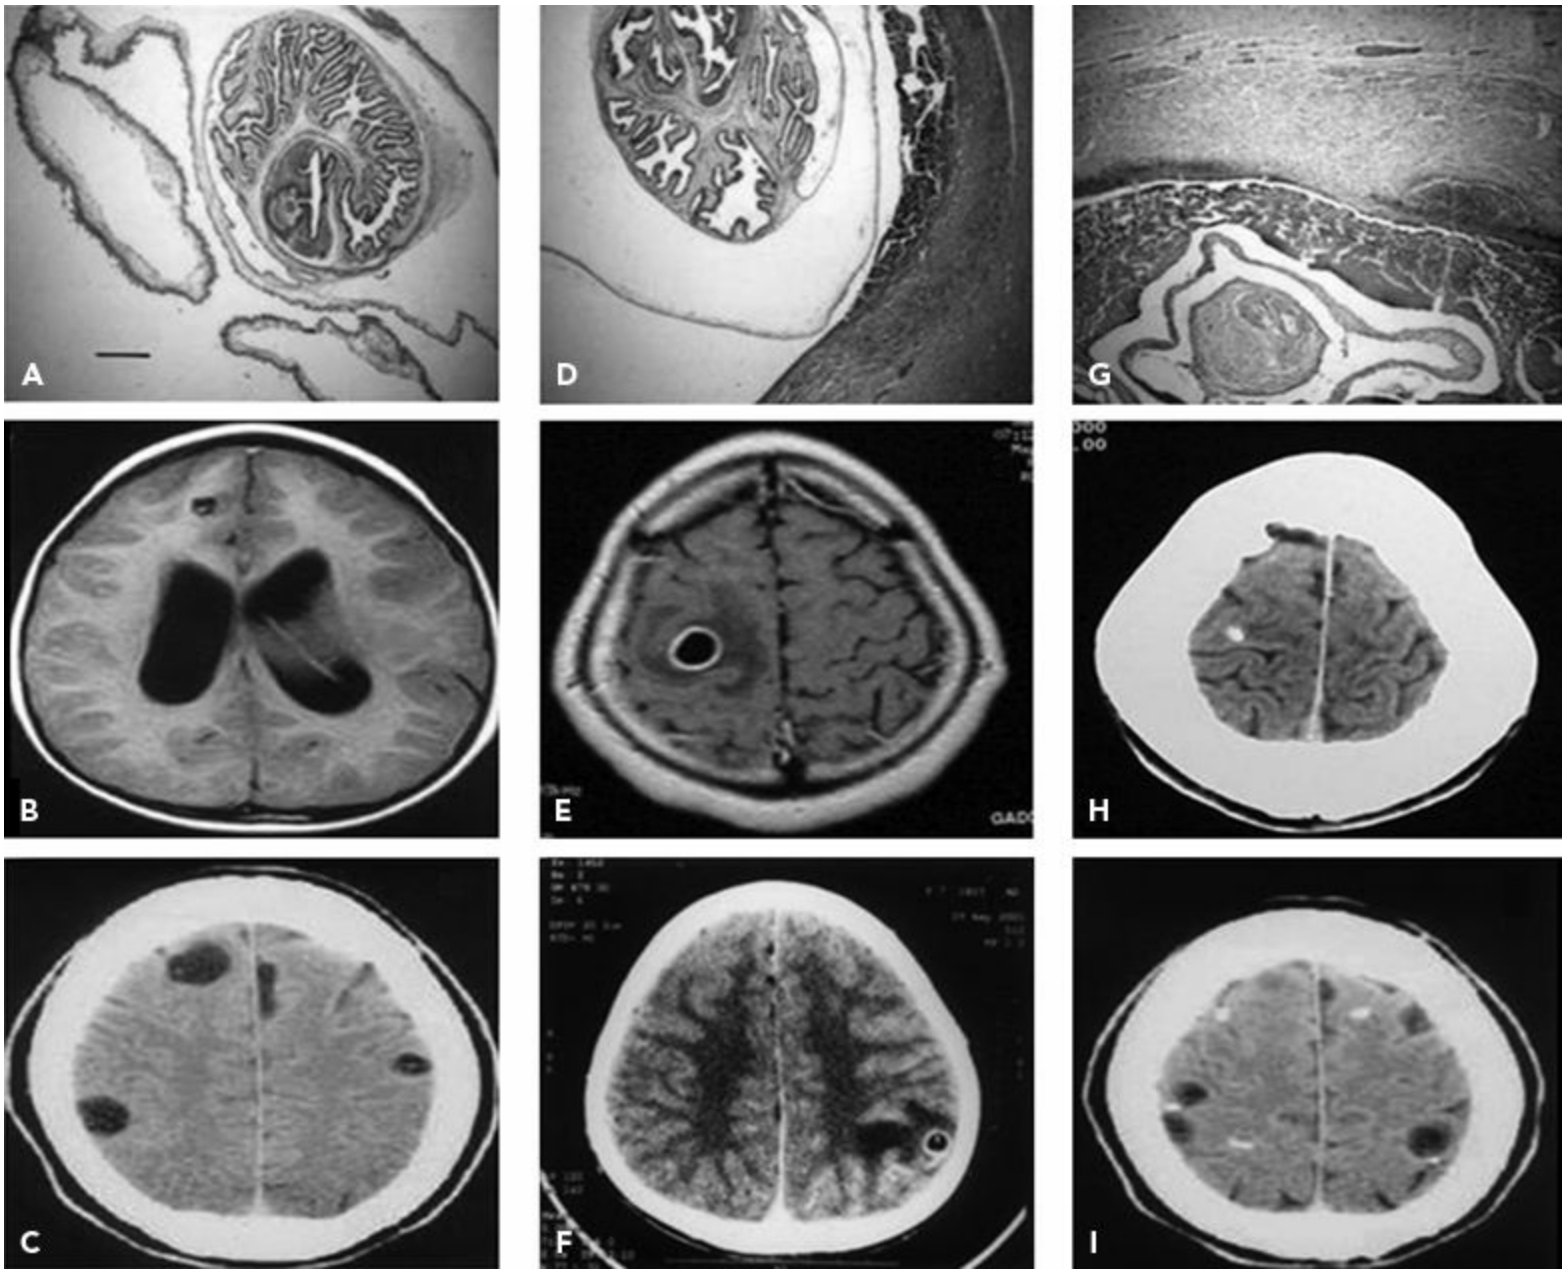

Figure 32.1. Histopathologic and imaging stages of the T. solium cysticercus in the brain parenchyma. **A:** Histologic features of the vesicular stage with a well-defined cysticercus including its extensive canalicular network and no surrounding inflammation. **B:** T1-weighted MRI showing a cyst in its active (vesicular) stage with a well-defined eccentric scolex and no surrounding edema. **C:** Unenhanced CT showing multiple active vesicular cysts. **D:** Histologic features of the colloidal stage (corresponding to the degenerating or encephalitic/transitional on imaging) with surrounding inflammation. **E:** Gadolinium-enhanced MRI demonstrating a ring-enhancing lesion in the brain parenchyma corresponding to the degenerating (transitional or encephalitic) stage. **F:** Contrast-enhanced CT showing a similar ring-enhancing lesion probably corresponding to the granular–nodular pathologic stage. **G:** Histologic depiction of the fibrocalcific parasite corresponding to the dead or inactive parasite with little surrounding inflammation. **H:** CT appearance of inactive, fibrocalcific nodule. **I:** CT demonstrating multiple NCC, some live, active and others calcified, thus multiple

stages at any given point of time. (**A, D**, and **G**, Courtesy of Alfonso Escobar, UNAM, Mexico; **B, C**, and **I**, from Singh G, Prabhakar S. Taenia solium Cysticercosis: From Basic to Clinical Science. Oxon, UK: CAB International, with permission.)

Symptoms of cysticercosis are almost always the result of brain infestation and depend on the location, stage, and number of cysts in the brain. Seizures, which occur in nearly 80% of cases of NCC, are most characteristic of parenchymal location (16). The number of cysts in the brain also has a bearing on the clinical presentation. When cysts are extremely frequent, especially in 100s, the clinical presentation is dominated by features of raised intracranial pressure, dementia, and focal neurologic deficits (17). Conversely, patients with solitary cysticercus granuloma or a small number of cysts present with few seizures, and these are usually easily controlled with antiepileptic drugs (AEDs) (18).

Other CNS Infections

Several CNS infections are notable for their association with seizures and epilepsy. CNS tuberculosis, especially when presenting with cerebral tuberculoma, bacterial brain abscess, fungal infections including cryptococcal meningitis, and subacute sclerosing panencephalitis deserve mention due to a notable frequency of both early and late unprovoked seizures (19).

BURDEN OF CNS INFECTIONS

The epidemiology of many CNS infectious disorders has changed in the recent past, and these changes have perhaps impacted their association with epilepsy. For instance, the introduction of H. influenzae type b (Hib) and S. pneumoniae conjugate vaccines has led to a decline in the incidence of bacterial meningitis in the United States from 2/100,000 in the 1990s to 1.38/100,000 in 2007 (20). Likewise, attempts to control transmission of N. meningitides meningitis and malaria in sub-Saharan Africa and of cysticercosis in South and Central Americas have led to a prefatory decline in the incidence of these disorders. At the same time, land development and increasing human traffic between endemic resource-poor countries and high-income countries have also contributed to the changing epidemiology of CNS infections. For example in the United States where T. solium was once considered eradicated, large numbers of NCC cases have been reported from states with the largest volume of Latino immigrants, that is, California, Texas, and Oregon (21). In California alone, where NCC is a reportable disease, there occurred 805 hospitalizations with a discharge diagnosis of NCC in 2009, amounting to 304 hospitalized people (estimated incidence: 0.8/100,000) with six deaths (22). Nearly 85% of those hospitalized were Latinos.

An estimated 19,000 hospitalizations and 1400 deaths with a diagnosis of viral encephalitis take place each year in the Unites States (4). Elsewhere, the burden has not been precisely investigated but is probably enormous. About 30,000 to 50,000 cases of Japanese B encephalitis are recorded annually from South and Southeast Asia (23). In sub-Saharan Africa, where over 80% of malaria episodes are recorded, an estimated 600,000 cases of cerebral malaria occur each year among children, of whom 100,000 (20%) die and 20,000 are left with serious neurologic sequelae beyond 6 months (24,25). Likewise, in this region, the estimated annual incidence of meningococcus meningitis is 20/100,000 population, amounting to 500,000 cases each year (26). The estimated burden of NCC in Latin America alone is 400,000 among a population of 75 million (27). A high prevalence of NCC, albeit of lesser magnitude, has also lately been documented in South Asia and sub-Saharan Africa (28,29).

ASSOCIATION BETWEEN CNS INFECTIONS AND EPILEPSY

Longitudinal data representing the magnitude of risk of epilepsy following a CNS infection episode are available for the Olmsted County community in Minnesota (30). In this community, the 20-year risk of unprovoked seizures was 22% following an episode of encephalitis with early (<7 days) seizures, 10% in the absence of early seizures, 13% after an episode of bacterial meningitis with early seizures, and only 2% after meningitis in the absence of early seizures. Aseptic meningitis does not appear to increase the risk of late unprovoked seizures. In incidence studies from western high-income countries, CNS infections constitute the putative etiology in 5% of new-onset epilepsies (31). Community-based figures on incidence in resource-poor countries are not available but numbers are probably even higher.

Lately, the association between several infectious disorders and epilepsy has been studied in endemically specified geographic regions. Both in Latin America and India, a number of case–control studies using serology or brain imaging as evidence of infection have demonstrated a significant association between cysticercus infection and epilepsy (32–34). These studies have consistently shown that NCC is a risk factor for roughly one-third of active epilepsies in endemic communities (32). Likewise, studies using standard case definitions for cerebral malaria from Kenya, Mali, and Gabon have established a moderate association between the cerebral malaria and epilepsy (35–37). In contrast with these association studies, in which causality between the infection and epilepsy appears plausible, studies in disparate locations (including Burundi, Bolivia, and Italy) have also suggested an association between exposure to Toxocara canis (dog roundworm) and epilepsy (38–40). It might be clarified here that the demonstration of an association does not imply causality between T. canis infection and epilepsy. For one reason, brain infection with T. canis has rarely been documented either by imaging or pathology. For another, it is possible that a confounding variable, for example, socioeconomic deprivation, which is a risk factor for both T. canis infection and epilepsy, might account for the association. Moreover, the findings of an association have not been confirmed in other regions (33).

SEIZURES IN RELATION TO CNS INFECTIONS (PROVOKED VERSUS UNPROVOKED)

Seizures are common during the active (often acute) phase of CNS infections and are referred to as "early," "acute asymptomatic," or "provoked" seizures. In the Olmsted County community, 15% of all acute symptomatic seizures were associated with CNS infections, yielding an age-adjusted incidence of 5.2/100,00 person-years (41). Early seizures occur in 33% of the cases with bacterial meningitis, 40% to 60% of HSV encephalitis, and in up to 67% of Japanese B encephalitis (1,42).

In many acute CNS infections, seizures may occur as subtle nonconvulsive seizures or as convulsive status epilepticus. Both convulsive and nonconvulsive status epilepticus have been documented in bacterial meningitis, HSV and Japanese B encephalitides, and cerebral malaria (43–45). The documentation of status epilepticus during the acute infection episode correlates with increased intracranial pressure and poor outcome (43,45).

The structural and pathophysiologic correlates of seizures during acute infections vary and include focal hemorrhagic necrosis in the cerebral cortex (HSV-1 and other encephalitides),

vasculitis and infarcts (bacterial meningitis), cerebral abscesses (pyogenic, tubercular and fungal), the release of interleukins, anti-infective medications (e.g., imipenem, flouroquinones, and isoniazid), raised intracranial pressure and disruption of the blood–brain barrier (46).

The definition of acute symptomatic seizures was recently revised (47). In the context of CNS infections, seizures might be considered as acute symptomatic (or provoked) if these occur during the phase of active infection. The categorization of acute symptomatic or provoked seizures as early seizures is easily understood in acute CNS infections (e.g., bacterial meningitis, viral encephalitis, and cerebral malaria) but becomes problematic in the case of chronic CNS infections such as NCC. It has been suggested that seizures occurring in relation to the degenerating stages (colloidal vesicular or granulonodular stages) of NCC are provoked, while those occurring in relation to the inactive (or fibrocalcified) stage are unprovoked (48). The degenerating stages are characterized by a breakdown of the blood–brain barrier and host inflammatory response surrounding the cerebral cysticercus. The cellular and molecular phenomena associated with inflammatory degeneration probably provoke seizures (49). Even so, recent follow-up studies of patients with calcified cerebral cysticerci have shown that roughly 50% continue to have seizures. Of these, in 50% without ongoing seizures, the occurrence of seizures is related to an unpredictable and sporadic release of antigenic material from the calcified cysticercus remnants, thereby engendering breakdown of the blood–brain barrier and inflammatory response in the surrounding cerebral parenchyma (50). These episodes are characterized by contrast enhancement and surrounding edema around the calcified cysticercus (Fig. 32.2). Hence, these unpredictable events underscore the problems in categorizing seizures in relation to NCC as “acute symptomatic” or “unprovoked.”

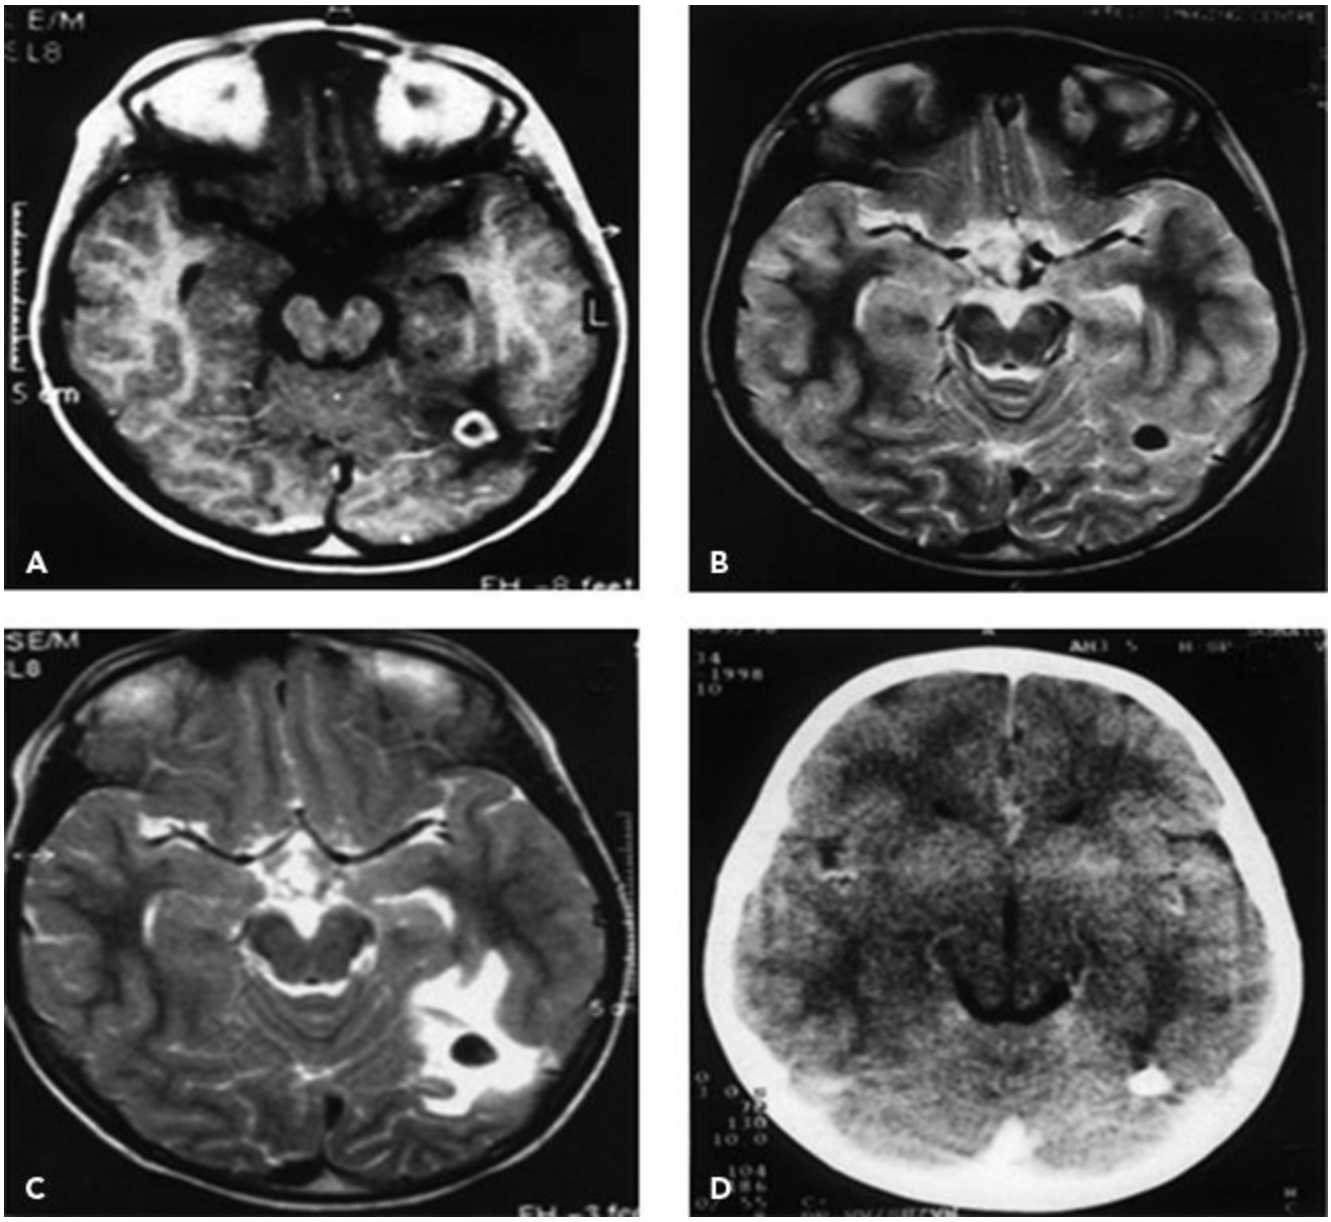

Figure 32.2. Resolution of a cysticercus granuloma and the subsequent reappearance and resolution of perilesional edema. **A:** Initial gadolinium-enhanced MRI in a patient with recent seizures showing a single annular-enhancing lesion. **B:** Follow-up T2-MRI 6 months later showing resolution with calcification. **C:** T2-MRI performed another 14 months later, when the patient developed seizure recurrence, showing perilesional edema around the calcific nodule. **D:** CT scan performed another 6 months later showing resolution of the edema around the calcific nodule. (From Singh G, Prabhakar S. Taenia solium Cysticercosis: From Basic to Clinical Science. Oxon, UK: CAB International, with permission.)

The occurrence of early seizures during the CNS infection episode increases the risk of late unprovoked seizures (amounting to epilepsy if recurrent) (30). This risk might be as high as 24% when the infection episode associated with early seizures leaves behind a structural residue in the cerebral parenchyma (51). In addition, the risk of a late seizure is particularly high when the infection episode is accompanied by status epilepticus instead of an uncomplicated seizure.

TREATMENT CONSIDERATIONS

There are few data in the form of clinical trials and observational follow-up studies to support the choice and duration of AED treatment in people with epilepsy associated with CNS infections. Treatment policies might therefore follow guidelines for treatment of symptomatic epilepsies associated with structural cerebral lesion(s). Two additional issues merit consideration. One is the

putative effect of treatment interventions in relation to the infectious disorder on the subsequent risk of development and outcome of epilepsy. The other is the range of drug interactions between AEDs and medications used to treat the infectious disorder.

The treatment of CNS infections comprises antibiotics for bacterial meningitis, antivirals for viral encephalitis, antimalarial medications for cerebral malaria, and antihelminthic agents (albendazole and praziquantel) for NCC. Other agents, for example, corticosteroids in bacterial meningitis and NCC and AEDs during the active phase of the infectious disorder, might also be administered. When administered early during the course of bacterial meningitis, corticosteroids reduce the risk of certain neurologic sequelae (e.g., sensorineural deafness), but the effect of the risk of development of unprovoked seizures has not been studied. The administration of AEDs during the acute infection episode (in bacterial meningitis, viral encephalitis, and cerebral malaria) does not appear to influence the risk of development of subsequent epilepsy.

Treatment of NCC comprises of antihelminthic agents (albendazole and praziquantel) with or without corticosteroids. A randomized, placebo-controlled trial of albendazole in people with live NCC demonstrated significantly improved clearance of the parasite with treatment (52). However, the benefits of administration of albendazole with respect to seizure outcome were less certain. Overall, there was no significant difference in the number of subjects in the treated and placebo groups who remained seizure free over a 30-month follow-up period (52). Many more controlled trials have studied the effects of albendazole and corticosteroids in people with NCC. Meta-analyses of trials of antihelminthic treatments and corticosteroids alone in solitary cysticercus granuloma have suggested that while antihelminthic treatment is associated with greater chances of seizure freedom, treatment with a short course of corticosteroid alone does not influence seizure recurrence rates (53).

The other issue of concern is the range of drug interactions between AEDs and anti-infective medications used in the treatment of CNS infections. These interactions (Tables 32.1 and Table 32.2) might adversely impact not only the treatment of the infectious disorder leading to reduced chances of a cure but also epilepsy resulting either inadequate seizure control due to reduced AED levels or conversely, AED toxicity.

Table 32.1 Effect of Anti-Infective Agents on AEDs

Anti-infective agent	Indication for use	Interaction/effect	Putative mechanism of effect	References
Meropenem	Bacterial meningitis; severe sepsis	Reduced plasma levels of valproic acid	Unknown	(54)
Chloramphenicol[a]	Brain abscess	Phenytoin and phenobarbital toxicity	Hepatic enzyme inhibition	(55)
Isoniazid[b]	CNS tuberculosis	Increased plasma levels of carbamazepine, valproic acid, phenobarbital, and ethosuccimide	Hepatic enzyme inhibition	(56–58)
Rifampicin[b]	CNS tuberculosis	Reduced plasma levels of carbamazepine, phenobarbital, phenytoin, ethosuccimide, and lamotrigine	Hepatic enzyme induction	(59)

[a]Chloramphenicol is rarely if ever used in western countries but continues to be used in some resource-poor countries.
[b]Since isoniazid and rifampicin is invariably used in combination in the treatment of tuberculosis, they balance out each other's effect on AED levels.

Table 32.2 Effect of Aeds on Plasma Levels of Anti-Infective Agents

AEDs	Interaction/effect on anti-infective agent	Mechanism of action	Indication for use of anti-infective agent	References
Phenytoin, carbamazepine	Reduced plasma levels of praziquantel	Hepatic enzyme induction	NCC	(60)
Phenytoin, carbamazepine	Reduced plasma levels of albendazole[a]	Hepatic enzyme induction	NCC	(61)

[a]The clinical significance of this interaction is uncertain.

SURGICALLY REMEDIABLE EPILEPSY IN RELATION TO CNS INFECTIONS

Heretofore, the prognosis for seizure control with standard single AEDs in disorders such as NCC was believed to be good. Furthermore, antecedent CNS infection (e.g., meningitis and encephalitis) conferred a poor prognosis following surgery for medically intractable epilepsy owing to the widespread cerebral damage sustained thereof. Thus both, the development of refractoriness to AED treatment in NCC and the potential for benefit following surgical treatment for epilepsy following meningitis and encephalitis, were not well appreciated, largely due to absence of systematic follow-up studies of CNS infections.

MEDICALLY REFRACTORY EPILEPSY IN ASSOCIATION WITH CALCIFIED CEREBRAL CYSTICERCI

Rare cases with AED-refractory seizures shown to arise from the vicinity of a calcified cerebral cysticercus and having benefited from surgical lesionectomy alone have been documented (62,63). Perhaps more common is the occurrence of mesial temporal lobe epilepsy with hippocampal sclerosis and a calcified cysticercus located within or in its close proximity (62,64). The hippocampus is not a preferred location for the cysticercus. In general, the cysts commonly lodge in the frontal and parietal lobes, in keeping with the differential proportion of blood supply delivered to various lobes of the brain (65). However, when a cyst does lodge within or close to the hippocampus, the likelihood of developing recurrent and poorly controlled seizures appears to be high, partly due to vulnerability of the hippocampus to insults and partly due to presence of neuronal circuitry conducive to epileptogenesis. In this situation, the prognosis for seizure control following standard temporal resections that include the calcified cysticercus is excellent (62).

A distinct clinical scenario is the finding of one or more calcified cerebral cysticercus lesions in association with unilateral hippocampal sclerosis upon imaging studies in people with medically refractory mesial temporal lobe epilepsy. Calcified cysticerci might be identified on imaging studies in a sizeable proportion of completely asymptomatic individuals in communities that are endemic for T. solium infestation (66). Hence, it is not surprising that a proportion of patients undergoing presurgical evaluation in epilepsy centers located in endemic regions (e.g., Brazil or India) demonstrate one or more calcified cysticerci on imaging studies. This might imply that the calcified

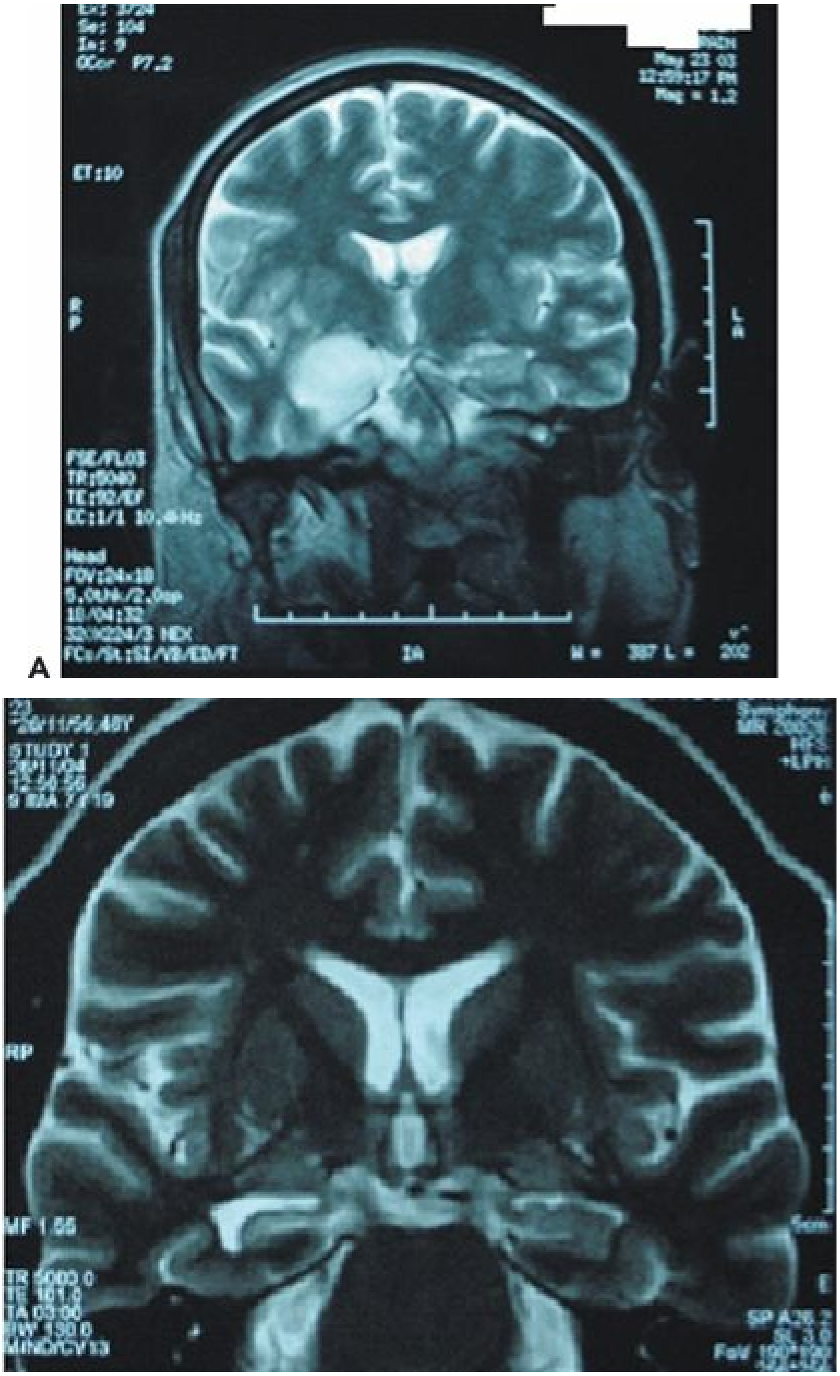
cysticerci are detected as mere coincidental findings on imaging studies in people with hippocampal sclerosis.

A cross-sectional study at a Brazilian epilepsy center found a significant association between calcified cysticerci and hippocampal sclerosis but not other substrates for surgically remediable epilepsy (e.g., tumors, developmental malformations, etc.) (67). A moot point relating to the implied association between the calcified cysticercus and hippocampal sclerosis is whether NCC interacts with the development of the hippocampal pathology (e.g., as an antecedent or as a result of kindling initiated by NCC-associated seizures) or if the occurrence of NCC and hippocampal sclerosis is purely coincidental. Another controversial area is whether the interaction influences the choice of surgical approaches to medically intractable epilepsy with hippocampal sclerosis and calcified NCC. A Brazilian report of 32 patients with hippocampal sclerosis in association with calcified NCC described Engel Class I seizure outcome in 82% following standard anteromesial temporal resection alone (68). Conversely, in a report from India, seizure freedom was observed in only one out of four patients following temporal resection alone (62). In another two patients in whom independent seizures were demonstrated to arise from both the hippocampus and the calcified NCC, complete seizure freedom was obtained following temporal resection along with lesionectomy (resection of the calcified NCC) due to suspected dual pathology. Although these data are preliminary, it is recommended that the surgical approach to hippocampal sclerosis associated with calcified NCC be decided on a case-by-case basis, keeping in mind that seizures might arise from either the hippocampus or from both, the hippocampus and the calcified NCC.

MEDICALLY INTRACTABLE EPILEPSY WITH ANTECEDENT MENINGITIS AND ENCEPHALITIS

The development of medically intractable epilepsy with antecedent meningitis or encephalitis can take place in one of the following three forms:

1. Unilateral hippocampal sclerosis with antecedent meningitis or encephalitis: The antecedent infection (more commonly meningitis and less commonly encephalitis) usually occurs before the age of five years (69). Mesial temporal lobe epilepsy (Fig. 32.3) follows the infection episode after a latent period of several years (70,71). The prognosis for seizure control following standard temporal lobe resections is excellent (72).
2. Bilateral hippocampal sclerosis with antecedent meningitis or encephalitis: Although there is a potential for independent seizure origin from either or both mesial temporal lobes, epilepsy surgery might still be a feasible option provided that a sufficient number of seizures have been recorded and are demonstrated to arise from only one side (69,73).
3. Neocortical epilepsies with antecedent meningitis or encephalitis: The infection episode (most often encephalitis) takes place after the age of five years (69). The epilepsy has an onset soon after the infection episode and has a catastrophic evolution (70). The seizure outcome following neocortical resection is not good. It is unclear whether the poor outcome is related to inadequate localization of the epileptogenic zone or to the presence of multiple epileptogenic foci.



A
B

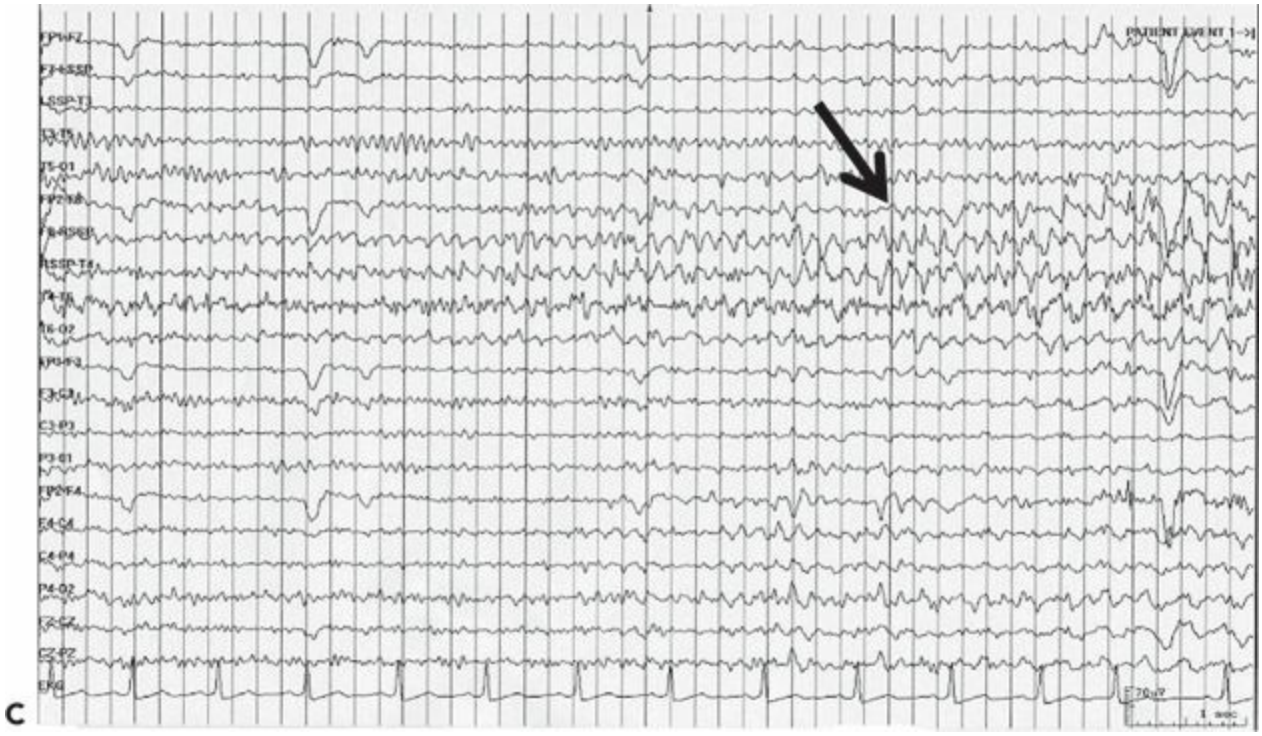


Figure 32.3. Postencephalitic epilepsy. **A:** T2-weighted coronal MRI demonstrating predominantly right mesial temporal hyperintensity and swelling during presumed HSV-1 encephalitis. **B:** Follow-up coronal T2 MRI of the same patient 2 years later revealed sclerosis within an atrophic right hippocampus. **C:** Ictal EEG in the same patient demonstrating an electrographic seizure origin from the right temporal lobe.

SEIZURE OUTCOME AND PROGNOSIS

There are virtually no systematic data on seizure recurrence rates, remission following standard AED treatment, the proportion of patients who go on to develop intractable epilepsy and mortality in people with postmeningitic/encephalitic epilepsy. In the absence of such data, it might be assumed that course and outcome of postmeningitic/encephalitic epilepsy is similar to other symptomatic epilepsies.

A follow-up study of people with mixed collection of NCC (including single and multiple, active and inactive stages) documented seizure recurrence in 40% over 2 years (74). Factors associated with seizure outcome in people with NCC have been studied in some detail. These include the stage, number (solitary versus multiple), and perhaps location of the cyst/s in the cerebral parenchyma. In follow-up studies of a solitary degenerating cysticercus granuloma, seizure recurrence rates of up to 48% over a period of 6 to 15 months have been documented (18). On the other hand, a follow-up study (mean duration of 66 months) of solitary granuloma following resolution documented a recurrence rate of 15% (75). Thus, it appears that seizure outcome might be classified according to the stage in the evolution of the cysticercus: (1) outcome during the period in which the cyst is actively degenerating and (2) outcome following resolution (i.e., the inactive stage of cysticercus). The risk of seizure recurrence is high as long as the cyst is degenerating but is reduced once the cyst resolves. In the postresolution period, the risk remains comparatively high when the cyst resolves leaving behind a calcified residue. Roughly 50% of people with a calcified NCC continue to have seizures in the postresolution period (50).

CHAPTER 33 AUTOIMMUNE ISSUES IN EPILEPSY

AHSAN N.V. MOOSA

Recognition of the role of autoimmune mechanisms in the pathogenesis of several acquired neurologic disorders has improved our ability to treat disorders previously considered untreatable. This had the greatest impact on disorders of myelin in the peripheral and central nervous system leading to improved outcome for patients with inflammatory neuropathies and multiple sclerosis. In the field of epilepsy, the role of autoimmune mechanisms has been long overlooked. Recent research in the field of autoimmune/limbic encephalitis (LE) has yielded a variety of autoantibodies against target antigens that are considered to be closely linked to epileptogenesis and cognition (1). This raised the possibility that autoimmune mechanisms may play a role in the pathogenesis of some acquired focal epilepsy syndromes and neuropsychiatric disorders. This may have profound practical implications as treatment of epilepsy has traditionally been toward preventing seizures with antiseizure medications, with little or no role for treatment for the primary etiology of epilepsy. Furthermore, nearly one-third of patients with epilepsy do not have a specific etiology for their epilepsy (2,3). Identification of a specific etiology that has therapeutic implications may potentially affect the outcome of these patients (4).

In this chapter, we review the current role of autoimmune antibodies in epilepsy and related conditions under two sections. The first section deals with various types of autoimmune LE and the roles of newly recognized autoantibodies. The second section attempts to review the current status of autoimmune mechanisms in patients in whom the major manifestation is epilepsy. An excellent review of Rasmussen encephalitis (RE) can be found in Chapter 23. This will not be discussed in this chapter. Well-known systemic autoimmune disorders such as systemic lupus erythematosus, sarcoidosis, celiac disease, and their manifestations as seizures or epilepsy are not discussed here.

AUTOIMMUNE ANTIBODIES AND LIMBIC ENCEPHALITIS

In the past, LE was essentially synonymous with paraneoplastic LE, related to cancers (frequently small cell lung cancer) in adults with poor prognosis (5). Anti-Hu, anti-Ta, and anti-Ma were the major antineuronal antibodies associated with paraneoplastic LE; in some patients, no specific antibodies were detected. In the past decade, recognition of the other autoantibodies against neuronal surface and their frequent occurrence outside the paraneoplastic setting has revolutionized the management of patients with LE (1,6). Antibodies linked with paraneoplastic/autoimmune encephalitis can be categorized into four broad categories: (i) onconeuronal antibodies to intracellular nuclear or cytoplasmic antigens; (ii) antibodies to synaptic antigens; (iii) antibodies to neuronal cell surface antigens; and (iv) antibodies of unclear significance (1). The antibodies in the

later three categories have been shown to be associated with isolated refractory epilepsy (Fig. 33.1).

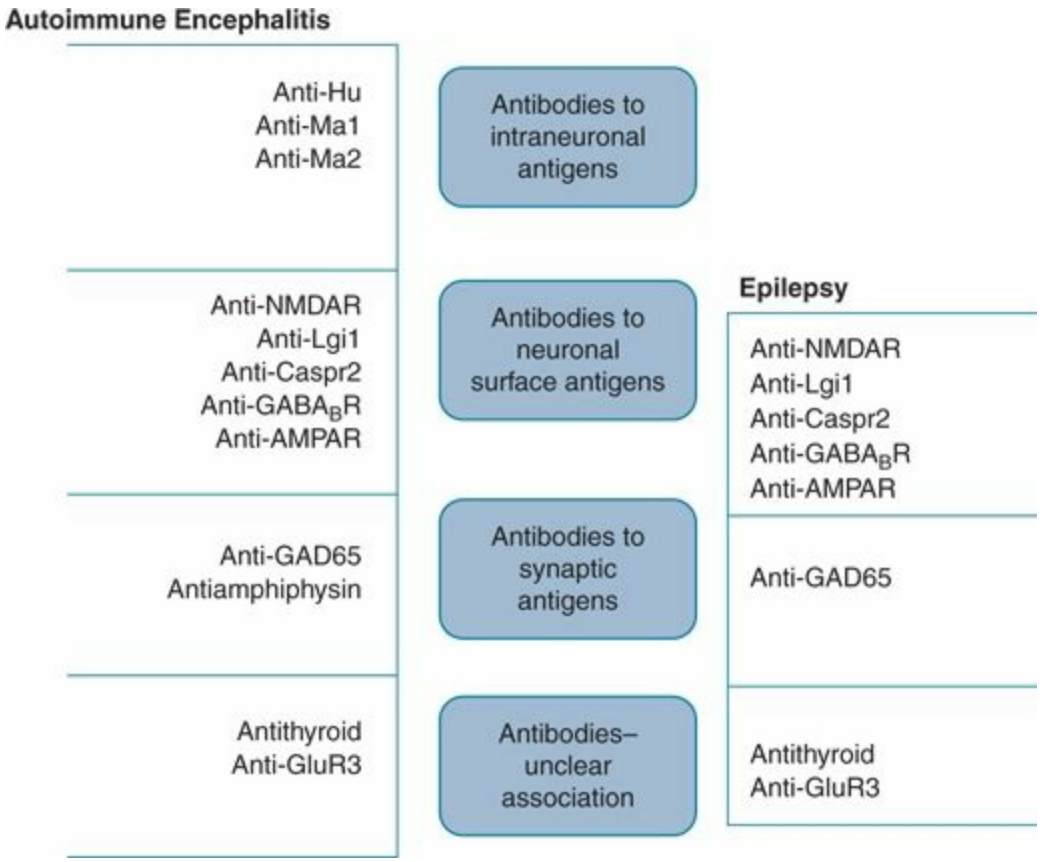

Figure 33.1. Four broad categories of autoantibodies noted in LE and refractory epilepsy.

(i) Onconeural Antibodies to Intracellular Antigens

Antibodies in this group were the first ones to be recognized in classical paraneoplastic encephalitis (5). The target antigens for the antibodies in this group include Hu, Ma1, and Ma2; these antigens reside in the cytoplasm or nucleus of the neurons (5,7,8). Because of the intracellular location of the antigens, the antibodies have poor access to these antigens and are generally not considered to be pathogenic. Most of the neurologic disorders that occur in this setting are T-cell mediated. The antibodies merely serve as a disease marker and are likely not directly involved in the neuronal injury. These antibodies are strongly linked to cancers with shared target antigens in the neoplasm and in the neurons. Presence of these antibodies in a patient with a presentation compatible with paraneoplastic syndrome warrants a diligent search and surveillance for occult tumors. Most well studied in this group are the anti-Hu antibodies, which are present in nearly 20% of patients with small cell lung carcinoma (SCLC). However, only 0.01% of patients with SCLC develop paraneoplastic features, presumably due to high tolerance to anti-Hu in normal individuals (1,9). Paraneoplastic syndromes with these antibodies include peripheral neuropathy, cerebellar ataxia, LE, autonomic disorders, and brainstem encephalitis. Recovery from these paraneoplastic syndromes is incomplete, and immunotherapies targeted to antibodies are often ineffective. Primary manifestation as chronic epilepsy is uncommon in this group of disorders.

(ii) Antibodies to Synaptic Antigens

The two classical antibodies in this group are anti-glutamic acid decarboxylase (GAD) antibodies

and antiamphiphysin antibodies. Antigens GAD65 and amphiphysin are located in the presynaptic terminals and thus are intracellular in location but are exposed to the extracellular environment during the recycling of the synaptic vesicles. Antibodies to both these antigens are associated with stiff person syndrome (10,11). The amphiphysin antibody is strongly associated with breast cancer, but anti-GAD is commonly nonparaneoplastic. Existing evidence supports both cell-mediated and antibody-mediated injury in anti-GAD antibody–associated disorders and predominantly antibody-mediated injury in amphiphysin-related conditions.

Anti-GAD Antibodies in Limbic Encephalitis and Epilepsy

Anti-GAD antibodies have been reported with multiple clinical syndromes such as stiff person syndrome, progressive encephalomyelitis with rigidity and myoclonus, ataxia, LE, and epilepsy (11–13). However, the exact pathogenic significance of the antibodies in causation of LE is debatable. In a series of 53 patients with LE, 9 (17%) were found to have anti-GAD antibodies and 10 patients had antibodies to VGKC complex (14). Patients with anti-GAD antibodies were younger, more likely to have refractory epilepsy, had less satisfactory response to immunotherapy, and also were more likely to harbor other antibodies. None of the patients with anti-GAD antibodies had neoplasms. The pathogenic role of anti-GAD antibodies (limited access to target antigen) has been questioned as GAD65 is a predominantly intracellular protein. Other yet to be characterized antibodies may play a role in the pathogenesis, and anti-GAD may be a marker for this disorder. From this perspective, the status of this anti-GAD encephalitis may be similar to antithyroid antibody–related neurologic disorders such as Hashimoto encephalopathy (HE). Anti-GAD antibodies have been studied in patients with epilepsy outside the setting of LE. In a case-controlled study of 253 patients with epilepsy, anti-GAD antibodies were noted in 15 (5.9%) epilepsy patients compared to 3 (1.5%) of 200 controls; temporal lobe epilepsy (TLE) predominated in this study (15). As noted in other studies, patients with anti-GAD antibodies were more likely to have other autoantibodies.

(iii) Antibodies to Neuronal Surface Antigens

Characterization of antibodies to neuronal cell surface antigens has advanced the field of autoimmune encephalitis significantly in the past decade (6). Research in patients with previously unknown nonparaneoplastic syndromes lead to discovery of several antibodies that have relevance to epilepsy. Some of the target antigens of these antibodies include N-methyl-D-aspartate (NMDA) receptors (16), voltage-gated potassium channel (VGKC) complex proteins (17–19), α-amino- 3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) receptors (20), and γ-aminobutyric acid B ($GABA_B$) receptors (21). The antibodies to these cell surface antigens have ready access to their targets and are likely to be pathogenic (1,6). Similarities between the symptoms of pharmacologic dysfunction of the receptors and these autoimmune disorders further strengthen the role of the antibodies in the pathogenesis. Clinical observation of recovery from the disease after immunotherapy targeted to reduce antibodies further confirms the pathogenic role of these antibodies (1).

VGKC Complex Antibodies

Antibodies to VGKC were initially recognized in neuromyotonia and later in Morvan syndrome. Later in 2001, initial reports of LE related to VGKC were reported (22). Early reports suggested that these

antibodies targeted potassium channel receptor subunits Kv1.1 and Kv1.2 (17,22). Subsequently, it was recognized in vitro studies, that antibody testing using cells expressing VGKC subunits were negative, thereby suggesting a possible role of other target antigens closely linked to VGKC (18,23). Further research in this area revealed three candidate antigens—Lgi1, Caspr2, and contactin-2. Lgi1 is a synaptic protein that binds to ADAM23 (a presynaptic protein) and ADAM22 (a postsynaptic protein), and it regulates the Kv1.1 and Kv1.2 subunits of VGKC. Caspr2 is located in the juxtanodal regions of the myelinated axons, and this along with contactin-2 and other proteins enables accumulation of VGKC subunits in the juxtanodal region. Lgi1 is primarily a CNS protein (hippocampus), and the Caspr2 is present in both the central and peripheral nervous system. The roles of the Lgi1 and Caspr2 are well established in LE, but contactin-2 was frequently noted along with other antibodies, and hence, its pathogenic significance is poorly understood (1,18,19,23).

In a series of 96 patients with "VGKC antibodies" (antibodies to VGKC extracted from mammalian brain tissue), only 3 had antibodies to potassium channel subunits (23). Majority of antibodies were directed to other proteins closely associated with VGKC: 55 patients had antibodies against Lgi1 antigen, 19 against Caspr2, and 5 against contactin-2. Remaining 18 patients had no antibodies to any of these antigens. Lgi1 antibodies are typically associated with nonparaneoplastic LE; neuromyotonia and Morvan syndrome presentations were much less frequent with Lgi1 antibodies (23). Recent reports suggest that some patients with Lgi1 antibodies may have a unique faciobrachial (sometimes crural) dystonic seizures, and this may herald the onset of LE (24,25). Sleep disorders (hypersomnia, insomnia, REM behavioral disorders) are frequent in one-third of patients. Hyponatremia was common (34 of 55 patients) in patients with Lgi1 antibodies. Two-thirds of patients with LE had medial temporal signal changes on MRI. Patients with Caspr2 antibodies had more variable manifestations including LE (7 of 19 cases), neuromyotonia (7 of 19 cases), and Morvan syndrome (3 of 19 cases). Caspr2 is also more closely linked to a paraneoplastic syndrome (thymomas). Response to immunotherapy is often good in these patients especially if they are nonparaneoplastic (18,19,23). It is interesting to note reports of mutations of genes of Lgi1 and Caspr2 being linked to seizures and encephalopathy (26,27).

Anti-NMDAR Encephalitis

Anti–N-methyl-D-aspartate receptor (NMDAR) encephalitis was first reported in 2007 as a paraneoplastic encephalitis in young women with ovarian teratoma (16). Classical clinical features include a prodromal phase of viral illness–like symptoms, followed by behavioral and neuropsychiatric symptoms of LE (delusions, hallucination, change in mood, behavior, personality, and temporal lobe seizures). Later, decreased level of consciousness, autonomic instability, extrapyramidal disorders, and not infrequently hypoventilation requiring mechanical ventilation may ensue (16,28). Abnormal sleep patterns—most frequently insomnia and occasionally hypersomnia—may occur. Despite a severe clinical course, most patients respond to immunotherapy and tumor removal. These patients were detected to have antibodies that target the NR1 subunit of the NMDAR, in their serum and CSF. In vitro studies in rodent brain have shown that these antibodies decrease the number of synaptic NMDA receptors. Later, it was discovered that anti-NMDAR encephalitis may occur as a nonparaneoplastic disorder (29,30). Several hundred cases have been since reported in both sexes and in all age groups, including young children. In children, nonparaneoplastic NMDAR encephalitis is more common (30–32). Seizures occur in more than two-thirds of patients and are common in both children and adults. Autonomic dysfunction is less frequent in children. Most

recently, the California encephalitis project that study the epidemiology of encephalitis found anti-NMDAR encephalitis as the leading cause for encephalitis in patients aged <30 years (33).

In a series of 100 patients that included children and adults, brain MRI has been reported to be abnormal in 55% of cases. Distributions of abnormalities include cortical/subcortical T2/FLAIR signal abnormalities (most frequently in temporal lobes), 39%; cerebellar, 6%; brainstem, 6%; and basal ganglia, 5%. Contrast enhancement was noted in the cortex, basal ganglia, or meninges in 14%. CSF analysis showed pleocytosis in 95% of patients. Oligoclonal bands were reported in 26% of patients. CSF abnormalities may vary depending on the stage of the disease, with CSF pleocytosis in the early stages and oligoclonal bands in the later stages of the disease. EEG abnormalities can be nonspecific with slow wave and/or focal epileptiform abnormalities (28). Recently, a unique EEG pattern termed as "extreme delta brush" has been noted in 30% of adult patients with anti-NMDAR encephalitis (34). This pattern consists of a diffuse, delta (approximately 1 Hz) slowing with superimposed bursts of beta frequency activity in the frontal regions, thus morphologically resembling the delta brushes seen in neonates.

Treatment consists of corticosteroids, intravenous immunoglobulin, and/or plasma exchange as first-line therapy. Tumor removal is critical for rapid recovery in paraneoplastic cases. In patients with poor response to first-line therapy, treatment with cyclophosphamide or rituximab may be necessary. Response to treatment is good with over 75% (in a series of 100 patients) making substantial or full recovery. Patients with tumor that was removed early recovered better than those without tumor. Relapses may occur in 15% of patients (28).

Anti-AMPA Receptor Encephalitis

Anti-AMPA receptor encephalitis is another newly recognized cause for paraneoplastic and nonparaneoplastic autoimmune encephalitis, first reported in 2009 (20). AMPA are a form of glutamate receptors formed by tetramers of GluR1, R2, R3, and R4 subunits. AMPA receptors in hippocampus are composed predominantly of GluR1 and R2 heteromers. Using sera and CSF from patients with LE positive for immunoreactivity to neuropil antigens (negative for previously known antibodies) on tissue studies, the target antigen was determined to be GluR1/R2 receptors (1,20,35). Further studies confirmed that these antibodies decrease the number of AMPA receptors and thus are directly pathogenic. Immunohistochemistry of the tumor tissues in paraneoplastic cases confirmed expression of GluR1/R2 antigen in the tumor cells. In a series of 10 patients, the median age at presentation was 60 years. LE was the primary manifestation in these patients, presenting with a subacute memory loss, confusion, and disorientation. Seizures were reported in four patients, with refractory status epilepticus in one. CSF pleocytosis is common, and bilateral medial temporal lobe abnormalities on MRI typical of LE were noted in 80% of patients. Seven of 10 patients had underlying neoplasms—tumors of the thymus in 3, lung in 2 and breast in 2 patients (20).

Immunotherapy used in these patients was similar to treatment described earlier in anti-NMDAR encephalitis. All nine patients who received immunotherapy improved. Relapses of LE were reported in five patients. Prevention and treatment of relapses are important for long-term prognosis. Neurologic prognosis is unaffected by the tumor per se, but presence of other antibodies may influence the outcome (20). One patient with anti-GAD antibodies and another with anti-CRMP2 had poor outcome. This may indicate additional T-cell–mediated injury mechanisms, which often respond poorly to immunotherapy.

Anti-$GABA_B$ Receptor Encephalitis

Anti-$GABA_B$ receptor encephalitis was first reported in 2010 from a pool of patients with paraneoplastic/immune-mediated encephalitis negative for previously well-recognized antibodies (21). A subsequent series of 20 patients with anti-$GABA_B$ antibodies emphasized the LE presentation in 17 patients; others presentations include ataxia, opsoclonus–myoclonus syndrome, and status epilepticus (36). Similar to anti-AMPA receptor encephalitis, patients with anti-$GABA_B$ receptor encephalitis are older (median 60 years). Seizures are frequent in up to 80% of patients. Striking MRI T2/FLAIR signal abnormalities in one or both medial temporal lobe abnormalities occur in two-thirds of patients. Mild pleocytosis was noted in 68% of patients, and minimal elevation of CSF protein is common. About half of the patients with anti-$GABA_B$ receptor encephalitis had SCLC, and a quarter had other onconeuronal antibodies to antigens such as Ri, amphiphysin, or SOX1; two patients without tumor had NMDAR and GAD65 antibodies. Of 17 patients (in a series of 20) with anti-$GABA_B$ receptor encephalitis who had immunotherapy, complete neurologic recovery was noted in 7 and partial recovery in 8 patients. Presence or absence of tumor determines the long-term prognosis, worse in the former (36,37).

(iv) Antibodies of unclear significance: Antithyroid antibodies and Hashimoto Encephalopathy

Hashimoto encephalopathy (HE) was one of the early recognized entities with presumed autoimmune basis with excellent response to steroids in many cases. Unlike other cases with LE, the presentation in HE is variable. Two common presentations include acute encephalopathy with myoclonus and generalized tonic-clonic seizures, and stroke-like presentation with encephalopathy (38,39). Presence of antithyroid antibodies (anti–thyroid peroxidase and/or antimicrosomal) associated with Hashimoto thyroiditis was a clue to the autoimmune nature of the disorder. Later, it was confirmed that the thyroid antibodies per se do not have any direct pathogenic role, and they may serve merely as a marker for the autoimmune disorder. It is well known that patients with preexisting autoimmune disorders are more prone to develop other autoimmune disorders. Thus, HE may be viewed as an autoimmune neurologic disorder in a patient with Hashimoto thyroiditis. As thyroid antibodies are relatively common in general population, any altered mental status in a patient with thyroid antibodies carries the risk of being labeled as HE. Hence, many authors preferred to include treatment response to steroids as a key criterion in the diagnosis of this disorder. As the thyroid antibodies has no relevance to the disease (other than a surrogate marker), alternate terms such as “steroid-responsive encephalopathy associated with autoimmune thyroiditis” (SREAT) has been proposed (40).

In a review of 85 patients with HE, the mean age at presentation was 44 years (range, 9 to 78 years) with women 3.5 times more commonly affected than men (38). Clinical manifestations included seizures (66%), myoclonus (38%), status epilepticus (12%), stroke-like episodes (27%), and psychosis (38%). A Creutzfeldt–Jakob disease–like presentation has also been described. Mild elevations of protein in CSF are common. Brain MRI frequently show varying degrees of white matter abnormalities without any diagnostic pattern. EEG may show slowing or epileptiform abnormalities and not infrequently triphasic waves. Thyroid status ranged from hypo- to hyperthyroidism, but subclinical hypothyroidism was the most common abnormality. Of those treated with steroids, 96% improved with therapy. A remitting–relapsing course was noted in as high as 60%

of patients. As clinical features of SREAT and other autoimmune LE related to known antibodies (e.g., VGKC complex, NMDAR, etc.) overlap, all patients should undergo testing for these better established entities (40,41). Thus, the diagnosis of SREAT remains a diagnosis of exclusion.

EPILEPSY WITH AN OCCULT AUTOIMMUNE ETIOLOGY

The field of autoimmune/LE has advanced tremendously in the past decade with the discovery of newer antibodies and recognition of nonparaneoplastic entities. As seizures are a common manifestation in patients with autoimmune encephalitis, researchers attempted to study the autoimmune mechanisms in patients with refractory epilepsy. Furthermore, many of the target antigens to recently recognized antibodies were closely linked to epileptogenesis. Autoantibodies in patients with refractory epilepsy have been reported in the recent years, but the true pathogenic role of these antibodies in patients with isolated refractory epilepsy is still a matter of debate (4,42–45). As some of these autoantibodies may be present in normal population, the significance of the "positive antibodies" in the serum should be carefully interpreted. This is similar to a positive antinuclear antibody in a patient with chronic aches and pains, and trying to make sense if the patient has an underlying autoimmune disorder. Large case–control studies are required to address the significance of such results.

Autoimmune Mechanisms in Adult-Onset Temporal Lobe Epilepsy

Similarities in the involvements of substrates (temporal and other limbic structures) in TLE and LE prompted researchers to postulate LE as an initiating event in some adult-onset TLEs (46,47). As a significant proportion of adult-onset TLE do not have a precise etiology, the autoimmune hypothesis appeared exciting and was explored. Bien et al. (47) studied a series of 38 patients with adult-onset TLE (median age at onset, 37.5 years) and found a possible autoimmune etiology in 20 (53%) patients. Nine of these patients had definite preceding LE, and the other 11 had features of hippocampal swelling preceding atrophy, suggesting an inflammatory process at the onset. Referral bias and lack of control data may have affected the results in this study, but the possibility of autoimmune process as etiology in some patients with adult-onset TLE remains. However, the lack of inflammation on most surgical temporal lobectomy specimens is a major argument against an active ongoing inflammatory process. One of the plausible ways to explain the lack of inflammation on histopathology is to postulate two different phases for LE-related TLE: an acute or subacute inflammatory phase of LE and a chronic phase of TLE (46,47). The initial inflammatory phase could be for few weeks or months with a monophasic course followed by a chronic course of medically intractable epilepsy. Surgery is typically performed in the later phase thus potentially explaining the lack of active inflammation. This may also mean that anti-inflammatory immunotherapy may not be effective once chronic epilepsy is established. Whether the course of the epilepsy may be affected by early immunotherapy remains to be proven.

Febrile Infection–Related Epilepsy Syndrome

New-onset refractory status epilepticus (NORSE) without an obvious etiology is the hallmark of febrile infection–related epilepsy syndrome (FIRES) (48–50). This syndrome has been reported by

various authors under different names, including devastating epilepsy in school-age children (DESC), acute encephalitis with refractory repetitive partial seizures (AERRPS), and fever-induced refractory epileptic encephalopathy in school-age children (FIRES). Another related entity NORSE was primarily reported in adults and may be different from FIRES. In a retrospective multicenter study of 77 patients with FIRES, the median age of onset of FIRES was 8 years (49). Patients often have a prodromal febrile illness followed by explosive-onset epilepsy. Seizures are usually partial with or without secondary generalization. EEG shows multifocal epileptogenicity (commonly temporal and frontal regions) in majority of cases. Seizures are refractory despite aggressive medical therapy. Most patients require continuous intravenous sedative medications to achieve medication- induced burst suppression (49).

In the series of 77 patients with FIRES, prognosis was poor in majority. Nine patients (12%) died during the acute phase, and 93% of survivors had refractory epilepsy on follow-up. Only 12 of the survivors recovered to a relatively normal cognitive level (49). Extensive workup for infections and metabolic and genetic causes has been negative in these patients. Common abnormal findings on MRI include bilateral hyperintense signal changes in hippocampi and occasionally in the peri-insular region. Autoimmune mechanisms have been proposed as the etiology, but no definite evidence has been found to support this hypothesis; published reports with brain biopsy reported no inflammation (51). A recent study on known neuronal antibodies has not shown any markers. No treatment has been shown to have a consistent positive response. Anecdotal success with steroids or IVIG has been reported, but several patients in large series showed no response to multiple modes of immunomodulation. The pathogenesis of FIRES remains unresolved at this time.

Autoantibodies in Chronic/New-Onset Epilepsy

Autoimmune mechanisms have been explored in other types of chronic/new-onset epilepsy as well. Initial reports suggested increased occurrence of GAD antibodies in patients with epilepsy, more frequently in TLE (15). Recent studies reported the occurrence of other antibodies in patients with epilepsy.

In a recent prospective case-controlled study of 114 children with new-onset epilepsy and 65 children without epilepsy, 9.7% in the epilepsy cohort were positive for one of the autoantibodies compared to 4.6% of controls (difference not statistically significant) (52). VGKC, NMDAR, and Caspr2 were the antibodies detected; two patients had both VGKC and NMDAR antibodies detected in their serum. Seven of the 10 positive patients had been categorized as “unknown cause” based on the recently proposed etiologic categories of epilepsy by ILAE. Other three patients had “known etiologies” that include MELAS (Mitochondrial encephalomyopathy, lactic acidosis and stroke like episodes), partial callosal agenesis and heterotopia, and febrile seizure plus syndrome. Positive antibodies in well- established genetic conditions raise concerns about “false- positive” tests. Authors of this study are appropriately cautious about the significance of the positive antibodies alerting to the possibility of an epiphenomenon secondary to neuronal injury and activated immune system (52,53). In a similar study in adults, the antibodies were noted to be equally prevalent in new-onset epilepsy as well as established cases of chronic epilepsy, arguing against this being an epiphenomenon (54). Of note, none of the patients in these studies received any immunotherapy driven by antibody testing.

Another recent retrospective study provides more compelling evidence to support autoimmune etiology with some insight into the response to treatment (55). In this case series, 32 patients with

suspected autoimmune epilepsy were studied. Recurrent medically refractory seizures were the primary manifestation in this cohort. Autoimmune etiology was supported by one or many of the following features: positive autoantibodies (91%), inflammatory findings on CSF (31%), and "inflammatory pattern" on MRI (63%). Autoantibodies detected include VGKC complexes (56%), GAD65 (22%), and CRMP-2 in two patients; and anti-NMDAR, Ma-2, and ganglionic acetylcholine receptor antibody in one patient each. Findings from this study suggest that patients with unusually high seizure burden, multifocal epilepsy, coexisting other autoimmune disorders, and prior history of tumors are more likely to have an autoimmune etiology. Majority of patients in this study (27 of 32) received immunotherapy. At a median follow-up of 17 months, 67% were seizure free and 81% reported significant improvement. Majority of the patients in this series had daily seizures despite two or three antiepileptic drugs prior to immunotherapy, and thus the improvement in seizure control is beyond expected for usual change of antiepileptic drugs, which was not restricted during the immunotherapy. Patients with shorter time before initiation of immunotherapy responded better than patients who were treated late (55). This report suggests that, it may be reasonable to consider immunotherapy such as a course of steroids or intravenous immunoglobulin in patients with evidence for autoimmunity and refractory epilepsy. Potential benefits of immunotherapy should be carefully weighed against the risks of the treatment, and the treatment for each patient should be individualized.

Positive Autoantibodies: True Positive or False Positive?

Understanding the true significance of a positive antibody test in serum has always been a problem in autoimmune disorders as these antibodies may be present in normal population or it may be a nonspecific marker of immune activation following tissue injury. In general, any positive diagnostic test should be validated by comparison with a diagnostic gold standard test. However, no such gold standard test exists in this new field of autoimmune epilepsy. In the absence of such a specific gold standard test to compare with, a definitive clinical diagnosis is critical to assign the significance of a positive autoantibody test. This is best illustrated in the experience of positive GluR3 antibodies in RE. Early reports of GluR3 antibodies in RE raised the possibility of this being antibody-mediated encephalitis. However, later reports showed that GluR3 is neither a specific nor a sensitive marker for RE (56–58). It was noted to be positive in other focal epilepsies and was concluded that these antibodies were an epiphenomenon (58). In the case of RE, the significance of the antibody test could be studied, as the diagnosis of RE could be made with reasonable confidence on clinical and radiologic grounds. In the recent reports of "autoimmune epilepsy," there is no such gold standard to determine if these antibodies are truly significant. Establishing a clinical diagnostic gold standard may be required to verify the utility of these antibody tests.

Lancaster and Dalmau (1) caution about the false-positive antibodies in serum and warn against overreliance on serum testing in LE. Antibody tests using cell-based assay are generally considered significant when both serum and CSF shows typical well-defined antibodies in a compatible clinical setting. If only serum is tested positive and CSF is negative, these researchers recommend further testing of the serum using rat brain immunohistochemistry and cultures of neurons. If the tissue studies show immunoreactivity, an autoimmune diagnosis can be made. Such approaches have been used in identifying the antibodies (NMDAR) in schizophrenia, and the differences in results of antibody positivity among different studies were considered to be due to various degrees of specificity (some based on cell-based assay alone) (1,59). Similar approaches may be required to determine the significance of these antibodies in patients with isolated refractory epilepsy.

CONCLUSION

In the field of LE, many of the unknowns of the past have been proven to be autoimmune syndromes mediated by specific autoantibodies. Similarly, it remains to be proven if some patients with epilepsy of "unknown etiology" finally get categorized to be "autoimmune epilepsy." Currently, for general neurologists and epileptologists, investigating and treating a patient with an unequivocal presentation of LE poses minimal challenges. The workup (CSF analysis, testing for autoantibodies, imaging to look for occult tumors) and aggressive immunotherapy (steroids, intravenous immunoglobulins, and/or plasma exchange, and for refractory cases, cyclophosphamide and/or rituximab) are fairly straight forward from the existing current literature. On the contrary, investigating for autoimmune etiology in patients with isolated epilepsy presentation is faced with several questions. Who should be tested? How to interpret the results? How to distinguish true- from false-positive tests? What is optimal or sufficient autoimmune therapy? Further large-scale studies are needed to answer these questions. Acute/subacute presentation with difficult to control epilepsy, unknown etiology, preexisting autoimmune disorders, prior history of neoplasms, signs of CNS inflammation on MRI, focal hypermetabolic regions on brain fluorodeoxyglucose–positron emission tomography, CSF pleocytosis, elevated neopterins or presence of oligoclonal bands in CSF may be some of the indicators that may alert to the possibility of autoimmune epilepsy (55). Autoimmune workup and a trial of immunotherapy may be considered in selected patients with strong indicators of autoimmune epilepsy.

SECTION C DIAGNOSIS AND TREATMENT OF SEIZURES IN SPECIAL CLINICAL SETTINGS

ASSOCIATE EDITOR: HOWARD P. GOODKIN

CHAPTER 34 FEBRILE SEIZURES

SYNDI A. SEINFELD AND MICHAEL DUCHOWNY

Children with febrile seizures usually have better outcomes than children with epileptic convulsions. Although research supports most febrile seizures as being relatively benign, it is now accepted that a subgroup of children will experience consequences.

The National Institutes of Health (NIH) Consensus Development Conference on the Management of Febrile Seizures defined a febrile seizure as an event, usually occurring between 3 months and 5 years of age, which is associated with fever (1). There cannot be an intracranial infection or defined cause of the seizure. The International League Against Epilepsy Commission gives another operational definition of febrile seizures. It defines a febrile seizure as a seizure occurring in childhood after 1 month of age that is associated with a febrile illness not caused by a central nervous system (CNS) infection (2). These definitions emphasize age specificity and the absence of underlying brain abnormalities. In clinical practice both definitions must be interpreted with caution as intracranial infection may not be readily apparent, especially in very young infants.

The documented incidence of febrile seizures, from multiple studies, is 2% to 5% in the United States and Western Europe (3,4), but higher in other countries. For example, Japan has an incidence over 8% (5), India up to 10% (6) and Guam up to 14% (7). Familiarity with the clinical manifestations and long-term prognosis of these common events is essential in caring for affected individuals. Epidemiologic studies have been especially useful in identifying features of the seizures or the patients that are at risk for adverse consequences. Understanding these factors forms the basis of proper seizure management and family counseling.

PREDISPOSING FACTORS

Genetics

There is no consensus regarding the mode of inheritance of febrile seizures or their clinical expression. Currently most febrile seizures are assumed to have a polygenic basis (8). Febrile seizures are approximately two to three times more common among family members of affected children than in the general population (9,10). Significantly higher concordance rates are seen for febrile seizures in monozygotic twins as compared to dizygotic twins in multiple twin registries (11). A higher incidence of afebrile epilepsy has been found in first-degree relatives of patients with febrile seizures (12,13). The occurrence of febrile seizures in first-degree relatives is a risk factor for febrile seizure recurrence (14).

Sodium channel and GABA receptor gene mutations have been identified in families with febrile seizure related syndromes (15–17). Despite the identification of multiple febrile seizure loci and mutated genes, little evidence points to their direct contribution in the majority of febrile seizures reported in the most affected individuals.

The autosomal dominantly inherited syndrome of generalized epilepsy with febrile seizures plus

(GEFS+) was first described in a large kindred from rural Victoria, Australia (15). The clinical phenotype includes febrile seizures in early childhood, followed by persistent febrile seizures beyond age 6 years and a variety of heterogeneous afebrile generalized seizure phenotypes. Affected children typically cease having seizures by mid-adolescence. A missense mutation in the gene that encodes the neuronal voltage-gated SCN1A in families of GEFS+ patients has been identified in approximately one-third of patients with Dravet syndrome, a disorder typically presenting in infancy with febrile status epilepticus followed by multiple pharmaco-resistant seizure types (18). As the initial development and EEG studies are normal in children with Dravet syndrome, early diagnosis may be extremely challenging. The emergence of other seizure types and developmental regression between the ages of 1 and 4 years provide clues to diagnosis. Intellectual functioning is almost always severely impaired in children with Dravet syndrome.

Age

The onset of febrile seizures generally follows a bell-shaped pattern. Ninety percent of seizures occur within the first 3 years of life (4), 4% before 6 months, and 6% after age 3 years. Approximately 50% appear during the second year of life, with a peak incidence between ages 18 and 24 months (4). Children with longer febrile seizures have a younger median age at first febrile seizure (19). The limited age range in febrile seizures has never been satisfactorily explained, but presumptively is genetically determined.

Fever

Febrile seizures typically occur relatively early in an infectious illness. The contribution of the rate of rise versus the final temperature reached in inducing the seizure has been debated, but is not thought to cause febrile seizures. The incidence of febrile seizures does not increase in proportion to temperature elevation, and febrile seizures are generally uncommon in the later stages of a persistent illness. Febrile seizures typically are associated with common childhood illnesses, but none of the common childhood infectious illnesses is uniquely capable of activating febrile seizures.

Febrile seizures that occur after vaccination have not been found to be different from febrile seizures from any other cause, although vaccinations trigger the onset of seizures in one-third of patients with Dravet syndrome (20). The previously used whole-cell diphtheria/tetanus/pertussis and measles-containing vaccines have an established association with febrile seizures, but a newer acellular diphtheria, tetanus, and pertussis (DTaP) vaccine is less reactogenic and does not increase the risk of febrile seizures (20).

Associated Factors

The Danish birth cohorts (Aarhus Birth Cohort, Aalborg-Odense Cohort and the Danish National Birth Cohort) have demonstrated that low birth weight and short gestational age are significant risk factors for febrile seizures (21). Another study that evaluated occurrence of febrile seizures concluded that fetal growth retardation is associated with increased risk of febrile seizures and that adverse environmental and genetic factors during pregnancy may be important in the development of febrile seizures (22).

Proinflammatory cytokines have also been implicated in the pathogenesis of febrile seizures. Interleukin (IL)-1β, tumor necrosis factor-α, and nitrite levels are all increased in the CSF of children

with a febrile seizure (23). Increased secretion of IL-6 and IL-10 by liposaccharide-stimulated mononuclear cells is higher in patients with a history of previous febrile seizures (24). Other studies have proposed that there is a link between febrile seizures and a systemic respiratory alkalosis, irrespective of the severity of the underlying infection (25).

TYPES OF FEBRILE SEIZURES

Simple Febrile Convulsions

Simple febrile convulsions are solitary events, lasting <15 minutes and lacking focality. They occur in neurologically normal children and are not associated with persistent deficits. The source of the fever is always outside the CNS.

Simple febrile seizures are the most common type of febrile seizures. The current American Academy of Pediatrics (AAP) guideline for evaluation of a first simple febrile seizure is that the clinician should identify the source of the fever when a child presents within 12 hours of a simple febrile seizure (26). Because seizures in the setting of a febrile illness may result from CNS infection, trauma, or electrolyte disturbance, laboratory investigation is usually warranted even when findings on the physical examination are normal.

The evaluation of simple febrile seizures should rely primarily on careful history taking, and judicious laboratory and radiologic testing. The American Academy of Pediatrics, through its Committee on Quality Improvement, published practice parameters dealing with the evaluation of the child with a first febrile seizure and the long-term treatment of the child with simple febrile seizures that were updated in 2011 (26). The new recommendations suggest that for the first episode of simple febrile seizure a lumbar puncture is indicated only with signs suggestive of meningitis. Lumbar puncture should also be considered if there has been prior antibiotic treatment or in infants between ages 6 and 12 months if the child is not properly vaccinated against Haemophilus and Streptococcus pneumoniae.

Multiple studies evaluating the role of lumbar puncture in patients with simple febrile seizures provide no support for routine CSF sampling. Recent US studies suggest that the risk of bacterial meningitis presenting as a first simple febrile seizure is very low (27,28). The need for a lumbar puncture when a patient presents with febrile status epilepticus has not been revised. As part of the FEBSTAT study, 136 children had CSF samples from a non-traumatic lumbar puncture done on initial presentation, and it was confirmed that febrile status epilepticus rarely causes CSF pleocytosis (29). The CSF glucose and protein levels were unremarkable, and the temperature, age, seizure focality, and seizure duration did not affect results. Thus, CSF pleocytosis should not be attributed to febrile status epilepticus.

Electroencephalography has not been particularly useful in the evaluation of simple febrile seizures. Hospitalization is rarely necessary following a simple febrile seizure.

Complex Febrile Seizures

Febrile seizures that do not meet the criteria for simple febrile seizures are considered “complex.” The concept of a “complex” febrile seizure originated with epidemiologic studies indicating that several patient- and seizure-related variables predicted higher rates of subsequent epilepsy: seizure duration longer than 15 minutes, focal seizure manifestations, seizure recurrence within 24 hours,

abnormal neurologic status, and afebrile seizures in a parent or sibling (30). Six percent of patients with two or more risk factors developed afebrile epilepsy by the age of 7 years, compared with only 0.9% if risk factors were absent (30).

Febrile seizure duration can be represented by a model that accounts for two populations of children. One has a short duration and the other has a long duration, with a cutoff between the two being 10 minutes (19). Prolonged febrile seizures, lasting more than 10 minutes, are unlikely to stop spontaneously (31). If a patient presents with focal complex febrile seizure one should consider performing brain MRI to evaluate for a structural abnormality as an explanation for the seizure (31).

Studies conducted at the Mayo Clinic reveal a less favorable prognosis for patients with complex febrile seizures (32). Seventeen percent of neurologically impaired children with complex febrile seizure manifestations developed epilepsy by the third decade, compared with 2.5% of children who lacked risk factors. The occurrence of focal, recurrent, and prolonged seizures raised the risk for afebrile episodes to nearly 50%. Developmental delay and a younger age are associated with prolonged febrile seizures (19).

Complex febrile seizures must be managed more aggressively than simple febrile seizures. Meningitis must be excluded by history, but when there is a concern of fever etiology a CSF examination and neuroimaging studies are indicated.

Although children with complex febrile seizures are expected to have a higher rate of abnormal EEG recordings, confirmatory data are sparse. An EEG to evaluate for underlying focal abnormalities can assist with education and evaluation planning.

Febrile Status Epilepticus

Although most febrile seizures are self-limited, prolonged episodes and febrile status epilepticus are not rare, and constitute an important subgroup of complex febrile seizures. The phenomenology of febrile status epilepticus is currently being investigated in a prospective multi-center study. The study, Consequences of prolonged febrile seizures (FEBSTAT), recruited 199 children aged 1 month through 5 years who had a febrile seizure that lasted more than 30 minutes (31). Children recruited most often had focal seizures that were usually their first febrile seizure. Seizure duration in this group was typically very prolonged suggesting that the longer the seizure continued, the less likely it was to spontaneously cease.

The FEBSTAT study performed baseline EEGs within 72 hours of the episode of febrile status epilepticus. Review of their baseline EEGs showed that there was focal slowing or attenuation in a substantial proportion of children, and the slowing and attenuation were highly associated with MRI evidence of acute hippocampal injury (33). The study concluded that these EEG findings may be used as a sensitive and readily obtainable marker of acute injury associated with febrile status epilepticus.

An association between female sex and febrile status epilepticus has been observed in some studies (34), whereas others (4,31,35) have found a slight male predominance.

RISK ASSESSMENT IN FEBRILE SEIZURES

Febrile Seizure Recurrence

Approximately one-third of patients with febrile seizures experience additional attacks; of this group, one-half will have a third seizure (36,37) and 9% experience more than three attacks (30).

Age of onset is the most important predictor of febrile seizure recurrence. One-half of all infants younger than 1 year of age at the time of their first febrile seizure will have a recurrence, compared with 20% of children older than 3 years of age. Young age at onset, a history of febrile seizures in first-degree relatives, low-grade fever in the emergency department, and brief interval between fever onset and seizure presentation are strong independent predictors of febrile seizure recurrence (38). Recurrences generally occur within 1 year but are no more likely in children who had a complex febrile seizure than in those who experienced a simple febrile seizure. There is no evidence supporting a statistically significant relationship between the duration of a first febrile seizure and a recurrence (19).

Children with multiple risk factors experience the highest rates of febrile seizure recurrence. The presence of two or more risk factors is associated with a 30% or greater recurrence risk, whereas three risk factors are associated with a 60% or greater recurrence risk (38).

Epilepsy and the Association of Febrile Seizures with the Development of Hippocampal Sclerosis

Between 1.5% and 4.6% of children with febrile seizures develop afebrile seizures (39–42). This rate is significantly higher than in the general population and reflects primarily infants and children with one or more complex febrile seizures (30,43). The presence of a neurodevelopmental abnormality, a family history of epilepsy, and prolonged duration of fever are also proven risk factors for the development of epilepsy after experiencing a febrile seizure (44).

Although this association between febrile seizures and epilepsy is well documented, the mechanism that underlies this association is much less clear. A long-term goal of the prospective FEBSTAT study is to better define the relationship between prolonged febrile seizures, hippocampal sclerosis (HS) and mesial temporal lobe epilepsy (MTLE). Prior retrospective studies conducted in adults with MTLE found a significant association with febrile seizures but there has been no prospective confirmation of this relationship. To-date, the FEBSTAT study has performed a baseline MRI, with special attention to the hippocampus on 191 of the recruited children. A statistically significant abnormal or equivocally increased hippocampal T2 signal following febrile status epilepticus was observed in 22 children compared with none in the control group (31,45). Figure 34.1 demonstrates an example of MRI changes that have been seen in children that have had an episode of febrile status epilepticus. In addition, developmental abnormalities of the hippocampus were more common in the febrile status epilepticus group, with hippocampal malrotation being the most common finding. These imaging findings demonstrate that children with febrile status epilepticus are at risk for acute hippocampal injury and abnormalities in hippocampal development (45). Longer follow-up will be required to document whether these children develop MTLE and at what rate.

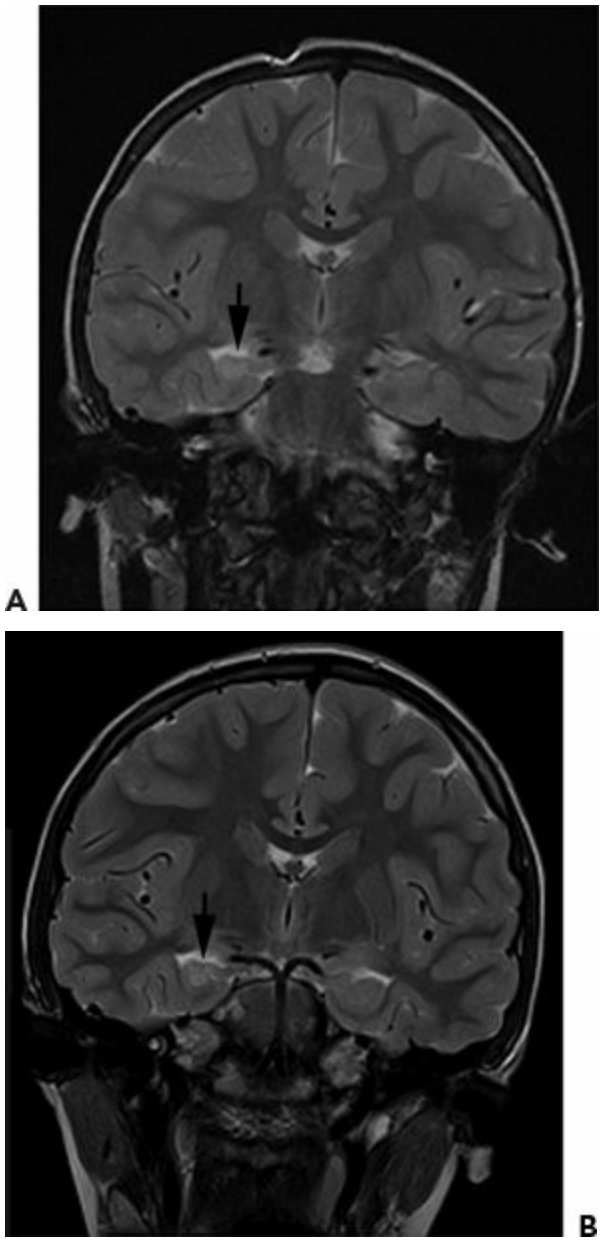

Figure 34.1. Brain MRI of a child that had a 2-hour febrile convulsion. **A:** Coronal image obtained from brain MRI performed <6 months after febrile status epilepticus. Image shows abnormal high T2 signal in the right hippocampus with slight volume loss. **B:** Coronal image obtained from brain MRI performed approximately 5 years after febrile status epilepticus. Image shows increased T2 signal intensity within the right hippocampus with associated slight volume loss.

Human Herpes Virus

Human herpes virus 6 (HHV6) is a common childhood infectious agent responsible for roseola infantum and several severe infectious syndromes. In immunocompromized patients, reactivation of viral activity may lead to severe limbic encephalitis. Examination of temporal lobectomy specimens reveals a high incidence of active HHV6B replication in hippocampal astrocytes (46). This association suggests a possible link between early viral infection, complex or prolonged febrile seizures and later HS.

As part of the FEBSTAT study, serum was evaluated for the presence of HHV-6A, HHV-6B, or HHV-7 DNA and RNA (31,47). The study concluded that HHV-6B infection is commonly associated with febrile status epilepticus, and HHV-7 infection is less frequently associated. Together HHV infections were identified in one-third of the febrile status epilepticus subjects (47). The study did not detect HHV-6B or HHV-7 DNA in the CSF of 23 subjects who presented in febrile status epilepticus

and had a documented HHV-6B or HHV-7 viremia.

FEBRILE SEIZURES AND NEUROPSYCHOLOGICAL STATUS

The consequences of febrile seizures on later intellectual functioning and behavior of children has been studied extensively. A cohort of 381 children with simple and complex febrile seizures was compared with a control group on measures of academic progress, intelligence, and behavior; there were no differences between groups in any measures (48).

Two large, longitudinal, population-based studies provide strong evidence that febrile seizures do not adversely affect neuropsychological status. Ellenberg and Nelson (49) studied intellectual and academic function following febrile seizures in 431 sibling pairs 7 years of age who were part of the National Collaborative Perinatal Project. Children with febrile seizures and normal intelligence achieved reading and spelling milestones at rates similar to those of their seizure-free siblings. The National Child Development Study, completed in the United Kingdom, also found that children with febrile seizures did not differ from controls in behavior, height, head circumference, or academic achievement (40). It is important to remember that the consequences of febrile seizures can be influenced by seizure duration.

THERAPY

It is accepted that antipyretic agents do not reduce the risk of febrile seizure or seizure recurrence. Prophylactic antiepileptic drug (AED) therapy for febrile seizures should be withheld, as the benefits of treatment do not outweigh the risks. Recurrent febrile seizures and later afebrile epilepsy, which are the major sequelae of a febrile seizure, are both rare. Despite their anxiety, family members should be counseled about the merits of withholding prophylactic treatment.

There are exceptions to the use of AEDs following the occurrence of complex febrile seizures, for example when there is significant risk for later epilepsy. However, even seemingly life-threatening seizures must be evaluated cautiously because neurologic impairment and death are extremely unlikely, even after febrile status epilepticus. The NIH consensus panel found that high-risk patients with two risk factors (e.g., abnormalities on neurologic examination, prolonged focal seizure, and family history of epilepsy) still had only a 13% chance of developing epilepsy. Moreover, although phenobarbital reduced febrile seizure recurrence, there is no firm evidence that the prevention of recurrent febrile seizures diminishes the risk for later epilepsy.

Febrile seizures often cease by the time a child is examined, but prolonged episodes should be treated similar to seizures of any other etiology. A child that is actively having a seizure should receive acute abortive treatment by 5 minutes after seizure onset. All prolonged convulsions carry an increased risk of complications, and treatment should be initiated before 5 minutes after seizure onset to help prevent prolonged seizure activity and consequences. A prolonged FS should be treated promptly by emergency medical services (EMS) or the emergency department. Initially a benzodiazepine should be used, for example rectally administered diazepam gel, but if continued seizure activity a full status epilepticus protocol should be initiated (44).

CONCLUSIONS

Febrile seizures are the most common seizure presentation in infancy and early childhood and are usually benign. Most events are self-limited and carry only a modest risk for febrile seizure recurrence. Febrile seizures are thus a genetically predetermined, age-dependent response to fever and are not classified as epilepsy. Treatment with prophylactic AEDs is not indicated. Febrile status epilepticus is frequently unrecognized and prolonged seizures frequently need medication to terminate the seizure (31). Unfortunately a small percentage of children with prolonged febrile seizures do have long term consequences.

Fewer than 10% of patients with febrile seizures experience severe or recurrent attacks. Risk factors for complex episodes are known, and the likelihood of developing epilepsy remains <5%. Diagnostic procedures or treatment should be performed on an individual basis; febrile status epilepticus must be treated as a medical emergency. Underlying neurologic disorders require investigation, and "epileptic seizures exacerbated by fever" should be distinguished from febrile seizures per se. There is no evidence that prophylactic administration of AEDs prevents the occurrence of later epilepsy.

CHAPTER 35 NEONATAL SEIZURES

KEVIN CHAPMAN, ELI M. MIZRAHI, AND ROBERT RYAN CLANCY

Neonatal seizures are a classic and ominous neurologic sign that can arise in any newborn infant. Their significance lies in their high incidence, association with acute neonatal encephalopathies, substantial mortality, neurologic morbidity, and the concern that seizures per se could extend the acute brain injury. Seizures in the neonate differ clinically and electrographically from those in mature infants and children. Diagnostic and treatment decisions remain limited by a paucity of rigorous scientific data for this population. This chapter reviews the significance of neonatal seizures; the pathophysiologic basis of clinical, electroclinical, and electrographic seizures; prognostic expectations; and etiologies and surveys current treatment options that might themselves pose a risk to the developing brain.

HISTORICAL BACKGROUND

The appearance of "seizures," "fits," or "convulsions" in newborn infants has been known since antiquity. It was naturally assumed that clinical seizures in neonates were always associated with abnormal, excessive, paroxysmal electrical discharges arising from repetitive neuronal firing in the cerebral cortex. Despite the identification of electroclinical correlations of seizures in mature individuals, progress in understanding the nosology of neonatal seizures was only recently notable. Although some neonatal seizures are accompanied by simultaneous epileptic discharges seen on EEG, not every clinical event in a neonate presenting as an abrupt "attack" is truly epileptic, and the relationship between neonatal seizures and the conventional connotations of the term epilepsy demands careful scrutiny. Thus, seizures in the neonate are now distributed into three classes (Fig. 35.1). "Electroclinical" seizures are abnormal, clinically observable events that are consistently founded on a specific epileptic mechanism and coincide with an obvious electrographic seizure during simultaneous EEG monitoring. "Clinical-only" seizures refer to other abnormal-appearing abrupt clinical events that are not associated with simultaneous electrographic seizure activity during EEG monitoring; they may be considered a type of nonepileptic seizure; "EEG-only" seizures lack definite clinical seizure activity; they are also called "subclinical" or "occult."

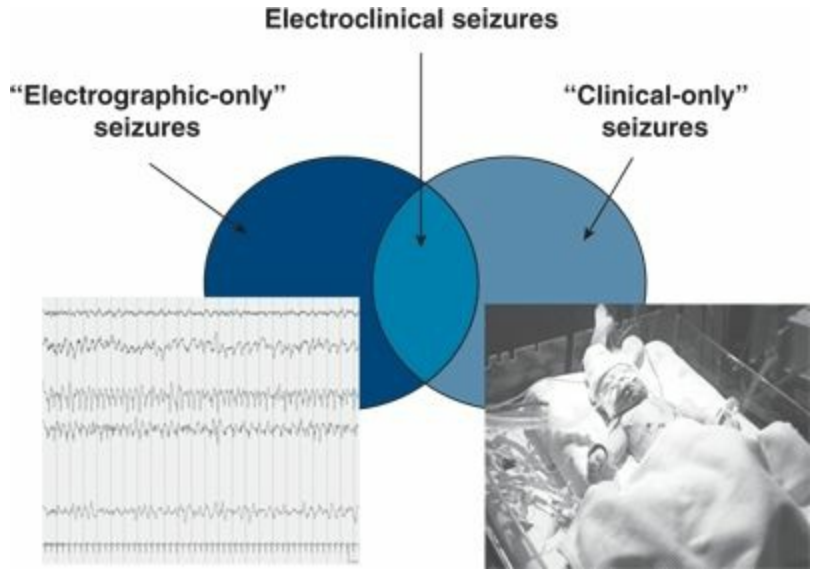

Figure 35.1. Three types of "seizures" in the newborn: "electrographic only," "electroclinical," and "clinical only."

SIGNIFICANCE OF NEONATAL SEIZURES

Incidence

The incidence of seizures in the first 28 days of life, one of the highest risk periods for seizures in humans, ranges between 1% and 5%. Depending on the methodology used, seizures occur at a rate of 0.95 to 5.5 per 1000 neonates (1–6), most within the 1st week of life (3). Unfortunately, most of these studies relied on clinical findings to identify seizures, which may underestimate the actual incidence. Incidence varies with specific risk factors. Lanska et al. (3) reported the incidence of seizures in all neonates to be 3.5 per 1000, but 57.5 per 1000 in very-low-birth-weight (<1500 g) infants, 4.4 per 1000 in low-birth-weight (1500 to 2499 g) infants, and 2.8 per 1000 in normal-birth-weight (2500 to 3999 g) infants. Scher et al. (7,8) described seizures in 3.9% of neonates younger than 30 weeks of conceptional age and in 1.5% of those older than 30 conceptional weeks.

The human newborn is especially vulnerable to a wide range of toxic or metabolic conditions. It is now well established that the neonatal brain itself may be especially prone to seizures when injured. One suspected mechanism of enhanced seizure susceptibility in the newborn is the relative imbalance between inhibition and excitation. Compared with more mature brains, the neonatal brain exhibits delayed maturation of inhibitory circuits and precocious maturation of excitatory circuits (9). According to studies in the neonatal rat, γ-aminobutyric acid (GABA)—the major inhibitory neurotransmitter in the mature brain—may exert paradoxically excitatory effects in early CNS development (10,11).

A developmentally dependent cation chloride cotransporter channel (KCC2)—which extrudes chloride into the extracellular space—does not reach mature levels in the rat hippocampus until after the third postnatal week (Fig. 35.2). Instead, early in development, the NKCC1 transporter predominates and actively transports chloride into the neuron. Thus, when the ligand-dependent $GABA_A$ receptor is activated in the immature rat, extracellular chloride follows its electrochemical gradient out of the neuron resulting in depolarization. After the appearance of KCC2, the intracellular concentration of chloride is kept low, and activation of the $GABA_A$ receptor allows chloride to run along its electrochemical gradient into the neuron. This leads to hyperpolarization and allows for the

inhibitory action of the receptor (12,13). Current electrophysiologic evidence suggests that this excitatory-to-inhibitory switch in the rat hippocampus is complete by postnatal day 14 (14,15), an age that may reflect the developmental state of a human toddler.

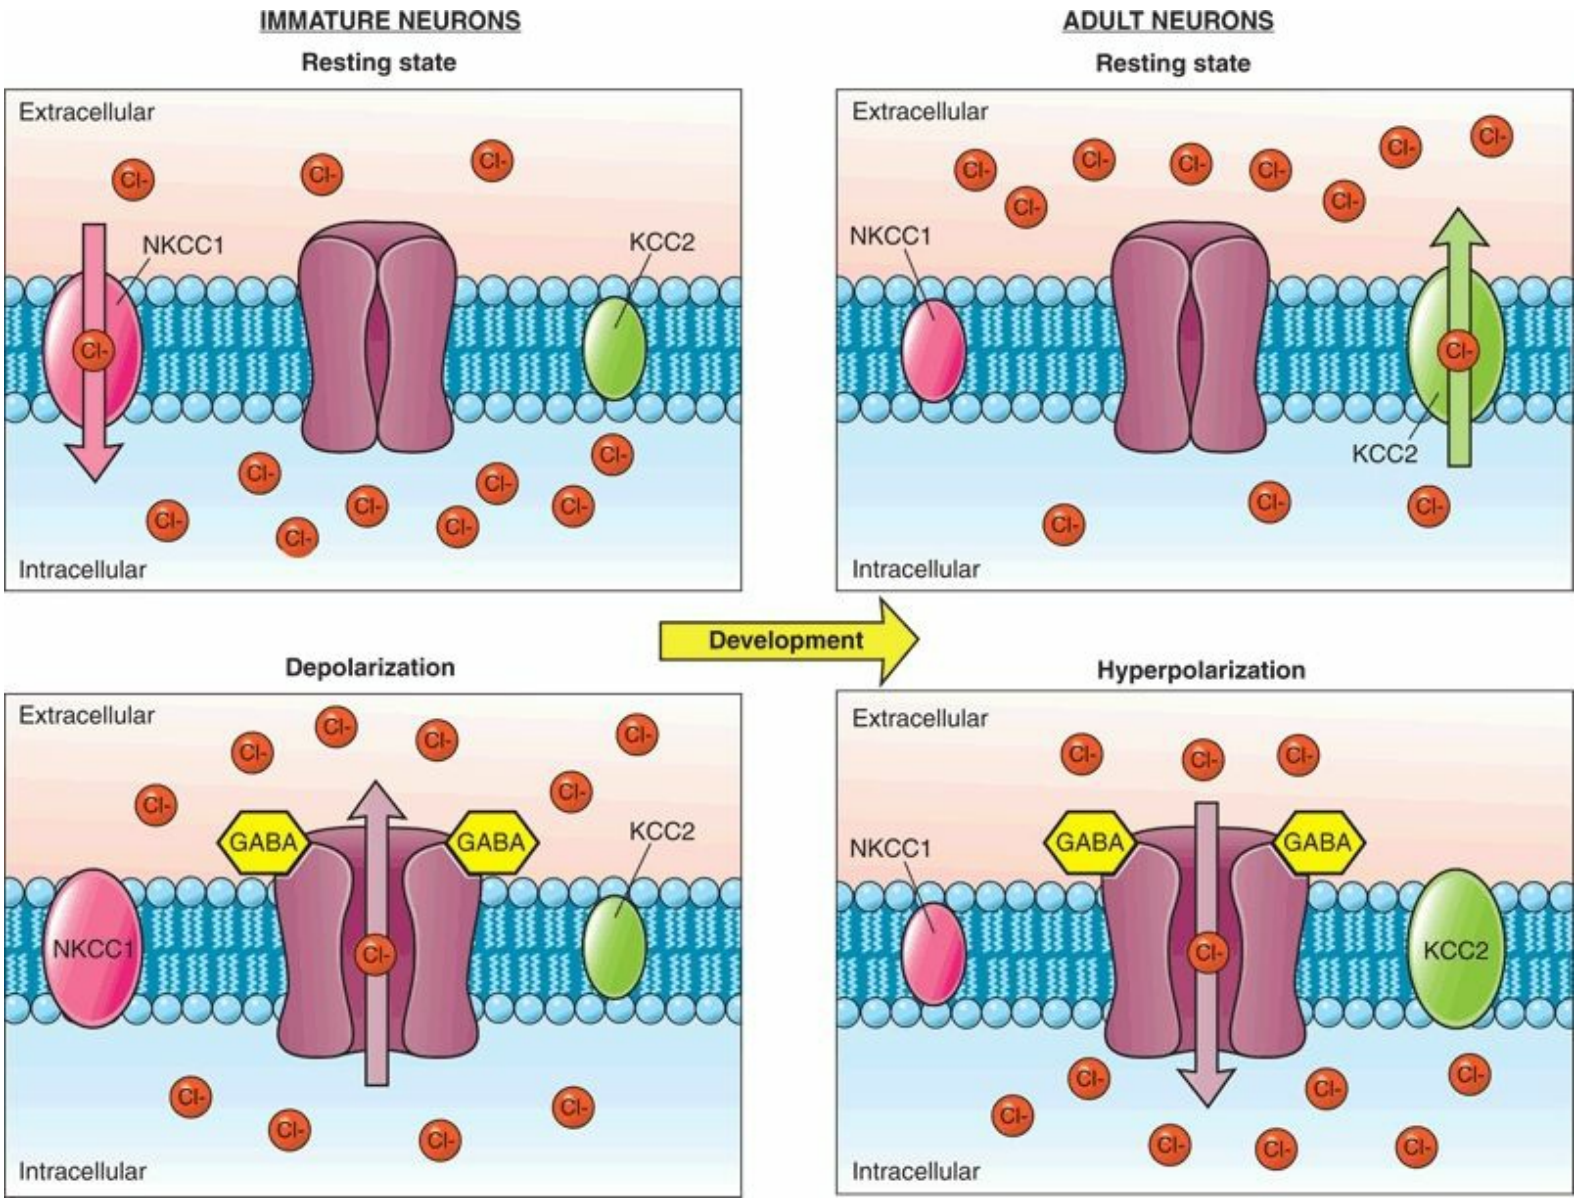

Figure 35.2. Changes in chloride homeostasis during development. In the immature neuron (left portion of panel), the NKCC1 cotransporter is primarily expressed and allows chloride to accumulate in the neuron. When GABA binds to its receptor, the negatively charged chloride ions leave the cell leading to depolarization of the neuron. In the mature neuron (right portion of panel), the chloride cotransporter KCC2 that functions to transport chloride out of the cell predominates. When GABA binds to its receptor, chloride enters the cell causing hyperpolarization of the neuron.

The paradoxical depolarizing effect of GABA during the neonatal period potentially contributes to the refractoriness of neonatal seizures to phenobarbital and benzodiazepines. Interestingly, recurrent neonatal seizures in rodent models lead to an increase in intracellular chloride via a NKCC1-dependent mechanism (16,17). In some experimental models of induced neonatal seizures, inhibition of the NKCC1 transporter with bumetanide alters chloride transport and significantly enhances the anticonvulsant effects of phenobarbital in the neonatal rat hippocampus (17,18). Clinical studies evaluating bumetanide add-on therapy are currently ongoing.

Glutamatergic receptors also regulate excitability in the immature neuron and undergo developmental changes that contribute to the propensity of the neonate to seizures. These receptors

can have various functional properties based on their subunit composition that changes during development. N-methyl-D-aspartate (NMDA) receptors in immature neurons express primarily the NR2B subunit that prolongs the duration of the excitatory postsynaptic potential. Increased expression of the NR2C, NR2D, and NR3A subunits confers a reduced sensitivity to blockade by magnesium, resulting in increased excitability (19).

Prognostic Significance

Neonatal seizures are a powerful prognostic indicator of mortality and neurologic morbidity. The summary report from Bergman et al. (2) of 1667 patients noted an overall mortality of 24.7% before 1969 and 18% after 1970. According to Lombroso (20), mortality decreased modestly from about 20% previously to 16% in the early 1980s. These improvements probably reflect better obstetrical management and modern neonatal intensive care. All of these studies relied on seizure diagnosis by clinical criteria and did not require EEG confirmation.

Survivors of neonatal seizures face an exceptionally high risk for cerebral palsy, often with mental retardation and chronic postnatal epilepsy. The National Collaborative Perinatal Population (NCPP) study (21,22) examined numerous clinical perinatal factors for their association with severe mental retardation, cerebral palsy, and microcephaly (Fig. 35.3). The clinical diagnosis of "neonatal seizures" was independently and significantly associated with these adverse outcomes and eclipsed only by "intracranial hemorrhage" in forecasting them.

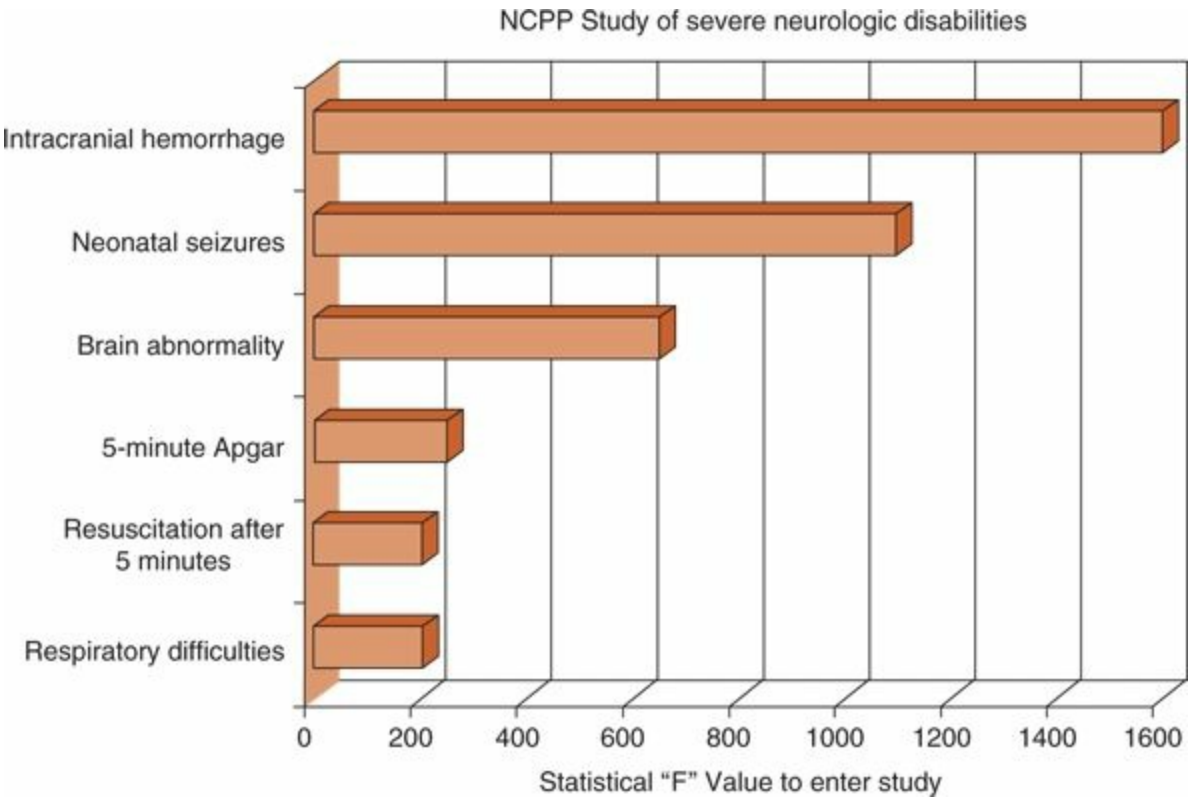

Figure 35.3. The National Collaborative Perinatal Population (NCPP) study prospectively followed more than 34,000 mothers to identify perinatal events associated with adverse outcomes. Fifty neonates were found with subsequent severe neurologic handicaps. Six independent variables, including neonatal seizures, were associated with such neurologically devastating outcomes. (Adapted from Nelson KB, Broman SH. Perinatal risk factors in children with serious motor and mental handicaps. Ann Neurol. 1977;2(5):371–377.)

Contemporary studies of the prognosis after neonatal seizures have emphasized the inclusion of infants whose seizure type was confirmed by EEG monitoring. Pisani et al. (23) identified 106

consecutively admitted neonates with video EEG–confirmed seizures over a 5-year period. The mortality rate was 19% with a favorable outcome found in only 34% of patients. Cerebral palsy was identified in 37% and developmental delay in 34%, and 21% had postnatal epilepsy at 24 months of follow-up.

Of the 207 full-term infants with video EEG–confirmed seizures prospectively enrolled by the Clinical Research Centers for Neonatal Seizures between 1992 and 1997, 28% died (24). Two-year follow-up data were available for 122 patients, or 86% of the survivors. Abnormal neurologic findings were noted in 42%. A Mental Developmental Index (MDI) score below 80 was present in 55%, a Psychomotor Developmental Index (PDI) score <80 in 50%, and chronic postnatal epilepsy in 26%.

Whether seizures themselves adversely affect the developing brain is difficult to determine from clinical studies. Seizure burden may appear to influence outcome because some infants who experience brief, infrequent seizures may have relatively good long-term outcomes, whereas those with prolonged seizures often do not fare as well. However, easily controlled or self-limited seizures may be the result of transient, successfully treated, or benign CNS disorders of neonates, while medically refractory neonatal seizures may stem from more sustained, less treatable, or more severe brain disorders. Legido et al. (25) studied 40 neonates with electrographic seizures detected on randomly timed routine EEG examinations and monitored them for cerebral palsy, mental retardation, and epilepsy. Overall neurologic outcome was more favorable in those with two or fewer seizures per hour than in those with more. In the subgroup with seizures caused by hypoxia–ischemia, cerebral palsy was more frequent when more than five seizures occurred per hour. However, these results might equally reflect more severe underlying injuries that triggered both the additional short-term seizures and greater morbidity on long-term follow-up. In another study, a higher seizure burden was independently associated with a worse neurodevelopmental outcome in hypoxic–ischemic encephalopathy (HIE; see section titled “Diffuse Hypoxic–Ischemic Etiologies” later in this chapter) even after controlling for the severity of hypoxic–ischemic brain injury (26).

A randomized trial was conducted evaluating the utility of treating electrographic seizures detected on amplitude-integrated EEG (aEEG; see section titled “Amplitude-Integrated EEG” later in this chapter). Patients with moderate to severe HIE and clinical seizures were started on aEEG, but they were randomized to treatment of seizures using only clinical evaluation or a combination of aEEG and clinical seizures. There was a trend to shorter seizure duration with treatment of both clinical and electrographic seizures compared to only those observed clinically. In addition, the group also found that a longer duration of seizure was associated with a greater severity of brain injury on MRI (27).

Attempting a balanced approach, McBride et al. (28) followed up 68 high-risk neonates with birth asphyxia, meningitis, and other stressors linked to neonatal seizures. All infants underwent long-term EEG monitoring. Forty developed electrographic seizures, while 28 did not. Based on logistic regression analysis, electrographic neonatal seizures were significantly correlated with death and cerebral palsy. Other investigators (29), using proton magnetic resonance spectroscopy (^{1}H-MRS), found an association of measures of seizure severity with impaired cerebral metabolism measured by lactate/choline and compromised neuronal integrity measured by N-acetylaspartate/choline and suggested this as evidence of brain injury not limited to structural damage detected by magnetic resonance imaging (MRI).

Clinical or EEG-detected seizures are relatively common after newborn heart surgery (NBHS) (30) and generally connote “gray matter” injury or dysfunction. In the Boston Circulatory Arrest Study

(BCAS), postoperative EEG seizures were detected in 27/136 (19.8%) and were associated with an 11-point reduction in the Bayley Scales of Infant Development (BSID) at 1-year follow-up (31). By 16 years of age, 139 (87%) of the original cohort of survivors participated in neurocognitive follow-up measuring academic achievement, memory, executive functions, visuospatial skills, attention, and social cognition. After adjustment for all other covariables, the occurrence of seizures in the postoperative period was the medical variable most consistently related to worse outcomes. The scores of both treatment groups tended to be lower than those of the test normative populations, with substantial proportions scoring ≤1 SDs below the expected mean (32).

EEG seizures were also detected commonly after NBHS at Children's Hospital of Philadelphia. EEG seizures were detected in 11% of 164 infants participating in the APOE polymorphisms study (33). At the 1-year follow-up evaluation, abnormal or suspect examination results occurred in 41/99 (41%) patients without seizures, compared with 11/15 (73%) patients with postoperative seizures ($P < 0.027$). Moreover, frontal-onset seizures predicted lower MDI scores ($P < 0.03$), but not lower scores ($P < 0.2$), compared with non–frontal-onset seizures (34). Neurocognitive testing was repeated in 132 (87%) of 151 survivors at 4 years. The outcomes assessed included cognition, language, attention, impulsivity, executive function, behavior problems, academic achievement, and visual and fine motor skills. Developmental evaluations were performed. After covariate adjustment, occurrence of an EEG seizure was associated with worse executive function ($P < 0.037$) and impaired social interactions/restricted behavior ($P < 0.05$). Seizures were not significantly associated with worse performance for cognition, language, attention, impulsivity, academic achievement, or motor skills (all $P > 0.1$) (35).

Neonatal Seizures Are Harmful to the Neonatal Rodent Brain

Neonatal seizures may be intrinsically harmful to the brain (36). Most seizures were long assumed to be the innocuous, albeit conspicuous, result of an acute injury, and the subsequent long-term neurodevelopmental abnormalities the result of their underlying causes, not the seizures themselves. Basic laboratory studies focused on the effects of seizures on the developing brain have not resolved the controversy (37–41). Immature animals are more resistant than older animals to some seizure-induced injury (42). The immature brain may be resistant to acute seizure-induced cell loss (39); however, functional abnormalities such as impairment of visuospatial memory and reduced seizure threshold (43) occur after seizures, and seizures have been noted to induce changes in brain development, including altered neurogenesis (44), synaptogenesis, synaptic pruning, neuronal migration, and the sequential expression of genes including neurotransmitter receptors and transporters (45,46).

While neonatal seizures seem to induce little histologic damage to the brain (42), studies have revealed that recurrent seizures can produce long-lasting changes in the developing brain, making them more prone to epilepsy and impairing future learning and behavior. Holmes et al. (47) documented impaired spatial learning and memory, decreased activity levels, significantly lower threshold to pentylenetetrazol-induced seizures, and sprouting of CA3 mossy fibers in adult rats that had recurrent neonatal seizures compared to those without neonatal seizures.

Alterations in receptor subunit expression have been implicated as a cause for some of the changes following neonatal seizures. Status epilepticus induced in neonatal rats produced decreased expression of the α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) receptor GluR2 subunit and increased susceptibility to kainate-induced seizures later in life (48). Another study

demonstrated that a single episode of seizures in neonatal rat pups (at P7) produced long-lasting alterations in excitatory glutamatergic synapses that impaired working memory in adulthood (49). Recurrent neonatal seizures likewise produced decreased NR2A expression (50). Hypoxia-induced neonatal seizures appear to decrease long-term potentiation in the hippocampus through an AMPA-mediated mechanism that is suspected to impair synaptic plasticity leading to cognitive impairment (51).

The most frequent clinical setting for the occurrence of neonatal seizures in both term and preterm neonates is following hypoxic–ischemic injury (52). A rodent study of hypoxia-induced seizures demonstrated a decrease in GluR2 receptor expression allowing an increase in calcium influx that may contribute to the chronic epileptogenic effects of hypoxia-induced neonatal seizures (53). Treatment with AMPA receptor antagonists, but not NMDA receptor or $GABA_A$ receptor antagonists, after hypoxia-induced seizures in neonatal rats reduced the susceptibility to seizures and seizure-induced injury later in life (54). Likewise, topiramate—which acts mechanistically in part by blocking AMPA/kainate receptors—exerts anticonvulsant activity against perinatal hypoxia-induced seizures (55). These studies highlight the potential utility of topiramate in neonates with seizures associated with hypoxic–ischemic encephalopathy, but the lack of an intravenous formulation makes treatment in critically ill children challenging (56). Nevertheless, in July 2013, the FDA approved the development of an orphan drug formulation of intravenous topiramate, specifically with the neonatal population in mind. Topiramate was found to be safe in one study of infants with HIE who were treated with hypothermia and oral topiramate; however, there was no difference in short-term outcomes (57).

A concern with recurrent neonatal seizures is the concept that "seizures beget seizures"—with recurrent seizures inducing secondary ictal-onset zones. An elegant study by Khalilov et al. (58) attempted to determine if GABA or NMDA signaling was required for creation of a secondary epileptogenic focus. Recurrent seizures were induced in one hippocampus with repeated doses of kainate that eventually propagated to the other hippocampus and established a secondary epileptogenic focus. Addition of an NMDA receptor antagonist to the seizure-naïve hippocampus (not stimulated with kainate) inhibited the creation of a "mirror focus." Interestingly, GABA-ergic synapses in this system became excitatory in the secondary focus, which is known to be an important contributor to epileptogenesis in the neonatal hippocampus. This study again supports the possible role of NMDA receptor antagonists in the clinical treatment of neonatal seizures.

Finally, neonatal seizures in rats alter the subsequent composition of the $GABA_A$ receptor. Each $GABA_A$ receptor is a pentamer in which five subunits assemble into a functional ligand-gated receptor (Fig. 35.4). The specific composition of an individual $GABA_A$ receptor depends on developmental age. In the studies of Zhang et al. (10), rats with neonatal seizures had a substantially higher proportion of the α_1 $GABA_A$ subunit than did control animals (Fig. 35.5) (59). Higher levels of the α_1 $GABA_A$ subunit may provide a protective role in decreasing the severity or frequency of seizures later in life following earlier neonatal seizures (60).

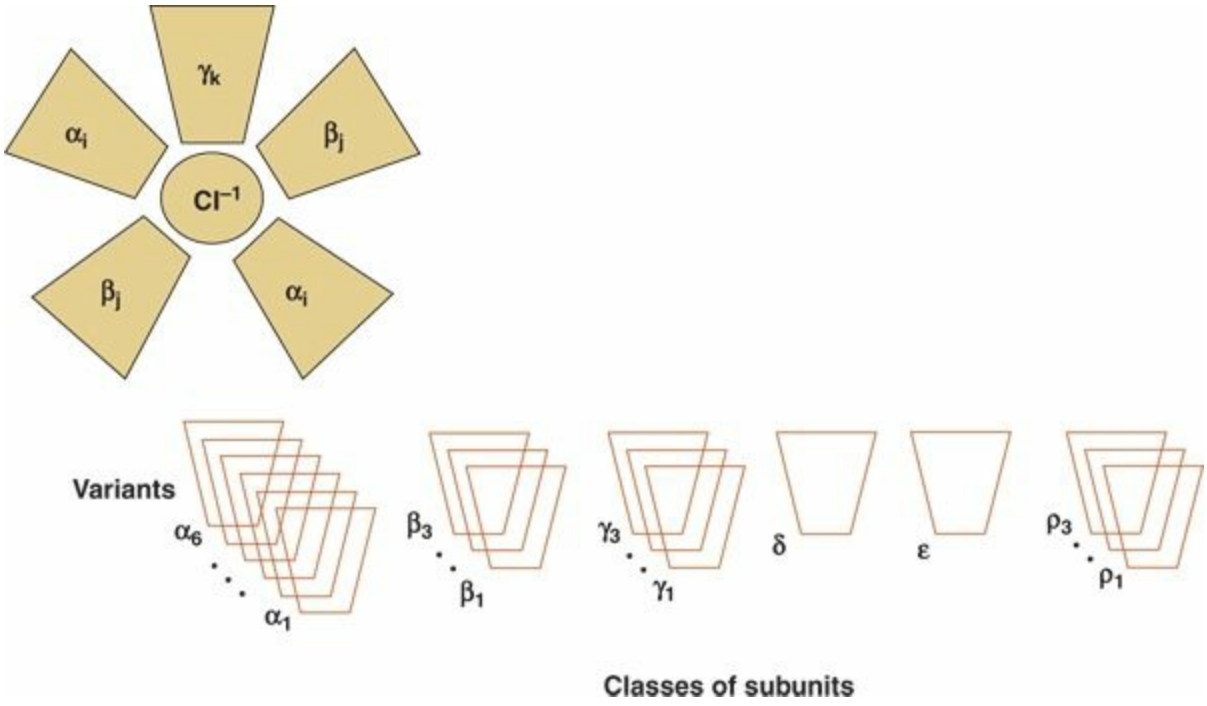

Figure 35.4. The γ-aminobutyric acid receptor is a pentamer structure composed of six possible classes of subunits. The subunits themselves may have multiple variants that are expressed at different developmental ages.

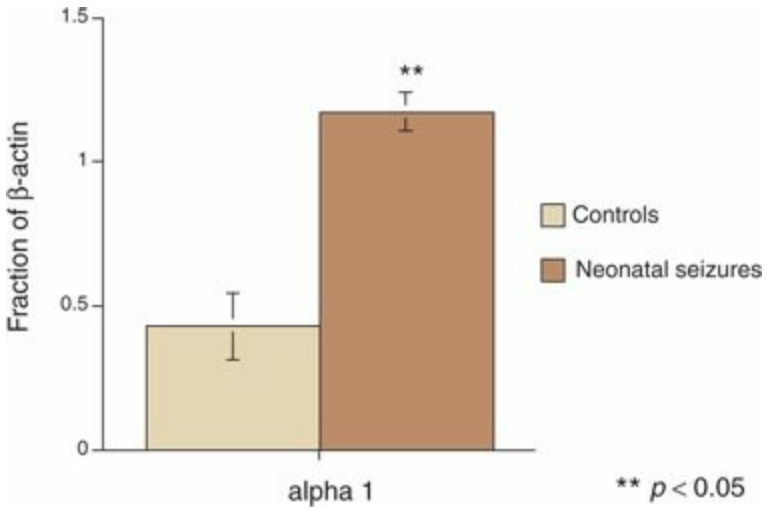

Figure 35.5. Rat pups subjected to seizures had significant differences in α-aminobutyric acid subunit receptor composition in later life compared with control animals. (Adapted from Brooks-Kayal AR, Shumate MD, Jin H, et al. Gamma-Aminobutyric acid (A) receptor subunit expression predicts functional changes in hippocampal dentate granule cells during postnatal development. J Neurochem. 2001;77(5):1266–1278.)

CLASSIFICATION AND CLINICAL FEATURES OF NEONATAL SEIZURES

Application of a syndromic classification to neonatal seizures is limited when considered in light of the classification of the International League Against Epilepsy (ILAE) (61). Almost all neonatal seizures are thought to be symptomatic, an acute reaction, or consequence of a specific etiology. The most recent ILAE classification addresses only five neonatal syndromes: benign neonatal seizures, benign familial neonatal epilepsy (BFNE), early myoclonic encephalopathy (EME), Ohtahara syndrome, and migrating partial seizures of infancy (61). These are discussed later.

Seizures in the neonate are uniquely different from those in older infants and children. These differences are based on mechanisms of epileptogenesis, the developmental state of the immature brain, and the relatively greater importance of nonepileptic mechanisms of seizure generation in this age group. Neonatal seizures may be classified by (i) clinical manifestations, (ii) the relationship between clinical seizures and electrical activity on the electroencephalogram, and (iii) seizure pathophysiology.

Clinical Classifications

A number of clinical classifications of neonatal seizures have been published (62–66). Early classifications focused on the clinical differences between seizures in neonates and those in older children: neonatal seizures were reported to be clonic or tonic, not tonic–clonic; when focal, they were either unifocal or multifocal. Later classifications included the term myoclonus. Another distinguishing feature of neonatal seizures is the occurrence of events described initially as "anarchic" (62) and thereafter "minimal" (67) or "subtle" (65). These events included oral–buccal–lingual movements such as sucking and chewing; movements of progression, such as bicycling of the legs and swimming movements of the arms; and random eye movements. First considered epileptic in origin, they were later deemed to be exaggerated reflex behaviors and thus were called "brainstem release phenomena" or "motor automatisms" (64). Table 35.1 lists the clinical characteristics of neonatal seizures according to a current classification scheme (68) that can be applied through observation.

Table 35.1 Clinical Characteristics, Classification, and Presumed Pathophysiology of Neonatal Seizures

Classification	Characteristics	Pathophysiologic basis
Focal clonic	Repetitive, rhythmic contraction of muscle groups of the limbs, face, or trunk May be unifocal or multifocal May occur synchronously or asynchronously in muscle groups on one side of the body May occur simultaneously but asynchronously on both sides Cannot be suppressed by restraint	Epileptic
Focal tonic	Sustained posturing of single limbs Sustained asymmetric posturing of the trunk Sustained eye deviation Cannot be provoked by stimulation or suppressed by restraint	Epileptic
Generalized tonic	Sustained symmetric posturing of limbs, trunk, and neck May be flexor, extensor, or mixed extensor/flexor May be provoked or intensified by stimulation May be suppressed by restraint or repositioning	Presumed nonepileptic
Myoclonic	Random, single, rapid contractions of muscle groups of the limbs, face, or trunk Typically not repetitive or may recur at a slow rate May be generalized, focal, or fragmentary May be provoked by stimulation	Epileptic or nonepileptic
Spasms	May be flexor, extensor, or mixed extensor/flexor May occur in clusters Cannot be provoked by stimulation or suppressed by restraint	Epileptic
Motor automatisms ocular signs	Random, roving eye movements or nystagmus (distinct from tonic eye deviation) May be provoked or intensified by tactile stimulation	Nonepileptic
Oral–buccal–lingual movements	Sucking, chewing, tongue protrusions May be provoked or intensified by stimulation	Nonepileptic
Progression movements	Rowing or swimming movements Pedaling or bicycling movements of the legs May be provoked or intensified by stimulation May be suppressed by restraint or repositioning	Nonepileptic
Complex purposeless movements	Sudden arousal with transient increased random activity of limbs May be provoked or intensified by stimulation	Nonepileptic

Seizure Pathophysiology

Clinical seizures may be classified as epileptic or nonepileptic (Table 35.2). Some clinical neonatal seizures are clearly epileptic, occurring in close association with EEG seizure activity, involving clinical events that can be neither provoked by stimulation nor suppressed by restraint and directly triggered by hypersynchronous cortical neuronal discharges. The following properties of the developing brain intensify seizure initiation, maintenance, and propagation: increases in cellular and synaptic excitation and a tendency to enhance propagation of an epileptic discharge (40,69–71). The clinical events that are most clearly epileptic in origin are focal clonic, focal tonic, some types of myoclonic, and rarely spasms (see Tables 35.1 and Table 35.2). Electrical-only seizures (also called subclinical or occult) are, by definition, epileptic.

Table 35.2 Classification of Neonatal Seizures by Electroclinical Findings

- Clinical seizures with a consistent electrocortical signature (epileptic)
  - Focal clonic
    - Unifocal
    - Multifocal
    - Hemiconvulsive
    - Axial
  - Focal tonic
    - Asymmetric truncal posturing
    - Limb posturing
    - Sustained eye deviation
  - Myoclonic
    - Generalized
    - Focal
  - Spasms
    - Flexor
    - Extensor
    - Mixed extensor/flexor
- Clinical seizures without a consistent electrocortical signature (presumed nonepileptic)
  - Myoclonic
    - Generalized
    - Focal
    - Fragmentary
  - Generalized tonic
    - Flexor
    - Extensor
    - Mixed extensor/flexor
  - Motor automatisms
    - Oral–buccal–lingual movements
    - Ocular signs
    - Progression movements
    - Complex purposeless movements
- Electrical seizures without clinical seizure activity

Best considered nonepileptic in origin (64) are events that occur in the absence of electrical seizure activity but that have clinical characteristics resembling reflex behaviors. Such clinical events, whether provoked by stimulation or arising spontaneously, can be suppressed or altered by restraining or repositioning the infant. The clinical events may grow in intensity with increases in the repetition rate of stimulation (temporal summation) or the sites of simultaneous stimulation (spatial summation). Some types of myoclonic events, generalized tonic posturing, and motor automatisms can be classified as "nonepileptic" (see Tables 35.1 and 35.2).

Paroxysmal clinical changes related to the autonomic nervous system have been proposed as manifestations of some seizures. These include stereotyped, episodic alterations in heart rate, respiration, and blood pressure (72–74). Skin flushing, salivation, apnea (75,76), and pupillary dilation may also be autonomic signs of seizures, but they are usually associated with other clinical manifestations, except in the therapeutically paralyzed infant (64).

Electrographic Seizures

Although visual observation is critical to the detection of clinical neonatal seizures, the electroencephalogram offers the most important means of confirmation and characterization. Infants with normal background activity are much less likely to develop seizures than are those with significant background abnormalities (77).

Interictal Background and Prediction Value

The ongoing cerebral electrical activity is the stage on which the drama of the episodic electrographic seizure unfolds. In many ways, the integrity of the EEG background is as critical than the mere presence or absence of the seizures themselves. For example, with or without electrographic seizures, an extremely abnormal EEG background (burst suppression or isoelectric recording) inherently conveys a sense of profound electrophysiologic disruption and forecasts a high risk for death or adverse neurologic outcome. Conversely, a nearly normal interictal EEG background suggests relatively preserved neurologic health despite the unwanted intrusion of the seizures.

The interictal background also occasionally can offer clues to seizure etiology. Persistently unifocal sharp waves (arising from a very limited region of the cortex) may suggest a restricted injury such as localized subarachnoid hemorrhage, contusion, or stroke, whereas multifocal sharp waves suggest diffuse dysfunction. Hypocalcemia is a consideration if a well-maintained background features excessive bilateral central spikes. Inborn errors of metabolism, such as maple syrup urine disease, are sometimes associated with distinctive vertex wicket spikes. Pseudoperiodic discharges raise the suspicion of herpes simplex virus encephalitis or an acute destructive localized lesion such as stroke or hemorrhage. A grossly abnormal electroencephalogram in the absence of any obviously acquired disease suggests cerebral dysgenesis.

Interictal EEG spikes per se have uncertain diagnostic significance (78). Interictal focal sharp waves and spikes are not typically considered indicators of epileptogenesis in the same way as they are in older children and adults. Compared with those of age-matched neonates without seizures (79,80), the interictal records of infants with electroencephalogram-confirmed seizures have background abnormalities, excessive numbers of "spikes" (lasting <200 msec) compared with sharp waves (lasting >200 msec), excessive occurrence of spikes or sharp waves per minute, and a tendency for "runs," "bursts," or "trains" of repetitive sharp waves. However, only a few infants with confirmed seizures exhibit all of these interictal characteristics, and many show no excessive spikes or sharp waves. Routine duration interictal EEGs are inadequate to characterize neonatal seizure burden (81).

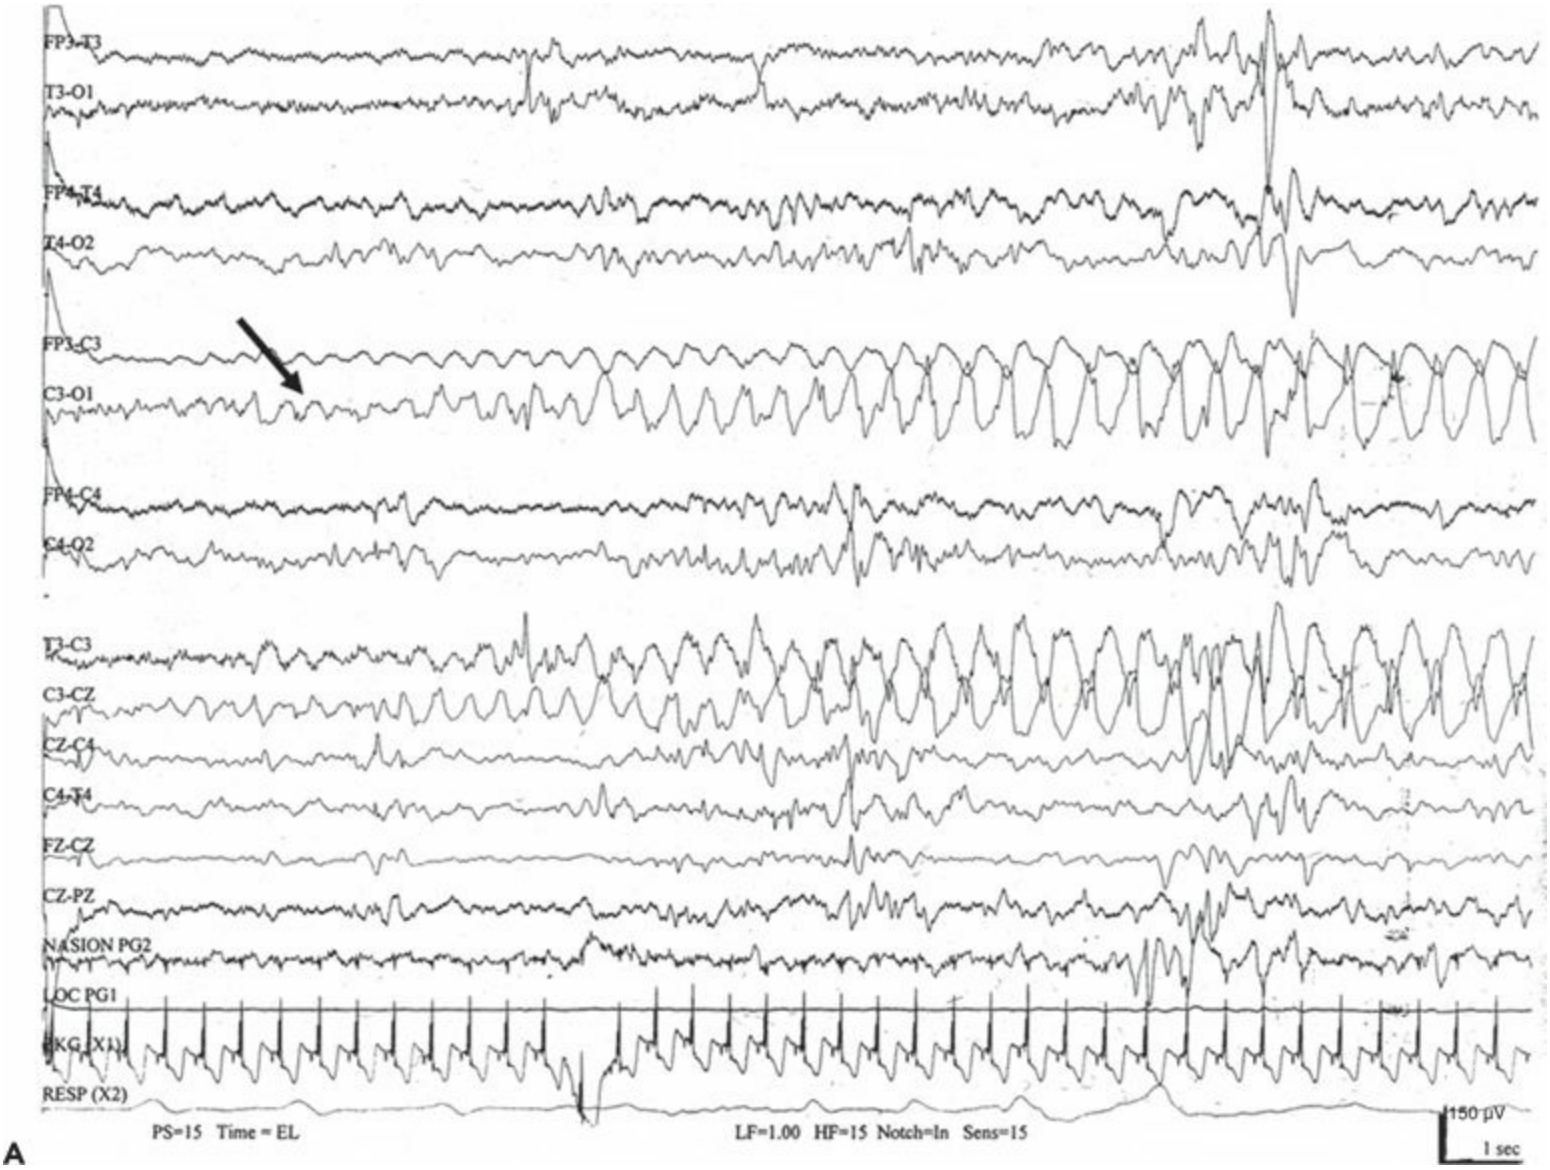
Characteristics

At the heart of the epileptic process is the abnormal, excessive, repetitive electrical firing of neurons. Affected neurons lose their autonomy and are engulfed by the synchronized bursts of repeated electrical discharges. As excitatory neurotransmission fails, the electrophysiologic cascade is interrupted and the seizure ends. Electrographic seizures in the neonate have varied appearances and are relatively rare before 34 to 35 weeks conceptional age. The morphology, spatial distribution, and temporal behavior of the seizure discharges may differ within and between individuals. Despite the differences between the term and preterm neonatal brain, the variety of types of electrographic seizures does not differ between them (82).

Morphology

An electrographic seizure is a discrete abnormal event lasting at least 10 seconds, with a definite beginning, middle, and end (83). No single morphologic pattern characterizes a seizure (Fig. 35.6). Even in the same patient, the ictal EEG activity may appear pleomorphic. The "typical" neonatal seizure begins as low-amplitude, rhythmic, or sinusoidal waveforms or spike or sharp waves. As the

seizure evolves, the amplitude of the ictal activity increases, while its frequency slows (84). Spikes or sharp waves are not necessarily present. Instead, rhythmic activity of any frequency (delta, theta, alpha, or beta) can make up the ictal patterns at the scalp surface.



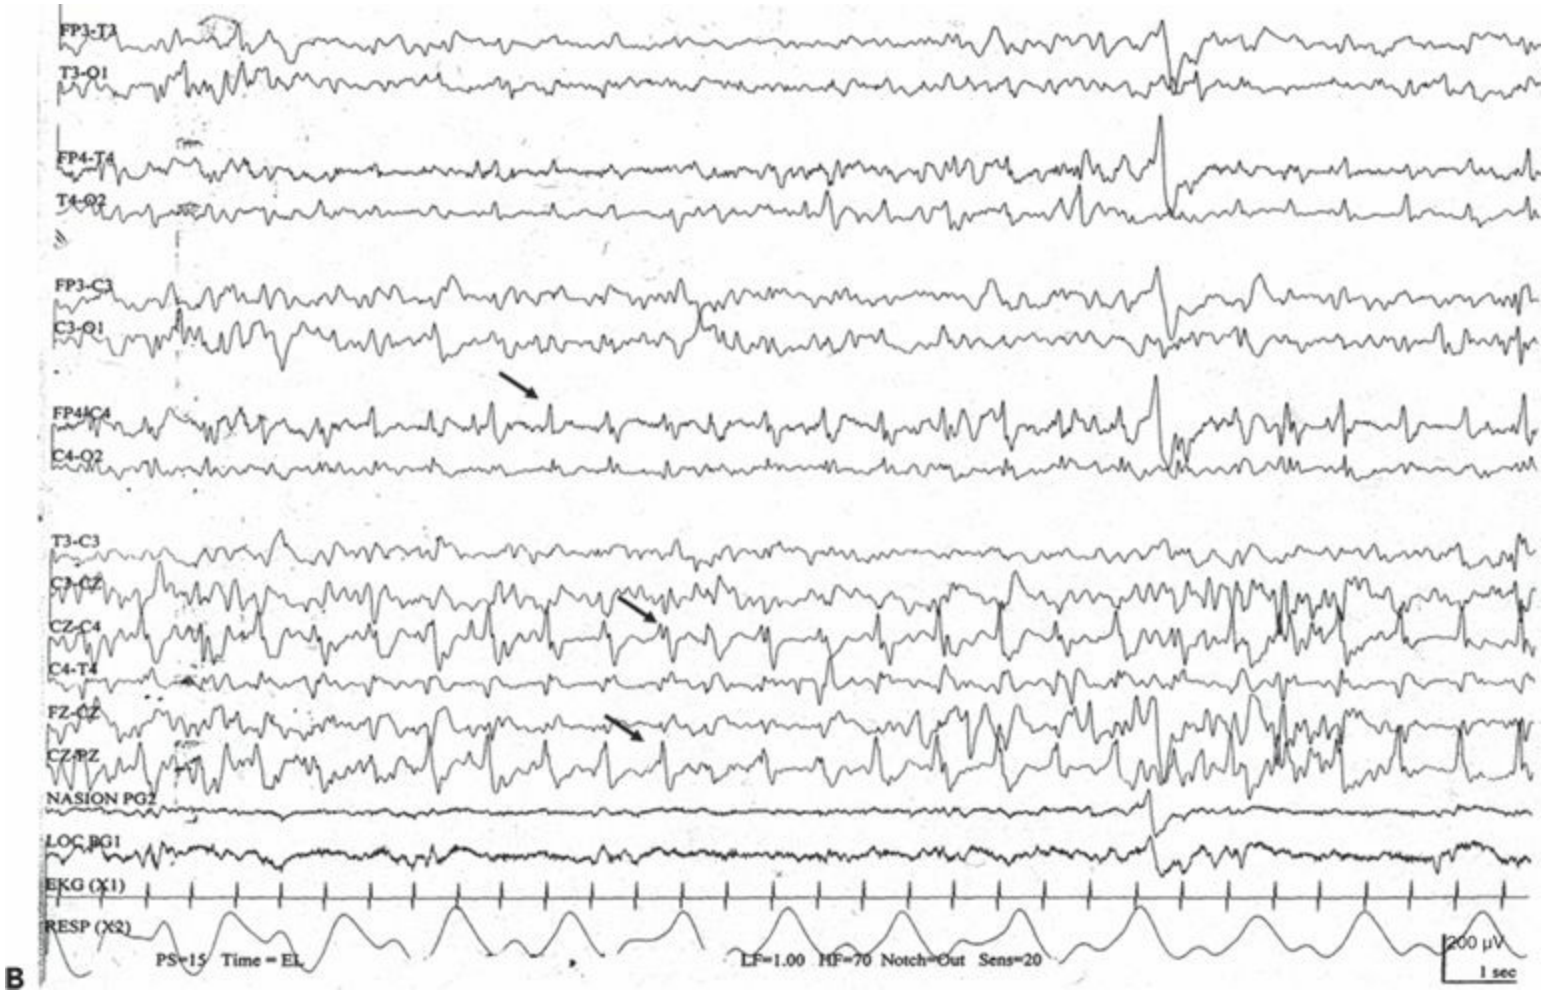


Figure 35.6. No single morphologic pattern characterizes electrographic neonatal seizures; rather, their distinctive behavior as a discrete, evolving electrographic event identifies them as ictal. **A:** A focal seizure arises from C_3 (arrow) as low-amplitude, rhythmic theta activity that gradually changes to higher- amplitude delta activity. **B:** An electrographic seizure is in progress as repetitive spikes in the right frontopolar, central, and midline vertex regions (arrows).

Spatial Distribution

In older children, generalized seizures may appear simultaneously, synchronously, and symmetrically in both hemispheres. In the neonatal brain, which lacks the physiologic organization necessary for such exquisite orchestration, individual seizures always arise focally and then migrate and spread. Seizures may also migrate from one hemisphere to another (68). Occasionally, simultaneous focal seizures may appear to behave independently, spreading to all brain regions and superficially masquerading as a "generalized seizure." However, the ictal patterns are not those of the truly generalized seizures.

Diffuse causes of encephalopathy such as meningitis, hypoglycemia, or hypoxia–ischemia may cause focal seizures or induce multiple seizures that each originate from different scalp regions—so-called multifocal-onset seizures; those that arise from the same scalp location are unifocal onset and raise the possibility of a localized structural abnormality such as a stroke (83), reflecting the restricted functional disturbance.

Temporal Profile

The typical duration of an individual electrographic neonatal seizure is about 1 to 2 minutes and is followed by an interictal period of variable length (Fig. 35.7). These temporal characteristics were

obtained from relatively brief tracings randomly selected during a variety of acute encephalopathies (8). A study of the temporal characteristics of 15 patients with HIE found the median seizure duration to be 206 seconds (interquartile range IQR 98 to 331 seconds) (85). Eleven of 15 patients had a total seizure duration in excess of 30 minutes per hour, a commonly used definition for neonatal status epilepticus, since solitary, prolonged electrographic seizures are uncommon in newborns. Repetitive brief serial seizures are much more characteristic than prolonged seizures lasting many hours. Other investigators have also reported status epilepticus during therapeutic hypothermia for neonatal HIE (86).

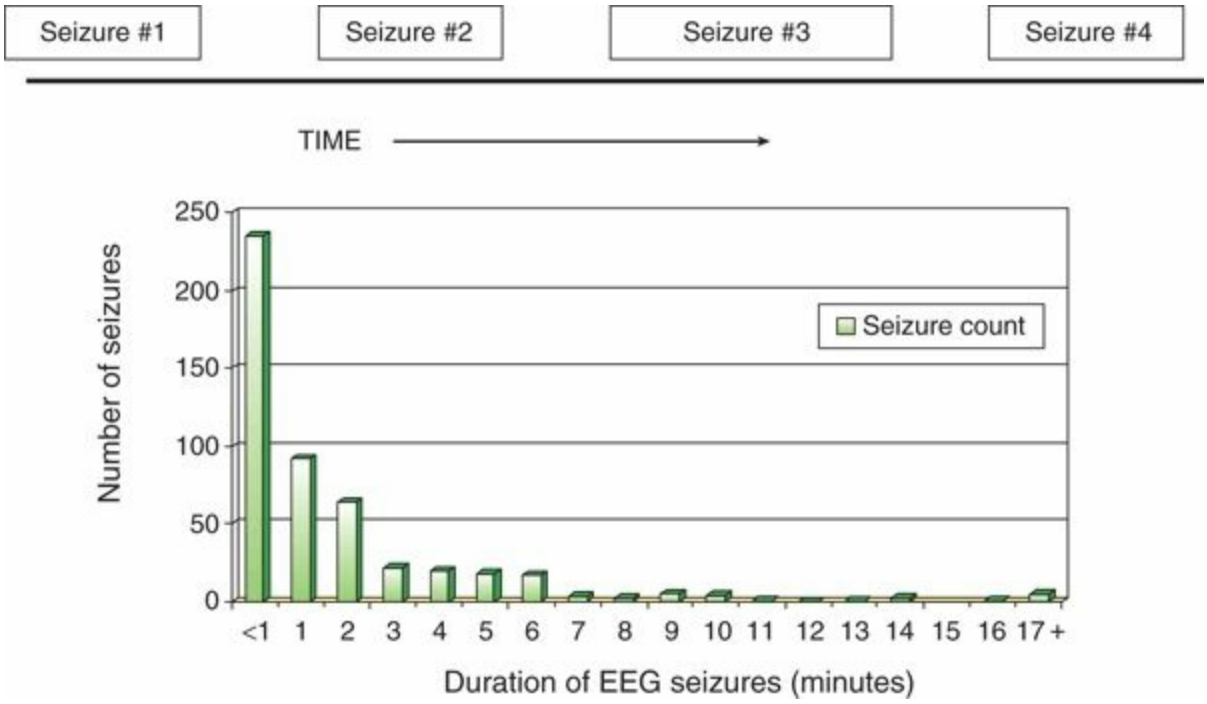

Figure 35.7. In most neonates with electrographic seizures, the electroencephalogram shows a series of brief ictal events, typically lasting <2 minutes, followed by varying- length interictal periods. The histogram shows the distribution of durations (minutes) of 487 electroencephalographic seizures recorded from 42 neonates. (Adapted from Clancy RR, Legido A. The exact ictal and interictal duration of electroencephalographic neonatal seizures. Epilepsia. 1987;28(5):537–541.)

Neonates may demonstrate events that have morphologic characteristics of electrographic seizures with a duration of <10 seconds. These discharges have been termed brief rhythmic discharges (BRDs) or brief intermittent rhythmic discharges (BIRDs) (87). The significance of these discharges is unclear. A study of 340 subjects noted that BIRDs had a higher association with leukomalacia or hypoglycemia and were associated a higher risk of neurodevelopmental abnormalities (88). Another limited study found no significant difference in mortality and neurodevelopmental outcome for subjects with BIRDs or electrographic seizures; however, subjects with BIRDs only were less likely to have postnatal seizures (89). Given their frequent association with clear electrographic seizures, care should be taken to scrutinize the EEG closely for seizures.

Special Ictal Electroencephalographic Morphologies

Some ictal patterns unique to the neonatal period are associated with severe encephalopathies. Electrical seizures of the depressed brain are long, low in voltage, and highly localized. They may be unifocal or multifocal and show little tendency to spread or modulate. Not associated with clinical seizures, they occur when the EEG background is depressed and undifferentiated and suggest a poor

prognosis. Alpha (α) seizure activity (90–92) is characterized by sudden, transient, rhythmic activity in the α frequency range (8 to 12 Hz) in the temporal or central region, unaccompanied by clinical events. An α discharge usually indicates a severe encephalopathy and poor prognosis.

Video-EEG monitoring has been the basis of clinical investigations into the classification, therapy, and prognosis of neonatal seizures (93–95). It has become more widely available, but remains limited at many locations.

Amplitude-Integrated EEG

Amplitude-integrated EEG (aEEG) is becoming increasingly used in the neonatal intensive care unit setting for bedside evaluation of cerebral activity. While various techniques are available, limited arrays of 2 or 4 two electrodes are commonly used to acquire data that are then processed and compressed to provide a simple trend of the background EEG activity in those regions (Fig. 35.8). Advantages over conventional EEG include widespread availability, ease of application, and the lack of dependence on specially trained neurophysiologists. The compressed data provides information about the background of the EEG that can be used for prognostic purposes, including inclusion in therapeutic neuroprotection (e.g., cerebral head cooling) (96). There is acceptable agreement between conventional EEG and aEEG background classifications when the tracings are normal or when markedly abnormal. For example, both techniques would correctly identify a flat or burst suppression tracing. However, the agreement between these two techniques is much poorer among the middle-ground, "moderately abnormal" aEEGs (97).

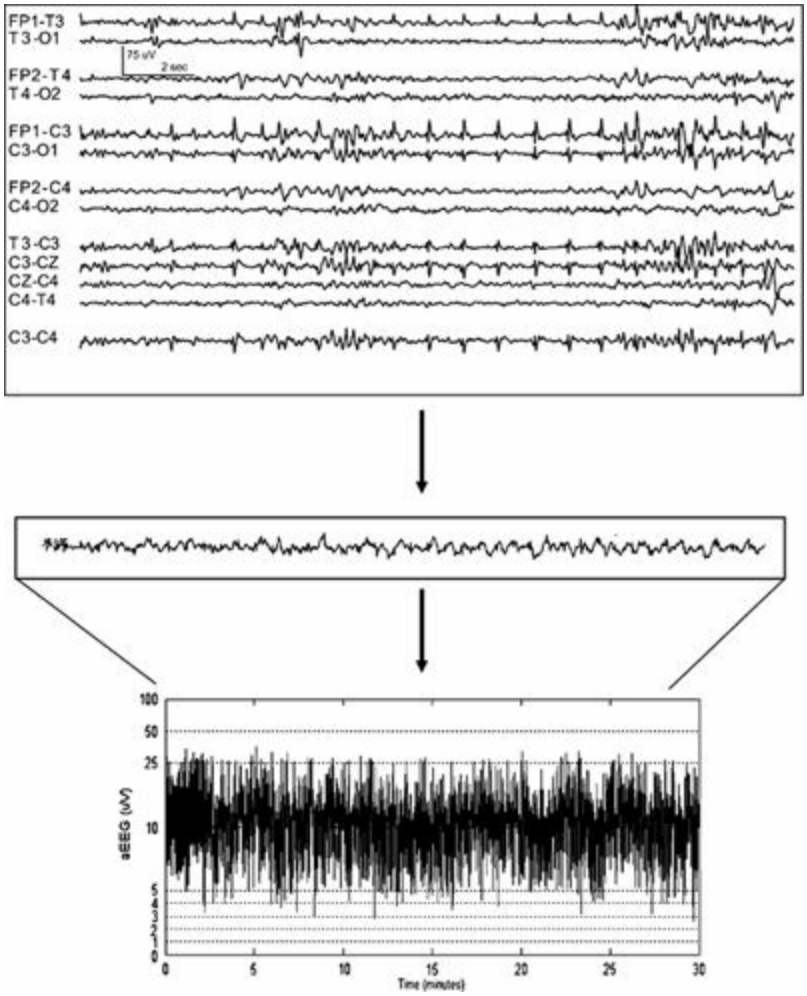

Figure 35.8. The routine neonatal EEG examination typically displays 12 or more channels from the full array of the 10 to 20 system.

Cerebral function monitors, such as aEEG, use a single channel from a pair of scalp electrodes (commonly the left and right parietal regions) and then process the raw EEG to a compressed display, which is very useful for reviewing long-term trends.

Neonatal seizures can be detected with aEEG as sudden elevations of the lower and upper margins of the background tracing (Fig. 35.9). Studies comparing neonatal seizure detection between aEEG and conventional EEG demonstrate that only 22% to 57% of infants with seizures are accurately identified by neonatologist readers. These readers correctly detected 12% to 38% of the seizures confirmed by conventional EEG (Table 35.3) (98,99). Certain seizure characteristics influence their identification: amplitude, duration, number of seizures per hour, and the spatial restrictions imparted by sampling just 1 or 2 electrode pairs (99). Clearly, aEEG cannot supplant conventional EEG but can provide very useful complementary information that may guide decision making at the bedside in real time.

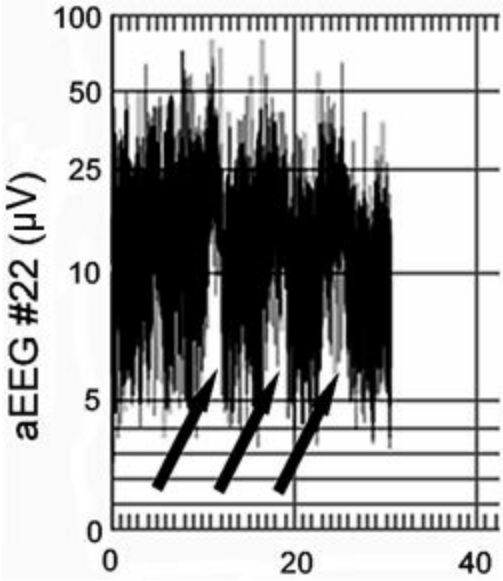

Figure 35.9. Thirty-minute aEEG in a term infant with three captured seizures (arrows).

Table 35.3 Comparisons of Conventional and Amplitude-Integrated EEG for Seizure Detection

Diagnostic tool	Neonates with seizures (%)	EEG seizures per neonate (%)
Conventional EEG ("gold standard")	100	100
Single channel of "raw" EEG (C3 → C4)	94	78
aEEG of single-channel EEG (C3 → C4)	22–57	12–38
Single channel of "raw" EEG at the forehead (Fp3 → Fp4)	66	46

Continuous EEG Monitoring (cEEG) of Neonates

The ACNS has published guidelines that provide a recommendation for monitoring neonates in the ICU (100). Listed indications for cEEG include evaluation for electrographic seizures and to judge

the severity of encephalopathy. The committee recommended monitoring of high-risk neonates for seizures for 24 hours and, if seizures are detected, until the patient is seizure free for at least 24 hours. The ACNS has also published a guideline for standardized terminology and categorization of cEEG in neonates (101).

Measures of Electrographic Seizure "Burden"

Most electrographic neonatal seizures do not provoke distinctive clinical signs (102) (Fig. 35.10). It would be useful to develop measures of the "burden" of electrographic seizures in individual infants.

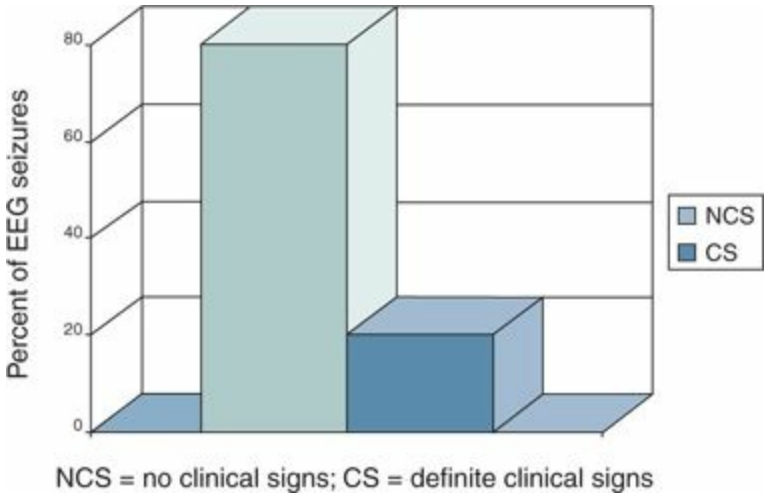

Figure 35.10. In one study, only 20% of electrographic neonatal seizures produce definite clinical signs. (Adapted from Clancy RR, Legido A, Lewis D. Occult neonatal seizures. Epilepsia. 1988;29(3):256–261.)

The simplest measure is to simply consider them dichotomously "present" or "absent." However, the number of recorded electrographic seizures varies widely, so a simple seizure frequency count could be used (Fig. 35.11). For example "there were four seizures in the 1st hour and two in the 2nd hour of monitoring." Because individual electrographic seizures also vary in length, another measure of EEG seizure burden is to describe the percentage of time in which seizure activity is present in any brain region. This can range from a 0% if no seizures are captured to 100% if the entire record demonstrates seizure activity anywhere in the brain. Unfortunately, there is only a modest (albeit statistically significant) correlation between seizure frequency counts and the percentages of the recordings showing seizure activity (99). The most detailed measure of seizure burden further incorporates knowledge of their numbers, durations, and spatial distributions. Individual electrographic seizures may remain confined to their area of origin or may spread substantially to other regions (103). This varies considerably among individual neonates (Fig. 35.12) (95). A comprehensive approach to measure EEG seizure burden, temporal–spatial analysis, reduces the entire neonatal montage into five nonoverlapping areas of interest (104): (Fig. 35.13). The percentage of ictal time at each of these five regions gives the most comprehensive picture of the geographic distribution of seizure burden. Future investigations may determine whether a "dose–response" curve exists between this fuller, temporal–spatial measure of seizure burden and eventual long-term neurodevelopmental follow-up.

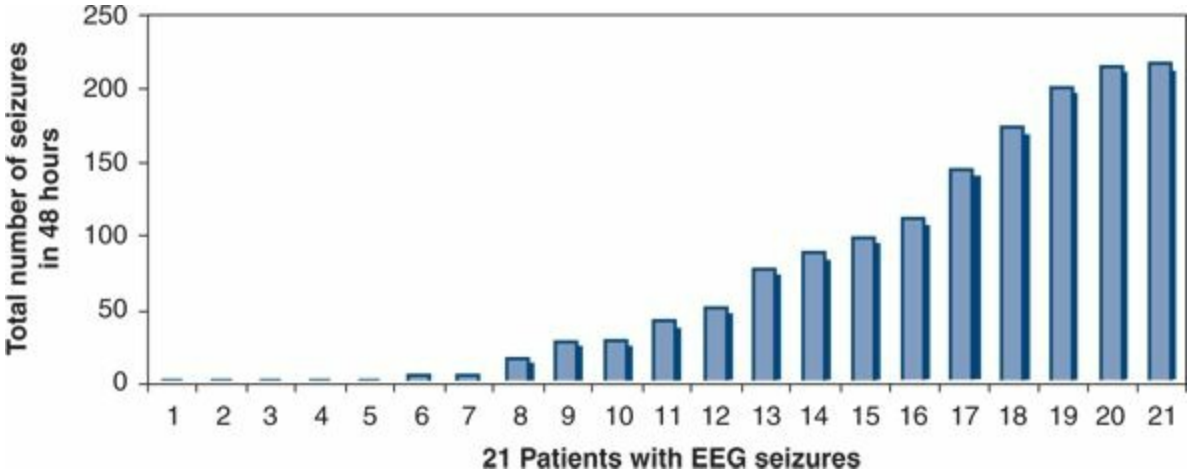

Figure 35.11. Distribution of the total number of electrographic neonatal seizures during 48 hours of electroencephalograph monitoring after newborn heart surgery. From 1 to 217 seizures occurred during the study period. (Adapted from Sharif U, Ichord R, Saymor JW, et al. Electrographic neonatal seizures after newborn heart surgery. Epilepsia. 2003;44:164.)

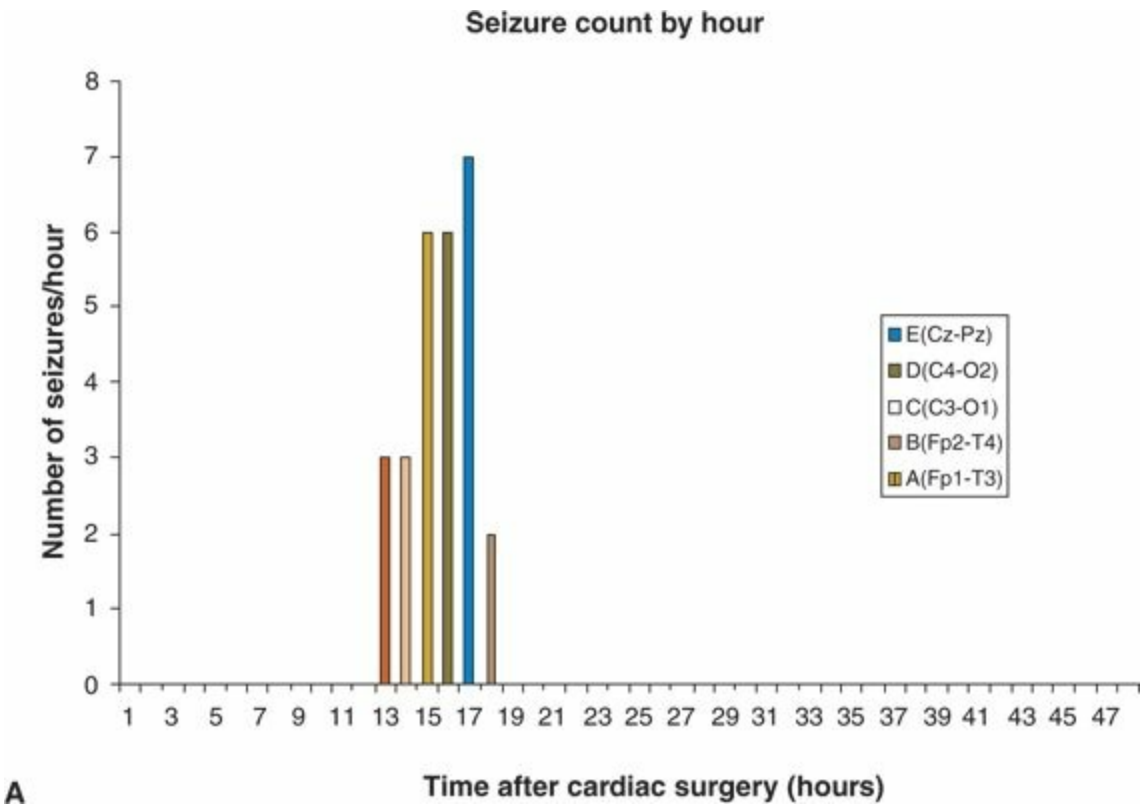

A

Figure 35.12. The spatial distribution of electroencephalographic (EEG) seizures varies among neonates. **A:** All EEG seizures begin in a single brain region (C_4–O_2). **B:** EEG seizures begin in four locations (C_Z–P_Z, C_4–O_2, C_3–O_1, and Fp_2–T_4). (Adapted from Sharif U, Ichord R, Saymor JW, et al. Electrographic neonatal seizures after newborn heart surgery. Epilepsia. 2003;44:164.)

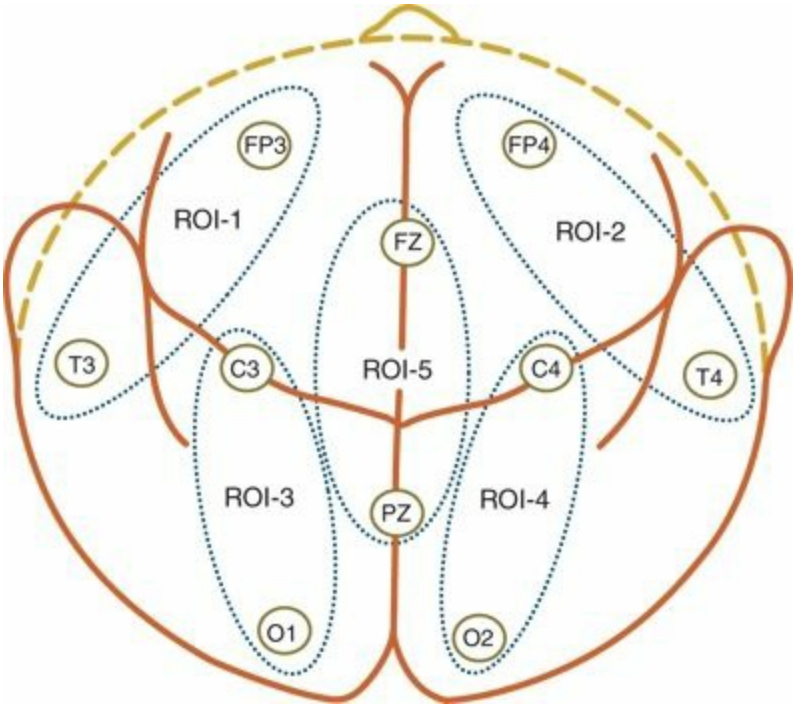

Figure 35.13. The entire array of the standard neonatal electroencephalogram can be reduced to five nonoverlapping regions of interest that identify the spatial characteristics of electroencephalographic seizures.

ETIOLOGIC FACTORS

Acute or chronic conditions can give rise to seizures. In most cases, specific causes can be determined after analysis of clinical and laboratory information (Table 35.4). Table 35.5 lists potential causes of neonatal seizures, but only a few are discussed in detail.

Table 35.4 Data to Determine the Etiology of Neonatal Seizures

Clinical	Complete history, general physical and neurologic examinations, eye examination
Neuroimaging	Computerized tomographic or magnetic resonance imaging
Blood tests	Arterial blood gases and pH
	Sodium, glucose, calcium, magnesium, ammonia, lactate and pyruvate, serum amino acids
	Comprehensive "neogen" panel[a]
	TORCH (toxoplasmosis, other infections, rubella, cytomegalovirus, and herpes simplex) titers
	Biotin
Urine tests	Reducing substances, sulfites, organic acids
	Toxicologic screen
Cerebrospinal fluid tests	Red and white blood cell counts
	Glucose and protein
	Culture
	Neurotransmitter profile[b]

[a]Varies by US states.

[b]In the proper clinical context.

Table 35.5 Etiologies of Neonatal Seizures

Acute	Chronic
Acute neonatal encephalopathy (includes classic hypoxic–ischemic encephalopathy, both ante- and intrapartum)	Isolated cerebral dysgenesis, e.g., lissencephaly, hemimegalencephaly
Arterial ischemic stroke	Cerebral dysgenesis associated with inborn errors of metabolism
Sinovenous thrombosis	Chronic infection (TORCH [toxoplasmosis, other infections, rubella, cytomegalovirus, and herpes simplex] syndromes)
Extracorporeal membrane oxygenation	Neurocutaneous syndromes
Congenital heart disease	▪ Incontinentia pigmenti (Bloch–Sulzberger syndrome)
Vein of Galen malformation	▪ Hypomelanosis of Ito
Giant arteriovenous malformation	▪ Sturge–Weber syndrome
Hypertensive encephalopathy	▪ Tuberous sclerosis
Intracranial hemorrhage (subdural subarachnoid, intraventricular, intraparenchymal)	▪ Linear sebaceous nevus (epidermal nevus syndrome)
Trauma (intrapartum and nonaccidental)	Genetic conditions
Infections (sepsis, meningitis, encephalitis)	▪ 22Q11 microdeletion
Transient, simple metabolic disorders	▪ ARX (aristaless-related homeobox) mutations
Inborn errors of metabolism (including pyridoxine-dependent seizures)	
Intoxication	Specific very early onset epilepsy syndromes
	▪ Fifth-day fits (benign neonatal convulsions)
	▪ Benign familial neonatal seizures
	▪ Early myoclonic encephalopathy
	▪ Early infantile epileptic encephalopathy
	▪ Migrating partial seizures of infancy

Acute Causes

Diffuse Hypoxic–Ischemic Etiologies

Probably the most common cause of neonatal seizures, "acute neonatal encephalopathy" (105) is characterized by depressed mental status (lethargy or coma), seizures, axial and appendicular hypotonia with an overall reduction in spontaneous motor activity, and clear evidence of bulbar dysfunction with poor sucking, and swallowing, and an inexpressive face (106). Care should be taken to separate this generic designation from neonatal HIE. Not every infant who is acutely encephalopathic has suffered hypoxia–ischemia (107). The American College of Obstetricians and Gynecologists Task Force on Neonatal Encephalopathy and Cerebral Palsy suggests four diagnostic criteria for HIE: (i) evidence of metabolic acidosis in fetal umbilical cord arterial blood obtained at delivery (pH value <7 and base deficit >12 mmol/L), (ii) early onset of severe or moderate neonatal encephalopathy in infants born at 34 or more weeks of gestation, (iii) subsequent cerebral palsy of the spastic quadriplegic or dyskinetic type, and (iv) exclusion of other identifiable etiologies such as trauma, coagulation disorders, infectious conditions, or genetic disorders (108). These four conditions should occur in the context of a "sentinel" hypoxic event immediately before or during labor, such as uterine rupture, abruption of the placenta, or prolapse of the umbilical cord. There should also be a sudden and sustained fetal bradycardia or the absence of fetal heart rate variability; persistent, late, or variable decelerations; Apgar scores of 0 to 3 after 5 minutes; and, in most, multisystem involvement within 72 hours of birth. Examples of multisystem malfunction (109) include acute renal tubular necrosis, elevated values of liver function tests, necrotizing enterocolitis from bowel ischemia, and depressed blood cell lines (e.g., thrombocytopenia) because of ischemic injury of the bone marrow (110). Early imaging studies should show acute diffuse cerebral abnormalities consistent with hypoxia–ischemia. A recent intriguing investigation in this specific hypoxic–ischemic scenario is the development of intraneuronal alkalosis as a specific trigger for seizures, which can be treated by unique paradigms of ventilatory management in which normocapnia was gradually, rather than abruptly, restored (111,112).

Other conditions that can clinically mimic acute neonatal HIE are some of the inborn errors of metabolism, pyridoxine dependency, stroke, coagulopathies, sinovenous thrombosis, and "fetal sepsis syndrome" (113–116), which can occur with sepsis or chorioamnionitis (117,118). The latter is suspected in a mother with abdominal pain and tenderness, fever, leukocytosis, and foul-smelling amniotic fluid and can be confirmed by pathologic examination of the placenta and umbilical cord (119).

Perinatal stroke is defined as a cerebrovascular event occurring between 28 weeks of gestation and 7 days of age. The incidence is 1 in 4000 live births (120). There are two main clinical presentations: (i) acute appearance of neonatal seizures, hypotonia, feeding difficulties, and, rarely, hemiparesis (83,119,121,122) (Fig. 35.14) and (ii) later discovery of stroke through the gradual appreciation of a congenital hemiparesis or the onset of a partial seizure disorder in an infant apparently healthy at birth. Risk factors include congenital heart defects (CHDs), blood and lipid disorders, infection, placental disorders, vasculopathy, trauma, dehydration, and extracorporeal membrane oxygenation (ECMO).

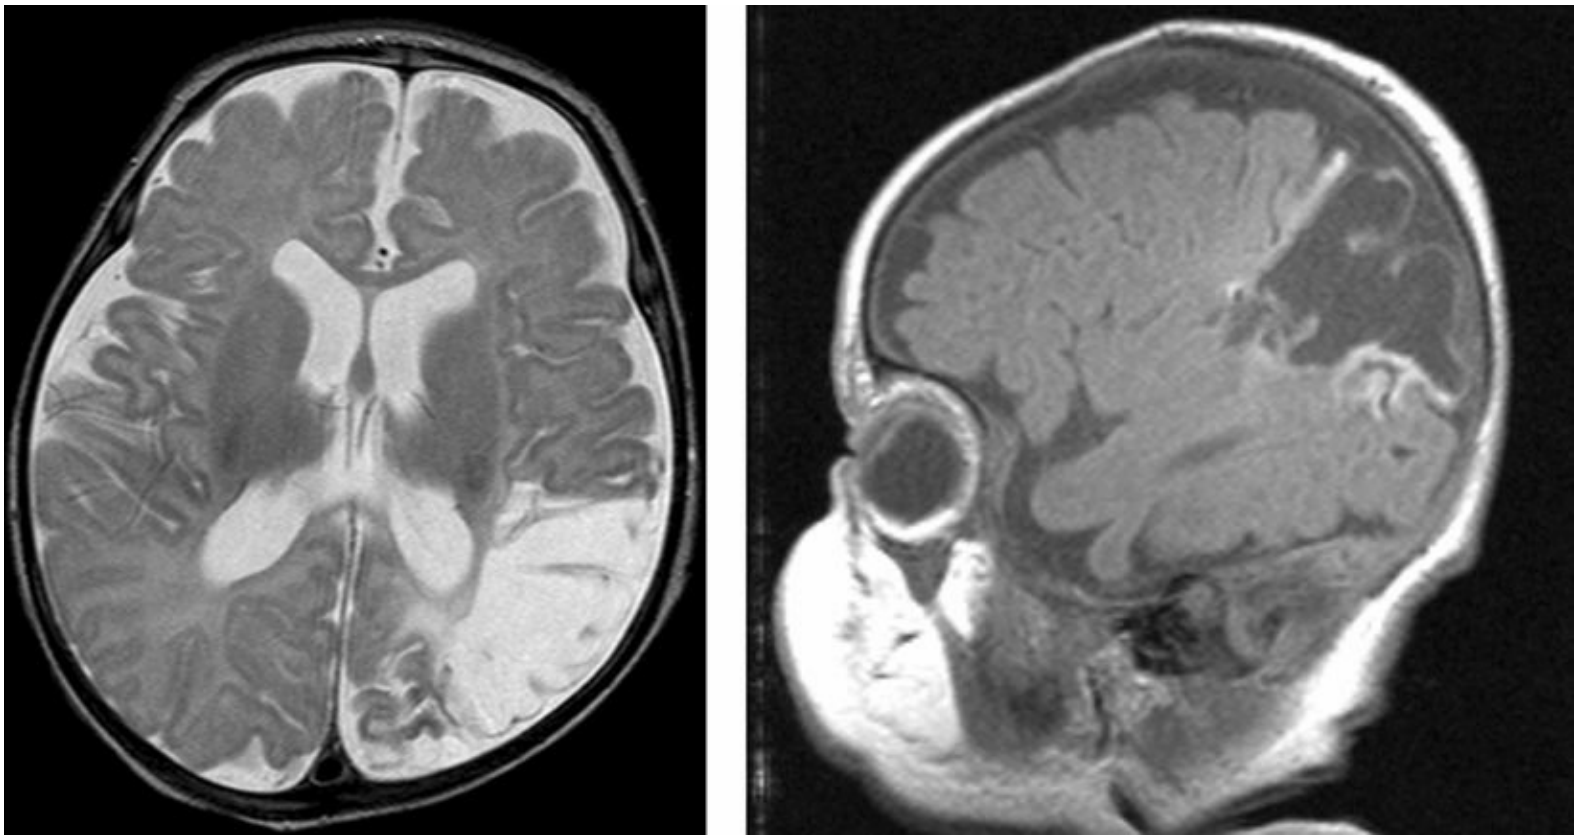

Figure 35.14. Arterial ischemic stroke in the distribution of the left middle cerebral artery in a 41-week–estimated gestational age infant with a prothrombotic disorder.

Cerebral sinovenous thrombosis is estimated to occur at a rate of 0.67 cases per 100,000 children per year (123,124) in neonates and older children. The neonatal presentation most frequently includes seizures (57% to 71%) and other nonspecific CNS signs such as lethargy (35% to 58%), but only infrequently frank hemiparesis (123,125) (Fig. 35.15). Maternal risk factors associated with thrombosis included preeclampsia/hypertension, gestational diabetes, and meconium aspiration or meconium-stained placenta (125). The sagittal and transverse sinuses are most commonly involved, but multiple sinus thromboses also occur. The reported outcomes include a variable mortality rates from 2% to 13%; 21% developed normally while 60% had cognitive impairment, 64% had motor impairment, and 40% had epilepsy (125,126).

Magnetic resonance venogram of a 2-week-old term infant admitted for seizures, lethargy, and dehydration. **A,B:** Thrombosis of the right transverse sinus was noted on the 1st day of hospitalization. **C,D:**By day 10, the thromboses had extended to the sigmoid, jugular, and straight sinuses.

ECMO is an effective therapy for newborn infants with life-threatening respiratory failure unresponsive to maximum conventional medical support. However, the procedure requires ligations of the right common carotid artery and right jugular vein at a time when the infants' underlying lung disease may render them particularly vulnerable to the effects of diffuse CNS hypoxia–ischemia. The high rate of subsequent neurologic morbidity among survivors raises the possibility that ECMO itself may contribute to ischemic–reperfusion brain injuries (127). A high proportion of survivors have MRI-identified focal parenchymal brain lesions, often announced by seizures during ECMO. Cerebral hemorrhage and infarction have been reported in 28% to 52% of ECMO-treated infants (128).

CHDs enhance the risk for neonatal seizures (129), which can arise preoperatively or postoperatively. Strokes may occur from multiple mechanisms including right-to-left intracardiac shunting or embolization during cardiac catheterization (130). CHDs also may be associated with the presence of other midline somatic defects including CNS anomalies. Seizures can arise from concurrent cerebral dysgenesis as well (131). Hypocalcemia may trigger seizures in the setting of DiGeorge syndrome. However, seizures usually arise after NBHS; they do not occur at random, but, rather, are influenced by suspected or confirmed genetic disorders, aortic arch obstruction, or the need for prolonged deep hypothermic circulatory arrest (132). This population is especially valuable for neuroprotection trials, because the child's status can be determined before surgery (133).

Metabolic Etiologies

Hypoglycemia, hyponatremia, hypernatremia, hypocalcemia, hypomagnesemia, and acute hyperbilirubinemia (acute kernicterus) can be associated with neonatal seizures. These conditions are detectable by simple screening tests (see Table 35.4).

Hypoglycemia may itself cause brain damage independent of the seizures. Causes of hypoglycemia that should be evaluated in children include simple prematurity, maternal diabetes, nesidioblastosis, galactosemia, defects of gluconeogenesis, glycogen storage diseases, and respiratory chain defects. Glucose transporter type I syndrome (GLUT I deficiency) is characterized by infantile seizures that usually begin between 6 and 12 weeks of life, developmental delay, ataxia,

and progressive microcephaly (134–136). Affected newborns appear normal at birth. Neonatal seizures, initially rare, increase in frequency as the developmental delay becomes evident. The resultant diminution in transported glucose at the blood–brain barrier markedly reduces brain and cerebrospinal fluid values. Genetic studies often implicate mutations in SLC2A1. The ketogenic diet is a highly effective treatment modality since it provides an alternate form of fuel for the CNS.

Inborn Errors of Metabolism

For a detailed discussion, see Chapter 31. The discussion below is limited to the diagnosis of common neonatal conditions amenable to treatment with a specific intervention.

Maple syrup urine disease, ketotic and nonketotic hyperglycinemia, and urea cycle disorders may all induce a severe acute encephalopathy with seizures. Nonketotic hyperglycinemia has a catastrophic clinical presentation (aptly named glycine encephalopathy) with intractable seizures, coma, hiccups, apnea, pupil-sparing ophthalmoparesis, spontaneous and stimulus-provoked myoclonus, and a burst suppression pattern on electroencephalography (137). Glycine levels are elevated in the blood and cerebrospinal fluid. The disorder represents an inability to cleave glycine, which is both an excitatory and inhibitory neurotransmitter. Treatment involves an NMDA receptor antagonist, as well as magnesium, sodium benzoate, and dextromethorphan.

The ketotic hyperglycinemias and propionic and methylmalonic acidemias present with overwhelming multisystem failure and dehydration, ketoacidosis, and fulminant CNS signs such as seizures, vomiting, and coma. Diagnosis is made by serum amino acid surveys and measurement of specific enzyme activity.

Carbamoyl phosphate synthetase deficiency, ornithine carbamoyltransferase deficiency, citrullinemia, and argininosuccinic acidemia are among the large number of urea cycle abnormalities, and each causes neonatal seizures in the 1st days or weeks of life. Coma and prominent bulbar dysfunction are noted with ophthalmoparesis, fixed pupils, absent gag reflex, poor sucking, and apnea. The degree of serum ammonia elevation may correlate with the discontinuity in the abnormal EEG backgrounds (138).

Biotinidase deficiency may produce alopecia, seborrheic dermatitis, developmental delay, hypotonia, and ataxia. Seizures may begin as early as the 1st week of life. The diagnosis is made by measurement of blood levels of biotinidase activity. Oral administration of free biotin daily is the treatment.

Pyridoxine-dependent seizures (139,140) usually arise between birth and 3 months of age, although atypical cases have been reported up to 3 years. Some seizures can be appreciated in utero (141). The neonate presents with agitation, irritability, jitteriness, diminished sleep, and intractable clonic seizures. The EEG patterns are entirely nonspecific and include abnormal backgrounds, excessive multifocal sharp waves, and focal electrographic seizures evolving to hypsarhythmia later in the 1st year. Intravenous administration of 50 to 100 mg of pyridoxine causes cessation of seizures and disappearance of epileptiform EEG activity within a few hours of administration. Lifelong therapy with pyridoxine 50 to 100 mg/day is necessary. Despite early treatment, some neonates are eventually retarded and show MRI evidence of a leukodystrophy. Mutations in α-aminoadipic semialdehyde (α-AASA) dehydrogenase (antiquitin) leading to inactivation of pyridoxal phosphate (PLP) have been found in multiple individuals with pyridoxine-dependent seizures (142). PLP is an essential cofactor in multiple enzymatic reactions, including the formation of GABA. Elevations of urinary α-AASA can be used as a screening tool for identifying individuals with antiquitin mutations.

However, this should not substitute for a pyridoxine trial, especially in the acute setting. Mutations in pyridox(am)ine 5′-phosphate oxidase may cause early neonatal seizures due to decreased synthesis of PLP. Treatment with PLP is necessary to overcome this defect (143).

Folinic acid–responsive neonatal seizures were first described by Hyland as the unexpected appearance of seizures in term infants during the first few hours or days of life (144). Subsequently intractable, the seizures were associated with severe developmental delay, progressive atrophy on MRI examination, and frequent bouts of status epilepticus. Analysis of cerebrospinal fluid by means of high-performance liquid chromatography with electrochemical detection consistently revealed a characteristic peak that aided in diagnosis. Seizures ceased and the EEG pattern improved after the administration of 2.5 mg of folinic acid twice daily. Gallagher et al. (145) identified the biochemical marker for folinic acid–responsive seizures in two individuals who were controlled with pyridoxine. They identified gene mutations in antiquitin in those two individuals along with seven other individuals with folinic acid–responsive seizures. The authors suggest that the two conditions are allelic and recommend considering treating patients with α-AASA dehydrogenase deficiency with both pyridoxine and folinic acid.

Deficiency of the molybdenum cofactor and isolated sulfite oxidase deficiency are autosomal recessive errors that produce severe neurologic symptoms resulting from a lack of sulfite oxidase activity (146). The presentation includes poor feeding, an abnormally pitched cry, jitteriness, and intractable seizures with the presence of sulfites in the urine. Synthesis of molybdenum cofactor requires the activities of at least six gene products including gephyrin (147), a scaffolding protein present at inhibitory synapses. Unfortunately, there is no effective treatment, and prognosis for neurologic recovery and survival is poor.

Neonatal Intoxications

Lidocaine or mepivacaine inadvertently injected into the fetal scalp during local pudendal analgesia for the mother, cocaine, heroin (148), amphetamines, propoxyphene, and theophylline also may cause seizures.

Chronic Causes

Cerebral Dysgenesis

Some neonatal seizures result from long-standing disorders, such as cerebral dysgenesis, neurocutaneous syndromes, genetic disorders, or very early onset epilepsy. An MRI scan should be performed early to uncover cerebral dysgenesis (149). In lissencephaly or hemimegalencephaly (Fig. 35.16), no acute cause for seizures such as neonatal depression or birth trauma is present, and the infant appears outwardly well yet experiences seizures. The identification of cerebral dysgenesis on neuroimaging should not dissuade the clinician from seeking evidence of inborn errors of metabolism, as both may coexist (e.g., cytochrome oxidase deficiency, glutaric aciduria types I and II, 3-hydroxyisobutyric aciduria, 3-methylglutaconic aciduria, 3-ketothiolase deficiency, sulfite oxidase deficiency, pyruvate dehydrogenase deficiency, neonatal adrenoleukodystrophy, fumaric aciduria, long ketotic hyperglycinemia, and Zellweger syndrome) (150).

Figure 35.16. Computed tomography scan of the head showing right hemimegalencephaly with dysplastic and enlarged right cerebral hemisphere. Brain magnetic resonance imaging provides better resolution and definition of the abnormality and reveals subtle involvement of the contralateral hemisphere.

TORCH Infections

Chronic TORCH (toxoplasmosis, other infections, rubella, cytomegalovirus, and herpes virus) infections can be identified by ophthalmologic changes, microcephaly, periventricular calcifications on neuroimaging, and appropriate serologic blood tests. Congenital infections acquired before the 4th month of gestation may cause an acquired form of migration defect and give rise to "dysgenetic" patterns on computed tomography (CT) or MRI scanning (151).

Neurocutaneous Syndromes

Among the neurocutaneous syndromes that may give rise to neonatal seizures is familial incontinentia pigmenti, a mixed syndrome of different mosaicisms (152). This X-linked dominant state is presumably lethal in males. Perinatal inflammatory vesicles are followed by verrucous patches that produce a distinctive pattern of hyperpigmentation and finally dermal scarring. The cause is a mutation in the IKBKG (NFκB essential modulator) gene (previously NEMO) located on Xq28 that renders cells susceptible to apoptosis when exposed to tumor necrosis factor alpha (TNF-α) (153). In contrast to the familial form, sporadic incontinentia pigmenti maps to Xp11 and is considered its "negative" pattern. Better known as hypomelanosis of Ito, its cutaneous lesions appear as areas of hypopigmentation.

Tuberous sclerosis may create neonatal seizures in two basic ways (154): first, through cortical tubers, which in the neonate may be easier to appreciate on CT scan than on MRI, and second, embolic stroke from intracardiac tumors. In the neonate, the classic neurocutaneous signs are often not apparent, except for hypomelanotic macules noted at or soon after birth; however, these may be evident only on skin examination under a Wood's lamp.

Linear sebaceous nevi are a family of disorders with distinctive raised, waxy, sometimes verrucous nevi on the scalp or face, associated with hemihypertrophy, hemimegalencephaly, and neonatal seizures (155).

Sturge–Weber syndrome is a sporadic syndrome featuring the distinctive port wine stain and associated vascular anomaly over the cortical surface. It may manifest with neonatal seizures.

Epilepsy Syndromes of Early Infantile Onset

In the 1970s, French neurologists coined the "fifth-day fits" (benign neonatal convulsions) to describe an electroclinical syndrome in which seizures unexpectedly arose between the 4th and 6th days of life (156). More than half had a distinctive "theta pointu alternant" pattern in which the bursts of cerebral electrical activity in the discontinuous parts of the record showed sharply contoured theta waves, especially in the central regions. This EEG pattern has also been recognized in patients with unmistakable HIE.

Benign familial neonatal epilepsy is the first idiopathic epilepsy syndrome discovered to be caused by a single gene mutation (157,158). Partial seizures unexpectedly begin by the 3rd day of life in neurologically normal-appearing patients, 10% to 15% of whom progress to epilepsy. Defects in KCNQ2 have been found to have a broad phenotypic spectrum ranging from classical BFNE to severe neonatal encephalopathy (157,159). BFNC with myokymia (160) has been reported as a separate mutation of KCNQ2, also on 20q13.3.

Migrating partial seizures in infancy constitute a constellation of unprovoked, alternating electroclinical seizures and subsequent neurodevelopmental devastation that was described in 1995 by Coppola et al. (161). Although multifocal neonatal seizures are not uncommon after infections, metabolic disorders, and hypoxia–ischemia, they can also accompany cerebral dysgenesis and some other neonatal seizure syndromes. In migrating partial seizures in infancy, healthy infants without cerebral dysplasia display multifocal partial seizures that arise independently and sequentially from both hemispheres (Fig. 35.17) within the first 6 months of life and progress through a period of intractability, ultimately leading to severe psychomotor retardation. As described in the original paper and later case reports, prognosis was very poor, with 28% mortality and the majority of survivors profoundly retarded and nonambulatory; however, later patients have fared somewhat better (162). A genetic etiology is presumed with a KCNT1 mutation found in two patients in a larger study of 14 patients (163).

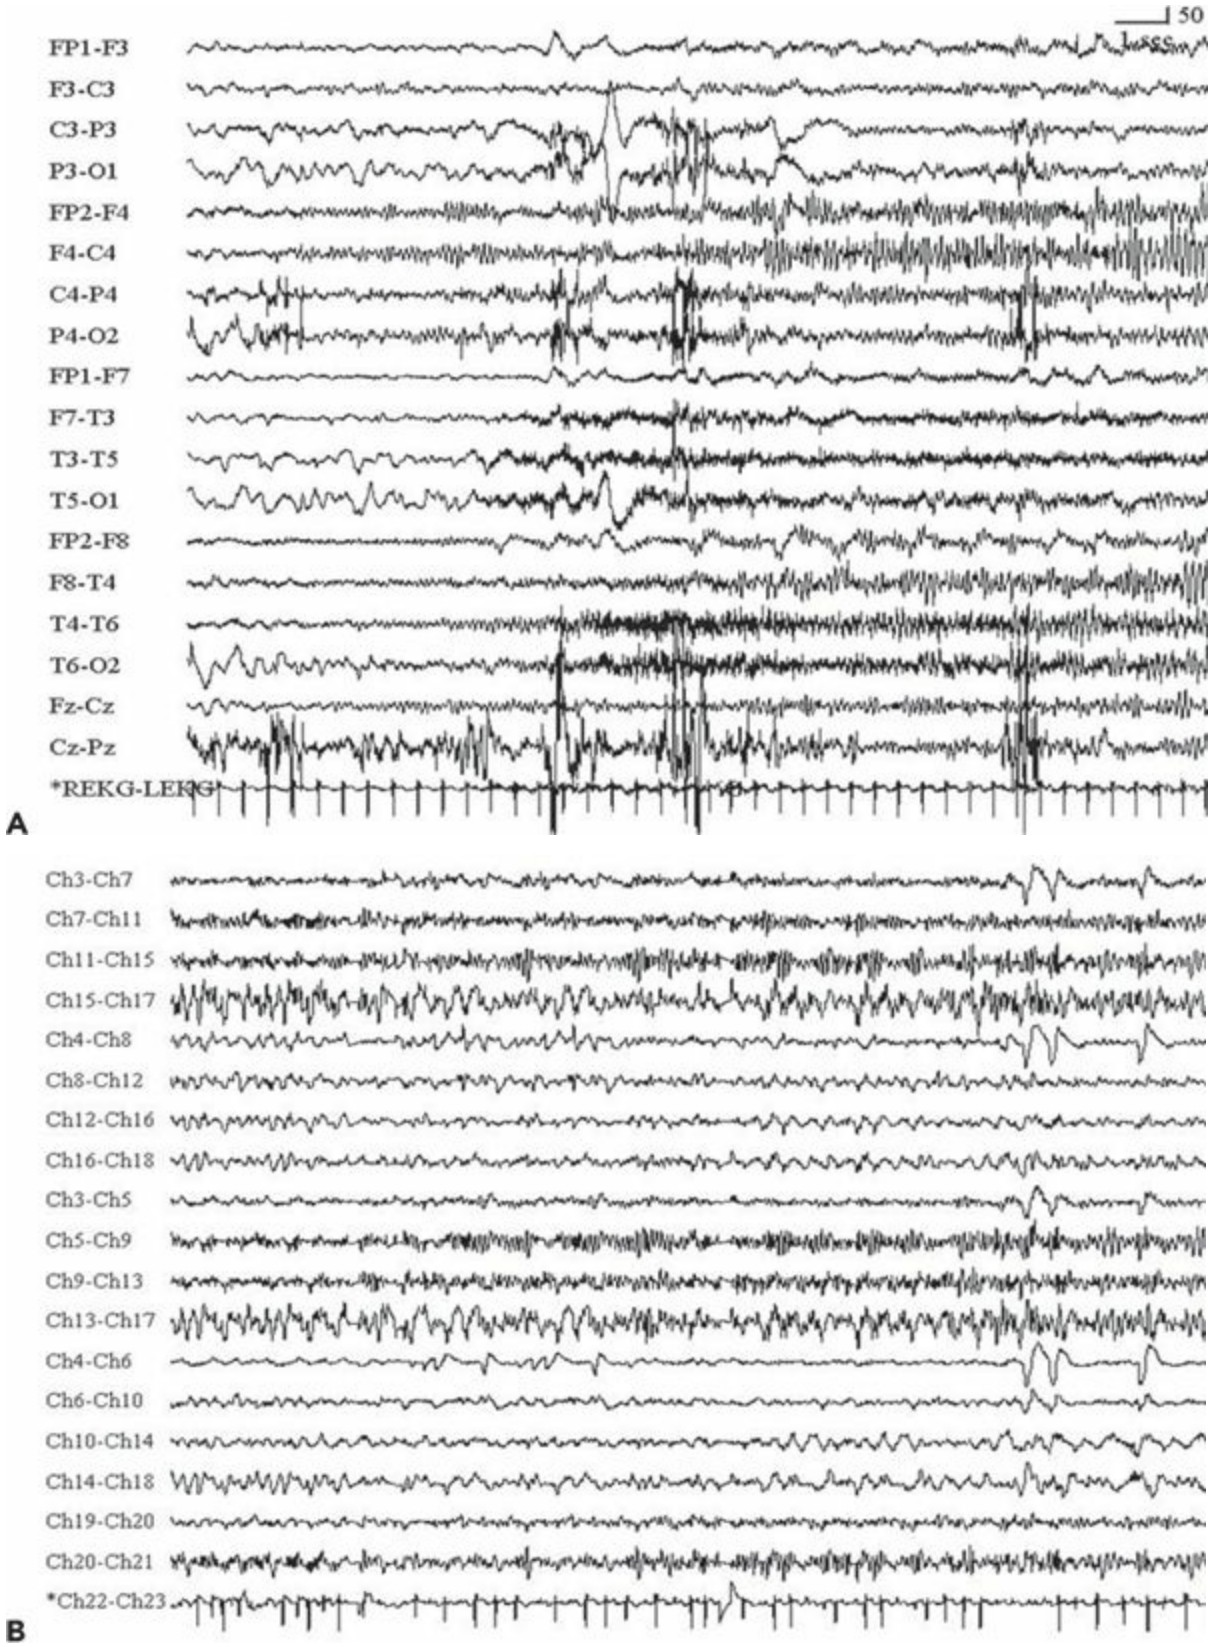

Figure 35.17. Migrating partial seizures in infancy. Seizure originating from the right hemisphere **(A)**, followed by one arising from the left hemisphere **(B)** (odd channel numbers represent the left hemisphere, and even channel numbers represent the right hemisphere). Note that the time axis of the electroencephalogram rhythm strip is slightly compressed. The time and amplitude calibration bar appears at the top of the figure: 1 second and 50 μV. (Adapted from Marsh E, Melamed S, Clancy R. Migrating partial seizures in early infancy: expanding the phenotype of a rare neonatal seizure type. Epilepsia. 2003;44:305, with permission.)

First described by Aicardi and Goutieres (164), EME is characterized by maternal reports of sustained, rhythmic fetal kicking, oligohydramnios or polyhydramnios, normal Apgar scores, and seizure onset from the 1st day of life to several months (typical age, 16 days). Clinical seizures

include erratic fragments of myoclonic activity, massive myoclonia, stimulus-sensitive myoclonia, and partial seizures. Electroencephalograms are eventually markedly abnormal, frequently with a burst suppression background. The myoclonic limb movements tend to occur during the burst periods of the burst suppression background (Fig. 35.18). All patients are completely resistant to antiepileptic drugs (AEDs). Other clinical features are progressive decline in head circumference percentiles, bulbar signs (especially apnea), feeding difficulties, cleft or high-arched palate, and severe psychomotor delay. A recent case report identified a disruption of the tyrosine protein kinase receptor ErbB4 in a patient with EME (165).

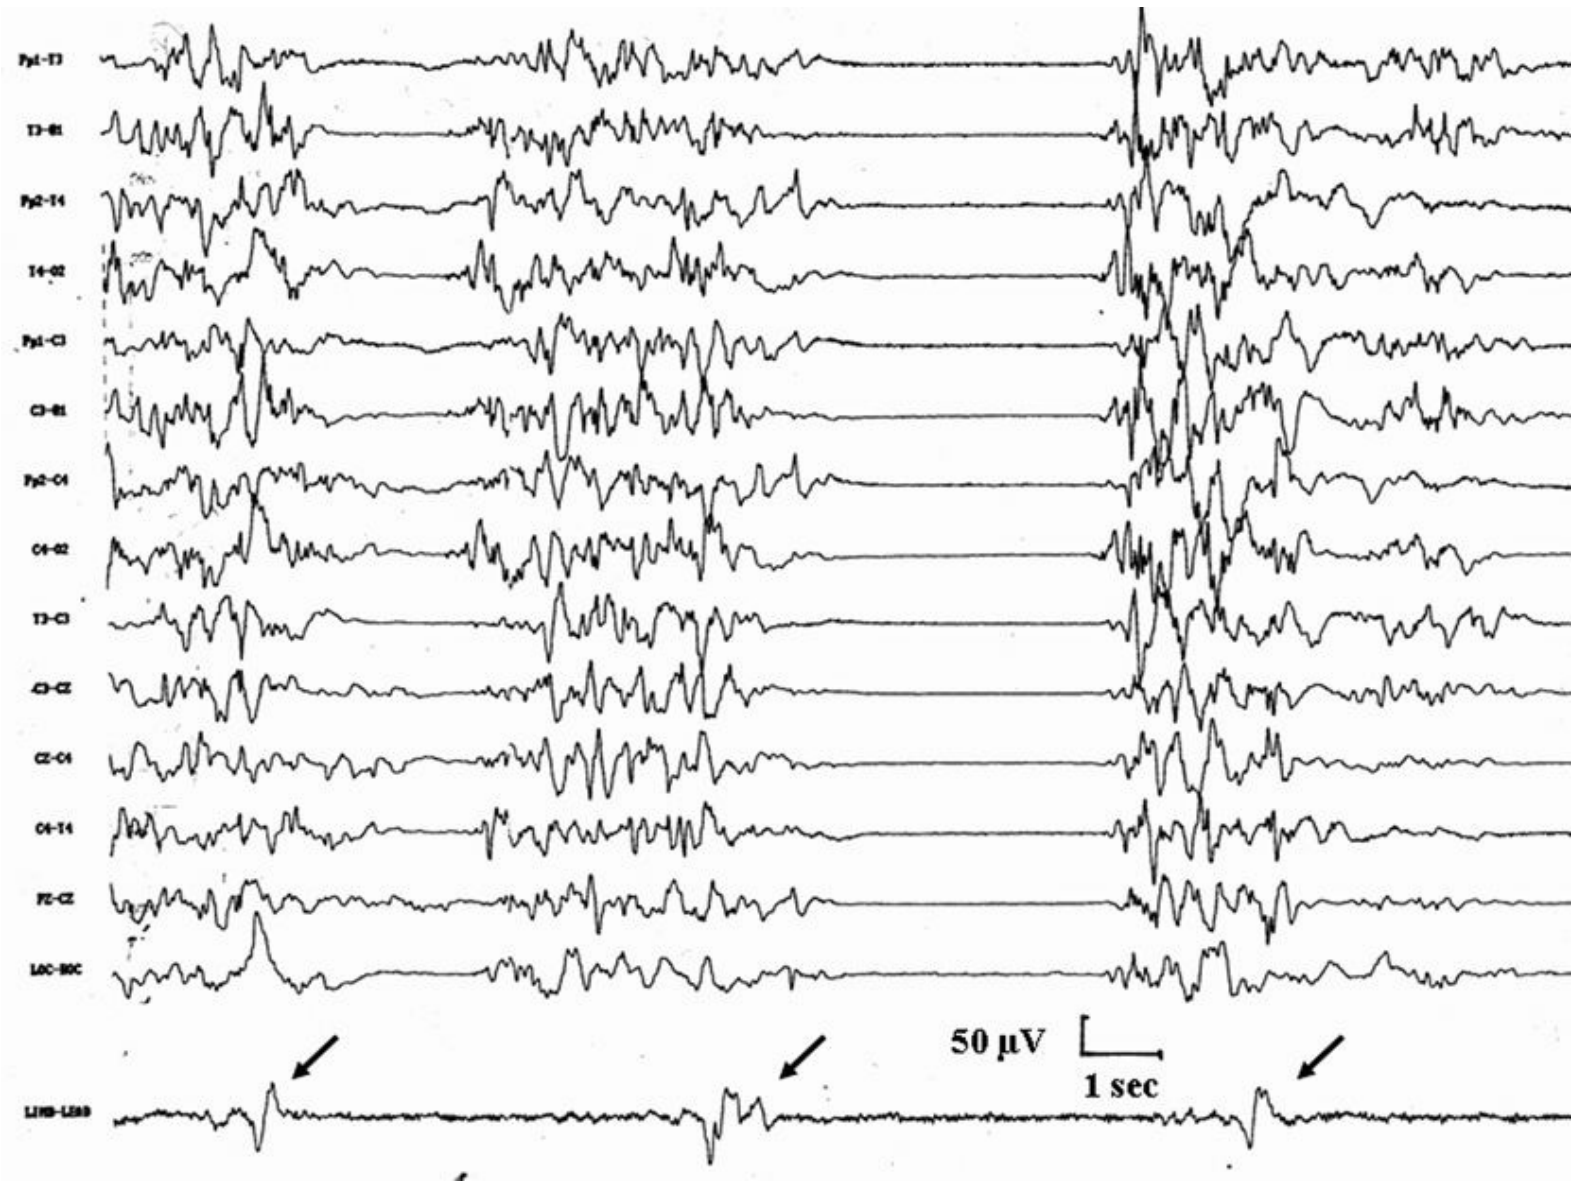

Figure 35.18. Burst suppression electroencephalographic pattern of early myoclonic epilepsy. The abnormal myoclonic movements, detected by the bottom electromyographic channel (arrows), occur during the "burst" periods of the tracing.

Early infantile epileptic encephalopathy (EIEE), also known as Ohtahara syndrome, is characterized by intractable tonic seizures in the setting of a severe encephalopathy and a burst suppression background pattern (166). In fact, the EEG findings alone appear similar to those of EME, and there is discussion that they may represent a spectrum of disease (167). Many infants with EIEE harbor overt cerebral dysgenesis or cortical dysplasias. Survivors often develop typical infantile spasms with hypsarhythmia and Lennox–Gastaut syndrome accompanied by multifocal spikes on the electroencephalogram. Cases of EIEE have been found in patients with ARX mutations (168).

Recently, 5 of 13 patients with EIEE were found to have mutations in the gene encoding syntaxin binding protein 1 (STXBP1) (169). The STXBP1 gene plays an important role in synaptic vesicle release.

TREATMENT

Despite the decadelong recognition of neonatal seizures, treatment recommendations rest almost entirely on conventional wisdom and traditional practices. Because AEDs are used to treat neonatal seizures of epileptic origin, initial consideration is given to the clinical and EEG features of the events. Discussion has also centered on the advisability of treating all epileptic neonatal seizures, as some are brief, infrequent, and self-limited. On the one hand, if the burden of seizures will be minimal, the infant need not be exposed to acute and long-term drug therapy. On the other hand, epileptic neonatal seizures that are long, frequent, and not self-limited are treated acutely and vigorously with AEDs.

No studies unequivocally demonstrate the efficacy of barbiturates in the treatment of neonatal seizures. In a randomized, controlled study (170), thiopental was administered soon after perinatal asphyxia. Seizures were diagnosed by clinical signs and occurred in 76% of treated infants and in 73% of a control (placebo) group. High doses of phenobarbital given after perinatal asphyxia resulted in a lower rate of recurrent seizures compared to placebo, although the difference was not statistically significant (171). Another randomized study using phenobarbital prophylactically in neonates with perinatal asphyxia found a statistically significant decrease in the incidence of neonatal seizures compared with placebo control (172). This study has some limitations, including a small number of patients with seizures and lack of EEG data for clinical confirmation or identification of electrographic seizures. In another study of 31 acutely ill neonates with electrographic seizures detected during continuous electroencephalograph monitoring, only two had a complete cessation of both clinical and EEG seizures with AEDs (173). Six had an equivocal electroclinical response. Clinical seizures stopped in 13, although the electrographic seizures persisted. The remaining 10 had persistent electroclinical seizures. Two studies (94,103) reported a mixed response of electroclinical seizures to phenobarbital. In a non–placebo-controlled comparison study (174), electrographic seizures ceased in 43% of the group treated with phenobarbital and in 45% of the group given phenytoin; however, the lack of a placebo control precluded determination of absolute efficacy. Video-EEG monitoring demonstrated cessation of seizures in 11 of 22 infants after administration of 40 mg/kg phenobarbital (94). In the remaining 11 nonresponders, 3 of 5 went on to respond to lignocaine while 0 of 6 responded to a benzodiazepine. According to a Cochrane review (175), "… at the present time, anticonvulsant therapy determined in the immediate period following perinatal asphyxia cannot be recommended for routine clinical practice, other than in the treatment of prolonged or frequent clinical seizures." In addition, another Cochrane review noted (176), ". . . there is little evidence from randomized controlled trials to support the use of any of the anticonvulsants currently used in the neonatal period."

In summary, despite the frequent empiric selection of phenobarbital in clinical practice for the treatment of neonatal seizures, evidence of its efficacy is limited, and animal studies raise concern that phenobarbital itself may have deleterious effects on the young nervous system (see section titled "Potential Deleterious Effects of Antiepileptic Drug Administration on the Immature CNS" later in the chapter). Few drugs for use in the newborn have been subjected to adequately powered, randomized, placebo-controlled investigations to demonstrate real safety and efficacy. Drugs with

potential for the treatment of neonatal seizures are no exception.

Nevertheless, in ordinary clinical practice, it is common to administer AEDs in an effort to reduce or eliminate seizures in the newborn. Early studies of neonatal seizures recommended loading doses of phenobarbital 15 to 20 mg/kg, with the intention of generating serum levels between 15 and 20 μg/mL, and followed by maintenance doses of 3 to 4 mg/kg/d.

The "mg/kg" dose of phenytoin should be calculated to achieve, but not exceed, free concentrations of 3 μg/mL (174,177). The dosing formula (3 μg/kg) × Vd (L/kg)/(% free binding) assumes a volume of distribution of 1 L/kg. Phenytoin has nonlinear pharmacokinetics: steady-state plasma concentrations at one dosing schedule do not predict those at another schedule (178,179). There are also variable rates of hepatic metabolism, serum binding, decreases in elimination rates during the 1st weeks of life, and variable bioavailability with different generic preparations. A redistribution of the AED after the initial dose decreases brain concentrations thereafter; thus, dosage must be tailored to the individual patient after therapy begins. Furthermore, phenytoin is strongly alkalotic and may lead to local venous thrombosis or tissue irritation. The use of fosphenytoin may reduce these risks.

While phenobarbital remains first-line therapy for neonatal seizures, there is some debate about second-line therapy. In two surveys of pediatric epileptologists in the United States and Europe, phenobarbital was identified as the treatment of choice, while intravenous benzodiazepines and fosphenytoin or phenytoin were also considered first-line therapy (180,181).

Benzodiazepines, typically lorazepam (0.15 mg/kg) and diazepam (0.3 mg/kg), can be effective therapies for refractory patients. Side effects of acute administration include hypotension and respiratory depression.

Alternative or adjuvant AEDs have also been empirically prescribed for refractory neonatal seizures. Clonazepam, lidocaine (182–184), and midazolam (185,186) are administered intravenously; carbamazepine (187), primidone (188), vigabatrin (189), and lamotrigine (190) are given orally. Levetiracetam has shown some efficacy in the treatment of neonatal seizures (191–193). A recently released anticonvulsant, ezogabine, works primarily as a potassium channel opener. In BFNE due to KCNQ2 mutations, seizures can arise from as little as a 20% disturbance in potassium conductance, making this an attractive candidate for future consideration in treating neonatal seizures, which typically respond incompletely to GABA-ergic medications.

The neuroprotective and antiseizure effects of topiramate in animal models suggest a promising role in the treatment of neonatal seizures. Limited case series reviewing the utility of topiramate in refractory neonatal seizures have shown some encouraging results. In one study, four of six patients had a favorable response with doses up to 10 mg/kg/d (194), while in another, three patients became seizure free following administration (195). An IV formulation of topiramate is under early investigation in the adult population (196), and the FDA has given approval to develop intravenous topiramate as an orphan drug in July 2013.

The administration of antiepileptic medications may terminate the clinical manifestation of the seizure while the electrographic discharge continues (174). This disconnect is often termed uncoupling and poses serious concerns for the clinician and researchers in determining response rates to AEDs. Scher et al. (197) found 58% of patients continued experiencing electrographic seizures after an administered AED had stopped their clinical seizures. This phenomenon may be explained by the caudal–rostral maturational switch from NKCC1 to KCC2, allowing medications to be more effective against brainstem and spinal cord neurons before more rostral structures (13). The relatively high rates of uncoupling stress the importance of EEG documentation of resolution of neonatal

seizures.

Chronic Postnatal Epilepsy and the Need for Long-Term Treatment

Chronic postnatal epilepsy is relatively common in the wake of neonatal seizures (Fig. 35.19). For many patients, permanent, fixed brain injuries, such as resolving stroke, ischemia, or traumatic lesions, serve as the nidus for future epilepsy. As mentioned, repeated neonatal seizures may have "instructed" the brain how to have future seizures, resulting in a persistent lowering of the seizure threshold (43) and the development of chronic epilepsy. In infants with EME or EIEE, neonatal seizures represent the beginning of very early onset epilepsy, which persists by its nature. The most common occurrence, however, is epilepsy after neonatal seizures triggered by acute neonatal conditions.

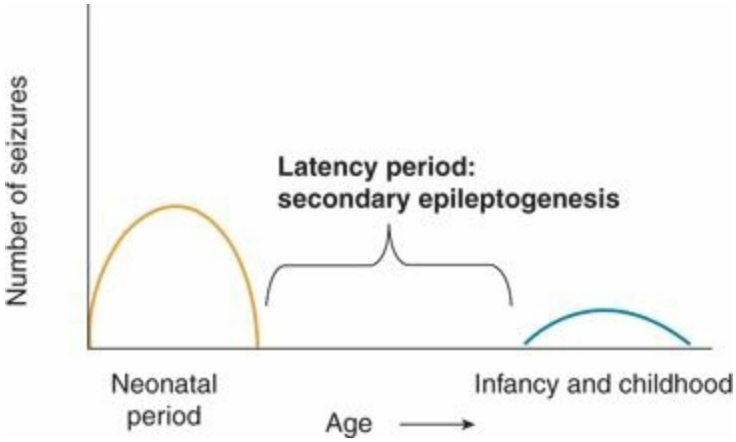

Figure 35.19. Acute neonatal seizures are often followed by chronic postnatal epilepsy. A latent period, during which secondary epileptogenesis develops, gives rise to spontaneous, unprovoked seizures.

Ellenberg et al. (198) found that approximately 20% of survivors of neonatal seizures experienced one or more seizures up to 7 years of age; nearly two-thirds of the seizures occur within the first 6 months of life. Other researchers (24,103,199–201) reported rates ranging from 17% to 30%. The 56% noted by Clancy et al. (202,203) may be explained by their inclusion of only infants whose EEG seizures were captured on a routine duration EEG. It is likely that some were discovered just by chance, but a large fraction of the group was probably in status epilepticus. Glass et al. also reported that after status epilepticus from HIE, 83% went on to develop postneonatal epilepsy (204).

Partial and generalized seizures characterize postneonatal epilepsy and do not seem to be preventable by the long-term administration of AEDs after neonatal seizures. It is not rare for catastrophic forms of epilepsy to arise after neonatal seizures including infantile spasms and the Lennox–Gastaut syndrome.

Not all neonates require extended therapy after acute seizures have been controlled, although no criteria for long-term maintenance AED use have been sufficiently studied. Reported schedules for discontinuation of maintenance therapy range from 1 week to 12 months after the last seizure (205); one currently used schedule withdraws AEDs 2 weeks after the last seizure (206).

Potential Deleterious Effects of Antiepileptic Drug Administration

on the Immature CNS

AEDs prevent or interrupt electrographic seizures by the blockade of voltage-dependent sodium channels and glutamatergic excitatory neurotransmission and enhancing of GABA-mediated inhibition. However, in this critical time of early brain development, suppression of synaptic transmission may have incidental undesirable consequences, because neuronal and synaptic pruning are activity dependent. Since the 1970s, it has been known that rat pups fed phenobarbital have later reductions in brain weight and in total brain cell count (207). How AEDs may harm the developing rat brain remains under investigation, but evidence suggests that these drugs may trigger apoptotic neurodegeneration in the rodent forebrain and suppress an endogenous neuroprotective system already in place (208). The clinical impact of these findings is less certain. Most neonates are given phenobarbital because of seizures, and it is difficult to determine how much of any long-term aftermath is the result of the seizures' underlying etiology, the attacks themselves, or the medications administered to suppress them. Some neonates receive phenobarbital for other reasons, such as to provide sedation or to accelerate hepatic maturity in neonatal hyperbilirubinemia, and appear to experience no ill effects. Likewise, benzodiazepines are commonly administered for sedation or to reduce agitation, and no obvious adverse effects are associated with their use, although careful studies are lacking.

CHAPTER 36 SEIZURES ASSOCIATED WITH NONNEUROLOGIC MEDICAL CONDITIONS

STEPHAN EISENSCHENK, JEAN E. CIBULA, AND MARIA I. HELLA

Seizures frequently arise during the course of medical illnesses that do not primarily affect the central nervous system (CNS). The truism that appropriate treatment depends on correct diagnosis emphasizes the importance of the differential diagnosis. A patient's history, including a review of medications and physical examination, should be informed by a consideration of the seizures as a symptom of CNS dysfunction. The urgency to pursue a diagnosis is related to the time of presentation following the seizure. In a neurologically intact patient without progressive symptoms, quick (within days), but not emergent (within hours), evaluation may be appropriate. Within the first 24 hours, vital signs, level of consciousness, and focality on examination determine urgency. The need for emergent neuroimaging studies and lumbar puncture depends on the likelihood of intracranial lesion, CNS or systemic infection, a patient's metabolic state, and the possibility of drug or alcohol intoxication. In a patient who presents more than 1 week after an initial seizure, recurrent attacks establish the diagnosis of epilepsy.

Several factors predispose a patient to seizures, including (i) changes in blood–brain barrier permeability as a result of infection, hypoxia, dysautoregulation of cerebral blood flow, or microdeposition of hemorrhage or edema secondary to vascular endothelial damage; (ii) alteration of neuronal excitability by exogenous or endogenous substances, such as excitatory and inhibitory neurotransmitters; (iii) inability of glial cells to regulate the neuronal extracellular environment; (iv) electrolyte imbalances; (v) hypoxia–ischemia; and (vi) direct and remote effects of neoplasm (1). Some patients without epilepsy may be genetically prone to seizures secondary to systemic factors.

Understanding the interaction of other organ systems is necessary for the appropriate management of seizures. In patients with hepatic or renal dysfunction, changes in pharmacokinetics induced by metabolic dysfunction alter treatment with antiepileptic drugs (AEDs). In cases of hepatic dysfunction, plasma concentrations must be correlated with serum albumin and protein levels and, if possible, free (unbound) levels. Patients with hepatic and renal failure may have normal serum and albumin levels, but altered protein binding, resulting in elevated concentrations of free drug (2).

METABOLIC DISORDERS

Metabolic disorders, although often suspected during outpatient evaluation of new-onset seizures, are found in <10% of patients and usually involve glucose metabolism (3). In the hospital setting, disorders of electrolytes and fluid balance predominate. Encephalopathies may be associated with electrolyte disturbances, hypocalcemia, hypercalcemia, hypoglycemia, hypothyroidism, thyrotoxic storm, adverse effects of drugs, organ failure, and many other conditions.

Hyponatremia

Because electrolyte disturbances are usually secondary processes, effective management of associated seizures begins with identification and treatment of the primary disorder in conjunction with cautious correction of the electrolyte disturbance. Hyponatremia, defined as a serum sodium level lower than 115 mEq/L, is one of the most frequently reported metabolic abnormalities, affecting 2.5% of hospitalized patients (4). Neurologic symptoms occur often in patients with acute hyponatremia (5,6), and convulsions in this setting have a mortality rate estimated to exceed 50% (7). Correction to levels higher than 120 mEq/L is essential; however, the rate of correction is controversial. Rapid correction of hyponatremia is associated with central pontine myelinolysis, manifested as pseudobulbar palsy and spastic quadriparesis (8). Originally described in patients with alcoholism and malnutrition, the condition was later observed in dehydrated patients undergoing rehydration (9), and in one small study (10), it was accompanied in each patient by a recent rapid increase in serum sodium levels. Pathologic features include symmetrical, noninflammatory demyelination in the basis pontis, with relative neuronal and axonal sparing. In animal models of central pontine myelinolysis, rapid correction of sustained vasopressin-induced hyponatremia with hypertonic saline was followed by demyelination (11). Some authorities consider a correction of more than 12 mEq/L/day to be unnecessarily aggressive (10).

Levels of serum sodium are most commonly reduced as a result of either sodium depletion or water "intoxication," or both (7); these are examples of hypoosmolar hyponatremia. Hyponatremia with normal osmolality is rare but may accompany hyperlipidemia or hyperproteinemia. Hyperosmolar hyponatremia occurs in such hyperosmolar states as hyperglycemia and is discussed later in this chapter. Hypoosmolar hyponatremia may occur with normal extracellular fluid volume, hypovolemia, or hypervolemia (12). Hypoosmolar hyponatremia with hypovolemia may follow renal (diuretic use, Addison disease) or extrarenal (vomiting, diarrhea, or "third spacing") loss. The syndrome of inappropriate antidiuretic hormone secretion, hypothyroidism, and some psychotropic agents may lead to hypoosmolar hyponatremia with normal volume. Hypoosmolar hyponatremia with hypervolemia, frequently seen with clinical edema, occurs in patients with cardiac failure and acute or chronic renal failure. The therapeutic implications of these conditions are significant, because appropriate treatment for normovolemic or hypervolemic hyperosmolar hyponatremia is water restriction. Hypovolemic hyponatremia is managed by replacement of water and sodium (12).

Finally, hyponatremia is sometimes considered to be an iatrogenic effect of prescribed medications, including diuretics, carbamazepine, oxcarbazepine, theophylline, amiodarone, and serotonin reuptake inhibitors (13). Hyponatremia can also be a complication of abuse of illicit substances, such as 3,4-methylenedioxy-N-methamphetamine (MDMA, or "ecstasy") (14,15).

Hypocalcemia

Although seizures resulting from severe hypocalcemia (<6 mg/dL) are relatively uncommon, they occur in approximately 25% of patients who present as medical emergencies (16). Severe, acute hypocalcemia most often follows thyroid or parathyroid surgery. Late-onset hypocalcemia with seizures may appear years after extensive thyroid surgery (17); the condition is believed to be rare and is not well understood. Hypocalcemia frequently complicates renal failure and acute pancreatitis (7) and may also occur along with vitamin D deficiency and renal tubular acidosis. Nutritional rickets is still reported, although rarely in the United States, occasionally with hypocalcemic seizures (18). Tetany is the most common neuromuscular accompaniment of hypocalcemia (19). Manifesting as

spontaneous, irregular, repetitive action potentials that originate in peripheral nerves, tetany is sometimes confused with a seizure. Latent tetany may be unmasked by hyperventilation or regional ischemia (Trousseau test). In the average adult, an intravenous (IV) bolus of 15 mL of 10% calcium gluconate solution (a calcium concentration of 9 mg/mL) administered slowly, along with cardiac monitoring, followed by infusion of the equivalent of 10 mL/hour of the same solution, should relieve seizures (20).

Hypomagnesemia

Hypomagnesemia is associated with seizures, but usually only at levels lower than 0.8 mEq/L (21). Because a related hypocalcemia may be produced by a decrease in, or end- organ resistance to, circulating levels of parathyroid hormone, magnesium levels should be measured in the patient with hypocalcemia who does not respond to calcium supplementation. Convulsions are treated with intramuscular injections of 50% magnesium sulfate every 6 hours. Because transient hypermagnesemia may induce respiratory muscle paralysis (21), IV injections of calcium gluconate should be administered concurrently.

Hypophosphatemia

Profound hypophosphatemia may accompany alcohol withdrawal, diabetic ketoacidosis, long-term intake of phosphate-binding antacids, recovery from extensive burns, hyperalimentation, and severe respiratory alkalosis. A sequence of symptoms consistent with metabolic encephalopathy involves irritability, apprehension, muscle weakness, numbness, paresthesias, dysarthria, confusion, obtundation, convulsive seizures, and coma (22). Generalized tonic–clonic seizures have been noted at phosphate levels lower than 1 mg/dL, and affected patients may not respond to AED therapy (23).

Disturbances in Glucose Metabolism

Hypoglycemia and nonketotic hyperglycemia may be associated with focal seizures; such seizures do not occur with ketotic hyperglycemia, however, probably because of the anticonvulsant action of the ketosis (24). Ketosis also involves intracellular acidosis with enhanced activity of glutamic acid decarboxylase, which leads to an increase in γ-aminobutyric acid (GABA) and a corresponding increase in seizure threshold.

Nonketotic hyperglycemia, with or without hyperosmolarity, may produce seizures and, in animal models, increases seizure frequency through brain dehydration, provided a cortical lesion is present (25). Focal motor seizures and epilepsia partialis continua, well-known complications of nonketotic hyperglycemia, occur in approximately 20% of patients (26).

Rarely, patients with focal seizures associated with nonketotic hyperglycemia may have reflex- or posture-induced epilepsy provoked by active or passive movement of an extremity (27,28) and usually have nonreflex seizures as well, related perhaps to an underlying focal cerebral ischemia. Such seizures are refractory to conventional anticonvulsant treatment. In fact, phenytoin may further increase the serum glucose level by inhibiting insulin release (29). Thus, correction of the underlying metabolic disturbance is of utmost importance.

Hypoglycemia is particularly seizure provoking and is most frequently related to insulin or oral hypoglycemic agents, although occasionally the etiology may not be obvious. Another common cause is the use of drugs that interact with oral hypoglycemic agents (30). Islet cell dysmaturation syndrome,

characterized by islet cell hyperplasia, pancreatic adenomatosis, and nesidioblastosis, is associated with infantile hyperinsulinemic hypoglycemia. Bjerke et al. (31) reported on 11 infants with this condition, 8 of whom presented with hypoglycemic seizures. Five infants had preoperative neurologic impairment. All showed improvement postoperatively, but only one infant had normal findings on neurologic examination. Early diagnosis is a decisive factor in averting long-term complications; treatment entails resection of the pancreas.

Hypoparathyroidism

Seizures occur in 30% to 70% of patients with hypoparathyroidism, usually along with tetany and hypocalcemia. They may be generalized tonic–clonic, focal motor, or, less frequently, atypical absence and akinetic seizures. Restoration of normal calcium levels is important for seizure prevention.

Thyroid Disorders

Hyperthyroidism is associated only rarely with seizures, although generalized and focal seizures have occurred in 10% of patients with thyrotoxicosis (32). Typically, thyrotoxicosis may be associated with nervousness, diaphoresis, heat intolerance, palpitations, tremor, and fatigue. Hashimoto thyroiditis often coexists with other autoimmune disorders (33), such as Hashimoto encephalopathy, a steroid-responsive relapsing condition (34) that produces seizures even in euthyroid patients (35).

Seizures have been reported in patients with myxedema. As many as 20% to 25% of patients with myxedemic coma have generalized convulsions. Also, patients with hypothyroidism may have obstructive sleep apnea (36) with hypoxic seizures (37).

Adrenal Disorders

Seizures are uncommon with adrenal insufficiency but may occur in patients with pheochromocytoma (38). More commonly, a pheochromocytoma-induced hypertensive crisis may trigger a hypertensive encephalopathy, characterized by altered mental status, focal neurologic signs and symptoms, and/or seizures. Other neurologic complications include stroke caused by cerebral infarction or an embolic event secondary to a mural thrombus from a dilated cardiomyopathy. Intracerebral hemorrhage may also occur because of uncontrolled hypertension. Additional symptoms are tremor, nausea, anxiety, sense of impending doom, epigastric pain, flank pain, constipation or diarrhea, and weight loss. These spells may last minutes to an hour. Blood pressure is almost always markedly elevated during the episode.

Uremia

A change in mental status is the hallmark of uremic encephalopathy, which also involves simultaneous neural depression (obtundation) and neural excitation (twitching, myoclonus, generalized seizures). Epileptic seizures occur in up to one-fourth of patients with uremia, and the reasons are quite varied.

Phenytoin is the AED usually administered to nontransplanted patients with uremia (see section Transplantation and Seizures later in this chapter). Critical changes in the pharmacokinetics of AEDs include (i) increased volume of distribution, producing lowered plasma drug levels; (ii) decreased protein binding, creating higher free drug levels; and (iii) increased hepatic enzyme oxygenation,

yielding increased plasma elimination (2). Because patients with uremia have plasma protein–binding abnormalities and because phenytoin is highly plasma bound, drug administration is different from that in nonuremic patients. In one study, a 2 mg/kg IV dose produced a level of 1.4 μg/mL in patients with uremia, compared with 2.9 μg/mL in control patients (39). In nonuremic patients, up to 10% of phenytoin is not protein bound, whereas in uremic patients, as much as 75% may not be protein bound. Thus, free phenytoin levels (between 1 and 2 μg/mL) should be used instead of total phenytoin levels to assess therapeutic efficacy (40). With gabapentin, pregabalin, lacosamide, and levetiracetam, which are eliminated via renal excretion, the usual total dose should be reduced equivalently to the reduction in creatinine clearance (41–43).

The treatment of renal failure may also lead to dialysis disequilibrium, characterized by headache, nausea, and irritability, which may progress to seizures, coma, and death attributable to the entry of free water into the brain, with resultant edema. Dialysis dementia, caused by the toxic effects of aluminum, is now rare. Renal transplant recipients may experience cerebrovascular disease, opportunistic infections, or malignant neoplasms, particularly primary lymphoma of the brain.

In uremic patients with renal insufficiency, adverse reactions to antibiotics are a common cause of seizures (44). Patients may have focal motor or generalized seizures, or myoclonus. In uremia, reduced protein binding increases the free fraction of highly protein-bound drugs in serum (and therefore in the CNS). Raised concentrations of neurotoxic agents, such as cephalosporins especially cefepime and ceftazidime, may increase seizure susceptibility, which may be enhanced further by the altered blood–brain barrier.

The hemodialysis patient represents a special challenge because of decreased concentrations of dialyzable AEDs. Plasma protein binding determines how effectively a drug can be dialyzed. Higher protein biding makes the medication less dialyzable. (45). Hence, levels of a drug such as phenobarbital (40% to 60% protein bound) will decrease during dialysis more than will levels of valproic acid (80% to 95% bound). One way, albeit cumbersome, to avoid “losing” an agent is to dialyze against a dialysate containing the drug. Another option, if seizures occur near the time of dialysis, is to use a highly protein-bound drug, such as valproic acid. For special considerations in the kidney transplant patient, see section Transplantation and Seizures.

Inborn Errors of Metabolism

Metabolic errors, either inborn or acquired, occur most often in early childhood. Phenylketonuria is the most common of several aminoacidopathies that may be associated with infantile spasms, and myoclonic or tonic–clonic seizures occur in one-fourth of these patients (46). Evidence of hypsarrhythmia may be seen on the electroencephalogram (EEG), but a high proportion of patients have abnormal EEGs without seizures.

Although hereditary fructose intolerance does not usually involve neurologic impairment, a small number of children experience seizures that are sometimes related to prolonged hypoglycemia (47).

Because excess ammonia is excreted as urea, disorders of the urea cycle, such as hyperammonemia, may be associated with symptoms ranging from coma and seizures to mild, nonspecific aberrations in neurologic function (46).

Various storage diseases result from abnormal accumulation of normal substrates and their catabolic products within lysosomes. The absence or inefficiency of lysosomal enzymes in such conditions as sphingolipidoses, mucopolysaccharidoses, mucolipidoses, glycogen storage diseases, and glycoproteinoses may give rise to seizures (46).

Purine syndromes and hyperuricemia are not usually associated with seizure disorders unless mental retardation or dementia coexists. Allopurinol is an important adjunctive treatment in some patients.

Porphyria

The disorders of heme biosynthesis are classified into two groups: erythropoietic and hepatic. Seizures and other neurologic manifestations occur only in the hepatic group, which comprises acute intermittent porphyria, hereditary coproporphyria, and variegate porphyria (48). Seizures affect approximately 15% of patients, usually during an acute attack (49) often precipitated by an iatrogenically introduced offending agent. The generalized (occasionally focal) seizures may begin up to 28 days after exposure to the agent. The epileptogenic mechanism is not well understood. Some authors have suggested that δ-aminolevulinic acid and porphobilinogen, both structurally similar to the neurotransmitters glutamate and GABA, are toxic to the nervous system, although clinical evidence refutes this contention (48).

A cornerstone of the treatment is the provision of a major portion of daily caloric requirements by carbohydrates to lower porphyrin excretion. Glucose prevents induction of hepatic δ-aminolevulinic acid synthetase in symptomatic patients, as does IV hematin. Porphyrogenic drugs, such as phenytoin, barbiturates, carbamazepine, succinimides, and oxazolidinediones, should be avoided. Drugs are considered unsafe if they induce experimental porphyria in animals. Using chick embryo hepatocyte culture, Reynolds and Miska (49) found that carbamazepine, clonazepam, and valproate increased porphyrin to levels comparable with those achieved with phenobarbital and phenytoin. In the past, bromides were recommended for the long-term management (50) and diazepam, paraldehyde, and IV magnesium sulfate therapy for the acute treatment of seizures (51). Serum bromide levels should be maintained between 60 and 90 μg/dL. Many side effects and a long half-life make bromides difficult to use. Bromides are excreted by the kidney, and paraldehyde is excreted unchanged by the lungs (the remainder by the liver). Levetiracetam has been used increasingly in patients with porphyria based on its efficacy, broad-spectrum control, and lower risk for exacerbating porphyria (52). Larson et al. (53) reported on one patient with intractable epilepsy who was safely managed with low-dose clonazepam and a high-carbohydrate diet after phenytoin and carbamazepine use had independently precipitated attacks. In two separate studies, gabapentin controlled complex partial and secondarily generalized seizures in patients with porphyria (54,55). Because gabapentin is excreted unmetabolized by the kidneys, it does not induce hepatic microsomal enzymes (56) and should not worsen hepatic cellular dysfunction. Alternatively, vigabatrin, which also does not induce hepatic metabolism, may be a useful antiseizure medication in patients with porphyria. Table 36.1 lists agents that are safe and unsafe to use in patients with porphyria (57).

Table 36.1 Safe and Unsafe Agents in Patients with Porphyria

Safe agents	Unsafe agents
Acetaminophen	Barbiturates
Acetazolamide	Carbamazepine
Allopurinol	Chloramphenicol
Aminoglycosides	Chlordiazepoxide
Amitriptyline	Diphenhydramine
Aspirin	Enalapril
Atropine	Ergot compounds
Bromides	Erythromycin
Bupivacaine	Ethanol
Chloral hydrate	Flucloxacillin
Chlorpromazine	Flufenamic acid
Codeine	Griseofulvin
Corticosteroids	Hydrochlorothiazide
Diazepam	Imipramine
Gabapentin	Lisinopril
Heparin	Methyldopa
Insulin	Metoclopramide
Levetiracetam	Nifedipine
Meclizine	Oral contraceptives
Meperidine	Pentazocine
Morphine	Phenytoin
Penicillins (see unsafe agents for exceptions)	Piroxicam
	Pivampicillin
Procaine	Progesterone
Prochlorperazine	Pyrazinamide
Promethazine	Rifampin
Propoxyphene	Sulfonamides
Propranolol	Theophylline
Propylthiouracil	Valproic acid
Quinidine	Verapamil
Streptomycin	Oral contraceptives
Temazepam	
Tetracycline	
Thyroxine	
Trifluoperazine	
Warfarin

OXYGEN DEPRIVATION

Perinatal Anoxia and Hypoxia

Whether it occurs in utero, during delivery, or in the neonatal period, significant anoxia can extensively damage the CNS and lead to neonatal seizures, which carry a risk for increased mortality. The pathophysiology, classification, diagnosis, evaluation, and treatment of neonatal seizures are covered in Chapter 35.

Adult Anoxia and Hypoxia

In adults, anoxic or hypoxic seizures are residuals of cardiac arrest, respiratory failure, anesthetic misfortune, carbon monoxide poisoning, or near-drowning. Precipitating cardiac sources typically are related to embolic stroke, 13% of which involve seizures (58) or hypoperfusion or hyperperfusion of

the cerebral cortex (2). Approximately 0.5% of patients who have undergone coronary bypass surgery experience seizures without evidence of focal CNS injury (59). In patients with respiratory disorder, acute hypercapnia may lower seizure threshold, whereas chronic stable hypoxia and hypercapnia rarely cause seizures. Subacute bacterial endocarditis can lead to septic emboli and intracranial mycotic aneurysms, which can produce seizures either from focal ischemia or from subarachnoid hemorrhage. Syncopal myoclonus and convulsive syncope may result from transient hypoxia.

Subtle seizures may involve only minimal facial or axial movement (60), increasing the suspicion for nonconvulsive status epilepticus that typically signifies a poor prognosis (61,62). Myoclonic status epilepticus or generalized myoclonic seizures that occur repetitively for 30 minutes are usually refractory to medical treatment (63). Concern has been raised that myoclonic status epilepticus may produce progressive neurologic injury in comatose patients resuscitated from cardiac arrest (63). When postanoxic myoclonic status epilepticus is associated with cranial areflexia, eye opening at the onset of myoclonic jerks, and EEG patterns that include generalized bilateral independent epileptiform discharges or burst suppression pattern, the outlook for neurologic recovery is grim (64).

Treatment is directed mainly toward preventing the cascade of hypoxic injury. Barbiturate medication and reduction of cerebral metabolic requirements by continuous hypothermia may prevent the delayed worsening (65). Frequently, the seizures cease after 3 to 5 days. Phenobarbital 300 mg/day, clonazepam 8 to 12 mg/day in three divided doses, and 4-hydroxytryptophan 100 to 400 mg/day have been recommended (66), as has valproic acid (67). Levetiracetam 1000 to 3000 mg/day may also be useful for posthypoxic seizures and myoclonus with less sedating effects (68).

ALCOHOL

Generalized tonic–clonic seizures occur during the first 48 hours of withdrawal from alcohol in intoxicated patients and are most common 12 to 24 hours after binge drinking (69). Seizures that occur more than 6 days following abstinence should not be ascribed to withdrawal. Interictal EEG findings are usually normal. Partial seizures often result from CNS infection or cerebral cicatrix caused by remote head trauma. Recent occult head trauma, including subdural hematoma, should be considered in any alcoholic patient. Although the incidence of alcoholism in patients with seizures is not higher than in the general population, alcoholic individuals do have a higher incidence of seizures (70).

The treatment depends on associated conditions, but replacement of alcohol is generally not recommended. To prevent the development of Wernicke–Korsakoff syndrome, thiamine should be administered prior to IV glucose. Magnesium deficiency should be corrected, as reduced levels may interfere with the action of thiamine. Preferred treatment is with benzodiazepines or paraldehyde. In countries outside the United States where paraldehyde is available, it may be administered in doses of 0.1 to 0.2 mL/kg orally or rectally every 2 to 4 hours. Diazepam, lorazepam, clorazepate, and chlordiazepoxide in conventional dosages are equally useful (71).

INFECTIONS

Infection is associated with seizures, both directly via parenchymal invasion by the pathogen and indirectly via neurotoxins. Direct parenchymal infections may be bacterial, fungal, mycobacterial, viral, spirochetal, or parasitic. Neurodegenerative disorders, such as Creutzfeldt–Jakob disease and

subacute sclerosing panencephalitis, can also result from CNS infection.

Meningitis

Patients with seizures, headache, or fever (even low grade) should undergo lumbar puncture once a mass lesion has been excluded. In the infant with diffuse, very high intracranial pressure, lumbar puncture should be delayed until antibiotics and pressure-reducing measures are initiated. The pathogenic cause of bacterial meningitis varies with age: In newborns, Escherichia coli and group B streptococcus are most common; in children 2 months to 12 years of age, Haemophilus influenzae, Streptococcus pneumoniae, and Neisseria meningitidis are usual; in children older than 12 years of age and in adults, S. pneumoniae and N. meningitidis are found most often; in adults older than 50 years of age, H. influenzae is increasingly being reported. In infants, geriatric patients, and the immunocompromised, Listeria monocytogenes must also be considered.

Encephalitis

The herpes simplex variety is the most common form of encephalitis associated with seizures (72). Fever, headache, and confusion are punctuated by both complex partial and generalized seizures secondary to the propensity of the virus to produce a hemorrhagic encephalitis involving the temporal lobe. Equine encephalitis, St. Louis encephalitis, and rabies also produce seizures.

Diazepam or lorazepam may be used for the acute control of seizures caused by meningitis or encephalitis. Recurrent seizures or the development of status epilepticus indicates the need for maintenance AED therapy.

Nonbacterial Chronic Meningitis

Lyme disease, a tick-borne spirochetosis, is associated with meningitis, encephalitis, and cranial or radicular neuropathies in up to 20% of patients. Seizures are not a prominent feature. Treatment consists of high-dose IV penicillin G in addition to AEDs (73).

Neurosyphilis is another spirochetal cause of seizures, which occasionally are the initial manifestation of syphilitic meningitis. In the early 20th century, 15% of patients with adult-onset seizures had underlying neurosyphilis. The incidence decreased dramatically over the years; however, the recent upsurge in primary syphilis among younger individuals is reflected in the report that seizures occur in approximately 25% of the patients with symptomatic neurosyphilis. The diagnosis rests on the demonstration of positive serologic findings and clinical symptoms, but the signs are not pathognomonic and often overlap with those of other diseases. IV penicillin remains the treatment of choice.

Sarcoidosis involves the CNS in approximately 5% to 15% of cases. Neurosarcoidosis should also be considered in patients with nonbacterial meningitis and seizures (74).

Opportunistic CNS Infections

Acquired immunodeficiency syndrome (AIDS) is associated with several unique neurologic disorders, and seizures may play a major role when opportunistic infections or metabolic abnormalities, especially cerebral toxoplasmosis or cryptococcal meningitis, occur. Listeria monocytogenes should also be considered in immunocompromised patients. Metabolic abnormalities,

particularly uremia and hypomagnesemia, predispose patients infected with the human immunodeficiency virus (HIV) to seizures. New-onset epilepsia partialis continua as an early manifestation of progressive multifocal leukoencephalopathy in patients with HIV-1 infection has been reported (75). CNS lymphoma in HIV-infected patients may also give rise to seizures.

Parasitic CNS Infections

In some areas, neurocysticercosis is the most commonly diagnosed cause of partial seizures. The adult pork tapeworm resides in the human small bowel after ingestion of infected meat. The oncospheres (hatched ova) penetrate the gut wall and develop into encysted larval forms, usually in the brain or skeletal muscle. Computed tomography (CT) scans reveal calcified lesions, cysts with little or no enhancement, and usually no sign of increased intracranial pressure. In the past, treatment involved the use of only praziquantel 50 mg/kg/day for 15 days or albendazole 15 mg/kg/day. However, while undergoing therapy, most patients had clinical exacerbations, including worsening seizures, attributed to inflammation with cyst expansion caused by the death of cysticerci. For this reason, treatment with the antihelminthic drug and steroids has been advocated. Antihelminthic agents by themselves do not change the course of neurocysticercosis or its associated epilepsy. A trial of antihelminthic agents combined with steroids or steroids alone showed comparable efficacy in terms of patients who were cyst free at 1 year or seizure free during follow-up (76).

Hydatid disease of the CNS (echinococcal infection) may result from exposure to dogs and sheep. Echinococcal cysts destroy bone, and a large proportion of such cysts are found in vertebrae. On CT scans, echinococcal brain cysts are fewer and larger than the cysts associated with cysticercosis. Treatment is usually surgical, largely because mebendazole and flubendazole have been associated with disease progression in up to 25% of patients. Nonetheless, adjuvant chemotherapy may be warranted in some cases (77).

Trichinosis may be encountered wherever undercooked trichina-infected pork is consumed. Complications of CNS migration include seizures, meningoencephalitis, and focal neurologic signs; eosinophilia is common during acute infection. Muscle biopsy may be necessary for diagnosis (72).

Cerebral malaria is similar to neurosyphilis, in that almost every neurologic sign and symptom has been attributed to the disorder. Diagnosis requires characteristic forms in the peripheral blood smear. Treatment depends on whether chloroquine resistance is present in the geographic region of infection.

Toxoplasmosis is a parasitic infection that affects adults, children, and infants. Use of immunosuppressive agents in patients with malignancies or transplants (see related sections later in this chapter), as well as recognition of AIDS, has emphasized the need to reconsider the neurologic sequelae of toxoplasmosis. Diagnosis may be elusive. Cerebrospinal fluid may reveal normal findings or mild pleocytosis (78). Serologic data may be difficult to interpret because encephalitis caused by Toxoplasma gondii may occur in patients who reactivate latent organisms and do not develop the serologic response of acute infection. CT scanning may reveal typical lesions. Therapy includes pyrimethamine and sulfadiazine or trisulfapyrimidines.

Cytomegalovirus retinitis, the most common ocular opportunistic infection in patients with AIDS (79), is increasingly being treated with a combination of foscarnet and ganciclovir. Foscarnet is also used to treat cytomegalovirus esophagitis associated with AIDS, but seizures have occurred with this agent, possibly as a result of changes in ionized calcium concentrations (80).

Systemic Infections

Systemic infection involving hypoxia (e.g., pneumonia) or metabolic changes may give rise to seizures. Through an indirect, poorly understood mechanism, seizures are prominent in two serious gastrointestinal (GI) infections: shigellosis and cholera. Ashkenazi et al. (81) demonstrated that the Shiga toxin is not essential for the development of the neurologic manifestations of shigellosis and that other toxic products may play a role.

Zvulunov et al. (82) examined 111 children who had convulsions with shigellosis and were followed for 3 to 18 years. No deaths or persistent motor deficits occurred. Only one child developed epilepsy by the age of 8 years; 15.7% of the children had recurrent febrile seizures. The convulsions associated with shigellosis have a favorable prognosis and do not necessitate long-term follow-up or treatment.

Most clinical manifestations of cholera are caused by fluid loss. Seizures, which are the most common CNS complication, occasionally occur both before and after treatment and may result from hypoglycemia or overcorrection of electrolyte abnormalities. The cornerstone of treatment, however, is fluid replacement. Up to 3% of body weight, or 30 mL/kg, should be administered during the first hour, followed by 7% for the next 5 to 6 hours. Lactated Ringer solution given IV with potassium chloride or isotonic saline and sodium lactate (in a 2:1 ratio) is used. Adjunctive treatment with a broad- spectrum antibiotic shortens the duration of diarrhea and hastens the excretion of Vibrio cholerae.

The seizures associated with shigellosis and cholera infection may share a common pathogenesis. Depletion of hepatic glycogen and resultant hypoglycemia are typically reported in children with these illnesses (83).

GASTROINTESTINAL DISEASE AND SEIZURES

In nontropical sprue, or celiac disease, damage to the small bowel by gluten-containing foods leads to chronic malabsorption. Approximately 10% of patients have significant neurologic manifestations, with the most frequent neurologic complication being seizures (reported in 1% to 10% of patients), which are often associated with bilateral occipital calcifications (84,85). Possible mechanisms include deficiencies of calcium, magnesium, and vitamins; genetic factors (86); and isolated CNS vasculitis (87). Malabsorption may be occult, and seizures may be the dominant feature. Strict gluten exclusion usually produces a rapid response.

Inflammatory bowel disease (ulcerative colitis and Crohn disease) is associated with a low incidence of focal or generalized seizures. Unsurprisingly, generalized seizures frequently accompany infection or dehydration. In approximately 50% of all patients with focal seizures, a vascular basis is suspected (88).

Whipple disease is a multisystem granulomatous disorder caused by Tropheryma whippelii (89). Approximately 10% of patients have dementia, ataxia, or oculomotor abnormalities; as many as 25% have seizures (90). Early treatment is important, as untreated patients with CNS involvement usually die within 12 months (91). Some patients develop cerebral manifestations after successful antibiotic treatment of GI symptoms (92). Although several agents that cross the blood–brain barrier, such as chloramphenicol and penicillin, have been suggested for treatment (93), a high incidence of CNS relapse led Keinath et al. (94) to recommend penicillin 1.2 million units and streptomycin 1.0 g/day for 10 to 14 days, followed by trimethoprim–sulfamethoxazole 1 double-strength tablet twice a day

for 1 year. Treatment of the underlying disease may not prevent seizures; however, in which case, AEDs in a suspension or elixir are usually required because malabsorption is a significant problem (95).

Hepatic Encephalopathy

Wilson disease, acquired hepatocerebral degeneration, Reye syndrome, and fulminant hepatic failure, among other disorders, may lead to hepatic encephalopathy. Manifestations progress through four stages. Stage 1 is incipient encephalopathy. In stage 2, mental status deteriorates and asterixis develops. In stage 3, focal or generalized seizures may occur. Stage 4 is marked by coma and decerebrate posturing.

The incidence of seizures varies from 2% to 33% (96). Hypoglycemia complicating liver failure may be responsible for some seizures. Hyperammonemia is associated with seizures and may contribute to the encephalopathy of primary hyperammonemic disorders; treatments that reduce ammonia levels also ameliorate the encephalopathy (96). Therapy should be directed toward the etiology of the hepatic failure; levels of GI protein and lactulose must be reduced. Long-term use of AEDs is not usually required unless there is a known predisposition to seizures (e.g., previous cerebral injury). Little experience with the use of AEDs has actually been reported. Those AEDs with sedative effects may precipitate coma and are generally contraindicated. Valproic acid and its salt should be avoided. Nonhepatic metabolized AEDs including levetiracetam and gabapentin are more likely to be efficacious and avoid further exacerbation of the liver failure.

INTOXICATION AND DRUG-RELATED SEIZURES

This section is not to be used as a guide to the management of drug intoxication. Rather, it reviews specific instances of intoxication during which intractable seizures sometimes develop.

Prescription Medication–Induced Seizures

Many medications provoke seizures in both epileptic and nonepileptic patients (Table 36.2). Predisposing factors include family history of seizures, concurrent illness, and high-dose intrathecal and IV administration. The convulsions are usually generalized with or without focal features; status epilepticus may occur in up to 15% of patients (97). Because many medical conditions result from polypharmacy, drug- induced seizures may be more common in geriatric patients.

Table 36.2 Agents Reported to Induce Seizures

Analgesics	Alfentanil, fentanyl, mefenamic acid, meperidine, pentazocine, propoxyphene, tramadol
Antibiotics	Ampicillin, carbenicillin, cephalosporins, imipenem, isoniazid, lindane, metronidazole, nalidixic acid, oxacillin, penicillin, pyrimethamine, ticarcillin
Antidepressants	Amitriptyline, bupropion, doxepin, fluoxetine, imipramine, maprotiline, mianserin, nomifensine, nortriptyline, paroxetine, sertraline, trazodone, venlafaxine
Antineoplastic agents	Busulfan, carmustine (BCNU), chlorambucil, cytosine arabinoside, methotrexate, vincristine
Antipsychotics	Clozapine, clomipramine, chlorpromazine, fluphenazine, haloperidol, olanzapine, perphenazine, pimozide, prochlorperazine, quetiapine, risperidone, thioridazine, trifluoperazine
Bronchial agents	Aminophylline, theophylline
General anesthetics	Enflurane, ketamine, methohexital
Local anesthetics	Bupivacaine, lidocaine, procaine
Sympathomimetics	Ephedrine, phenylpropanolamine, terbutaline
Others	Alcohol, amphetamines, anticholinergics, antihistamines, aqueous iodinated contrast agents, atenolol, baclofen, chloroquine, copper toxicity, cyclosporine, domperidone, ergonovine, flumazenil, folic acid, foscarnet, ganciclovir, hyperbaric oxygen, insulin, lithium, mefloquine, methylphenidate, methylxanthines, oxytocin, phencyclidine, ritonavir, tacrolimus (FK506)

Intoxication from treatment with tricyclic antidepressants (TCAs) has led to generalized tonic–clonic seizures at therapeutic levels in approximately 1% of the patients (98). Because desipramine is believed to have a lower risk for precipitating seizures than other drugs in this class, the agent is preferred in patients with known epilepsy (99). Physostigmine may reverse the neurologic manifestations of TCA reactions; however, because it may also cause asystole, hypotension, hypersalivation, and convulsions, this agent should not be used to treat TCA-induced seizures. Benzodiazepines are preferred as the initial treatment. The combination of clomipramine with valproic acid may result in elevation of clomipramine levels with associated seizures (100).

Fluoxetine, sertraline, and other selective serotonin reuptake inhibitors (SSRIs) have an associated seizure risk of approximately 0.2%. The SSRIs may have an antiepileptic effect at therapeutic doses (101). Fluvoxamine overdose has also been reported to provoke status epilepticus (102). When combined with other serotonergic agents or monoamine oxidase inhibitors, however, they may induce the "serotonin syndrome" of delirium, tremors, and, occasionally, seizures (103). Venlafaxine, a serotonin and norepinephrine reuptake inhibitor, has emerged as a common cause of

drug-induced seizures (104). There are reports of serotonin syndrome developing after concomitant use of antibiotics such as linezolid and the SSRI paroxetine, citalopram (105), and mirtazapine (106). Over-the-counter substances used in combination with SSRIs that have precipitated the serotonin syndrome include St. John's wort (107).

Antipsychotic agents have long been known to precipitate seizures (97). Both the phenothiazines and the haloperidol have been implicated, but the potential is greater with phenothiazines, and seizures occur more frequently with increasing dosage (108). Clozapine, an atypical antipsychotic agent (dibenzodiazepine class) used for the treatment of intractable schizophrenia, also produces an increased incidence of seizures with increasing dosage (109). Lithium may also precipitate seizures (110). If reduction of dosage is not practical, phenytoin or valproate may be added; however, carbamazepine should be avoided because antipsychotic agents may induce agranulocytosis.

The use of theophylline and other methylxanthines may lead to generalized tonic–clonic seizures; rarely, patients may experience seizures with nontoxic levels of theophylline. Seizures resulting from overdosage are best treated with IV diazepam. Massive overdosage may induce hypocalcemia and other electrolyte abnormalities (111).

Lidocaine precipitates seizures, usually in the setting of congestive heart failure, shock, or hepatic insufficiency. General anesthetics, such as ketamine and enflurane, are also implicated (see section Central Anticholinergic Syndrome). Alfentanil is a potent short-acting opioid agent that may induce clinical and electroencephalographic seizures (112). Meperidine, pentazocine, and propoxyphene, among other analgesic drugs, infrequently cause seizures (113).

Verapamil intoxication may be associated with seizures through the mechanism of hypocalcemia, although hypoxia also may have a contributing role (114). Interestingly, other calcium channel blockers have not been reported to produce this adverse effect.

Many antiparasitic agents and antimicrobials, particularly penicillins and cephalosporins in high concentrations, are known seizure precipitants. It should be noted that some antibiotics, such as the fluoroquinolones, may lower the seizure threshold. Carbapenem antimicrobials also have significant neurotoxic potential, with meropenem perhaps having the lowest incidence (115,116). Lindane, an antiparasitic shampoo active against head lice (Pediculosis capitis), has a rare association with generalized, self-limited seizures; it is best to use another agent should reinfestation occur. Seizures have not been reported with permethrin, another antipediculosis agent.

Severe isoniazid intoxication involves coma, intractable seizures, and metabolic acidosis. Ingestion of >80 mg/kg of body weight produces severe CNS symptoms that are rapidly reversed with IV administration of pyridoxine at 1 mg per every 1 mg of isoniazid (117). Conventional doses of short-acting barbiturates, phenytoin, or diazepam are also recommended to potentiate the effect of pyridoxine (118).

Recreational Drug-Induced Seizures

Alldredge et al. (119) retrospectively identified 49 cases of recreational drug-induced seizures in 47 patients seen between 1975 and 1987. Most patients experienced a single generalized tonic–clonic attack associated with acute drug intoxication, but seven patients had multiple seizures and two had status epilepticus. The recreational drugs implicated were cocaine (32 cases), amphetamines, heroin, and phencyclidine; a combination of drugs was responsible for 11 cases. Seizures occurred independently of the route of administration and were reported in both first-time and chronic abusers. A total of 10 patients (21%) reported prior seizures, all temporally associated with drug abuse.

Except for one patient who experienced prolonged status epilepticus causing a fixed neurologic deficit, most patients had no obvious short-term neurologic sequelae (119). Marijuana is unlikely to alter the seizure threshold (120) and is a common drug utilized by epileptics for self-medication. Patients with seizures who test positive for marijuana on toxicologic screening should be investigated for other illicit drugs and alcohol use.

Cocaine commonly gives rise to tremors and generalized seizures. Seizures can develop immediately following drug administration, without other toxic signs. Convulsions and death can occur within minutes of overdose. Pascual-Leone et al. (121) retrospectively studied 474 patients with medical complications related to acute cocaine intoxication. Of 403 patients who had no seizure history, approximately 10% had seizures within 90 minutes of cocaine use. The majority of seizures were single and generalized, induced by IV or "crack" cocaine, and were not associated with any lasting neurologic deficits. Most of the focal or repetitive attacks involved an acute intracerebral complication or concurrent use of other drugs. Of 71 patients with previous non–cocaine-related seizures, 17% presented with cocaine-induced seizures, most of which were multiple and of the same type as they had previously experienced (121).

The treatment of choice for recreational drug-induced seizures is lorazepam or clonazepam. Bicarbonate for acidosis, artificial ventilation, and cardiac monitoring are also useful, depending on the duration of the seizures. Urinary acidification accelerates excretion of the illicit drug. Chlorpromazine has also been recommended because it raised, rather than lowered, the seizure threshold in cocaine-intoxicated primates (122).

Acute overdose of amphetamine causes excitement, chest pain, hypertension, tachycardia, and sweating, followed by delirium, hallucinations, hyperpnea, cardiac arrhythmias, hyperpyrexia, seizures, coma, and death. Seizures are treated with benzodiazepines or, if long-term antiepileptic therapy is indicated, with phenytoin. Acidification of urine may enhance drug excretion.

Methamphetamine is a synthetic agent with toxic effects, including seizures, that is similar to those with amphetamine and cocaine (123). The amphetamine derivative (MDMA) stimulates the release and inhibits the reuptake of serotonin (5-HT) and other neurotransmitters, such as dopamine, to a lesser extent. Mild versions of the serotonin syndrome often develop, when hyperthermia, mental confusion, and hyperkinesia predominate (123). MDMA may also cause seizures in conjunction with rhabdomyolysis and hepatic dysfunction (124).

γ-Hydroxybutyric acid (GHB), or sodium oxybate, is an agent that is approved for use in patients with narcolepsy who experience episodes of cataplexy and excessive daytime sleepiness, It is also a popular agent among recreational drug users. GHB is a naturally occurring inhibitory substance in the human brain. GHB is believed to bind to $GABA_B$ and GHB-specific receptors. It blocks dopamine release at the synapse and produces an increase in intracellular dopamine. This is followed by a time-dependent leakage of dopamine from the neuron. Its abuse potential is secondary to its ability to induce a euphoric state, hallucinations, and relaxation without a hangover effect. Additional effects of increased sensuality and disinhibition further explain the popularity of the agent. Abusers will often ingest sufficient quantities to lead to a severely depressed level of consciousness. It is not uncommon to observe seizures in these cases. With acute overdose, patients have experienced delirium and transient respiratory depression, which can be fatal (125). The toxicity of GHB is dose dependent and can result in nausea, vomiting, hypotonia, bradycardia, hypothermia, random clonic movements, coma, respiratory depression, and apnea. Deaths involving solely the use of GHB appear to be rare and have involved the "recreational abuse" of the drug for its "euphoric" effects. Combining GHB with other depressants or psychoactive compounds may exacerbate its effects. GHB abuse frequently

involves the use of other substances, such as alcohol or MDMA (126).

CENTRAL ANTICHOLINERGIC SYNDROME

Many drugs used as anesthetic agents and in the intensive care unit may cause seizures. Although a discussion of each agent is beyond the scope of this chapter, we review the central anticholinergic syndrome (127), a common disorder associated with blockade of central cholinergic neurotransmission, whose symptoms are identical to those of atropine intoxication: seizures, agitation, hallucinations, disorientation, stupor, coma, and respiratory depression. Such disturbances may be induced by opiates, ketamine, etomidate, propofol, nitrous oxide, and halogenated inhalation anesthetics, as well as by such H_2-blocking agents as cimetidine. An individual predisposition exists for central anticholinergic syndrome that is unpredictable from laboratory findings or other signs. The postanesthetic syndrome can be prevented by administration of physostigmine during anesthesia.

OTHER SEIZURE PRECIPITANTS

Heavy metal intoxication, especially with lead and mercury, is a well-known seizure precipitant. Ingestion of lead from paint and inhalation of lead oxide are specific hazards among young children. Hyperbaric oxygenation provokes seizures, possibly as a toxic effect of oxygen itself. Some antineoplastic agents, such as chlorambucil and methotrexate, precipitate seizures. Table 36.2 lists other agents reported to induce seizures (128).

Increasingly utilized prophylactically and as alternative medicine, many herbs and other alternative treatments may increase the risk for seizures (129). This may be through intrinsic proconvulsive effects of contamination by heavy metals. These include cyanobacteria (aka spirulina, blue–green algae), ephedra (ma huang), Ginkgo biloba, pennyroyal, primrose oil, sage, star anise, star fruit, and wormwood. In addition, many herbs may have an effect on AED concentrations via the cytochrome P450 and P-glycoprotein systems.

More recently, there has also been concern that seizures may also be induced following consumption of energy drinks and supplements. It has been proposed that large consumption of compounds rich in caffeine, taurine, and guarana seed extract may provoke seizures (130). With the large consumption of energy drinks around the world, there is concern that there may be underestimation of the potential effects to induce seizures. Discussions also infer that the high intake of caffeine may induce sleep deprivation, or the concomitant higher consumption of alcohol with energy drinks may also be precipitating factors inducing seizures (131).

ECLAMPSIA

A condition unique to pregnancy and puerperium, eclampsia is characterized by convulsions following a preeclamptic state involving hypertension, proteinuria, edema, and coagulopathy, as well as headache, drowsiness, and hyperreflexia. Eclampsia is associated with a maternal mortality of 1% to 2% and a rate of complications of 35% (132). In the United States, magnesium sulfate is the chosen therapy, whereas in the United Kingdom, such conventional AEDs as phenytoin and diazepam are used (133,134). The antiepileptic action of magnesium sulfate is accompanied by hypotension, weakness, ataxia, respiratory depression, and coma. The recommended therapeutic range is 1.8 to 3.0 μmol/L; however, weakness and ataxia appear at 3.5 to 5.0 μmol/L and respiratory depression at 5.0

μmol/L (135). Kaplan et al. (136) argue that magnesium sulfate is not a proven AED; even at therapeutic levels, 12% of patients continued to have seizures in one study (137). The use of magnesium sulfate or conventional AEDs for preeclamptic or eclamptic seizures remains controversial. Because eclamptic seizures are clinically and electrographically indistinguishable from other generalized tonic–clonic attacks, the use of established AEDs, such as diazepam, lorazepam, and phenytoin, is recommended (136). In a randomized study of 2138 women with hypertension during labor (138), no eclamptic convulsions occurred in women receiving magnesium sulfate, whereas seizures were frequent with phenytoin use. Methodologic problems, however, involved the route of administration of the second phenytoin dose after loading and the low therapeutic phenytoin level at the time of the seizure.

Magnesium sulfate has a beneficial effect on factors leading to eclampsia and can reverse cerebral arterial vasoconstriction (139). By the time a neurologist is consulted, however, the patient will have received magnesium sulfate and will typically require additional AED treatment to control the seizures.

MALIGNANCY

Mechanisms for induction of seizures in patients with cancer include direct invasion of cortex or leptomeninges, metabolic derangements, opportunistic infection, and chemotherapeutic agents (140). Limbic encephalitis is a paraneoplastic syndrome seen in patients with small cell carcinoma, ovarian cancer commonly teratomas, germ cell tumors of the testes, or, less commonly, Hodgkin disease. Patients usually present with amnestic dementia, affective disturbance, and sometimes a personality change. During the illness, both complex partial and generalized seizures may occur. Paraneoplastic limbic encephalitis associated with anti-Hu (antineuronal nuclear antibody type 1) antibodies may present with seizures and precede the diagnosis of cancer (141). If the etiology of new-onset seizures is not defined in a patient with known cancer, frequent neuroimaging studies should assess the individual for metastatic disease. Chapter 33 details other paraneoplastic disorders that can present with seizures, including anti-NMDA receptor encephalitis.

Opsoclonus–myoclonus syndrome (myoclonic infantile encephalopathy) occurs most frequently in young children (mean age, 18 months). Approximately half of the cases have been reported in patients with neuroblastoma, but only approximately 3% of all neuroblastoma cases are complicated by the syndrome. Opsoclonus–myoclonus syndrome has been reported with carcinoma, including breast, ovarian, and small cell lung cancer, but occurs idiopathically as well. Because the idiopathic and paraneoplastic syndromes are indistinguishable clinically, opsoclonus–myoclonus syndrome should always prompt a search for neuroblastoma in children and these other cancers in adults. Symptoms respond to steroid or immunosuppressive therapy. In the majority of cases, successful treatment of the neuroblastoma or surgical resection of the primary cancer may lead to remission; however, the syndrome may reappear with or without tumor recurrence (142).

Finally, chronic treatment with nonhepatic metabolized AEDs including levetiracetam and gabapentin avoid drug interactions that may reduce the efficacy of chemotherapeutic agents.

VASCULITIS

Seizures as a manifestation of vasculitis may occur as a feature of encephalopathy, as a focal neurologic deficit, or in association with renal failure (143). The incidence of seizures increases with

the duration and severity of the underlying vasculitis (144) and ranges from 24% to 45% (145). The relationship of the seizure disorder to the underlying disease may not always be clear, however. A confounding feature of AED therapy is the occurrence of drug-induced systemic lupus erythematosus (146). Although this association has been challenged—the seizures were believed to be an initial manifestation of lupus—phenytoin-associated lupus and spontaneous lupus do have different loci of immunoregulation (147). Systemic necrotizing vasculitis and granulomatous vasculitis rarely present with seizures. Among patients with giant cell arteritis with nonocular signs, seizures occur in 1.5% (147). Behçet disease is associated with neurologic involvement in 10% to 25% of patients. Onset is usually acute, and seizures occasionally occur.

TRANSPLANTATION AND SEIZURES

Organ transplantation has led to newly recognized CNS disorders and new manifestations of old disorders. Seizures may occur in up to a third transplant patients. Seizures in patients anticipating or having undergone transplantation may be difficult to manage for several reasons: (i) these individuals are frequently metabolically stressed; (ii) preexisting diseases and preceding therapies may have affected the CNS (e.g., candidates for bone marrow transplantation may have received L-asparaginase, which is associated with acute intracerebral hemorrhage and infarction and ischemic seizures); and (iii) immunosuppressive agents, particularly cyclosporine and tacrolimus (FK506), may themselves provoke seizures.

Some transplant patients appear to have an increased risk for seizures. Wijdicks et al. (148) concluded that most new-onset seizures in 630 patients undergoing orthotopic liver transplantation resulted from immunosuppressant neurotoxicity (cyclosporine and FK506) and did not indicate a poor outcome. Vaughn et al. (149) reported that of 85 patients who had received a lung transplant, 22 had seizures (including 15 of 18 patients with cystic fibrosis); in patients younger than age 25 years, particularly those given IV methylprednisolone to prevent rejection, the seizure risk was increased. Bone marrow transplant recipients with human leukocyte antigen mismatch and unrelated donor material have an enhanced risk for seizures from cyclosporine neurotoxicity (150). Foscarnet, used to treat cytomegalovirus hepatitis following bone marrow transplantation (151), may also precipitate seizures (80). For the acute management of prolonged seizures, benzodiazepines are least likely to induce the enzyme system responsible for metabolizing immunosuppressant drugs (152).

Long-term management of transplant recipients with seizures is determined after the etiology has been ascertained. Because allograft survival is decreased with phenytoin or phenobarbital and steroids (153), the use of AEDs has been discouraged (154). The half-lives of prednisolone and, probably, cyclosporine (150) are decreased when phenobarbital, phenytoin, or carbamazepine is administered. Valproic acid is a reasonable choice, except in hepatic transplantation patients and in bone marrow transplantation patients during engraftment.

Levetiracetam and gabapentin may be useful in patients undergoing hepatic or bone marrow transplantation. These agents have renal elimination as unchanged drug from the systemic circulation, with very little protein binding and fewer drug interactions than other AEDs. Use of these AEDs in patients with renal failure must be modified, however.

When AEDs other than valproic acid, levetiracetam, lacosamide, or gabapentin are used, the doses of immunosuppressive agents should be increased to ensure therapeutic immunosuppression. Cyclosporine levels should be determined.

POSTERIOR REVERSIBLE ENCEPHALOPATHY SYNDROME

The clinical syndrome of posterior reversible encephalopathy syndrome (PRES) involves headache, encephalopathy, visual symptoms, and seizures. Conditions that may predispose to develop PRES include preeclampsia/eclampsia, posttransplantation, immune suppression, infection, autoimmune disease, chemotherapy, dialysis, and multiple metabolic disorders. Seizures have been noted relatively frequently in PRES. Clinical seizures occurred in more than 85% of cases of which there were multiple seizures in more than one-third of patients. Although infrequent, patients may also present with status epilepticus. Of those patients who recover, it is rare that they will have recurrent seizures (155,156).

CHAPTER 37 SLEEP AND EPILEPSY

NANCY FOLDVARY-SCHAEFER AND SILVIA NEME-MERCANTE

The relationship between sleep and epilepsy has been recognized since antiquity. In recent years, interest in the intersections of sleep medicine and epileptology has resulted in substantial progress in several important areas. Herein, we review the more firmly established relationships between sleep and epilepsy and sleep disorders in people with epilepsy.

SEIZURES AND THE SLEEP–WAKE CYCLE

Nineteenth century investigators recognized that most seizures occurred during evening or nighttime hours and that insufficient sleep activated seizures. Gowers classified seizures as nocturnal, diurnal, and diffuse. He noted that 21% of institutionalized patients had seizures exclusively at night, 42% only during the day, and 37% either night or day (1). Peaks in seizure occurrence during the night occurred most often near the end of the sleep period (05:00 to 06:00) and less often 1 to 2 hours after sleep onset, whereas diurnal seizures clustered in the early morning and late afternoon (2). Decades later, Janz found that generalized tonic–clonic seizures (GTCs) occurred in sleep in 44%, at awakening in 33%, and randomly in 23% of people with epilepsy (3). Important in the care and counseling of patients presenting with sleep-related seizures is that seizures occur during wakefulness within 2 years of epilepsy onset in 11% to 30% of cases (4,5). Several epilepsy syndromes are now recognized for seizures that occur predominately or exclusively from sleep (Table 37.1).

Table 37.1 Sleep-Related Epilepsy Syndromes

- Benign focal epilepsy of childhood with centrotemporal spikes
- Early-onset childhood occipital epilepsy (Panayiotopoulos syndrome)
- Nocturnal frontal lobe epilepsy
- Autosomal dominant nocturnal frontal lobe epilepsy
- Lennox–Gastaut syndrome (tonic seizures)
- Landau–Kleffner syndrome
- Epileptic encephalopathy with continuous spike-and-wave during sleep

In a study examining the distribution of 600 focal seizures across the sleep–wake cycle recorded during video–electroencephalogram (EEG) evaluations, 43% were found to arise from sleep, the majority from non–rapid eye movement (NREM) stage 1 (23%) or 2 (68%), and none arose from REM sleep (6). Secondary generalization tends to occur more often during sleep (28%) than wakefulness (18%), and frontal lobe seizures tend not to secondarily generalize during sleep (6–8). Differences in peak seizure occurrence in relation to the rise in salivary melatonin between patients with temporal and frontal lobe epilepsy were observed. Temporal lobe seizures occurred most frequently in the 6 hours before and frontal seizures 6 to 12 hours after the dim light melatonin onset,

suggesting that circadian influences may underlie some of these clinical observations (9).

Recent work has focused on clock time of seizures in different epilepsy syndromes. Using scalp EEG recordings, two studies found that temporal lobe seizures occurred more often during daytime hours with a peak incidence from 15:00 to 19:00, whereas extratemporal seizures peaked between 19:00 and 23:00 (10) or in the early morning hours associated with awakening (11). In an investigation involving 131 adult patients, peak timing of seizures varied by location of the seizure-onset zone identified by invasive EEG recordings (12). Specifically, mesial temporal lobe seizures had two peaks between 16:00 to 19:00 and 07:00 to 10:00, while neocortical temporal and occipital seizures peaked between 16:00 and 19:00, and frontal and parietal seizures between 04:00 and 07:00. In the second invasive EEG study, among 33 focal epilepsy cases, temporal lobe seizures occurred preferentially during the day (11:00 to 17:00), frontal seizures at night (23:00 to 05:00), and parietal seizures in the evening (17:00 to 23:00) (13).

The peak occurrence of generalized seizures was found to vary by seizure type with tonic–clonic seizures peaking between 06:00 and 09:00, tonic seizures between 21:00 and 24:00, absence seizures between 09:00 and 12:00, atonic seizures between 12:00 and 18:00, and myoclonic seizures between 06:00 and12:00 (14). Timing of epileptic spasms was found to be age dependent with peaks between 09:00 to 12:00 and 15:00 to 18:00 in children ≤3 years and between 06:00 to 09:00 in those older than 3 years (15).

Patients with sudden unexpected death in epilepsy (SUDEP) are more likely to have a history of nocturnal seizures than are people living with epilepsy (36% vs. 17%) (16). Most sleep-related cases of SUDEP occur between in the early morning hours (04:00 and 08:00). While the mechanisms underlying seizure timing are poorly elucidated, further investigation is warranted given the potential for therapeutic interventions.

EFFECTS OF SLEEP ON SEIZURES AND THE EEG IN EPILEPSY

The first systematic study of the diagnostic yield of sleep on the EEG was performed by Fred and Erma Gibbs in 1947 (17). Among 500 epilepsy patients, interictal epileptic discharges (IEDs) were observed in 36% of wake EEGs, increasing to 82% with sleep. Sleep activated additional epileptic foci in some patients who had only one focus during wake. The detection of IEDs by recording sleep was greatest for patients with focal seizures and least with absence seizures. Patients with psychomotor seizures often had normal wake EEGs, but 95% had IEDs during sleep.

Since these early observations, the activating effect of sleep on seizures and the EEG has been extensively investigated (18). The neuronal networks that generate wake, NREM sleep, and REM sleep give rise to different physiologic characteristics influencing the likelihood of seizure and IED occurrence (19,20). NREM sleep is a state of EEG synchronization and relative preservation of antigravity muscle tone. Synchronous oscillations of cortical neurons that generate sleep spindles, K complexes, and tonic background slow waves during NREM sleep promote seizure propagation and IEDs. In contrast, REM sleep is a desynchronized state characterized by the loss of skeletal muscle tone. Desynchronization of the EEG impedes seizure propagation during REM sleep and wake. Preservation of antigravity muscle tone during NREM sleep permits the expression of seizure-related movements, while its absence during REM sleep blocks the clinical expression of seizures.

Many studies demonstrate that NREM sleep activates IEDs in focal epilepsies (21,22). Interictal

spikes increase at sleep onset, peaking in stage 3 (slow-wave sleep [SWS]), and then declining in REM sleep to levels lower than wakefulness. Similarly, the field of an IED typically increases in NREM sleep, becoming more diffuse—even generalized in SWS compared to light NREM sleep and more restricted in REM sleep. The extent and laterality of IEDs during REM sleep may be useful in confirming the primary epileptogenic zone in patients with pharmacoresistant temporal lobe epilepsy (TLE) (21,22).

Variations in IEDs with the sleep–wake cycle are also observed in the generalized epilepsies, although sleep is a less important activator because IEDs are often present in the wake EEG (23). Sleep further activates IEDs in patients with absence and/or GTC seizures (23,24). Typically, spikes increase with sleep onset progressively through SWS, diminish sharply in REM sleep, and increase again in the morning after awakening. Generalized spike–wave discharges become more disorganized, increased in amplitude, and slow in frequency in NREM sleep, whereas their morphology in REM sleep and wakefulness is similar (24). The EEG is most abnormal after the morning awakening or nighttime arousals in patients with awakening epilepsies such as juvenile myoclonic epilepsy. In contrast, the EEG tends to be normal during wakefulness or show an increase in IEDs during sleep in the generalized sleep epilepsies.

EFFECTS OF SLEEP DEPRIVATION ON EPILEPSY

The effect of sleep deprivation on epilepsy has been the subject of much investigation. In the first systematic study, sleep-deprived EEGs were performed after 26 to 28 hours of wakefulness, and IEDs were seen in 34% of 89 subjects with at least one seizure and a normal routine EEG, 56% of 34 patients with convulsive epilepsy and IEDs on routine EEGs, and 0% of 20 patients with neurologic disorders other than epilepsy (25). Subsequent work suggested that for most seizure types, spontaneous sleep and sleep-deprived EEGs produce similar activation rates, and seizures are more likely to be activated by sleep or sleep deprivation in patients with generalized rather than focal epilepsy (24). In a study comparing the yield of different EEG protocols, IEDs were recorded in 28% of subjects only following total sleep deprivation (TSD), defined as 24 hours of more of sustained wakefulness, compared to routine wake and drug-induced sleep EEGs, and TSD activated a new epileptic focus in 7% of cases (26). As the yield of recording IEDs due to repeated recordings was estimated to be in the range of 14% to 19%, the authors claimed their findings were unlikely to be due to sampling effects. In recent study involving patients with new-onset epilepsy, IEDs were observed in 92% of TSD EEGs versus 58% of drug-induced sleep and 44% of routine recordings (27). Similarly, a prospective study of 721 subjects who had a second EEG (routine, drug-induced sleep or TSD) after an inconclusive initial EEG found a significantly greater percentage containing IEDs after TSD as compared to a second routine record (23% vs. 10%) (28). Comparative studies largely confirm that TSD activates IEDs in 23% to 93% of patients with definite or suspected seizures (18). Whether the activation of IEDs on EEG produced by sleep deprivation is due to sleep itself (greater amounts of sleep recorded, sampling effects) or because TSD exerts an independent activating effect is uncertain.

The effects of less extreme degrees of sleep deprivation on the EEG are not fully elucidated. Among 71 patients with focal epilepsy, the odds of a seizure the next day decreased for each hour of sleep the prior night (29). In another study based on 2-year sleep and seizure diaries completed by 14 adults with TLE, the probability of a seizure was significantly greater after a night of sleep deprivation (at least 1.5 hours less than usual) compared with normal sleep (30). Indeed, sleep

deprivation is reported as a seizure precipitant by up to one-third of people with epilepsy (3,29,31). Several studies using transmagnetic stimulation have reported a significant increase in cortical excitability following sleep deprivation in people with epilepsy compared to controls (32). These findings suggest that modest amounts of sleep loss can activate seizures and the EEG.

EFFECTS OF EPILEPSY THERAPIES ON SLEEP

Antiepileptic drugs (AEDs) have variable effects on nocturnal sleep and wakefulness (Table 37.2). The effects of AEDs may be due in part to a consolatory effect on sleep. Some AEDs tend to cause more sleepiness and drowsiness, while others can lead to insomnia.

Table 37.2 Effects of Chronic Antiepileptic Drug Therapy on Sleep Architecture[a]

	Sleep efficiency	Sleep latency	Stage 1	Stage 2	Stage 3	REM
Older AEDs						
Benzodiazepines	↑	↓	—	—	↓	↓
Carbamazepine	0	0	0	0	0	0
Ethosuximide	—	—	↑	—	↓	—
Phenobarbital	↑	↓	—	↑	0	↓
Phenytoin	0	↓	↑	↑	↓	0
Primidone	—	↓	—	—	—	0
Valproate	—	0	↑	↓	0	0
Newer AEDs						
Gabapentin	0	0	0	0	↑	↑
Lamotrigine	0	0	0	↑	↓	↑
Levetiracetam	0	0	↑	↑	↑	↓
Pregabalin	—	—	—	↓	—	↑
Tiagabine	↑	0	↓	0	↑	0
Topiramate	0	↓	0	0	0	0
Zonisamide	—	—	—	—	—	—

0, denotes no change; —, denotes not reported.

[a]Includes data acquired after achieving steady state.

Barbiturates and benzodiazepines suppress REM sleep, reduce sleep latency, and increase sleep efficiency, while phenytoin and valproic acid appear to increase light NREM sleep and increase arousals and awakenings (33). Carbamazepine (CBZ) is the most extensively investigated older AED. Studies suggest that the short- and long-term effects of CBZ on sleep differ. For example, a single 400-mg dose of controlled release CBZ in adults with newly diagnosed TLE and controls produced a significant reduction in REM sleep and increased stage shifts and REM sleep fragmentation, effects that reversed after 1 month of treatment (33).

Newer AEDs also affect sleep architecture but appear to have more favorable effects than do some of the older agents, perhaps contributing to their antiseizure properties. In particular, lamotrigine (LTG), topiramate, and zonisamide produce minimal alterations in sleep architecture in adult patients on relatively low-dose therapy, and LTG produced an increase in REM sleep in two studies (33–36). Gabapentin produced a deepening of sleep, increasing SWS percentage, and reducing sleep fragmentation in healthy subjects (37) and increased REM sleep in patients with epilepsy (33). Similarly, pregabalin was associated with a significant reduction in the number of awakenings and improvement in wake after sleep onset (38) and an increase in REM sleep (39) in patients with focal epilepsy, suggesting improvements in sleep continuity. Studies exploring the

effects of levetiracetam are conflicting, but generally also show consolatory effects on sleep in both healthy subjects and adults with epilepsy (40,41). Finally, in several studies, tiagabine has been shown to increase SWS and reduce sleep fragmentation in older, otherwise healthy adults (42).

Like AEDs, vagal nerve stimulation (VNS) produces alterations in sleep and wakefulness. Although improved daytime alertness has been observed, VNS stimulus intensity >1.5 mA has been associated with a reduction in REM sleep and increased awakenings, wake after sleep onset, and stage 1 sleep, suggesting a shift to lighter sleep stages and more sleep fragmentation (43). VNS therapy can produce cyclical reductions in airflow during sleep that at time meets the polysomnographic (PSG) criteria for sleep apnea in adults and children with epilepsy (44,45). Lowering the stimulus frequency from 30 to 20 Hz was shown to ameliorate VNS-induced respiratory events (46). Therefore, PSG should be performed prior to VNS implantation in all patients due to the potential development of sleep apnea. Patients should be monitored after implantation for sleep apnea symptoms. Repeat PSG should be performed in those with new-onset snoring, witnessed apnea, or daytime sleepiness and in patients with previously diagnosed sleep apnea as treatment adjustments may be required.

Sleep Organization in Epilepsy

A number of sleep architectural abnormalities have been reported in people with epilepsy. These include disruption and lability of REM sleep with reduced percentage of sleep time spent in REM sleep; increased percentage of wake after sleep onset; prolonged sleep or REM sleep onset; and increased number of arousals, awakenings, and stage shifts (47). These findings hold true even in seizure-free patients and are observed in patients with genetic generalized epilepsies and TLE, although more so in the latter. Sleep organization is more disrupted in TLE than in FLE, with more time wake after sleep onset, more awakenings, increased duration of light NREM sleep, reduced sleep efficiency, and reduced SWS (7,22).

Nocturnal generalized motor seizures in adults with genetic generalized epilepsy or focal epilepsy are associated with a decrease in total sleep time and REM sleep, prolonged REM latency, and increased light NREM sleep, increased percentage of time wake after sleep onset, and increased arousals (22,48). In a video–EEG series of TLE, a significant decrease in REM sleep was found on nights following daytime seizures, an even greater decrease in REM sleep on nights of seizures, and the greatest amount of REM suppression on nights in which seizures occurred early in the sleep period before the first appearance of REM sleep (48). Both diurnal and nocturnal seizures prolonged REM latency. Nocturnal, but not diurnal, seizures increased stage 1 sleep and decreased SWS. In a large study involving adults with epilepsy, compared to seizure-free patients, those who had generalized motor seizure during the day had significantly prolonged REM latency, increased stage 2 sleep, and decreased SWS and REM sleep the following night (49). A recent study reported a significant reduction in time in bed, total sleep time, REM sleep, SWS, and sleep efficiency as well as a significant increase in wake time after sleep onset in children with pharmacoresistant epilepsy compared to children with benign focal epilepsy and normal controls (50). In turn, a significant increase in REM sleep was observed in patients with mesial TLE seizure free at 2 years following resective surgery (51). Taken together, these findings suggest that sleep is inherently unstable in people with epilepsy; this instability promotes seizures, and seizures in turn fragment sleep, thus facilitating the epileptic process.

SLEEP–WAKE COMPLAINTS AND SLEEP DISORDERS IN EPILEPSY

Many sleep disorder symptoms and some primary sleep disorders including excessive daytime sleepiness (EDS), insomnia, and obstructive sleep apnea (OSA) are two to three times more common in people with epilepsy than in the general population (52–57) and adversely affect quality of life (52,54–56). This subject has been the focus of a comprehensive review (58).

EDS and insomnia are two of the most common complaints of people with epilepsy, often attributed to the effects of AEDs and seizures. One-third to one-half of the epileptic population report EDS (54,59). In a recent study involving 152 adults with epilepsy, 55% suffered from insomnia and more than 70% were rated as "poor sleepers" (56). Insomnia and poor sleep quality were significantly correlated with number of AEDs and depressive symptoms. As in the general population, sleep problems are more common among adults with epilepsy taking psychotropics for the treatment of mood disorders (55). In children with epilepsy, sleep problems are also common and adversely affect behavior and academic performance (57). Disturbed sleep, snoring, limb movements in sleep, daytime hyperactivity, EDS, and bedtime refusal are more common in children with epilepsy than in age-matched controls (57).

The prevalence of OSA in adults with epilepsy exceeds general population estimates of 25% for men and 10% for women (60). In the first PSG study, 33% of 39 patients (50% of males; 19% of females) with pharmacoresistant focal epilepsy without sleep complaints had OSA defined by an apnea–hypopnea index (AHI) of ≥10 (61). Predictors of OSA included male gender, higher body mass index (BMI), and a history of snoring, witnessed apnea, or nocturnal seizures. In a recent study involving 130 adults with epilepsy unselected for sleep disorders symptoms, the prevalence of OSA (AHI ≥ 10) was 30%, 16% having moderate-to-severe disease (62). Predictors of OSA included older age, dental problems, and higher standardized AED dose, a measure of drug burden. Male gender, older age, higher BMI, hypertension, and dental problems were associated with having a higher AHI. In older patients with epilepsy, the presence of sleep apnea is associated with worsening seizure control or late-onset seizures (63). Potential contributing factors include the effects of AEDs on upper airway tone as well as AEDs and inactivity leading to weight gain and endocrinopathies such as polycystic ovarian syndrome and hypothyroidism.

Understanding the predictors of OSA and other sleep disorders in epilepsy is important since treatment of OSA reduces seizures in 40% to 86% of cases, children included (58,64,65). A recent retrospective study found that continuous positive airway pressure (CPAP) therapy reduced seizure frequency by more than 50% (from 1.8 to 1 seizure per month) in 41 adults in the absence of AED adjustments (64). In another study, use of CPAP in 6 patients with focal epilepsy produced a marked reduction in spike rate on EEG, suggesting that sleep consolidation and correction of desaturation and hypercapnia may reduce epileptogenicity (66). These findings underscore the importance of routine screening and treatment of sleep disorders in people with epilepsy.

COMPLEX NOCTURNAL MOVEMENTS AND BEHAVIORS: DIFFERENTIATING NOCTURNAL SEIZURES AND PARASOMNIAS

While the differential diagnosis of abnormal sleep-related movements and behaviors is extensive, the focus of evaluation is usually on the distinction between nocturnal seizures and parasomnias (67). Parasomnias are undesirable physical events or experiences that occur during entry into sleep, within sleep, or during arousals from sleep that involve complex, seemingly purposely, goal-directed behaviors without consciousness. The primary parasomnias pertinent to this discussion are the NREM arousal disorders (confusional arousals, sleep terrors, and sleepwalking). Seizures in nocturnal frontal lobe epilepsy (NFLE) have a wide range of complexity and severity, overlapping considerably with disorders of arousal. Complex motor features typically of the hypermotor type involving complex movements of the trunk and proximal extremities that are repetitive, high-amplitude, and high-velocity, and asymmetric tonic seizures having dystonic, dyskinetic, and repetitive proximal movements are characteristic of NFLE (68). The lifetime prevalence of arousal disorders is nearly fivefold greater in relatives of probands with NFLE than in controls, suggesting an intrinsic link between the two (69).

A dysfunctional arousal mechanism involving the cholinergic system is hypothesized to underlie the shared pathophysiology of NFLE and NREM parasomnias. Mutations in the neuronal acetylcholine receptor in the autosomal dominant form of NFLE suggest a molecular basis for the disorder. These ion channel receptors are widely distributed on neuronal and glial membranes in cortical and subcortical regions, regulating the release of acetylcholine, gamma-hydroxybutyric acid, and glutamate, and producing a modulatory effect on arousals at the cortical and thalamic levels. Receptor mutations confer a gain of function with increased sensitivity to acetylcholine that is postulated to produce changes in the excitability of cortical and subcortical networks preferentially affecting the mesial frontal area facilitating intrinsic epileptogenesis and altering arousal mechanisms by destabilizing sleep (70). Activation of common pattern generators is thought to underlie the similar semiological manifestations of nocturnal seizures and arousal disorders (71). These are genetically determined neural circuits located in the mesencephalon, pons, and spinal cord that code for self-sustained patterns of behavior subserving innate motor behaviors essential for survival, such as feeding, locomotion, defense, and copulation.

The diagnosis of nocturnal seizures and parasomnias is often achieved through a comprehensive clinical history including timing, frequency, semiology, and evolution of typical events (Table 37.3). The Frontal Lobe Epilepsy and Parasomnias (FLEP) scale has been proposed as an adjunctive tool to identify patients with NFLE (Table 37.4) (72). A score of 0 or less is unlikely to be seen in epilepsy, whereas patients scoring 3 or greater generally have epilepsy. Laboratory testing is recommended for those with an FLEP score of +1 to +3. If diagnostic uncertainty persists despite routine clinical, EEG, and imaging assessments, video PSG with EEG (VPSG-EEG) may be warranted. This procedure combines PSG with 21-channel EEG to evaluate unexplained nocturnal behaviors when epileptic seizures are suspected, particularly when primary sleep disorders are under consideration and episodes are frequent. Due to the limitations of capturing a typical event in one night of recording, long-term VEEG is preferred when episodes do not occur at least every other night, primary sleep disorders such as OSA are not suspected, a history of postictal agitation or wandering exists, and patient cooperation is uncertain. In a recent VPSG-EEG analysis of 120 events of 44 patients with NFLE or NREM arousal disorders, 94% were correctly classified using a diagnostic decision tree based on a cluster analysis (73).

Table 37.3 Differentiating Nocturnal Frontal Lobe Epilepsy and Parasomnias

Feature	NFLE	Arousal disorders	REM behavior disorder
Age of onset	Variable, typically first or second decade	Usually first decade	Over 50
Sleep stage of origin	NREM 1 or 2, sleep–wake transitions	NREM 3	REM sleep
Timing of episodes	Anytime	First one-third of sleep period	Last one-third of sleep period
Duration of episodes	5–60 s	2–30 min	Seconds to 2 min
Frequency of episodes	Nightly clusters	Sporadic, rare clusters	Sporadic, rare clusters
Onset and offset	Sudden	Gradual	Sudden
Semiology of episodes	Highly stereotyped, hypermotor, asymmetric tonic/dystonic	Not stereotyped, variable complexity	Not highly stereotyped, vocalizations with self-protective behaviors and dream recall
Level of consciousness during episodes	Usually preserved	Variable	Poorly responsive
Postictal confusion	Typically absent	Present	Absent
Risk of injury	Low	High	Moderate
VPSG-EEG findings	Epileptic activity in <50%	SWS arousals, rhythmic delta pattern	REM sleep without atonia

From Foldvary-Schaefer N, Aksheikhtaha Z. Complex nocturnal behaviors: nocturnal seizures and parasomnias. Continuum (Minneap Minn). 2013;19(1):104–131.

Table 37.4 The Frontal Lobe Epilepsy and Parasomnia Scale

Clinical feature		Score
Age at onset	<55 y	0
	≥55 y	−1
Duration of typical event	<2 min	+1
	2–10 min	0
	10 min	−2
Typical number of events in single night	1 or 2	0
	3–5	+1
	>5	+2
Time of night events most commonly occur	Within 30 min of sleep onset	+1
	Other times	0
Events associated with definite aura	Yes	+2
	No	0
Wandering outside bedroom during events	Yes	−2
	No (or uncertain)	0
Complex, directed behaviors during events	Yes	−2
	No (or uncertain)	0
Prominent dystonic posturing, tonic limb extension, or cramping during events	Yes	+1
	No (or uncertain)	0
Event stereotypy	Highly stereotyped	+1
	Some variability/uncertain highly variable	0
		−1
Patient recollection of events	Yes, lucid recall	+1
	No or vague recollection only	0
Speech during events; if so, subsequent recollection of speech	No	0
	Yes, sounds only or single words	0
	Yes, coherent with incomplete or no recall	−2
	Yes, coherent speech with recall	+2
	Total score

CONCLUSION

Over a century of work has confirmed important links between sleep and epilepsy. Several epilepsy syndromes are now recognized for seizures that occur predominately or exclusively from sleep and investigations exploring the mechanisms underlying variations in seizure timing in epilepsies arising

from different regions is underway. Sleep is a critical modulator of IEDs and seizures, and significant sleep deprivation activates seizures and epileptic EEG abnormalities. People with epilepsy are prone to sleep instability, in part due to seizures, AEDs, and VNS therapy. The prevalence of insomnia and sleep apnea is increased in epilepsy patients, and untreated sleep disorders further increase daytime sleepiness and seizures. These observations underscore the importance of the routine assessment of sleep and wake complaints in people with epilepsy.

CHAPTER 38 STATUS EPILEPTICUS

HOWARD P. GOODKIN AND JAMES J. RIVIELLO, JR.

Status epilepticus (SE) is a life-threatening medical emergency that requires prompt recognition and immediate treatment. SE is not a disease in itself but rather a manifestation of either a primary central nervous system (CNS) insult or a systemic disorder with secondary CNS effects. It is important to identify and specifically treat the precipitating cause, thus preventing ongoing neurologic injury and seizure recurrence. A team approach, with an organized and systematic treatment regimen, planned in advance, is needed, including one for refractory status epilepticus (RSE). It is imperative that SE treatment rigorously adhere to basic neuroresuscitation principles—the ABCs (airway, breathing, circulation). Although the initial approach is standard, once the patient is stabilized, management must be individualized with the goal of terminating the seizure and treating the underlying condition.

DEFINITION

SE can present in many different forms that range from the easily recognized prolonged overt generalized convulsive SE to the more difficult to recognize nonconvulsive SE (NCSE) that is characterized by a prolonged continuous ictal electrographic discharge pattern, with or without obvious clinical signs. Given the broad range of clinical presentations and that the underlying mechanisms permitting prolonged seizures are not completely known, it has been difficult to develop definition and classification systems that are well accepted, comprehensive, mechanistic, and clinically useful.

At first, Gastaut's classic operational definition of SE as "an epileptic seizure that is sufficiently prolonged or repeated at sufficiently brief intervals so as to produce an unvarying and enduring epilepticus condition" (1) may seem vague, cumbersome, and insufficient as it fails to provide adequate guidance to the clinician. However, it has the advantage of allowing for a dynamic interpretation.

Other proposed operational definitions have attempted to be more precise by including a time duration (2,3). However, the basis for the time chosen has varied. As experimental studies demonstrated an increased risk of neuronal injury after 30 minutes when homeostatic mechanisms fail, the Working Group on Status Epilepticus of the Epilepsy Foundation of America (EFA) defined SE as >30 minutes of either a continuous seizure or two or more sequential seizures without full recovery of consciousness (4). In defining SE, others have chosen to emphasize the need for the prompt care of the patient and chosen to define the seizure duration required to fulfill the definition of SE in the 5- to 10-minute range (5). It is expected that future definitions of SE will continue to better define the mechanisms that underlie the self-sustained nature of these prolonged seizures.

CLASSIFICATION

The classification of the epilepsies and seizures is evolving (6). The classification of SE is no

different, and multiple schemas for the classification of SE have been proposed throughout the years. Traditionally, the prolonged, continuous, or repetitive seizures of SE have been separated from the self-limited seizures and classified into two broad categories—either generalized or focal (partial)—based on a combination of the electrographic pattern and seizure semiology (7–12).

In contrast, other proposed classification schemas have placed an emphasis on seizure semiology. One proposal divided SE into the categories of aura status, autonomic status, dyscognitive status, motor status (simple motor, i.e., focal motor without alteration of consciousness, and complex motor, i.e., focal motor with dyscognitive features), and special status (e.g., hypomotor status) (13). A more familiar predominantly semiologically based SE classification system divides SE into three broad categories of simple focal, convulsive, and nonconvulsive (14). However, the division between convulsive SE and NCSE may not be so obvious as subtle convulsive SE or NCSE—characterized by no obvious clinical signs despite marked impairment of consciousness and bilateral EEG discharges—may evolve from convulsive SE or follow its unsuccessful treatment.

In a study of 458 patients from the Netherlands (1980–1987) (15–17), generalized convulsive SE occurred in 346 (77%), NCSE in 65 (13%), and simple partial SE in 47 (10%). Of patients with NCSE, 40 had complex partial SE and 25 had absence SE. In this study, within the nonconvulsive group of SE patients, focal signs occurred more often with complex partial SE and a fluctuating consciousness was more common with absence SE, with the majority of patients in both groups having prior epilepsy (15). With simple partial SE, 46 patients had somatomotor features and 1 had aphasia with hallucinations (16).

As future classification systems are developed, psychogenic nonepileptic SE, which occurs in adults (18) and children (19,20), should likely be included as a special category to assure clinical recognition of these events. Pseudostatus epilepticus may occur as an expression of Munchausen syndrome (factitious disorder by proxy) (21).

THE CLINICAL AND ELECTROGRAPHIC STAGES OF STATUS EPILEPTICUS

The clinical stages of SE include the premonitory (prodromal) stage, the incipient stage, the early stage, the "transition stage" to the late or established stage, the refractory stage (22), and postictal stage (Table 38.1).

Table 38.1 Stages of Status Epilepticus

Premonitory	
Incipient[a]	0–5 min
Early[a]	5–30 min
Transition	From early to established
Established (late)	30–60 min
Refractory	After 60 min
Postictal	

[a]Special circumstances of the early and incipient stages for which early anesthetic therapy should be considered are listed in Table 38.2.

The premonitory stage consists of confusion, myoclonus, or increasing seizure frequency, the early stage consists of a continuous seizure, and the refractory stage may consist of subtle generalized

convulsive SE or NCSE. It has now become clear that the "transition" stage from the early to the late stage of SE is not fixed in time and may vary depending on the underlying etiology. SE should not be considered refractory if therapy has been inadequate.

A predictable sequence of EEG progression occurs during the clinical stages in experimental models and humans: (i) discrete seizures with interictal slowing, (ii) waxing and waning of ictal discharges, (iii) continuous ictal discharges, (iv) continuous ictal discharges punctuated by flat periods, and (v) periodic epileptiform discharges (PEDs) on a flat background (Fig. 38.1) (23,24). However, every episode of SE does not pass through every one of these defined stages (25) (Fig. 38.2). The PED stage may also consist of either lateralized or bilateral patterns (23). The response to treatment appears to depend on the electrographic stage (see below: Trends in Patients with Status Epilepticus). In one study (23), discrete seizures were all controlled with diazepam (six of six patients); whereas in the PED stage, the seizure stopped in only one of six patients and overt clinical seizures were converted to either subtle or electrographic seizures in the five of six patients.

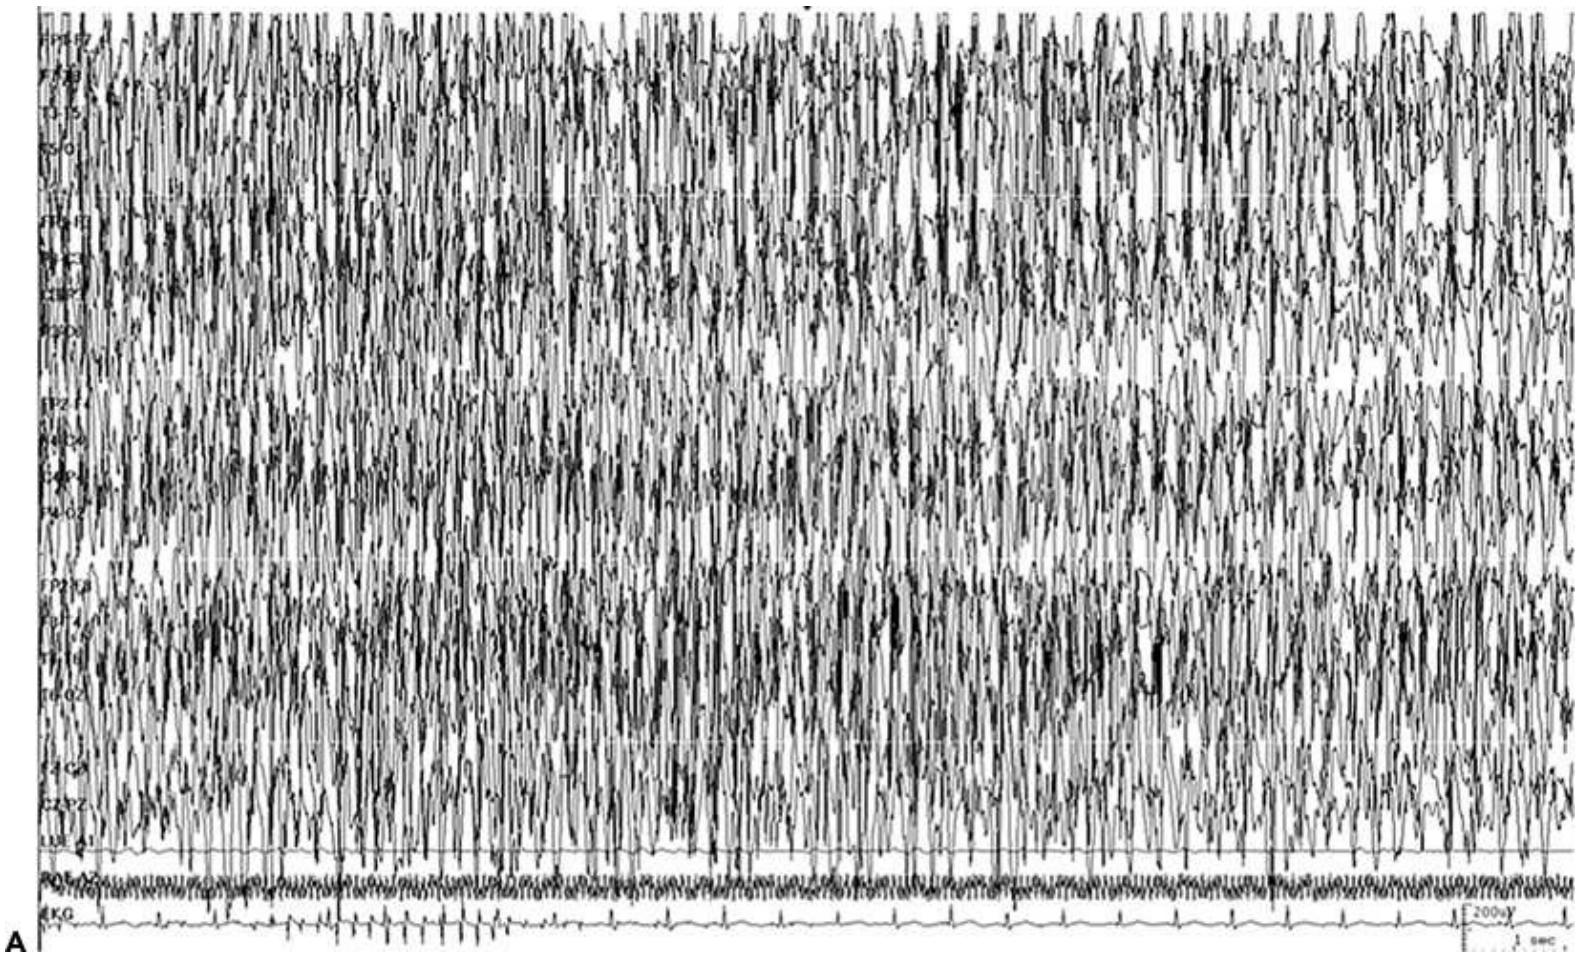
Figure 38.1. A: Continuous ictal discharges. **B:**PEDs on a flat background.



A

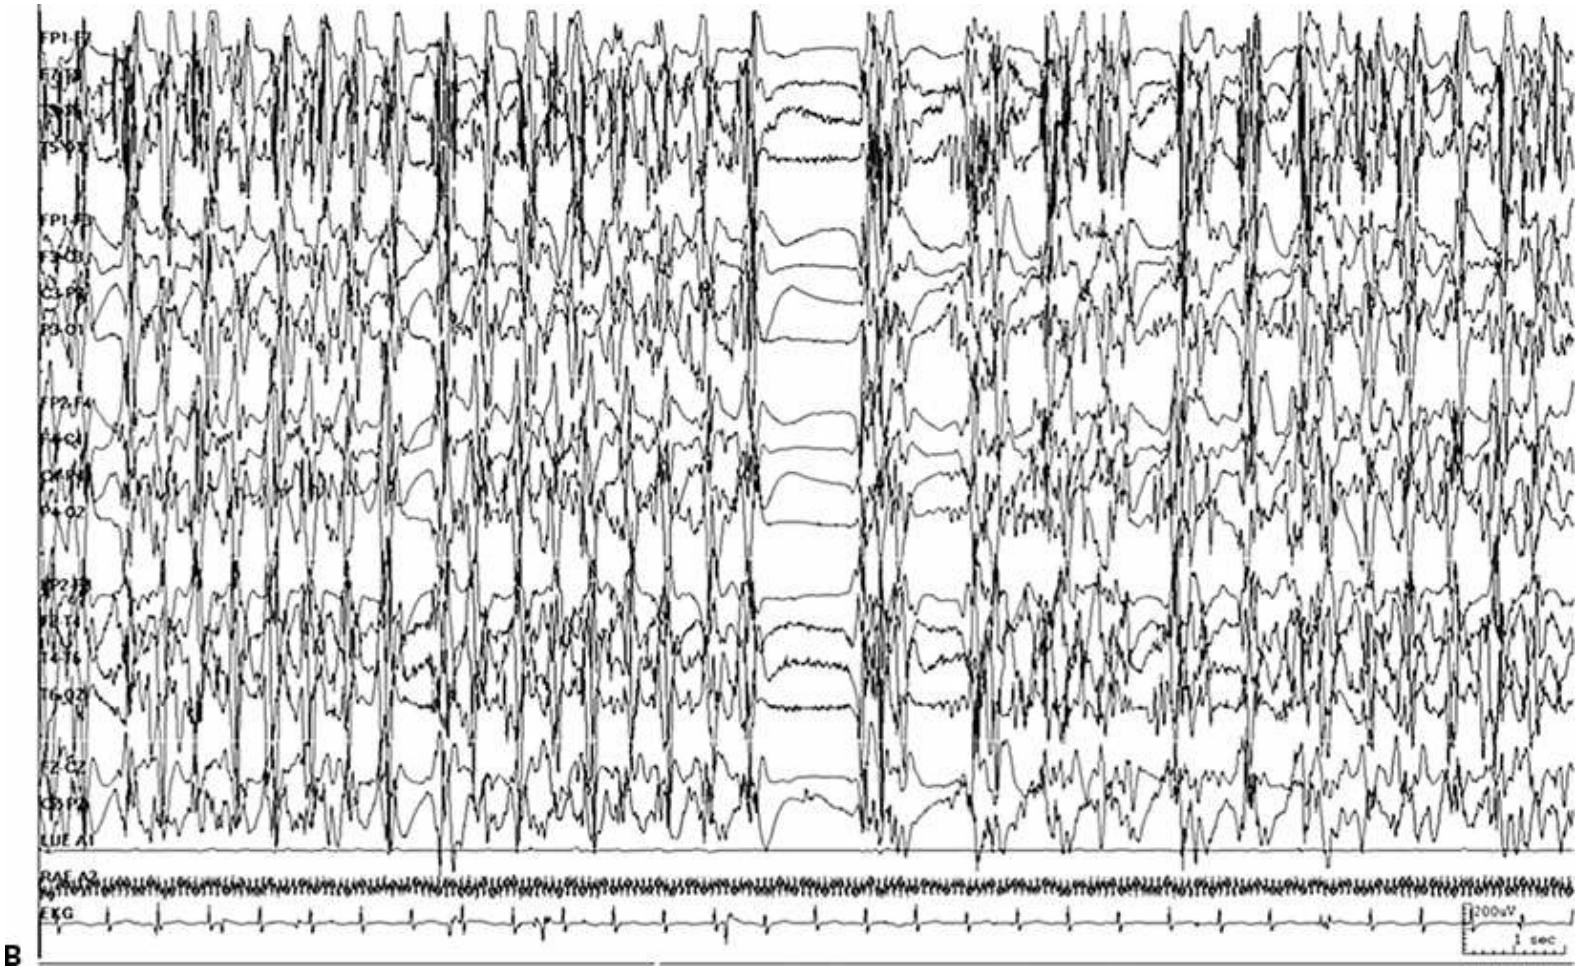


Figure 38.2. Same patient, different seizure. **A:** Continuous ictal discharge. **B:** Continuous ictal discharges punctuated by flat periods.

TRENDS IN PATIENTS WITH STATUS EPILEPTICUS

As prolonged seizures are unlikely to spontaneously cease, the overall trend in SE has been to decrease the time duration required for diagnosis and to treat as soon as possible. Although the EFA Working Group defined SE as a seizure duration >30 minutes, the Working Group recommended treatment as soon as 10 minutes after seizure onset (5). Lowenstein et al. (6) proposed an operational definition for generalized convulsive SE in adults and older children (>5 years of age) of ≥5 minutes of either a continuous seizure or two or more discrete seizures between which there is incomplete recovery of consciousness. In the Veterans Affairs (VA) Cooperative Study (26), which compared various first-line antiepileptic drugs (AEDs), treatment for SE was initiated at 10 minutes, and the San Francisco Prehospital Treatment study used 5 minutes (27). Beran has questioned waiting even as long as 5 minutes to treat an ongoing seizure (28). Similarly, Lowenstein and Alldredge had recommended immediately proceeding to anesthesia in the special case of SE developing while in the ICU (2). Table 38.2 lists other special circumstances for which immediate treatment during the early stage or even the incipient stage of SE (see Table 38.1) is recommended (29).

Table 38.2 Special Circumstances of the Early Stage

Postoperative patients, especially cardiac surgery and neurosurgery
Brain tumor, head trauma, increased intracranial pressure, intracranial hematoma, subarachnoid hemorrhage
Stroke: Ischemic, hemorrhagic
CNS infections (meningitis, encephalitis, brain abscess)
Organ failure, especially hepatic or multisystem failure
Hyperthermia, malignant hyperthermia, hyperthyroidism
Metabolic disorders prone to increased intracranial pressure, diabetic ketoacidosis, or organic acid disorders

Clinical data characterizing the duration of a typical seizure support this trend of earlier treatment. A typical clinical seizure rarely lasts as long as 5 minutes. A typical generalized tonic–clonic seizure lasts 31 to 51 seconds, with a postictal phase of a few seconds to 4 minutes (30). In an inpatient study, mean seizure duration was 62 seconds, with a range of 16 to 108 seconds (31). In complex partial seizures in children, the typical duration was 97 seconds (32). In a prospective study of new-onset seizures in children, the frequency distribution of seizure duration was best described as the sum of two groups: one with a mean of 3.6 minutes (76% of cases) and the other with a mean of 31 minutes (24% of cases); if the seizure duration was 5 to 10 minutes, it was unlikely to cease spontaneously within the next few minutes (33).

The trend for the prompt treatment of SE during the early stage is supported by clinical and experimental studies characterizing the treatment of SE. In the prospective VA Cooperative Study, the first-line treatment of shorter-duration overt generalized SE was more successful than the first-line treatment of the more prolonged subtle SE, independent of treatment arm. In addition, in post hoc analysis, it was demonstrated that when the first-line AEDs failed, there was only a 5.3% response to a third AED (22). Although the response rate to treatment with a third AED was higher (58%) in a retrospective study of 83 episodes of SE in 74 patients (34), it has been posited that this difference reflects earlier treatment.

A time-dependent efficacy of treatment has also been observed in experimental models of SE. Following induction of SE with the combination of lithium and the cholinergic agonist pilocarpine, diazepam was effective in controlling SE shortly after onset but was effective in only 17% of rats in the late electrographic stages of SE (35). This finding was later confirmed in a second model of SE for both diazepam and phenytoin (36). This decrease in the benzodiazepine response occurs rapidly after the onset of SE and in young animals with ages corresponding to a human toddler (37–39). Diazepam and the other benzodiazepines enhance the function of a subset of benzodiazepine-sensitive $GABA_A$ receptors. Several studies (40–43) have demonstrated that the surface expression of these $GABA_A$ receptors declines during SE and have postulated that this reduction in surface expression, which is the result of activity-dependent, subunit-specific trafficking of $GABA_A$ receptors, partially accounts for the time-dependent efficacy of the benzodiazepines.

PATHOPHYSIOLOGY

Mechanistically, SE occurs when factors that "normally" terminate seizures fail allowing the seizure to persist and self-propagate (5,44). What are these pathophysiologic mechanisms? In simplistic terms, SE results from decreased cerebral inhibition, excessive cerebral excitation, or a combination of both. A rapid modification in the properties of $GABA_A$ receptors (37,45) and excitatory amino

acid receptors (46,47) through mechanisms such as altered receptor trafficking (see above) likely contributes to the reduction in inhibition and increase in excitation.

Excessive excitation itself may cause neuronal injury and cell death, referred to as excitotoxic injury. This has been demonstrated in experimental models, such as in kainic acid–induced limbic seizures (48), but its occurrence in humans had been questioned. An outbreak of domoic acid poisoning, an excitotoxic agent, with acute symptoms, including SE, was associated with neuronal loss and astrocytosis that was greatest in the hippocampus and amygdala; this is similar to the seizures induced by kainic acid (49,50). A survivor developed epilepsy and, after death, autopsy revealed hippocampal sclerosis (51).

Prolonged seizures in anesthetized baboons cause irreversible neuronal injury (52,53). Lothman outlined the alterations in systemic and brain metabolism occurring with prolonged SE (54): decreased brain oxygen tension, mismatch between the sustained increase in oxygen and glucose utilization and a fall in cerebral blood flow, and depletion of brain glucose and oxygen. In the incipient or early stages of SE, brain compensatory mechanisms may protect against neuronal injury. However at some point, the ability to compensate for neuronal injury is exhausted, and the risk of neuronal injury increases. This point defines the transition stage from early to late (established) SE. During all stages, the ability to compensate requires adequate airway and good breathing, circulation, and cerebral blood flow.

EPIDEMIOLOGY OF STATUS EPILEPTICUS

There have been two large, population-based studies in the United States—one performed in Richmond, Virginia (55) and the other in Rochester, Minnesota (56). These two studies estimate that 60,000 to 150,000 episodes of SE occur per year in the United States resulting in approximately 55,000 deaths per year. Overall, SE accounts for 1% to 8% of hospital admissions for epilepsy. Between 4% and 16% of patients with epilepsy will have at least one episode of SE, with one-third of the cases occurring as the presenting symptom in patients with a first unprovoked seizure, one-third in patients with established epilepsy, and one-third in those with no history of epilepsy (57).

The incidence has varied by location: the rate in the study performed in Richmond was 41/100,000 (55) and the rate in the Rochester study was 18/100,000 (56). Lower rates were observed in a study performed in California (58), where the overall rate of generalized convulsive SE was 6.2/100,000, and in European studies, where the incidence rate was 9.9/100,000 in Switzerland (59), 15.8/100,000 in Germany (60), and 13.1/100,000 in Bologna (61).

A consistent finding across studies is that higher incidence rates occur at the extremes of life. For example, in the California study, the incidence rate for children <5 years of age was 7.5/100,000 and the incidence rate for the elderly was 22.3/100,000. In children, SE is most common in the very young, especially those <2 years of age (62). In the community- based prospective North London Status Epilepticus in Childhood Surveillance Study (NLSTEPSS), the incidence of SE during childhood was from 17 to 23/100,000/year (63). For children with epilepsy, SE typically occurs within 2 years of the onset of epilepsy (64), and recurrent SE is more likely with an underlying neurologic disorder (65).

ETIOLOGY OF STATUS EPILEPTICUS

As previously noted, SE is not a disease but the end result of multiple causes. These causes may be

acute or remote to the episode. There may be a remote cause for the epilepsy with a new acute precipitant for the episode of SE. SE may be observed as part of a progressive encephalopathy resulting from a genetic disorder. In some cases, the cause of the SE may remain unknown (66).

In several studies of adult SE, trauma, tumor, and vascular disease were the most frequently identified causes, although idiopathic and unknown causes were also common (67–70). Etiology also differs among centers and by ages. In San Francisco, noncompliance with AEDs and alcohol withdrawal were the two most common etiologies (Table 38.3) (67,70), whereas cerebrovascular damage was the most common etiology in Richmond (71).

Table 38.3 Etiology in the San Francisco Studies: Changes Over Time

Etiology	1970s (number of cases)	1980s (number of cases)
Anticonvulsant withdrawal	27	48
Alcohol related	15	43
Drug intoxication	10	14
CNS infection	4	12
Refractory epilepsy	—	10
Trauma	3	8
Tumor	4	7
Metabolic disorders	8	7
Stroke	15	6
Cardiac arrest	4	6
Unknown	15	8

CNS, central nervous system.

From refs Lowenstein DH, Alldredge BK. Status epilepticus at an urban public hospital in the 1980s. Neurology. 1993;43:483–488; Aminoff MJ, Simon RP. Status epilepticus. Causes, clinical features and consequences in 98 patients. Am J Med. 1980;69:657–666.

For children in North London, the age-adjusted incidence for acute symptomatic SE was 16.9% in those <1 year of age, 2.5% in those 1 to 4 years, and 0.1% in those 5 to 15 years of age. The incidence of an acute on remote (remote symptomatic with an acute precipitant) was 6%, 5.3%, and 0.7%, respectively. A prolonged febrile seizure occurred in 4.1/100,000, acute symptomatic causes in 2.2/100,000, remote symptomatic in 2.3/100,000, acute on remote in 2.1/100,000, idiopathic in 1.4/100,000, cryptogenic in 0.2/100,000, and unclassified in 1/100,000 (63).

As the Richmond study included adults and children, the etiologies in these two groups can be directly compared (Table 38.4). In adults, cerebrovascular disease was the most common etiology, occurring in 25.2%, versus only 3.3% in children, whereas in children, fever or infection was the most common cause, occurring in 35.7% versus only 4.6% in adults. Medication change was a major cause in both adults and children—20% in children versus 19% in adults (71). The incidence of tumors was higher in older studies (68,69).

Table 38.4 Comparison of Etiology in Children and Adults in the Richmond Study

Etiology	% Of children (<16 years)	% Of adults (>16 years)
Cerebrovascular	3.3	25.2
Medication change	19.8	18.9
Anoxia	5.3	10.7
EtOH/drug-related	2.4	12.2
Metabolic	8.2	8.8
Unknown	9.3	8.1
Fever/infection	35.7	4.6
Trauma	3.5	4.6
Tumor	0.7	4.3
CNS infection	4.8	1.8
Congenital	7.0	0.8

PROGNOSIS OF PATIENT WITH STATUS EPILEPTICUS

Although many people may survive an episode of SE, even refractory SE, with no or limited untoward effects (72,73), SE can be life threatening and has been associated with long-term neurologic sequelae. The prognosis of SE depends partially on etiology (74), duration (2,75), and age (62). Recently, concern has been raised that prognosis may be affected by the use of anesthetic agents and the need for intubation and mechanical ventilation (76).

The mortality rate in modern, general SE series ranges from 4% (77) to 37% (78) and is higher with an acute precipitant (78). An acute precipitant is more likely when there is no prior history of epilepsy (78,79), but may also be responsible for death in persons with known epilepsy with SE. In one series, 63% of patients survived, 28.6% died from the underlying cause, 6.6% died from other causes, and 1.8% died from the SE itself (78). In a retrospective study of 74 patients (80), the mortality rate was 21% (14/85) and was higher with acute symptomatic seizures and older ages. Interestingly, in a study limited only to patients with de novo SE (81), SE occurring in patients already hospitalized, the mortality was very high—61% (25/41).

Short-term versus long-term mortality was compared using data from the Rochester study (82–84): Mortality was 19% (38/201) within the first 30 days, but cumulative mortality was 43% over 10 years (82). The long-term mortality risk increased with an SE duration >24 hours, acute symptomatic etiology, and myoclonic SE (82).

In the Richmond study, the mortality rate was 32% when the duration was >60 minutes versus only 2.7% when the duration was 30 to 59 minutes (85). Other factors associated with a high mortality rate in the Richmond study included anoxia and older age, whereas a low mortality rate was associated with alcohol and AED withdrawal (85).

In the Netherlands study (17), prognosis of patients with generalized convulsive SE was related to treatment adequacy. A favorable outcome occurred in 263 of 346 patients (76%), with outcome related to cause, duration >4 hours, more than one medical complication, and quality of care. In order to analyze the treatment effects, therapy was classified as insufficient when the wrong AED dose or route was used, if an unnecessary delay occurred, if mechanical ventilation was not used despite respiratory insufficiency or medical complications, or if neuromuscular paralysis was used without

EEG monitoring (in order to detect seizure activity). The most common reason for classifying therapy as insufficient was an inadequate AED dose. In the patients with a favorable outcome (n = 263), therapy was classified as good or sufficient in 85.6% and considered insufficient in only 10.3%; in those with sequelae (n = 45), therapy was inadequate in 22.2%. When the morbidity was from SE itself, insufficient therapy occurred in 50% of patients. With the occurrence of death (n = 38), therapy was sufficient in 44.7% of patients, and in cases of death due to SE itself, therapy was considered insufficient in 62% of patients (17).

The mortality rate in pediatric SE ranges from 3% to 11% and is also related to etiology and age (77,86–92). In one study, the mortality was 4%, occurring only with acute symptomatic or progressive symptomatic etiologies (86). In NLSTEPSS, the overall mortality was 3%. In the Richmond study, for children ranging in age from 0 months to 16 years (n = 598), the overall mortality rate was 6.2% (37 of 598). The highest rates occurred during the first 6 months of life (24%; 18 of 75) and between 6 and 12 months of age (9.25%; 5 of 54) with a low rate (2.98%; 4 of 469) in children older than 1 year (93). The difference likely reflects a higher incidence of symptomatic SE in the youngest children. With respect to morbidity following SE in children, a minority of children will have new-onset motor dysfunction and loss of previously obtained milestones (77,92). A Canadian study of SE reported 34% of 40 children with an SE duration of 30 to 720 minutes had subsequent neurodevelopmental deterioration (94). Even in children with febrile SE, speech deficits have been reported (95).

An increase in morbidity and mortality has also been reported with NCSE, which is related to SE duration (36 hours to >72 hours) (96). However, this increased morbidity with NCSE is controversial (97–99). Following cardiopulmonary resuscitation, SE, status myoclonus, and myoclonic SE are predictive of a poor outcome (100). On EEG, burst suppression (101) and PEDs are predictive of a poor outcome (102), whereas a normal EEG is associated with a good prognosis (103).

MANAGEMENT OF STATUS EPILEPTICUS

The initial management of patients with SE begins with the ABCs—airway, breathing, and circulation (Table 38.5). Diagnostic studies are then selected, depending on a patient's history and physical examination (not all studies need to be obtained for every patient). Serum glucose should be checked immediately with bedside glucose testing to rapidly diagnose hypoglycemia. A complete blood count may be helpful for diagnosing infection, although leukocytosis may occur with SE. Electrolytes, calcium, phosphorous, and magnesium values may also be helpful. Lumbar puncture (LP) should be considered in the febrile patient, although CSF pleocytosis may occur without infection, presumably due to a breakdown in the blood–brain barrier (104). In one study, the highest CSF white blood cell count from SE alone (no acute insult) was 28×10^6/L (105). If there is concern about increased intracranial pressure or a structural lesion, LP can be deferred until neuroimaging is performed. If there is evidence of infection, antibiotics can be administered prior to LP. In those taking an AED, levels should be obtained as low AED levels may contribute to the development of SE in both adults and children (106,107). A practice parameter on the diagnostic assessment of the child with SE has been produced (108). When done, electrolytes or glucose were abnormal in 6%, blood cultures were abnormal in 2.5%, a CNS infection was found in 12.5%, an ingestion was found in 3.6%, an inborn error of metabolism was found in 4.2%, and AED levels were low in 32%.

Table 38.5 Immediate Management of Status Epilepticus

The A B Cs:
▪ Stabilize and maintain the Airway; position head to avoid airway obstruction
▪ Establish Breathing (i.e., ventilation): administer oxygen by nasal cannula or mask
▪ Maintain the Circulation: start intravenous (IV) line
▪ Monitor the vital signs: pulse (ECG monitoring), respiratory rate, blood pressure, temperature, pulse oximetry; check bedside glucose
Start intravenous (IV) line:
▪ Use normal saline
▪ Consider thiamine 100 mg, followed by 50 mL of D50%
▪ Determine what studies are needed
▪ Consider CBC, electrolytes, calcium, phosphorus, magnesium, AED levels, toxicology
▪ Lumbar puncture (especially if febrile)
▪ Neuroimaging, cranial CAT scan, or MRI
▪ EEG, if diagnosis initially in doubt
Points from history:
▪ Has an AED been given (prehospital treatment or inpatient), is the patient on any AEDs (especially phenobarbital or phenytoin), or are there any allergies or has the patient ever had Stevens–Johnson syndrome?
▪ Characteristics of past seizures: is there a history of status epilepticus?
▪ Are treatable causes present (any acute precipitants)?
▪ Fever or illness, head trauma, possible electrolyte imbalance, intoxications, toxin exposure?
▪ Are chronic medical conditions present, or is the patient on steroid therapy? (if so, needs stress coverage)

ECG, electrocardiogram; CBC, complete blood count; AED, antiepileptic drug; CAT, computerized axial tomography; MRI, magnetic resonance imaging; EEG, electroencephalography.

Neuroimaging options include cranial computed axial tomography (CAT) scan and magnetic resonance imaging (MRI). CAT scans are readily available on an emergency basis and should identify all disorders demanding immediate intervention, such as tumor or hydrocephalus, but may not show the early phases of infarction. CAT scan and MRI may detect focal changes, which may be transient (109), secondary to a focal seizure (suggesting the origin of the focus), with MRI the more sensitive technique. Although these lesions may mimic those of ischemic stroke, they are reported to cross vascular territories (110). Changes in diffusion-weighted images and the apparent diffusion coefficient suggest both cytotoxic and vasogenic edema (111). Progressive changes also occur, such as hippocampal atrophy and sclerosis, or global atrophy (112,113). In the FEBSTAT study, a prospective study of children between 1 month and 5 years of age who have experienced an episode of febrile SE, 9% (17/191) were found to have increased T2 signal in the hippocampus, maximum in Sommer sector, when imaging was completed within 72 hours of presentation, and another approximately 2.5% (5/191) had an equivocal finding. None of the 96 children with a first simple febrile seizure who made up the control group were found to have a similar increase in signal (114). Repeat imaging in this cohort obtained approximately 1 year later demonstrated retarded hippocampal growth after febrile SE and, in several of the children with acute findings, the development of imaging characteristics of hippocampal sclerosis (115). The North London Group found in a cohort of 80 children that 20% to 30% of the children (0.18 to 15.5 years) had evidence of

hippocampal volume loss on MR imaging of the brain 1 month following an episode of convulsive SE of any etiology (116). In a fatal case of unexplained SE, high-signal lesions in the mesial temporal lobes and hippocampal neuronal loss were reported (117). In general, neuroimaging should be performed in all patients with new-onset SE, especially if there is no prior history of epilepsy.

Intoxication with certain agents, particularly theophylline (79,81,118) and isoniazid (INH) (119), which may involve acidosis (120) and is treated with pyridoxine (vitamin B_6) (121), may predispose individuals to generalized convulsive SE or NCSE. Immunosuppressants such as cyclosporine (122) or tacrolimus and ifosfamide (123) may predispose individuals to NCSE, which may also occur when phenytoin and carbamazepine are used in patients with idiopathic generalized epilepsy (124); lithium (125), tiagabine (126), and amoxapine (127) may also be implicated. Fatal SE has occurred with flumazenil; therefore, caution should be exercised in patients with a history of seizures and chronic benzodiazepine use or when a mixed overdose is suspected (128).

An EEG is not immediately needed for treatment. Indications for emergency EEG include unexplained altered awareness (to exclude NCSE) (Fig. 38.3), the use of neuromuscular paralysis in a patient with SE, high-dose suppressive therapy for refractory SE, and no return to baseline or improvement in mental status following control of overt convulsive movements (to exclude ongoing subtle SE) (129). NCSE occurs in 14% of adults (130) and 26% of children (131) in whom generalized convulsive SE has been controlled after treatment. In a retrospective study of children who experienced an episode of convulsive SE and subsequently underwent continuous EEG monitoring in an intensive care setting, a third were discovered to have electrographic seizures (132). In another study, NCSE was detected in 8% of all comatose patients (101). Therefore, the EEG should be used when the diagnosis is in doubt, especially in patients with pseudoseizures.

ANTIEPILEPTIC DRUG THERAPY FOR STATUS EPILEPTICUS

Treatment should be aimed at controlling SE as soon as possible, particularly before brain compensatory mechanisms fail. Despite adequate oxygenation and ventilation, such failure has been reported within 30 to 60 minutes in experimental SE (54) and within 30 to 45 minutes in humans (2). Systemic and metabolic changes occur early, with increases in blood pressure, lactate, and glucose levels. Both respiratory and metabolic acidosis may develop, although the former is more common (133). Initially, brain parenchymal oxygenation, lactate, glucose, and oxygen utilization remain stable, cerebral blood flow increases, but cerebral glucose slightly decreases. In later stages, blood pressure may be normal or decrease slightly, glucose may decrease, and hyperthermia and respiratory compromise may occur, leading to hypoxia and hypercarbia. Decreases in brain parenchymal oxygenation, cerebral blood flow, and brain glucose all contribute to an energy mismatch (54). Neuron-specific enolase, a marker of brain injury, is elevated in the serum following both convulsive and NCSE (134,135).

Neuronal injury may occur in the absence of metabolic derangement. In paralyzed and ventilated baboons given bicuculline, a $GABA_A$ receptor competitive antagonist, to induce electrographic SE

(52,53), neuronal loss was observed in the neocortex and hippocampus. Brain lesions following flurothyl-induced SE in the paralyzed and well-oxygenated rat include hypermetabolic infarction of the substantia nigra (136). In humans, neuronal loss was seen following SE in three patients without hypotension, hypoxemia, hypoglycemia, or hyperthermia (137).

Most of the AEDs used to treat SE have the potential for respiratory and cardiac depression, especially when administered by a loading dose (138) or when an excessive dose is used (139). Therefore, protecting the airway, controlling ventilation, and monitoring cardiac and hemodynamic function are mandatory. Intravenous (IV) administration is the preferred route for the treatment of SE, especially in the inpatient setting, but if IV access is difficult, intramuscular (IM), rectal, or intranasal routes have been used.

Primary AEDs for SE

The benzodiazepines (lorazepam, diazepam, midazolam), phenytoin or its prodrug form fosphenytoin, and phenobarbital are the current drugs of first choice for the initial therapy in patients with SE (Table 38.6). However, some advocate the early use of the secondary agents (e.g., valproic acid, levetiracetam, anesthetics).

Table 38.6 First-Line (Emergent Initial Therapy) Intravenous Antiepileptic Drugs

AED	Dose	Rate	Max
Lorazepam	0.1 mg/kg	2 mg/min (2–5)	8 mg
Diazepam	0.2 mg/kg	5 mg/min	16–20 mg
Fosphenytoin	20 mg PE/kg	Up to 3 mg PE/kg/min	150 mg/min (adult)
Phenytoin	20 mg/kg	Up to 1 mg/kg/min	50 mg/min (adult) 25 mg/min (child) 20 mg/min (elderly)
Phenobarbital	20 mg/kg	1 mg/kg/min	100 mg/min (adult) 30 mg/min (child)

Treatment of SE is typically initiated with a benzodiazepine. Diazepam was rapidly applied to the treatment of SE soon after its discovery and has remained a mainstay of treatment. Theoretically, compared to lorazepam, diazepam should have a more rapid onset of action because of greater lipid solubility (138). However, this high lipid solubility results in a rapid redistribution to inactive tissues, such as fat, which can result in high rates of seizure recurrence (140,141).

Lorazepam has been used in both adults and children (142,143). Although expected to have a slower time to onset than diazepam, the times of onset of lorazepam 4 mg and diazepam 10 mg in the treatment of SE in adults were similar (144). In that double-blind study, SE was controlled in 89% of episodes with lorazepam versus 76% with diazepam, with similar rates of adverse events (144). Because of a smaller volume of distribution, lorazepam should have a longer anticonvulsant activity and, thus, a lower rate of seizure recurrence than diazepam (145,146). In a recently completed prospective randomized multicenter trial, lorazepam 0.1 mg/kg IV and diazepam 0.2 mg/kg IV were equally effective in terminating convulsive SE in children (3 months to younger than 18 years) in the emergency department. Interestingly, at these doses, there were no differences in the rate of recurrence up to 4 hours (147).

Midazolam, due to its water solubility, may be administered intranasally or intramuscularly if there is no IV access, and it has been associated with less sedation and respiratory depression (148).

The efficacy of intramuscular midazolam in the out-of-hospital treatment of convulsive SE in children and adults was prospectively compared to intravenous lorazepam in the double-blind, randomized RAMPART trial (149). Upon emergency department arrival, seizures had stopped in 73.4% of the subjects in the midazolam group and 63.4% in the lorazepam group. Seizure recurrence was low in both groups, and there was no difference in adverse events. Although designed as a noninferiority study, the results do support statistical superiority of intramuscular midazolam in the prehospital treatment of convulsive SE.

Phenytoin may be administered by an IV loading dose in normal saline (it precipitates with dextrose) at 20 mg/kg (15 mg/kg in the elderly), which rapidly achieves a therapeutic level without respiratory depression or sedation and can also provide maintenance therapy (150–152). This lack of sedation is important for monitoring mental status, such as in patients with head trauma. The infusion rate should be no faster than 1 mg/kg/min in a child (not to exceed 25 mg/minute), 50 mg/minute in an adult, and 20 mg/minute in the elderly. Pulse and blood pressure should be monitored. If hypotension develops, the infusion rate should be decreased. In adults, a therapeutic level should be maintained for up to 24 hours after a loading dose has been administered (153), but may not last as long in children (153). A level obtained 2 hours after loading may help guide the timing of maintenance therapy with phenytoin (153).

IV phenytoin has an alkaline pH and contains solvents that can cause vascular irritation, cardiac depression, and hypotension. The purple glove syndrome, consisting of distal limb edema, discoloration, and pain, may occur following IV phenytoin infiltration; treatment may require fasciotomies and amputation. In one series, purple glove syndrome occurred in nine of 152 patients (154); in a prospective series, it occurred in only three of 179 patients (155). The syndrome has also been reported following oral dosing in a child (156).

The phosphate ester prodrug of phenytoin, fosphenytoin, is dosed as phenytoin equivalents (PE) at 20 mg PE/kg. It can be administered in a dextrose solution. Fosphenytoin is water soluble and may be given by the IM route, with paresthesias and injection site pruritus as possible adverse effects. Bioavailability is 100% compared to phenytoin, and the conversion half-life is 7 to 15 minutes (157). Fosphenytoin is rapidly converted to phenytoin by serum and tissue alkaline phosphatases (158). It may be difficult to maintain therapeutic levels in infants, and additional doses may be required (159); subtherapeutic free phenytoin levels also occur in older children (160). A 2-hour phenytoin level is suggested to ensure conversion (160). Side effects are more likely in patients with hypoalbuminemia, renal failure, or hepatic failure and in the elderly, because of the presence of higher free phenytoin levels. In these patients, the infusion rate should be decreased by 25% to 50% (157). The only advantage of IV phenytoin over IV fosphenytoin is significantly lower cost.

Phenobarbital has been used to treat SE in all age groups. Respiratory depression and sedation occur. Caution is advised, especially when phenobarbital is administered in combination with other sedative AEDs (such as benzodiazepines). In a randomized trial of diazepam and phenytoin versus phenobarbital (10 mg/kg IV), phenobarbital resulted in a shorter median seizure time (5 minutes vs. 9 minutes) and response latency (5.5 minutes vs. 15 minutes), with a similar incidence of intubation, hypotension, and arrhythmia (161). The loading dose for phenobarbital is 15 to 20 mg/kg, administered at a rate no higher than 100 mg/minute in older children and adults and 20 mg/kg in neonates and infants (160).

The landmark VA Cooperative Study (26) compared the efficacy of various first-line agents—lorazepam (0.1 mg/kg), phenobarbital (15 mg/kg), diazepam (0.15 mg/kg) plus phenytoin (18 mg/kg), and phenytoin alone (18 mg/kg)—in the treatment of SE with successful treatment defined as control

of the seizure within 20 minutes (27). Treatment efficacy of overt generalized convulsive SE was similar with lorazepam (65%), phenobarbital (58%), and diazepam plus phenytoin (56%), whereas phenytoin alone was associated with lower efficacy (44%). This result may be related to a 4.7-minute infusion time with lorazepam versus 33 minutes with phenytoin alone.

Second-Line Agents for Status Epilepticus

Sodium valproate (VPA) has been available in IV form since 1995 (Depacon, Abbott Laboratories, North Chicago, IL) (162). Although it is not yet approved by the U.S. Food and Drug Administration (US FDA) for the treatment of SE, doses of 15 to 33 mg/kg have been administered safely in adults (163–172) at a rate of 20 to 50 mg/minute (164). In a review of 13 elderly patients with SE and hypotension, a mean loading dose of 25 mg/kg at 35 mg/minute was associated with no change in blood pressure (165). In one study, an infusion rate of 3 mg/kg/min was associated with hypotension in 2 of 72 patients (168).

One study has suggested that VPA may be an appropriate first-line medication under narrow conditions (173). Two studies have evaluated IV phenytoin versus IV VPA as first-line therapy for SE. The first used IV VPA 30 mg/kg over 15 minutes or IV PHT 18 mg/kg at a rate of 50 mg/minute; if SE continued, the other AED was used (174). Used as initial therapy, SE was controlled in 66% with VPA versus 42% with PHT; in the refractory patients, VPA was effective in 79% versus 25% with PHT. The side effects were similar. In the second study (175), there was equal efficacy (88% for both) with side effects of 12% with PHT versus none with VPA. In diazepam-resistant SE, 31/41 (76%) episodes of SE were controlled with a VPA 25 mg/kg loading dose over 30 minutes. The probability of successful treatment with VPA was time-dependent: if the VPA was given early (within 3 hours), next-line therapy with anesthesia was required in only 5%, but when VPA was given later, anesthesia was needed in 60% (176).

In children, loading doses of 10 to 30 mg/kg have been used, with most using the higher-dose ranges; an infusion rate of 1 mg/kg/h was not associated with serious side effects (169). A 20-mg/kg loading dose should produce a serum level of 75 mg/L (170). Valproate is safe in adults and children (163,168,172). One study reported on 48 IV VPA doses, mean 22 mg/kg (range 7.5 to 41.5 mg/kg) with a mean infusion rate of 5 mg/minute, with only 1 adverse event, burning at the infusion site (177). Hypotension occurred in one child at an infusion rate of 30 mg/kg/h (0.5 mg/kg/min) (171). A loading dose of 10 to 25 mg/kg over 30 minutes has been used in neonates (178).

Levetiracetam (LEV) is available in an IV preparation and has been used to control SE (179,180), typically as second-line therapy. A recent retrospective multicenter observational study identified that this agent was not uncommonly used following benzodiazepine failure (181). The pharmacokinetic profile is similar for IV and oral LEV with no difference following an oral or IV dose of 500 to 1500 mg in adults (182). LEV levels peak within 2 hours, a steady state is achieved within 2 days, and there are no significant drug interactions (183). IV LEV with a mean loading dose of 944 mg (range 250 to 1500 mg) controlled 16/18 episodes of SE following benzodiazepine failure (184). A 20 mg/kg loading dose followed by 15 mg/kg BID after 6 hours controlled SE in 82% overall and in 11/12 (92%) as first-line therapy (185). 2/50 (4%) developed thrombocytopenia. In a study comparing the effectiveness of PHT, VPA, and LEV following benzodiazepine failure, LEV 20 mg/kg was found to fail more often than VPA 20 mg/kg. In that study, LEV accounted for approximately 17% of second-line treatment failures (186). In nine children with acute seizure exacerbations or refractory SE, a loading dose of 10 to 30 mg/kg was given over 30 minutes, with a mean dose of 228 mg/kg/d.

One child had an increase of seizures, and no agitation or behavioral problems occurred (187).

Lacosamide, which enhances the slow inactivation of voltage-gated sodium channels, was approved by the U.S. FDA in 2008 for adjunctive therapy for focal-onset seizures in patients 17 years of age and older. However, as it is available in an intravenous formulation, it is not surprising that it has been used for the treatment of SE with some success in both adults and children (188–192). A loading dose of 400 mg appears to be more effective than 200 mg in the treatment of refractory seizure clusters and SE (193). In a more recent retrospective study, lacosamide (median bolus dose of 400 mg) as a third-line agent administered at a median of 19 hours after SE onset following the failure of a benzodiazepine and LEV successfully terminated the status in 7 of 21 patients (194).

TREATMENT GUIDELINES FOR STATUS EPILEPTICUS

Standard treatment guidelines are needed in advance of all medical emergencies, to improve the quality of emergency care (195,196). The treatment guideline can then be analyzed and modified if the data demonstrate that the protocols are not resulting in improved care (197,198). To this end, there are a few randomized clinical trials, the EFA Working Group timetable (4), treatment surveys (199), and various societies' treatment guidelines, that can assist in this process (200,201). A survey of the UK Intensive Care Society revealed that only 12% of the respondents used a specific protocol (202) and that first-line therapy was frequently with a benzodiazepine plus phenytoin. In a US survey of neurologists and intensivists (N = 106), 76% used lorazepam first, with 95% using phenobarbital or phenytoin if lorazepam failed (203). A survey of epileptologists was conducted to establish consensus guidelines for first-line, second-line, and third-line treatment options for epilepsy syndromes (204). A treatment of choice was determined if selected by >50% of respondents. Lorazepam was considered the treatment of choice for generalized convulsive, focal, and absence SE, with diazepam or phenytoin considered first-line treatment for generalized convulsive SE and focal SE; diazepam and sodium valproate were considered first-line treatment for absence epilepsy (204).

Prior to the VA Cooperative Study, the EFA Working Group suggested either lorazepam or diazepam as first-line therapy, but now, lorazepam is initially used by many (2,203,204). European guidelines have used either lorazepam or diazepam for first-line therapy. Most guidelines still use either phenytoin or phenobarbital if a benzodiazepine fails, but there is increasing use of either VPA or LEV. We use 0.1 mg/kg lorazepam initially for children, at a maximum dose of 4 mg when IV access is available; if IV access is not available, diazepam or lorazepam can be administered rectally or fosphenytoin or midazolam via the IM route. However, although there are theoretical reasons to support the use of lorazepam over diazepam (as discussed above), a review of randomized clinical trials in children found no evidence that treatment with IV lorazepam was better than treatment with diazepam (205), which is further supported by the results of a prospective, randomized clinical trial comparing lorazepam to diazepam in the treatment of pediatric SE (147).

The Neurocritical Care Society guideline for the evaluation and management of SE states that definitive control of SE should be obtained within 60 minutes of onset. Treatment occurs in stages, first line through fourth or fifth line. This guideline suggested the use of emergent initial therapy (first line), urgent control therapy (second line), and refractory therapy (third through fifth line) in order to emphasize the need for the emergent control of SE (201).

Treatment of Refractory Status Epilepticus

Refractory SE occurs when seizures persist despite adequate treatment with a first- and second-line agent (201). The mortality in adults with refractory SE varies from 39% to 48% (206) and in children, from 16% to 43.5% (66,207,208). Etiology is a very important determinant, with a higher mortality among acute symptomatic patients (17,34,66,78,80). In children, the data also demonstrate that etiology is related to prognosis (66).

If convulsive activity has stopped but mental status does not improve, NCSE must be excluded, which occurs in 14% of adults (130) and 25% of children (131), and in 8% of those with unexplained coma (101). An immediate EEG is performed, if available; if not available, additional empiric AED therapy must be considered.

If SE persists following the use of the second conventional AED, then continuous intravenous infusion AEDs should be administered (Table 38.7). The treatment goal is to stop SE immediately and to prevent seizure recurrence. However, it is important to recognize that continuous infusion AEDs have been linked with several untoward effects including mechanical ventilation, hypotension, and infection as well as potentially increasing the risk of death (76,209–212).

Table 38.7 Agents Used in Refractory Status Epilepticus

Intravenous:
Pentobarbital
Midazolam
Thiopental
Propofol
Phenobarbital
Diazepam
Lorazepam
Ketamine
Lidocaine
Chlormethiazole
Etomidate
Magnesium (especially for eclampsia)
Rectal:
Paraldehyde
Chloral hydrate
Others:
Hypothermia, with pentobarbital
Inhalational agents, especially isoflurane
Vagal nerve stimulation (VNS)
Ketogenic diet

Pentobarbital has been the most widely used agent under these circumstances (213–220), administered at 2 to 10 mg/kg followed by a continuous infusion. Midazolam has a shorter half-life and is associated with less sedation (148,221–226). Adults with RSE with maximum midazolam infusion rates of approximately 3 mg/kg/h were found to have less withdrawal seizures and potentially lower risk of mortality at discharge compared to those in which the maximum infusion rate was lower at 0.4 mg/kg/h (227). High-dose phenobarbital is also used; it is associated with less cardiovascular depression than pentobarbital (228,229) but has a longer half-life.

Other agents used include benzodiazepines (230,231), thiopental (232), lidocaine (233–235), inhalational anesthetics such as isoflurane (Forane, Baxter Pharmaceuticals, Deerfield, IL)

(235–237), and propofol (238,239). Propofol has two main advantages: a rapid onset and a short duration of action. One study with pentobarbital and propofol in adults showed equal efficacy, but propofol controlled SE in 2.6 minutes versus 123 minutes with pentobarbital (238). Another study in children with RSE reported an efficacy of 64% with propofol versus 55% with thiopental, and no side effects with propofol, with infusion rates <5 mg/kg/h (240,241). Propofol may cause metabolic acidosis with prolonged use in children (242,243). In adults, deaths have occurred with high propofol infusion rates (244), which is known as propofol infusion syndrome (245). Even in an adult study that showed equal efficacy for seizure control, a 57% mortality rate was reported with propofol versus only 17% with midazolam (221). Therefore, propofol should be used with caution, especially in children and ideally for a short time only, and the infusion rate should not exceed 67 μg/kg/min (246). Immediate control can be achieved and then another agent used if long-term suppression is needed.

The N-methyl-D-aspartate receptor antagonist ketamine may also have a role in the treatment of RSE (247–252). A recent multicenter retrospective review of 58 subjects from 10 academic medical centers treated with ketamine found that ketamine was potentially successful in up to a third of the episodes of SE. Ketamine was not successful when used after a failure of seven or more drugs or when introduced at least 8 days after SE onset. In those in which ketamine was deemed to contribute to the control of SE, the dosing was >0.9 mg/kg/h. Overall, ketamine was found to be well tolerated with many of the untoward effects that occurred during the ketamine dosing being attributed to the concurrent medications (253).

Chlormethiazole (254), etomidate (255), and clonazepam (256) are used in Europe; paraldehyde (257) and chloral hydrate (258) may be administered rectally, although paraldehyde is no longer available in the United States. Hypothermia (259–261), vagal nerve stimulation (262), and surgery (263) have also been used. The ketogenic diet may also have a role, especially in children diagnosed with febrile infection–related epilepsy syndrome (264–266).

To date, no prospective study has been conducted in patients with refractory SE. In a systematic review of refractory SE treatment with pentobarbital, propofol, or midazolam (267), pentobarbital was associated with better seizure control than the other two agents. In the UK survey (N = 408), if first-line treatment failed, 142 (35%) of the respondents used a benzodiazepine infusion and 130 (32%) used a general anesthetic. If seizures continued, 333 (82%) used thiopentone and 56 (14%) used propofol (202). Based on the consensus guidelines, the drug of choice for "therapeutic coma" in patients with generalized convulsive SE and focal SE was pentobarbital, and first-line agents were midazolam and propofol; for absence seizures, pentobarbital was the drug of choice, with no other first-line options, and midazolam was considered second-line therapy (204). In the US survey, when generalized convulsive SE was refractory to two AEDs, 43% of respondents used phenobarbital, 16% used valproate, and 19% gave one of three agents (pentobarbital, midazolam, or propofol) by continuous infusion (203).

Whether clinical seizures alone or both clinical and electrographic seizures need complete control is controversial (201,268,269). In this situation, many clinicians use continuous infusion AEDs titrated to a burst suppression pattern on EEG, aiming for complete control of both the clinical and electrographic seizures. Some aim only for control of clinical seizures (without EEG monitoring). In the US survey, the titration goal with a continuous infusion was burst suppression in 56% of respondents versus elimination of seizures in 41% (203), whereas in a European survey, up to 70% titrated the EEG to a burst suppression pattern (270). However, the outcome is not related to the extent of EEG burst suppression and is more dependent on etiology (271).

Even if a burst suppression pattern is the goal, the degree of suppression needed is unclear. We

have used a burst suppression pattern as the clinical end point, aiming for an interburst interval of at least 5 seconds in duration (66,272). In an analysis of the depth of EEG suppression with barbiturate anesthetics (pentobarbital or thiopental) in adults, persistent seizure control was better with electrocerebral inactivity on EEG (17 of 20) versus a burst suppression pattern (6 of 12 patients) (273,274). Using a midazolam infusion to eliminate all clinical and electrographic seizures and reaching burst suppression only if needed, acute treatment failure occurred in 18% of episodes, breakthrough seizures in 56%, posttreatment seizures in 68%, and treatment failure in 18% (225). In the systematic review, breakthrough seizures occurred less frequently with titration to EEG background suppression (53%) versus titration to seizure suppression only (4%). However, hypotension occurred more often with titration to background suppression (267).

Prolonged continuous infusion AEDs can be used (66,275), usually with various AED combinations. A continuous infusion AED is used initially for a short time (12 to 24 hours); the infusion is then tapered, and if SE recurs, the sequence restarts (55,66,272). Mirski et al. (276) recommended prolonged therapy with a potentially good prognosis: a healthy patient (no premorbid illness), a self-limited disease, and with neuroimaging not indicating a poor prognosis. Bramstedt et al. (277) recommended ethically withholding suppressive therapy if only expected to sustain organic life. We have treated children for prolonged periods of up to 146 days (66,275), and a 26-year-old with encephalitis was treated for 11 months (278). In our experience with children, no survivor of acute symptomatic refractory SE (n = 7) returned to baseline, and all subsequently developed refractory epilepsy; seizure recurrence was reported upon drug tapering in two children and within 1 to 16 months in the other five (225). In our entire group with refractory SE, 32% returned to baseline (66), and in the adult systematic review, only 29% (48 of 164 patients) returned to baseline (267).

Infectious or inflammatory disorders may predispose to refractory SE. In one series, 7/22 had "presumed encephalitis" (66,275). Kramer also reported severe RSE from "presumed encephalitis" (279). Holtkamp reported encephalitis as a predictor for RSE (280) and referred to this as a "malignant variant" (281). Wilder-Smith defined the syndrome of new-onset refractory status epilepticus (282). Characteristic features include female gender, young age, previous good health, CSF pleocytosis, antecedent febrile illness, and prolonged treatment. We reported complete seizure control during suppression in 5/7 in this group, with then a seizure recurrence and the development of refractory epilepsy ranging from 1 to 16 months later (275). The occurrence of this latent period raises the question if neuroprotective, antiepileptic, or even immunomodulatory agents might be helpful in this situation. Although the RSE that accompanies so-called febrile infection–related epilepsy syndrome (FIRES) has been attributed to acute neuroinflammation (283,284), the absence of a latent period has led others to hypothesis that FIRES is best conceptualized as chronic neocortical epilepsy with explosive onset (285).

Several specific repetitive disorders have been reported in SE: Stimulus-induced rhythmic, periodic, or ictal discharges (286) and cycling seizures (287) have been reported. Acute encephalitis with refractory, repetitive partial seizures has been described in children with encephalitis (288,289). These have an abrupt onset in the setting of a fever following an antecedent infection; are brief, focal seizures; occur with an escalating frequency; and are resistant to standard anticonvulsants and require high-dose suppressive therapy for control.

Prehospital Treatment

The advent of intrarectally administered AEDS permits the premonitory or early stage to be treated

prior to hospital arrival (290–292), although other routes of administration are also used. The prospective San Francisco Prehospital Treatment study (N = 205) found that lorazepam was potentially more effective than was diazepam in terminating SE out of hospital (59% response with lorazepam vs. 43% response with diazepam and 21% response with placebo; P = 0.001) (27). In a retrospective study of 38 children with generalized convulsive SE, use of prehospital diazepam (0.6 mg/kg rectally) was associated with a shorter seizure duration (32 minutes vs. 60 minutes) and a reduced likelihood of seizure recurrence in the emergency department (58% vs. 85%), with no difference with respect to intubation (293). Rectal diazepam can be administered at home for the treatment of SE or serial seizures; the maximum dose is 20 mg. A rectal gel preparation, Diastat (Xcel Pharmaceuticals, San Diego, CA), is available, which is easier to administer (294–296). Although only approved by the US FDA for the treatment of selected, refractory, patients on stable regimens of AEDs for the treatment of seizure exacerbation, Diastat is used as a therapeutic remedy for SE at home; IV benzodiazepines are still preferable for the treatment of inpatients. Lorazepam can be administered sublingually (297), and midazolam can be given by intranasal or buccal mucosa routes (298), with rapid buccal absorption documented by serum levels and EEG beta activity (299). The efficacy of intranasal midazolam (0.2 mg/kg) is equivalent to that of IV diazepam (0.3 mg/kg) for the treatment of prolonged febrile seizures (300), and buccal midazolam (10 mg) and rectal diazepam (10 mg) have shown equal efficacy for seizures >5 minutes (298). As previously noted, the RAMPART study demonstrated the utility of intramuscular midazolam in the prehospital treatment of convulsive SE (149). Paraldehyde is included in a UK pediatric treatment protocol (196), but as previously noted, it is no longer available in the United States.

Emergency Department or Inpatient Treatment

Lorazepam 0.1 mg/kg should be administered initially. A suggested treatment sequence follows, as outlined in Table 38.8 (301–303).

Table 38.8 A Suggested Timetable for the Treatment of Status Epilepticus

Time (min)	Action	
0–5	Diagnose status epilepticus by observing continuing seizure activity (time = 0) Give oxygen by nasal cannula or mask; position head for optimal airway patency Obtain vital signs and pulse oximetry Establish IV line; draw venous blood samples for glucose level, serum chemistries, hematology studies, toxicology screens, and AED levels (if applicable) If hypoglycemia is established, or blood glucose measurement not available, administer glucose; in adults, give thiamine first (100 mg), followed by 50 mL of 50% glucose by direct push into IV line; in children, give 2 mL/kg of 25% glucose	
5	If seizure continues, give lorazepam 0.1 mg/kg, at 2 mg/min	
10–20	If seizure continues, give fosphenytoin 20 mg PE/kg, or if not available, phenytoin 20 mg/kg (in children, give a second dose of lorazepam 0.1 mg/kg, before giving fosphenytoin or phenytoin)	
20	Give phenobarbital 20 mg/kg	
30	Give additional fosphenytoin 10 mg PE/kg	
40	IV valproate 40 mg/kg	
40–60[a]	Continuous intravenous infusion AEDs (intravenous anesthesia):	Pentobarbital 5–15 mg/kg loading dose Midazolam 0.2 mg/kg loading dose Propofol 1–2 mg/kg loading dose Thiopental 5 mg/kg All followed by intravenous infusions

[a]May consider the use of continuous intravenous infusion AEDs after failure of the first two AEDs [RSE, Neurocritical Care Society Guideline (201)].

AED, antiepileptic drug.

CHAPTER 39 APPLICATION OF ELECTROENCEPHALOGRAPHY IN THE INTENSIVE CARE SETTING

STEPHEN HANTUS, NICHOLAS S. ABEND, AND DEEPAK LACHHWANI

INTRODUCTION

Convulsive seizures have been described since we have been recording human history (1). The discovery of nonconvulsive seizures in critically ill patients has been a more recent development (1). It has been known that convulsive seizures can lose the convulsive component and degenerate into subtle clinical signs (ictal nystagmus, subtle facial twitches), and the electrical activity of seizure may persist after clinical signs have stopped (2). It has also been appreciated that primary neurologic injuries can result in epileptiform discharges and seizures (2). However, the scope of the problem was not appreciated until the late 1990s and onward when the technology of portable digital video EEG and the development of neurologic specialty ICUs provided the environment that led to the investigations that highlighted the prevalence of nonconvulsive seizures in the critical care setting. In the last 10 years, the interest and volume of ICU EEG studies have increased with the awareness of nonconvulsive seizures. The challenge going forward will be to define the benefits of critical care monitoring and the selective use in high-risk cases. In this chapter, data describing the incidence of seizures, the length of monitoring recommended, preliminary outcome studies, and the current state of practice in ICU EEG monitoring are discussed in the setting of adult and pediatric patients.

CONTINUOUS EEG MONITORING IN ADULT PATIENTS

The use of continuous EEG (cEEG) monitoring in adult patients has increased dramatically with the awareness of nonconvulsive seizures and the high-risk conditions that require close monitoring. One aspect of this awareness is having neurointensivists who specialize in the critical needs of patients with primary neurologic injury. Neuro-ICUs provide a concentrated area of expertise, and EEG equipment can be focused on these high-risk patients (1). Patients in the medical ICU, in the surgical ICU, and located throughout the hospital can also be at risk and have been studied in the use of ICU EEG. The coordination of the epileptologist with the neurointensivist provides an effective partnership in treating patients at risk for nonconvulsive seizures. The role of ICU EEG has primarily been to detect subclinical seizures, but the detections of nonepileptic spells (myoclonic jerks, posturing, subtle twitching), monitoring the level of sedation, detecting ischemia in the setting of vasospasm, and developing a prognosis have all been described.

EEG Seizure Epidemiology

A number of studies have attempted to estimate the incidence of nonconvulsive seizures in patients presenting to the hospital. However, these studies are biased to some degree resulting in a range of incidence from 8% to 37% of patients with altered mental status in the hospital have EEG seizures recorded. Initial studies were conducted with patients presenting for emergency EEG, and thus the population was selected to include the patients that clinicians felt were likely having seizures. Privitera et al. (3) studied 198 patients prospectively with altered mental status presenting for emergency EEG and found that 74 (37%) were having seizures. A study by Towne et al. (4) examined 236 patients who presented to the ICU in coma, but without a clinical signs or suspicion of seizure. In this sample, 19 patients (8%) had EEG changes consistent with nonconvulsive status epilepticus. In a large retrospective series, Claassen et al. (5) reviewed 570 patients with unexplained altered mental status and found 110 patients (19%) were having electrographic seizures. Thus, in multiple institutions with different patient populations and different study designs, the consistent result has been that a significant portion of patients (approximately 20%) evaluated in the critical care setting with altered mental status have electrographic seizures recorded, most without clinical signs.

Certain etiologies of altered mental status in the critical care setting have been shown to have particular risk for nonconvulsive seizures. By identifying patients at highest risk for seizures, they can be targeted for early EEG monitoring and resources directed away from lower-risk patients. Patients with intracranial hemorrhage (ICH), ischemic stroke, traumatic brain injury (TBI), anoxic brain injury, central nervous system (CNS) infections, and subarachnoid hemorrhage (SAH) are particularly at risk (Fig. 39.1).

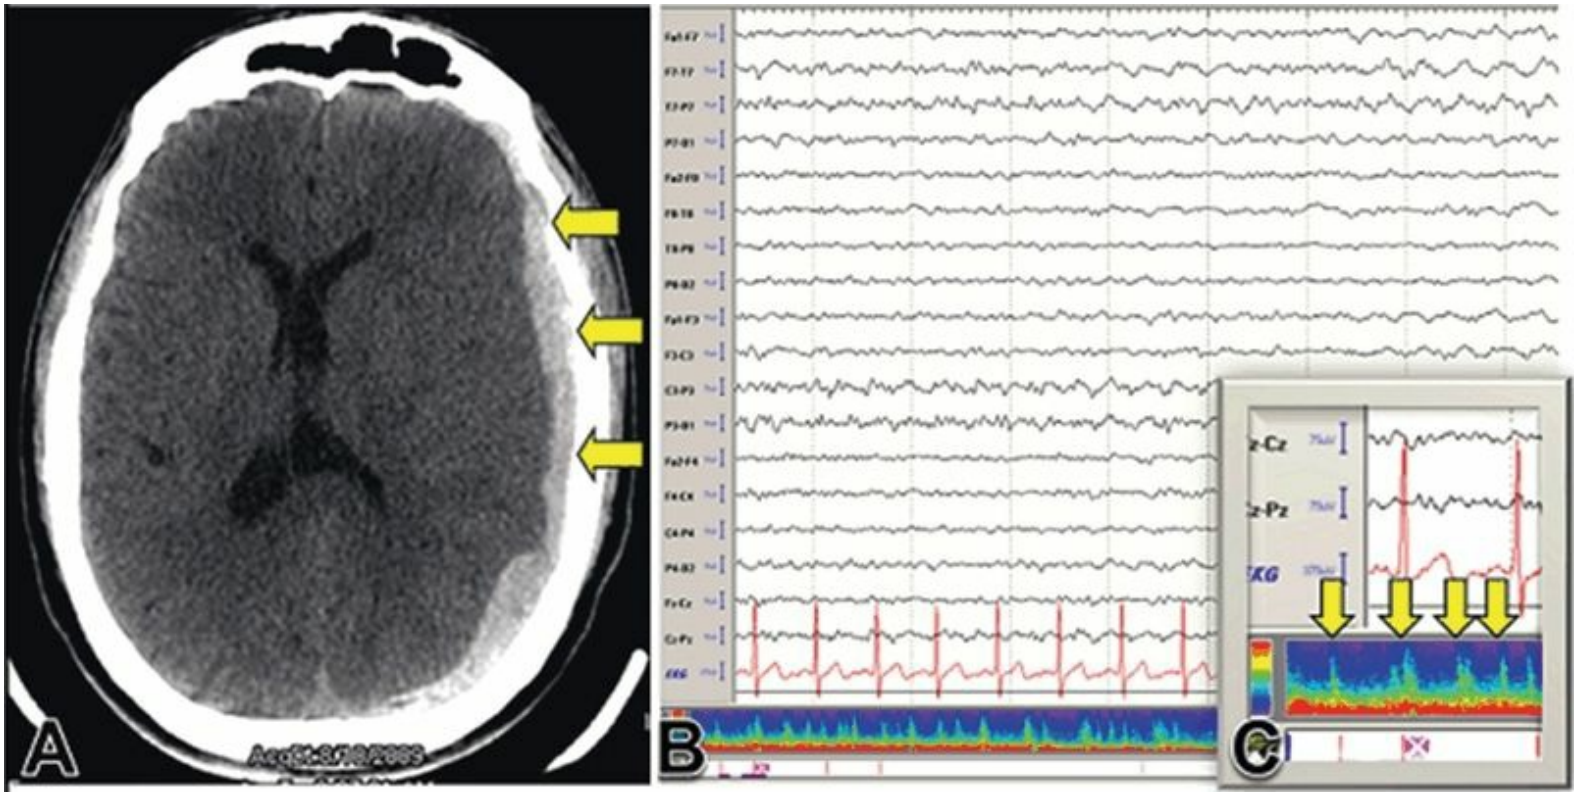

Figure 39.1. A: Patient who presented with altered mental status and headache with a CT brain showing a left hemisphere subdural hematoma with midline shift (arrows). **B:**EEG of this patient showing left hemisphere seizure pattern that is slowly evolving in frequency. **C:**Expansion of the DSA trend analysis showing multiple seizures in the record (arrows).

Intracranial Hemorrhage

In a study by Claassen et al. (6), 102 patients with ICH were recorded on cEEG and 18% were found to be having electrographic seizures and 31% were associated with seizures in some form at presentation (19 had clinical seizures prior to cEEG recording). Seizures in this series were more likely to be recorded with hemorrhages that expanded by 30% or more and with cortical bleeds. A study by Vespa et al. (7) studied 63 patients with ICH and found 18 (28%) with seizures on cEEG monitoring. Seizures were recorded most often in lobar hemorrhages, but were found in 21% of subcortical hemorrhages as well.

Ischemic Stroke

A series of 177 patients with acute ischemic stroke were described by Mecarelli et al. (8) with 15 patients (6.5%) having seizures on EEG monitoring. It was also noted that periodic lateralized epileptiform discharges were recorded in 6% of patients with stroke, and this subset of patients had a 71% incidence of seizures. In the series by Claassen et al. (5), 6 patients of the 56 with ischemic strokes (11%) had seizures recorded on cEEG monitoring. The rate of seizures detected in acute ischemic stroke has been consistently less than ICH and TBI; however, the rates of chronic epilepsy after the acute symptomatic seizures will require future studies.

Traumatic Brain Injury

Acute TBI has been associated with EEG seizure activity that often occurs in the first 14 days after injury. A study by Vespa et al. (9) described 94 patients with TBI who underwent cEEG monitoring, and 21 patients (22%) had electrographic seizures. Another series of 70 patients with TBI found 23 patients (33%) with electrographic seizures recorded on cEEG monitoring. The seizures in these series were often not adequately treated with “prophylactic” doses of phenytoin and required cEEG for diagnosis as well as management of ongoing seizure treatments.

Anoxic Brain Injury

The detection of seizures in the setting of anoxic brain injury has been described in multiple series and often carries a grim prognosis. The use of therapeutic hypothermia has changed the use of cEEG for prognosis (10). A study looking at 101 patients with anoxic injury after cardiac arrest found 12 patients (12%) to have nonconvulsive status epilepticus. The majority of these patients had EEG recorded in the first 8 hours of monitoring (with 12 hours of the cardiac arrest). The outcome in this study was dismal with only one of the patients with EEG seizures survived to a vegetative state. The background reactivity of cEEG recordings to painful stimulation has been reported to have strong predictive value of prognosis after anoxic injury (11). In a study of 34 patients with anoxic brain injury, 7 patients (20%) had EEG seizures recorded. Among the nonsurvivors of the cohort, 75% had nonreactive background to stimulation, 73% had prolonged discontinuous activity (burst suppression), and 47% had seizures. The survivors in the cohort all had reactive backgrounds and did not have EEG seizure activity. The background reactivity changes seen in this study were noted during therapeutic hypothermia. A study of 95 patients with anoxic injury found 26 patients (27%) with EEG seizures. They also described two seizures patterns, one arising from burst suppression and one arising from a cEEG background (12). Seizures were still associated with a dismal prognosis

with mortalities around 100% in most studies, but 2 (out of 10) patients who had seizures arising from a cEEG pattern regained consciousness.

CNS Infections/Inflammation

Encephalitis or meningoencephalitis is a risk factor for seizures and has been reported to be associated with EEG seizures in 6% to 29% of patients (5,13). In a study of patients with bacterial meningitis, seizures occurred in 121 of 696 patients (17%). The patients with seizures had worse outcomes (41% mortality) than patients without seizures (16% mortality). Viral encephalitis has also been shown to have risk of EEG seizures with 5% of all seizures being attributed to suspected viral encephalitis in one study (14). Autoimmune encephalitis is becoming increasingly recognized as an etiologic agent in critical care status epilepticus. Some of these patients have a paraneoplastic disorder with antibodies against an occult tumor, but many have autoantibodies without an obvious source. Patients often present with refractory status epilepticus that does not respond to traditional antiseizure medications and requires aggressive immunotherapy. There is also evidence that some patients with infectious viral encephalitis (herpes encephalitis) can develop autoantibodies that then contribute to the generation of seizures and neurologic deterioration (15,16). There has also been a typical EEG pattern often present on the initial EEG of some patients with anti-NMDA receptor encephalitis. This pattern, the so-called delta brush, which is characterized by high-amplitude delta waves and overlying fast activity, may be helpful for identifying these patients and guiding therapy (17).

Subarachnoid Hemorrhage

EEG seizures have been reported in 3% to 26% of comatose patients with SAH. Claassen et al. (18) studied 247 patients with SAH and found EEG seizures in 17 patients (7%). SAHs with associated subdural hemorrhage or cerebral infarction were predictive of patients with seizures. Patients with seizures reported poorer quality of life and experience prolonged recovery times. Another study examined 389 patients with SAH and found 11 patients with nonconvulsive status epilepticus (3%). Patients with poor neurologic grade and associated structural lesions (intracerebral hemorrhage and stroke) were more likely to have seizures (19). In addition to being at risk for EEG seizures, patients with SAH are at risk for delayed cerebral ischemia (DCI). DCI may result in stroke and cause a clinical deficit, but in poor-grade SAH, there is often no neurologic exam to follow (patients are often comatose). Quantitative EEG trend monitoring of cEEG recording has been shown to detect DCI prior to cerebral infarction and in time for intervention. Claassen et al. (20) examined 34 patients with SAH and identified 9 patients with DCI. For patients who experienced DCI, the alpha–delta ratio was significantly decreased (24%) compared to an increase (3%) in the alpha–delta ratio for those patients without DCI. In a study from Montreal, 13 patients were studied with quantitative EEG and 8 patients were determined to have DCI. DCI was predicted by using a quantitative EEG method termed the composite alpha index (CAI). In 3 of the 8 patients, changes in the CAI predicted the changes of DCI 24 hours prior to clinical change (21). cEEG has also been used to develop prognosis in poor-grade SAH. When 116 patients were followed for functional outcome, predictors of poor outcome were periodic epileptiform discharges, electrographic status epilepticus, and the absence of sleep architecture (22).

EEG Monitoring Duration

Determining the length of cEEG monitoring in adult patients admitted to the neuro-ICU with altered mental status is complex and can vary based on etiology, EEG findings, and the degree of altered mental status. If time to first seizure is examined, then a 40% yield of seizures is found at 20 minutes, 50% yield at 1 hour, and 80% to 90% yield at 24 hours for most patients (5). Thus, a minimum recording time of cEEG monitoring for a patient with altered mental status in the critical care setting is 24 hours; however, some situations may require additional monitoring. Patients who have periodic lateralizing epileptiform discharges (PLEDs) have been shown to have a delayed detection of seizure onset that requires 48 hours of monitoring (5). Patients with PLEDs also have a 50% to 70% chance of having seizures recorded sometimes during the record demonstrating the importance of monitoring this population on cEEG monitoring (23,24). Comatose state has also been associated with a prolonged need for monitoring, and 48 hours has been suggested as a minimum time of recording (5). In patients with intracerebral hemorrhage, EEG seizures were detected in 56% in the first hour and 94% by 48 hours, suggesting prolonged monitoring may also be useful in this population (6). Monitoring patients for DCI after SAH typically requires up to 7 to 10 days of monitoring depending on the patient's clinical course (20,21). Finally, patients with EEG seizures in the record require additional monitoring. In patients who do not present with clinical signs, video EEG is necessary to make the diagnosis, and once the nonconvulsive seizures have been treated, an additional 48 hours of continuous monitoring is common practice, but may vary based on the clinical needs.

EEG Seizures and Outcome

The use of cEEG in the critical care setting has dramatically increased the number of patients diagnosed with seizures in the hospital. Unfortunately, there is not a wealth of outcome data to guide treatment of these seizures and to understand their significance. Outcome studies have shown that patients with an acute neurologic injury (stroke, hemorrhage) with seizures have a worse functional outcome than patients with the same primary neurologic injury without seizures. Such findings may suggest that the seizures may contribute to the extent of injury. Research addressing the effect of treating these acute symptomatic seizures on functional outcome is required. The majority of outcome studies that have been done to date have focused on anoxic brain injury (11,12). From these studies, it is clear that EEG seizures in the setting of anoxia are a negative prognostic sign and are typically associated with a 90% to 100% mortality. Treatment of EEG seizures in anoxic brain injury has not been shown to improve outcome. The use of cEEG to demonstrate reactive background during therapeutic hypothermia has been shown to predict outcome (12). Future studies will need to address the effect of treating nonconvulsive seizures in other etiologies and the factors that predict the development of chronic epilepsy after nonconvulsive seizures are recorded in the setting of an acute neurologic injury.

Current Practice and Guidelines

The use of cEEG has rapidly increased in the past decade. Patients with altered mental status and/or acute neurologic injury are at risk for nonconvulsive seizures and are candidates for monitoring. The number of patients that meet these criteria is often daunting, and a conservation of resources is needed. Focusing on the high-risk etiologies (presented above) and the patients with the most profound altered mental status is a good practice to utilize equipment in the high-yield patients. There

is a consensus statement that was published by the neurointensive care section of the European Society of Intensive Care Medicine (25). Their conclusions were to use EEG monitoring in convulsive status epilepticus and to rule out nonconvulsive status epilepticus in brain-injured patients and in comatose ICU patients without primary brain injury who have unexplained and persistent alerted consciousness.

CONTINUOUS EEG MONITORING IN PEDIATRIC PATIENTS

cEEG monitoring in critically ill children is generally performed in multidisciplinary pediatric and neonatal ICUs. There are few designated pediatric or neonatal neuro-ICUs, so care is generally provided by collaborating intensivists, encephalographers, and intensive care neurology consult teams. Despite the paucity of dedicated pediatric or neonatal neuro-ICUs, judicious use of cEEG has seen a growing footprint in the last 5 years. The pediatric literature is rich with available data highlighting the important role played by cEEG in optimizing neurologic health–related outcome in critically ill neonates and children.

Electrographic Seizure Epidemiology

Observational studies of children undergoing clinically indicated cEEG in pediatric intensive care units have reported electrographic seizures in 10% to 40% of children, and about one-third of children with electrographic seizures have a sufficiently high seizure burden to be categorized as electrographic status epilepticus (26–38). Indications for cEEG differ across studies, but most included a primary indication related to "acute ongoing encephalopathy." The largest study of cEEG in critically ill children retrospectively enrolled 550 children from 11 tertiary care centers in North America. Electrographic seizures occurred in 30% of 550 children, and in 33% of children with electrographic seizures, the seizure burden was classified as electrographic status epilepticus. Many children with electrographic seizures would not be identified without cEEG. In the multicenter study, 35% of children had exclusively EEG-only seizures (37), and these data are consistent with other single-center studies (26,27,29–31,33–36,39). Several studies have demonstrated that EEG-only seizures occur even in children who have not received any or recent paralytics, indicating there is an ongoing dissociation of electrical brain activity and outward mechanical signs (electromechanical uncoupling) (35,36). Identifying children at higher risk of electrographic seizures is complex since electrographic seizures have been reported in both large heterogeneous cohorts (37) and smaller single brain insult etiology cohorts (28,32–34). However, several risk factors have been reported including infants being at higher risk than older children (29,32,34,35,37), convulsive seizures (30,37,39), or status epilepticus (29) prior to cEEG, the presence of acute structural brain injury (28–30,32–34,39), and the presence of interictal epileptiform discharges (29,33,37,39), or periodic epileptiform discharges (26). Although these risk factors are statistically significant, the absolute difference in seizure risk is often only 10% to 20%, so these risk factors may have limited clinical utility in selecting patients to undergo cEEG.

Critically ill neonates are also at high risk for electrographic seizures (40–43), and about one-third of neonates with electrographic seizures have a sufficiently high seizure burden to be categorized as electrographic status epilepticus (41,43,44). Seizures have been identified as common in some specific cohorts of neonates including 33% to 65% of neonates treated with therapeutic

hypothermia for hypoxic–ischemic encephalopathy (41–43), as well as many neonates with stroke, undergoing extracorporeal membrane oxygenation, with meningoencephalitis, and in the perioperative period of congenital heart disease surgery (40). EEG monitoring is often advocated for neonates at risk for seizures for three main reasons. First, clinical factors and interictal EEG features have a limited ability to predict which neonates will experience seizures during acute hospitalization. Second, about 80% to 90% of electrographic seizures in neonates are EEG-only seizures, particularly after administration of anticonvulsants, which may terminate electroclinical seizures while EEG-only seizures persist (electromechanical uncoupling), and therefore would not be identified even with optimal clinical observation. Third, even experienced bedside caregivers have difficulty distinguishing between electroclinical seizures and nonepileptic movements in critically ill neonates based on clinical observation alone, leading to underdiagnosis of seizures and overdiagnosis of nonepileptic events as seizures. Due to these issues with clinical diagnosis alone, the American Clinical Neurophysiology Society's guideline on neonatal EEG monitoring states that "conventional video-EEG monitoring is the gold standard for neonatal seizure identification and quantification and should be used whenever available for seizure identification and differential diagnosis of abnormal appearing, paroxysmal clinical events. It is the ideal tool to measure the exact number and duration of seizures, their site(s) of onset and spatial patterns of migration (45)."

EEG Monitoring Duration

Decisions regarding the duration of cEEG must balance the physician's interest in identifying seizures with practical concerns regarding the significant resources cEEG requires. A number of observational studies of critically ill children undergoing clinically indicated cEEG have reported that about 50% and 90% of patients with electrographic seizures are identified with 1 hour and 24 to 48 hours of cEEG, respectively (26,27,29,30,33,35,36,39). These data are consistent with current clinical practice. The Neurocritical Care Society's status epilepticus guideline strongly recommends performing 48 hours of cEEG following acute brain insult in comatose patients (46).

In neonates with hypoxic–ischemic encephalopathy (41–43) or cardiac surgery (40), most seizures occur in the initial 48 hours. Few data are available regarding other acute brain insult types. The American Clinical Neurophysiology Society's guideline addressing cEEG in critically ill neonates recommends performing 24 hours of cEEG (45).

There are two important limitations regarding the timing data. First, most of the studies were observational studies in which patients underwent 1 to 3 days of clinically indicated cEEG, so some patients may have experienced seizures after cEEG discontinuation. In specific circumstances, seizures are known to occur later in time, such as following cardiac arrest resuscitation (28) or in neonates with hypoxic–ischemic encephalopathy (15,16). Second, most of these studies used timing at the onset of cEEG and not the onset of the acute brain insult. This makes generalizability to a given patient difficult since patients may present or be transferred at varying times relative to insult onset.

Electrographic Seizures and Outcome

Several studies in critically ill children have reported associations between a high seizure burden and worse clinical outcome after adjustment for potential confounders related to acute encephalopathy etiology and critical illness severity (31,37,47,48). A prospective observational study of 1 to 3 channel EEGs in 204 critically ill neonates and children found that electrographic seizures were

associated with a higher risk of unfavorable neurologic outcome (odds ratio 15.4) in a multivariable analysis that included age, etiology, pediatric index of mortality score, Adelaide coma score, and EEG background category (31). Several other studies aimed to evaluate the effect of seizure burden and classified children as having no seizures, electrographic seizures, or electrographic status epilepticus. A single-center study of 200 children in the pediatric ICU with outcome assessed at discharge identified an association between electrographic status epilepticus (but not electrographic seizures) and higher mortality (odds ratio 5.1) and worsening pediatric cerebral performance category (odds ratio 17.3) in multivariable analyses including seizure category, age, acute neurologic disorder, prior neurodevelopmental status, and EEG background category (47). A larger multicenter study of 550 children in the pediatric ICU reported an association between electrographic status epilepticus (but not electrographic seizures) and mortality (odds ratio 2.4) in a multivariable analysis that included seizure category, acute encephalopathy etiology, and EEG background (37). A single-center prospective study evaluated 259 critically ill infants and children who underwent cEEG. Seizures occurred in 36% of subjects, and these constituted status epilepticus in 9% of subjects. The mean maximum seizure burden per hour was 15.7% in subjects with neurologic decline versus 1.8% in subjects without neurologic decline. In a multivariable analysis that adjusted for diagnosis and illness severity, for every 1% increase in the maximum hourly seizure burden, the odds of neurologic decline increased by 1.13. Seizures were not associated with mortality (38). A study addressing long-term outcome obtained follow-up data at a median of 2.7 years following ICU admission from 60 children who were neurodevelopmentally normal prior to pediatric ICU admission and underwent clinically indicated cEEG. Multivariable analysis including acute neurologic diagnosis category, EEG background category, age, and several other clinical variables identified an association between electrographic status epilepticus (but not electrographic seizures) and unfavorable Glasgow Outcome Scale (Extended Pediatric Version) category (odds ratio 6.36), lower Pediatric Quality of Life Inventory scores (23.07 points lower), and an increased risk of subsequently diagnosed epilepsy (odds ratio 13.3) (48).

In neonates, several studies that have adjusted for the severity of brain injury have reported an association between electrographic seizures or electrographic status epilepticus and worse neurodevelopmental outcomes (49–52). A prospective study of 77 term neonates with hypoxic–ischemic encephalopathy adjusted for initial injury on magnetic resonance imaging (MRI) and still identified an association between seizure category and full-scale intelligence quotients at 4 years (49). A study of 129 neonates with encephalopathy adjusted for the initial degree of clinical encephalopathy and for brain injury severity on MRI and still identified an association between neonatal status epilepticus and an increased risk for subsequent epilepsy (hazard ratio 35.8) (50). A study of 106 neonates utilized multivariable analysis including cerebral ultrasound findings and identified an association between status epilepticus and an increased risk for adverse neurologic outcomes (odds ratio 20.3) and postneonatal epilepsy (odds ratio 6.5) (51). A study of 218 term neonates with neonatal encephalopathy included multivariable analysis including hypothermia group, birth weight, Apgar scores, and encephalopathy grade and identified an association between the absence of amplitude-integrated EEG identified seizures and better 18 month outcome (odds ratio 0.46) (52). A study of 85 term neonates with hypoxic–ischemic encephalopathy managed with therapeutic hypothermia who underwent cEEG or amplitude-integrated EEG and MRI found that on multivariate logistic regression, high seizure burden was independently associated with greater MRI injury (43).

Infants with congenital heart disease have undergone extensive study. In a cohort of 139 children

with D-transposition of the great arteries followed to adolescence, multivariable analysis found postoperative seizures as infants (electroclinical seizures or EEG-only seizures) were the medical variable most consistently associated with worse outcome, including clinically meaningful lower scores on reading and math composites, general memory index, executive function, and visuospatial testing (53). In a second cohort of 132 infants with congenital heart disease followed up at 4 years, a multivariable analysis including clinical and operative factors found that presence of postoperative seizures (which were all EEG-only seizures) was associated with worse executive function and impaired social interactions/restricted behavior (54).

Together, these findings suggest there may be a dose- dependent or threshold effect of seizures upon clinical outcomes, with high seizure burdens having clinically relevant adverse impacts. However, further study is needed to determine whether seizure identification and management improves neurodevelopmental outcomes.

Current Practice and Guidelines

A recent survey of cEEG use in the pediatric intensive care units of 61 large pediatric hospitals in North America reported that the median number of patients who underwent cEEG per month increased about 30% from 2010 to 2011. Indications for cEEG included determining whether events of unclear etiology were seizures in 100% of centers, identifying electrographic seizures in patients considered at risk (altered mental status following a convulsion, altered mental status in a patient with a known acute brain injury, and altered mental status of unknown etiology) in 90% of centers, and using cEEG as a pathway component (i.e., following resuscitation from cardiac arrest or with severe TBI) in 50% of centers (55). An international survey of neurologists and neonatologists reported monitoring of "at-risk" neonates with EEG by 24%, amplitude-integrated EEG in 24%, both in 19%, and none in 34%. Only 8% reported that seizure diagnosis was made by clinical and not EEG or amplitude-integrated EEG criteria (56).

Guidelines related to cEEG are available from the Neurocritical Care Society for children (46) and the American Clinical Neurophysiology Society for neonates (45). Both advocate for the use of cEEG for the identification of electrographic seizures in at-risk patients. The Neurocritical Care Society's status epilepticus guideline identifies at-risk patients as those with persisting altered mental status for more than 10 minutes after convulsive seizures or status epilepticus or encephalopathic children after resuscitation from cardiac arrest, with TBI, with ICH, or with unexplained encephalopathy. The guideline strongly recommends 48 hours of cEEG in comatose patients and that status epilepticus management should continue until all electrographic seizures (not just clinical seizures) are halted (46). The American Clinical Neurophysiology Society's guideline identifies at-risk neonates as those with acute neonatal encephalopathy including hypoxic–ischemic encephalopathy, cardiac or pulmonary risks for brain injury, CNS infections, neurotrauma, inborn errors of metabolism, stroke, or genetic/syndromic diseases at risk for seizures. The guideline recommends cEEG for at least 24 hours (45).

SECTION D DIFFERENTIAL DIAGNOSIS OF EPILEPSY

ASSOCIATE EDITOR: TOBIAS LODDENKEMPER

CHAPTER 40 PSYCHOGENIC NONEPILEPTIC SEIZURES

W. CURT LAFRANCE, JR. AND HAMADA I. HAMID

TERMINOLOGY AND CLASSIFICATION

Psychogenic nonepileptic seizures (PNES) are time-limited, paroxysmal alterations in consciousness, motor activity, sensation, and/or cognition, with psychological underpinnings that are not associated with ictal epileptiform discharges. PNES are commonly seen in emergency rooms and across epilepsy centers and are one of the most common forms of conversion disorder. While neurologists have debated on the name for PNES, past labels, such as "hysterical fits" and "pseudoseizures," are avoided today because of the pejorative connotations of those terms (1). Some neurologists have argued that including the term "seizure" in PNES may confuse patients, families, and other caregivers, and they propose terms such as attacks, spells, episodes, or events (2). However, just as headaches can be qualified as either migraine or tension, "seizure" can be either epileptic or nonepileptic, with diagnoses made using electroencephalogram (EEG), history, and clinical judgment (3).

For some patients, it may take several visits to accept the diagnosis of PNES, especially if they have been under the impression they have had epileptic seizures for many years. Rather than imposing terms such as attacks, spells, and fits, terms that may distance patients and providers, sharing the common language of "seizure" may facilitate communication and meet the patients where they are, conceptually and psychologically. The term "psychogenic" distinguishes events from physiologic nonepileptic causes, such as syncope or alcohol withdrawal seizures, and these are not recurring, unprovoked epileptic seizures. As discussed in this chapter, accepting the diagnosis, the patients' label, as well as ownership of the illness may be important for successful treatment.

The challenge in naming and classifying PNES is not simply a territorial, semantic, or reimbursement issue, but it reflects how PNES is conceptualized. The Diagnostic and Statistical Manual of Mental Disorders, 5th edition (DSM-5) classifies PNES as it was in DSM-IV, a conversion disorder also termed a "functional neurologic disorder" (4). In contrast, the International Classification of Diseases-10 (ICD-10) categorizes PNES as a dissociative disorder. Conversion and dissociative disorders, though sometimes conflated under the category of "medically unexplained symptoms," have developed as distinct conceptual models that may have implications on how the illness is explained to a patient, as well as how a clinician approaches treatment (5). The concept of dissociation emerged from the psychodynamic tradition, in which the integration of thought, affect, sensory experience, and behavior is impaired by psychological trauma. Dissociative symptoms may manifest as amnesia, fugue, identity disorders, or unexplained sensory and motor behavior with change in the level of consciousness. The DSM-II subcategorized hysterical neurosis into conversion and dissociative subtypes, with the former representing neurologic symptoms (such as psychogenic paralysis, movement disorders, or seizures) and the later denoting changes in consciousness or identity (such as fugue or multiple personality disorder) (5). The DSM-III introduced the category of

somatoform disorders, which represented symptoms associated with a medical disorder that are thought to be psychologically driven. As a result, much of the discourse regarding "somatization" exists in the primary care and internal medicine literature (6). As conversion disorders began to be subsumed within the category of somatoform disorders, somatization and conversion became more prominent in the neurology literature. Conversely, this discourse of dissociative disorders became primarily restricted to the mental health literature. Consequently, the role of dissociation in illnesses such as PNES began to be underemphasized. Clinicians may not address dissociative features of PNES as much as the physical or somatic complaints of the patients.

One subtlety to approaching PNES as a somatization disorder, as opposed to a dissociative disorder, is that somatization is often understood as an unconscious impairment or limitation in the ability of patients to express or communicate emotional distress. Whether the difficulty of communication is due to cultural, developmental, or psychodynamic reasons, therapists' treatment is premised on providing patients with the communication tools to express their emotions in a healthy manner. In contrast, the approach to dissociative disorders may include preventing the triggers that lead to the trance-like states or how to reintegrate sensory systems during dissociative episodes.

Another way to understand the relationship between dissociation and somatization is across a psychological continuum. Dissociation may represent a defense mechanism in which the mind disconnects from the environment or blocks thoughts altogether, usually associated with a past or present traumatic event. In contrast, with somatization, instead of thought blocking and disengaging from the environment, emotional distress is expressed as a physical symptom (6). In spite of the common psychological substrate, the role of somatization and dissociation in PNES continues to be contested by some. Studies tend to emphasize that PNES is associated with other somatization symptoms and disorders (7–9) more than dissociative symptoms. Somatization in PNES is associated with greater seizure severity and worse outcomes independent of dissociative symptoms (10,11). In contrast, dissociative episodes may involve regressed behavior that is not consistent with seizures. Still, people argue that understanding PNES as a dissociative disorder may be useful because, theoretically, somatic symptoms may be understood as expressions of dissociating consciousness from somatosensory experience or behavior (12). Independent of the nosology discussion, an approach that has been conveyed to and readily understood by patients is that PNES are symptom manifestations of an underlying conflict or stressor. Once patients and family members grasp this concept, progress is made in addressing the underlying issues.

EPIDEMIOLOGY

The majority of studies documenting the prevalence of PNES take place in seizure monitoring units. Across centers, 20% to 40% of people admitted for evaluation of seizures are diagnosed as PNES (13–16). These numbers are similar for veteran population (16). Three incidence studies, to date, have been conducted to assess the proportion of new onset PNES in the community. The first was conducted in Iceland, which estimated, based on 1996 population data, an annual incidence of 1.4 per 100,000 in people older than 15 years (17). The study was possible because there is only one neurophysiologic service in the country; therefore, it should not be considered a community-based sample. The second study, conducted in Hamilton County, Ohio, used a similar methodology (18). Since there were only two centers with EEG capacity to evaluate people with PNES, they assumed that they would capture all (if not most) citizens of Hamilton county who experienced PNES. The primary limitation of this methodology is a potential underestimation of incidence, that is, if patients

with PNES are evaluated elsewhere or do not seek medical services. The Ohio study estimated a PNES incidence of 3.03/100,000 person-years, which is double the rate of the Iceland study. A third study prospectively identified first presentations of PNES from a population of 367,566, over 3 years. PNES were diagnosed in 68 patients, in 54 of whom the diagnosis was confirmed by video/EEG recording, indicating an incidence of 4.90/100,000/year (15). The studies demonstrated that more women were affected with PNES—73% in the Ohio study and 78.6% in the Iceland study. Also younger adults have the highest average incidence with 3.4/100,000 person-years in 15- to 24-year-olds in Iceland and 4.38/100,000 in 25- to 44-year-olds in Ohio, respectively. A door-to-door community-based study to determine the incidence and prevalence of PNES would be both resource intensive and not feasible given the requirement for video-electroencephalographic (VEEG) confirmation of events. Based on the extrapolation that the prevalence of epilepsy is 0.5% to 1%, the proportion of medically refractory epilepsy is 20% to 30%, the proportion of medically refractory people with epilepsy that are referred to epilepsy centers is 20% to 55%, and the percentage of people admitted to epilepsy centers are diagnosed with PNES is 10% to 20%, then the prevalence of PNES is estimated to be 2 to 33 per 100,000 (14).

The consistent finding that PNES occurs more commonly in women (up to three time more likely) than in men is often attributed to higher reports of sexual abuse among women (19,20). Men with PNES are more likely to report work-related problems (20) and present with more violent motor PNES (21). Younger age, poor socioeconomic status, and increased psychosocial stressors have also been reported as risk factors for PNES (22–24). Among the most studied risk factors for PNES are psychiatric comorbidity and psychological profiles. Extensively reviewed elsewhere (25,26) and based on relatively small studies (with sample sizes ranging from 20 to 85 subjects), people with PNES have relatively higher rates of depression, anxiety, and personality disorders compared to community and people with epilepsy. For instance, depressive disorders range from 13% to 60% and anxiety disorders from 10% to 70% in people with PNES. Borderline personality disorders ranged from 10% to 38% of people with PNES compared to 3% to 5% of controls with epilepsy. Psychiatric comorbidity markedly impacts quality of life (27) and should be addressed. Both neuropsychological as well as psychological profiles are limited at diagnosing PNES (10,28), but they may be useful in determining the patient's psychosocial needs, cognitive strengths and limitations, and prognosis.

DIAGNOSIS

VEEG remains the gold standard for diagnosis PNES (29). Recent studies, however, have demonstrated that key historical features in the descriptions from family members and/or significant others of witnessed events may be accurate in identifying PNES (30). As reviewed elsewhere (31–33), symptoms, signs, and semiology may help distinguish epileptic seizures (ES) from PNES; however, no one symptom or sign can definitively establish the diagnosis of PNES (33).

History

Many clinicians begin to consider PNES in the differential diagnosis when a patient is not responding to antiepileptic drugs (AEDs) or when a patient's profile or symptoms are not consistent with ES. However, many symptoms expected to be reported in ES are also reported in PNES: 59.2% people with PNES may report history of events during sleep as opposed to 47% of people with ES (34); urinary incontinence has been shown to occur in 44% of patients with PNES, as opposed to 57% with

ES (35); prodromal phenomena such as sensory auras or premonitions have been reported in 59% of patients with PNES (36); postictal confusion has been reported in 55% of PNES patients who report losing consciousness during attacks (36); and tongue biting is reported in 0% to 18% of people with PNES (37–40). Although several features of PNES, such as forced eye closure, asynchronous movements, side-to-side head movements, prolonged duration, pelvic thrusting, preserved awareness, and others influencing the ictal event, are sensitive for diagnosing PNES (Table 40.1), eyewitness reports by family and significant others have been shown to be very unreliable in identifying PNES based on these symptoms (41).

Table 40.1 Sensitivity of Identifying PNES Correctly Based on Clinical Symptoms, Signs, and Diagnostic Procedures

Clinical Indicator	Sensitivity	Reference
History		
Eye witness	25%	(41)
Preserved awareness		
Eye flutter	42%	
Others can intensify or alleviate	25%	
Patient procedure		
Hypnotic seizure induction	77%	(42)
IV saline procedure induction	91%	
Bedside assessment by clinician		
Ictal cognitive assessment	54%	(43)
Ictal semiology		
Long duration	—	
Closed eyes	52%–96%	(32,44)
Fluctuating course	47%–88%	
Asynchronous movements	9%–56%	
Side-to-side head movements	15%–36%	
Pelvic thrusting	7%–44%	
Ictal weeping	4%–37%	
Recall for period of apparent unconsciousness	63%	
Review of video (without EEG) by neurologist	87%	(45)
Review of video (without EEG) by epileptologist		
Psychological testing		
MMPI II	30%–92%	(46)
Laboratory testing		
Prolactin level (CPS, GTC)	46%, 60%	(47)
Neuroimaging		
Postictal SPECT	70%–73%	(48)

CPS, complex partial seizure; GTC, generalized tonic–clonic seizure; MMPI II, Minnesota Multiphasic Personality Inventory-2.

When shown a video of ES and PNES, neurologists are highly accurate (89%) in distinguishing the two types of seizures (45). Importantly, neurologists are accurate in diagnosing PNES by video when considering the constellation of signs. However, when attempting to make the diagnosis based on one sign on video, they are not as accurate (41). Likewise, when presented with the history alone, neurologists have a high sensitivity for ES, but specificity was only 50%, with simple partial epileptic seizures and PNES being frequently missed (15). With the nearly ubiquitous availability of

video cameras on smart phones, patients and their significant others may be able to provide the data for a clinician to help make the diagnosis. The primary limitation would be the quality of the video and the strong likelihood that only part of the PNES would be captured without the beginning of the event.

Laboratory and Neuroimaging

Use of prolactin (PRL) level has been extensively reviewed in an American Academy of Neurology (AAN) technical guideline report (47). Pooled data, of studies distinguishing both complex partial and generalized seizures from PNES, demonstrate that PRL are highly specific (95.9% to 96.3%) but not that sensitive (46.1% to 60%). PRL fluctuates with circadian rhythm, time of day, quality of sleep, and with syncope. Most studies demonstrating utility of PRL level measured baseline levels and within 30 minutes after the seizure since levels begin to attenuate within hours of the seizure. AAN guidelines suggest that PRL levels should be drawn within 20 minutes of the seizure to be most useful. Criteria for determining elevated PRL have included a 300% increase from baseline; reaching >25 ng/mL; and reaching > 32 ng/mL for females and >23 ng/mL for males. A rise in PRL level does not occur in simple partial epileptic seizures. Syncope has been shown to elevate PRL levels; therefore, PRL are likely not useful to distinguish between ES and syncope.

The majority of structural neuroimaging studies in people with PNES are within normal limits, although abnormalities are present in a significant minority of studies (49). While there is an increased interest in studying neuroimaging changes in people with somatization and dissociative disorders (50–52), including PNES (53,54), neuroimaging does not distinguish between ES and PNES. Two studies have shown that changes in interictal and postictal single photon emission computed tomography (SPECT) may be useful when semiology of PNES is atypical or VEEG is unclear (48,55).

Neurophysiology/EEG Monitoring

Several studies have demonstrated that nonspecific interictal EEG abnormalities may be seen in people with PNES that may be due to overreading of normal variants on the EEG (56), comorbid medical and psychiatric issues (such as traumatic brain injury or psychotropic medications) (57), and misdiagnosis of frontal lobe seizures (58). Criteria for VEEG diagnosis have also been debated. Research studies have varied in how many of the typical events should be captured and how to interpret interictal epileptiform activity (31). Studies vary regarding how many episodes should be captured to determine the diagnosis, whether interictal discharges rule out PNES, whether to include preictal and postictal EEG changes as part of the criteria, and the how to use psychogenic semiology in the diagnosis (31). The gold standard is to capture a PNES that is typical of the events the patient experiences in the community. The entire event should be captured, and there should be ideally no epileptiform activity on VEEG before, during, or after the event. In addition, the semiology can provide helpful information (listed in Table 40.1). The heart rate, for example, tends to accelerate relative to baseline during ES but not PNES and can distinguish between the two with a sensitivity of 83% and specificity of 96% (59). Postictal agitation and confusion are seen in both ES and PNES (60); however, PNES is distinguished from ES postictally by shallow rapid breathing as opposed to deep, heavy breathing in ES (61). Recently, the International League Against Epilepsy PNES Task Force proposed criteria for diagnostic levels of certainty for PNES to offer guidance in events that

cannot be captured by VEEG either because the technology is not available or because events are too infrequent to expect capture (Table 40.2) (30). The three criteria involve history, semiology, and EEG and levels include "Documented," "Clinically established," "Probable," and "Possible PNES."

Table 40.2 Overview of Proposed Diagnostic Levels of Certainty for PNES

Diagnostic level	History	Witnessed event/semiology	EEG
Possible	+	By witness or self-report/ description	No epileptiform activity in routine or sleep-deprived *interictal* EEG
Probable	+	By clinician who reviewed video recording or in person, showing semiology typical of PNES	No epileptiform activity in routine or sleep-deprived *interictal* EEG
Clinically established	+	By clinician experienced in diagnosis of seizure disorders (on video or in person), showing semiology typical of PNES, while not on EEG	No epileptiform activity in routine or ambulatory *ictal* EEG during a typical ictus/event in which the semiology would make ictal epileptiform EEG activity expectable during equivalent epileptic seizures
Documented	+	By clinician experienced in diagnosis of seizure disorders, showing semiology typical of PNES, while on VEEG	No epileptiform activity immediately before, during, or after ictus captured on *ictal* VEEG with typical PNES semiology

As noted in the text, additional tests may affect the certainty of the diagnosis—for instance, self-protective maneuvers or forced eye closure during unresponsiveness or normal postictal prolactin levels with convulsive seizures.

+, history characteristics consistent with PNES; EEG, electroencephalogram.

COURSE OF ILLNESS

Due to the delay in the diagnosis of PNES, most (if not all) people with PNES experience some stigma and restructure their lives around the diagnosis of epilepsy. Furthermore, the delay in diagnosis and treatment as epileptic seizures frequently results in unnecessary use of AEDs, incurring the risk of side effects, as well as the high cost of chronic use (16). Less commonly, patients may be inappropriately referred for neurosurgical interventions for "medically intractable epilepsy" (62). Standard medical care (SMC) at this time is limited to communicating the diagnosis of PNES, tapering AEDs in patients with PNES only and referring to a psychiatrist or psychologist for psychiatric comorbidities (63). Although a few small studies have shown marginal improvement in the frequency of PNES with only communicating the diagnosis, SMC has not shown significant improvement in depression and anxiety symptoms, quality of life measures, utilization of health care resources, dependence of state welfare programs, or employment status. Unlike people with epilepsy who have improvement in quality of life (QOL) with seizure remission (64), in the minority of patients (approximately 30%) who experience PNES remission with SMC, utilization of health care services, quality of life, anxiety, depression, somatization, and unemployment status are not better than those who continue to experience PNES (65). People who suffer from PNES die earlier than the

general population (66) and have a high rate of self-injury, as well as suicide attempts (35). Therefore, overall people with PNES have worse outcomes than people with ES. As reviewed elsewhere (67), factors that are associated with lower remission of PNES include the following: adulthood during the age of PNES onset (68), female gender (69), receiving social security benefits (70), lower education (8,71), unemployment (8,70), difficulty forming relationships (37), not accepting the diagnosis of PNES (70), people with more violent psychogenic seizure semiology (72), and higher level of psychopathology (69,73). In particular, people with delusions, paranoia, and bizarre behavior are less likely to achieve PNES control (74). Personality characteristics, including lower emotional dysregulation, inhibitedness, and compulsivity scores, are associated with better outcomes (8).

TREATMENT

Prior editions of this chapter have almost exclusively focused on PNES as a differential diagnosis. However, the emerging literature (75–77) on treatment warrants review of the increase in evidence-based therapies. Once the diagnosis of PNES is made, there are three critical phases to treatment of PNES: presentation of the diagnosis, gaining control over the symptoms, and maintenance therapy (77). Some neurologists argue that providing the diagnosis of PNES itself is (at least part of) the treatment for PNES, but as discussed SMC is associated with poor outcome. Open-labeled psychological interventions, including psychodynamically oriented, as well as cognitive behavioral therapies (CBTs) (78,79), and pilot pharmacologic clinical trials (80) have demonstrated improved outcomes. Two pilot studies of CBT for PNES focused on PNES-related trigger prevention has resulted in seizure freedom of 25% (78) and 65% (81) and a >50% reduction of seizure frequency in 76% and 81% of subjects enrolled, respectively.

Pharmacologic trials for PNES include the use of psychotropic medications and analgesics (82). In a double-blinded, placebo-controlled, 12-week clinical trial of sertraline, 38 subjects were enrolled and 26 (68%) completed the study (80). Subjects who received sertraline had a 45% reduction in seizures from baseline, compared to an 8% increase in those who received placebo. No significant difference was seen in depression, anxiety, impulsivity, somatic symptoms, QOL, and psychosocial functioning scores. This feasibility study was not powered to demonstrate efficacy, but interestingly showed improvement in seizure frequency independent of mood and anxiety symptoms. A 5-month, open-label prospective study of venlafaxine required subjects to have a comorbid DSM-IV diagnosis of an anxiety and/or unipolar depressive disorder (83). Of the 19 subjects that completed the trial, 8 were seizure free at 5 months, 15 (88%) had >50% reduction in frequency of seizures, 11 (65%) had >50% reduction in depression scores, and 7 (41%) had >50% reduction in anxiety scores. Absence of a control arm makes it difficult to determine how much of the improvement was due to the medication. A recent pilot multicenter randomized trial comparing a workbook-based psychotherapy (84), workbook psychotherapy plus SSRI, SSRI alone, and SMC revealed significant seizure reduction and improvement in comorbidities in the psychotherapy and psychotherapy plus SSRI arms and no improvement in the SMC arm (85). The study illustrates that effective treatments exist for PNES and that the current standard of treatment (usually supportive psychotherapy) is not adequate in treating patients with PNES.

CONCLUSION

Much has been learned recently about the nature and consequences of PNES, which have been documented in the medical literature for centuries. As information is increasingly available on the characteristics and treatments for PNES, neurologists, mental health providers, and other health care professionals not only should consider PNES in the differential diagnosis of paroxysms but should also actively be engaged in providing care for these patients. The risk of unnecessary AED, emergency room visits, hospital admissions, unnecessary procedures, and self-injury is exceedingly high. Clinicians may play a central role in not only diagnosing PNES but also referring patients to appropriate mental health treatment. Neurologic clinics and epilepsy centers may even consider collaborating closely with mental health professionals to develop multidisciplinary care for conversion disorders beyond PNES, such as psychogenic movement disorders or other psychosomatic complaints (86). Hope for improvement in PNES is present not only for patients and family members but also for neurologists who evaluate and care for this challenging population.

CHAPTER 41 OTHER NONEPILEPTIC PAROXYSMAL DISORDERS

ELIA M. PESTANA KNIGHT AND JOHN M. PELLOCK

A number of conditions cause intermittent and recurring symptoms that look like epilepsy. Although seizures must be considered in the differential diagnosis, the clinical characteristics sometimes clearly differentiate these disorders from true seizures. These so-called nonepileptic paroxysmal disorders tend to recur episodically. They must not be confused with seizures because treatment with antiepileptic drugs is usually unnecessary and unsuccessful, leading to adverse effects, and alternative etiologies may be overlooked (1–6).

For the clinician dealing with a paroxysmal disorder, the patient's age and an accurate description of the event, including the time of occurrence (during wakefulness or sleep), can lead to the correct diagnosis (7,8). Nevertheless, some nonepileptic symptoms can be present in a patient who also has epilepsy, and unusual repetitive movements can be misdiagnosed as seizures when the actual seizures have been controlled by medication. Prensky (7) classified such symptoms as unusual movements, loss of tone or consciousness, respiratory derangements, perceptual disturbances, behavior disorders, and episodic behaviors related to disease states (Table 41.1).

Table 41.1 Common Symptoms of Nonepileptiform Paroxysmal Disorders

- Unusual movement
  - Jitteriness, tremor
  - Masturbation
  - Shuddering
    - Benign sleep myoclonus
  - Startle responses
    - Paroxysmal torticollis
  - Self-stimulation
    - Head banging (rhythmic movement disorder)
    - Tics (Tourette syndrome)
    - Paroxysmal dyskinesia
  - Pseudoseizures
  - Eye movement
  - Head nodding
  - Paroxysmal tonic upgaze
- Loss of tone or consciousness
  - Syncope
  - Drop attacks
  - Narcolepsy/cataplexy
  - Attention deficit
  - Acute hemiplegia
- Respiratory derangements
  - Apnea
  - Breath holding
  - Hyperventilation
- Perceptual disturbances
  - Dizziness
  - Vertigo
  - Headache
  - Abdominal pain
- Episodic features of specific disorders
  - Ataxia
  - Tetralogy spells
  - Hydrocephalic spells
  - Cardiac arrhythmias
  - Hypoglycemia
  - Hypocalcemia
  - Periodic paralysis
  - Hyperthyroidism
  - Gastroesophageal reflux
  - Rumination
  - Drug poisoning
  - Cerebrovascular events
- Behavior disorders
  - Night terrors
  - Sleepwalking
  - Nightmares
  - Rage
  - Confusion
  - Fear
- Acute psychotic symptoms
  - Fugue
  - Phobia
  - Panic attacks
  - Hallucinations
  - Autism
- Munchausen syndrome by proxy

The following overview of nonepileptic paroxysmal disorders is organized by age, type, and time of occurrence. Psychogenic nonepileptic seizures are discussed in Chapter 40.

INFANCY

Sleep

During infancy, at least two paroxysmal behaviors may be confused with seizures: repetitive episodes of head banging while the infant is falling asleep and benign neonatal myoclonus usually occurring during sleep.

Head Banging (Rhythmic Movement Disorder)

Rhythmic movement disorders, such as repetitive motion of the head, trunk, or extremities, usually occur as a parasomnia during the transition from wakefulness to sleep or from sustained sleep (9). Head banging can last from 15 to 30 minutes as the infant drifts off to sleep and, unlike similar daytime activity, is usually not related to emotional disturbance, frustration, or anger. No abnormal electroencephalographic (EEG) findings are noted. These benign movements usually disappear within 1 year of onset, typically by the second or third year of life, without treatment (7,9).

Benign Neonatal Myoclonus

Rapid and forceful myoclonic movements may involve one extremity or many parts of the body. Occurring during sleep in early infancy, these bilateral, asynchronous, and asymmetric movements usually migrate from one muscle group to another. Unlike seizures, their rhythmic jerking is not prolonged, although clusters of these movements may occur episodically during all stages of sleep. Attacks are usually only a few minutes long but may last up to hours. Myoclonus is not stimulus sensitive, and EEG shows no epileptiform activity. The movements stop as the infant is awakened and should never be seen in a fully awake and alert state. No treatment is required, but clonazepam or other benzodiazepines have been suggested in children who demonstrate a large amount of benign myoclonic activity. The movements typically disappear over several months (10).

Wakefulness

Jitteriness

Neonates and young infants demonstrate this rapid generalized tremulousness, which in neonates may be severe enough to be mistaken for clonic seizures. The infants are alert, and the movements may be decreased by passive flexion or repositioning of the extremities. Although jitteriness may occur spontaneously, it is typically provoked or increased by stimulation. Because neonatal jitteriness may be caused by certain pathologic states, jittery newborns are more likely than normal infants to experience seizures, and their EEG tracings may show abnormalities. Central nervous system dysfunction is the suspected etiology, but hypoxic–ischemic insults, metabolic encephalopathies such as hypoglycemia and hypocalcemia, drug intoxication or withdrawal, and intracranial hemorrhage may play a role and should be ruled out, if symptoms persist. The more benign forms of jitteriness usually decrease without specific therapy. Prognosis depends on the etiology and in neonates with severe, prolonged jitteriness may be guarded. Nevertheless, in 38 full-term infants who were jittery after 6 weeks of age, the movements resolved at a mean age of 7.2 months; 92% had normal findings

on neurodevelopmental examinations at age 3 years (11). Sedative agents may be used, but their adverse effects usually increase the irritability (11,12).

Head Banging or Rolling and Body Rocking

Head banging, head rolling, and body rocking often occur in awake infants (7). In older infants, head banging may be part of a temper tantrum. Head rolling and body rocking seemingly are pleasurable forms of self-stimulation and may be related to infantile masturbation. If the infants are touched or their attention is diverted, the repetitive movements cease. They are more common in irritable, excessively active, cognitively challenged infants (7). Nevertheless, most of this activity decreases during the second year. Particularly, bothersome movements may be diminished by behavior modification techniques, but drug treatment usually is unnecessary.

Infantile Gratification Behavior (Infantile Masturbation)

Gratification behavior or infantile masturbation is a form of self-stimulation in infancy (13,14). Infantile masturbation is part of the normal sexual human development. It may mimic abdominal pain, seizures, or dyskinesias. Although infantile masturbation has been typically described in infant girls, it is also present in boys, but due to cultural reasons, episodes in boys may not be brought to the attention of health professionals.

The typical description of the events includes sitting with the legs held tightly together or straddle the bars of the crib or playpen or other toys and rock back and forth. Distracting stimuli usually stop these movements, but some children become irritable when interrupted. Events typically disappear over the period of several months. Masturbation in older children is less likely to be confused with seizure activity. In some cognitively impaired children with autism, self-stimulation can also be associated with a fugue state. Because these children are difficult to arouse during the activity, seizures are commonly suspected (15). Once the diagnosis is made, parents may be taken aback by the terminology due to social stigma associated with the term masturbation. We therefore offer gratification behavior as an alternative diagnostic term that may be accepted more easily by families.

Benign Myoclonus of Early Infancy

These myoclonic movements occur in children during wakefulness state and may resemble infantile spasms but are not associated with EEG abnormalities. Infants are usually healthy, with no evidence of neurologic deterioration. The myoclonic episodes abate without treatment after a few months (16).

Spasmodic Torticollis

Spasmodic torticollis is a disorder characterized by sudden, repetitive episodes of head tilting or turning to one side with rotation of the face to the opposite side. The episodes may last from minutes to days. During episodes, children are irritable and uncomfortable but alert and responsive. Although movements may present in a recurrent and episodic pattern, EEG findings remain normal. Nystagmus is not associated with this disorder. The etiology is unknown, although dystonia and labyrinthine imbalance have been proposed. A family history of torticollis or migraine may be present. Similar tonic or head, neck, and body rotary movements may also be seen with gastroesophageal reflux (Sandifer syndrome), but these usually last longer than spasmodic torticollis (17–20).

The differential diagnosis includes congenital, inflammatory, and neoplastic conditions of the posterior fossa, cervical cord, spine, and neck. During these conditions, the episodes of torticollis are sustained and lack the usual on-and-off variability. An evaluation is necessary, but spasmodic torticollis usually subsides without treatment during the first few years of life.

Spasmus Nutans

Head nodding, head tilt, and nystagmus comprise spasmus nutans. Head nodding or intermittent nystagmus (or both) is usually noted at 4 to 12 months of age. Interestingly, nystagmus may be more prominent in one eye. The symptoms can vary depending on position, direction of gaze, and time of day. The children are clinically alert, and although symptoms may fluctuate throughout the day, episodic alterations in level of consciousness do not occur. Spasmus nutans usually remits spontaneously within 1 or 2 years after onset but may last as long as 8 years. Minor EEG abnormalities may be noted, but classic epileptiform discharges are not associated. Because mass lesions of the optic chiasm or third ventricle have been noted in a small proportion of these infants, computed tomography or magnetic resonance imaging studies are usually recommended. It is difficult to distinguish eye movements persisting into later childhood or adulthood from congenital nystagmus (21–23).

Opsoclonus

Opsoclonus is a rare abnormality characterized by rapid, conjugate, multidirectional, oscillating eye movements that are usually continuous but may vary in intensity. Because of this variation and occasionally associated myoclonic movements, generalized or partial seizures may be suspected. The children remain responsive and alert. Opsoclonus usually implies a neurologic disorder such as ataxia myoclonus or myoclonus. Children who develop these signs early in life may have a paraneoplastic syndrome caused by an underlying neuroblastoma (24–26). The triad of opsoclonus, myoclonus, and encephalopathy is termed Kinsbourne encephalopathy (dancing eyes, dancing feet) and responds to removal of the neural crest tumor or treatment with corticosteroids or corticotropin (27). Other forms of episodic ataxia in association with nystagmus may be seen in later infancy and childhood, but rarely true opsoclonus (8).

Rumination

Rumination attacks involve hyperextension of the neck, repetitive swallowing, and protrusion of the tongue. Episodes are thought to be related to abnormal esophageal peristalsis and typically follow or accompany feeding. The child is alert but sometimes seems distressed and uncomfortable. Variable feeding techniques are helpful in this disorder, which resolves as the child matures (28).

Startle Disease or Hyperekplexia

Hyperekplexia together with stimulus-induced disorders and neuropsychiatric startle syndrome are part of the startle syndromes (Table 41.2) (29). Hyperekplexia is a rare familial disorder with autosomal dominant or autosomal recessive inheritance, but some cases are sporadic (29,30). At least five genes have been described in the context of hyperekplexia to date, and over 80% have been linked to mutations of the alpha subunit of the glycine receptor (GLRA1). Other genes include GLRB,

SLC6A5, GPHN, and ARHGEF9, while frequently no mutation can be found (30).

Table 41.2 Differential Diagnosis of Three Groups of Startle Syndromes

Hyperekplexia	Stimulus-induced disorders	Neuropsychiatric disorders
Neonatal stiffness, startle, and stiffness with startle	Nonepileptic	Startle-induced tics
Excessive startling	Without rigidity	Culture-specific syndrome
Cerebral	Paroxysmal kinesigenic dyskinesias	Latah
Cerebral palsy	Episodic ataxia	Jumping Frenchmen of Maine
Postanoxic encephalopathy	Cataplexia (narcolepsy)	Myriachit
Occlusion of posterior thalamic arteries	Reflex myoclonus	Functional startle syndromes
Posttraumatic	With rigidity	Anxiety disorder
Paraneoplastic	Stiff person syndrome	Posttraumatic stress syndrome
Multiple sclerosis and lateral sclerosis	Progressive encephalomyelitis with rigidity	
Cerebral abscess with encephalitis	Strychnine poisoning	
Brainstem	Tetanus	
Brainstem infarction	Epileptic	
Brainstem hemorrhage	Reflex epilepsy	
Brainstem encephalopathy	Progressive myoclonic epilepsy	
Pontocerebellar hypoplasia	Pyridoxine-dependent epilepsy	
Posterior fossa malformation		
Medulla compression		
Multiple system atrophy		

Modified from Bakker MJ, van Dijk JG, van den Maadenberg AM, et al. Startle syndromes. Lancet Neurol. 2006;5:513–524.

In the past, any type of exaggerated startle response was labeled hyperekplexia. It has now become clear that many of these cases may simply represent an augmented normal startle reflex (31), and we therefore reserve the term hyperekplexia for patients presenting with the three main clinical symptoms of generalized stiffness (hypertonia), excessive startle beginning at birth and a short period of generalized stiffness following the startle reflex (32). Hyperekplexia may lead to falls. Clinically, the infant becomes stiff when handled, and episodes of severe hypertonia may also present with apnea and bradycardia. At times, forced flexion of the neck or hips may interrupt episodes. Also noted, along with transient hypertonia, are falling attacks without loss of consciousness, ataxia, generalized hyperreflexia, episodic shaking of the limbs resembling clonus, and excessive startle. While the interictal electroencephalogram is normal, a spike may be associated with a startle attack. Whether this discharge represents an evoked response to the stimulus or an artifact is a subject of debate. The disorder must be distinguished from so-called startle epilepsy, in which a startle is followed by a partial or generalized seizure, which suggests a defect in inhibitory regulation of brainstem centers (33,34). The prognosis in hyperekplexia is variable (31). Seizures do not develop after this benign disorder. However, clonazepam and valproic acid have been used to treat associated startles, stiffness, jerking, and falling (35,36).

Shuddering Attacks

Shuddering attacks far exceed the normal shivering frequently seen in older infants and children. A very rapid tremor involves the head, arms, trunk, and even the legs; the upper extremities are adducted and flexed at the elbows or, less often, adducted and extended. The episodes may begin as early as 4 months of age and decrease gradually in frequency and intensity before age 10 years. Treatment with antiepileptic drugs does not modify the attacks. Except for movement artifact, results of electroencephalography are normal. While earlier reports linked shuddering attacks with early

manifestations of essential tremor (37,38), findings could not be confirmed in a more recent series (39).

Alternating Hemiplegia

Alternating hemiplegia of childhood may be confused with epilepsy because of the paroxysmal episodes of weakness, hypertonicity, or dystonia. Presenting as tonic or dystonic events, these intermittent attacks may alternate from side to side and at times progress to quadriplegia. They usually occur at least monthly and may be part of a larger neurologic syndrome in children with delayed or retarded development who also have seizures, ataxia, and choreoathetosis. Attacks begin before 18 months of age and can be precipitated by emotional factors or fatigue. The hemiplegic episodes may last minutes or hours, and recent genetic studies linked the clinical presentation with the ATP1A3 gene, which encodes a Na^+,K^+-ATPase, an ion pump responsible for maintaining sodium and potassium electrochemical gradients across the plasma membrane (40). Although anticonvulsants and typical migraine treatments are unsuccessful, flunarizine, a calcium channel blocker (5 mg/kg/day), has been reported to reduce recurrences (41,42).

Paroxysmal Tonic Upgaze

Age of onset of paroxysmal tonic upgaze is within the first year of life, with the earliest cases described at age 2 weeks, but some cases are detected during the preschool years. Episodes are described as upward, and tonic deviation of the eyes as a single symptoms or eye movement can be associated with altered movement coordination or ataxia. Events are typically brief but occasionally can last up to 30 minutes. The frequency of the events ranges from rare episodes to daily leading to consider the diagnosis of epileptic seizures. There is a predilection for boys. Neurologic assessment may be normal or may reveal hypotonia and developmental delays. Prognosis is benign with complete improvement of the symptoms before age 2 years in most cases (43).

Respiratory Derangements and Syncope

Primary breathing disorders usually occur without associated epilepsy. At times, however, respiratory symptoms may be confused with epilepsy, or, rarely, tonic stiffening, clonic jerks, or seizures may follow primary apnea (44). An electroencephalogram or polysomnogram recorded during the event may easily distinguish a respiratory abnormality associated with true seizures from one completely independent of epilepsy.

Infant Apnea or Apparent Life-Threatening Events

Apnea usually occurs during sleep and may be associated with centrally mediated hypoventilation, airway obstruction, aspiration, or congenital hypoventilation. Formerly called (near) sudden infant death syndrome, these symptoms have now been termed apparent life-threatening events. During central apnea, chest and abdominal movements decrease simultaneously with a drop in airflow. During obstructive apnea, movements of the chest or abdomen (or both) continue, but there is diminished air flow. Central apnea presumably results from a disturbance of the respiratory centers, whereas obstructive apnea is related to a peripheral blockage of airflow. Some infants may also have a mixed form of the disorder. A few jerks may occur with the apneic episodes but do not represent

epileptic myoclonus. The apnea that follows a seizure is a form of central apnea with postictal hypoventilation. Primary apnea, however, is only rarely followed by seizures (45,46).

The etiology and characteristics of apneic episodes vary among infants. Apnea of prematurity responds to treatment with xanthine derivatives. In older infants with primary central apnea, elevated cerebrospinal fluid levels of β-endorphin have been reported, and treatment with the opioid antagonist naltrexone has been successful (47). The role of home cardiopulmonary monitors is controversial. Parents should be encouraged to follow the recommendations of the American Academy of Pediatrics that healthy term infants be put to sleep on their back or side to decrease the risk of apnea and possible sudden infant death syndrome (48).

Although apnea occurs less often when the child is fully awake, it may be associated with gastroesophageal reflux (49,50). Aspiration may follow. Reflux is frequently accompanied by staring, flailing movements of the extremities or posturing of the trunk, possibly in response to the pain of acidic contents washing back into the esophagus. Gastroesophageal reflux is more common when infants are laid supine after feeding. Diagnosis is established by radiologic demonstration of reflux or by abnormal esophageal pH levels. Reflux is treated by upright positioning of the baby during and after feeding (51), thickened feedings, and the use of agents to alter sphincter tone and, in infants who do not respond to medical treatment, very rarely, Nissen fundoplication.

Cyanotic Breath-Holding Spells

Although common between the ages of 6 months and 6 years, cyanotic infant syncope (breath-holding spells) is frequently confused with tonic seizures (52). Typically precipitated by fear, frustration, or minor injury, the spells involve vigorous crying, following which the child stops breathing, often in expiration. Cyanosis occurs within several seconds, followed by loss of consciousness, limpness, and falling. Prolonged hypoxia may cause tonic stiffening or brief clonic jerking of the body. After 1 or 2 minutes of unresponsiveness, consciousness returns quickly, although the infant may be briefly tired or irritable. The crucial diagnostic point is the history of an external event, however minor, precipitating the episode. The electroencephalogram does not show interictal epileptiform discharges but may reveal slowing or suppression during the anoxic event. The pathophysiologic mechanism is not well understood, but correction of any underlying anemia may reduce the attacks (53). Children with pallid breath-holding spells have autonomic dysregulation caused by parasympathetic disturbance distinct from that found in cyanotic breath-holding (54). Although the episodes appear unpleasant for the child, they do not result in neurologic damage. Antiepileptic medication may be appropriate for the rare patients with frequent postsyncopal generalized tonic–clonic seizures triggered by the anoxia.

Pallid Syncope

Precipitated by injury or fright, sometimes trivial, pallid infant syncope occurs in response to transient cardiac asystole in infants with a hypersensitive cardioinhibitory reflex. Minimal crying, perhaps only a gasp, and no obvious apnea precede loss of consciousness. The child collapses limply and subsequently may have posturing or clonic movements before regaining consciousness after a few minutes (52,55–57). The asystolic episodes may be reproduced by ocular compression, but this procedure is risky and of uncertain clinical utility as it may lead to iatrogenic prolonged asystole and cardiac arrest. As with cyanotic breath-holding spells, the key to diagnosis is the association with precipitating events.

The long-term prognosis is benign. Most children require no treatment, although atropine has been recommended for frequent pallid attacks or those followed by generalized tonic–clonic seizures (58). A trial of the anticholinergic drug atropine sulfate 0.01 mg/kg every 24 hours in divided doses (maximum 0.4 mg/day) may increase heart rate by blocking vagal input. Atropine should not be prescribed during very hot weather because hyperpyrexia may occur.

CHILDREN

Sleep

Myoclonus

Nocturnal myoclonic movements, called "sleep starts" or "hypnic jerks" and associated with a sensation of falling, are less common in older children and adolescents than in infants (10). The subtle involuntary jerks of the extremities or the entire body occur while the child is falling asleep or being aroused. Repetitive rhythmic jerking is uncommon, although several series of jerks can occur during the night. The jerks are not associated with epileptiform activity, but a sensory-evoked response or evidence of arousal may be present on the electroencephalogram (59–62).

Periodic repetitive movements that resemble myoclonus are seen in deeper stages of sleep and may arouse the patient so that daytime drowsiness is noted. These movements are more common in rapid eye movement (REM) than in non–rapid eye movement (NREM) sleep and are clearly distinguished from epilepsy on sleep polysomnographic recordings. In very severe cases, a treatment trial with benzodiazepine may be helpful.

Hypnagogic Paroxysmal Dystonia

In hypnagogic paroxysmal dystonia, an extremely rare disorder, sleep may be briefly interrupted by seemingly severe dystonic movements of the limbs lasting a few minutes. Episodes are sometimes accompanied by prolonged vocalization. No EEG abnormality is noted. Carbamazepine may decrease the attacks. It is not clear whether some or all patients with this clinical syndrome actually have seizures arising from the supplementary motor area (60,63).

Nightmares

Nightmares occur during REM sleep and are rarely confused with seizures. Although children may be restless during the dream, they usually do not scream out, sit up, or have the marked motor symptoms, autonomic activity, and extreme sorrow seen with night terrors. Incontinence may be present, however. Remembrance of the content of nightmares may lead to a fear of sleeping alone. An electroencephalogram recorded during these events shows no abnormalities (7).

Night Terrors (Pavor Nocturnus)

Night terrors, most common in children between the ages of 5 and 12 years, begin from 30 minutes to several hours after sleep onset, usually during NREM slow-wave sleep or sleep stage N3 according to the American Academy of Sleep Medicine terminology. Diaphoretic and with dilated pupils, the

children sit up in bed, crying or screaming inconsolably for several minutes before calming down. Sleep resumes after the attack, and children do not recall the event. No treatment is recommended (64,65).

Sleepwalking

Approximately 15% of all children experience at least one episode of sleepwalking or somnambulism, which usually occurs 1 to 3 hours after sleep onset (NREM slow-wave sleep or sleep stage N3). The etiology is unknown, but a familial prevalence is noted. Mumbling and sleeptalking, the child walks about in a trance and returns to bed. Semipurposeful activity such as dressing, opening doors, eating, and touching objects during an episode of somnambulism may be confused with automatisms of complex partial seizures. The eyes are open, and the child rarely walks into objects. Amnesia follows, and no violence occurs during the event. Treatment is usually not required, except for protecting the wandering child from injuries during the night. Benzodiazepine therapy may be helpful in frequent or prolonged attacks (3,66,67).

Wakefulness

Myoclonus

In many normal, awake children, anxiety or exercise may cause an occasional isolated myoclonic jerk. Treatment is rarely necessary.

Multifocal myoclonus may occur in patients with progressive degenerative diseases or during an acute encephalopathy. It may be difficult to distinguish these movements from chorea, and these two disorders may coexist in some encephalopathic illnesses. Myoclonus persists in sleep, whereas chorea usually disappears during sleep (7).

Chorea

Usually seen as rapid jerks of the distal portions of the extremities, choreiform movements may affect muscles of the face, tongue, and proximal portions of the extremities. When associated with athetosis, chorea involves slower, more writhing movements of distal portions of the extremities. The jerks may be so fluid or continuous that they are camouflaged. Acute chorea may accompany metabolic disorders but is more likely in patients recovering from illnesses such as encephalitis. Other causes are Sydenham chorea seen in the setting of β-hemolytic streptococcal infection, drug ingestion, and mass lesions or stroke involving the basal ganglia. Treatment depends primarily on the etiology, but movements may respond to haloperidol or a benzodiazepine such as clonazepam (68,69).

Tics

Like chorea, most tics are present during wakefulness and disappear with sleep. They usually involve one or more muscle groups, are stereotyped and repetitive, and appear suddenly and intermittently. Movements may be simple or complex, rhythmic, or irregular. Facial twitches, head shaking, eye blinking, sniffling, throat clearing, and shoulder shrugging are typical, although more complex facial distortions, arm swaying, and jumping have been noted. These purposeless movements cannot be completely controlled, but they may be inhibited voluntarily for brief periods and are frequently

exacerbated by stress or startle (70–72).

In Tourette syndrome, complex vocal and motor tics are frequently associated with learning disabilities, hyperactivity, attention deficits, and compulsive behaviors. The incidence of simple and complex tics is high in relatives of these patients. The disorder varies in severity but tends to be lifelong, although it may stabilize or improve slightly in adolescence or early adulthood. Combinations of behavior therapy and medical treatment of tics and compulsive behavior are indicated. Haloperidol, pimozide, and clonidine have been used successfully for behavior control. Stimulants such as methylphenidate may initially exacerbate tics (70–72).

Paroxysmal Dyskinesias

Paroxysmal dyskinesias are rare disorders characterized by repetitive episodes of relatively severe dystonia or choreoathetosis (or both). Multiple brief attacks occur daily, precipitated by startle, stress, movement, or arousal from sleep (73). Consciousness is preserved, but discomfort is evident. Both sporadic and familial types have been described. Kinesigenic dyskinesia frequently is associated with the onset of movement as well as with prior hypoxic injury, hypoglycemia, and thyrotoxicosis. Alcohol, caffeine, excitement, stress, and fatigue may exacerbate attacks of paroxysmal dystonic choreoathetosis, a familial form of the disorder. Although the electroencephalogram displays normal findings during the episodes, the paroxysmal dystonic form responds to antiepileptic drugs such as carbamazepine (73–76).

Stereotypic Movements

Other repetitive movements have been mistaken for seizures, especially in neurologically impaired children. Stereotypy is seen in individuals with autism, sensory disabilities, intellectual disabilities, or developmental disabilities (77–79).

Donat and Wright (80) noted head shaking and nodding, lateral and vertical nystagmus, staring, tongue thrusting, chewing movements, periodic hyperventilation, tonic posturing, tics, and excessive startle reactions in these patients, many of whom had been treated unnecessarily for epilepsy.

A behavior is defined as stereotypy when "involves repetition, rigidity and invariance, as well as a tendency to be inappropriate in nature" (81). The stereotypical behaviors may be verbal or nonverbal and involve fine or gross motor movements or simple and complex movements. Behaviors can occur with and without objects (77). Some stereotypies can involve self injurious behavior (78). Other common example of stereotypies include hand flapping, body rocking, toe walking, spinning objects, sniffing, immediate and delayed echolalia, and running objects across one's peripheral vision (77). Self-stimulatory behaviors such as rhythmic hand shaking, body rocking, and head swaying, performed during apparent unawareness of surroundings, also are common in cognitively impaired children with specific neurologic diagnoses. Rett syndrome should be suspected when repetitive "hand-washing" movements are noted in retarded girls (70). Deaf or blind children frequently resort to self-stimulation such as hitting their ears or poking at their eyes or ears, which has been misidentified as epilepsy. Behavior training is frequently more successful than medication in controlling these movements (80).

Head Nodding

Head nodding or head drops may be of epileptic or nonepileptic origin. A study by Brunquell et al.

(82) showed that epileptic head drops were associated with ictal changes in facial expression and subtle myoclonic extremity movements. Rapid drops followed by slow recovery indicated seizures. When the recovery and drop phases were of similar velocity or when repetitive head bobbing occurred, nonepileptic conditions were much more common.

Staring Spells

When ordinary daydreaming or inattentive periods are repetitive and children do not respond to tactile or auditory stimulation being called, the behaviors may be classified as absence (petit mal) seizures. During innocent daydreaming, posture is maintained and automatisms do not occur. Staring spells are usually nonepileptic in normal children with normal EEG findings, when parents report preserved responsiveness to touch, body rocking, or identification without limb twitches, upward eye movements, interrupted play, or urinary incontinence (83). Children with attention deficit hyperactivity disorder sometimes have staring spells that resemble absence or complex partial seizures. Although unresponsive to verbal stimuli, these children generally become alert immediately on being touched and frequently recall what was said during the staring spell. During these spells, the electroencephalogram pattern is normal. Attention deficit hyperactivity disorder affects 3% to 10% of children and has a male predominance. Stimulants are most widely used, but other medications may be necessary to ameliorate behavior in refractory cases. Antiepileptic drugs are usually ineffective (60,84–87).

Headaches

Recurrent headaches are rarely the sole manifestation of seizures. However, postictal headaches are not uncommon, especially following a generalized convulsion. Headaches may also precede seizures. As an isolated ictal symptom, headache occurs most frequently in children with complex partial seizures (88). Children with ictal headaches experience sudden diffuse pain, often have a history of cerebral injury, derive no relief from sleep, and lack a family history of migraine. Distinguishing headache from paroxysmal recurrent migraine may be difficult in young children when the headache's throbbing unilateral nature is absent or not readily apparent. Migraine, however, is more prevalent than epilepsy. In addition, ictal electroencephalograms during migraine usually show slowing, whereas those during epilepsy demonstrate a clear paroxysmal change. Associated gastrointestinal disturbance and a strong family history of migraine help establish the appropriate diagnosis (88–94).

Epilepsy and migraine can coexist. Children with migraine have a 3% to 7% incidence of epilepsy, and as many as 20% exhibit epileptiform discharges on interictal electroencephalograms (91). Up to 60% of children with migraine obtain significant relief with antiepileptic medication (93,94). Other variants of migraine that may be confused with seizures include cyclic vomiting (abdominal pain), acute confusional states, and benign paroxysmal vertigo.

Recurrent Abdominal Pain

Recurrent abdominal pain may be associated with vomiting, pallor, or even fever and has been noted in migraine and epilepsy. Usually, these complaints indicate neither diagnosis, although some children with recurrent abdominal pain or vomiting may experience migraine later in life (7,95). About 7% to 76% of children with recurrent abdominal pain exhibit interictal paroxysmal EEG changes. Approximately 15% of these patients have a diagnosis of seizures, and more than 40% have

recurrent headaches (7). A family history of migraine is found in approximately 20% (94). Although most of these children do not respond to antiepileptic drugs, approximately 20% obtain relief from antimigraine medications such as β-blockers or tricyclic antidepressants (7,91,95).

Confusional Migraine

Migraine may present in an unusual and sometimes bizarre fashion as confusion, hyperactivity, partial or total amnesia, disorientation, impaired responsiveness, lethargy, and vomiting (96). These episodes must be distinguished from toxic or metabolic encephalopathy, encephalitis, acute psychosis, head trauma, and sepsis as well as from an ictal or postictal confusional state. Confusional migraine usually persists for several hours, less commonly for days, and spontaneously clears following sleep. The diagnosis is usually made following the episode when the patient or family reports severe headache or visual symptoms heralding the onset of the event or a history of similar events. During and soon after the episodes, an electroencephalogram may demonstrate regional slowing, a nondiagnostic finding.

Benign Paroxysmal Vertigo

Benign paroxysmal vertigo consists of brief recurrent episodes of disequilibrium of variable duration that may be misinterpreted as seizures. Lasting from minutes to hours, the attacks of vertigo occur as often as two to three times per week but rarely as infrequently as every 2 to 3 months. Tinnitus, hearing loss, and brainstem signs have been implicated as causes, but the onset is sudden, and the child is usually unable to walk. Extreme distress and nausea are noted, but the patient remains alert and responsive during attacks. Nystagmus or torticollis is frequently observed. Between attacks, examination and electroencephalography reveal normal results. A minority of children show dysfunction on vestibular testing but show no abnormalities on audiograms. A family history of migraine is common, and most of these children experience migraines later in life. No treatment is indicated because the attacks do not respond well to either antiepileptic or antimigraine medications. Benign paroxysmal vertigo usually subsides by ages 6 to 8 years (60,97,98).

Stool-Withholding Activity and Constipation

Children may have sudden interruption of activity and assume a motionless posture with slight truncal flexion and leg stiffening when experiencing discomfort from withholding stool (99). The withholding behavior, which may be mistaken for absence or tonic seizures, evolves as a way to prevent the painful passage of stool that is large and hard because of chronic constipation. At times, stool withholding occurs in the setting of a painful anal fissure. Small jerks of the limbs may be misperceived as myoclonus, and the child may have fecal incontinence. The behavior resolves with treatment of the chronic constipation.

Rage Attacks

The episodic dyscontrol syndrome, or recurrent attacks of rage following minimal provocation, may be seen in children with or without epilepsy. The behavior often seems completely out of character. Rage may be more common in hyperactive children or those with conduct and personality disorders. Similar dyscontrol and near rage have been seen following head injury with frontal or temporal lobe

lesions. Ictal rage is rare, unprovoked, and usually not directed toward an individual. Following attacks of rage and the appearance of near psychosis, the child resumes a normal state, may recall the episode, and feel remorseful. Behavior frequently can be modified during the event. Depending on the cause of the associated syndrome, β-blockers (100), stimulant drugs, and carbamazepine along with other antiepileptic drugs have been used to control outbursts (101).

Munchausen Syndrome by Proxy

Munchausen syndrome, or factitious disorder, describes a consistent simulation of illness leading to unnecessary investigations and treatments. When a parent or caregiver pursues such a deception using a child, the situation is called Munchausen syndrome by proxy. Infants may be brought to child neurologists with parental reports suggesting apnea, seizures, or cyanosis; older children may be described to have episodes of loss of consciousness, convulsions, ataxia, headache, hyperactivity, chorea, weakness, gait difficulties, or paralysis. Accompanying symptoms may include gastrointestinal disorders or a history of unusual accidents and injuries that are poorly explained and almost never observed by anyone but the parent(s) (Table 41.3). Sometimes the child also becomes persuaded of the reality of the "illness" and develops independent factitious symptoms such as psychogenic seizures.

Table 41.3 Clinical Features of Munchausen Syndrome by Proxy

Persistent and recurrent unexplained illness
Clinical signs at variance with the child's health status
Unusual or remarkable signs or symptoms
Signs and symptoms not recurring in the parent's absence
Mother or caregiver overattentive or refuses to leave the hospital
Mother or caregiver not appropriately concerned about prognosis
Lack of anticipated response of clinical syndrome
"Rare" clinical syndrome

The perpetrator is often the mother, who appears initially to be a model parent but has a pathologic need for the child to be sick (102–104). Usually young, articulate, and middle class, she has an unnatural attachment to her child, coexisting personality disorder, and somatizing behavior. The mother often has some medical training, for example, as a nurse. Families are usually dysfunctional. The parents' exaggerated and constant need for illness and medical intervention may lead to the child's death.

Treatment is similar to that of child abuse and typically involves a pediatrician, child psychiatrist, nurse, and social workers. The child is separated from the parents, and details of the history are corroborated. Medical and neurologic evaluations rule out specific disease processes. Admission of a child with paroxysmal symptoms to a video monitoring unit may help to demonstrate this behavior in both mother and child (105).

Future serious psychological disturbances are a significant possibility. Good relationships with the nonabusive father or other parent, successful short-term foster parenting before return to the mother or long-term placement with the same foster parents, long-term treatment or successful remarriage of the mother, and early adoption are associated with more favorable outcome for the

child (106).

LATE CHILDHOOD, ADOLESCENCE, AND ADULTHOOD

Wakefulness

Syncope

Syncope is common in adolescents or older children and usually can be distinguished from seizures by description. Warning signs of lightheadedness, dizziness, and visual dimming ("graying out" or "browning out," "like a curtain coming down") occur in most patients. Nausea is common before or after the event, and a feeling of heat or cold and profuse sweating are frequent accompaniments. A particular stimulus such as the sight of blood with vasovagal syncope, minor trauma, or being in a warm, crowded place often elicits the attack. Orthostatic syncope may follow prolonged standing or sudden change in posture. The family history may disclose similar events (107). Reflex syncope may be seen with coughing, swallowing, or micturition (108). Table 41.4 lists frequent causes of syncope. A few clonic jerks or incontinence occurring late in syncope complicate the picture, but a full history usually elucidates the cause (92). Physical examination frequently yields normal results, although supine and standing blood pressure measurements may implicate or rule out an orthostatic cause. There may be examination evidence of a drop in blood pressure (usually >20/10 mm Hg) within 3 minutes of standing, associated with syncope or presyncope. Sinus bradycardia on rapid standing is also highly suggestive of orthostatic hypotension. A search for arrhythmia and murmur is warranted, as cardiac causes of syncope are primarily obstructive lesions or arrhythmias not otherwise clinically evident (108,109). Syncope associated with ophthalmoplegia, retinitis pigmentosa, deafness, ataxia, or seeming myopathy mandates an urgent evaluation for heart block (Kearns–Sayre syndrome) (110).

Table 41.4 Causes of Syncope

Vasovagal	Fear
	Pain
	Unpleasant sights
Reflex	Cough
	Micturition
	Swallowing
	Carotid sinus pressure
Decreased venous return	Orthostatic
	Soldier syncope (standing at attention)
	With the Valsalva maneuver
Decreased blood volume	
No clear precipitating event	
Cardiac	Arrhythmia
	Obstructive outflow
Cerebrovascular insufficiency	
Familial	
Undetermined cause	

Electrocardiographic monitoring and echocardiography are frequently more valuable than electroencephalography in establishing the diagnosis. Tilt table testing may be helpful in this regard (111,112).

Narcolepsy and Cataplexy

Narcolepsy is a state of excessive daytime drowsiness causing rapid brief sleep, sometimes during conversation or play; the patient usually awakens refreshed. Narcolepsy also includes sleep paralysis (transient episodes of inability to move on awakening) and brief hallucinations on arousal along with cataplexy, although not all patients demonstrate the complete syndrome. Measurement of sleep latency through electroencephalogram recordings reveals the appearance of REM sleep within 10 minutes in narcoleptic patients. Narcolepsy may be treated with a stimulant drug (113–115).

Cataplexy produces a sudden loss of tone with a drop to the ground in response to an unexpected touch or emotional stimulus such as laughter. Consciousness is not lost during these brief attacks. Coexistent narcolepsy is common.

Basilar Migraine

Most common in adolescent girls, basilar migraine begins with a sudden loss of consciousness followed by severe occipital or vertex headache. Dizziness, vertigo, bilateral visual loss, and, less often, diplopia, dysarthria, and bilateral paresthesias, may occur. A history of headache or a family history of migraine is helpful in making the diagnosis. Of note, interictal paroxysmal EEG discharges may be seen in this population. Children may respond to classic migraine therapy or antiepileptic drugs (105,106,116,117). Due to vasoconstriction, ergot alkaloids and triptans are generally not recommended (89).

Tremor

An involuntary movement characterized by rhythmic oscillations of a particular part of the body, tremor, may appear at rest or with only certain movements. Consequently, it is occasionally mistaken for seizure activity, particularly when the movement is severe and proximal such as in the “wing-beating tremor” of Wilson disease or related basal ganglia disorders. Tremors disappear during sleep. Examination at rest and during activities, possibly by manipulating the affected body part while observing the tremor, usually can define the movement by varying or obliterating the tremor. The electroencephalogram is unchanged as the tremor escalates and diminishes (118).

Panic Disorders

Panic attacks may occur as acute events associated with a chronic anxiety disorder or in patients suffering from depression or schizophrenia. These attacks last for minutes to hours and are accompanied by palpitations, sweating, dizziness or vertigo, and feelings of unreality. The following symptoms also have been noted: dyspnea or smothering sensations, unsteadiness or faintness, palpitations or tachycardia, trembling or shaking, choking, nausea or abdominal distress, depersonalization or derealization, numbness or tingling, flushes or chills, chest pain or discomfort,

and fears of dying, aura, or losing control. An electroencephalogram recorded at the time of the attacks differentiates ictal fear and nonepileptic panic attacks (119).

Panic disorders involve spontaneous panic attacks and may be associated with agoraphobia. Although they may begin in adolescence, the average age at onset is in the late 20s. Psychiatric therapy is indicated (120).

Acute fugue, phobias, hallucinations, and autistic behaviors may seem to represent seizures; however, associated features and EEG findings usually distinguish these behavioral disorders from epilepsy.

DISEASE-RELATED BEHAVIORS

Several disease states include recurrent symptoms that are misdiagnosed as epilepsy. Episodes of cyanosis, dyspnea, and unconsciousness followed by a convulsion may occur in as many as 10% to 20% of children with congenital heart disease, particularly those with significant hypoxemia. In "tet" spells, young children with tetralogy of Fallot squat nearly motionless during exercise as their cardiac reserve recovers (121).

Children and adults with shunted hydrocephalus may have seizures, although these are not usual (122). Obstruction associated with the third ventricle or aqueduct may cause the bobble-head doll syndrome (two to four head oscillations per second) in mentally retarded children (123). In hydrocephalic patients treated with ventricular shunting, acute decompensation may increase seizure frequency or give rise to symptoms misdiagnosed as seizures. So-called hydrocephalic attacks, characterized by tonic, opisthotonic postures frequently associated with a generalized tremor, are caused by increased intracranial pressure and herniation. Head tilt or dystonia may also indicate increased intracranial pressure, a posterior fossa mass, or a Chiari malformation. Urgent evaluation for malfunctioning shunt or increased intracranial pressure is warranted with any of these symptoms.

The episodic nature of periodic paralysis may lead to misidentification of the symptoms as epilepsy. Familial and sporadic cases typically are associated with disorders of sodium and potassium metabolism. Acetazolamide is useful in some forms of the disorder (124).

Cerebrovascular disorders of various types and etiologies may have transient recurrent symptoms and thus may be confused with epilepsy. The exact clinical presentation of cerebrovascular disorders in both children and adults depends primarily on the size and location of the brain lesion and on the etiology of the vascular compromise (125,126). Transient ischemic attacks, episodes of ischemic neurologic deficits lasting <24 hours, are typically caused by small emboli or local hemodynamic factors that temporarily prevent adequate brain perfusion. Symptoms begin suddenly following an embolus, with the deficit reaching maximum severity almost immediately. Function returns several minutes or hours after the onset of symptoms. Symptomatology is characteristically separated into carotid artery syndromes with symptoms of middle cerebral artery, anterior cerebral, and lacunar deficits. The latter are most common in adults with long-standing hypertension and may be characterized by pure motor hemiparesis or monoparesis and isolated hemianesthesia. Vertebrobasilar syndromes, especially transient ischemic attacks, may be mistaken for epilepsy because of recurrence and duration and may present with ataxia, dysarthria, nausea, vomiting, vertigo, and even coma. Homonymous hemianopsia may result from posterior cerebral artery occlusion. The subclavian steal syndrome is associated with stenosis or occlusion of the subclavian artery proximal to the origin of the vertebral artery. Retrograde flow through the vertebral artery into the poststenotic subclavian artery may occur. Vertigo, ataxia, syncope, and visual disturbance occur intermittently

when blood is diverted into the distal subclavian artery. Vigorous exercise of the arms tends to produce symptoms. The brachial and radial pulses in the affected extremity are absent or diminished.

The etiology of cerebral embolism includes cardiopulmonary disorders, traumatic injuries to blood vessels like dissection, and congenital or inflammatory arterial disorders. Besides blood products, air emboli, foreign body embolism with pellets, needles, or talcum, or fat emboli may be noted. In adults, carotid and vertebrobasilar occlusion with or without embolization is typically associated with systemic cerebrovascular disease. In younger black patients, sickle cell disease always must be considered as an etiology of cerebrovascular symptoms. It is sometimes difficult to distinguish between transient ischemic attacks and brief seizures in these patients who have multiple areas of infarction. Because strokes may occur on the basis of both large- and small-vessel abnormalities associated with sickle cell disease, symptoms may vary.

Transient global amnesia deserves special mention as a symptom that may or may not be related to epilepsy. Multiple authors argue that it is either of vascular origin or related to seizures. Recurrent attacks may occur in up to 25% of cases. Attacks, however, last hours rather than minutes, and the most frequently observed EEG changes are small sharp spikes of questionable significance (127).

CONCLUSIONS

A variety of paroxysmal events may be confused with epilepsy. A careful medical history with description of events before, during, and after the spell; age of onset; time of occurrence; and clinical course aided by a thorough physical examination frequently clarify the nature of these episodes. Home video recordings of the episodes may be extremely helpful. The routine or specialized use of electroencephalography or polysomnography provides further characterization. Dual diagnoses are possible. Abnormal findings on neurologic examination are not uncommon in patients with nonepileptic events. Previously noted interictal EEG abnormalities should be reviewed to modify the interpretation of false-positive records (128).

PART IV ANTIEPILEPTIC MEDICATIONS

SECTION A GENERAL PRINCIPLES OF ANTIEPILEPTIC DRUG THERAPY

CHAPTER 42 ANTIEPILEPTIC DRUG DEVELOPMENT AND EXPERIMENTAL MODELS

MELISSA L. BARKER-HALISKI AND H. STEVE WHITE

ANIMAL MODELS FOR ANTIEPILEPTIC DRUG DISCOVERY

All of the currently available antiepileptic drugs (AEDs) approved for the treatment of epilepsy have been identified and developed as a result of their ability to block seizures in one or more of the available rodent seizure and epilepsy models. Since 1993, over a dozen new AEDs have been made available for patients with epilepsy. These new drugs have provided increased seizure control, appear to be better tolerated, and display fewer drug–drug interactions. Unfortunately, seizures remain uncontrolled in a substantial percentage of the patient population, and thus there continues to be a significant unmet need for the patient with refractory epilepsy. As such, efforts continue in the hope that more efficacious and safer AEDs will be identified for this population.

At the present time, a new drug for the symptomatic treatment of epilepsy, regardless of mechanism, must always demonstrate some degree of efficacy in one or more animal seizure models before it proceeds down the drug development pathway and is ultimately validated in well-controlled double-blinded randomized clinical trials. Typically, a compound will be evaluated for its ability to block convulsive seizures in models of generalized and focal seizures. This approach provides the necessary proof of concept to support the further development of a new chemical entity. However, as there remains a large population of patients who are refractory to current AEDs, new animal models of epilepsy and screening approaches are being applied in the early identification and characterization of potential AEDs. Previous reviews discuss the advantages and limitations of the various strategies in greater detail (1–3). This chapter briefly reviews the approach that is often employed in the early identification and characterization of the antiseizure profile of an investigational drug, followed by a discussion of efforts to develop new models of refractory and acquired epilepsy in the drug screening process.

In Vivo Testing

It is important to note that no single laboratory test will establish the presence or absence of anticonvulsant activity or fully predict the clinical utility of an investigational AED. Nonetheless, the animal models that have been developed and utilized since phenytoin (PHT) was first identified using the maximal electroshock (MES) seizure model (4), do possess varying degrees of face validity. Historically, the successful identification of PHT using the cat MES test by Merritt and Putnam (4) and its subsequent acceptance as an effective drug for the management of human generalized seizures

with tonic components provided the validation required to consider the MES test as a useful model of human generalized seizures with tonic–clonic components. In addition to the MES test, the subcutaneous pentylenetetrazol (sc PTZ) test, and the various forms of kindling represent two other important in vivo model systems that have played a key role over the last 40 years in the early identification and characterization of AEDs that may be useful for the treatment of generalized and focal seizures (1,5,6).

ASSESSING ADVERSE EFFECTS IN ANIMALS

For the patient with refractory epilepsy, the clinical utility of currently available AEDs is limited in a large part by a lack of efficacy at doses that do not produce dose-limiting side effects. With respect to assessing central nervous system–related adverse effects, preclinical testing includes behavioral observations, activity measurements, and models evaluating the potential impact of an AED on overt motor function. Among the latter models, the rotarod test is commonly used to quantify a therapeutic index (TI) (7). The extent to which an AED impairs the ability of an animal to remain on a rotating rod is determined at various doses. A TI can then be quantified by comparing the median toxic (TD_{50}) dose of an AED that impairs performance on the rotarod against the median effective (ED_{50}) antiseizure dose in the same species.

The validity of using normal animals in an attempt to predict adverse effects in epilepsy patients has been brought into question ever since Loscher and Honack (8) demonstrated that N-methyl-D-aspartate (NMDA) antagonists produced more ataxia, hyperactivity, and stereotypic behaviors in amygdala-kindled rats than they did in normal rats. This finding was subsequently confirmed in humans when the potential antiepileptic properties of the competitive NMDA antagonist D-CPPene was tested (9). D-CPPene was well tolerated in healthy volunteers in doses up to 2000 mg/day; whereas doses of 500 to 1000 mg/day induced severe adverse effects such as confusion, hallucination, ataxia, impaired concentration, and sedation when used as add-on therapy in eight patients with refractory complex partial epilepsy. Interestingly, similar doses of D-CPPene in healthy volunteers and epilepsy patients produced higher exposure levels in the healthy volunteers versus epilepsy patients. These results suggest that pharmacodynamic factors were responsible for the severe adverse effects observed in patients with epilepsy. The enhanced susceptibility of fully amygdala-kindled rats to the behavioral adverse effects of NMDA antagonists has also been observed with several AEDs (10). Thus, this phenomenon appears to represent a permanent reactivity specific for limbic kindling because it has not been observed after chemical kindling (11). Collectively, these findings suggest that the neuronal substrate is altered in the epileptic brain in such a way that it leads to a worsened adverse effect profile of AEDs. These findings underlie the importance of using fully limbic kindled animals (or animals with spontaneous seizures) for assessing the adverse effects of an AED. However, a highly promising AED should not necessarily be discarded because of adverse effects observed in an animal model. This information should be used to guide decisions regarding the advancement of one analog over another when testing a series of structurally related molecules.

In addition to the screening for overt motor impairments that can be used to calculate TI, a novel compound should also be assessed on the basis of off-target liabilities on behavioral and cognitive performance. Historically, many AEDs have been associated with significant adverse cognitive effects (2,3). There is now a concerted effort to develop novel treatments that can not only bring symptomatic seizure relief but also do so without conferring adverse cognitive effects either from or exacerbated by the investigational drug itself (2,12). Moreover, efforts to develop therapies that can

concurrently address the comorbidities of epilepsy are also under way. Comorbidities of epilepsy can include cognitive impairment, depression, suicidality, anxiety, attention deficits, and migraine; all of which can often be as detrimental to quality of life as the seizures themselves. In fact, comorbidities of epilepsy are one of the National Institutes of Health (NIH) Benchmark areas for research in epilepsy. Thus, drug screening and testing efforts to develop new treatments for epilepsy must also address developing treatments for comorbidities associated with epilepsy (12), and not just those that arise as side effects from AEDs. Fortunately for the epilepsy research community, many of the animal models currently available for drug screening and testing also present with behavioral and cognitive abnormalities, such as the post–status epilepticus models of temporal lobe epilepsy discussed below (13). The mouse model of Dravet syndrome also presents with autistic-like behaviors and cognitive deficits that can be rescued with low-dose treatment with clonazepam (14). Thus, future efforts in drug screening and testing should attempt to not only understand the effects of a novel compound on the seizure severity and presentation but also examine the potential for a compound to affect comorbidities present in the animal model under scrutiny (12–14). Such efforts may likely prove fruitful in the improvement of patient drug adherence, quality of life, and seizure control should an investigational compound ultimately progress to clinical use.

STRATEGIES FOR ANTIEPILEPTIC DRUG DISCOVERY

Three different approaches are routinely employed in the identification of new AEDs. These include (i) random screening of new chemical entities for anticonvulsant activity; (ii) structural modifications of existing AEDs; and (iii) rational, target-based drug discovery. Over the decades, each of these approaches has contributed to the discovery of new AEDs. Regardless of the approach by which a new drug is synthesized, the first proof-of-concept study almost always involves testing it in one or more of the animal models described above; for example, the MES, sc PTZ and/or kindling model. With the exception of levetiracetam, all of the currently available AEDs (and those currently in development) have been found to possess activity in one or more of these models. A further evaluation found levetiracetam to possess anticonvulsant properties in the amygdala-kindled rat and to display a marked and persistent ability to inhibit kindling acquisition (15–17). Levetiracetam was also found to be active in a variety of genetic animal models of epilepsy, for example, epilepsy-like mice (18), the audiogenic seizure–susceptible rat, and the Genetic Absence Epileptic Rat of Strasbourg (GAERS), a highly useful model of spike–wave seizures (19). Levetiracetam was also shown to be active in the mouse 6-Hz seizure model (20).

The ultimate development of LEV illustrates the limitations of relying solely upon the use of acute seizures evoked by MES and sc PTZ in normal animals as a valid screening procedure to identify drugs for a disease that is characterized by a chronic network hypersynchrony and spontaneous seizures. It is becoming clear that these "traditional models," such as the MES and sc PTZ tests, may only be able to identify drugs that share characteristics with other, currently available AEDs, thereby likely not providing much improvement in treating the refractory patient population (21). Thus, to usher in a new era of drug discovery, it is important to use a battery of models during random screening of new chemical entities that include animal models with (i) an acquired epilepsy, kindling-induced hyperexcitability, or alteration in seizure threshold; (ii) induced or natural mutations associated with an altered seizure threshold or spontaneous seizure expression; and (iii) new models

of pharmacoresistant epilepsy to address the needs of the therapy-resistant patient population (22). This does not imply that the acute seizure models are of little value. Fortunately for the patient with epilepsy, these models have yielded several drugs that have proven to be effective for the treatment of their seizures.

MODELS OF PHARMACORESISTANCE

The models summarized in Table 42.1 have been used successfully to identify effective therapies for human epilepsy. Clinical experience has demonstrated that they are effective for a large fraction of the patients with focal and generalized seizures. Unfortunately, as mentioned above, there still remains a substantial need for the identification of therapies for the patient with refractory seizures. To this point, one might argue that the acute models summarized in Table 42.1 are not predictive of efficacy in those patients with refractory epilepsy. Thus, identification and characterization of one or more model systems that could predict efficacy in the pharmacoresistant patient is an area of active pursuit by the epilepsy research community (2).

Table 42.1 Correlation Between Anticonvulsant Efficacy and Clinical Utility of Antiepileptic Drugs in Experimental Animal Models

Experimental model	Generalized seizures with tonic and/or clonic components	Myoclonic/ generalized absence seizures	Generalized absence seizures	Focal seizures
MES (tonic extension) (1)	CBZ, PHT, VPA, PB (FBM, GBP, LCM, LTG, PGB, RUF, TPM, ZNS) (EZG, PRL)			
Sc PTZ (clonic seizures) (1)		ESM, VPA, PB[a], BZD (FBM, GBP, PGB, RUF, TGB[a], VGB[a]) (EZG, PRL)		
Spike–wave discharges[b]			ESM, VPA, BZD (LTG, TPM, LVT)	
Electrical kindling (focal seizures)				CBZ, PHT, VPA, PB, BZD (FBM, GBP, LCM, LTG, TPM, TGB, ZNS, LVT, VGB) (EZG, PRL)
PHT-resistant kindled rat (24,25)				(LVT, GBP, TPM, FBM, LTG)
LTG-resistant kindled rat (24–26)				VPA (EZG)
6 Hz (44 mA) (20)				VPA (LVT)

BZD, benzodiazepines; CBZ, carbamazepine; ESM, ethosuximide; EZG, ezogabine; FBM, felbamate; GBP, gabapentin; LTG, lamotrigine; LVT, levetiracetam; PB, phenobarbital; PHT, phenytoin; LCM, lacosamide; PGB, pregabalin; PRL, perampanel; RUF, rufinamide; TGB, tiagabine; TPM, topiramate; VPA, valproic acid; ZNS, zonisamide; VGB, vigabatrin.

[a]PB, TGB, and VGB block clonic seizures induced by sc PTZ but are inactive against generalized absence seizures and may exacerbate spike–wave seizures.

[b]Data summarized from GBL, GAERS, and lh/lh spike–wave models (16).

[ ], second-generation AED; ( ), third-generation AED.

At the present time, there are a number of potentially interesting model systems of therapy

resistance available. Models of "pharmacoresistant" epilepsy should meet certain criteria; that is, "pharmacoresistance" can be defined as persistent seizure activity that does not respond to monotherapy at tolerable doses with at least two currently available AEDs (3). Ideally, it can be hoped that any proposed model will lead to the identification of a new therapy that will ultimately be highly effective in humans resistant to existing AEDs. In recent years, a number of in vivo model systems have been characterized that display a phenotype consistent with pharmacoresistant epilepsy and are the subject of the discussion below. These models include the PHT-resistant kindled rat (23,24), the LTG-resistant kindled rat (25–28), the 6-Hz psychomotor seizure model of partial epilepsy (20), and models of temporal lobe epilepsy (29). All of these models have some utility when attempting to differentiate an investigational drug's antiseizure profile from existing AEDs. Moreover, more emphasis may be placed on the value of these models for screening in the future. At the present time, many investigational AEDs are routinely evaluated in the LTG-resistant kindled rat and 6-Hz mouse model (3,25,26). Because it is not known whether efficacy in any of these models will yield a drug candidate that proves to be highly effective in the patient with refractory epilepsy, a continued effort should be made to employ as many novel models as possible in the evaluation of an investigational AED.

The Lamotrigine-Resistant Kindled Rat Model

Kindling is a well-established experimental model of focal seizures with generalized components. Over the years, Loscher et al. have conducted extensive pharmacologic evaluations in the kindled rat model. They were among the first to demonstrate that AEDs were less effective against the fully expressed kindled seizure than were MES-induced generalized tonic extension seizures (23,30,31). Moreover, Loscher (23) developed the PHT-resistant model, which demonstrated that pharmacoresistant kindled rats could be effectively applied to screening novel compounds. In addition to the PHT-resistant model, the LTG-resistant kindled rat model of partial epilepsy is now available and routinely used to screen investigational compounds (29). Perhaps most important when considering the application of the LTG-resistant kindled rat model to drug screening is the observation that LTG-resistant rats are also refractory to CBZ and PHT, but not VPA or the KCNQ2 ($Kv_{7.2}$) activator EZG (25–27). In this regard, the LTG-resistant kindled rat can serve as an early model of drug-resistant epilepsy to differentiate novel AEDs from PHT, LTG, and CBZ.

The Low-Frequency (6 Hz) Electroshock Seizure Model

In many respects, the 6-Hz seizure model offers many of the same advantages of the MES test. Like the MES test, the 6-Hz seizure can be acutely evoked using standard corneal electroshock. Moreover, it is a high-throughput model and requires minimal technical expertise. The main difference between the 6-Hz and MES tests is the frequency (6 Hz vs. 50 Hz) and duration (3 seconds vs. 0.2 seconds) of the stimulation employed. The low-frequency, long-duration stimulus results in a seizure that is characterized by immobility, forelimb clonus, Straub tail, and facial automatisms and is thought to more closely model human focal seizures (20,32). The finding that LEV was found to be active at a specific stimulus intensity where other AEDs display little to no efficacy illustrates the use of the 6-Hz model as a screen for novel compounds, particularly when one considers that LEV was inactive in the acute seizure models such as the MES and sc PTZ seizure tests (7). Thus, the incorporation of a simple acute screen that would minimize the chances of "missing" a unique drug like LEV is an

important consideration when setting up a testing protocol to evaluate investigational AEDs.

Models of Temporal Lobe Epilepsy

Models of refractory mesial temporal lobe epilepsy (mTLE) are now important tools in the differentiation of investigational AEDs. A concerted effort has been made by the epilepsy research community to develop models of therapy-resistant epilepsy to identify potential treatments for the approximately 30% of patients refractory to currently available AEDs. As such, several new mTLE models are in development; any of which have the potential to provide significant clinical benefit (13,30,33). These chronic epilepsy models differ significantly from the more traditional animal models in that seizures are spontaneously evolving and not evoked. Moreover, these models fulfill an important characteristic of the ideal model system; that is, they display spontaneous recurrent seizures (13,30). For example, the post–status epilepticus rat model of mTLE, provides an investigator with the opportunity to evaluate the efficacy of a given treatment on seizure frequency, seizure type (i.e., focal or generalized), and the liability for tolerance development following chronic treatment. Unfortunately, drug trials in animal mTLE models take on another level of complexity. The trials are extremely laborious and time-consuming and require a greater level of technical expertise. As such, there have only been a few pharmacologic studies conducted to date (34–38). Having said this, the advantages of mTLE models in the ability to differentiate a given compound from the established AEDs is well worth the investment. Furthermore, acute brain sections collected from mTLE models also present with spontaneous recurrent epileptiform discharges that show varying degrees of responsiveness to drug treatment (39,40); thereby expanding the screening and testing capabilities of these epilepsy models. All of these models are being used with increasing frequency in the search for novel AEDs. Unfortunately, none of these models have been validated clinically and thus, it is too early to say whether any of them will lead to the identification of a next-generation AED. Importantly, the use of these models has led to the development of novel drug-testing protocols in animals that more closely resemble clinical protocols (30).

NEW APPROACHES TO ANTIEPILEPTIC DRUG DISCOVERY

While established models and models of pharmacoresistance will continue to provide invaluable information in the screening and identification of novel treatments for epilepsy, a substantial need remains to develop new and unique models of epilepsy that can facilitate efforts to identify the next generation of clinical treatments. With the exception of the mTLE models described above, many of the available acute seizure models are models of epileptic seizures rather than models of epilepsy. Thus, efforts to add models to the drug screening and testing repertoire should also attempt to identify models that more closely mimic the human epilepsy phenotype, rather than the seizures alone. Emerging evidence on the contributing factors underlying epileptogenesis as well as improved genetic approaches for drug screening and testing may ultimately provide previously drug-refractory patients with a palliative, if not curative, treatment.

Models of Acquired Epilepsy

Models of infection-induced or posttraumatic epilepsy are beginning to emerge as potentially useful

differentiation tools in the identification of new treatments for refractory epilepsy. Evidence suggests that inflammatory processes are up-regulated and may, in fact, be a contributing factor to epileptogenesis (41). Proinflammatory cytokines are highly expressed in various animal seizure models (38,41), and patients with epilepsy (42). Of note, human patients with viral infection–induced encephalitis who present with seizures during the acute infection period are up to 22 times more likely to develop spontaneous, unprovoked seizures than the general population (43). Therefore identifying and developing models that specifically target the pathogenic infection–induced inflammatory events contributing to epileptogenesis may ultimately prove to be useful in AED screening and testing. Additionally, identifying compounds to selectively target inflammation may be useful in posttraumatic (PTE) models of acquired epilepsies (44), as epilepsy associated with traumatic brain injury in humans is often drug refractory (45). It is also reasonable to believe that models of inflammation and acquired epilepsy will identify compounds with novel, and as yet unexplored, mechanisms of action that may prove effective in the refractory human epilepsy patient. Unfortunately, models of infection-induced seizures (s.f. (46)) and PTE models (s.f. (44)) remain largely underutilized in the early identification and characterization of investigational AEDs; moreover, much work is required to fully characterize the effects of currently available AEDs in these models. Needless to say, the availability of data from these and other emerging models with available AEDs will likely prove productive in the treatment of drug-refractory epilepsy patients.

Novel Genetic Screening Tools

Advances in our understanding at the molecular and genetic level have led to the development of vertebrate models with known genetic defects that resemble the human condition. Their availability to the general scientific community has provided greater insight into the role of various molecular targets in ictogenesis and epileptogenesis. Detailed pharmacologic characterization with existing AEDs is now possible using genetic models, such as the Scn1a+/- mouse model of Dravet syndrome (14). More recently, Baraban et al. (47,48) have pioneered drug screening and testing in the zebrafish (Danio rerio) as a potential high throughput system for identifying anticonvulsants using both chemoconvulsants and genetic mutations to model human epilepsies. The zebrafish model of Dravet syndrome (Scn1a mutants), for example, is responsive to stiripentol and valproate (47), both of which are used in the clinical treatment of Dravet's syndrome patients (49). Thus, high-throughput screening in this and other genetic, zebrafish models could provide an effective means to rapidly and cost-effectively identify potential investigational compounds for one or more of the genetic epilepsies (47), which could then be moved to more in-depth assessment in available mammalian models. Furthermore, these and other mutant animal models represent important tools for evaluating the therapeutic potential of an investigational drug in a model system that more closely approximates human genetic epilepsy. Mechanism- and target-specific drug discovery efforts in these genetic models may also likely prove useful in selectively targeting the causal pathways of human genetic epilepsies (2). To this point, genetic models will likely play an important role in efforts to develop personalized medicines for those patients with a known genetic mutation.

CONCLUSION

Currently, there are no known preventive treatments available and the treatment of epilepsy is purely symptomatic. The identification and characterization of an investigational AED relies entirely on the

use of a variety of animal seizure and epilepsy models. Those drugs that were discovered with this approach that displayed a favorable therapeutic window and showed no significant preclinical toxicity were advanced into clinical add-on epilepsy trials with patients with refractory partial seizures. Since 1993, many new therapies have been brought to the market for the treatment of epilepsy. Despite the success of this approach, as many as one in three patients with focal seizures still remain refractory to available AEDs. It is clear that there is a need to move beyond the conventional animal models and to explore other animal models and molecular targets by which neuronal hyperexcitability may be reduced. Levetiracetam demonstrated that a new therapy does not have to be effective in the traditional seizure models to be effective in the patient with epilepsy. Moreover, there is no a priori reason to believe that the truly novel AED that will demonstrate a substantial impact in the treatment of the patient with refractory epilepsy will have an anticonvulsant profile that resembles any of the available therapies, including levetiracetam. This implies that the scientist interested in developing a drug for this patient population will need to take a substantial risk when advancing a novel drug into a clinical trial. Only then will we likely find a therapy that provides the level of efficacy for which patients continue to hope.

CHAPTER 43 MECHANISMS OF ACTION OF ANTIEPILEPTIC DRUGS

MICHAEL A. ROGAWSKI AND JOSÉ ENRIQUE CAVAZOS

Antiepileptic drugs (AEDs) protect against seizures through interactions with a variety of cellular targets. By affecting the functional activity of these targets, AEDs suppress abnormal hypersynchronous activity in brain circuits, leading to protection against seizures. The actions on these targets can be categorized into four broad groups: (i) modulation of voltage-gated ion channels, including sodium, calcium, and potassium channels; (ii) enhancement of GABA inhibition through effects on $GABA_A$ receptors, the GAT-1 GABA transporter, or GABA transaminase; (iii) direct modulation of synaptic release through effects on components of the release machinery, including SV2A and α2δ; and (iv) inhibition of synaptic excitation mediated by ionotropic glutamate receptors, including AMPA receptors (Table 43.1). The ultimate effects of these interactions are to modify the bursting properties of neurons and to reduce synchronization in localized neuronal ensembles. In addition, AEDs inhibit the spread of abnormal firing to distant sites. Some seizures, including typical generalized absence seizures, result from thalamocortical synchronization. AEDs effective in these seizure types interfere with the rhythm-generating mechanisms that underlie synchronized activity in the thalamocortical circuit. In this chapter, we consider each of the targets and discuss how AEDs affect the activity of these targets.

Table 43.1 Molecular Targets of Clinically Used AEDs

Molecular target	AEDs that act on target
Voltage-gated ion channels	
Voltage-gated sodium channels	Phenytoin, fosphenytoin,[a] carbamazepine, oxcarbazepine,[b] eslicarbazepine acetate,[c] lamotrigine, and lacosamide; possibly, topiramate, zonisamide, and rufinamide
Voltage-gated calcium channels	Ethosuximide
Voltage-gated potassium channels	Ezogabine
GABA inhibition	
$GABA_A$ receptors	Phenobarbital, primidone, and benzodiazepines including diazepam, lorazepam, and clonazepam; possibly, topiramate and felbamate
GAT-1 GABA transporter	Tiagabine
GABA transaminase	Vigabatrin
Synaptic release machinery	
SV2A	Levetiracetam
α2δ	Gabapentin, gabapentin enacarbil,[d] and pregabalin
Ionotropic glutamate receptors	
AMPA receptor	Perampanel
Mixed/unknown	Valproate, felbamate, topiramate, zonisamide, rufinamide, and adrenocorticotropin

[a]Fosphenytoin is a prodrug for phenytoin.

[b]Oxcarbazepine serves largely as a prodrug for licarbazepine, mainly S-licarbazepine.

[c]Eslicarbazepine acetate is a prodrug for S-licarbazepine.

[d]Gabapentin enacarbil is a prodrug for gabapentin.

Many AED targets are ion channels, most notably voltage- gated sodium and potassium channels and $GABA_A$ receptors. It is interesting to note that certain idiopathic epilepsy syndromes are believed to be the result of mutations in these same ion channels (see Chapter 4).

VOLTAGE-GATED ION CHANNELS

Voltage-Gated Sodium Channels

Voltage-gated sodium channels play an essential role in the initiation and propagation of action potentials in neurons. Neuronal depolarizations by a few millivolts, ordinarily as a result of synaptic activation of glutamate receptors (mainly AMPA receptors), activate sodium channels, causing opening of the channels and influx of sodium. The channels then inactivate within milliseconds. Influx of sodium ions during the brief time that sodium channels are open generates the depolarizing component of the action potential. Although the bulk of sodium channels inactivate, about 1% of the sodium current is noninactivating resulting in a small persistent sodium current (I_{NaP}), which is carried by the same channels as the fast transient current. I_{NaP} facilitates epileptic burst firing by reducing the threshold for action potential generation, sustaining repetitive firing, and enhancing depolarizing synaptic currents (1). Some AEDs, most notably phenytoin, inhibit I_{NaP}, which is believed to contribute to their efficacy (2).

Voltage-gated sodium channels are multimeric protein complexes, composed of a large α subunit that forms four subunit-like homologous domains (designated I to IV) and one or more smaller β subunits (3). The ion-conducting pore is contained within the α subunit, as are the elements of the channel that mediate its fundamental physiologic properties including rapid inactivation. There are nine voltage-gated sodium channels, designated $Na_v1.1$ to $Na_v1.9$. $Na_v1.2$ is the predominant form in brain neurons, but $Na_v1.1$ and $Na_v1.6$ are also expressed in the brain. Mutations in each of these channels have been associated with various genetic epilepsies (4).

AEDs that protect against seizures through an interaction with voltage-gated sodium channels are commonly referred to as “sodium channel blockers.” They are among the most frequently used drugs in the treatment of focal and primary generalized tonic–clonic seizures and include phenytoin, carbamazepine, lamotrigine, oxcarbazepine (as well as its active metabolite licarbazepine), and lacosamide. AEDs that interact with voltage-gated sodium channels exhibit a characteristic “use-dependent” blocking action so that they inhibit high-frequency trains of action potentials much more potently than they inhibit individual action potentials or firing at low frequencies. Because they also exhibit a “voltage dependence” to their blocking action, sodium channel–blocking AEDs are more potent at inhibiting action potentials that ride on a depolarized plateau potential as characteristically occurs in seizures. Thus, sodium channel–blocking AEDs preferentially inhibit seizure discharges in relation to normal ongoing neural activity. By virtue of their ability to inhibit the action potential invasion of nerve terminals, sodium channel–blocking AEDs inhibit the release of diverse

neurotransmitters including glutamate; whether this is responsible for the therapeutic activity of the drugs is uncertain (5).

The binding site on sodium channels for sodium channel–blocking AEDs is believed to overlap the binding site of local anesthetics, which is within the pore of the channel and is formed by the S6 segments of domains I, II, and IV. Sodium channel–blocking AEDs bind with higher affinity to this site when the channel is in the inactivated state, and, when such a drug is bound, the channel is stabilized in the inactivated state. When neurons are depolarized and firing rapidly, sodium channels spend a greater amount time in the inactivated state and are able to accumulate bound drug so that they become trapped in the inactivated state. This accounts for the use- and voltage-dependent blocking action that they exhibit. Phenytoin, carbamazepine, and lamotrigine are considered "classical" sodium channel–blocking AEDs. Lacosamide also is believed to exert its therapeutic effects by interacting with sodium channels (6). Unlike other sodium channel–blocking AEDs, lacosamide does not inhibit high-frequency repetitive spike firing on the time scale of 100s of milliseconds. It does, however, inhibit spike firing in long trains of spikes on the time scale of 1 to 2 seconds. It has been proposed that the very slow action of lacosamide is due to an enhancement of a distinct and poorly understood form of inactivation, referred to as "slow inactivation." However, an alternative explanation is that lacosamide binds more slowly to fast inactivated sodium channels than do the other sodium channel–blocking AEDs. In any case, the unusually slow development of block produced by lacosamide during high-frequency activity could allow lacosamide to better discriminate between seizure-like pathologic firing and normal network activity.

T-Type Voltage-Gated Calcium Channels

Low voltage-activated (T-type) calcium channels play a role in the intrinsic thalamocortical oscillations that underlie the spike-and-wave discharges of generalized absence seizures (7–9). There are three T-type Ca^{2+} channel isoforms encoded by separate genes, denoted as $Ca_v3.1$ (α1G), $Ca_v3.2$ (α1H), and $Ca_v3.3$ (α1I). All three T-type calcium channel isoforms are expressed in thalamocortical circuits (10). $Ca_v3.1$ is prominently expressed in thalamic relay neurons in the dorsal thalamus, which plays a key role in absence seizures; $Ca_v3.2$ and to a lesser extent $Ca_v3.3$ are prominently expressed in thalamic reticular neurons. All three T-type calcium channel isoforms are expressed in the cortex, with $Ca_v3.2$ mainly localized to layer V. In non-REM sleep, including during delta waves, sleep spindles, and K complexes, the thalamocortical circuit switches from a tonic to oscillatory mode of firing, but in absence epilepsy, this switching can occur inappropriately, even during wakefulness (11,12). T-type calcium channels in the thalamus and cortex contribute to the abnormal behavior of the circuit. These channels generate low-threshold spikes, leading to burst firing and oscillatory behavior (13). GABA-ergic neurons of the thalamic reticular nucleus are also critically involved in absence seizures as they hyperpolarize thalamic relay neurons, which deinactivate T-type calcium channels allowing the channels to generate burst firing and the propagation of spike-and-wave discharges in the thalamocortical circuit (14).

Ethosuximide, which is highly efficacious in the treatment of absence seizures but not other seizure types, seems to act by inhibition of T-type calcium channels in the thalamocortical circuit (15–17). At clinically relevant concentrations (20 to 40 μg/mL), some but not all investigators have observed a partial (20% to 30%) reduction of T-type calcium current by ethosuximide. However, studies with recombinant T-type calcium channels have confirmed that ethosuximide blocks all three

channel types (18). The block increases when the current is activated from more depolarized potentials and when T-type calcium channels are inactivated as especially occurs during high-frequency activation, so that the drug has selectivity for pathologic behavior in the thalamocortical circuit, which is associated with neuronal depolarization and inactivation of T-type calcium channels. Effects on other membrane currents, including I_{NaP} and calcium-activated potassium current, may contribute to the efficacy of ethosuximide in absence epilepsy (17). Remarkably, results in animal models indicate that early treatment with ethosuximide can have disease-modifying (antiepileptogenic) effects, causing a persistent reduction in seizures and mitigation of behavioral comorbidities (19,20). These actions may be caused by epigenetic modifications. A study showing that children with absence epilepsy who receive ethosuximide are more likely than those who receive valproic acid to achieve long-term remission is consistent with the disease-modifying actions observed in animal studies (21).

The efficacy of some other AEDs may also depend, at least in part, on actions at T-type calcium channels. Zonisamide, in addition to effects on voltage-activated sodium channels, may also block T-type calcium channels (11), thus accounting for its likely efficacy in absence epilepsy (22). Similarly, there is evidence that valproate, a drug of choice in absence epilepsy, may also inhibit T-type calcium channels (17).

K_V7 Voltage-Gated Potassium Channels

Voltage-gated potassium channels are a diverse and evolutionarily ancient group of ion channels that serve a variety of key functions in the nervous system. Opening of potassium channels drives the membrane potential toward a hyperpolarized level, which serves to repolarize depolarizing events (such as action potentials and synaptic potentials) and cause a generalized reduction in excitability. In 1998, the first genes for a human idiopathic epilepsy were identified (23). These genes, designated KCNQ2 and KCNQ3, encoded novel brain potassium channel subunits, $K_v7.2$ and $K_v7.3$, respectively, that are homologous to a previously identified cardiac potassium channel $K_v7.1$, encoded by KCNQ1 (LQT1). The novel brain potassium channels mediate the M-current, a potassium current that increases as the membrane potential in neurons approach action potential threshold. K_v7 channels, together with HCN (hyperpolarization-activated cyclic nucleotide-gated potassium channels) and KCa2/SK (small-conductance calcium-activated potassium channels), generate the medium after hyperpolarization, which is elicited by a burst of action potentials and serves to limit further firing (24). K_v7 potassium channels therefore contribute to spike- frequency adaptation and can be considered to serve as a "brake" on epileptic firing. The K_v7 family of potassium channels is now known to contain five members, including $K_v7.1$, which is expressed predominantly in the heart, and $K_v7.2$ to $K_v7.5$, which are expressed exclusively in the nervous system (25).

Ezogabine, which is efficacious in the treatment of partial seizures, acts as a positive modulator of the nervous system K_v7 potassium channels ($K_v7.2$ to $K_v7.5$) but does not affect the cardiac member of the family ($K_v7.1$). Of particular relevance to the antiseizure action of ezogabine is its action on the M-current, which is predominantly carried by channels composed of $K_v7.2$ and $K_v7.3$, although $K_v7.5$ alone or in combination with $K_v7.3$ also contributes (26,27). Ezogabine causes a hyperpolarizing shift in the activation of K_v7 channels such that more M-current is generated near resting potential. It also causes a change in the kinetics of single KCNQ channels to favor channel

opening, thus increasing the macroscopic M-current; ezogabine does not alter the single-channel conductance of individual K_v7 channels (28). Many K_v7 channels in the brain are believed to be $K_v7.2/K_v7.3$ heteromers, which are highly sensitive to ezogabine (EC_{50}, 1.6 μM) (27). Peak plasma levels of ezogabine range from 354 to 717 ng/mL (1.2 to 2.4 μM) (29), and plasma protein binding is 80% so that free plasma concentrations are estimated to be about 0.2 to 0.5 μM; brain concentrations are expected to be similar. Therefore, therapeutic concentrations likely only modestly potentiate the most sensitive K_v7 channels and do not affect less sensitive channels. The binding site for ezogabine in $K_v7.2/K_v7.3$ heteromers is in a pocket formed by the pore-lining S5 membrane segment of one subunit and the pore-lining S6 membrane segment of the neighboring subunit (30,31). Channel opening may expose the pocket, permitting binding of ezogabine, which stabilizes the open-channel conformation.

GABA INHIBITION

GABA, the neurotransmitter of local inhibitory interneurons, acts through $GABA_A$ receptors and $GABA_B$ receptors. $GABA_A$ receptors, which are Cys loop-type ligand-gated chloride channels, represent an important target for AEDs and will be considered here; $GABA_B$ receptors, which are heterodimeric G protein–coupled receptors that activate potassium channels and inhibit calcium channels, are distinct in structure and function from $GABA_A$ receptors and are not a target of any AED. Although only about one in five cortical neurons is GABA-ergic (32), these neurons play a critical role in controlling the firing rate and timing of principal (excitatory) neurons. In addition, they synchronize local neuronal ensembles and restrain the generation of abnormal epileptic behavior. Consequently, enhancement of GABA-ergic inhibition is a key mechanism of AED action.

$GABA_A$ Receptors

$GABA_A$ receptors are heteropentameric protein complexes localized to the postsynaptic membrane of inhibitory synapses where they mediate fast neuronal inhibition on a millisecond time scale. They are also located extrasynaptically where they respond to ambient GABA in the extracellular milieu and confer tonic (long-term) inhibition. There are 19 known $GABA_A$ receptor subunits (α1 to 6, β1 to 3, γ1 to 3, δ, ε, θ, π, and ρ1 to 3). However, the bulk (60%) of synaptic $GABA_A$ receptors are believed to have the α1β2γ2 configuration, and a considerable fraction of the remainder (15% to 20%) are α2β3γ2. Among the receptor subtypes that contribute to tonic signaling in the brain regions relevant to epilepsy are α4βxδ receptors, which are believed to mediate the tonic current in dentate granule cells and thalamocortical neurons, and α5-containing $GABA_A$ receptors in CA1 pyramidal cells (33).

Benzodiazepines, such a diazepam, lorazepam, and clonazepam, and barbiturates, such as phenobarbital, are AEDs that act on $GABA_A$ receptors as positive allosteric modulators. At higher concentration, barbiturates can directly activate $GABA_A$ receptors in the absence of GABA (34), whereas benzodiazepines cannot. Benzodiazepines are specific for synaptic $GABA_A$ receptors containing the γ2 subunit and act to allosterically modulate these receptors to increase the channel opening frequency resulting in enhanced synaptic inhibition. This confers a broad-spectrum anticonvulsant action. In most epilepsy syndromes, the specific cellular types that are involved in the

antiseizure activity of benzodiazepines are not known. However, in the case of absence epilepsy, it is believed that benzodiazepines desynchronize the thalamocortical oscillations underlying generalized spike-and-wave discharges by specific effects on α3-containing $GABA_A$ receptors in the thalamic reticular nucleus (35). Barbiturates, presumably because they are not specific for α3-containing $GABA_A$ receptors, are not active in absence epilepsy and may even aggravate absence seizures. In contrast to benzodiazepines, barbiturates do not appear to increase the frequency of GABA-induced chloride channel opening, but instead increase the channel open time. In addition to effects on $GABA_A$ receptors, barbiturates modulate other ion channel systems, including calcium and sodium channels, and these actions may contribute to therapeutic activity (36).

GAT-1 GABA Transporter

The action of neurotransmitter GABA is terminated by uptake into neurons and glial cell by membrane-bound GABA transporters, of which there are four types, termed GAT-1, BGT-1, GAT-2, and GAT-3. GAT-1 (encoded by the SLC6A1 gene), the predominant form in the forebrain (including the neocortex and hippocampus), is localized to GABA-ergic terminals as well as to glial processes near GABA synapses. Tiagabine is a highly selective inhibitor of GAT-1 in neurons and glia (37). Inhibition of GAT-1 by tiagabine suppresses the translocation of extracellular GABA into the intracellular compartment, thus raising extracellular GABA levels. Functionally, tiagabine prolongs GABA-mediated inhibitory synaptic responses, and the marked elevation in extracellular GABA it produces may lead to activation of extrasynaptic GABA receptors.

GABA Transaminase

4-Aminobutyrate aminotransferase (GABA transaminase), an enzyme that catalyzes the conversion of GABA and 2-oxoglutarate into succinic semialdehyde and glutamate, is responsible for the metabolic inactivation of GABA. Inhibition of GABA transaminase with vigabatrin (γ-vinyl GABA), an irreversible suicide inhibitor of the enzyme, leads to marked increases in brain GABA levels. Although the antiseizure action of vigabatrin is believed to reflect inactivation of GABA transaminase, how this occurs is not straightforward and does not appear to be due to an enhancement of inhibitory synaptic transmission. In contrast to the action of tiagabine, vigabatrin does not elicit larger or more prolonged $GABA_A$ receptor–mediated synaptic responses (38,39). Rather, preincubation of brain slices with vigabatrin irreversibly inhibited miniature and evoked inhibitory postsynaptic currents. Additional experiments suggested that the paradoxical effect resulted from a reduction in the GABA content of synaptic vesicles caused by GABA transaminase inhibition. In contrast to the effect on GABA-mediated synaptic transmission, vigabatrin caused an increase in nonsynaptic tonic $GABA_A$ receptor current. This steady current is believed to be mediated by the action of GABA in the extracellular milieu acting on extrasynaptic $GABA_A$ receptors. High levels of intracellular GABA cause a reversal of GABA transporters, resulting in a marked elevation in extracellular GABA, which is likely responsible for the increase in tonic $GABA_A$ receptor current. It can be concluded that vigabatrin causes divergent effects on synaptic and extrasynaptic GABA-mediated inhibition, with seizure protection resulting from a predominance of the extrasynaptic action. Interestingly, in the early period after administration of vigabatrin to animals, there is a reduction in seizure threshold, whereas the anticonvulsant actions become evident only later (40,41).

Thus, vigabatrin has a biphasic action with proconvulsant effects likely related to suppression of synaptic GABA-ergic neurotransmission and anticonvulsant effects due to spillover of GABA into the extracellular space and activation of extrasynaptic $GABA_A$ receptors. Interestingly, individuals with a rare genetic deficiency of GABA transaminase experience refractory seizures, supporting the view that inhibition of GABA transaminase is in fact the proconvulsant mechanism of vigabatrin (42).

SYNAPTIC RELEASE MACHINERY

SV2A

A variety of lines of evidence support the conclusion that SV2A, a membrane glycoprotein found in the secretory vesicles of neurons and endocrine cells and possibly immune cells, is the molecular target for levetiracetam (43,44). There is a strong correlation between the affinity of levetiracetam analogs for binding to SV2A and the potency of the analogs in several animal seizure models. Moreover, seizure protection conferred by levetiracetam and other SV2A ligands strongly correlates with the degree of SV2A occupancy in vivo. Finally, the anticonvulsant efficacy of levetiracetam but not valproate, which does not interact with SV2A, is reduced in $SV2A^{+/-}$ mice that have one copy of SV2A disrupted by gene targeting. The precise way in which binding of levetiracetam to SV2A leads to seizure protection is not understood.

Indeed, the function of SV2A itself is obscure. Among the various functions proposed are roles in calcium-dependent exocytosis, neurotransmitter loading/retention in synaptic vesicles, and synaptic vesicle priming, as well as transport of vesicle constituents. SV2A is one of three homologous of SV2 proteins that belong to the major facilitator superfamily of 12-transmembrane domain transporters. Despite substantial effort, no transport function of these proteins has been identified, although studies with protein tomography have found that SV2A can adopt two alternate conformations consistent with a transporter role (45). Interestingly, however, levetiracetam binding does not cause a large-scale conformational change in SV2A or lock a specific conformational state of the protein as would an inhibitor of transport. Apparently, the drug has a more subtle effect on the protein. Although the function of SV2A is still poorly defined, $SV2A^{-/-}$ knockout mice exhibit a lethal seizure phenotype demonstrating that SV2A in some way serves to restrain seizures.

A series of recent studies has examined the impact of levetiracetam on synaptic transmission in brain slice recordings (46). Although the drug had no effect on synaptic physiology with low-frequency activation, levetiracetam did reduce the synaptic release of both excitatory (glutamate) and inhibitory (GABA) neurotransmitters during high-frequency activation. The frequency dependence is compatible with the selective suppression of epileptic activity. Modulation of synaptic release is a common mechanism of many AEDs, including sodium channel blockers that indirectly inhibit release at both excitatory and inhibitory synapses by inhibiting action potential firing. It seems that drugs that suppress inhibition and excitation can effectively protect against seizures and they are not often proconvulsant. However, it is noteworthy that in some instances AEDs (notably phenytoin) can have proconvulsant effects.

α2δ-1

The gabapentinoids gabapentin and pregabalin act by binding to the α2δ-1 protein, which is an

accessory subunit of voltage-gated calcium channels (47,48). α2δ-1 is located heterogeneously in the brain, particularly at presynaptic sites on excitatory (glutamatergic) neurons. Dense expression is observed in areas relevant to epilepsy, including in excitatory hippocampal mossy fibers and in the neocortex and amygdala. In contrast, α2δ-1 has minimal expression in the thalamus, and it is noteworthy that gabapentinoids are not active in absence seizures, which as discussed above are dependent upon this brain structure. Four α2δ subunits have been identified, but gabapentinoids only bind to α2δ-1 and α2δ-2 owing to the presence of an RRR motif containing a critical arginine that is required for binding. Seizure protection conferred by gabapentinoids is eliminated in mice bearing a mutation in this motif (RRR mutated to RRA) in α2δ-1, demonstrating that α2δ-1 and not α2δ-2 is relevant for pharmacologic activity. Interestingly, deletion of α2δ-1 or α2δ-2 in mice is associated with absence epilepsy or enhanced seizure susceptibility (49,50).

The precise way in which binding of gabapentin and pregabalin to the α2δ-1 protein confers seizure protection is not well understood (51). Although some studies have found that the drugs inhibit calcium channel currents, most have not and it is generally believed that calcium channel inhibition is not the mechanism of action of gabapentinoids (52–54). Regardless of whether the drugs inhibit calcium channel function, they do seem to block the release of various neurotransmitters, including glutamate, and this may account for the antiseizure activity (55). There is some evidence that gabapentinoids cause internalization of calcium channels by reducing trafficking to the cell membrane (56,57). Whether this action could account for the rapid antiseizure effects of gabapentinoids in animal models is uncertain.

AMPA RECEPTORS

Perampanel is the first selective AMPA receptor antagonist approved for epilepsy treatment. Whereas $GABA_A$ receptors mediate fast synaptic inhibition, AMPA receptors are cation channels that serve as the main mediators of fast (millisecond time scale) synaptic excitation. It has been long appreciated that cascading excitation within networks of synaptically connected neurons is a key mechanism of epileptic synchronization, at least in the hippocampal CA3 region and possibly in other brain areas (58). Epileptic activity emerges from the network when GABA-mediated inhibition is deficient, and indeed chronic alterations in inhibition represent a leading hypothesis to explain some forms of epilepsy.

Fast synaptic excitation is elicited by the exocytotic release of glutamate from excitatory principal neurons, which diffuses across the synaptic cleft and interacts with ionotropic glutamate receptors (iGluRs) of the AMPA and NMDA types to generate excitatory postsynaptic potentials (EPSPs). Summation of EPSPs leads to the firing of action potentials by the postsynaptic neuron. AMPA receptors have a special role in epileptic activity as epileptic synchronization cannot occur when AMPA receptors are blocked. In contrast, kainate receptors, which are iGluRs that have a similar structure to AMPA receptors, do not have a similarly essential role as kainate receptor knockout does not interfere with seizure generation (59). NMDA receptors are thought to contribute to epileptiform activity, but the blockade of NMDA receptors is insufficient to abolish epileptiform discharges in many seizure models (60). Pharmacologic blockade of AMPA receptors has broad-spectrum anticonvulsant activity in in vitro and animal seizure models.

Perampanel is a potent noncompetitive antagonist of AMPA receptors that does not affect NMDA receptor responses and has no known affects on other ion channels or molecular targets at therapeutically relevant concentrations (61). Therapeutic blood levels are expected to result in brain

concentrations that would produce only low levels of inhibition of AMPA receptors. However, such low-level block of AMPA receptors is apparently sufficient to exert a clinical antiseizure action. Perampanel has a relatively low therapeutic window. Adverse central nervous system effects such as dizziness, irritability, and somnolence are common, particularly at higher-dose levels, emphasizing the importance of AMPA receptors in brain function.

MIXED/UNKNOWN ACTIONS

Valproate

Although valproate is one of the most valuable AEDs, the mechanism by which it protects against seizures is poorly understood. Valproate has multiple pharmacologic actions (62,63). Since it has been difficult to relate any one mechanism to the drug's broad spectrum of activity, it has been proposed that combined actions on several targets could account for its therapeutic properties. Although the actions of valproate on GABA systems are not straightforward, among the various pharmacologic effects that have been described, those related to GABA mechanisms are among the most likely to be relevant to valproate's antiseizure activity. For example, valproate increases the turnover of GABA, and this might be associated with enhanced synaptic or extrasynaptic inhibition. At high concentrations, valproate affects voltage-gated sodium channels, but recent studies in brain slice recordings have failed to provide support for sodium channel block as a relevant mechanism to explain clinical activity (64). Similarly, despite efficacy in absence epilepsy, there is little support for effects on T-type calcium channels. It is likely that valproate has pharmacologic actions relevant to its antiseizure activity that remain to be elucidated.

Felbamate

Felbamate, at concentrations within the therapeutic range, has been shown both to act as positive modulators of $GABA_A$ receptors and also to inhibit NMDA receptors (65). Felbamate potentiates GABA responses via an interaction with a site on the $GABA_A$ receptor that is distinct from the benzodiazepine recognition site. This action may be of relevance to felbamate's clinical activity. Although drugs that block NMDA receptors can exert antiseizure effects in certain animal models, there is doubt whether blockade of NMDA receptors is a useful strategy to treat epilepsy (66). Therefore, it is uncertain whether the NMDA receptor–blocking activity of felbamate is relevant to its clinical antiseizure activity.

Topiramate

As is the case for valproate and felbamate, the broad-spectrum anticonvulsant activity of topiramate is likely to result from mixed effects on several targets (67). Among topiramate's diverse pharmacologic actions, effects on voltage-activated sodium channels, $GABA_A$ receptor subtypes, AMPA or kainate receptors, and types II and IV carbonic anhydrase isoenzymes are potentially relevant to seizure protection. Unlike other AEDs, the effects on ion channels are unlikely to occur through direct modulation of channel gating. Rather, the pharmacologic actions of topiramate seem to be mediated indirectly, possibly through effects on channel phosphorylation.

The effects of topiramate on sodium channels occur at relatively low, therapeutically relevant concentrations and could be similar to the effects of other sodium channel–blocking AEDs (68). In addition to effects on fast sodium currents, topiramate, like phenytoin, blocks I_{NaP} at low concentrations. Effects of topiramate on $GABA_A$ receptors could contribute to the broad spectrum of activity of topiramate. Topiramate is not active in animal models, such as the pentylenetetrazol test, that are typically sensitive to drugs that positively modulate $GABA_A$ receptors. Nevertheless, the drug does have activity in an absence epilepsy model and can affect pentylenetetrazol threshold, which is consistent with effects on $GABA_A$ receptors. There is evidence that topiramate may preferentially modulate a subset of $GABA_A$ receptors and that drug sensitivity is dependent upon the β-subunit type (69).

Several authors have suggested that actions on fast glutamate- mediated excitatory neurotransmission could contribute to topiramate's antiseizure activity. In cultured neurons, the drug has been reported to inhibit responses to kainate, an agonist of AMPA and kainate receptors, leading to the conclusion that topiramate could be an antagonist of either AMPA or kainate receptors (70). Recently, kainate receptors have been found to be an unlikely target for an antiseizure agent (71). Whether actions of topiramate on glutamate-mediated neurotransmission contribute to its anticonvulsant activity remains to be determined.

The action of topiramate on carbonic anhydrase has been assumed not to contribute to its clinical efficacy because there is no cross-tolerance to the anticonvulsant activity of topiramate when tolerance occurs to the classical carbonic anhydrase inhibitor acetazolamide in mice. However, a recent review left open the possibility that carbonic anhydrase inhibition could, in part, play a role (67).

Zonisamide

There are some similarities between topiramate and zonisamide as they both contain a sulfur atom and both inhibit carbonic anhydrase. In addition, like topiramate, zonisamide may act on voltage-dependent sodium channels (72). Physiologic studies do not support an action on $GABA_A$ receptors. Unlike topiramate, there are reports that zonisamide can inhibit T-type voltage-gated calcium channels (73), which may account for its activity in absence epilepsy.

Rufinamide

The unique spectrum of clinical activity of rufinamide in the treatment of the Lennox–Gastaut syndrome suggests that it has a distinct mechanism of action (26). However, to date, rufinamide has only been shown to interact with voltage-gated sodium channels, and the effects are subtle. Relevant concentrations of the drug may, at least for some subunit isoforms, cause a depolarization in the activation voltage and slowing of recovery from inactivation, which would be expected to reduce neuronal excitability (74). Clearly, the effects on sodium channels cannot explain the special clinical activity of rufinamide.

Adrenocorticotropin

The mechanism of adreocorticotropin (ACTH) in the treatment of infantile spasms is not understood (75). ACTH stimulates glucocorticoid (cortisol) synthesis and release from the zona fasciculata of the

adrenal cortex. The cortisol could produce an antiinflammatory action or have some other action in the brain to influence infantile spasms. Indeed, glucocorticoids are well recognized to themselves have therapeutic activity in the treatment of infantile spasms; whether ACTH is truly superior remains to be demonstrated conclusively. One possible additional action of ACTH that could contribute to enhanced activity is stimulation of neurosteroid synthesis. In addition to its actions with respect to glucocorticoids, ACTH also stimulates deoxycorticosterone (DOC) release from the zona glomerulosa of the adrenal cortex. DOC is, in part, converted to the anticonvulsant neurosteroid tetrahydro-DOC, which is a positive allosteric modulator of $GABA_A$ receptors (76). It has been hypothesized that the tetrahydro-DOC could, at least in part, contribute to the ability of ACTH to terminate infantile spasms.

BASIS OF COMBINATIONAL TREATMENT

All clinically used AEDs protect against seizures in animal models as single agents. Studies with early AEDs suggested that the seizure protection conferred by drug combinations is simply additive (77). Since the use of more than one agent compounds the risk of side effects, these and other observations led to the recommendation that AEDs should be tried sequentially in monotherapy before combining agents. More recent experimental data suggest that combining drugs with complementary mechanisms of action might lead to synergism for efficacy (78). Observational studies of results obtained in clinical practice have shown that combining newer AEDs with different mechanisms of action may have greater effectiveness (a combination of efficacy and tolerability) than combining drugs with similar mechanisms of action (79). Consequently, an understanding of mechanism may impact clinical decision making in regard to the choice of drug combinations.

CHAPTER 44 PHARMACOKINETICS AND DRUG INTERACTIONS

GAIL D. ANDERSON

Pharmacokinetics is the study of the effect of the body on a drug. The pharmacokinetic parameters determine the relationship between an administered dose and the concentration of the drug in the body. The main pharmacokinetic parameters include absorption, distribution, metabolism, and excretion. Table 44.1 summarizes the pharmacokinetic parameters for the most commonly used antiepileptic drugs (AEDs). Pharmacodynamics is the study of the factors that relate to the efficacy and safety of the drug and determines the relationship between concentration and effect. The relationship between pharmacokinetics and pharmacodynamics is illustrated in Table Figure 44.1.

Table 44.1 Pharmacokinetic Parameters of AEDS

AED	F (%)	V_d (L/kg)	Protein binding (%)	$T_{1/2}$ (h)	Renal (%)	Routes of elimination hepatic isozymes involved	Active metabolite
Carbamazepine	70–80	0.8–2	75	12–17	<1	CYP3A4 (major), CYP1A2, 2C8	Yes
Clobazam	87	0.9–1.4	85–93	10–30	nk	CYP2C19, 3A4	Yes
Clonazepam	90	3.2	85	22–40	<1	CYP3A4	Yes
Eslicarbazepine[a]	—	nk	30	20–24	66	UGT1A4, UGT1A9, UGT2B4, UGT2B7, UGT2B17	No
Ethosuximide	>90	0.6–0.7	0	25–60	20	CYP3A4 (major), 2E1	No
Ezogabine	60	2–3	80	6–10	20–30	UGT, NAT2	Yes
Felbamate	>90	0.7–1.0	22–25	20–23	50	UGT, CYP3A4 (20%), 2E1	No
Gabapentin	30–60	0.85	0	5–9	>90	None	No
Lacosamide	100	0.6	<15	13	40	Not identified	No
Lamotrigine	98	0.9–1.3	55	12–60	<1	UGT1A4	No
Levetiracetam	100	0.5–0.7	<10	6–8	66	Amidase	No

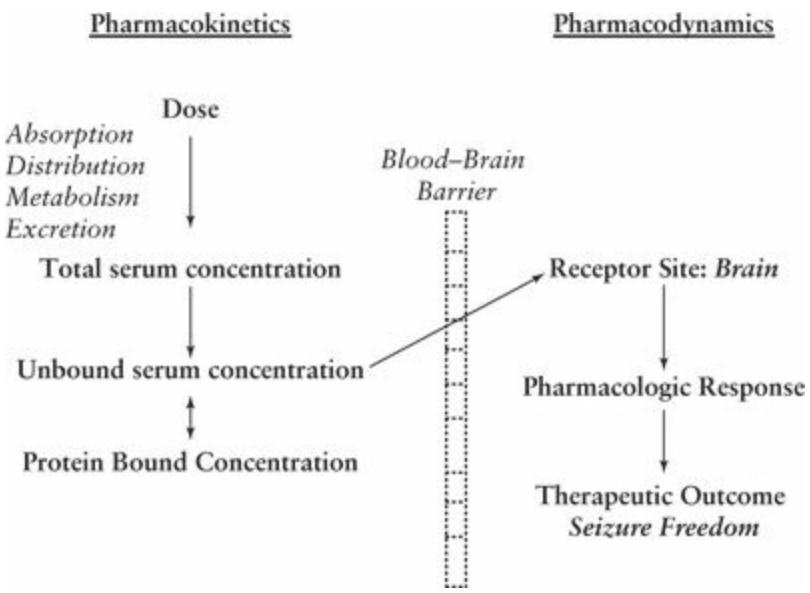

Figure 44.1. Relationship between pharmacokinetics and pharmacodynamics.

PHARMACOKINETIC PARAMETERS

Absorption

Absorption refers to the passage of the drug from its site of administration into the systemic circulation and is defined by the rate at which the drug leaves the site of administration and the extent at which it occurs. The rate of absorption is generally a first-order process, where the rate of absorption is dependent on the amount of drug. Some drugs can follow zero-order kinetics with a constant release of drug independent of the amount of drug. Bioavailability (F) is the amount of the administered drug that reaches the systemic circulation. F is dependent on the fraction absorbed through the gastrointestinal (GI) tract plus the fraction lost due to first-pass metabolism. After intravenous (IV) administration, bioavailability is equal to 1.0. Bioavailability for other non-IV formulations is determined by comparing the area under the concentration time curve (AUC) obtained after IV administration of a drug and the AUC obtained after administration by another route (i.e., oral). Most drugs are absorbed by passive diffusion in the GI tract where the rate of absorption is proportional to the drug concentration gradient across the barrier. Other drugs are absorbed by a combination of passive and active transport by proteins that can increase and/or decrease absorption depending on their location and whether they are influx or efflux transporters (1). Influx transporters that increase oral absorption include the organic anion transporters (OAT), organic cation transporters (OCT), organic anion–transporting polypeptides (OATP), peptide transporters, and large neutral amino acid transporter 1 (LAT). The oral absorption of gabapentin is dependent on active transport by the LAT (2). Conversely, efflux transporters, including P-glycoprotein (PGP), breast cancer resistance protein (BCRP), multidrug resistance proteins (MRP), and multidrug and toxin extrusion proteins (MATE), can limit drug absorption by increasing the excretion of drugs into the intestinal lumen from the systemic circulation (3). First-pass metabolism of a drug can occur in the GI tract and in the liver resulting in a decreased bioavailability. The fraction lost in the GI tract can be due to metabolism via hydrolysis, glucuronidation, sulfation, and oxidation, with cytochrome P450 3A4 (CYP3A4), the most dominant cytochrome P450 in the GI tract. Many drugs, including carbamazepine (4), are substrates of PGP and CYP3A4, both involved in decreasing oral absorption. Drugs that are high extraction ratio (ER) drugs can undergo significant first-pass liver metabolism.

Extended-release formulations are used to decrease the frequency of dosing for drugs with rapid elimination to improve convenience and compliance. For extended-release drugs, the rate-limiting step in drug elimination is the absorption rate of the drug and not the elimination rate. Use of an extended- release product can decrease the peak to trough fluctuation in serum concentrations and theoretically improve the therapeutic benefit of the drug by decreasing adverse events associated with higher peak concentrations. Other drugs are delayed release, for example, enteric-coated valproate. The enteric coating improves tolerability by decreasing absorption within the stomach and delaying absorption until the formulation reaches the intestines.

Bioequivalence is defined as chemical, when the drug meets the same chemical and physical standards; biologic, when the administered drug yields similar concentrations in blood; and therapeutic, when the drug provides equal therapeutic benefits in clinical trials. Generic drugs are chemically and biologically equivalent. Manufacturers do not have to prove therapeutic equivalence. Bioequivalence studies are single-dose, crossover studies done in healthy subjects comparing a generic product to the brand-name product. A generic product is considered bioequivalent if the mean AUC, maximum concentration (C_{max}), and the 90% confidence interval for each parameter are within 80% and 125% of the brand product. There has been a history of problems with generic versions of the older AEDs, specifically carbamazepine and phenytoin, as summarized in several reviews. Nuwer et al. (5) described three pharmacokinetic properties that predisposed the older AEDs to problems with their generic formulations: low water solubility, narrow therapeutic range, and nonlinear pharmacokinetics. The Biopharmaceutics Classification System (BCS) was designed to correlate a drug's aqueous solubility and permeability with the rate and extent of oral drug absorption (6). BCS can also provide an estimate for the likelihood of problems with generics. Drugs with high solubility and permeability are unlikely to demonstrate generic-related problems. Using the criteria, the historical problems with generic products of phenytoin and carbamazepine are predictable. The same criterion predicts that the majority of the new AEDs should not be predisposed to similar problems due to their high aqueous solubility and permeability. There have been reports from patients and neurologists of increased side effects or seizures on generic substitution (7). A recent evaluation of 141 generic AED products in 258 bioequivalence studies found that there was less than a 15% difference in the AUC and C_{max} compared to the reference product in 99% and 89% of the studies, respectively (8). The AED with the lowest solubility, oxcarbazepine, had the highest variability. In a systematic review of published 13 prospective and 7 retrospective studies, the highest quality studies (prospective, class I and II evidence), found that there was no significant difference between brand and generic formulations in safety and efficacy (9). In contrast, several retrospective studies of lower quality (class III evidence) did find a difference.

Distribution

Distribution is the process of reversible transfer of drug to and from the site of measurement. Central nervous system distribution is unique due to the blood–brain barrier (BBB). Lipid-soluble and unbound drugs have significantly higher distribution across the BBB than do water-soluble and protein-bound drugs. Both influx and efflux transport proteins alter brain distribution (3). Influx transporters involved in drug distribution include LAT, monocarboxylate transporter 1 (MCT1), and OATP. The brain uptake of gabapentin and pregabalin is dependent on the influx transporter, LAT1 (10). PGP and BRRP are the primary efflux transporters involved in transporting drugs from the brain to the blood and form an important part of the BBB. After initial reports of the overexpression of PGP

in patients with refractory epilepsy (11), it was hypothesized that increased expression of drug efflux transporters, specifically PGP and MRPs, reduce the concentration of AEDs in the brain resulting in pharmacoresistance (12). Although there is experimental evidence that phenytoin, phenobarbital, lamotrigine, and oxcarbazepine are PGP substrates, many of the other AEDs that are ineffective in refractory epilepsy are not substrates, suggesting there is not a major role of efflux transporters in pharmacoresistance (13,14).

The volume of distribution (V_d) is a measure of the apparent space in the body available to contain the drug. V_d relates the amount of drug in the body to the concentration of drug in the plasma. Therefore, the initial concentration (C_o) attained after administration of a single or bolus dose (D) is dependent on the V_d of the drug. The dose is based on either ideal or total body weight depending on the physiochemical characteristic of the drug. Lipophilic drugs will distribute into adipose tissue, and V_d will be dependent on total body weight. In contrast, for water-soluble drugs, V_d is dependent on ideal or lean body weight. V_d can be used to calculate both loading and bolus doses needed to achieve a desired concentration.

$$C_o = \frac{D}{V_d} \quad (1)$$

For the AEDs, albumin is the primary binding protein, with the exception of carbamazepine, which is bound to both albumin and alpha$_1$-acid glycoprotein (α_1-AGP). Albumin concentrations are decreased in the neonate, in the elderly, in hepatic and renal disease, during pregnancy, and after trauma. α_1-AGP is an acute-phase reactive protein and is decreased in neonates and increased in conditions of inflammation and trauma. For the majority of the drugs, protein binding is linear, and the percent unbound is a constant within the range of concentrations used clinically. Valproate is the one exception. Valproate is highly protein bound, and due to its high molar concentration, valproate saturates albumin-binding sites within the therapeutic range (15). An increase in the percent unbound as the dose increases results in measured total valproate concentrations increasing less than proportionally with increasing doses. Conversely, unbound valproate concentrations will increase linearly with increasing dose, and total valproate concentrations will no longer reflect unbound or active concentrations.

Elimination Processes

Drugs are eliminated by metabolism and/or excretion of unchanged drug by the kidneys or GI tract. Metabolism occurs predominantly in the liver with the GI, kidneys, lung and serum as other possible sites of metabolism. For the large majority of drugs, elimination is linear; the elimination rate is proportional to the amount of drug present. For drugs following linear kinetics, clearance is constant, and serum concentrations increase proportional with increasing doses. Unlike other drugs, phenytoin is unique in that its elimination is nonlinear due to saturation of metabolism within the normal dosage range. This saturation of metabolic processes results in a decreased clearance with increasing doses. For drugs like phenytoin with nonlinear elimination, serum concentrations will increase more than expected with increasing doses.

Clearance (Cl) is the most useful pharmacokinetic parameter for evaluating an elimination mechanism. It can also be used to estimate the average steady-state concentrations ($C_{ave,ss}$) attained

on multiple dosing. Physiologically, Cl is the loss of drug across an organ of elimination and is determined by the blood flow to the organ that metabolizes or eliminates the drug and the efficiency of the organ in extracting the drug. The efficiency is measured by the ER, defined as the ratio of the difference between the concentration into and out of the organ (C_{in} - C_{out}) to the concentration entering the organ (C_{in}). Cl is described in terms of the eliminating organ; hepatic clearance (Cl_H) and renal clearance (Cl_R) with total Cl determined by the sum of all the partial clearances. After multiple dosing, $C_{ave,ss}$ is dependent on the dose/interval (D/τ), Cl, and F (Eq. (2)).

$$C_{ave,ss} = \frac{F \cdot D/\tau}{Cl} \quad (2)$$

The elimination half-life ($T_{1/2}$) is the time required for the serum concentrations to decrease by 50% and is independent of dose. As shown in Eq. (3), $T_{1/2}$ is dependent on the Cl and V_d. It takes five $T_{1/2}$s to reach steady-state concentrations with multiple dosing and to eliminate greater than 95% of the drug on discontinuation.

$$T_{1/2} = \frac{0.693 \cdot V_d}{Cl} \quad (3)$$

Excretion

The renal excretion of unchanged drug and metabolites includes the processes of glomerular filtration (GFR), active tubular secretion, and passive reabsorption. The major transporter involved in renal secretion of drugs are OAT, OCT, PGP, and MRP (3). For drugs that are predominantly excreted unchanged in the urine, renal function can be assessed using the serum creatinine (SCR) to estimate creatinine clearance (CrCl) or GFR (eGRF). The Cl of creatinine is dependent on GFR and tubular secretion and is greater than GFR. The relationship between a drug's Cl and CrCl (or eGFR) can be used to estimate doses regiment needed to attain therapeutic concentrations. For most drugs that are significantly excreted unchanged in the urine, the relationship between Cl and CrCl (or eGFR) is linear with the y-intercept reflecting the nonrenal portion of the Cl. CrCl can be estimated using the Cockroft–Gault equation (16), the modified diet in renal disease (MDRD) equation (17), or the chronic kidney disease epidemiology (CKD-EPI) (18). The Cockroft–Gault equation estimates CrCl and requires knowledge of the patients' age, sex, and lean body weight (LBW). The MDRD equation was developed in 1070 patients with chronic renal failure. More recently, the CKD-EPI method was developed using a cross-sectional analysis with pooled data obtained from research studies and clinical population of 8254 patients with measured GFR. The CKD-EPI method performs better at higher GFR. The MDRD and CKD-EPI equations estimate GFR, do not require information on LBW, and also take into account ethnic differences in renal function. The majority of clinical laboratories in the United States were reporting eGFR with a measured SCR using the MDRD equation in 2008. More recently, the CKD-EPI is now used by QUEST and LabCorp, the two largest laboratory service providers in the United States (19). For the majority of the currently marketed drugs, the Cockcroft–Gault method was used to estimate renal function and to determine the relationship between CrCl and Cl (or Cl/F) to recommend dosing guidelines. As clinical laboratories are reporting eGFR, Park et al. evaluated data in the FDA database for 26 approved drugs that require renal dosage adjustment to determine if the MDRD equation could be used interchangeable with the Cockcroft–Gault (20). Only

8% of the dosage recommendations were changed to a different dosage class if the MDRD determined eGFR adjusted for BSA (20). Therefore, the eGFR can be used to guide drug dosing.

Excretion of drugs into breast milk can occur during lactation. The dose of a drug that the infant receives during breast-feeding is dependent on the amount excreted into the breast milk, the daily volume of milk ingested, and the average plasma concentrations of the mother. The physiochemical properties of a drug will determine how much of the drug will be excreted into the breast milk, including its lipophilicity and protein-binding and ionization properties. The milk-to-plasma concentration ratio has large inter- and intrasubject variability and is often not known. In contrast, protein binding is usually known, and knowledge of the protein-binding properties of a drug can provide a quick and easy tool to estimate exposure of an infant to medication from breast-feeding. Based on an extensive literature review of case reports that included infant concentrations from breast-fed infants exposed to maternal drugs (21), measurable concentrations of drug in the infant did not occur for drugs that were at least 85% protein bound, if there was no placental exposure immediately prior to or during delivery.

Metabolism

Metabolic reactions are primarily catalyzed by the cytochrome P450 (CYP) and UDP-glucuronosyltransferase (UGT) enzymes. However, the second- and third-generation AEDs are also metabolized by a variety of other non-CYP/UGT enzymes (Table 44.1). CYPs are a family of multiple enzymes with the individual isozymes being composed of three major families (CYP1, CYP2, and CYP3). Seven primary isozymes are involved in the hepatic metabolism of most drugs: CYP1A2, CYP2A6, CYP2C8/9, CYP2C19, CYP2D6, CYP2E1, and CYP3A4. The most abundant isozyme, CYP3A4, which accounts for approximately 30% of the total hepatic CYP, has the broadest substrate specificity and is involved in the metabolism of more than 50% of all drugs. The UGTs are family of enzymes that catalyze the transfer of a glucuronic acid moiety from a donor cosubstrate UDPGA. The activity of the metabolic enzymes is dependent on genetic, physiologic, and environmental effects.

Genetic polymorphisms in the expression of CYP1A2, CYP2B6, CYP2C8, CYP2C9, CYP2C19, CYP2D6, CYP3A5, UGT1A1, N-acetyltransferases (NAT2), and thiopurine S-methyltransferase (TPMT) have been identified. Poor metabolizers are homozygous for the mutant gene. Extensive metabolizers are either homozygous or heterozygous for the wild-type gene, with heterozygous carriers having intermediate metabolic activity. Ultrametabolizers have multiple copies of the gene for CYP2D6 and a promoter region polymorphism for CYP2C19 resulting in increased metabolism of CYP2D6 and CYP2C19 substrates, respectively. In addition, the predominant variants of CYP2D6 in Asian and African-American (*10 and *17, respectively) are alleles with reduced enzyme activity. Overall, there is a large interethnic variability in the proportion of poor metabolizers, intermediate metabolizers, and ultrametabolizers, which is beyond the scope of this chapter (22).

The pharmacokinetic hepatic model of elimination is a physiologically based model where hepatic clearance (Cl_H) is dependent on the unbound fraction of the drug in the blood (f_u), activity of the metabolic enzymes (Cl_{int}), and hepatic blood flow (Q_H).

$$Cl_H = \frac{Q_H \cdot (f_u \cdot Cl_{int})}{Q_H + (f_u \cdot Cl_{int})} \quad (4)$$

For low extraction ratio drugs (ER < 0.3), and $f_u \cdot Cl_{int} < Q_H$, Cl is dependent on protein binding and intrinsic clearance. For high ER drugs (ER > 0.7), $f_u \cdot Cl_{int} > Q_H$ and Cl is dependent on Q_H.

Protein Binding and Hepatic Metabolism

Protein-binding effects are only clinically significant for two different types of highly protein-bound drugs that are predominantly eliminated by hepatic elimination (23). For low ER drugs that undergo dosage adjustment by monitoring total concentrations, total concentrations will underestimate unbound or active concentrations. This has been shown for both phenytoin and valproate in the elderly (24) and in pregnant women (25,26) with epilepsy. Total concentrations decreased significantly more than unbound concentrations with decreased albumin concentrations. Adjusting doses based on total concentrations will result in higher doses of valproate and phenytoin than needed to maintain therapeutic unbound concentrations. As the teratogenicity of valproate and phenytoin has been found to be dose dependent, minimizing unnecessary dosing increases during pregnancy is desirable. Ideally, unbound concentrations should be measured. Unbound phenytoin concentrations are clinically available and should be utilized whenever possible. Valproate unbound concentrations are not routinely available to the clinician as they may be unreliable due to problems in sample collection. Patients need to be monitored based on clinical measures, that is, a change in seizure frequency and/or presence of adverse effects in the case of the AEDs.

For high ER drugs with a narrow therapeutic window and administered by nonoral routes, the AUC of unbound drug can be significantly increased and result in increased pharmacologic effect. The AUC of low ER drugs is independent of protein binding (23). Of the parenterally available AEDs, only midazolam is a high protein bound, and high ER drug.

METHODS TO DETERMINE PHARMACOKINETIC PARAMETERS

Pharmacokinetic parameters are determined using concentration time data by both compartmental and noncompartmental methods of analysis. The majority of drugs are eliminated by a first-order process, that is, the elimination rate is dependent on concentration, and serum concentration time data can be modeled using either a one-compartment or a two-compartment model. For one-compartment model, distribution is considered instantaneous, and concentrations decline exponentially with time, and a plot of log concentration versus time is linear. For a two-compartment model, the first exponential phase is primarily dependent on distribution into a peripheral compartment, and the second exponential phase is dependent on elimination after distribution is complete. The terminal elimination rate constant (β) is determined by linear regression of the log concentration time data obtained during the terminal exponential phase. The elimination half-life ($T_{1/2}$) is calculated as $0.693/\beta$. Peak serum concentration (C_{max}) and the time to peak (T_{max}) are obtained by visual inspection of the data. The AUC is calculated by the log-linear trapezoidal method. Cl is estimated by the ratio of dose to AUC. If the drug is administered orally, an apparent oral clearance (Cl/F) is defined as D/AUC as bioavailability is unknown or assumed. Renal clearance (Cl_R) is calculated as product as the fraction of the dose excreted unchanged in the urine and Cl.

PHYSIOLOGIC AND PATHOLOGIC EFFECTS ON PHARMACOKINETICS

The effect of age (27,28), pregnancy (21,29), drug interactions (30–32), renal disease (33), and/or hepatic disease (34) on AED dosing will depend on the fraction of the AED eliminated by renal and/or hepatic elimination, the metabolic isozymes involved, as well as the extent of protein binding, if therapeutic drug monitoring is involved (Table 44.1). This section provides the theoretical basis for the physiologic and pathologic effects on drug pharmacokinetics. Refer to review articles (9,13–19) and chapters on individual AEDs for more specific information.

Age

Gastric pH is increased in neonates, infants, and young children, decreasing to adult values by 2 years of age. The incidence of hypochlorhydria also increases significantly after age 70. GI motility is decreased in neonates, reaches adult levels in older infants, and then decreases in the elderly. The bioavailability of drugs given orally that are weak acids, like phenytoin and phenobarbital, may be decreased in infants, young children, and the elderly due to their higher gastric pH. In neonates and infants, the increased total body water-to-body fat ratio contributes to an increase in the V_d of hydrophilic drugs, and may require larger mg/kg loading doses of some drugs to achieve therapeutic concentrations. Albumin and α_1-AGP concentrations are decreased in the neonates and young infant. Albumin concentrations alone are decreased in the elderly resulting in decreased protein binding for highly bound drugs. The clinical significance of decreased protein binding is described above for low and high ER drugs. At birth, GFR is approximately 40 mL/min/1.73 m^2 in the full-term neonate and increases steadily to 80% to 90% of adults function by 1 year. From ages 40 to 80, kidney function declines at approximately 10% to 20% decrease per decade. Therefore, in general, weight-normalized doses of drugs excreted predominately unchanged by the kidneys need to be reduced in neonates, infants, and the elderly. In the past, there was a general assumption that all hepatic drug metabolism was increased in children compared to adults. There is now evidence that in children, hepatic metabolism can be increased or not changed compared to adults depending on metabolic pathway involved in the elimination of the drug (26). Significantly, higher weight-corrected doses are needed in children than in adults for drugs metabolized by CYP1A2, CYP2C9, and CYP3A4. In contrast, weight-corrected doses for drugs metabolized by CYP2C19, CYP2D6, NAT2, and UGT in children are similar to those in adults. In the elderly, the activity of all of the CYPs is decreased resulting in a need for decreased doses. Doses of drugs metabolized by the conjugating enzymes, NAT2 and UGT, do not need to be decreased.

Pregnancy

Despite the many physiologic changes that occur during pregnancy that could affect absorption, bioavailability does not appear to be altered. Decreased albumin and α_1-AGP concentrations during pregnancy will result in decreased protein binding for highly bound drugs. The clinical significance of decreased protein binding is described above and is important for both valproate and phenytoin, specifically. Renal clearance and the activity of the CYP3A4, CYP2D6, CYP2C9, and UGT isozymes are increased during pregnancy, and drugs eliminated by these pathways may need dosage increases

during pregnancy (25,26). In contrast, CYP1A2 and CYP2C19 activity is decreased, and drugs metabolized by these CYP isozymes may require a decrease in dosage during pregnancy (21).

Renal Disease

The effect of renal disease, in addition to declining renal function in the elderly and the immature renal function in neonates and infants, all result in decreased Cl for drugs that are predominantly excreted unchanged in the urine. For drugs with both renal and hepatic Cl, the effect of renal dysfunction is proportionate to the fraction of the Cl of the drug dependent on renal clearance. The ability to estimate renal function using SCR provides a method of determining the dose required to maintain a therapeutic effect without toxicity. In addition, to a decreased Cl, renal disease is associated with decreased albumin concentrations, which will result in decreased protein binding for highly bound drugs.

Liver Disease

Unlike renal disease, there are no specific markers of liver function that can be used to provide guidance in dosage adjustments. Liver function tests (LFTs) primarily are a measure of the extent of cell death. For example, LFTs are significantly increased in acute hepatitis; however, metabolic enzyme function is maintained, and doses of drugs eliminated by liver metabolism do not need to be altered (26,27). Conversely, acute and chronic cirrhosis results in a decreased ability to metabolize drugs due to effects on the metabolic enzymes and hepatic blood flow. The metabolic enzymes are differentially affected depending on the severity of the cirrhosis with the Cl of drugs metabolized by CYP2C19 affected first during mild liver disease (34). The activity of CYP2C19 is significantly decreased with mild liver disease and remains at a decreased level with increasing severity of disease. CYP1A2, CYP2D6, and CYP3A4 activity is also decreased in mild cirrhosis, but to a lesser extent than CYP2C19, and continues to decrease with increasing severity of disease. CYP2C9 and CYP2E1 are not significantly decreased in mild to moderate liver disease; however, the activity of the enzymes all decrease with more severe cirrhosis. The Cl of drugs metabolized by the conjugating enzymes (UGT and NAT2) is not affected until the patient reaches end-stage liver disease. End-stage liver disease also decreases the renal clearance of drugs. Decreased albumin and α_1-AGP concentrations occur due to decreased synthesis and result in increased free fractions of highly protein-bound drugs.

DRUG INTERACTIONS

Drug interactions can occur by pharmacokinetic or pharmacodynamic mechanisms. Pharmacodynamic interactions occur when the pharmacology of one agent alters the pharmacology or effect of the other drug without altering the serum concentration. Theoretically, the interaction can occur at the receptor or site of action or indirectly by affecting other physiologic mechanisms. The most commonly occurring AEDs are pharmacokinetic interactions, where one drug alters the serum concentrations of another. Pharmacokinetic interactions include hepatic enzyme induction, enzyme inhibition, and protein-binding displacement. Many of the AEDs are either specific or broad-spectrum inducers and/or inhibitors of metabolic enzymes (Table 44.2). In addition, many of the AEDs are eliminated by pathways that are affected by induction and/or inhibition by other AEDs and non-AEDs (Table 44.3).

Table 44.2 Effect of AEDs on Hepatic Metabolic Enzymes

AED	Effect	Metabolic enzyme/ transporters involved
Carbamazepine	Inducer	CYP1A2, CYP2C9, CYP2C19, CYP3A, UGT
Clonazepam	Inducer	CYP3A4, UGT
Eslicarbazepine	Inducer	CYP2C9, CYP3A4
Ethosuximide	No effect	
Ezogabine	Inducer	UGTs
Felbamate	Inducer	CYP3A4
	Inhibitor	CYP2C19, β-oxidation
Gabapentin	No effect	
Lacosamide	No Effect	
Lamotrigine	Inducer	UGT
	Inhibitor	UGT, CYP2C19
Levetiracetam	No effect	
Oxcarbazepine	Inducer	CYP3A4
	Inhibitor	CYP2C19
Perampanel	No effect	
Phenobarbital/ Primidone	Inducer	CYP1A, CYP2A6, CYP2B, CYP2C9, CYP2C19, CYP3A, UGT
Phenytoin	Inducer	CYP2C9, CYP2C19, CYP3A, UGT
Pregabalin	No effect	
Rufinamide	Inducer	CYP3A4
Stiripentol	Inhibitor	CYP1A2, CYP2C9, CYP2C19, CYP2D6, CYP3A4
Tiagabine	No effect	
Topiramate	Inducer	CYP3A4
	Inhibitor	CYP2C19
Valproate	Inhibitor	CYP2C9, UGT, epoxide hydrolase
Vigabatrin	No effect	
Zonisamide	No effect	

CYP, Cytochrome P450; UGT, UDP-glucuronosyltransferase; NAT, N-acetyltransferase; PG, p-glycoprotein; MRP, multiresistance protein.

Table 44.3 Inducers and Inhibitors of Cytochrome P450 (CYP) isozymes and UDP-Glucuronosyltranferases (UGT) Involved in AED Metabolism[a]

Isozyme	AED substrate	Inducers[a]		Inhibitors[a]		
CYP1A2	Carbamazepine	Carbamazepine Phenobarbital Phenytoin Primidone Rifampin		Fluvoxamine		
CYP2C8	Carbamazepine	Phenobarbital				
CYP2C9	Carbamazepine Phenobarbital Phenytoin Valproate	Carbamazepine Phenobarbital Phenytoin Primidone Rifampin		Amiodarone Cimetidine Fluconazole Gemfibrozil	Miconazole Propoxyphene Sulfaphenazole Valproate	
CYP2C19	Clobazam N-Desmethylclobazam Diazepam N-Desmethyldiazepam Phenobarbital Phenytoin Valproate	Carbamazepine Phenobarbital Phenytoin Primidone Rifampin St. John's wort		Felbamate Fluoxetine Fluvoxamine Isoniazid Ticlopidine		
CYP3A4	Carbamazepine Clobazam Diazepam Eslicarbazepine Ethosuximide Perampanel Tiagabine[b]	Carbamazepine Eslicarbazepine Felbamate Oxcarbazepine Phenobarbital Phenytoin Rifampin St. John's wort Topiramate		Amprenavir Atazanavir Cimetidine Clarithromycin Danazol Darunavir Diltiazem Erythromycin	Fluconazole Grapefruit juice Indinavir Isoniazid Itraconazole Ketoconazole Miconazole Nelfinavir	Propoxyphene Quinupristin Ritonavir Saquinavir Telithromycin Troleandomycin Verapamil
UGTs	Ezogabine Lamotrigine Lorazepam MHD (oxcarbazepine) Retigabine Valproate	Carbamazepine Ertapenem[d] HRT[c] Imipenem[d] Lamotrigine Lithium[c] Lopinavir/ritonavir[c]	Meropenem[d] OCs[c] Oxcarbazepine Panipenem[d] Phenobarbital Phenytoin Primidone	Valproate		

[a]The drugs listed below have been shown to be inhibitors/inducers of the various CYP and UGT isozymes. Not all interactions have been demonstrated for all drugs. Caution should be used with concurrent therapy of known inhibitors and inducers.

[b]The fraction of the clearance associated with the pathway small; therefore, CYP3A4 inhibitors do not significantly effect tiagabine serum concentrations.

[c]Oral contraceptives (OCs), HRT (hormone replacement therapy), lithium, and lopinavir/ritonavir decrease the lamotrigine concentrations. OCs decreases the concentrations of lorazepam and valproate. The effect on retigabine has not been evaluated.

[d]The carbapenem antibiotics have only been shown to decrease valproate concentrations.

Knowledge of the specific CYP or UGT isozymes involved in the metabolism of the AEDs allows prediction of potential inhibition and induction interactions. Less is known regarding the induction and inhibition potential of the non-CYP and UGT enzymes. The extent of the drug interaction is more difficult to predict than the type of interaction. A large number of patient and drug factors will influence the extent of the induction or inhibition. Intersubject variability in the expression of the CYP and UGT isozymes will influence the fraction of the dose associated with each metabolic pathway that is inhibited.

Hepatic enzyme induction is generally the result of an increase in the amount of enzyme protein. In most cases, enzyme induction results in an increase in the rate of metabolism of the affected drug, a decrease in the serum concentration of a parent drug, and possibly a loss of clinical efficacy. If the affected drug has an active metabolite, induction can result in increased metabolite concentrations and

potentially an increase in the therapeutic effect and toxicity of the drug. Carbamazepine, phenytoin, phenobarbital, and primidone (via the phenobarbital metabolite) are broad-spectrum inducers of several CYP and UGT isozymes. Only St. John's wort and rifampin are non-AED broad-spectrum inducers (Table 44.3). Enzyme induction causes major effects on a limited number of extensively metabolized drugs (>75% metabolized) with a low therapeutic index. For the drugs listed in Table 44.4, addition or removal of a broad-spectrum inducer could result in loss of efficacy or toxicity if serum concentrations are not adjusted. Dosage adjustments of approximately 50% to 100%, with careful clinical monitoring, may be required.

Table 44.4 Drugs in Which Addition or Discontinuation of a Hepatic Enzyme Inducer Could Cause Clinically Significant Effects

Drug category	Specific drugs		
Analgesics	Alfentanil Fentanyl	Methadone Morphine	
Antidepressant drugs[a]	Amitriptyline Amoxapine Clomipramine	Desipramine Doxepin Imipramine	Nortriptyline Protriptyline Trimipramine
Antiepileptic drugs	Carbamazepine Clobazam Ethosuximide Felbamate	Lamotrigine Perampanel Phenytoin Stiripentol	Tiagabine Topiramate Valproate Zonisamide
Anti-infectious agents	Itraconazole Ketoconazole	Mebendazole Voriconazole	
Antipsychotic agents	Aripiprazole Clozapine Haloperidol	Quetiapine Risperidone	
Antiviral agents	Amprenavir Atazanavir Darunavir Delavirdine	Efavirenz Indinavir Nelfinavir Ritonavir	Saquinavir Tipranavir Zidovudine
Benzodiazepines	Alprazolam Clonazepam	Diazepam Lorazepam	Midazolam Triazolam
Calcium channel blockers	Amlodipine Bepridil Diltiazem Felodipine	Isradipine Nicardipine Nifedipine Nimodipine	Nisodipine Nitrendipine Verapamil
Cardioactive drugs	Amiodarone Digoxin	Disopyramide Procainamide	Propranolol Quinidine
Corticosteroids	Cortisone Betamethasone Dexamethasone Hydrocortisone	Methylprednisolone Prednisolone Prednisone Triamcinolone	
HMG-CoA reductase inhibitors Immunosuppressants Oral anticoagulants Oral contraceptives	Atorvastatin Cyclosporine Dicumarol Conjugated estrogens Ethinyl estradiol	Lovastatin Sirolimus Warfarin Levonorgestrel Norethindrone	Simvastatin Tacrolimus
Miscellaneous	Cyclophosphamide[b] Theophylline	Thiotepa[b] Vincristine	Imatinib

[a]Many antidepressants have active metabolites; therefore, the effect of enzyme induction on efficacy is unpredictable.

[b]Increased exposure to active metabolite is associated with increased toxicity.

The amount of enzyme induction is proportional to the dose of the inducing agent. This has been shown for phenytoin, phenobarbital, and carbamazepine. The time required for induction depends on both the time to reach steady state of the inducing agent and the rate of synthesis of new enzymes. Because induction is a gradual process, allowing time for gradual increases in the dose of the affected drug is required. The time course of deinduction is dependent on the rate of degradation of the enzyme and the time required eliminating the inducing drug. For the AEDs, the rate-limiting step in deinduction is the elimination of the inducing drug. When the inducer is removed, serum concentrations of the affected drug will increase. Serious adverse events can occur if the dose of the affected drug is not reduced. The magnitude and timing of these interactions are critical to allow clinicians to adjust doses in such a way to maintain therapeutic effect and avoid toxicity. For carbamazepine, the majority of the induction occurs within 1 week of initiation and is completed within approximately 3 weeks (35). Maximal induction occurs approximately 1 to 2 weeks after initiation phenytoin therapy corresponding to the approximately time to steady-state phenytoin concentrations (36). Theoretically, deinduction requires a similar period of time. For phenobarbital, the time course of induction and deinduction is primarily dependent on the long elimination half-life. Induction usually begins in approximately 1 week; with maximal induction occurring 2 to 3 weeks after phenobarbital therapy is initiated (37). The time course of the deinduction will follow a similar course, as phenobarbital serum concentrations decline over 2 to 3 weeks following removal of drug.

Hepatic enzyme inhibition results in a decrease in the rate of metabolism of the affected drug. Clinically, this is associated with an increased serum concentration of the affected drug and potentially an increased pharmacologic response. Enzyme inhibition can be rapidly reversible, slowly reversible, or irreversible. Rapidly reversible inhibition occurs due to competition at the enzyme site. The extent of inhibition is dependent on the dose of the inhibitor as the majority of inhibition interactions are competitive. The onset of the interaction is frequently rapid, and the extent of the interaction is highly variable. The initial effects of hepatic enzyme inhibition usually occur within 24 hours of addition of the inhibitor, but the time to maximal inhibition will depend on the time needed to achieve steady state of both the affected drug and the inhibiting drug. Irreversible or mechanism-based inhibition occurs when an inhibitor binds irreversibly to the enzyme. The time course of deinhibition is dependent not only on the elimination half-life of the inhibitor but also on the time to synthesis new metabolic enzyme. The most well-known mechanistic-based inhibitor is grapefruit juice (38).

Protein-binding displacement interactions result from the displacement of one drug with less affinity for the protein by another drug with greater affinity. Clinically significant interactions occur only with highly protein-bound drugs (>90%). For highly protein-bound drugs that are primarily eliminated by low extraction hepatic metabolism, protein-binding displacement causes a decrease in total serum concentrations of the displaced drug and no change in the unbound drug. Transient increases in unbound drug can be associated with acute toxicity. For most AEDs, total serum concentrations are used for clinical monitoring. Interpretation of total concentrations in the context of protein-binding interactions will result in dosing adjustments that will possibly lead to AED toxicity. In the case of AEDs, phenytoin and valproate are the only drugs involved in clinically important protein-binding interactions (39).

Drug interactions can also involve inhibition or induction of intestinal transporters (PGP, BCRP), inhibition of hepatic uptake transporters (OATP), and transporters involved in renal secretion (OAT, OCT, MATE, PGP) (1).

Effect of AEDs on Other Drugs

AEDs are associated with a wide range of drug interactions [for reviews, see (30–32) and the drug-specific chapters]. Carbamazepine, phenytoin, phenobarbital, and primidone (via the phenobarbital metabolite) are broad-spectrum inducers of several CYP and UGT isozymes. Stiripentol and valproate are both broad-spectrum inhibitors of a variety of metabolic isozymes. Eslicarbazepine, ezogabine, clonazepam, felbamate, lamotrigine, oxcarbazepine, rufinamide, and topiramate are inhibitors and inducers of select metabolic enzymes. Ethosuximide, gabapentin, lacosamide, levetiracetam, perampanel, pregabalin, tiagabine, vigabatrin, and zonisamide are neither inducers nor inhibitors of metabolic enzymes and do not significantly alter the serum concentrations of other drugs (Table 44.3).

Effect of Other Drugs on AEDs

The effect of other drugs on the AEDs can by and large be predicted based on their pharmacokinetic characteristics (Table 44.1), knowledge of the specific pathways of elimination, and known inducers and inhibitors (Table 44.3). Serum concentrations of AEDs that are eliminated predominantly by renal excretion of unchanged drug (gabapentin, pregabalin, and vigabatrin) are not affected by coadministration of other drugs. Serum concentrations of AEDs that are extensively metabolized by CYP and/or UGTs will be decreased in the presence of broad-spectrum and selective enzyme inducers. Serum concentrations of AEDs that are eliminated by both renal and hepatic metabolism (eslicarbazepine, felbamate, levetiracetam, oxcarbazepine, perampanel, and topiramate) will decrease less than those that are predominantly metabolized. The pharmacologic effects of a drug interaction will be more unpredictable for those AEDs with active metabolites, for example, carbamazepine and clobazam, depending on the relative effect of the interaction on parent and/or active metabolite.

CHAPTER 45 INITIATION AND DISCONTINUATION OF ANTIEPILEPTIC DRUGS

VARDA GROSS-TSUR, RUTH C. SHINNAR, AND SHLOMO SHINNAR

Over the past two decades, there has been much information about the prognosis of seizure disorders, the effects of antiepileptic drug (AED) therapy on prognosis, and the relative risks of both seizures and AED therapy. This chapter reviews the clinical decision making in initiating and discontinuing AEDs in children and adults, with particular emphasis on the data regarding the recurrence risk for seizures in different settings and the effect of AEDs on this risk. Initiating and discontinuing AED therapy are then addressed in the context of an individualized therapeutic approach that emphasizes weighing the risks and benefits of drug therapy versus both the statistical risk of another seizure and the consequences of such an event.

RECURRENCE RISK FOLLOWING A FIRST UNPROVOKED SEIZURE

To develop a rational approach to the management of individuals who present with an initial unprovoked seizure, it is necessary to have some understanding of the natural history and prognosis of the disorder in this setting. Approximately one-third to one-half of children and adults with seizures will initially present to medical attention following a single seizure (1,2). The remainder will already have a history of prior events at the time of presentation. It is the group who presents with a single seizure that is most relevant to this discussion. In accordance with the International League Against Epilepsy (ILAE) guidelines for epidemiologic research in epilepsy, a first unprovoked seizure is defined as a seizure or flurry of seizures all occurring within 24 hours in a person older than 1 month of age with no prior history of unprovoked seizures (3).

Since 1982, a number of studies have attempted to address the recurrence risk following a first unprovoked seizure using a variety of recruitment and identification techniques (4–22). The reported overall recurrence risk following a first unprovoked seizure in children and adults varies from 27% to 71%. Studies that carefully excluded those with prior seizures report recurrence risks of 27% to 52% (4–18). Higher recurrence risks are, with one exception (19), reported from studies that included subjects who already had recurrent seizures at the time of identification and who were, thus, more properly considered to have newly diagnosed epilepsy.

While there is considerable disparity in the absolute recurrence risk reported in the different studies, the time course of recurrence is remarkably similar among all studies (5). The majority of recurrences occur early, with approximately 50% of recurrences occurring within 6 months of the initial seizure and over 80% within 2 years of the initial seizure (5,13). Late recurrences are unusual,

but they have occurred up to 10 years after the initial seizure (13,14). This time course is true in studies that report both low and high recurrence risks (4,5,7–10,12–14,19–21).

A relatively small number of factors are associated with a differential recurrence risk. The most important of these are the etiology of the seizure, the electroencephalogram (EEG), and whether the first seizure occurred in wakefulness or sleep. These factors are consistent across most studies regardless of the absolute risk of recurrence reported in the individual study (4,5,7–15,18,20,21). Factors not associated with a significant change in the recurrence risk include the age of onset, the number of seizures in the first 24 hours, and the duration of the initial seizure. The absolute recurrence risks appear similar in children and adults (5), although the consequences of such a recurrence are quite different. Selected risk factors are discussed below.

Etiology

In the ILAE classification, etiology of seizures is classified as remote symptomatic, cryptogenic, or idiopathic (3). Remote symptomatic seizures are those without an immediate cause but with an identifiable prior brain injury or the presence of a static encephalopathy such as mental retardation or cerebral palsy, which are known to be associated with an increased risk of seizures. Cryptogenic seizures are those occurring in otherwise normal individuals with no clear etiology. Until recently, cryptogenic seizures were also called idiopathic. In the new classification, idiopathic is reserved for seizures occurring in the context of the presumed genetic epilepsies such as benign rolandic and childhood absence (23,24). However, much of the literature on the recurrence risk following a first unprovoked seizure lumps idiopathic and cryptogenic together as idiopathic using the original classification developed by Hauser et al. (8).

Not surprisingly, both children and adults with a remote symptomatic first seizure have higher risk of recurrence than do those with a cryptogenic first seizure. A meta-analysis of the studies published up to 1990 found that the relative risk of recurrence following a remote symptomatic first seizure was 1.8 (95% confidence interval, 1.5, 2.1) compared to those with a cryptogenic first seizure (5). Comparable findings are reported in more recent studies (13,15,21). Idiopathic first unprovoked seizures occur almost exclusively in children. Although the long-term prognosis of these children is quite favorable, the recurrence risk is actually comparable to those with a remote symptomatic first seizure (13). This is because, by definition, to meet the criteria for an idiopathic first seizure, they must have an abnormal EEG (23,24).

Electroencephalogram

The EEG is an important predictor of recurrence, particularly in cases that are not remote symptomatic and in children (5,7,8,10–13,15–18,21,25). Studies of recurrence risk following a first seizure in childhood have uniformly reported that those with an abnormal EEG have a higher recurrence risk than do those with a normal EEG (5,7,12,13,15,21,25). For this reason, the American Academy of Neurology's recently published guideline on the evaluation of children with a first unprovoked seizure considers an EEG to be a standard part of the evaluation (21). A recent guideline on the diagnostic evaluation of adults with a first seizure also recommends an EEG, though the level of evidence is not as strong as in children (26). Epileptiform abnormalities are more important than nonepileptiform ones, but any EEG abnormality increases the recurrence risk in cases that are not remote symptomatic (25). In our study, the risk of seizure recurrence within 24 months for children

with an idiopathic/cryptogenic first seizure was 25% for those with a normal EEG, 34% for those with nonepileptiform abnormalities, and 54% for those with epileptiform abnormalities (25). Whereas in our data, any clearly abnormal electroencephalographic patterns—including generalized spike and wave, focal spikes, and focal or generalized slowing—increased the risk of recurrence, Camfield et al. (7) reported that only epileptiform abnormalities substantially increase the risk of recurrence in children. Despite minor disagreements as to which electroencephalographic patterns are most significant, the EEG appears to be the most important predictor of recurrence in children with a cryptogenic/idiopathic first seizure. In addition, it is the EEG that primarily distinguishes whether a neurologically normal child with a first seizure is classified as cryptogenic or idiopathic.

In adults, the data are more controversial. The majority of studies do find an increased recurrence risk associated with an abnormal EEG (5,9,10,18), although one study failed to find a significant effect (11). Hauser et al. (8) found that generalized spike-and-wave patterns are predictive of recurrence but not focal spikes. A meta-analysis of these studies concluded that the overall data do support an association between an abnormal EEG and an increased recurrence risk in adults as well (5), although which electroencephalographic patterns besides generalized spike and wave are important remains unclear (5,9,10,18). As the recent guideline points out, an EEG is recommended not only to assess recurrence risk but also to help classify the type of epilepsy and potentially identify a specific syndrome (26).

Sleep State at Time of First Seizure

In adults, seizures that occur at night are associated with a higher recurrence risk than are those that occur in the daytime (11). In children, whose sleep patterns may include daytime naps, the association is more clearly between sleep state and recurrence risk rather than time of day (13,27). Interestingly, the association is not just because nocturnal seizures tend to occur in certain epilepsy syndromes. Thus, even children whose EEG has centrotemporal spikes and who meet the criteria for benign rolandic seizures (24) have a higher recurrence risk if the first seizure occurs during sleep than if it occurs while awake (27). Furthermore, if the first seizure occurs during sleep, there is a high likelihood that the second one, should it occur, will also occur during sleep (27). In our series, the 2-year recurrence risk was 53% for children whose initial seizure occurred during sleep compared with a 30% risk for those whose initial seizure occurred while awake (13). On multivariable analysis, etiology, the EEG, and sleep state were the major significant predictors of outcome. From a therapeutic point of view, the implication of a seizure during sleep is unclear. While the recurrence risk is higher, recurrences will tend to occur in sleep. As the major risk of a brief seizure in children or adults is that it may happen at a time or place where the impairment of consciousness will have serious consequences, the morbidity of a seizure during sleep is fairly low in both cases.

Seizure Classification

In some studies, the risk of recurrence following a first unprovoked seizure is higher in subjects with a partial seizure than in those with a generalized first seizure (5). This association is mostly found on univariate analysis and disappears once the effect of etiology and the EEG are accounted for (5,8,12,13). Partial seizures are more common in those with a remote symptomatic first seizure and in children with an abnormal EEG (12). Note that some generalized seizure types, such as absence and myoclonic, very rarely present as a first seizure and so would be excluded from studies of first

seizure (16,21). Generalized seizures that present to medical attention at the time of the first seizure are usually tonic–clonic (13).

Duration of Initial Seizure

In children, the duration of the first seizure is not associated with a differential recurrence risk. In our study, 48 (12%) of 407 children (38 cryptogenic/idiopathic, 10 remote symptomatic) presented with status epilepticus (duration longer than 30 minutes) as their first unprovoked seizure (13). The recurrence risk in these children was not different from that in children whose first seizure was briefer. However, if a recurrence did occur, it was likely to be prolonged (13,28). Of the 24 children with an initial episode of status who experienced a seizure recurrence, 5 (21%) recurred with status. Of the 147 children who presented with an initial brief seizure and experienced a seizure recurrence, only 2 (1%) recurred with status epilepticus ($P < 0.001$). In adults, there is a suggestion that a prolonged first seizure, particularly in remote symptomatic cases, is associated with a higher risk of recurrence (10).

Number of Seizures in 24 Hours

The ILAE definition of a first unprovoked seizure includes a seizure flurry occurring within 24 hours (3). Well-designed prospective studies in both children (13) and adults (29) have found no difference in recurrence risks in patients who present with a cluster of seizures in 1 day compared with those who present with a single seizure. This is not an uncommon event and occurs in about 25% of cases. The data support the epidemiologic definition of a cluster as being a single event and do not suggest an increased risk of further seizures.

Treatment Following a First Seizure

Five randomized clinical trials in children and adults examined the efficacy of treatment after a first unprovoked seizure (6,20,30–34). Two well-designed prospective studies that randomized subjects to treatment or placebo following a first unprovoked seizure found that treatment reduced the recurrence risk by approximately half (6,20,30). The larger Italian study included both children and adults (20,30). However, while recurrence risk was reduced, there was no difference in long-term outcomes between the two groups. Equal proportions were in 2-year remission after 5 years of follow-up (30). Although the authors of this study initially recommended treatment following a first seizure, once it became apparent that early treatment did not affect long-term prognosis, they changed their recommendation, suggesting that in the majority of cases, treatment should not be recommended before a second seizure occurred (30). In the more recent Multicentre Trial for Early Epilepsy and Single Seizures, immediate treatment after a first unprovoked seizure reduced the risk of recurrence from 50% to 25% but did not alter long-term outcome (34,35). In general, the accumulating evidence from a large number of studies indicates that AED therapy is effective in reducing the risk of a recurrent seizure but does not alter the underlying disorder and therefore does not change long-term prognosis (36). Based on these data and assessment of risk-to-benefit, the American Academy of Neurology has issued a practice parameter on AED therapy following a first unprovoked seizure in children and adolescents (33). This parameter recommends that (i) treatment with AEDs is not indicated for the prevention of the development of epilepsy and (ii) treatment with an AED may be considered in circumstances where the benefits of reducing the risk of a second seizure outweigh the

risks of pharmacologic and psychosocial side effects. The authors rarely prescribe AEDs after a single seizure. A practice parameter addressing this issue in adults is currently under development, but the epidemiologic data and the data from randomized clinical trials are increasingly in favor of not routinely treating after a single seizure even in adults.

What Happens After Two Seizures?

Two studies in adults (9) and children (14) examined what happens after a second seizure. In adults, the recurrence risk after a second seizure is 70%, leading Hauser et al.(9) to conclude that, in adults, once a second seizure has occurred, treatment with AEDs is appropriate. In children, the recurrence risk following a second seizure is also approximately 70%. Those with a remote symptomatic etiology and those whose second seizure occurs within 6 months of the first have a higher recurrence risk (14). Interestingly, factors such as an abnormal EEG and sleep state at the time of the seizure, which help to differentiate those who only have one seizure from those who experienced a recurrence, are no longer associated with a differential risk of further seizures once a second seizure occurs (14). Despite the similarities in recurrence risk, the issue of treatment following a second seizure in children is less straightforward than in adults. Many of these children have idiopathic self-limited epilepsy syndromes, such as benign rolandic, where the need for treatment has been questioned (37–39). In addition, the frequency of seizures in this group is low, with only 25% of children who had 2 seizures experiencing 10 or more seizures over a 10-year period (14). Thus, the decision regarding treatment in children with cryptogenic/idiopathic seizures who have a second seizure must be individualized and take into account whether the seizures are part of a benign self-limited syndrome, as well as the frequency of the seizures and the relative risks and benefits of treatment.

WITHDRAWAL OF ANTIEPILEPTIC DRUGS IN THOSE WHO HAVE BEEN SEIZURE FREE ON ANTIEPILEPTIC DRUG THERAPY

AED therapy effectively controls seizures in the majority of patients with epilepsy. The preponderance of evidence indicates that most patients with epilepsy will become seizure free on AEDs within a few years of diagnosis (40–47). However, the long-term use of AEDs carries with it significant morbidity. Therefore, the issue of whether one can withdraw AEDs in patients with epilepsy after a seizure-free interval becomes important in the treatment of a vast number of patients.

A large number of prospective and retrospective studies including children, adolescents, and adults, involving thousands of subjects, have been done over the past 25 years on the question of remission and relapse rates after withdrawal of AEDs (41,48–81). A meta-analysis of the available literature reported a pooled risk of relapse of 25% at 1 year and 29% at 2 years following AED withdrawal (50).

In childhood-onset epilepsy, the majority of studies report that 60% to 75% of children and adolescents with epilepsy who have been seizure free for more than 2 to 4 years on medication will remain so after AEDs are withdrawn (48–51,57–59,61–65,67,72–75,78,80,81). Exceptionally low recurrence rates of 8% to 12% were reported in studies that limited subject entry to neurologically normal children with normal EEGs, many of whom were followed since the onset of their seizures

(66,77).

In the past, it was thought that adult-onset epilepsy had a far less favorable prognosis for remission than did childhood-onset epilepsy and that withdrawal of medications was rarely feasible in this population. Although the prognosis in adults does appear to be worse than in children, newer studies suggest that the differences are smaller than thought. Four years after onset, the majority of adults with new-onset seizures will be at least 2 years seizure free (45,46). Many adults self-discontinue their medications and are still seizure free years later (40,80). Studies of withdrawing AEDs in adults report recurrence rates of 28% to 66% (51,54,60,64,67,69,79), which is a much larger range than that reported in pediatric studies. However, it should be noted that studies that reported the lowest recurrence risks (54) limited themselves to patients followed since onset of their seizures and who had absence of other presumed risk factors. In pediatric studies, such selected populations have reported recurrence risks of <20%.

The preponderance of data at this time indicates that the recurrence risk following withdrawal of AEDs is somewhat higher in adult-onset epilepsy than in childhood-onset epilepsy with a relative risk of approximately 1.3 (50). However, much of the increased risk reported in some studies is a result of the higher risk of recurrence in adolescent-onset seizures (50,72). Selected populations of adults may have low recurrence risks. Two reports showed no differences in recurrence risks between children and adults (54,79). However, these studies have the highest reported recurrence risks for children (31% to 40%) and the lowest reported recurrence risks for adults (35% to 40%). In addition, their definition of children exceeds the usual limits of the term. In one study, 38% of the subjects had childhood onset, but this was defined as onset before 15 years of age (54). Several studies in children have reported that an age of onset older than 10 or 12 years was associated with a higher recurrence risk, presumably because this already reflects early adult-onset epilepsy (52,71–73,77).

The data on adolescents indicate that the recurrence rate is more a function of the age at onset than the age at withdrawal of medications (50,72,73). Studies of childhood-onset epilepsy that included adolescents have reported low recurrence risk (49,50,52,58,66,72,73,75,77). Studies of adolescents and adults that have primarily included adolescent-onset cases have reported recurrence rates similar to those seen in adults (50,54,64,79). One retrospective study limited to adolescents with adolescent-onset seizures reported a recurrence rate of 49% (70). A recent meta-analysis found that adolescent-onset epilepsy has a higher recurrence risk following AED withdrawal than either childhood- (relative risk, 1.79) or adult-onset (relative risk, 1.34) epilepsy (50).

When recurrences do occur after discontinuation of AEDs, they tend to occur early (50,72). The timing of recurrence is similar in studies of both children and adults and is independent of the absolute recurrence risk. Many occur as the medications are being tapered. At least half the recurrences occur within 6 months of medication withdrawal, 60% to 90% of recurrences occur within 1 year of withdrawal, and more than 85% of recurrences occur within 5 years (50,5153,55,59,63–65,67,68,70,73,74,76,80). One series in adults reported that 68% of relapses were during drug withdrawal and an additional 24% occurred during the first year after discontinuation of treatment (69). Although late recurrences do occur, they are uncommon (62,72,82). There is no secondary peak in recurrence risk years after discontinuing medications.

In analyzing recurrence risks following withdrawal of AEDs, one must also consider the recurrence risk of patients who are candidates for medication withdrawal but are maintained on AEDs. Annegers et al. (40) found a mean relapse risk of 1.6% per year in patients who were in remission for 5 or more years. Similarly, Oller-Daurella et al. (83) reported a 12.6% recurrence rate

in a group of patients who were maintained on AEDs after being in remission for 5 or more years. One large-scale, randomized trial of continued AED therapy versus slow withdrawal in 1013 patients who were seizure free for 2 or more years found a 22% recurrence rate in those maintained on medications compared with a 42% recurrence rate in those whose medications were withdrawn (68). However, after 2 years, the subsequent recurrence risks were identical, suggesting that the increased risk of recurrence attributable to AED withdrawal occurs only in the first 2 years. Late recurrences occur but are not attributable to AED withdrawal. These relapse rates must also be considered when deciding on whether to continue long-term AED therapy. Interestingly, in a 30-year follow-up study of 178 patients with epilepsy, there was a slightly higher recurrence rate in those patients who remained on AEDs, although the two groups were not randomized and were, therefore, not fully comparable (47).

RISK FACTORS FOR RECURRENCE

Clinically, it is important to identify subgroups with better or less favorable prognoses for maintaining seizure remission off medications. It is essential to quantify the significance of risk factors such as etiology, age of onset, type of seizure, and the EEG; however, different studies give very different results. A discussion of potential risk factors and their significance is presented below.

Etiology and Neurologic Status

Patients with remote symptomatic epilepsy associated with a prior neurologic insult, congenital malformation, motor handicap, brain tumor, mental retardation, progressive metabolic disease, trauma, or stroke are less likely to attain complete seizure control than are those with cryptogenic or idiopathic epilepsy (40,43,47).

Even in patients with remote symptomatic epilepsy who do attain seizure remission while on medications, current data indicate that the relapse rate after discontinuation of AEDs is higher than in those with cryptogenic seizures. In one study of 264 children and adolescents, the cumulative recurrence risk 2 years following withdrawal of medications was 26% in the cryptogenic group and 42% in the neurologically abnormal group ($P < 0.005$) (72). Despite the increased risk of recurrence in the neurologically abnormal group, the majority of this population was successfully withdrawn from AEDs. The severity of mental retardation was an additional prognostic factor within this group.

Similar results have been found in other studies (50,58,62–64). A recent study of the prognosis of epilepsy in children with cerebral palsy and epilepsy (55) found that the majority of these children did not achieve remission. However, of the 69 children who achieved a 2-year seizure remission and had their medication withdrawn, 58% remained seizure free. The type of cerebral palsy was associated with a differential risk of recurrence. With one exception (65), studies that did not find such an association either had very few (73) remote symptomatic cases or were restricted to those with cryptogenic epilepsy (54,66,69,77,79). A meta-analysis estimated the relative risk of recurrence in those with remote symptomatic epilepsy compared with cryptogenic epilepsy to be 1.55 (50). This applies to all remote symptomatic causes including both mental retardation and cerebral palsy. Within the remote symptomatic group, those with severe mental retardation have the highest recurrence risk (72).

Age

As discussed, adolescent- and adult-onset epilepsy are associated with a somewhat poorer prognosis for successful withdrawal of AED therapy (50,60,64,67,69,70,72), although selected populations may do well (54,79). The discussion that follows focuses on differences within the pediatric age group.

Many studies report that an age of onset younger than 12 years is associated with a lower recurrence risk following discontinuation of medication than is an older age of onset (49,50,52,58,64,71–73,77). This corresponds to the known higher remission rates in the younger group (40,43,84).

There is some controversy as to whether a very young age of onset of younger than 2 (58,72,84) or 3 years (57,78) may be a poor prognostic factor. Studies that include large numbers of children with remote symptomatic epilepsy have found a worse prognosis in the very young (58), whereas studies of mostly cryptogenic epilepsy have produced conflicting results (57,65,73,78). In one study that examined this question (72), 73% of the children with age of onset older than 12 years and 45% of those with age of onset younger than 2 years experienced seizure recurrence compared with 26% of those with age of onset between 2 and 12 years ($P < 0.0001$). However, the poorer prognosis in those with a very young age of onset was limited to the remote symptomatic group (72). These data are consistent with the findings of Huttenlocher et al. (85) that neurologically abnormal children with seizure onset at younger than 2 years of age had a poor prognosis for entering remission.

There are no convincing data that withdrawing AEDs during puberty are associated with a higher risk of recurrence (38,62,63,73,86). In fact, with the exception of one isolated report (82), studies on the remission of seizures and on withdrawing AEDs (40,62,63,72,73,75) do not show a reproducible pattern that correlates with puberty. The probability of attaining remission and of maintaining remission after medication withdrawal is more a function of the age of onset and the duration of the seizure disorder, without a special role for puberty.

Electroencephalogram

An abnormal interictal EEG, particularly one with epileptiform features, is often cited as a predictor of relapse after AED withdrawal (4,50,73,87,88). Results of actual studies in children and adults, however, are conflicting.

In children, a substantial number of studies found that the EEG prior to discontinuation of AEDs was an important predictor of outcome (38,41,50,58,70–73,75). Interestingly, any electroencephalographic abnormality, not just a frankly epileptiform one, was associated with an increased risk of relapse. In a study that examined specific features of the EEG, the presence of either slowing or spikes was associated with an increased risk, and the presence of both in the same patient was associated with a very high risk of recurrence (73). Two studies reported that only certain specific epileptiform patterns, such as irregular generalized spike-and-wave pattern, were associated with an increased recurrence risk following medication withdrawal (41,87).

Further evidence for the importance of the EEG as a predictor of outcome can be inferred from three large studies (49,66,77). Because these studies excluded children with abnormal EEGs and report very low recurrence risks of 8% to 12%, they provide indirect evidence for the importance of the EEG as a predictor of recurrence. However, some studies in children did not find the EEG to be predictive (52,63). The studies that did find the EEG to be predictive were mainly of children with cryptogenic seizures. In studies that specifically analyzed the relationship between the EEG and outcome in both cryptogenic and remote symptomatic cases, the EEG was a significant predictor of outcome only in the cryptogenic group (72).

The EEG prior to treatment may also have some predictive value. Certain electroencephalographic patterns are markers for specific epileptic syndromes, such as benign rolandic epilepsy, childhood absence, or juvenile myoclonic epilepsy, which are thought to have a particularly favorable or unfavorable prognosis for remaining in remission following drug withdrawal (24,38,86,89). Changes in the EEG between the onset of seizures and time of medication withdrawal may also have a prognostic value (54,73).

The number of adult studies that have examined this issue is relatively small. Callaghan et al. (54) reported that an abnormal EEG was associated with an increased risk of recurrence. However, several other adult studies reported no such association (69,79). At present, the preponderance of evidence indicates that an abnormal EEG is a predictor of recurrence in children with cryptogenic epilepsy but not in those with remote symptomatic epilepsy. In adults, the data are inconclusive but suggest that an abnormal EEG is associated with a modest increase in recurrence risk (50,51,88). Whether specific electroencephalographic patterns are associated with an increased recurrence risk is a question that requires further study.

Epilepsy Syndrome

Epilepsy syndromes are known to be associated with a differential prognosis for remission (23,24,90). Syndromes such as benign rolandic epilepsy have a particularly favorable prognosis for remission and for successfully discontinuing AEDs, even if the EEG is still abnormal (72), as EEG normalization occurs later than the clinical disappearance of seizures (23). Juvenile myoclonic epilepsy, while having a favorable prognosis for remission on medications, usually requires prolonged treatment and has a high relapse rate when medications are withdrawn (24,89). Syndromes such as Lennox–Gastaut have a poor prognosis for remission even on medications (24,47,90). Overall, patients with both idiopathic and cryptogenic epilepsy syndromes have a similar prognosis (47,72,90). Interestingly, while specific idiopathic syndromes and the various other generalized epilepsy syndromes have different prognoses, the various nonidiopathic partial epilepsies do not appear to have major differences in the relapse rate following medication withdrawal (72). Unfortunately, there is a paucity of such information as few studies of AED withdrawal provide information by epilepsy syndrome. It is clear that future studies will focus on epilepsy syndrome as a major predictor of long-term prognosis and management, both at the time of diagnosis and when in remission on medications (23,42,72,90).

Other Risk Factors

Other risk factors, such as duration of epilepsy, number of seizures, seizure type, and the medication used, have not been consistently associated with a differential risk of relapse following AED withdrawal in either children or adults.

Duration of epilepsy and number of seizures are closely interrelated. A long duration of epilepsy increases the risk of recurrence, although the magnitude of the effect is small (62,63). One study also reported that having more than 30 generalized tonic–clonic seizures was associated with a high risk of recurrence after discontinuation of therapy (58). In a community-based practice, most people are easily controlled within a short time after therapy is initiated so that these factors will rarely be important (42,46,47).

The specific AED used also has not been consistently associated with the risk of recurrence,

although one well-designed study reported an increased recurrence risk in adults who were on valproate compared with those on other AEDs (54). Note that all the published studies on AED withdrawal are reporting the results of AED withdrawal from the old AEDs (barbiturates, phenytoin, carbamazepine, valproate, and ethosuximide). The serum drug level does not seem to have a great impact on recurrence risk. Patients who have not had seizures for several years often have "subtherapeutic" levels, and few have high levels. Available studies show little or no correlation between drug level prior to discontinuation and seizure recurrence and outcome (73) or a very modest effect (58).

Seizure type has also not been consistently associated with recurrence risk, except that children with multiple seizure types have a poorer prognosis (62,63,81). The data regarding partial seizures are conflicting (50,52,54,58,62–64,67,72,73,75). Note that specific seizure types may be surrogate markers for epilepsy syndromes with a more favorable or less favorable prognosis. At this time, it is not clear that any specific seizure type is associated with an increased risk of recurrence following discontinuation of medication.

HOW LONG TO TREAT AND HOW RAPIDLY TO TAPER?

Duration of Seizure-Free Interval Prior to Attempting Withdrawal of Antiepileptic Drugs

The chances of remaining seizure free after medication withdrawal is similar whether a 2-year (49,52,54,64,72,73,75) or a 4-year seizure-free interval (58,62,63,67,72,75) is used. One study that evaluated seizure-free intervals of 1 or more years did find that a longer seizure-free period was associated with a slightly lower recurrence risk (75). However, the higher relapse rates were primarily observed in those who were withdrawn after 1 year. In general, the epidemiologic data do not support the need for treatment beyond 2 years in cases where AED withdrawal is being considered.

A few investigators attempted to withdraw AEDs in children with epilepsy after a seizure-free interval of 1 year or less (56,71,87). A meta-analysis found a pooled relative risk of 1.3 for withdrawal prior to 2 years seizure free versus 2 or more years seizure free (88). While the recurrence risks in these studies are somewhat higher than in studies that used a longer seizure-free interval, they do suggest that, in selected populations, a shorter seizure-free interval may be sufficient. The higher recurrence risks reflect the fact that when a less stringent criterion for remission is used, fewer patients are actually in long-term remission. Long-term outcomes are not adversely affected by early discontinuation (71).

Duration of Medication Taper

Once the decision to withdraw AEDs has been made, the clinician needs to decide on how quickly the medications can be withdrawn. Many clinicians have used slow tapering schedules lasting many months or even years, thinking that they would reduce the risk of recurrence. Even the randomized study from the Medical Research Council (MRC) AED Drug Withdrawal Group (67) used a relatively slow taper. There is general agreement that abrupt discontinuation of AEDs is inadvisable

in an outpatient setting and may increase the risk of seizure recurrence. Beyond that, there is much heated debate primarily based on mythology. A well-designed, prospective, randomized clinical trial has provided solid data on this issue (74). The study compared a rapid 6-week AED taper with a more gradual 9-month taper in children with epilepsy whose AEDs were being discontinued after a 2-year or longer seizure-free interval. There were no differences in recurrence risk at 2 years between the groups with short and long tapering regimens. This well-designed study should finally settle this long-standing controversy, although specific drugs, such as barbiturates and benzodiazepines, might require slightly longer tapering periods. Note that a long tapering period will not alter the recurrence risk at 2 years but may delay the recurrence and, thus, tends to prolong the period of uncertainty. Thus, a relatively short taper period is particularly important in adolescents and adults if we advise them to stop driving for 6 months to a year following AED withdrawal.

Prognosis Following Relapse

The majority of patients who relapse after medication withdrawal will become seizure-free and in remission after AEDs are restarted, although not necessarily immediately (47,71,83,91,92). The prognosis for long-term remission appears to be primarily a function of the underlying epilepsy syndrome. The MRC randomized study of medication withdrawal in children and adults found that the prognosis for seizure control after recurrence in patients with previously well-controlled seizures was no different in those who were withdrawn from AED therapy and relapsed and those who relapsed while remaining on AED therapy (92).

WITHDRAWAL OF ANTIEPILEPTIC DRUGS AFTER SUCCESSFUL RESECTIVE SURGERY

Epilepsy surgery is the treatment of choice in suitable patients with refractory epilepsy. Patients with intractable epilepsy who undergo resective surgery are considered a class 1 successful outcome if they are seizure free following surgery, whether they are on AEDs (93,94). In the past, the tendency was to maintain them on at least one AED indefinitely (94). The issue of whether and for how long patients who are seizure free following surgery need to remain on chronic AED therapy is receiving increased attention. Several retrospective studies in adults report that approximately 60% of patients with medically refractory epilepsy who become seizure free after resective surgery remain so when AEDs are withdrawn (95–97). Younger age at surgery and presence of hippocampal sclerosis on imaging were favorable predictors for seizure freedom after AED discontinuation (98–101). Factors consistently associated with a high risk of relapse include age older than 30 years at time of surgery, longer duration of epilepsy, persistent epileptiform discharges on EEG, and normal imaging preoperatively (98–101). Following neocorical resections, reported risk of relapse following medication reduction may be much higher, particularly when imaging is negative (102) Successful withdrawal of AEDs following resective surgery has also been reported in children (103,104). Generally, the risks of medication withdrawal in this population appear similar to those seen in those with remote symptomatic epilepsy in remission on medications (50,72). It, therefore, appears reasonable to consider medication withdrawal in patients who are seizure free following resective surgery (94,97,103). The prognostic factors for successful medication withdrawal are not well defined but appear to be different than for those who become seizure free with medical therapy (97). The optimal timing for medication withdrawal in this population is not clear.

In principle, one can ask, following a potentially curative procedure, why wait more than a short seizure-free interval, such as 6 months or a year, before attempting withdrawal in this population (97). Berg et al. (105) reported that many of the relapses in patients who attained at least 1-year seizure, remission occurred while reducing or eliminating the AEDs. The risk of recurrence was not higher than in those who continued AEDs (105–107). The physician should remember that while some patients may be eager to try coming off medication in the belief that they are cured (97), many may be unwilling to jeopardize their newly achieved seizure-free state (107). The decisions need to be individualized, based on the potential risks and benefits in each case and the personal preferences of the patient.

Further, well-controlled prospective studies are needed to provide rational practice guidelines to inform the clinical decision in this setting.

RISKS OF NOT TREATING OR OF DISCONTINUING ANTIEPILEPTIC DRUGS

The major risk associated with not treating after first seizure or of discontinuing AED therapy is having a seizure recurrence. The potential consequences of the seizure recurrence include both direct consequences and psychosocial impact. There is no convincing evidence that a brief seizure causes brain damage (33,39,108,109). Serious injury from a brief seizure is a relatively uncommon event usually related to the impairment of consciousness or loss of consciousness that occurred at an inopportune time or place (e.g., driving, riding a bicycle, swimming, on a stairway, cooking) (25,39,83). These are much less likely to occur in children who are usually in a supervised environment and are not driving, operating heavy machinery, or cooking. In a study of withdrawing AEDs in 264 children with epilepsy who were seizure free on medication, there were 100 recurrences (83). Of these, 2 experienced status epilepticus as their initial recurrence and have done well after reinitiation of AEDs with no long-term consequences. Five sustained an injury as a result of the initial recurrence, including 4 with lacerations and 1 with a broken arm. Thus, the rate of serious injury was quite low. Most reports of serious injuries in patients with epilepsy discuss patients with intractable epilepsy who experience injuries such as burns in the context of frequent seizures (110,111).

Status epilepticus is a concern, particularly in adults. It should be noted that the morbidity of status epilepticus in both children and adults is primarily a function of etiology, and in this clinical setting will be low (109,112–114). Furthermore, the risk of status epilepticus in this population is low and essentially limited to those who have had it before (13,28). While status epilepticus is frequently reported in patients with epilepsy who are noncompliant (112,113), the occurrence of status epilepticus in patients who are withdrawn from their AEDs after a seizure-free interval is very low (73,83). Sudden Unexplained Death in Epilepsy is of increasing concern but has not been reported in those not treated after a first seizure unless they have had many more seizures (20,25,34,115) and has not been reported in trials of discontinuation of medications in patients who are seizure free.

Some authors, most notably Reynolds, have expressed concern that, in addition to the potential for injury, the consequences of a seizure include a worse long-term prognosis, and thus, argue that treatment is indicated even after a single seizure (19,116). This view is largely based on Gower's statement that "The tendency of the disease is toward self-perpetuation; each attack facilitates the

occurrence of the next by increasing the instability of the nerve elements" (117), which became the basis for the popular notion that "seizures beget seizures." Current epidemiologic data and data from controlled clinical trials indicate that this is not the case (16,17,30,33,37,92,108,112). Studies in developing countries, where treatment delays are a result of the unavailability of AEDs, show no difference in response rate in those with many prior seizures compared with new-onset patients (37,118). Prognosis is primarily a function of the underlying epilepsy syndrome, and although treatment with AEDs does reduce the risk of subsequent seizures, it does not alter the long-term prognosis for seizure control and remission (16,30,33,37,118). The decision to treat should, therefore, be made on the grounds that the patient has had a sufficient number of events to justify initiating therapy or is at sufficiently high risk for seizure recurrence to justify continued therapy and not with the hope of somehow preventing the development of "chronic" epilepsy (33).

Although a seizure may be a dramatic and frightening event, the long-term psychosocial impact of an isolated seizure in children is minimal. In adults, the psychosocial impact can be more serious, and includes the loss of driving privileges and possible adverse effects on employment (119,120). Social stigma of seizures is also much more a concern in adolescents and adults.

RISKS OF INITIATING OR CONTINUING TREATMENT WITH ANTIEPILEPTIC DRUGS

Although effective in controlling seizures, AEDs are associated with a variety of significant side effects that must be considered when deciding to initiate or to continue treatment (Table 45.1). Physicians are generally familiar with systemic side effects, including idiosyncratic, acute, and chronic. Idiosyncratic and acute adverse events sufficient to require discontinuation of the drug occur in 15% or more of patients newly treated with an AED and need to be considered when deciding whether to initiate AED therapy. They are not generally a major concern when deciding whether to continue AEDs in patients who are seizure free as almost all those patients are on stable drug regimens without evidence of acute toxicity. Chronic toxicity is a concern in both settings. There is evidence that children may be more susceptible to chronic toxicity from AEDs (33). In the elderly, an additional concern is drug–drug interaction, as many of these patients are on multiple other medications that also are protein bound and metabolized by the cytochrome P450 system. Adverse effects on many AEDs on bone health are also of increasing concern (121).

Table 45.1 Risks and Adverse Effects of AED Therapy and of Seizures[a]

Risks of AED therapy	Risks of seizures
Systemic toxicity	Physical injury
Idiosyncratic	Loss of consciousness
Dose related	Falls
Chronic toxicity	Status epilepticus
Children and adolescents	
	Sports injuries
	Bathing/swimming: drowning
Adolescents and adults	
Teratogenicity	Driving accidents
	Bathing/shower: scalding
	Cooking injuries, burns
Higher cortical functions	
Cognitive impairment	Impairment in postictal state
Children	
Adverse effects on behavior	
Psychosocial	
Need for daily medication	Fear of subsequent seizures
Labeling as chronic illness	Loss of privacy
	Stigma of seizures
Children and adolescents	
	Restrictions on school/social activities
Adolescents and adults	
	Restrictions on driving
	Difficulties providing childcare
Economic/temporal	
Cost of medications	Time lost because of seizure and recovery
Cost/time of laboratory tests	
Cost/time of physician visits	
Adolescents and adults	
	Discrimination in employment

[a]Some adverse effects of seizures may also occur with AED therapy. Adverse effects listed by age group, such as behavioral effects and bathtub drowning, are meant to indicate the predominant age group in which they occur and do not exclude their occurrence in other age groups.

It is now recognized that AED therapy is associated with a variety of both cognitive and behavioral adverse effects (33,122). These are more common in children, and sometimes are difficult to recognize. In particular, children on medications since their preschool years may not be identified as having side effects from medications. Only when medications are stopped does it become apparent that the child's performance was impaired by the drug. Adults can also experience cognitive and behavioral adverse events from AED therapy. Increasingly, studies of new AEDs include measures of neuropsychological function to help address this issue. The reason phenobarbital is no longer considered a first-line drug in adults with epilepsy is not because of its efficacy, which is excellent, but because of the impairment of cognition and behavior associated with its use. Although other agents are less of an issue, all AEDs can have adverse effects on cognition and behavior (33,122).

For women of childbearing age, including adolescents, a discussion of the risks of treatment must include consideration of the potential teratogenicity of these compounds (123). As the major teratogenic effects usually occur in the first few weeks of gestation, often before a woman is aware that she is pregnant, the physician must always consider this issue in advance. It impacts both on the decision to initiate or withdraw AED therapy and on the choice of AED. One must also consider that

many pregnancies, particularly in adolescents, are unplanned. Furthermore, enzyme-inducing AEDs may reduce the efficacy of oral contraceptives by inducing the hepatic enzyme systems responsible for their metabolism (123). For this reason, we are reluctant to initiate AED therapy in adolescent females and are particularly aggressive in trying to withdraw them from medications after a 2-year seizure-free interval, even if their other risk factors are not favorable.

A hidden side effect of continued AED treatment is that of being labeled (see Table 45.1). People with single seizures or epilepsy who have not had a seizure in many years and are off medications are considered to be healthy both by themselves and society. Those individuals can lead normal lives with very few restrictions. Unless they choose to, they rarely need to disclose that they once had seizures. In contrast, even if a patient only had a single seizure or is seizure-free for many years, being on AED therapy implies chronic illness to both the patient and those around the patient (33,120,123). Continued use of medication requires ongoing medical care to prescribe and monitor the medication and establishes that the individual is a patient in need of treatment for a chronic condition. It also implies certain restrictions in driving and may have an adverse impact on obtaining employment and other social issues. Labeling is a problem in both children and adults. The MRC study reported that psychosocial outcomes were improved in adults who were successfully withdrawn from AED therapy (120). In children and adolescents there is the additional problem that the perception of any chronic illness adversely affects the normal psychosocial maturation process, particularly in adolescents (38,124).

COUNSELING FAMILIES

Decisions on initiating or discontinuing AEDs ultimately depend on a relative assessment of risks and benefits. These are assessed differently by physicians and by patients and their families. Therefore, providing appropriate education and counseling to the patients and their families is critical, regardless of the final therapeutic decision. Both seizures and AED therapy are associated with some risks. Even though patients with good prognostic factors have a lower risk of recurrence, this risk is not zero even if they stay on medications. Conversely, those with poor risk factors may nevertheless maintain remission off medications. The risk of adverse events from AED therapy is essentially independent of the recurrence risk and always needs to be considered, as does the psychosocial impact of both seizures and continued AED therapy. Education assists the patient and family in making an informed decision, helps them to fully participate in the plan of care, and prepares them to deal with psychosocial consequences of the diagnosis. Informed decision making by the physician, in consultation with the family, maximizes the chances of good long-term outcomes.

Patients and families need to be reassured that the risk of a serious injury or death from an isolated seizure is low. They also need to be counseled about appropriate first aid for seizures and safety information. This is a particular problem for adults, as they are more likely to engage in activities that may predispose them to injury should a seizure occur. Places of employment may or may not be accommodating to the person at risk for a seizure.

A discussion of possible restrictions on activities is also important. Parents will need to be told that most of the child's activities can be continued, although some, such as swimming, may need closer supervision. Adolescents and adults will need specific instructions regarding activities such as swimming, cooking, and driving. Counseling often allays fears and educates the patient and family on safety precautions. This reduces the chance for injury from seizures, if the patient is treated. Educational programs are available for school personnel—teachers, nurses, and students—and

information for babysitters is also readily available. Note that, in the case of the child or adult with a first seizure, this discussion is equally applicable whether one decides to initiate AED therapy, as therapy reduces, but does not eliminate, the risk of seizure recurrence.

The information provided must be individualized to both the situation and the sophistication level of the patient and the family. The family of a patient with epilepsy who is seizure free on medications should be familiar with the side effects of AED therapy and with seizures, and be able to discuss recurrence risks from withdrawing AEDs and the potential consequences. In the case of patients with a first seizure, the discussion needs to be more comprehensive, including first-aid measures in case of a recurrence, potential adverse effects of AEDs, risks of recurrence, impact on long-term prognosis of delaying therapy until after a second seizure, and restrictions on activity that will occur with or without therapy. It may be difficult to accomplish this in one session, especially in the emergency department where the circumstances may not be conducive to a calm discussion of the relative risks and benefits and where key information on recurrence risks, such as the results of the electroencephalograph or an imaging study, may not be available.

Families will usually be interested in information that will help them manage the illness or specific problems. Lengthy explanations on any one issue may be confusing and are usually not helpful. Children and adults may have fear of accidents, fear of the loss of friends, fear of taking "drugs," and other less well-defined concerns. A parent's perception of the child's disorder will be an important factor in later coping and will ultimately impact on the perception of quality of life. Adults may have to make major lifestyle changes. The practitioner's prejudices regarding treatment options will undoubtedly come into play during these discussions, but the different options need to be discussed. Although more time-consuming than issuing a prescription, this counseling is necessary for both informed decision making and for favorable long-term outcomes.

A THERAPEUTIC APPROACH

Initiating Antiepileptic Drug Therapy

In children with a first seizure, there is an emerging consensus that treatment after a first unprovoked seizure is usually not indicated (6,7,12–14,33,39,50), particularly in neurologically normal children with a brief first seizure (33). We will rarely treat a child with a first unprovoked seizure, even in the presence of risk factors such as a remote symptomatic etiology, an abnormal EEG, or a prolonged first seizure (13,14). In children with infrequent brief seizures, particularly in the context of a self-limited benign childhood epilepsy, many clinicians do not initiate AED therapy even after a second or third seizure (14,16,37–39). This is based on an assessment of the relative risks and benefits of AED therapy in children who will most likely enter remission with or without treatment and who will most likely continue to have only infrequent seizures (14). However, there is no consensus on this issue.

In adults, the decision to treat or not after a first seizure remains more controversial (9,17,30,116). However, prospective studies show lower recurrence risks than previously thought and a well-designed, prospective, randomized study demonstrated no impact on long-term prognosis from delaying therapy (30,33,36). Therefore, a growing number of clinicians are delaying initiating long-term AED therapy after a single seizure (9,17,30). This is particularly true in young adults who would be committing to long-term therapy and in women of childbearing potential. Following two seizures, the risk of further seizures is approximately 70%, and, in general, AED treatment is

indicated (9). The major exception may be a woman who wishes to have children in the immediate future and who has had two brief seizures. In this setting, there is no definite answer, and the clinician and the patient must again weigh the relative risks and benefits of initiating therapy at that time or waiting (123).

In both children and adults, a thorough evaluation of the patient, including a detailed history and neurologic examination, as well as appropriate laboratory studies, such as an electroencephalograph and an imaging study when indicated, are important (21). Of particular importance is a careful history of prior events that may be seizures (21). A substantial proportion of patients who first come to medical attention with a seizure turn out to have had prior episodes that were also seizures (1,2,12,21). This is particularly true for patients who present with a first convulsive episode and, after a careful history is taken, are found to have had prior nonconvulsive episodes of absence or complex partial seizures. These patients fall into the category of newly diagnosed epilepsy, and not first seizure, and usually need treatment.

Withdrawing Antiepileptic Drug Therapy

The question of continuing or withdrawing AED therapy in a given patient must be considered based on an analysis of the relative risks and benefits. The goal is to achieve the best possible outcome for that patient, whether the ultimate decision is to treat or not. In considering the risks of seizure recurrence, the statistical risk of relapse is only one piece of the puzzle. One must consider not only the mathematical probability of seizure recurrence but the consequences of such a recurrence. The risk of seizure recurrence following medication withdrawal in children is somewhat lower than in adults, and, in addition, there are identifiable subgroups with a particularly favorable prognosis. Adverse effects of continued AED therapy are also clearly more an issue with children than with adults, particularly adult males. However, it is in the area of potential consequences of a recurrence that the differences are most pronounced.

The adult who is driving and employed can suffer significant adverse social and economic consequences from having a seizure. In addition, an adult is more likely than is a child to have the seizure in a setting where a physical injury may occur as a result of impaired consciousness (e.g., driving, operating machinery, cooking). Therefore, a 30% risk of recurrence, which is very acceptable in most children, may be unacceptable to adults because of the more serious consequences of a recurrence. When these are taken into account, patient preferences clearly depend on age and gender, despite similar statistical risks. In the British MRC AED withdrawal study, the psychosocial outcomes of those who successfully came off AEDs were better, and the statistical risk of recurrence was similar to those seen in children (67,68). However, when other adult patients were counseled based on the results of that study, the majority chose to remain on AED therapy (119). Nevertheless, adults who are seizure free on their AEDs for 2 or more years should have the option of AED withdrawal discussed, even if the recommendation of the clinician is to remain on medications, as some patients will find the risk-to-benefit ratio favorable (119,125). Women of childbearing age are a special category, where a more aggressive approach to AED withdrawal may be indicated for reasons already discussed (123,125). Another category where a more aggressive approach should be considered is young adults of either gender with childhood-onset epilepsy who are still on medications. A chance at AED withdrawal, especially if they do not need to drive, should be considered before committing them to life-long therapy (38).

The reverse argument may be made for young children. In this group, the risk of relapse is smaller

and, depending on the degree of parental supervision, the consequences relatively minor, whereas the risks of side effects from medications are greater. It is much safer to withdraw AEDs in this environment than when the patient is an adult. The risk-to-benefit analysis favors attempting medication withdrawal even in those with a higher risk of relapse (38,56,87).

Adolescents are a special case with additional issues. Adolescents with any chronic illness tend to become noncompliant as part of adolescence. We would far rather withdraw AEDs in a controlled fashion and make the explicit contract that if a recurrence occurs both the patient and the clinician know that medications are needed, than have the adolescent drive and then become noncompliant. In adolescent women, issues of teratogenicity also need to be considered, especially as most pregnancies in this age group are unplanned. Even if immediate pregnancy is not a major concern, these young women will soon be entering their childbearing years and decision making needs to take this into account (123). On a risk-to-benefit basis, it is rational to attempt medication withdrawal at least once in adolescents, particularly young women, even if they have risk factors for recurrence. A possible exception to this discussion of adolescents is young men with juvenile myoclonic epilepsy, where there is a very high recurrence risk (24,89). This needs to be discussed with the patient. Even then, however, one attempt at withdrawal may be reasonable as the prognosis may be more variable than previously thought (24,90). In the authors' experience, the majority of adolescents who are offered the choice will choose to attempt medication withdrawal, especially if this choice is presented to them before they are driving.

The clinical data do not demonstrate any significant advantages of waiting more than 2 years before attempting AED withdrawal. The exception to this may be the child with an age-dependent epilepsy, where a longer wait may alter the recurrence risk as the underlying syndrome is more likely to be in remission. However, these are precisely the children with a favorable long-term prognosis where AED withdrawal is often successful even after a brief treatment period (37,56,72,87,88).

Once the decision to withdraw AED therapy is made, the taper should be fairly rapid, as randomized clinical studies show no advantage to a slow taper (74). A slow taper has the additional disadvantage of prolonging the period of uncertainty. In general, we taper a single AED over 4 to 6 weeks. For the patient on two AEDs, we often first taper one AED and see if the patient can be maintained on monotherapy. If the patient remains seizure free on monotherapy, then a second withdrawal is attempted with the plan of treating with monotherapy only if there is a recurrence.

CONCLUSION

Given the consequences of long-term drug therapy and its lack of effect on long-term prognosis following a first seizure, we generally do not recommend treatment following a first unprovoked seizure in either children or adults. Following a second seizure, treatment is generally indicated in adults and needs to be considered in children. In children and adolescents who are seizure free on AEDs for at least 2 years, at least one attempt should be made at medication withdrawal, even if risk factors for recurrence are present. In adults, the risk-to-benefit equation in this setting is less clear, and decisions must be individualized after discussion of the risks and benefits with the patient.

The approach presented in this chapter emphasizes that both seizures and the therapies available carry some risk and that optimal patient care requires careful balancing of these risks and benefits. Assessment of risk requires not only ascertaining the statistical risk of a seizure recurrence or of an adverse event but also the consequences of such an event. This risk-to-benefit approach is useful not only in deciding whether to initiate or discontinue AED therapy but also in other treatment decisions.

This includes deciding whether to add a second drug, to try experimental drugs or therapies such as the ketogenic diet, or to consider epilepsy surgery. In all cases, one must balance the risks and benefits of the proposed alternatives, which may change as new information becomes available. Whatever the decision, it should be made jointly by the medical providers and the patient and family after careful discussion, including not only an assessment of the risks and benefits of treatment but also an understanding that individual patients and clinicians place different values on different outcomes and on the acceptability of certain risks.

CHAPTER 46 HORMONES, CATAMENIAL EPILEPSY, SEXUAL FUNCTION, AND REPRODUCTIVE AND BONE HEALTH IN EPILEPSY

SCOTT J. STEVENS AND CYNTHIA L. HARDEN

Steroid hormones alter neuronal excitability, and these hormones in turn can be altered by seizures, by epilepsy, and by the pharmacokinetic effects of antiepileptic medications. Steroid hormones that are neurophysiologically active and alter the seizure threshold are known as neuroactive steroids or neurosteroids.

This chapter reviews and discusses the actions of neurosteroids on cortical excitability and epilepsy, the effect of seizures and antiepileptic medications on steroid hormones, and then focuses on catamenial epilepsy and sexual function in addition to reproductive and bone health issues in people with epilepsy.

EFFECTS OF NEUROSTEROIDS ON NEURONAL EXCITABILITY

The effect of steroid hormones on neuronal excitability has been an area of translational research, studied at molecular, animal, and clinical levels. Neurosteroids can modulate neuronal excitability through nongenomic direct membrane-mediated effects or receptor-mediated effects through the indirect genomic pathway that regulates protein synthesis. The two primary female reproductive hormones, estrogen and progesterone, are neurosteroids, which have been shown to have differing effects on neuronal excitability.

Estrogen

Estrogen works through both nongenomic and genomic pathways by binding to estrogen receptors that are widely spread throughout the brain (1). In summary, estrogen has excitatory effects by facilitating kindling and lowering the electroshock seizure threshold (2,3), activating preexisting cortical epileptogenic regions (4), in addition to increasing the severity of chemically induced seizures (5,6). This is thought to be secondary to decreasing the conduction of chloride through the G-aminobutyric acid $(GABA)_A$ receptor complex and the inhibition of GABA synthesis, an inhibitory central neurotransmitter (7). It has also been shown that estradiol increases the neuronal response to glutamate, an excitatory central neurotransmitter, through agonist effects on the N-methyl-D-aspartate receptor (8). In addition to having proconvulsive properties, estrogen has also been shown to have

anticonvulsant properties. The dose, route of administration, chronic versus acute administration, and species of estrogen can determine if it is a proconvulsant or anticonvulsant (9). This finding may be useful in determining if estrogen can possibly be used as future therapy for treating patients with epilepsy.

Progesterone

Unlike estrogen, which primarily acts by decreasing chloride conduction, progesterone has been found to increase chloride conductance at the $GABA_A$ receptor complex, promoting neuroinhibition (10). This effect is modulated primarily through the action of allopregnanolone, a neuroactive progesterone metabolite. Allopregnanolone has a neuromodulatory effect similar to that of a potent benzodiazepine and is much stronger than that of phenobarbital; however, it binds to a unique $GABA_A$ receptor site (10). It is therefore believed that progesterone, mainly through the action of its metabolites, has strong anticonvulsant properties.

Progesterone has the ability to increase the electroconvulsive shock threshold and increase the threshold for chemically induced seizures (9). It has been shown in experimental models that cyclical changes in the concentrations of progesterone and allopregnanolone can predictably alter the susceptibility to seizures. However, cyclical hormonal changes likely do not fully account for seizure exacerbations in women with catamenial epilepsy (11).

Testosterone

In addition to the two neurosteroids above, testosterone also has the ability to alter the seizure threshold. Androgens are metabolized into estrogens and 5α-reduced androgens by two different enzyme pathways, and these two classes of metabolic products have opposite neuroexcitatory effects. The estrogens are derived from precursor androgens through the action of a cytochrome P450 enzyme, aromatase, and are proconvulsant as described above. In contrast, the 5α-reduced androgens act as substrates for the biosynthesis of 5α-androstane-3α-diol, an anticonvulsant molecule that is structurally similar to allopregnanolone and has similar neuromodulatory effects on the activity of the $GABA_A$ receptor (12). Additionally, two other endogenous testosterone metabolites found in men, androsterone and etiocholanolone, also have been found to have anticonvulsant properties (13).

Cortical Distribution of Neurosteroid Receptors

The differential effects of steroid hormones on neuronal excitability, endocrine function, and reproductive behavior may to some extent be explained by anatomic specificity and changes with maturation in the cortical distribution of steroid hormone receptors. Estrogen receptors are located mainly in the mesial temporal lobe (limbic cortex) and hypothalamus, while progesterone and androgen receptors are diffusely distributed throughout the brain (14). The distribution of these receptors is not static and is modified throughout development (15). These findings may partially explain why there is a variation in seizure expression with changes in age and reproductive function.

HORMONE DISTURBANCES IN EPILEPSY

Decreased libido, infertility, early menopause, and polycystic ovarian syndrome (PCOS) are found

more commonly in patients with epilepsy than in the general population (16). Epilepsy can affect steroid hormone concentrations in men and women by disrupting the hypothalamic–pituitary–gonadal axis. Additionally, certain antiepileptic drugs (AEDs) are known to alter the metabolism of reproductive hormones.

Gonadotropin-releasing hormone (GnRH) is produced in the preoptic area of the hypothalamus and is responsible for regulating the release of follicle-stimulating hormone (FSH) and luteinizing hormone (LH) from the anterior pituitary through pulsatile secretion. FSH promotes development of the primary ovarian follicle and secretion of estradiol in women and controls spermatogenesis in men. LH stimulates ovulation and formation of the corpus luteum in women and simulates interstitial cell secretion of androgens in men. Additionally, prolactin, which inhibits sexual behavior in both sexes and can cause impotence in men at high levels, is also under hypothalamic regulation (17).

Certain regions within the brain, especially the amygdala, have been found to have connections with the hypothalamic cells responsible for secreting GnRH, making the GnRH cell population susceptible to injury from limbic seizures. This can explain why the pulsatile secretion of LH has been found to be altered in women with certain types of seizures (18). Additionally, interictal levels of growth hormone and prolactin have been found to be elevated in many epileptic patients, with levels of prolactin increasing more than twofold after certain types of seizures (19). Seizure lateralization is important in the etiology of certain epilepsy-induced reproductive endocrine disorders. One study of women with complex partial seizures showed that those exhibiting right temporal lobe discharges were found to be more likely to have hypogonadotropic hypogonadism, while those women with left temporal lobe discharges were found more likely to have PCOS (20).

EFFECTS OF ANTIEPILEPTIC DRUGS ON REPRODUCTIVE HORMONES

AED inducers, in general, decrease concentrations of reproductive steroid hormones by increasing hepatic metabolism and inducing the production of sex hormone–binding globulin, which in turn decreases free levels of reproductive steroid hormones (21). As compared to patients taking noninducing AEDs, women taking inducing agents are found to have lower estrogen and androgen levels, while men on these agents are found to have lower testosterone levels (21). Medications that decrease the concentration of reproductive steroid hormones include phenobarbital, phenytoin, carbamazepine, primidone, topiramate, oxcarbazepine, rufinamide, and clobazam (16). Medications that have little effect on the concentrations of reproductive steroid hormones include ethosuximide, gabapentin, lamotrigine, levetiracetam, zonisamide, pregabalin, lacosamide, and retigabine (16).

Although valproate decreases free testosterone levels in men (22), testosterone levels generally rise in women taking valproate through inhibition of cytochrome P450 isoenzymes and aromatase (23,24). This is clinically important, since there is an increased incidence of PCOS is women taking valproate. Levetiracetam binds to the SV2A receptor in brain, gonadal, and endocrine tissues. It has been suggested to have a direct gonadal effect in men, increasing total testosterone levels 1 month after the onset of treatment (25). These findings with levetiracetam illustrate that the pharmacokinetic effects of AEDs may only be part of the overall explanation for the changes in hormone levels associated with these medications.

CATAMENIAL EPILEPSY

As described above, estrogen and progesterone can alter the seizure threshold. In experimental models of epilepsy, it has been found that these two hormones fluctuate throughout the course of a regular menstrual cycle, changing seizure susceptibility throughout the cycle (26). Catamenial epilepsy is the clustering of seizures in alignment with the female reproductive cycle. This phenomenon is believed to occur secondary to the properties of the neurosteroids in combination with the natural cyclic variation of their serum levels throughout the course of each menstrual cycle (27).

The Menstrual Cycle and Patterns of Catamenial Seizures

The typical average menstrual cycle is approximately 28 days and starts on the first day of menses. Ovulation takes place on day 14 and is preceded by the follicular phase on days 1 through 13. The luteal phase begins after the oocyte is released and has a fairly invariant duration of 14 days, in which the dominant follicle forms the corpus luteum, which releases progesterone. Therefore, progesterone levels, in a normal menstrual cycle, are higher during the luteal phase than during the follicular phase, then rapidly decreasing several days prior to menses.

Two predominant patterns of catamenial seizures are seen during normal ovulatory cycles, perimenstrual (C1) and periovulatory (C2), with the perimenstrual pattern being most common. Seizure frequency is linked to the ratio of serum estradiol to progesterone, with higher ratios leading to seizure clustering (27). In the normal cycle, this ratio is highest during the premenstrual period and the days preceding ovulation, and is lowest during the mid-luteal phase. The premenstrual rise in seizure frequency has been described to possibly be secondary to the rapid withdrawal of progesterone, analogous to a benzodiazepine withdrawal (28,29). The increased frequency of seizures found in the days prior to ovulation is thought to be secondary to the rapid, steep increase in serum estradiol prior to the increase in serum progesterone that occurs at ovulation (28,29). During the mid-luteal phase, serum progesterone levels are higher than those of serum estradiol, making the occurrence of seizures less likely. Anovulatory cycles are the exception to these findings, in which a rise in serum estrogen still occurs without an increase in serum progesterone (29). These relationships can be seen in Figure 46.1.

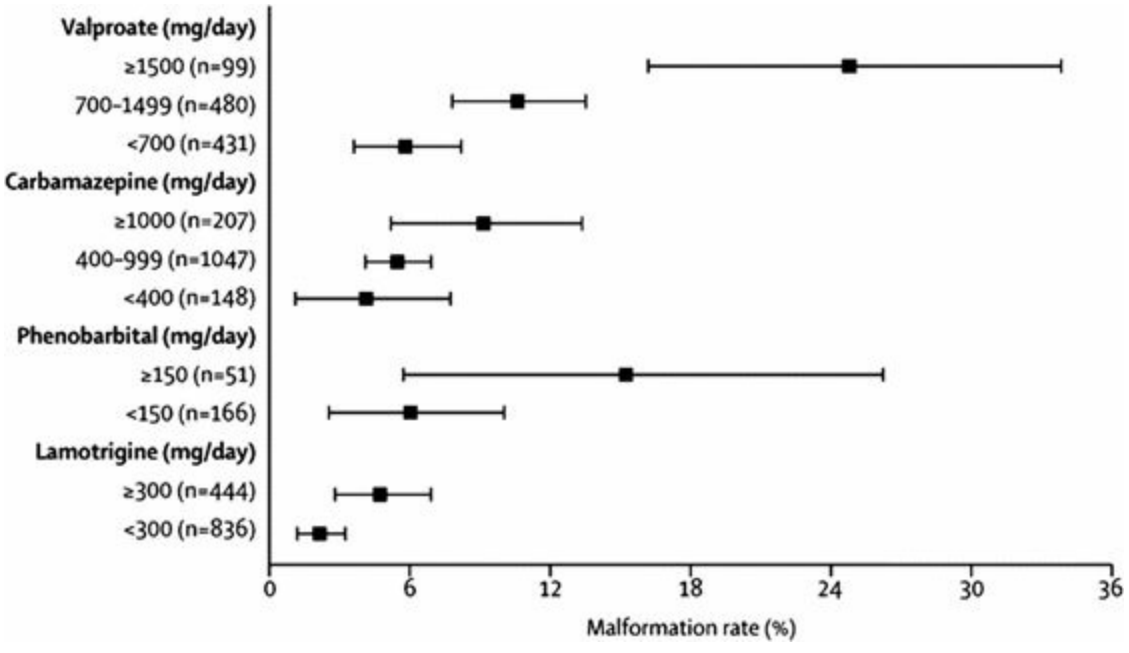

Figure 46.1. Three patterns of catamenial epilepsy: perimenstrual (C1) and periovulatory (C2) exacerbations during normal ovulatory cycles and entire second half of the cycle (C3) exacerbation during ILP cycles. F, follicular phase; L, luteal phase; M, menstruation; O, ovulation. (From Herzog AG. Catamenial epilepsy: definition, prevalence, pathophysiology and treatment. Seizure. 2008;17:151–159.)

A third pattern of catamenial seizures (C3) is seen in patients with inadequate luteal phase (ILP) cycles and occurs less frequently than the other two catamenial seizure patterns. Women with abnormal FSH secretion have decreased progesterone production secondary to poor development of the follicle and a poorly developed and functioning corpus luteum. This is known as ILP. Although ILP cycles can occasionally occur in normal women, they may also be caused by problems with the hypothalamic pituitary axis, ovarian defects, or defects in luteal cell steroidogenesis (30). ILP cycles have been shown to occur more in women with epilepsy than in healthy controls (31), which is likely related to dysfunction of inputs to the hypothalamus from ictal and interictal discharges. Estrogen levels are not affected, creating an increased estradiol/progesterone ratio and increased seizure occurrence from days 10 to 3 of the menstrual cycle (29). These findings are illustrated in Figure 46.1.

Effect of Menstrual Cyclic Antiepileptic Drug Levels on Seizure Occurrence

In addition to the pharmacodynamic effects of endogenous reproductive steroids on seizure occurrence, it has also been postulated that the pharmacokinetic effects of neurosteroids can alter the metabolism of AEDs. One study reported that phenytoin levels on day 28 in women with catamenial seizures were significantly lower than in women without cyclic exacerbations (32). However, it has also been shown in other studies that there is no relationship between neurosteroid levels and serum AED levels (32,33). In general, alterations in AED levels do not account for catamenial seizure exacerbations, while endogenous hormonal cycling has more influence.

Treatment of Catamenial Epilepsy

The first-line treatment for all patients with epilepsy is a first-line AED. However, adjunctive therapy with acetazolamide, benzodiazepines, and hormonal therapy may prove beneficial in managing patients with catamenial epilepsy. Most of the treatment interventions for women with catamenial epilepsy have been aimed at treating the premenstrual seizure exacerbations in women with regular menstrual periods (Fig. 46.2). Treatments are usually started during the second half of the menstrual cycle (days 14 to 26), starting treatment a prescribed number of days after menstrual bleeding.

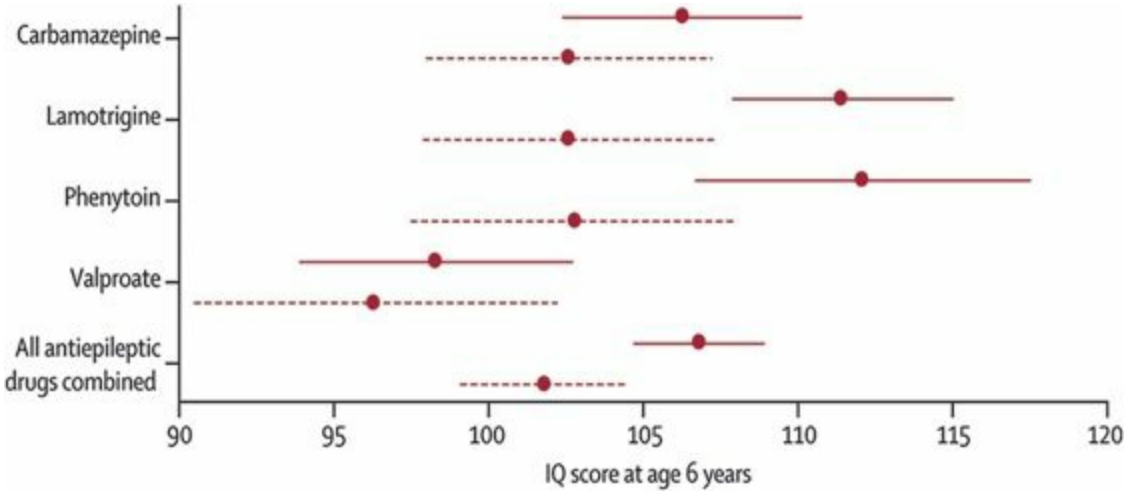

Figure 46.2. Treatment algorithm for catamenial C1 (perimenstrual) pattern of seizures. Most treatments are for focal-onset seizures in women with regular menses. C1 level 3, three times more seizures on days 25 to 3 compared with other days of the month; AEDs, antiepileptic drugs; PHT, phenytoin; IM, intramuscularly. *If menses start before day 26, start dose tapering on that day according to the same pattern of decreases. †Widely undertaken but not supported by data from randomized, controlled trails. ‡Increased risk of osteoporosis and slow return to normal fertility. (From Harden CL, Pennell PB. Neuroendocrine considerations in the treatment of men and women with epilepsy. Lancet Neurol. 2013;12:72–83.)

Although never studied in randomized trials, acetazolamide has been used in the treatment of catamenial epilepsy for over 50 years. It must be used over short periods during the menstrual cycle, since tolerance can rapidly develop to its anticonvulsant properties. It has been shown to be most effective at doses of 250 to 500 mg daily from 3 to 7 days prior to menses until day 1 of the menstrual cycle (34,35).

Benzodiazepines have also been used in women with epilepsy, with clobazam being the only formally studied treatment for catamenial seizures. Clobazam, at 20 to 30 mg/day for 10 days, starting 2 to 4 days premenstrually has been shown to reduce seizure frequency as compared to placebo (36).

In addition to the medications above, it is also reasonable to temporarily increase the dose of the patient's regular antiepileptic medication at specific times during the menstrual cycle. However, this should be avoided with phenytoin since there is a risk of toxicity associated with its nonlinear kinetics.

Since progesterone has mainly been shown to have anticonvulsant properties, it can be hypothesized that progesterone and its metabolites may be used in conjunction with current antiepileptic medications to treat women with catamenial epilepsy. Medroxyprogesterone acetate (MPA) is a synthetic progestin-only contraceptive agent that is administered every 10 to 12 weeks intramuscularly and stops the regular menstrual cycle. In patients with catamenial epilepsy, it has been shown to decrease seizure frequency by 39% at 1-year follow-up (37). However, this agent has been shown to have adverse side effects of slow return to normal fertility and increased risk of osteoporosis. Therefore, it should be considered only if catamenial exacerbations are severe and intractable to other interventions.

Although natural progesterone is not yet approved for use in the treatment of seizures, it is clear that natural progesterone could play an important role in the treatment of women with catamenial epilepsy. A small open-label study with long-term follow-up of women with catamenial seizures taking progesterone lozenges showed a significant reduction in seizure frequency when progesterone was taken during the exacerbation phase of the cycle (38). A recent randomized, double-blind, placebo-controlled multicenter clinical trial concluded that when all patients with catamenial

epilepsy were grouped together, there was no overall benefit of natural progesterone as compared to placebo (39). However, further analysis showed that progesterone was much more effective in women with at least three times or greater increase in seizure frequency during the perimenstrual phase (3 days prior to menses to 3 days after onset of menses) as compared to other days in the month (39). The degree of perimenstrual seizure exacerbation was found to be a significant predictor of response to progesterone treatment when progesterone was given as 200 mg oral lozenges twice daily on days 14 to 28, with possible taper days 26 to 28 (39). A proposed treatment algorithm of patients with seizure clustering during the perimenstrual phase is shown in Figure 46.2.

ORAL CONTRACEPTIVE AGENTS IN WOMEN WITH EPILEPSY

Oral contraceptive pills have been found in case reports to decrease seizure frequency but have not yet been systemically studied. They are, however, often used in women with epilepsy to prevent unwanted high-risk pregnancies. When these agents are used, it must be noted that they are inducers of the P450 system and may decrease the effectiveness of AEDs, which are hepatically metabolized. Furthermore, a noninducing AED should be used in combination with oral contraceptive pills when possible, to prevent increased metabolism and decreased efficacy of the contraceptive agent.

SEXUAL DYSFUNCTION AND REPRODUCTIVE HEALTH IN EPILEPSY

Sexual Dysfunction

It is important to take a detailed sexual history in all patients with a history of epilepsy. It has been shown that patients with epilepsy have a higher incidence of sexual dysfunction, mainly manifested by decreased sexual desire and potency, as compared to patients with other neurologic diseases (40). As previously discussed, there are AEDs that interact with endogenous hormones, and seizures have the ability to alter the hypothalamic–pituitary–gonadal axis. These findings, in combination with living with a perceived stigma (41) and the adverse influences of depressed mood and poor self-esteem (42), create a multifactorial etiology for sexual dysfunction in patients with epilepsy.

It is also important for the physician to bring up the topic of sexual dysfunction, since the frequency with which sexual complaints are volunteered is largely dependent on the attitude of the physician (43). When discussing sexual dysfunction, social factors, mood, hormone levels, and the effect of AEDs must all be assessed. The patient's somatic, psychological, and social well-being, as well as the dynamics of the couple and family, must all be explored (43). It must also be remembered that the sexual dysfunction may not always be secondary to epilepsy, and a full medical workup is often required as well. In addition to a complete physical and neurologic examination, patients with sexual dysfunction should undergo laboratory evaluation looking at the following serum levels: testosterone, sex hormone–binding globulin, FSH, LH, prolactin, hemoglobin A1C, and TSH. If a clear cause of sexual dysfunction cannot be elicited, urologic or gynecologic consultation may be necessary.

Vaginal dryness and dyspareunia may be treated with over-the-counter moisturizing and

lubrication products in addition to prolongation of foreplay. Phosphodiesterase inhibitors have been used in men to treat erectile dysfunction but have no effect on libido or sexual desire, which are controlled mainly by testosterone. A combination of testosterone and an aromatase inhibitor may hypothetically be beneficial in treating men with epilepsy having sexual dysfunction by increasing free serum testosterone levels and decreasing serum estradiol levels. Aromatase inhibitors in men with epilepsy have been shown to increase testosterone levels and possibly decrease seizure frequency, increase mood, and improve sexual functioning, but this combination needs to be further studies before making any definite judgments about their role in clinical practice (44,45).

Birth Rates

Population-based studies have shown that both men and women with epilepsy have lower birth rates than the general population and that adults with active epilepsy have lower birth rates in comparison to those who no longer have seizures after childhood (46,47). Decreased birth rates may be in part secondary psychosocial factors affecting patients with epilepsy such as choosing not to enter into romantic relationships or deciding not to have children. Additionally, patients with epilepsy have been shown to have decreased fertility, defined as the absence of contraception after 1 year of unprotected intercourse.

Fertility in Men with Epilepsy

Abnormal spermatogenesis may be a cause of infertility in men with epilepsy. A study of 60 men with epilepsy and 41 controls found the frequency of morphologically abnormal sperm to be significantly higher among men treated with carbamazepine, oxcarbazepine, and valproate compared the control group. Poor sperm motility was found in men taking valproate or carbamazepine, and the frequency of abnormally low sperm concentration was highest in men taking carbamazepine (22). Men treated with phenytoin have also been found to have morphologically abnormal sperm in addition to lower seminal volume, spermatozoa concentration, and total sperm count (48). However, temporal lobe epilepsy itself has also been documented to cause testicular failure independent of AED use (49). These findings indicate that both seizures and AEDs have effects on the hypothalamic–pituitary–gonadal axis in men that can impair fertility.

Fertility in Women with Epilepsy

Disturbances in the hypothalamic–pituitary–gonadal axis secondary to seizures or AEDs make women with epilepsy more likely to have early perimenopause and menopause, increased rates of anovulatory cycles, and a frequent occurrence of PCOS all of which are associated with decreased fertility (50,51). PCOS is defined as the presence of hyperandrogenism (clinical and/or biochemical), ovarian dysfunction (oligo-anovulation and/or polycystic ovaries), and the exclusion of related disorders (52). It is currently thought that PCOS is multigenic in etiology and susceptible to a variety of environmental triggers, which are as of yet unclear (53). Secondary to likely hypothalamic and pituitary dysregulation, there is elevated LH secretion and an increased ratio of LH to FSH, with produces polycystic follicles that are premature and deficient in aromatase, leading to increased serum androgen levels. The androgen is converted to estrogen by aromatase in the periphery, which feeds back to the pituitary to dysregulate normal LH secretion (54).

In addition to the effect of seizures on the hypothalamic–pituitary–gonadal axis creating an

increased risk for PCOS, it has also been shown that patients on valproate are at increased risk for the symptoms associated with PCOS (55). A recent study of women with epilepsy found that the incidence of PCOS was twice that of the general population (56). Taking valproate and younger age of seizure onset were risk factors for getting PCOS. Taking these findings into account, physicians must assess for abnormal menstrual cycles, hirsutism, acne, male pattern balding, and weight gain at each visit in women with epilepsy. Women with an early age of seizure onset, and women on valproate, should have a higher index of suspicion. If PCOS features are present, patients should be referred to an endocrinologist, gynecologist, or both for further evaluation and possible treatment. In addition, it is reasonable to consider alternative agents if valproate is part of the AED regimen.

Women with epilepsy, in addition to an increased occurrence of PCOS, also are at risk of early perimenopause and menopause, often in the late fourth decade or early fifth decade of life. A negative correlation has been reported between the age at menopause and seizure frequency, with women having frequent seizures experiencing earlier menopause (51). As in PCOS, the mechanism for this finding is likely related to hypothalamic–pituitary–gonadal axis dysfunction producing dysregulation of maturation of ovarian follicles, which leads to early loss of follicles available for ovulation.

Perimenopause and Menopause

No prospective information exists on the course of epilepsy as women progress through the transition to menopause. However, a cross-sectional study evaluated the effect of menopause and perimenopause on the course of epilepsy (57). The perimenopausal group consisted of 39 women with a history of epilepsy. Nearly two-thirds of the women reported an increase in seizure frequency during perimenopause, with those women having a history of catamenial epilepsy more likely to have increased seizures. The increase in seizure frequency during perimenopause is likely secondary to the elevation of the estrogen/progesterone ratio during this period. Evaluation of the postmenopausal women with epilepsy showed no overall direction change in seizure frequency (57). However, a history of catamenial epilepsy was significantly associated with a decrease in seizures after menopause.

Hormone Replacement Therapy

In the cross-sectional study listed above, postmenopausal was found to have an increase in seizure frequency after starting hormone replacement therapy (HRT), which usually consisted of an estrogen in combination with a synthetic progestin (57). These results prompted further investigation in the form of a double-blind, randomized, placebo-controlled trial using three study groups: women taking single-dose combination HRT (0.625 mg of conjugated equine estrogens [CEEs] plus 2.5 mg of MPA, or CEE/MPA) daily, double-dose CEE/MPA, or placebo (58). Increased seizure frequency was associated with increasing the CEE/MPA dose, suggesting that this regimen should not be used in postmenopausal women with epilepsy. Perhaps a regimen combining natural progesterone with estrogen may be alternatively considered in women requiring HRT.

BONE HEALTH IN EPILEPSY

Both men and women with epilepsy have an increased propensity to fractures due to medication side effects (e.g., ataxia and dizziness), coexisting neurologic deficits (e.g., cerebral palsy), and seizure-

related falls (59) in addition to the bone damaging effects of certain antiepileptic agents. The use of certain AEDs increases the risk of decreased bone density and abnormalities in bone metabolism. Hepatic enzyme inducers, such as phenytoin, carbamazepine, phenobarbital, and primidone, and noninducing AEDs such as valproate, are known to be associated with accelerated rate of bone loss and development of secondary osteopenia and osteoporosis with an increase in the risk for fractures (60). Limited evidence is available regarding the newer AEDs.

It is believed that the cytochrome P450 enzyme–inducing effects of certain AEDs are the main mechanism for bone disease. The enzyme induction leads to increased breakdown of vitamin D to inactive metabolites, which results in reduced calcium absorption, with secondary hyperparathyroidism, increased bone resorption and accelerated bone loss, and more rapid turnover of bone (61). These mechanisms have been postulated by the findings of decreased vitamin D and calcium levels (62,63) and increased levels of bone-specific alkaline phosphatase and makers of osteoblast and osteoclast activity (64,65). Other mechanisms for the negative impact of AEDs on bone have been hypothesized, such as direct impact on calcium absorption or on bone cells, disruption of vitamin K metabolism, changes in calcitonin secretion, and changes to the hypothalamic–pituitary–gonadal axis, which may adversely impact bone health (66).

There are not currently any official recommendations for investigating and treating bone disease in patients with epilepsy. Measuring bone mineral density with dual x-ray absorptiometry is the most sensitive predictor of fracture in patients at risk (66). FRAX is an online screening tool used to calculate a patient's risk of low bone mineral density and fracture by evaluating a patient's prior bone health history and risk factors for bone disease (66). This questionnaire, in combination with measurements of bone mineral density, can be performed on patients with long-term AED exposure, particularly if they have other risk factors for bone disease. Routine vitamin D levels can also be checked in patients treated with enzyme-inducing AEDs (60). Furthermore, antiepileptic medications associated with a negative impact on bone should be avoided in patients with risk factors for bone disease.

It has been shown that patients with epilepsy shown to have low bone mineral density who were treated with high-dose vitamin D had significant increases in bone mineral density (67). These findings suggest that epileptic patients treated with AEDs should have adequate daily intake of calcium and vitamin D and that patients taking enzyme-inducing AEDs may require higher doses of vitamin D than the recommended daily allowance and possible calcium supplementation if necessary (66).

A prospective 2-year double-blind, randomized, placebo-controlled study of male veterans with epilepsy treated with phenytoin, phenobarbital, valproate, or carbamazepine evaluated the use of the bisphosphonate, risedronate, on bone mineral density (68). The study found that the use of risedronate plus calcium and vitamin D lead to a significantly greater increase in bone mineral density at the lumbar spine as compared to placebo patients only receiving vitamin D and calcium. However, the difference in total body and proximal bilateral femoral bone mineral density between the two groups was not significant. Five new vertebral compression deformities and one nonvertebral fracture were only observed in the placebo group, but no vertebral or nonvertebral fractures were observed in the group receiving bisphosphonate treatment. However, the long-term use of bisphosphonates in the epileptic patient population has not yet been studied, and patients requiring such therapy should be referred to a bone specialist.

SUMMARY

Seizures and their treatment affect reproductive functioning and bone health in people with epilepsy. Additionally, the effects of neurosteroids on cortical excitability complicate seizure management in women with epilepsy, with estrogen increasing and progesterone decreasing seizure likelihood. Catamenial epilepsy, the clustering of seizures in alignment with the female reproductive cycle, is a phenomenon that occurs secondary to fluctuations in neurosteroid levels during specific time periods in the menstrual cycle. Although AEDs are first-line treatment for catamenial seizures, other adjunctive therapies have been studied and are used in common practice.

Patients with epilepsy also have an increased incidence of sexual dysfunction and infertility secondary to alteration of the hypothalamic–pituitary–gonadal axis by seizures and AEDs. It is important to take a detailed sexual and medical history, possibly discontinue any AEDs that may be contributing to sexual dysfunction and consult appropriate outside consolation if needed. Furthermore, it is important to council patients with epilepsy taking hormone-based contraception to use an AED that does not interact with their hormonal birth control.

There is an increased risk of osteopenia and osteoporosis in patients with epilepsy, especially if they are on an enzyme-inducing AED. Patients must be screened for low bone density and should have vitamin D levels checked. All epileptic patients treated with AEDs should have adequate daily intake of calcium and vitamin D. If bone loss is detected on routine screening, a bone specialist should be consulted.

CHAPTER 47 TREATMENT OF EPILEPSY DURING PREGNANCY

PAGE B. PENNELL

INTRODUCTION

Medical care of adolescent and adult women with epilepsy during the childbearing years presents specific clinical challenges. When making treatment recommendations, the practitioner needs to not only consider seizure types and epilepsy syndromes, efficacy, and side effect profiles of the different antiepileptic drugs (AEDs) but also consider additional key factors when selecting which medication to prescribe. From the initial prescription and repeated at every subsequent visit, the AEDs prescribed should be considered in light of the risks of the medications during any potential pregnancy, planned or unplanned, and the potential interactions with the form of contraception used.

CONTRACEPTION

Effective contraception in women with epilepsy is essential to allow for preconception planning and to implement the measures known to improve pregnancy outcomes. However, concomitant use of AEDs and hormonal contraceptives is complicated because of the bidirectional pharmacokinetic interactions, the pharmacodynamic consequences, and the potential effects on seizure control.

The enzyme-inducing AEDs lead to rapid clearance of sex steroid hormones (SSHs) and may allow ovulation in women taking oral contraceptives (OCs) or other hormonal forms of birth control (vaginal ring, patch). Table 47.1 categorizes the different AEDs according to the degree of induction of female SSHs. This classification is derived primarily from pharmacokinetic interaction studies between the AED and OC formulations, but when direct interaction studies with OCs are not available, the categorization has to be inferred from studies with other medications that undergo hepatic clearance. Prior authors have recommended “high-dose” OCs with EIAEDs assuming enzyme induction will lower levels to what occurs with an effective lower-dose OC. A few OCs with higher doses of ethinyl estradiol (EE) and progestin remain available but are infrequently used in practice for healthy women. No direct evidence supports efficacy in this situation. The CDC Medical Eligibility Criteria for contraception classified certain AEDs (phenytoin [PHT], carbamazepine [CBZ], phenobarbital [PB], primidone [PRM], topiramate [TPM], and oxcarbazepine [OXC]) as a category 3: The risks (birth control failure) generally outweigh the benefits (1). The authors state that the use of other contraceptives should be encouraged for women who are long-term users of any of these drugs. For women on EIAEDs that cause substantial changes in SSH levels (see Table 47.1), one of the long-acting reversible contraceptives (LARCs) should be encouraged. These include a progestin implant, intramuscular medroxyprogesterone acetate, and the intrauterine devices (IUDs). The levonorgestrel IUD prevents pregnancy by local hormonally mediated changes in cervical mucus, which are not likely to be impacted by hepatic changes in p450 enzyme induction. One reassuring

prospective registry study in the United Kingdom demonstrated a pregnancy rate of 1.1 per 100 women years for 56 women using the LNG-IUD with enzyme-inducing AEDs (2).

Table 47.1 Antiepileptic Drugs: Degree of Induction of Metabolism of Hormonal Contraceptive Agents

Strong inducers[a]	Weak inducers[a]	Noninducers
Phenobarbital	Topiramate	Ethosuximide
Phenytoin	Lamotrigine	Valproate
Carbamazepine	Felbamate	Gabapentin
Primidone	Rufinamide	Clonazepam
Oxcarbazepine	Clobazam	Tiagabine
		Levetiracetam
		Zonisamide
		Pregabalin
		Vigabatrin
		Lacosamide
		Ezogabine

[a]Avoid concomitant use with the lowest dose oral contraceptive pills, and additional nonhormonal forms of contraception should be used.

PREGNANCY

Epilepsy is the most common neurologic disorder that requires continuous treatment during pregnancy, and AEDs are one of the most frequent chronic teratogen exposures. Approximately one-half million women with epilepsy are of childbearing age in the United States, and 3 to 5 births per 1000 will be to women with epilepsy (3). However, it is estimated that the total number of children in the United States exposed in utero to AEDs is substantially greater with the emergence of AED use for other illnesses including headache, chronic pain, and mood disorders.

Treatment during pregnancy is a precarious balancing act between the teratogenic risks of AEDs and maintaining maternal seizure control. However, pregnancy registries and more intensive observational studies have provided key data that allow us to lower the risk for the developing fetus to rates closer to the general population. These findings should be key considerations when counseling and treating adolescents and women with epilepsy during their reproductive years (3–5).

MAJOR CONGENITAL MALFORMATIONS

Offspring of women with epilepsy on AEDs are at an increased risk for major congenital malformations (MCMs) and minor anomalies. Minor anomalies are defined as structural deviations from the norm that do not constitute a threat to health. Minor anomalies affect 6% to 20% of infants born to women with epilepsy, approximately 2.5-fold the rate of the general population. Although not of direct health consequence, the finding of a minor anomaly should lead to enhanced vigilance about the child's health and neurodevelopment.

Major congenital malformations (MCMs) are defined as an abnormality of an essential anatomical structure present at birth that interferes significantly with function and/or requires major intervention. The reported MCM rates in the general population vary between 1.6% and 3.2%, and women with a history of epilepsy but on no AEDs show similar MCM rates. The average MCM rates

among all AED exposures vary between 3.1% and 9%, or approximately two- to threefold higher than the general population (3,6).

The MCMs most commonly reported following in utero AED exposure include congenital heart disease, cleft lip/palate, urogenital defects, skeletal defects, and neural tube defects. The abnormal neural tube closure usually occurs between the 3rd and 4th weeks of gestation. By the time most women realize they are pregnant, it is too late to make medication adjustments to avoid malformations (Table 47.2).

Table 47.2 Relative Timing and Developmental Pathology of Certain Major Congenital Malformations

Tissues	Malformations	Postconceptional age
CNS	Neural tube defect	28 d
Heart	Ventricular septal defect	42 d
Face	Cleft lip	36 d
	Cleft maxillary palate	47–70 d

AED Monotherapies

The information we have gained regarding specific AEDs and risk for MCMs has increased dramatically over the last two decades. Data obtained from large, prospective pregnancy registries from different parts of the world have demonstrated remarkably consistent findings for many of the AEDs. The 2009 AAN Practice Parameter updates on "Management issues for women with epilepsy—focus on pregnancy" (3) led to many important conclusions about intrauterine first-trimester exposure and risk for MCMs: (i) It is highly probable that valproic acid (VPA) exposure has higher risk of MCMs compared to CBZ and possible compared to PHT or lamotrigine (LTG). (ii) Compared to untreated women with epilepsy (WWE) it is probable that VPA as part of polytherapy and possible that VPA as monotherapy contribute to the development of MCMs. (iii) It is probable that AED polytherapy as compared to monotherapy regimens contributes to the development of MCMs. (iv) CBZ probably does not substantially increase the risk of MCMs in the offspring of WWE. (v) There is probably a relationship between the doses of VPA and of LTG and the risk of development of MCMs in the offspring of WWE. Additionally, for specific types of MCMS, findings included the following: (i) PHT possibly contributes to the risk of cleft palate, (ii) CBZ possibly contributes to the risk of posterior cleft palate, (iii) VPA probably contributes to neural tube defects and facial clefts and possibly contributes to hypospadias, and (iv) PB possibly contributes to cardiac malformations.

Since this evidence-based review of the literature, several large prospective pregnancy registries scattered across different regions of the world continue to provide valuable information. They reveal a very consistent pattern of amplified risk for the development of MCM in pregnancies exposed to VPA. The registries have also provided updated information on additional AEDs that further refines our ability to lower the teratogenicity risk in women with epilepsy.

The UK Epilepsy and Pregnancy Register reported on findings with TPM use in 178 live births (7). Although the confidence intervals were wide, this preliminary information noted an MCM rate of 4.8% for monotherapy use and even higher for use of TPM as polytherapy. They also noted a particularly higher rate of oral clefts, approximately 11 times their background rate, and a high rate of hypospadias. The risk of oral clefts with TPM has been replicated in other studies (8).

Using data from the National Birth Defects Prevention Study, Werler et al. (9) reported that increased risks were observed for VPA and neural tube defects (OR, 9.7; 95% CI, 3.4 to 27.5), oral clefts (OR, 4.4; 95% CI, 1.6 to 12.2), heart defects (OR, 2.0; 95% CI, 0.78 to 5.3), and hypospadias (OR, 2.4; 95% CI, 0.62 to 9.0). Increased risks were observed for CBZ and neural tube defects (OR, 5.0; 95% CI, 1.9 to 12.7). Similarly, the European Surveillance of Congenital Anomalies (EUROCAT) antiepileptic-study database, which is derived from population-based congenital anomaly registries, also reported significantly increased risks for VPA monotherapy and spina bifida, atrial septal defect, cleft palate, hypospadias, polydactyly, and craniosynostosis (10). Spina bifida was the only specific MCM associated with CBZ monotherapy compared with no AEDs (OR, 2.6; 95% CI, 1.2 to 5.3), but the risk was smaller than for VPA (11,12).

The North American AED Pregnancy Registry released findings comparing the risk of MCMs among infants exposed to different AED monotherapies during the first trimester, as well as to an unexposed reference group (13). The LTG monotherapy group was chosen as the exposed reference group for the other AEDs because of a low MCM rate and tight confidence intervals (2.0% [95% CI, 1.4 to 2.8]). Table 47.3 in this article can serve as a particularly instructive tool during the preconceptional counseling phase of women with epilepsy, with detailed information on many of the AEDs with sample size and calculation of confidence intervals for the risk numbers presented. Additional analysis included the risk of MCM by average daily VPA dose during the first trimester and confirms prior reports of a dose-related risk for VPA and MCM. However, the upper limit of the confidence intervals for the lowest VPA daily dosage group (<500 mg) reached over 7%, and this is an uncommon dose range to maintain seizure control.

Table 47.3 Risk of major congenital malformations identified among infants who had been exposed to a specific AED monotherapy regimen during the first trimester and relative risk of MCMs compared to both unexposed and to lamotrigine groups: North America Pregnancy Registry 1997–2011

	Unexposed[a]	LTG	CBZ	PHT	LEV	TPM	VPA	PB	OXC	GBP	ZNS	CLZ
MCM[b] % 95% CI	1.1 (0.37–2.6)	2.0 (1.4–2.8)	3.0 (2.1–4.2)	2.9 (1.5–5.0)	2.4 (1.2–4.3)	4.2 (2.4–6.8)	9.3 (6.4–13.0)	5.5 (2.8–9.7)	2.2 (0.6–5.5)	0.7 (0.02–3.8)	0 (0.0–3.3)	3.1 (0.4–10.8)
RR to unexposed 95% CI	Reference	1.8 (0.7–4.6)	2.7 (1.0–7.0)	2.6 (0.9–7.4)	2.2 (0.8–6.4)	3.8 (1.4–10.6)	9.0 (3.4–23.3)	5.1 (1.8–14.9)	2.0 (0.5–7.4)	0.6 (0.07–5.2)	NA NA	2.8 (0.5–14.8)
RR to LTG 95% CI		Reference	1.5 (0.9–2.5)	1.5 (0.7–2.9)	1.2 (0.6–2.5)	2.2 (1.2–4.0)	5.1 (3.0–8.5)	2.9 (1.4–5.8)	1.1 (0.4–3.2)	0.3 (0.05–2.5)	NA NA	1.6 (0.4–6.8)

[a]The unexposed internal comparison group were pregnant women not taking an AED, who were recruited from among the friends and family members of the enrolled women taking an AED.

[b]Diagnosed during pregnancy or before 12 wks after birth. Confirmed by review of medical records.

AED, antiepileptic drug; MCM, major congenital malformations; RR, relative risk; CI, confidence interval; LTG, lamotrigine; CBZ, carbamazepine; PHT, phenytoin; LEV, levetiracetam; TPM, topiramate; VPA, valproate; PB, phenobarbital; OXC, oxcarbazepine; GBP, gabapentin; ZNS, zonisamide; CLZ, clonazepam.

Adapted from Hernández-Díaz S, Smith CR, Shen A, et al.; North American AED Pregnancy Registry; North American AED Pregnancy Registry. Comparative safety of antiepileptic drugs during pregnancy. Neurology. 2012;78(21):1692–1699.

Hernandez-Diaz et al. (13) also examined the frequency of specific MCMs for each AED and reported that VPA was associated with an increased risk of hypospadias, neural tube defects, and cardiovascular malformations; PB was associated with an increased risk of cardiovascular malformations; and the risk of oral clefts was higher among infants exposed to PB, VPA, and TPM,

consistent with previous reports.

The UK and Ireland Epilepsy and Pregnancy Registers combined results for first-trimester exposure to levetiracetam (LEV) with outcome data for 304 monotherapy pregnancies and 367 polytherapy pregnancies (14). The MCM rate in the LEV monotherapy group was 0.70% (95% confidence interval [CI], 0.19% to 2.51%) and in the polytherapy group was 5.56% (95% CI, 3.54% to 8.56%); the MCM rate in the polytherapy group was lower when LEV was given with LTG (1.77%; 95% CI, 0.49% to 6.22%) than when given with VPA (6.90%; 95% CI, 1.91% to 21.96%) or CBZ (9.38%; 95% CI, 4.37% to 18.98%).

A recent report from the European and International Registry of Antiepileptic Drugs and Pregnancy (EURAP) confirmed that in addition to the type of AED, dose of the AED at conception also affects rates of MCMs (15). MCM rates in pregnancies exposed to CBZ, LTG, VPA, and PB were analyzed by dose at time of conception (not throughout the first trimester or entire pregnancy). The lowest rates of MCMs occurred with LTG < 300 mg/day (2.0%; 95% CI, 1.19 to 3.24), and this group was used as the comparator group. Risks of MCMs were higher with VPA and PB at all doses and with CBZ at >400 mg/day. Additionally, an increase in MCM rates was observed with increasing doses for all of the four AEDs (Fig. 47.1).

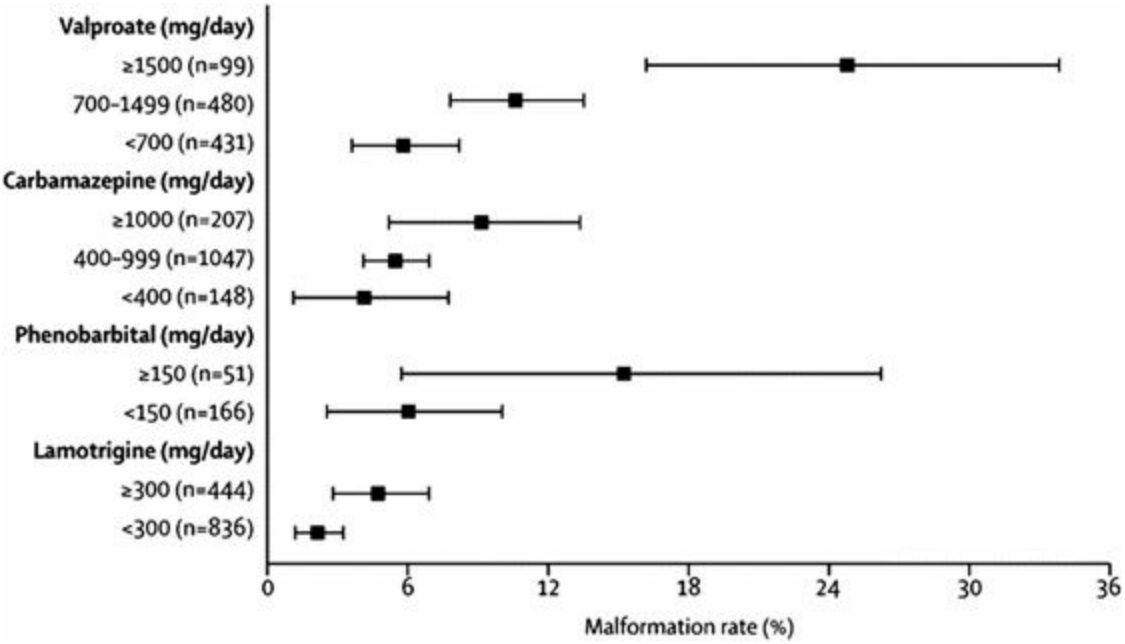

Figure 47.1. Rates of major congenital malformations at 1 year after birth in relation to exposure to AED monotherapy according to data from the International Registry of Antiepileptic Drugs and Pregnancy. Bars represent 95% confidence interval. (From Tomson T, Battino D, Bonizzoni E, et al.; for the EURAP study group. Dose-dependent risk of malformations with antiepileptic drugs: an analysis of data from the EURAP epilepsy and pregnancy registry. Lancet Neurol. 2011;10(7):609–617.)

Recent data support the concern that the amount of fetal exposure to an AED is important, as well as the type of AED. Therefore, reduction of the dose prior to conception while maintaining seizure control can further reduce the risk of structural teratogenicity. Determining the women's individual target concentration preconception can be a valuable tool for therapeutic drug monitoring during pregnancy (see below).

AED Polytherapy

The rates of MCMs have been reported as higher across several studies for women on AED

polytherapy compared to AED monotherapy regimens (3). These results led to the recommendation that AED monotherapy is preferred to polytherapy during pregnancy and should be achieved during the preconception planning phase (3). However, Holmes et al. (16) reported that data from the North American AED Pregnancy Registry suggest that not all AED polytherapy combinations are alike. Concentrating on LTG or CBZ as polytherapy, both AEDs had relatively modest rates for MCMs if the polytherapy combination was with any AED other than VPA. The MCM rates were 9.1% for LTG plus VPA (OR, 5.0; 95% CI, 1.5 to 14.0 compared with LTG monotherapy) but only 2.9% for LTG with any other AED (1.5; 0.7 to 3.0); likewise, the risks were 15.4% for CBZ plus VPA (OR, 6.2; 95% CI, 2.0 to 16.5 compared with CBZ monotherapy) and 2.5% for CBZ plus any other AED (0.8; 0.3 to 1.9).

NEURODEVELOPMENTAL OUTCOMES

Studies investigating cognitive outcome in children of women with epilepsy report an increased risk of mental deficiency (3,17). Verbal scores on neuropsychometric measures may be selectively more involved. A variety of factors contribute to the cognitive problems of children of mothers with epilepsy, but AEDs appear to play a major role. Factors other than specific AED use that have been associated with cognitive impairment include seizures, a high number of minor anomalies, major malformations, decreased maternal education, impaired maternal–child relations, and maternal focal seizure disorder (17). It is possible that these risk factors are not only additive but synergistic.

The 2009 AAN Practice Parameter Updates reported the following conclusions about in utero exposure (throughout the entire pregnancy) and risk for poor cognitive outcomes (3): (i) cognition is probably not reduced in children of untreated WWE, (ii) CBZ probably does not increase poor cognitive outcomes compared to unexposed controls, (iii) monotherapy exposure to VPA probably reduces cognitive outcomes, (iv) monotherapy exposure to PHT or PB possibly reduces cognitive outcomes, and (v) AED polytherapy exposure probably reduces cognitive outcomes as compared to AED monotherapy.

Since the 2009 AAN Practice Parameter update, several notable reports have contributed to our understanding of the various contributors to adverse neurodevelopmental outcomes and the pattern seen. The Neurodevelopmental Effects of Antiepileptic Drugs (NEAD) study was a prospective, observational, multicenter study in the United States and United Kingdom and assessed the neurodevelopmental effects of in utero exposure to four monotherapy groups (CBZ, VPA, PHT, and LTG) (18). The primary outcome was intelligence quotient (IQ) at age 6 years, adjusted for maternal IQ, AED type, AED-standardized dose, gestational age at birth, and use of periconceptional folate. Primary analysis included 305 mothers and 311 children, with 224 children completing the 6-year follow-up. Multivariate analysis demonstrated that the VPA-exposed children had lower age-6 IQ compared to CBZ, LTG, or PHT, and they did poorly on several specific measures. High doses of VPA were negatively correlated with IQ, verbal ability, nonverbal ability, memory, and executive function, while the other AEDs did not have a dose effect. Interestingly, mean IQs were higher in the children of mothers who took periconceptional folic acid (Fig. 47.2). This key evidence of a beneficial effect of supplemental folic acid taken prior to and early in pregnancy in women with epilepsy on AEDs supports the recommendation that all women of childbearing age should be encouraged to take supplemental folic acid given the high unplanned pregnancy rate.

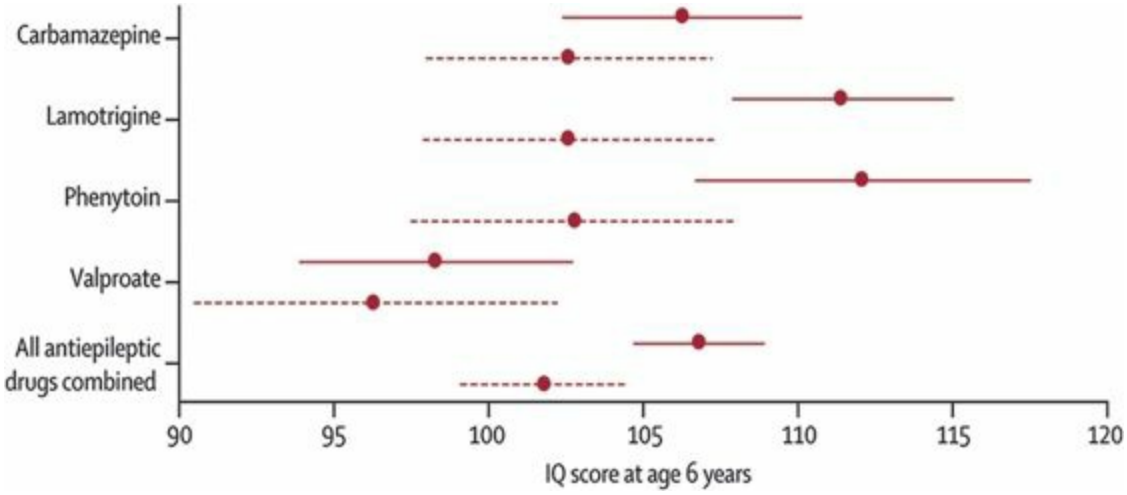

Figure 47.2. Child IQ at 6 years of age, by exposure to maternal AED use and periconceptional folate. Mean (95% confidence intervals) are shown for folate (solid lines) and no folate (dashed lines). (IQ, intelligence quotient.) (From Meador KJ, Baker GA, Browning N, et al.; for the NEAD Study Group. Fetal antiepileptic drug exposure and cognitive outcomes at age 6 years (NEAD study): a prospective observational study. Lancet Neurol. 2013;12(3):244–252.)

The neurodevelopment research group from Liverpool and Manchester also reported that children assessed at age 6 years who were exposed to VPA in utero had a higher prevalence of neurodevelopmental disorders (19). Multiple logistic regression analysis revealed that the children born to WWE and exposed to VPA monotherapy and VPA polytherapy were, respectively, six times (aOR, 6.05; 95% CI, 1.65 to 24.53; P = 0.007) and 10 times (aOR, 9.97; 95% CI, 1.82 to 49.40; P = 0.005) more likely to be diagnosed with a neurodevelopmental disorder than controls. Moreover, autism spectrum disorder (ASD) was the most frequent diagnosis for the VPA-exposed children.

A population-based study from Denmark found that in the 508 children exposed to VPA, an absolute risk for ASD of 4.42% (95% CI, 2.59% to 7.46) (adjusted HR, 2.9 [95% CI, 1.7 to 4.9]) and an absolute risk for childhood autism of 2.50% (95% CI, 1.30% to 4.81%) (adjusted HR, 5.2 [95% CI, 2.7 to 10.0]) (20). When restricting the cohort to the children born to women with epilepsy, risks were similarly elevated in those children exposed to VPA but not with other AED exposures.

The Norwegian Mother and Child Cohort Study evaluated reports from mothers of their child's motor development, language, social skills, and autistic traits with use of standardized screening tools at 18 months and 36 months of age (21). The AED-exposed children had increased risk of abnormal score for gross motor skills, sentence skills, and autistic traits. Limitations include small sample size at very young ages to assess neurodevelopment, with very small individual AED groups, lack of use of diagnostic testing and criteria, and lack of screening for intellectual disabilities in the children or even in the mothers. Follow-up studies are needed to confirm if increased risks for these traits exist across a variety of AED exposures.

Neurodevelopmental outcomes for LEV have recently been published. The Liverpool and Manchester Neurodevelopment Group with the United Kingdom Epilepsy and Pregnancy Registry reported on the neurodevelopmental outcomes of children exposed in utero to LEV compared to control children and children exposed in utero to VPA (22). Testing of the children occurred at ages 36 to 54 months. After adjusting for confounding variables, children exposed to VPA in utero scored lower on measures of gross motor skills, comprehension language abilities, and expressive language abilities compared to children exposed in utero to LEV. Children exposed to LEV in utero did not differ from the unexposed control children.

In summary, if a prescriber chooses to place an adolescent or adult woman of childbearing age on

VPA, he/she is putting her potential children at a substantially greater risk for MCMs, lower IQ, and ASD.

NEONATAL COMPLICATIONS

Recent reports suggest that there may be increased risk for other neonatal complications for offspring of women with epilepsy on AEDs. Findings from the 2009 AAN/AES Practice Parameter Update concluded the following (3): (i) neonates of WWE taking AEDs probably have an increased risk of being small for gestational age (SGA) of about twice the expected rate and (ii) neonates of WWE possibly have an increased risk of a 1-minute Apgar score of <7 of about twice the expected rate. Since this parameter was released, a study from Taiwan reported that seizures in mothers with epilepsy during pregnancy were independently associated with approximately a 1.5-fold increased risk for preterm delivery or infants being born SGA (23). A secondary analysis of the neonatal outcomes from the NEAD cohort reported that adverse neonatal outcome risks may differ between the AEDs; the odds ratio for SGA was higher for the VPA and CBZ groups, and reduced 1-minute Apgar scores occurred more frequently in the PHT and VPA groups (24).

The North American AED Pregnancy Registry reported that prenatal exposure to TPM or ZNS was associated with higher risk for SGA births compared to prenatal exposure to LTG (25). The prevalence of SGA was 6.8% for LTG, 12.2% for ZNS (RR, 1.6; 95% CI, 0.9 to 2.8), and 17.9% for TPM (RR, 2.4; 95% CI, 1.8 to 3.3). Similar results were found when a group of unexposed newborns was used as the reference.

SEIZURES DURING PREGNANCY

The effect of pregnancy on seizure frequency is variable. Approximately 20% to 33% of patients will have an increase in their seizures, 7% to 25% will have a decrease in seizures, and 50% to 83% will experience no significant change. EURAP reported on a large but selective cohort of WWE entering pregnancy on monotherapy (26). Two-thirds of women remained seizure free throughout pregnancy, and women with genetic generalized epilepsies were more likely to remain seizure free than women with localization-related epilepsies. The physiologic changes and psychosocial adjustments that accompany pregnancy can alter seizure frequency, including changes in sex hormone concentrations, changes in AED metabolism, sleep deprivation, and new stresses. Noncompliance with medications is common during pregnancy and is in large part due to the strong message that any drugs during pregnancy are harmful to the fetus. Teratogenic effects of AEDs are well described, but risks to the fetus are often exaggerated or misrepresented. Proper education about the risks of AEDs versus the risks of seizures can be very helpful in assuring compliance during pregnancy.

The risk of seizures to the fetus should be discussed thoroughly with the patient and other family members. Generalized tonic–clonic convulsions can cause maternal and fetal hypoxia and acidosis, fetal heart rate decelerations, and miscarriages and still births. Nonconvulsive seizures can cause trauma, which can result in ruptured fetal membranes with an increased risk of infection, premature labor, and even fetal death. In addition to the physical risks of seizures to the developing fetus, reemergence of seizures in a woman who had previously experienced seizure control can be devastating. Besides the immediate risk to herself and the fetus, the loss of the ability to drive legally can have remarkable psychosocial effects.

AED MANAGEMENT DURING PREGNANCY

Maintaining seizure stability during pregnancy is dependent on maintaining therapeutic concentrations of the baseline AED. The target concentration should be individually determined, ideally in the preconception phase, for each woman according to her epilepsy history and prior seizure control relative to AED concentrations. During pregnancy, management of the AED dosing becomes complex and requires a more intensive approach than during nonpregnant stages. Clearance of most of the AEDs increases during pregnancy, resulting in a decrease in serum concentrations (Table 47.4) (4,27). Several physiologic factors contribute to the decline in AED levels during pregnancy: induction of the hepatic microsomal enzymes by the increased SSHs, increased volume of distribution, decreased concentration of the binding proteins albumin and alpha-1-acid-glycoprotein, increased renal blood flow, and alterations in drug absorption.

Table 47.4 Alterations of AED Clearance and/or Concentrations During Pregnancy: Summary of Class I, II, and III Studies (4,27)

AED	Reported increases in clearance	Reported decreases in total concentrations	Reported changes in free AED or metabolites
PHT	19%–150%	60%–70%	Free PHT clearance increased in TM3 by 25%; free PHT concentration decreased by 16%–40% in TM3
CBZ	–11% to +27%	0%–12%	No change
PB	60%	55%	Decrease in free PB concentration by 50%
PRM	Inconsistent	Inconsistent	Decrease in derived PB concentrations, with lower PB/PRM ratios
VPA	Increased by TM2 and TM3		No change in clearance of free VPA; free fraction increased by TM2 and TM3
ESX	Inconsistent	Inconsistent	
LTG	65%–230%, substantial interindividual variability		89% increase in clearance of free LTG
OXC		MHD and active moiety decreased by 36%–61%	
LEV	243%	60% by TM3	

AED, antiepileptic drug; TM, trimester; PHT, phenytoin; CBZ, carbamazepine; PRM, primidone; PB, phenobarbital; VPA, valproic acid; ESX, ethosuximide; LTG, lamotrigine; OXC, oxcarbazepine; MHD, monohydroxy derivative of oxcarbazepine; LEV, levetiracetam.

From Pennell PB, Hovinga CA. Antiepileptic drug therapy in pregnancy I: gestation-induced effects on AED pharmacokinetics. Int Rev Neurobiol. 2008;83:227–240.

The 2009 AAN/AES Practice Parameter Update concluded the following: Pregnancy probably causes an increase in the clearance and a decrease in the concentration of LTG, PHT, and to a lesser extent CBZ and possibly decreases the level of LEV and the active OXC metabolite, the monohydroxy derivative (4).

The magnitude of the enhanced clearance of LTG during pregnancy exceeds that described for

many of the older AEDs, because it is primarily eliminated via hepatic glucuronidation. This elimination pathway appears particularly susceptible to activation during pregnancy, due to direct effects of rising SSH levels. In the prospective EURAP registry, pregnancies on LTG monotherapy were less likely to be seizure free (58.2%), had a greater likelihood of deterioration in seizure control from the first to the second or third trimesters (19.9%), and were more likely to require an increase in drug load (26). Pennell et al. (28) reported findings from a class I prospective, observational study of 53 pregnancies in 53 women, using 305 samples throughout preconception baseline, pregnancy, and postpartum. Both LTG free and total clearance were increased during all three trimesters, with peaks of 94% (total) and 89% (free) in the third trimester. This study also examined therapeutic drug monitoring and seizure frequency, and changes in LTG dosing to avoid postpartum toxicity. The authors reported that seizure frequency significantly increased when the LTG level decreased to 65% of the preconceptional individualized target LTG concentration. This finding supports the recommendation to monitor levels of LTG and possibly other AEDs for which the levels decrease during pregnancy. A retrospective analysis of pregnant women on a variety of AEDs also demonstrated that seizures worsened significantly during the second trimester when the AED concentration fell by greater than 35% from the preconception baseline concentration (29).

The importance of individual therapeutic drug monitoring for LTG during pregnancy is underscored by a model-based analysis of LTG clearance changes during pregnancy (30). Two subpopulations were identified; 23% of women had only a minimal increase in clearance throughout pregnancy, while 77% of women exhibited a 10-fold higher rate of gestational age–associated increase in clearance. It is probable that the differences are related to different pharmacogenomic profiles (e.g., UGT1A4), but further studies need to be completed. The authors also commented that based on the model, postpartum doses should be tapered to preconception dose ranges within 3 weeks of delivery.

Previous studies on LTG noted a rapid decrease in LTG clearance during the early postpartum period with reports of symptomatic toxicity. Pennell et al. (28) examined the effectiveness of using an empiric postpartum taper schedule for LTG, with steady decreases in dosing at postpartum days 3, 7, and 10, with return to preconception dose or preconception dose plus 50 mg to help counteract the effects of sleep deprivation. Patients were assessed for symptoms of LTG toxicity (dizziness, imbalance, and blurred or double vision). Nonadherence to the standard taper schedule was associated with significantly higher risk of experiencing postpartum toxicity. Most of the other AED levels gradually increase after delivery and plateau by 10 weeks postpartum. The exact time course is not as well established for the other AEDs, but AED doses should be adjusted and/or levels should be followed during the postpartum period.

BREAST-FEEDING

Most infants of women with epilepsy can successfully breast-feed without complications. The concentrations of the different AEDs in breast milk are considerably less than those in maternal serum (Table 47.5). The infant's serum concentration is determined by this factor as well as the AED elimination half-life in neonates (31). A detailed study of excretion of lamotrigine into breast milk, infant serum concentrations, and infant laboratory studies demonstrated safety of women on LTG breast-feeding (32). The benefits of breast-feeding are believed to outweigh the small risk of adverse effects of AEDs. This recommendation needs to be balanced with consideration of minimizing sleep disruption. A common compromise is to elicit the help of family members and friends to provide one

or two bottle feedings per 24 hours of either formula or pumped breast milk and allow the mother at least one stretch of uninterrupted sleep.

Table 47.5 Antiepileptic Drug Exposure Through Breast Milk (4,30)

AEDs	Breast milk/maternal concentration	Adult half-life	Neonate half-life
CBZ	0.36–0.41	8–25	8–36
PHT	0.06–0.19	12–15	15–105
PB	0.36–0.46	75–125	100–500
ESX	0.86–1.36	32–60	32–38
PRM	0.72	4–12	7–60
VPA	0.01–0.1	6–20	30–60
LTG	0.5–0.77	30	—
ZNS	0.41–0.93	63	61–109
TPM	0.86	21	24
GBP	0.7–1.3	7–9	14
OXC	0.5–0.65	19.3	17–22
LEV	0.8–1.3	6–8	16–18

AED, antiepileptic drug; CBZ, carbamazepine; PHT, phenytoin; PB, phenobarbital; ESX, ethosuximide; PRM, primidone; VPA, valproic acid; LTG, lamotrigine; TPM, topiramate; ZNS, zonisamide; OXC, oxcarbazepine; LEV, levetiracetam.

From Hovinga CA, Pennell PB. Antiepileptic drug therapy in pregnancy II: fetal and neonatal exposure. Int Rev Neurobiol. 2008;83:241–258.

Recent data from the NEAD cohort that included mothers on PHT, LTG, VPA, or CBZ monotherapy actually demonstrated a benefit to breast-feeding (33). Meador et al. compared the age-6 IQ between children who breast-fed (43%) to those who did not. Adjusted IQ was actually higher by 4 points for children who were breast-fed versus those who were not, and verbal ability measures were also higher in the breast-fed children. The improved neurodevelopmental outcomes in the NEAD children that were breast-fed support the recommendation to breast-feed despite continued exposure to AEDs via breast milk.

SUMMARY

Improving maternal and fetal outcomes for women with epilepsy involves effective preconceptional counseling and preparation. The importance of planned pregnancies with effective birth control should be emphasized, with consideration of the interactions described in this chapter. LARC methods are preferred for many women with epilepsy. The consistent findings of increased risk for MCMs and neurodevelopmental deficits with VPA use during pregnancy should enter into the physician's daily treatment decisions, as well as the newer findings of differential risks between types and doses of the other AEDs. Figure 47.3 summarizes the author's interpretation of the available data at the time of authorship. The risk profiles include data about MCMs and neurodevelopmental outcomes when available, with consideration of the range of relative risks reported from multiple studies, number of subjects studied, and confidence intervals. The AEDs that are omitted do not have enough reported monotherapy data to be included. These risk profiles will likely change as new data become available. Folic acid supplementation should be encouraged in all women of childbearing age on any AED. Maintaining seizure control during pregnancy is important, and therapeutic drug monitoring of serum AED levels can help achieve that goal, especially for AEDs that undergo substantial pregnancy-associated changes in clearance. Knowledge and appreciation of

these key principles enhance our ability to make informed treatment recommendations that not only provide favorable seizure control but also improved maternal and child outcomes.

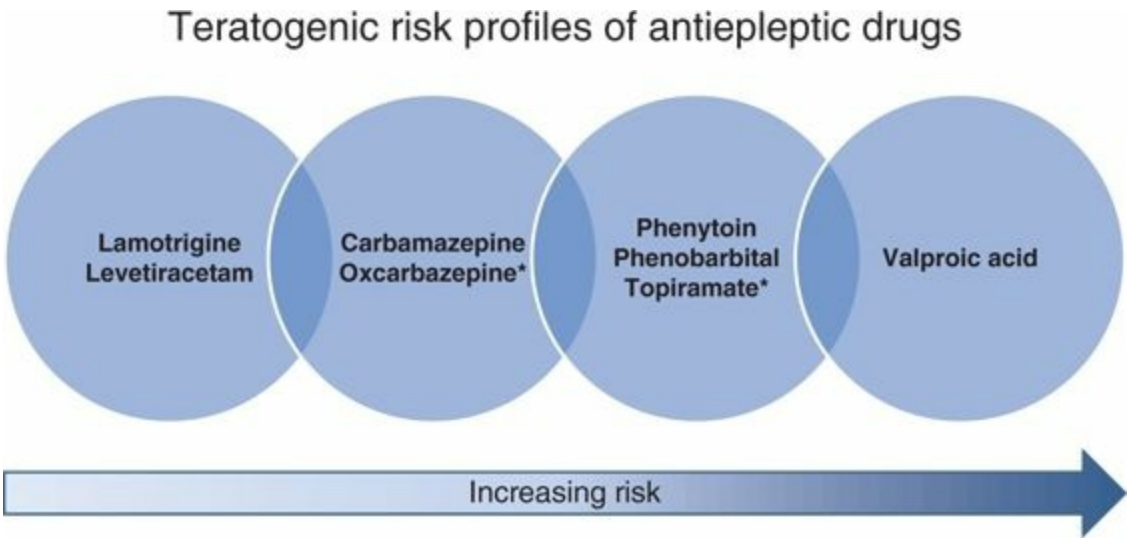

Figure 47.3. Summary of relative teratogenic risk profiles of antiepileptic drugs, based on available data at the time of authorship. The risk profiles include data about major congenital malformations and neurodevelopmental outcomes when available, with consideration of the range of relative risks reported from multiple studies, number of subjects studied, and confidence intervals. CHAPTER 48 INDIVIDUAL APPROACH TO LABORATORY MONITORING OF ANTIEPILEPTIC DRUGS

SVEIN I. JOHANNESSEN AND PHILIP N. PATSALOS

INTRODUCTION

Antiepileptic drugs (AEDs) are the mainstay of treatment of patients with epilepsy. However, because treatment is prophylactic and efficacy is not readily measured since seizures occur at irregular intervals and sometimes drug toxicity is difficult to distinguish from the underlying epilepsy, AED therapeutic drug monitoring (TDM) has provided an invaluable surrogate marker so as to help individualize treatment. Indeed, AED TDM is defined as the measurement and the clinical use of drug concentrations (levels) in serum or plasma but increasingly in saliva, to adjust the individual drug dosage and schedule to each patient's individual therapeutic requirement.

Epilepsy, in addition, has specific features that make it particularly amenable to AED TDM, namely, it begins predominantly in early life; it is a chronic condition that often lasts for years, decades, or for a lifetime; the majority of patients require long-term therapy, and 30% of patients require long-term polytherapy (1); and during transition from childhood, adolescence, adulthood, and old age, there are significant changes in a patient's physiologic and pathologic state, including hepatic, renal, and other diseases resulting in changing and altered AED pharmacokinetic characteristics and thus individualization of AED dosage is of paramount importance (2). Those AED blood concentrations that reflect patient pharmacokinetic variability (due, for example, to age, gender, metabolic capacity, comorbidities) provide an invaluable surrogate marker for patient management (3,4).

TERMINOLOGY AND DEFINITIONS

New terminology and definitions for TDM of AEDs have been suggested on behalf of the International League Against Epilepsy (3). Terms such as "reference ranges," "therapeutic ranges," "optimal ranges," "target ranges," and "target concentrations" have been used interchangeably, often with different meanings. Clear definitions are therefore important.

The Concept of an AED Reference Range

Two separate terms are now recommended to define drug concentration ranges in relation to their clinical effects. The "reference range" can be defined as a range of drug concentrations and based on a variable number of studies, which is quoted by a laboratory and specifies a lower limit below which a therapeutic response is relatively unlikely to occur and an upper limit above which toxicity is

relatively likely to occur. The reference range is therefore not a "therapeutic range," which is associated with the best response in a given patient. The therapeutic range will vary between different patients and can therefore only be determined for the individual patient. Thus, the term "individual therapeutic concentration" is recommended for use (3,5).

Reference ranges have been quoted for the first-generation AEDs (carbamazepine, phenytoin, phenobarbital, and valproic acid) for many years and are often used rigorously to guide TDM and patient care. However, it is rarely noted that these ranges are based on limited data in highly selected patients. For example for phenytoin, which probably has the best-documented relationship between serum concentrations and clinical effect, its generally quoted range of 10 to 20 mg/L (40 to 79 μmol/L) is constructed from various studies (6–11). Buchthal et al. (6), in their study of 80 patients with at least one "grand mal" seizure per week, found that only 6 out of 24 (25%) improved at serum phenytoin concentrations below 10 mg/L, 21 out of 27 patients (77%) improved at concentrations above 10 mg/L, and the majority of patients with concentrations above 30 mg/L experienced adverse effects. The study of Kutt et al. (7) helped to further define the upper limit of the range in that nystagmus was observed in all their patients with serum phenytoin concentrations above 20 mg/L, ataxia was observed at phenytoin concentrations above 30 mg/L, and occurred in all patients at concentrations above 40 mg/L. A subsequent prospective study of 32 outpatients with "grand mal" seizures gave further support to the quoted therapeutic range (8). However, these early studies were all conducted in patients with severe epilepsy and frequent generalized tonic–clonic seizure; patients with newly diagnosed and perhaps easier to treat epilepsy were excluded. Indeed, Schmidt et al. (9,10) subsequently demonstrated that not only does the severity of the epilepsy influences which serum concentration is needed to obtain seizure control but also the seizure type. That one-third of previously untreated patients with newly diagnosed epilepsy were controlled with phenytoin concentrations below the usually recommended range (11) has seriously challenged the value of the lower limit of the therapeutic range, and it is being increasingly recognized that there is a considerable individual variation in what is the optimal serum phenytoin concentration and this applies to all AEDs.

For the second- and third-generation AEDs, reference values are available (Table 48.1), and these values are based on Phase II and Phase III clinical trials population data as recently highlighted by the newest AED perampanel whereby robust pharmacokinetic/pharmacodynamic data have been used to define its reference range (12).

Table 48.1 Some Pharmacokinetic Characteristics and Reference Ranges of AEDs

Drug	Time to peak concentration (hours)	Time to steady state (days)	Half-life monotherapy, adults (hours)	Half-life AED + enzyme inducers (hours)	Half-life monotherapy, children (hours)	Half-life monotherapy, elderly (hours)	Serum protein binding (%)	Reference range (mg/L)	Reference range (μmol/L)	Active metabolite
Carbamazepine	4–8[a]	2–4	8–20[b]	5–12[b]	10–13[b]	30–50[b]	75	4–12	17–51	Carbamazepine–epoxide

The Individual Therapeutic Concentrations

Despite the shortcomings of present reference ranges, TDM may be useful by employing the concept of "individual therapeutic concentrations" using intraindividual comparisons of drug serum concentrations (3,5). The drug concentration at which a patient has an optimal effect will serve as the individual reference for comparison if future treatment failures should occur and to check if the change in the clinical status of the patient is related to pharmacokinetic alterations or not. The concept of the individual therapeutic concentration may therefore be helpful even without a well-defined reference range. The basis for TDM will rely on a relationship between drug serum concentration and clinical effect in the individual patient, depending on the mechanism of drug action and possible influence by pharmacologically active metabolites and pharmacokinetic intraindividual variability. Thus, an optimal AED treatment can be best guided by identifying the "individual therapeutic concentration" (3,5).

IMPACT OF TDM ON CLINICAL OUTCOME

Although studies of the impact of TDM on treatment outcome in terms of optimum seizure control are scarce (12–15), two randomized studies comparing treatment outcome with or without the use of TDM have been reported (14,15). Neither study, however, provided evidence for the usefulness of routine monitoring of AEDs in the general epilepsy population, which, however, does not argue

against the value of TDM in special situations and clinical indications.

CLINICAL INDICATIONS FOR MONITORING ANTIEPILEPTIC DRUGS

Traditionally, TDM has been applied to the older first-generation AEDs (carbamazepine, phenytoin, phenobarbital primidone, and valproic acid), primarily because not only do they exhibit substantial interpatient pharmacokinetic variability but also they have narrow therapeutic indices. Nevertheless, TDM is increasingly being used to individualize treatment with the various new second- (vigabatrin, lamotrigine, gabapentin, pregabalin, levetiracetam, oxcarbazepine, tiagabine, topiramate, and zonisamide) and third-generation (lacosamide, retigabine, eslicarbazepine acetate, and perampanel) AEDs and also for the orphan AEDs (stiripentol and rufinamide), and the indications for monitoring are exactly the same for all AEDs (Table 48.2) (3,4,16). Some key pharmacokinetic characteristics that impact on TDM and the reference ranges for the various AEDs are shown in Table 48.1. Indications for AED TDM are discussed in the following sections.

Table 48.2 Clinical Indications for Monitoring Antiepileptic Drugs

Reasons for TDM	Possible clinical consequence
When a drug therapy is initiated, or when a dose change occurs	To determine the serum concentration for a particular dose so as to guide therapy. To confirm that the degree of serum concentration change is reflective of the dose change; this is particularly important for AEDs that exhibit nonlinear pharmacokinetics
When the desired therapeutic outcome is achieved	To establish the "individual therapeutic concentration" of a given AED
Suspected nonadherence	Serum concentrations will reveal whether or not drug adherence is occurring
Therapeutic failure	To establish whether a lack of efficacy may be due to too low dose/serum concentration or indeed a too high dose/serum concentration that may produce a paradoxical worsening of seizures
When adverse effects occur	To confirm whether the serum concentration is high and is therefore the probable cause of drug toxicity
Individual variations between dose and serum concentrations	Pharmacogenetic variability, ethnicity, age, pharmacoresistance, concurrent illness, organ function (liver, kidneys) and pharmacokinetics are among factors that contribute to interindividual variability
Pharmacokinetic variability in special patient populations	Children, pregnant women, and the elderly require different dose requirements due to alteration in AED pharmacokinetics
Pharmacokinetic interactions	Pharmacokinetic interactions are common in epilepsy and result in increases or decreases in AED serum concentrations with potential exacerbation of adverse effects or seizure breakthrough, respectively
The emergency situation: drug overdose status epilepticus	To guide when the AED dose should be reinstated so as to maintain seizure control To determine whether drug nonadherence has occurred and to guide dosage regimen so as to control seizures

Drug Interactions

Pharmacokinetic interactions with AEDs represent a major indication for AED TDM. These interactions involve changes in serum concentrations consequent to changes in metabolism, principally due to enzyme induction or inhibition and are well described (17–22). Enzyme induction can result in a decrease in serum concentrations and potentially seizure breakthrough while enzyme inhibition can result in increased serum concentrations and potentially neurologic toxicity. Typically, enzyme induction completes within 14 to 21 days, and thus TDM should be undertaken after this period has elapsed. The maximum consequence of enzyme inhibition interactions, whereby new steady-state serum concentrations are achieved, is directly dependent on the half-life of the inhibited drug and typically occurs 4–6 half-lives after the inhibiting drug is coprescribed. Thus, TDM can be readily used to characterize the time course and magnitude of these interactions and make dosage adjustments as necessary.

For most patients, seizure freedom is readily achieved by use of AED monotherapy. However, 30% of patients require polytherapy AEDs (the use of two or more AEDs), and it is these patients that are susceptible to pharmacokinetic AED versus AED interactions. Being aware of which AEDs have a propensity to cause pharmacokinetic interactions and to choose those that do not interact or have minimal propensity to interact, along with knowledge of the mechanism of interaction, is important (22). Thus carbamazepine, phenytoin, phenobarbital, and primidone are potent enzyme inducers, while valproate is a potent enzyme inhibitor, and they may affect the serum concentration of other AEDs (17). In contrast, gabapentin, levetiracetam, lacosamide, pregabalin, and vigabatrin are not likely to be involved in pharmacokinetic interactions due to the fact that they do not undergo metabolism via cytochrome P450 (CYP) or uridine glucuronyl transferase (UGT)-mediated metabolism and instead are excreted renally.

Interactions between AEDs and other drugs used to treat concurrent pathologies are also important and similarly require TDM so as to individualize treatment. These include analgesics, antimicrobials, antineoplastic agents, cardioactive drugs, immunosuppressants, psychotropic drugs, and steroids, including oral contraceptives (18,21,23).

Regarding oral contraceptives, the estrogen component enhances metabolism via UGTs so that AEDs (lamotrigine, oxcarbazepine, and valproate) whose metabolism is via this enzyme system experience decreases in serum concentrations, in some patients by up to 50% (24,25). Conversely, many AEDs (carbamazepine, phenytoin, and phenobarbital) enhance the metabolism of oral contraceptives and compromise contraceptive control.

It should be remembered that when an interacting drug is withdrawn, the interaction will go in reverse, and therefore it is important to reverse any dosage adjustments made accordingly and is best guided by TDM. Finally, identification of pharmacodynamic interactions can similarly benefit from TDM because any change in the clinical status of a patient (seizure exacerbation or increased adverse effects) that is not associated with a change in serum AED concentration is concluded by default as a pharmacodynamic interaction.

Special Patient Populations

Children and Adolescents

Children differ from the adult population due to rapid changes in pharmacokinetics during infancy and early childhood, due to physiologic alterations early in life. For most AEDs studied in youngest children, the elimination half-life is reduced because the clearance is high, especially from 6 months of age and to about 6 years of age. The volume of distribution may also differ (2,4,26). The clinical consequence is that children will need a higher dosage per kilogram of body weight than in older children or adults. This pharmacokinetic variability in children makes it difficult to predict optimal doses and serum concentrations, and thus, TDM is particularly helpful in these patients.

Pregnant Women

In pregnant women, rapid changes in pharmacokinetics are expected as a consequence of various physiologic changes including decreased absorption, altered distribution, decreased protein binding, increased metabolism due to increased enzyme capacity in the liver CYP isoenzymes and UGTs, and increased drug excretion (4,27,28). During this period, TDM is particularly helpful in patient management. For highly protein-bound drugs, management may best be guided by measurement of unbound concentrations (29). Significant pharmacokinetic changes have been recorded for lamotrigine, with an increase in clearance of 50% to 330%, with the most pronounced effect occurring in late pregnancy (28–32). Levetiracetam plasma concentrations can decrease by 60% in the third trimester compared to baseline (33). The metabolism of oxcarbazepine also increases during pregnancy due to enhanced glucuronidation, as the concentrations of the most active enantiomer (S-(+)-10-hydroxycarbazepine) metabolite is increased 1.5- to 13-fold after delivery. Serum concentrations of topiramate also appear to decline gradually throughout pregnancy. The mechanisms are not known, but increased glomerular filtration may play a major role (33,34). Other AEDs that are associated with decreases in serum concentrations during pregnancy and that may benefit from TDM so as to optimize therapy include felbamate, gabapentin, pregabalin, tiagabine, vigabatrin, and zonisamide (28,35,36).

Elderly

The oral clearance of almost all AEDs is reduced in the elderly. Reductions of 10% to 90% have been observed but are most often in the range of 30% to 50% (2). The elderly, with increased morbidity, exhibit pronounced physiologic alterations that affect the pharmacokinetic characteristics of AEDs namely decreased absorption, altered distribution, decreased capacity of metabolizing enzymes, decreased blood flow to eliminating organs, and impaired hepatic and renal function. Additionally, age-related changes in pharmacodynamics and an increased likelihood of drug interactions, because of treatment of concomitant comorbidities, affect the efficacy and safety not only of AEDs but also of concomitant therapy. TDM can guide attainment of targeted concentrations and maintaining these concentrations over time, especially as comedications are added or discontinued. For highly protein-bound AEDs, measurement of unbound concentrations may be indicated. Interpretation of drug concentrations in the elderly should also take into account the fact that the elderly may show increased pharmacodynamic sensitivity to AEDs, and therefore, therapeutic and toxic effects may develop at relatively low concentrations. Thus, interpretation of drug concentration measurements should be interpreted more cautiously.

Hepatic and Renal Disease

Most AEDs are metabolized by the liver, and thus, hepatic disease may alter their clearance (4). In addition, as the liver is the source of many proteins, serum protein binding may also be affected. Studies evaluating serum AED concentrations during hepatic illness are sparse, and there is no test that will predict the degree of change in clearance. Thus, in any person with hepatic disease, AED TDM should be undertaken, and for highly bound AEDs, free concentration monitoring may better guide treatment.

Renal function is of special importance for drugs eliminated in part or primarily by renal excretion, such as primidone, pregabalin, gabapentin, levetiracetam, lacosamide, and vigabatrin (4). Creatinine clearance is a useful measure of renal function, but the measurement of AED serum concentrations can provide better guidance to adjust doses. Also, because many AEDs are efficiently removed during dialysis, AED TDM can also help guide the replacement dosages needed so as to maintain optimum seizure control. For highly bound drugs, free serum concentrations increase significantly in patients with renal disease, and therefore, treatment may be best guided by monitoring free serum concentrations.

Adherence (Compliance)

Nonadherence is a major problem in the treatment of epilepsy as it compromises seizure control. Indeed, the nonadherence rate in children and adults with epilepsy has been determined to be of the order of 33% to 39% (37,38). In the elderly, suboptimal adherence such as underdosing, overdosing, missed doses, or makeup doses is well recognized and alters serum AED concentrations and, potentially, clinical response (39). TDM is useful in identifying nonadherence, but it should be remembered that TDM can only identify short-term nonadherence and not long-term or intermittent nonadherence.

What to Measure

Serum or plasma is the matrix of choice for AED TDM. However, for many AEDs, saliva is a well-validated alternative matrix since concentrations in saliva reflect the pharmacologically relevant serum unbound drug concentrations as recently reviewed by Patsalos and Berry (40). Saliva sampling is simple and noninvasive, multiple serial samples can be readily collected, and it can be undertaken by patients themselves or by their caregivers and is particularly useful in children who often dislike or fear venipuncture. Saliva AED concentrations, however, can be affected by the sampling conditions and by contamination of mucus and the presence of residual drug and food in the mouth. Under well-controlled conditions, saliva AED concentrations can be used to individualize AED treatment and can be particularly useful in clinical settings whereby protein binding is altered for highly protein-bound AEDs (3,40).

Sampling Time

Routinely, the sampling time for individual patients should be standardized so as to have comparable results. It should be remembered, however, that the references ranges are based on trough concentrations (41,42). Samples should be drawn at steady state, which occurs at 4–6 half-lives after starting treatment or a dose adjustment. The ideal sampling time for all AEDs is after an overnight fast and just before ingestion of the morning dose (trough concentrations). Sampling just before the next scheduled dose is also useful. In the outpatient setting, the morning dose can be postponed for at

most 1 hour; however, overall, it is best that sampling time in relation to dose ingestion is recorded so as to better interpret the results. If toxic symptoms present, sampling should occur at time the patient is experiencing adverse effects so as to determine whether indeed the symptoms are drug related.

CONCLUSIONS

AED TDM is a useful tool to optimize and individualize the treatment of patients with epilepsy because it provides important information so as to guide dosage adjustment in patients with unexpected treatment outcomes and in specific age groups (children and the elderly) where the clinical assessment of treatment effects may be particularly difficult. This is in part due to the characteristics of epilepsy and also because of the pharmacokinetic variability of AEDs. The relative value of TDM will depend on the characteristics of the AED, and all the new AEDs have properties that suggest a role for TDM. For most AEDs, reference ranges have been reported, which define the serum concentrations at which most patients are expected to exhibit an optimal clinical response. However, because of individual variation, many patients may require serum concentrations outside the reference ranges, and thus, patient management is best guided by determination of the "individual therapeutic concentration," which is defined as the drug concentration at which an individual achieves seizure freedom or optimum seizure control with tolerable adverse effects.

CHAPTER 49 GENETIC INFLUENCES ON RESPONSES TO DRUGS USED TO TREAT EPILEPSY

THOMAS N. FERRARO

CHAPTER OBJECTIVES

The goal of this chapter is to provide an update on the major topics in antiepilepsy drug (AED) pharmacogenetics. Introductory sections provide background for understanding drug response as a complex trait, describe factors that have limited the clinical application of basic research findings, address elements of common genetic variation, and discuss the concept of genetic association as related to general pharmacology. The main body of the chapter is intended to assess the current state of the field of AED pharmacogenetics by reviewing the major genes that have been documented to have variation that impacts the clinical effects of AEDs. The chapter concludes with a summary and look ahead to future research directions.

INTRODUCTION

Pharmacogenetics is the field of biomedical science that is concerned with the relationship between variability in DNA sequence and variability in response to specific drugs or classes of drugs (1). The ultimate goal of pharmacogenetics is to individualize drug therapy based upon analysis of specific gene variants or other genetic biomarkers that can predict the best possible clinical outcome. However, there are a very limited number of accepted biomarkers for responses to antiepileptic drugs (AEDs) (2,3), and thus, this goal has yet to be achieved. Therapeutic response to drug administration is a highly complex trait (4) that depends not only upon variability in the genome but also upon variability in the environment (5) including factors such as smoking, diet, and coadministered medications. Pharmacogenetic studies of various classes of drugs estimate modest heritability for drug effects (6). Importantly, the influence of environmental factors that affect drug responses hinders identification of genetic factors, and inadequate control of the environment has contributed to the slow progress in the field of AED pharmacogenetics. Nonetheless, given the large fraction of epilepsy patients who do not derive adequate therapeutic benefit from currently available medications, and the potential for individual genetic variation to play a role in this pharmacoresistance (7), great effort continues to be expended on studying the correlation between the effects of AEDs and genetic polymorphisms and on attempting to identify specific genetic markers that will guide the therapeutic decision-making process.

Apart from environmental factors, several constraints in the design of studies to evaluate influences of genetics on response to AEDs can be identified as obstacles in the field. One is related to the relatively small magnitude of effect of individual genetic variants. Complex phenotypes, including those involving responses to AEDs, are recognized to involve multiple genes each with a partial effect on overall phenotype (8–10). This makes the identification of any one causative polymorphism highly challenging, particularly in the setting of uncontrolled environmental factors. Another is lack of a standardized means to quantify therapeutic benefit in terms of seizure reduction, one that is specifically designed for pharmacogenetic studies. A set of guidelines for classifying pharmacoresistance was recently codified by the International League Against Epilepsy (11); however, these guidelines have not been adopted by all laboratories, and they were generally not followed in conduct of the large body of earlier work. A third major obstacle is related to the clinical heterogeneity of epilepsy and the lack of information on the seizure phenotypes of patients included in some notable studies (12). It is possible that genetic influences on pharmacoresistance vary according to epilepsy subtype, and studies that combine different subtypes may introduce confounding variables. A related issue involves the selection of patients with regard to specific drug treatments. Many

studies include patients treated with a variety of drugs (13), referring to the phenotype of "multidrug resistance," and whereas there are some common biologic mechanisms among clinically effective AEDs (14), the genes involved in determining therapeutic responsiveness or resistance may be at least in part drug specific. Thus, it is possible that genetic effects are masked by resulting "noise" in studies that do not parse patients by specific AED. Another critical factor that has limited AED pharmacogenetic studies, although not unique to AEDs, is the relatively small size of patient populations and lack of statistical power. On the other hand, positive results in some studies may be questioned because of failure to correct for multiple statistical testing or population stratification. These factors and others have so far limited the clinical application of AED pharmacogenetic research. Whereas a variety of factors have been identified as obstacles, an area that has pushed the field forward has been genetic technology and advances in nucleic acid analysis. The ability to acquire a vast amount of genetic information from any individual rapidly and economically is already having a major impact in the field of medicine and is bound to have even greater importance in the future, particularly as related to pharmacogenetics.

GENETIC VARIATION AND GENETIC ANALYSIS

Shown in Table 49.1 are several types of structural variants that are commonly observed in human chromosomal DNA including single-base deletions, insertions, and substitutions, the latter representing the largest class DNA variation in the human genome (15). However, while any of these types of variants may impact the function of a gene product relevant to drug action, single-base substitutions, more commonly known as single nucleotide polymorphisms (SNPs), are the largest source of genetic variation between individuals and are likely most relevant to pharmacogenetics (16,17). The development of SNPs and SNP marker maps allows essentially any gene to be surveyed for variants that are associated with a phenotype. The typical experimental design for a pharmacogenetic study is analogous to the familiar "case–control" genetic association study, and it involves direct comparison of SNP genotypes for genes of interest between drug "responders," patients who derive a therapeutic benefit from drug therapy, and drug "nonresponders", those who do not (18). An important extension of this research approach involves comparison of haplotypes, or sets of SNP genotypes, at linked loci; this may help to distinguish whether a particular SNP is in itself functional or whether it is a surrogate for other tightly linked variants (19). Broad application of this strategy in genome-wide association studies has also become technically feasible and is now accelerating the pace of discovery in pharmacogenetics (20). On the horizon are targeted, whole-exome and whole-genome next generation DNA sequencing strategies that will facilitate the highest possible level of personalized drug treatment (21,22).

Table 49.1 Common Forms of DNA Variants Relevant to AED Pharmacology[a]

Variant	Description
Missense	Exonic single nucleotide substitution; produces protein amino acid substitution
Nonsense	Exonic single nucleotide substitution; creates premature translation stop codon
Splice site	Intronic single nucleotide substitution; adds or removes splice site; alters transcript exon composition
Regulatory	Single or polynucleotide insertion, deletion, or substitution in 3′ or 5′ untranslated region; alters gene expression level
Frameshift	Exonic insertion or deletion; changes protein amino acid sequence

[a]Genetic effects on pharmacology arise due to the influence of variation in the DNA sequence of genes encoding proteins that are therapeutic drug targets as well as proteins that are involved with the absorption, metabolism, distribution, and excretion of drugs.

DRUG RESPONDERS AND NONRESPONDERS

In pharmacogenetic studies of AEDs that address end points related to therapeutic benefit, determining which patients are "responders" and which are "nonresponders" is a critical and controversial issue. The assignment of patients to one of these groups will obviously have a major impact on results; however, inspection of the literature reveals substantial variability in the definition of these two response categories. Establishing which patients have derived clinical benefit from treatment, and which have not, is highly dependent upon the criteria utilized for assessment, and therefore, it is imperative for research teams to adopt uniform standards for valid comparison and confirmation of results. Recently, guidelines for defining resistance to AEDs were proposed by the International League Against Epilepsy (11). Epilepsy is recommended being classified as drug resistant if there is continued expression of seizures following a trial of at least two drugs (in monotherapy or polytherapy) that were appropriately selected for the type of epilepsy exhibited, correctly administered, and well tolerated. Conversely, drug responsiveness is defined as freedom from seizures for the period of at least 1 year, or three times longer than the previous interparoxysmal period (whichever is longer). Such guidelines have been proposed previously (23) and have led to more consistency in recent studies; however, strict adherence to these criteria will be required as the field moves toward large multicenter studies that combine patient data collected in diverse settings.

SEIZURE AND AED PHENOTYPES

Currently, there are no widely accepted standards for categorizing seizures in pharmacogenetic studies, a factor that has led to some confusion in the literature and has hindered progress. Whereas detailed seizure phenotypes are clearly important and can be highly informative (24), it is difficult to standardize and implement clinical research protocols that involve intensive collection of seizure data, especially in outpatient or primary care settings. On the other hand, self-reporting of seizure history by patients is also a major detriment to AED pharmacogenetic studies, even when data are basic, such as the number and duration of seizures. Similarly, qualitative ratings of seizure type

and/or severity, while possibly amenable to reliable assessment in certain clinical settings (25), are prone to significant nonspecific variability in ambulatory settings and in multicenter studies. Outcomes that are based upon complete seizure freedom may be more objective and less prone to reporting error; however, this strict criterion may reduce the number of responsive patients below practical limits of inclusion for robust studies. It is necessary to develop novel approaches to the challenges associated with establishing valid seizure response variables in AED pharmacogenetic studies, such as automation of EEG trait characterization (26), possibly with personal EEG devices that are more portable, are less obtrusive, and offer the possibility of remote data capture (27,28). Thus, while the limitations of AED pharmacogenetic studies have been known for some time, many studies are retrospective, utilizing preexisting AED response data from electronic or analog patient records that are often incomplete, lacking in detail, and prone to error. These factors must be taken into account both when designing new studies and when reviewing previous studies.

Because all drugs have multiple effects, including AEDs, multiple responses can be monitored and dissected genetically in pharmacogenetic studies. These responses are not limited to abrogation of seizures but may also include aspects of general pharmacology as well as biochemical, physiologic, or behavioral side effects of the drugs. Detailed phenotyping of patient responses to drug therapy may ultimately help to adopt standardized criteria for evaluating the relationship between genetic variability and AED effects. Additionally, since the effects of genetic variability may not be the same for all response end points, there is significant value added to studies that provide a high level of clinical information related to therapy, including data on seizure semiology, blood drug levels, metabolites, and drug interactions among others. In general, clinically relevant responses in epilepsy patients are tied to the pharmacology of AEDs. Two main categories of end points cover the range of responses that may be monitored in individual subjects, pharmacokinetic and pharmacodynamic. This classical distinction in the field of pharmacology represents a useful framework within which to ask questions about pharmacogenetics, and it is used here to organize discussion of relevant molecules.

PHARMACOKINETICS

The current state of the field of pharmacogenetics of AEDs is related in large part to genetic association studies in which statistical relationships are sought between clinical outcome variables and common polymorphisms in genes whose protein products are involved in pharmacokinetic processes. There are four basic sets of processes that constitute pharmacokinetics: (i) modalities by which drugs are administered to patients; (ii) the physiologic means by which they are distributed throughout the body and delivered to specific organs, tissues, and cells; (iii) the enzymatic pathways via which they are metabolized; and (iv) the mechanisms used to eliminate them and their metabolites from the body. There are many endogenous molecules that interact with drugs and that play specific roles in these pharmacokinetic processes; close coordination of the function of these molecules is critical for drugs to exert therapeutic effects. Sometimes underemphasized are the complexities associated with statistical analysis and modeling of pharmacokinetic processes for AEDs (29).

From the perspective of AED pharmacogenetics, the most studied endogenous molecules relevant to pharmacokinetics are drug transport proteins and drug-metabolizing enzymes. In general, these molecules play major roles in determining drug efficacy, time course of effect, and toxicity. Transporter proteins and enzymes that mediate drug biotransformation are from families in which members may be highly polymorphic and have similar or overlapping functions. The relative role of a

particular drug transport protein is dependent upon the specific AED and the expression level of the transport protein at the target brain site, which, in the case of epilepsy, may vary from patient to patient. Similarly, drug biotransformation may be shunted down alternative metabolic pathways based on substrate concentration or the activity levels of individual enzymes in different patients. Although some part of the difference between patients in drug transport and drug metabolism is a result of environmental influences, such as diet, exercise, and smoking (30), a substantial component is also a result of genetic variability, and studies suggest that both genetically mediated overexpression of cellular drug efflux pumps (31) and altered activity of polymorphic drug-metabolizing enzymes (32) may have a clinically relevant impact on the outcome of treatment with AEDs.

DRUG TRANSPORTERS

The processes of drug absorption, distribution, and excretion involve numerous transport proteins that are expressed on various cell types in many organs and tissues including vasculature, small intestine, brain, liver, and kidney. Several families of drug transport proteins potentially relevant to AED therapy have been identified; however, there is controversy regarding the role of specific molecules and their substrate specificity. This controversy stems in part from the many closely related members of protein transport families, tissue-specific expression of isoforms, species differences, and differences in assay parameters, all of which hinder the interpretation of data (33,34). These factors and others have prevented full elucidation of the role of drug transport proteins in the absorption, distribution, and elimination of AEDs in humans.

ATP-Binding Cassette Proteins

ATP-binding cassette (ABC) proteins are ATPase-dependent membrane transporters that mediate drug efflux from various types of cells including epithelium, endothelium, glial cells, and neurons (35). In the intestine, ABC transporters promote the excretion of drugs into the lumen (36) and could theoretically affect bioavailability of orally administered AEDs by inhibiting their absorption into the bloodstream. In endothelial cells of cerebrovasculature and choroid plexus, ABC transporters could extrude drugs absorbed from the blood and potentially restrict access to the brain (37). They are recognized as a factor of very high potential impact with regard to pharmacoresistance in epilepsy (38).

Although there is considerable evidence to support the concept that ABC transporters are relevant to the pharmacology of AEDs, studies on the substrate specificity of these transporters have yielded conflicting results with regard to their interactions with individual drugs. Analysis of prior work suggests that of currently available AEDs, phenytoin, phenobarbital, oxcarbazepine, and lamotrigine are highly likely to serve as substrates for ABC transport proteins (39,40). There is also evidence that levetiracetam, carbamazepine, felbamate, topiramate, valproate, and gabapentin interact with ABC transporters although there are conflicting data on these agents (39,40). Overall, this work has helped in the formulation of the hypothesis that high levels of transporter expression in epithelial cells lining the gastrointestinal tract and/or in endothelial cells constituting the blood–brain barrier contribute to pharmacoresistant epilepsy and has led directly to efforts to use transport inhibitors to increase penetration of AEDs into the brain (41).

Studies in animal models (42) and in humans with pharmacoresistant epilepsy (43) suggest that recurrent seizure activity increases expression of ABC transporter expression; however, the effects of

AED treatment on the expression of P-glycoprotein (44,45), the major ABC transport protein (46), complicate interpretation of results in human studies. It is also possible that interindividual differences in baseline expression or function of transporter proteins are involved in determining which patients will respond to a given medication. Positive genetic association between ABC gene variants and AED effects would represent strong evidence for a functional relationship and could be used to establish genotype-specific treatment guidelines that would optimize therapeutic drug regiments. Studies to date have focused on two members of the ABC transporter gene family: ABCB1 and ABCC2.

ABCB1

ABCB1, also known as MDR1 (multidrug resistance gene 1), encodes P-glycoprotein, a 1280 amino acid residue product (46). C3435T (rs1045642) is a common SNP in exon 26 of the ABCB1 gene with a minor allele frequency that shows significant ethnic differences (47). It is a synonymous polymorphism predicting an isoleucine residue in the intracellular C-terminal segment of the protein, and it may be the most comprehensively studied variant in AED pharmacogenetics. The functional effect of this variation is manifest as a change in protein folding due to the differential rate of protein synthesis caused by usage of an alternate codon (AUU for the T allele and AUA for the C allele) resulting in altered drug transport properties (48). As more P-glycoprotein is produced, specific tRNA species become depleted, and the role of alternative codon usage may be more critical (48). Thus, there is strong rationale for considering this variant as a potential factor in AED pharmacogenetics. Two other exonic SNPs in ABCB1 that have also been the focus of multiple studies are C1236T in exon 12 and G2677T/A in exon 21. The latter SNP is nonsynonymous and predicts a change from an alanine residue (G) to a threonine (T) or serine (A).

Studies designed to assess the role of C3435T and other ABCB1 SNPs in therapeutic responses to AEDs have been numerous and conflicting with nearly as many reporting positive associations as negative associations. A summary of these studies is shown in Table 49.2. Notably, among positive reports for C3435T, there is also discordance with regard to the allele or genotype associated with drug resistance. Early studies in Caucasian populations suggested that drug resistance was associated with the CC genotype (12) or with haplotypes containing the C allele (50). In contrast, the TT genotype was associated with drug resistance in Asian patients with epilepsy (57,63). Such ethnic differences suggested that C3435T may be linked to other ABCB1 polymorphisms that influence AED responses. Subsequent reports have revealed that the T allele and TT genotype may also be associated with drug resistance in Caucasian epilepsy patients (87) and the C allele and CC genotype may be associated with drug resistance in Asian patients with epilepsy (92). This suggests a potentially complex influence of ABCB1 genetic variability that requires further research to fully elucidate.

Table 49.2 Summary of ABCB1 Association Studies Related to AED Treatment Outcome

Author	Year	Population	Reference	SNPs	Association result[a]
Siddiqui et al.	2003	Caucasian; Asian	(12)	C3435T	CC genotype associated with drug resistance
Tan et al.	2004	Caucasian	(49)	C3435T	Negative
Zimprich et al.	2004	Caucasian	(50)	C1236T, G2677T/A, C3435T	Haplotype including C3435T associated with drug responsiveness
Soranzo et al.	2004	CEPH Families	(51)	Three intronic SNPs	Negative
Sills et al.	2005	Caucasian	(52)	C3435T	Negative
Hung et al.	2005	Han Chinese	(53)	C1236T, G2677T/A, C3435T	Haplotypes CGC, TGC, and TTT (for C1236T, G2677T, and C3435T) associated with drug resistance
Leschziner et al.	2006	Caucasian	(54)	C1236T, G2677T, C3435T	Negative
Kim et al.	2006	Korean	(55)	C3435T	Negative
Kim et al.	2006	Korean	(56)	C1236T, G2677T, C3435T	Negative
Seo et al.	2006	Japanese	(57)	T-129C, C1236T, G2677T/A, C3435T	T allele and TT genotype at C3435T and TT genotype at G2677T/A associated with drug resistance; haplotypes
Leschziner et al.	2007	Caucasian	(58)	C1236T, G2677T, C3435T	Negative
Shahwan et al.	2007	Caucasian	(59)	C3435T; 8 tagging SNPs	Negative
Chen et al.	2007	Han Chinese	(60)	C3435T	Negative
Ebid et al.	2007	Egyptian	(61)	C3435T	C allele associated with drug resistance
Hung et al.	2007	Han Chinese	(62)	C1236T, G2677T/A, C3435T	T allele at both G2677T and C3435T and their interaction term associated with drug resistance
Kwan et al.	2007	Han Chinese	(63)	C3435T	TT genotype associated with drug resistance
Simon et al.	2007	Caucasian	(64)	T-129C, C1236T, G2677T/A, C3435T	2677T allele associated with low plasma phenytoin levels
Dericioglu et al.	2008	Turkish	(65)	C3435T	Negative
Ozgon et al.	2008	Turkish	(66)	C3435T	Negative
Basic et al.	2008	Croatian	(67)	C3435T	CC genotype associated with low CSF/serum phenobarbital ratio and with drug resistance
Szoeke et al.	2009	Caucasian	(68)	C3435T	Negative
von Stülpnagel et al.	2009	Caucasian	(69)	C1236T, G2677T/A, C3435T	Negative

Author	Year	Population	Reference	SNPs	Association result[a]

Hung et al.	2012	Han Chinese	(84)		Negative
Hung et al.	2012	Han Chinese	(85)	C1236T, G2677T/A, C3435T	C1236T, G2677T/A associated with phenytoin concentration/ dose ratio
Ponnala et al.	2012	Indian	(86)	C3435T	T allele and CT and TT genotypes associated with drug resistance.
Sterjev et al.	2012	Macedonian	(87)	C3435T	CT and TT genotypes associated with drug resistance
Lovrić et al.	2012	Croatian	(88)	C1236T, G2677T/A, C3435T	Associated with lamotrigine serum concentrations
Emich-Widera et al.	2013	Not Specified	(89)	C3435T	Negative
Seven et al.	2013	Turkish	(90)	C3435T, G2677T/A	Children; Negative
Shaheen et al.	2013	Indian	(91)	C3435T	TT genotype associated with drug resistance
Subenthiran et al.	2013	Malaysian	(92)	C3435T, G2677T/A	3435TT and 2677TT genotypes associated with response to CBZ; GCGC haplotype associate with resistance
Puranik	2013		(93)		Associated with carbamazepine clearance

[a]Association results are based on the significance of the P-value in the original publication. "Negative" refers to a P-value that was determined to be statistically not significant.

The large number of studies on the influence of C3435T and other ABCB1 SNPs on AED responses in epilepsy patients has spawned several meta-analyses permitting an increase in statistical power and helping to address issues associated with multiple testing artifacts. An early meta-analysis (94) combined data from over 1000 patients but failed to demonstrate a statistically significant association of C3435T with multidrug resistance. The next published meta-analysis also focused specifically on C3435T, involved 11 studies including over 3300 drug refractory and 1600 drug-responsive epilepsy patients (95), and it also obtained negative results both with and without segregation of studies by country of origin. A third meta-analysis included 22 studies (96), and it too was negative irrespective of segregation of ethnic subgroups. This latter study conducted a separate analysis including only reports meeting the International League Against Epilepsy's recommendation for drug resistance, but this was also negative. A subsequent update of this latter meta-analysis included 25 studies and examined 3-SNP haplotypes in addition to C3435T genotypes and allele frequencies (81), but again no positive association was documented. Thus, despite a number of provocative literature reports, based upon the outcome of several meta-analyses, the impact of ABCB1 genotype on AED response is unclear. The addition of new studies to the literature since the time of the last meta-analysis, both positive (79,82,83,86,87,91,92) and negative (77,78,85,89,90), provides impetus for another combined meta-analysis and a reassessment of the impact of ABCB1 genetic variation on therapeutic response to AEDs. However, it is likely that inadequate control of variables including diet, smoking, exercise, epilepsy subtype, and issues related to polypharmacy such as inclusion of drugs that may not be substrates for the ABCB1 transporter will continue to have a negative impact on such attempts.

With regard to pharmacokinetic end points, several studies have attempted to correlate ABCB1 genotypes with levels of AEDs. A study in European patients showed that low plasma levels of both phenytoin and carbamazepine are associated with the T allele of G2677T SNP but not with SNPs at positions 129, 1236, or 3425 (64). A subsequent study of Han Chinese epilepsy patients on phenytoin monotherapy reported that ABCB1 genotypes at C1236T, G2677T, or C3435T had no clear effect on maintenance dose or plasma drug levels (85). An earlier study involving a 6-month trial of phenobarbital monotherapy in Croatian epilepsy patients reported that whereas there was no effect of ABCB1 polymorphisms at G2677T or C3435T on serum drug levels, patients with the CC genotype had significantly lower CSF drug levels and significantly more seizures than patients with CT or TT genotypes (67). On the other hand, a recent study in Croatian patients showed that the CC genotype of the C1236T SNP was associated with high plasma lamotrigine levels compared to TT and CT patients; no effect of genotype at either C3435T or G2677T/A was observed (88). Steady-state and dose-corrected lamotrigine concentrations were also shown to be significantly associated with C1236T as well as with G2677T, and the 3-SNP haplotype 1236C–2677G–3435C was associated with significantly higher lamotrigine plasma levels compared to several other common haplotypes, although a complicating aspect of the study is that the majority of the patients were taking multiple AEDs in addition to lamotrigine (88). Overall, while there is some suggestion that ABCB1 genotypes are involved in shaping clinically relevant parameters of AED pharmacokinetics, it is not yet possible to develop a clear picture of which SNPs are most relevant and which AEDs are affected.

ABCC1 and ABCC2

ABCC1 encodes multidrug resistance–associated protein 1 (MRP1), a 1522 amino acid residue drug transporter protein (97). ABCC1 is ubiquitously expressed and its substrate specificity overlaps with

that of ABCB1 (98). While this gene has been shown to be highly polymorphic (99), no clinically significant associations have been recognized. ABCC2 encodes multidrug resistance–associated protein 2 (MRP2, ABCC2), a 1545 amino acid residue protein that also may be involved in the transport of AEDs (98,100) and is up-regulated in the brain tissues of patients with epilepsy, similar to ABCB1 (101–104). In an early study, no association between the ABCC2 genotypes or haplotypes, and responsiveness to AEDs was observed in nearly 300 Japanese epilepsy patients (105). Subsequently, it was shown that carriers of the putatively low-expression 24T variant were significantly overrepresented among nonresponders, a finding that was confirmed by comparing young responders with adult drug-refractory patients (106). Following this, it was reported that carriers of the nonsynonymous polymorphism, G1249A (V417I, rs2273697), were more frequent among responders, and the allele was more prevalent among the subgroup of patients receiving carbamazepine or oxcarbazepine, but not in patients receiving other AEDs (107). In another study, ABCC2 C-24T (exon 1) and C3972T (exon 10) polymorphisms and one ABCC2 haplotype were associated with multidrug pharmacoresistance (108). Evidence for clinical relevance of the nonsynonymous G1249A (V417I) variant comes from a study reporting that presence of the A allele is an independent determinant of adverse neurologic effects caused by carbamazepine (109). Functional experiments using an ATPase assay in conjunction with flow cytometry indicated that carbamazepine was a substrate of MRP2 and that the 417I variation selectively reduced carbamazepine transport across the cell membrane (109). However, not all studies of ABCC2 have been positive. In a study of drug-resistant and drug-responsive Han Chinese epilepsy patients, no statistically significant genotype or haplotype associations were detected following analysis of 25 tagging SNPs from ABCC2, ABCC5, and ABCG2 genes (110). Similarly, a recent study did not identify any significant association between genetic polymorphisms of the C-24T and G1249A of ABCC2 or any combined effect in response to AED treatment and development of drug resistance in patients with partial complex epilepsy (111).

Thus, as is the case with ABCB1, numerous genetic association analyses between common ABCC2 polymorphism and response to AEDs have been reported; however, as described above, results are conflicting and difficult to interpret clearly. In attempts to integrate available data and support this line of investigation, two meta-analyses have recently been undertaken. One analyzed the effect of the G1249A (V417I) polymorphism in 6 published studies, involving 2213 patients (1100 patients with drug-resistant epilepsy and 1113 controls with drug-responsive epilepsy) and showed that variant genotypes were associated with a significantly decreased risk of AED resistance (112). A stratified analysis by ethnicity showed similar findings for Caucasians in an additive model again suggesting that the ABCC2 G1249A polymorphism is significantly associated with a decreased risk of AED resistance (112). The other meta-analysis involved 8 studies that included 1294 responders and 1529 nonresponders, and it analyzed all the commonly reported variants that included C-24T, G1249A (V417I), and C3972T (I1324I) (113). Although preliminary analyses showed an overall significant association of high activity promoter variant C-24T, the T allele being associated with beneficial therapeutic response to AEDs, the association was lost after testing for multiple corrections. Thus, taken together, results of the two meta-analyses suggest a possible role of the ABCC2 transporter variants in altered drug response in patients with epilepsy; however, the genetic mechanism underlying this effect is unclear, and the magnitude of its influence in determining overall response to AEDs, if any, remains to be elucidated.

SLC3A2 and SLC7A5

Another protein complex documented to affect to membrane flux of AEDs is the large neutral amino acid transporter, also called L-amino acid transporter or system L, a heterodimer encoded by the genes SLC3A2 and SLC7A5 (114,115). Although there is evidence to support a role for system L in the absorption of pregabalin and gabapentin (116,117), data on the role of genetic variation in this system with regard to individual differences in drug effects in general are sparse (118).

SLC22A4

SLC22A4 encodes the organic cation transporter 1 (OCTN1) and may be involved in the absorption and excretion of certain cationic drugs. Gabapentin is an AED that does not undergo extensive metabolism and whose absorption and renal elimination appear to involve membrane transporters. To test the hypothesis that variation in SLC22A4 plays a role in gabapentin pharmacokinetics, the common variant L503F was analyzed in relation to gabapentin clearance (119). Results showed that in subjects homozygous for the variant phenylalanine allele, gabapentin renal clearance approximates the glomerular filtration rate, whereas in subjects homozygous for the wild-type leucine allele, gabapentin undergoes net secretion in the kidney. This finding was supported by in vitro studies showing that OCTN1 facilitates the Na^+-independent transport of gabapentin and that the OCTN1 phenylalanine variant is deficient in gabapentin transport activity (119). It was concluded that OCTN1 contributes to active tubular secretion of gabapentin and that this effect may be diminished or absent in individuals carrying the OCTN1 phenylalanine variant. The results of this study underscore the clinical relevance of genetic variation in renal drug transporters with regard to active drug secretion and suggest it may be involved in explaining interpatient variability observed regarding the effects of certain AEDs including gabapentin.

DRUG-METABOLIZING ENZYMES

Biotransformation of AEDs is diverse and involves a host of different enzyme proteins (120). Genetic effects are observed as a result of the many drug-metabolizing enzymes that are products of polymorphic genes (121), and it is important to note that these polymorphisms exhibit significant ethnic differences (122). Drug metabolism is generally recognized to proceed in two phases. Phase I reactions involve the cytochrome P450 (CYP) family of mixed function oxidases. Although numerous CYP family members have been identified (http://www.cypalleles.ki.se/), only four (CYP1, CYP2, CYP3, and CYP4) are involved in drug metabolism. CYP enzymes mediate a wide array of reactions involving both xenobiotics and endogenous substrates alike. They incorporate one atom of molecular oxygen into the substrate and the other atom into water. In general, phase 1 reactions involve the addition of a functional group, which is then used as a site of conjugation in phase 2 reactions.

With respect to phase 1 drug metabolism, the most common reaction involving CYP enzymes is hydroxylation (123). The highly polymorphic nature of the CYP gene family has functional relevance with regard to the pharmacology and clinical use of many AEDs. Most AEDs undergo phase 1 metabolism including phenytoin, phenobarbital, carbamazepine, valproate, diazepam, ethosuximide, zonisamide, felbamate, and tiagabine (124,125). In some cases, phase 1 metabolism activates AEDs and contributes to therapeutic or toxic effects (126). Other AEDs are metabolized primarily by non-CYP mechanisms or undergo phase II metabolism directly including lacosamide, rufinamide,

topiramate, and vigabatrin (127). Levetiracetam and gabapentin are excreted mostly unchanged in the urine.

Phase 2 metabolism involves various conjugation reactions that increase hydrophilicity and facilitate renal excretion of a drug or phase 1 drug metabolite. Among the common endogenous molecules conjugated to xenobiotics are acetyl and sulfate moieties, glucuronic acid, glycine, and glutathione (123). The enzymes that are involved in conjugating these endogenous compounds to exogenous drug substrates represent another level of potential genetic influence since functional polymorphisms are also known to exist in all the major phase 2 enzyme systems including N-acetyltransferases, sulfatases, glucuronidases, and glutathione synthetase. There is evidence that some of these variants are relevant to the pharmacology of AEDs.

Table 49.3 shows a summary of polymorphic drug- metabolizing enzymes studied in relation to the pharmacology of AEDs. For the most part, pharmacogenetic studies of drug-metabolizing enzymes for AEDs have focused on pharmacokinetic phenotypes such as the influence of variants on the relationship between dosage and plasma levels. Variants of phase 1 enzymes with impaired activity are often associated with higher plasma levels. In a number of studies, this has been related to increased drug toxicity and a requirement for dosage reduction. Studies of the influence of genetic variation in AED-metabolizing enzymes on therapeutic responses to AEDs are less frequent and the results less clear with regard to clinical relevance. Following are key genes whose variation has been suggested to be most relevant to the pharmacology of AEDs.

Table 49.3 Summary of Reported Associations Between Variation in Genes for Drug Metabolism Enzymes and AED Treatment Endpoints

Gene	AED[a]	Association result	Reference
CYP2C19	PHT	Variant alleles associated with maximal elimination rate	(128–130)
		Variant allele associated with decreased elimination Km and lower p-HPPH/PHT ratios	(131)
		Variant allele associated with higher plasma levels	(64,67,78,85,88,89,97–127,132–138)
		Haplotype associated with drug resistance	(90)
	PBN	Total clearance significantly decreased in homozygous variant	(139)
	CLB	Variant alleles associated with decreased clearance and higher plasma N-CLB/CLB dose ratios	(134–136)
	PB	No association with PB clearance, volume of distribution or plasma level	(140)
	ZNS	Variant alleles associated with decreased clearance	(141)
	VPA	Variant alleles associated with decreased clearance	(137)
CYP2C9	PHT	Variant allele associated with decreased elimination rate	(129,130)
		Variant allele associated with decreased V_{max} of elimination and decreased p-HPPH/PHT ratios	(131)
		Promoter variant associated with decreased clearance	(142)
		Variant allele associated with decreased dose requirement	(85,143–145)
		Variant allele associated with higher plasma levels	(85,138,146,147)
		Promoter variant associated with dose requirement	(148)
		Variant allele and haplotype associated with drug resistance	(90)
	VPA	No association of variants with levels of hepatotoxic 4-diene-VPA	(149)
		Variant *3 allele associated with higher plasma VPA	(150)
		Variant alleles associated with reduced clearance	(151)
	MULTI	Variant alleles associated with multidrug resistance	(82)
	PB	Variant allele associated with decreased clearance	(152)
CYP2A6	VPA	Variant *4 allele associated with higher plasma VPA	(150)
CYP2B6	VPA	Variant allele associated with higher plasma VPA	(150)
CYP3A4	CBZ	Variant allele associated with altered clearance	(93)
CYP3A5	CBZ	Variant allele associated with higher steady-state level	(153)
EPHX1	CBZ	Variant allele associated with altered metabolite ratios	(93)
		Variant allele associated with maintenance dose	(154)
		Variant allele associated with higher plasma levels	(155)
NAT2	CLZ	Variant alleles associated with lower V_{max} for formation of acetylated metabolite in vitro	(156)

Gene	AED[a]	Association result	Reference
	PHT	Variant alleles associated with increased half-life, decreased clearance, toxicity	(157)
POR	CLB	Variant genotype associated with increased clearance	(134)
UGT1A3	VPA	Variant allele associated with low trough plasma level	(158)
UGT1A4	LTG	Variant allele associated with low serum levels	(159)
UGT1A6	VPA	Variant allele associated with low concentration–dose ratio	(160,161)
UGT2B7	VPA	Variant allele associated with decreased clearance	(13)
		Variant allele associated with low concentration–dose ratio	(160)
		Variant allele associated with low serum level	(162)
	LTG	Variant promoter allele associated with low concentration–dose ratio	(163)

[a]PHT, phenytoin; PBN, pentobarbitone; CLB, clobazam; PB, phenobarbital; ZNS, zonisamide; VPA, valproate acid; MULTI, polypharmacy; CBZ, carbamazepine; CLZ, clonazepam; LTG, lamotrigine.

CYP2C19

The CYP2C family is the most extensively studied enzyme system in relation to AEDs. It is a large gene family that is highly expressed in the liver, and its various isoforms exhibit numerous polymorphisms including some that are functional and that are clinically relevant to drug biotransformation. CYP2C19 was the first isoform to gain prominence with regard to its potential for pharmacogenetic relevance. Initial studies showed that variants of the CYP2C19 gene had a significant influence on the metabolism of the AED mephenytoin (132,133). Since that time, a role for CYP2C19 variants in the effects of other AEDs has been suggested. For example, the ratio of the plasma concentration of the active metabolite of clozaban, N-desmethylclobazam, to the administered dose of clozaban (the so-called CD ratio) is significantly greater in patients harboring CYP2C19 variants (134,135). In a related study, the concomitant use of hepatic enzyme inducers (phenytoin and carbamazepine) reduced the CD ratio of clozaban independent of CYP2C19 genotype; however, ratios for N-desmethylclobazam were only elevated in patients harboring variant alleles (136). This latter study showed that when the cutoff value of the CD ratio for N-desmethylclobazam was set at 10.0 (μg/mL)/(mg/kg) for predicting the CYP2C19 variant status, the sensitivity and specificity were 94.4% and 95.7%, respectively (136). Screening tests such as this which allow better management of AED polypharmacy have high potential clinical utility.

Epilepsy patients who harbor CYP2C19 variants have been reported to have significantly reduced clearance of several other AEDs including phenytoin and diazepam. Although phenytoin is primarily metabolized by CYP2C9, a number of studies have suggested that epilepsy patients with CYP2C19 low-activity ("poor metabolizer") variants may have significantly decreased clearance (128–130,137,138), a significantly higher CD ratio (85) and a significantly lower ratio of plasma metabolite to parent drug level (131). With respect to diazepam, CYP2C19 catalyzes N-demethylation and 3-hydroxylation reactions, both of which generate therapeutically active compounds (164). CYP2C19 variants increase plasma elimination half-lives of diazepam, and its metabolites and the clearance of diazepam was significantly lower in individuals harboring variant alleles (165). Clearance of zonisamide has also been shown to be lower in CYP2C19 variant carriers

(141) as has clearance of valproic acid (137). One study that examined the relationship between CYP2C19 genotypes and the plasma level, volume of distribution and clearance of phenobarbital was negative (140).

Although there are notable ethnic differences in the frequency of CYP2C19 variant alleles, the wild-type or extensive metabolizer phenotype predominates in all populations so far studied (122). CYP2C19 variant alleles are more frequent in Asian populations (13% to 23%) compared to whites and African Americans (1% to 6%) (166). The main defective allele, CYP2C19*2, occurs in 30% of Chinese and between 15% and 17% in Caucasian and African American populations. CYP2C19*3 occurs in about 5% of individuals of Chinese descent and is very rare in Caucasians (167). Although CYP2C19*2 and CYP2C19*3 alleles together explain essentially all poor metabolizers of Asian descent, it only explains about 80% of Caucasian poor metabolizers (168). Thus, additional variants await discovery in this population, and in the interim such variants may be a cause of "idiosyncratic" reactions.

CYP2C9

CYP2C9 is the primary enzyme responsible for the metabolism of phenytoin. Of the many CYP2C9 alleles identified, the wild-type allele encodes an enzyme with the highest activity; variants encode enzymes with reduced activities that confer "poor metabolizer" phenotypes (169–171). CYP2C9 variants thus have been associated with a number of pharmacokinetic parameters including high plasma or serum level (138,143,146,147), reduced clearance (129,130,144,172) and lower dose requirement (85,143–145) compared to patients who carry only wild-type alleles. In one study, the mean maximal drug elimination rate was 40% lower in patients harboring CYP2C9 variants (131).

A major implication of CYP2C9 variants that substantially decrease the rate of phenytoin metabolism and elimination is related to the possibility of drug accumulation and toxicity. Several studies have investigated the relationship between CYP2C9 variants and adverse reactions to phenytoin, particularly neurologic signs such as weakness, lethargy, motor incoordination, slurred speech, cognitive disturbance, and memory loss. Early case reports of phenytoin-treated patients harboring known (173) or novel (174) variants highlighted this potential problem. Subsequently, a study of nearly 300 epilepsy patients treated with phenytoin showed that there was a significantly greater frequency of CYP2C9 variants in the 20% of the patients who exhibited neurotoxic effects compared to the 80% who did not (175). This report was confirmed by others showing an association between phenytoin toxicity and CYP2C9 variants in large patient populations (176,177). Taken together, these reports document the clinical relevance of CYP2C9 variants with regard to dose-related nonspecific neurologic toxicity induced by phenytoin. A more specific abnormal neurologic phenotype associated with long-term phenytoin treatment is cerebellar atrophy, and a recent study has shown that this effect is also related to CYP2C9 gene variants (178). Interestingly, two other recent studies have reported protective effects of CYP2C9 variants in epilepsy patients treated with phenytoin, one showing reduced risk for atherosclerosis (179) and another showing increased bone mineral density (180).

The AEDs valproate and phenobarbital may also be substrates for CYP2C9, and they too have been studied in relation to genotype. In a population of Japanese epilepsy patients, phenobarbital clearance was shown to be reduced by nearly one-half in those carrying CYP2C9 variants (152). CYP2C9 variants are also reported to be associated with higher valproate plasma levels (150) and decreased valproate clearance (137) but have no effect on production of the hepatotoxic 2,4-diene

valproate metabolite (149). All of these studies suggest a broad influence of CYP2C9 variants on AED pharmacology.

In addition to effects on AED pharmacokinetics, CYP2C9 polymorphisms have also been studied in relation to multidrug resistance. One study showed a marginally significant difference between drug-responsive and drug-resistant patients for frequency of the CYP2C9*3 variant (A1075C) (82). A subsequent study confirmed the association between CYP2C9*3 and drug resistance and also demonstrated an association with haplotypes containing variants for both CYP2C9 and CYP2C19 (90). It is noteworthy that positive results were obtained in the above studies despite patients having been treated with multiple AEDs, some of which are not substrates for CYP2C9 or CYP2C19.

CYP3A

The CYP3A family has several members relevant to the metabolism of AEDs. CYP3A4 is one of the most prominent members of the hepatic microsomal P450 system (181) and is involved in the metabolism of many diverse drugs (182). AED substrates for this enzyme and the closely related CYP3A5 include carbamazepine, tiagabine, and felbamate. Zonisamide is metabolized mostly by the CYP3A4 and CYP3A5 but also by CYP3A7 (183). Valproate is metabolized by CYP3A1 (184).

Pharmacogenetic studies involving CYP3A variants have been conducted in regard to the pharmacology of carbamazepine primarily because this family is involved in the formation of the 10,11-epoxide, a major carbamazepine metabolite. In one study, steady-state plasma levels of carbamazepine were higher in patients harboring the CYP3A5*3 variant (153). In another study, clearance of carbamazepine was reduced in patients harboring the CYP3A4*1B variant (93). These results suggest that CYP3A variants are functional and may affect the use of carbamazepine. However, effects of CYP3A4 genotype on carbamazepine levels are not observed in all studies (155), and no relationship is observed between CYP3A4 genotype, carbamazepine pharmacokinetics, and therapeutic response (155). A study investigating a possible relationship between CYP3A4 genotype and the pharmacokinetics of zonisamide also reported negative results (164).

EPHX1

EPHX1 encodes human microsomal epoxide hydrolase, a major phase 1 enzyme involved in the detoxification of aromatic drug molecules. This enzyme catalyzes the conversion of epoxides to less toxic dihydrodiols that subsequently can be conjugated with glucuronic acid or glutathione and excreted in phase 2. In the case of carbamazepine, 10,11-CBZ-epoxide is further deactivated by the action of epoxide hydrolase to give inactive 10,11-CBZ-diol that is excreted as a glucuronide. Several AED pharmacogenetic studies of EPHX1 have been reported on patients treated with carbamazepine. In one study, a multivariate model that included patient age and genotypes for SNPs T337C and A416G revealed a significant association with carbamazepine maintenance dose (154). In another study, EPHX1 SNPs were associated with greater CBZ-10,11-trans dihydrodiol:CBZ 10-11 epoxide ratios (93). However, while studies continue to confirm that EPHX1 A416G affects carbamazepine levels, there is a lack of association with drug resistance (155). In addition to carbamazepine, another AED whose metabolism involves the action of epoxide hydrolase is phenytoin (185). In a study focused on the fetal toxicity of phenytoin, maternal EPHX1 Y113H and H139R variants were associated with congenital malformations whereas the Y113/H139 haplotype was protective (186).

UGT1A and UGT2B

UGT1A and UGT2B, along with UGT2A, are genes that encode isoforms of the enzyme uridine 5′-diphospho-glucuronosyltransferase (UDP-glucuronosyltransferase, UGT), a glycosyltransferase that catalyzes the transfer of the glucuronic acid component of UDP-glucuronic acid to a small hydrophobic molecule (187). Such glucuronidation reactions are critical elements of phase 2 drug metabolism (123,188). Extensive genetic variation exists in the UGT1A and UGT2B genes (189,190), and since several AEDs use the UGT pathway, this variation is beginning to be examined in regards to AED pharmacotherapy.

Glucuronidation pathways involving UGT enzymes are particularly important for valproate and lamotrigine. One study showed that trough plasma levels of valproate were lower in patients carrying the UGT1A3*5 variant (158). Another study examined pediatric patients with background CYP2C9*1/*1 genotypes undergoing AED polypharmacy and showed that valproate plasma levels were lower in those who were homozygous CC for the UGT2B7 C161T variant (13). Analysis of a set of six candidate genes relevant to valproate pharmacology identified UGT2B7 as a functionally important gene showing a significant association between dosage (mg/kg/day) and the UGT1A6 T19G, A541G, and A552C variants, carriers of which exhibited a lower valproate CD ratio and thus were observed to require higher drug doses to achieve a therapeutic effect (160). A subsequent study refined this observation reporting that patients who were double heterozygotes at nucleotide variants T19G, A541G, and A552C in UGT1A6 exhibited lower plasma valproate levels and required higher valproate doses (161). Finally, a recent study of A268G and G211T in the UGT2B7 gene showed that the plasma valproate concentration in patients homozygous AA for A268G was significantly higher than that of patients who were GG (162). Similar positive associations have been reported between UGT genes and pharmacokinetic parameters for lamotrigine, an AED that is metabolized predominantly by glucuronidation. The major inactive urinary metabolites are a 2-N-glucuronide (76%) and a 5-N-glucuronide (10%). Thus, in one study that looked at the relationship between lamotrigine CD ratios and UGT2B7, a significant association was found with a 5′UTR promoter SNP suggesting that increased expression of glucuronidation enzymes results in increased clearance and lower levels (163). Another study examined two SNPs predicting amino acid substitutions in UGT1A4, P24T, and L48V and reported that serum levels of lamotrigine in nonsmoking patients undergoing monotherapy who carried a valine residue at position 48 were 52% lower compared to nonsmoking monotherapy patients who were homozygous for the wild-type leucine allele (159). Together, these results confirm an important effect of genetic variation in phase 2 drug-metabolizing systems on the pharmacology of certain AEDs.

NAT2

The NAT2 gene encodes an N-acetyltransferase isozyme that functions to both activate and deactivate certain arylamine and hydrazine drugs. Variation in this gene is responsible for the N-acetylation polymorphism in which human populations segregate into rapid, intermediate, and slow acetylator phenotypes (191). N-acetylation is not recognized to play a major role in the metabolism of AEDs however there are some acetylation pathways involving metabolites of clonazepam and to a lesser extent phenytoin. One study on phenytoin reported that a poor metabolizer phenotype with increased drug half-life, decreased clearance and signs of toxicity were associated with the presence of the *5A (C481T) and *5C (A803G) variants (157). A study of patients treated with clonazepam showed that the presence of *5B and *6A variant alleles was associated with a 20-fold lower rate of 7-

aminoclonazepam acetylation in vitro (156). These studies confirm that variant NAT2 alleles can significantly impact AED pharmacokinetics and may have clinical relevance.

ADVERSE REACTIONS

Genetic influences on adverse reactions to certain AEDs have been suggested for a number of years (192), and now there is growing evidence for such effects in several realms. Whereas some common AED side effects and general toxicity are associated with genetic variation in metabolic or transport systems as described in preceding sections of this chapter, there are some reported variations that predispose or cause specific and often severe adverse drug reactions. In one study, a significant association was reported between the glutathione S-transferase M1 null allele and carbamazepine hepatotoxicity (193). Hepatotoxicity is potentially more problematic and severe during treatment with valproate and several studies have investigated genetic links with phenotypes reflecting liver injury or dysfunction such as elevation of transaminase levels. One study reported an association between valproate-induced hepatotoxicity and a nonsynonymous SNP predicting the variant V16A in superoxide dismutase type 2 (194). Another study discovered an even stronger association with the nonsynonymous Q1236H in POLG, the gene encoding the mitochondrial DNA polymerase γ (195). Mutations in POLG cause Alpers–Huttenlocher syndrome, a neurometabolic disorder associated with an increased risk of developing fatal valproate hepatotoxicity (196), which served as a clue to facilitate the discovery of the important influence of the common polymorphism Q1236H in other cases of severe valproate hepatotoxicity (195). Another valproate adverse phenotype examined, although in patients with bipolar disease, is a metabolic syndrome involving altered plasma leptin and lipid levels (197). This study analyzed a C825T variant of the gene GNB3, which was previously linked to metabolic abnormalities, and reported a strong association between T allele carriers and a lower risk for valproate-induced metabolic abnormalities (197). Several other genes are notable for their role in severe adverse drug reactions are methylenetetrahydrofolate reductase (MTHFR) and HLA-B, and these are discussed in the following sections.

MTHFR

One of the first potentially clinically significant discoveries involved a variant in the MTHFR gene, C677T, which was reported to be an independent predictor of hyperhomocysteinemia patients treated with phenytoin or carbamazepine (198). This study led to the conclusion that patients with a TT genotype have a higher folate requirement to maintain normal levels of homocysteine and folic acid. The results of subsequent studies were equivocal however (199–202), with the most recent study reporting no relationship between homocystinuria and polymorphisms in any genes associated with homocysteine metabolism (203). Thus, the relationship between genetic variation in the MTHFR gene and folate requirements remains unclear.

HLA-B*1502

AED-induced immune-mediated hypersensitivity reactions often involve dermatologic disorders ranging from mild rash to toxic epidermal necrolysis (TEN) and Stevens–Johnson syndrome (SJS), potentially fatal conditions characterized by severe skin lesions over the entire body (204,205). Drugs whose chemical structure involves an aromatic ring such as carbamazepine, phenytoin,

lamotrigine, and phenobarbital are most likely to cause exaggerated adverse reactions (206,207). Ability to reliably screen patients for hypersensitivity to AEDs prior to initiation of therapy would be a major therapeutic advance.

New insight into carbamazepine-induced SJS was gained 10 years ago with the discovery of its strong relationship to the HLA-B*1502 allele (208). The initial observation was extended in a larger population of patients and whereas the strength of the association between HLA-B*1502 and carbamazepine-induced TEN/SJS increased further, it was shown that this allele was not associated with other carbamazepine-induced cutaneous side effects such as maculopapular eruption or hypersensitivity syndrome (209). At the same time, it was discovered that Caucasian patients with carbamazepine-induced TEN/SJS do not harbor the HLA-B*1502 allele (210,211). This is consistent with the vanishingly low frequency of this allele in most parts of the world (212), and thus, the link between HLA-B*1502 and CBZ-induced SJS is viewed primarily as an issue in treating individuals having descended from certain regions of Asia where the allele is more common. Subsequently, it was demonstrated that the association between HLA-B*1502 and carbamazepine-induced SJS in some Asian populations could be extended to the drugs phenytoin and lamotrigine (213). Following this was a report of a significant association between HLA-B*1502 and phenytoin- and carbamazepine- induced SJS/TEN in a patient group from Thailand (214), the first positive result in a non-Chinese population, and another report showing that HLA-B*1502 was not associated with carbamazepine-induced SJS/TEN in patients of Japanese ancestry (215). Based on the positive reports, the U.S. Food and Drug Administration added a warning to the label of carbamazepine that recommends screening for HLA-B*1502 in patients of certain Asian ancestry prior to initiating treatment with carbamazepine (216). However, carbamazepine-induced SJS/TEN was subsequently linked to HLA-B*1502 in additional patient populations such as one from India (217).

Aside from HLA-B*1502, there is evidence for other HLA alleles to be associated with AED-induced SJS/TEN in non-Chinese patient populations. For example, HLA-B*5901(218) and HLA-B*1511 (219) as well as HLA-A31, HLA-A11, and HLA-B51 (220) are candidate markers for susceptibility to carbamazepine-induced SJS and other adverse cutaneous reactions involving carbamazepine in Japanese patients. In addition, a study in patients of Northern European ancestry revealed that the presence of the HLA-A*3101 allele was associated with a fivefold increase in the risk for carbamazepine-induced hypersensitivity reactions, including SJS and maculopapular eruption (221). Korean patients appear to be at risk from both HLA-B*1511 and HLA-B*3101, but not from HLA-B*1502 (222). Most recently, a systematic review and meta-analysis involving 20 studies determined HLA-A*3101 and HLA-B*1502 as risk markers and HLA-B*4001 as a protective marker for susceptibility to cutaneous adverse drug reactions when comparing intolerant with tolerant patients (223). Furthermore, stratification by clinical outcome showed HLA-B*1502 and HLA-B*1511 as risk markers and HLA-A*2402 as a protective marker for bullous lesions in the Asians, whereas HLA-A*3101 was observed to be a universal risk marker for all cutaneous adverse drug reactions and HLA-B*4001 observed to be a protective marker specifically in Chinese populations (223).

PHARMACODYNAMICS

There are numerous drugs currently approved to treat epilepsy, but there are substantially fewer proven mechanisms of AED action, and there is considerable overlap between mechanisms of available drugs (14). Table 49.4 lists many of the standard and novel AEDs and their primary

therapeutic target. Polymorphisms in the genes that encode these targets may impact the action and effects of AEDs. The most common mechanism of AED action involves inhibition of voltage-dependent sodium channels. SCN1A is the gene that encodes the major subunit of the primary neuronal voltage-dependent sodium channel, Na(V)1.1, and thus, considerable attention has been given to genetic variation in SCN1A with regard to polymorphisms that may affect the action and efficacy of AEDs as a general class. Pharmacogenetic studies of AED targets other than SCN1A and related sodium channel subunit genes have been relatively sparse.

Table 49.4 Primary Targets for Common Antiepilepsy Drugs[a]

Antiepilepsy drug	Primary therapeutic target
Acetazolamide	Carbonic anhydrase
Carbamazepine	Voltage-dependent sodium channel
Benzodiazepines	GABA-A receptor
Ethosuximide	T-type calcium channel
Felbamate	Voltage-dependent sodium channel, NMDA glutamate receptor
Gabapentin	α2δ subunit L-type calcium channel
Lamotrigine	Voltage-dependent sodium channel
Levetiracetam	SV2A synaptic vesicle protein
Phenytoin	Voltage-dependent sodium channel
Pregabalin	α2δ subunit L-type calcium channel
Retigabine	KCNQ potassium channel
Tiagabine	GABA transporter, glutamate receptor
Topiramate	Voltage-dependent sodium channel, AMPA/kainate glutamate receptor
Valproate	Voltage-dependent sodium channel; T-type calcium channel; GABA transaminase
Vigabatrin	GABA transaminase
Zonisamide	Voltage-dependent sodium channel

SCN1A

Detailed study of the SCN1A gene led to the discovery of an intronic polymorphism that disrupts the consensus sequence of the 5′ splice donor site of a highly conserved alternative exon (5N), affects the proportion of the alternative transcripts in individuals with a history of epilepsy, and was reported to be significantly associated with maximum doses in regular usage of both carbamazepine and phenytoin (145). This polymorphism is identified as IVS5-91 G>A (rs3812718); however, data on rs3812718 are sometimes described as a C/T SNP (alleles complemented to the “plus” DNA strand) such that the original publication reported that the T allele is associated with an increased

maintenance dose of phenytoin in epilepsy patients as compared to allele C and that the TT genotype is associated with increased dose of carbamazepine compared to CC genotype (145). The C/T polymorphism is located in the 5′ splice donor site of a highly conserved, alternatively spliced fetally expressed exon, and the major allele (T or A) disrupts the consensus sequence of the so-called 5N fetal exon, possibly reducing the expression of this exon relative to the so-called 5A adult exon (145). In a follow-up study, genotypes TT and CT were shown to be weakly associated with higher maintenance doses of both phenytoin and carbamazepine as compared to genotype CC; however, this relationship did not withstand correction for multiple statistical testing (224), suggesting the need for additional independent studies.

The IVS5-91 G>A variant has subsequently been studied in relation to AED effects by several other laboratories. Initial attempts at independent replication were conflicting, with a lack of association reported between IVS5-91G>A and carbamazepine maintenance doses in one study (225) and a significant association reported between the CC genotype and resistance to carbamazepine in another study (151). In a subsequent study, lack of association was reported between the C allele and response to carbamazepine or oxcarbazepine in patients treated for epilepsy (226). However, in a more recent study of patients who reached a stable maintenance dose of carbamazepine (dosage not changed for at least 1 year) under good compliance and good seizure control, the TT genotype was significantly associated with increased dose of carbamazepine and decreased concentration–dose ratio compared to CC and CT genotypes (84). A similar positive result was reported in a study of the relationship between this variant and phenytoin pharmacokinetics showing a significant association with concentration–dose ratios covaried by age, gender, and epilepsy type (85).

Other recent reports have also been confirmatory. In a study of carbamazepine tolerability assessed over 2 years by retention rates (the proportion of patients who continued to take carbamazepine over the preceding 3 months), CC and CT genotypes were associated with increased tolerability and increased therapeutic response compared to TT genotype (227). And in a companion study, patients with the CC and CT genotypes had a higher retention rate than those with the TT genotype, with the TT genotype also shown to be a significant predictor of nonretention defined as termination of carbamazepine monotherapy (due to drug allergy, CNS effects, or inadequate seizure control) before the end of the 12-month study period (228). On the other hand, a very recent, multicenter study reported that, after 1000 permutation testing for each marker or haplotype and Bonferroni correction, the T allele was not associated with response to carbamazepine or valproic acid, a result confirmed in a follow-up meta-analysis of over 1300 drug-resistant and 1100 drug-responsive epilepsy patients in which drug response was defined as complete seizure freedom for at least 1 year during monotherapy treatment, and drug resistance was defined as any seizure occurring within a 1-year period of treatment (229). A number of other negative reports have also recently been published between IVS5-91 G>A and resistance to carbamazepine (155,230). Thus overall, there are significant conflicts in the literature with regard to the influence of SCN1A IVS5-91G>A, and the clinical relevance of this variant remains to be established.

Functional evidence to support a role for IVS5-91 G>A in differential responsiveness to AEDs has also been reported. For example, Na(V)1.1-5N (i.e., fetal exon) channels exhibited enhanced tonic block and enhanced use-dependent block by both phenytoin and lamotrigine compared to Na(V)1.1-5A (i.e., adult exon) channels (231). Phenytoin and lamotrigine also induced shifts in steady-state inactivation and recovery from fast inactivation for both splice isoforms; however, no splice isoform differences were observed for channel inhibition by carbamazepine, suggesting that Na(V)1.1 channels containing exon 5N, which are decreased in proportion to 5A channels in

individuals carrying the major A (T) allele of IVS5-91 G>A (145), are more sensitive to the commonly used AEDs phenytoin and lamotrigine, but not to carbamazepine (231). On the other hand, functional evidence for an effect of IVS5-91 G>A on carbamazepine comes from a very recent in vivo study in humans in which the effects of the rs3812718 genotype were assessed on cortical excitability at baseline and after administration of carbamazepine (232). Paired-pulse transcranial magnetic stimulation was applied in 92 healthy volunteers with the homozygous genotypes AA (TT) or GG (CC) of rs3812718 at baseline and after administration of 400 mg of carbamazepine or placebo in a double-blind, randomized, crossover design with results showing that the GG (CC) genotype was associated with a higher carbamazepine-induced increase in the duration of the "cortical silent period" as compared to AA, reflecting a genetic influence on GABAergic inhibition by cortical interneurons (232) and suggesting that GG individuals are more sensitive to the effects of carbamazepine. These provocative findings create impetus to further examine the potential pharmacogenetic impact of IVS5-91 G>A on AED action and therapeutic effects.

In addition to IVS5-91 G>A in SCN1A, several other SCN1A variants have been studied in relation to AEDs including A3184G (rs2298771), which predicts an A1056T amino acid substitution. In an initial investigation, this SNP was shown to be without effect on a multidrug resistance phenotype (233); however, a follow-up revealed that the proportion of AA genotype carriers exhibiting seizure freedom was significantly higher than that of AG plus GG genotype carriers (227,228). A SNP in SCN1B has also been studied in regard to multidrug resistance and was reported to have an effect in a gene-by-gene interaction model involving variants in SCN2A (234).

SCN2A and SCN3A

Other sodium channel subunit genes whose variation has been investigated in relation to AEDs include SCN2A and SCN3A. One potentially relevant variant in SCN2A is rs17183814, a nonsynonymous SNP, G61478A, that predicts an R19K amino acid substitution. In one study, the A allele was associated with resistance to carbamazepine, phenobarbital, phenytoin, or valproic acid as compared to the G allele although the statistical significance did not withstand correction for multiple testing (233). Subsequently, a follow-up study by the same authors reported that the A allele was associated with lack of therapeutic response to carbamazepine, phenytoin, and valproic acid (82). A recent independent study that also included a meta-analysis was unable to confirm prior results (229), suggesting additional research is required on this variant. Another SCN2A variant that has been studied in relation to AEDs is the intronic SNP IVS7-32A>G or rs2304016. In a study examining therapeutic responses to AEDs, it was reported that the A allele is associated with lack of therapeutic response to carbamazepine, lamotrigine, oxcarbazepine, phenytoin, and topiramate compared to the G allele, a result that was confirmed in a haplotype analysis (235). The SNP is located within the putative splicing branch site for splicing exons 7 and 9; thus, PCR of reverse-transcribed RNA from blood or brain of patients with different IVS7-32A>G genotypes was performed using primers in exons 7 and 9, but results showed no skipping of exon 8, and real-time PCR showed no difference in SCN2A mRNA levels among genotypes (235) leaving the mechanism underlying the putative pharmacogenetic effect of this SCN2A variant in question.

GABA-Related AED Target Genes

GABRA1 is a gene that encodes a primary subunit of the GABA-A receptor, a direct or indirect

target of multiple AEDs, and 6136171A>G (rs2290732) is a polymorphism in the 3′-untranslated region that has potential pharmacogenetic relevance. In a 2-year study of genetic influences on carbamazepine tolerability in which the phenotype was measured as the proportion of patients who continued to take the drug for seizures over the previous 3 months, results showed patients with the AA plus AG genotypes had significantly greater retention rates than patients with the GG genotype (227,228), suggesting that AA and AG patients better tolerated carbamazepine and obtained greater therapeutic benefit. Another GABA-related target gene that has been studied is SLC6A11, which encodes GAT3, an astrocytic–neuronal GABA transport protein. Distribution of alleles and genotypes of a synonymous SNP, C1572T, C524C, were analyzed in multidrug resistance epilepsy patients, and a significant association was reported between the resistance phenotype and both the T allele and CT/TT genotypes, a result that was confirmed in a replication arm of the study (236), suggesting that SLC6A11 (GAT3) C1572T may be one of the contributing factors with an effect on AED pharmacoresistance.

Other AED Target Genes

Despite the critical relationship between glutamatergic neurotransmission and seizures, there are surprisingly few published AED pharmacogenetics studies on genes in pathways involving glutamate. In one accessible report, the G allele of a 5′ promoter SNP -2000G>T in the NMDA glutamate receptor subunit gene GRIN2B (rs1019385) was associated with lower valproate dosages, and the GG genotype was associated with lower valproate dosages and also a higher CD ratio (160). Other potential effects of genetic variation on glutamatergic synapses are unknown. Another neurotransmitter-related gene that has been studied in relation to AEDs is SLC6A4, the gene encoding the serotonin transporter protein 5-HTT with a single report showing that responsiveness to ACTH in pediatric patients being treated for infantile spasms was higher in patients homozygous for a common 44 base pair insertion polymorphism (237), although the relevance of this finding is not readily apparent given the relatively distant relationship between the action of ACTH and serotonin pathways in the brain. A study with better biologic plausibility examined the association between the effect of ACTH in patients with infantile spasms and variation in MCR2, the gene that encodes the melanocortin 2 receptor, and reported that a 4-SNP promoter haplotype with functional effects on receptor expression in vitro was associated with a good therapeutic response to ACTH (238). One additional study of note was designed based on the hypothesis that inflammatory processes play a role in epilepsy, and it examined variation in genes encoding molecules in the cytokine pathway. Thus, analysis of SNPs in IL-1β, TNF-α, and IL-6 showed that IL-6 G174C (rs1800795) was significantly associated with seizure frequency and drug refractory epilepsy (239) helping to reinforce the concept that genetic variability within the inflammasome may be relevant to epilepsy and to interindividual differences in the therapeutic effects of AEDs.

SUMMARY AND FUTURE PERSPECTIVE

The field of AED pharmacogenetics continues to advance knowledge regarding the gene variants and related mechanisms that contribute to differences between patients in both therapeutic and adverse effects of AEDs; however, the utility of this information in routine clinical practice remains limited. With regard to adverse effects, the discovery of the relationship between specific HLA alleles and rare severe adverse skin reactions caused by some AEDs is an area of high medical relevance and

stands as probably the most important achievement in AED pharmacogenetics to date. Thus, HLA-B*1502 has high predictive value and is considered a validated biomarker for carbamazepine-induced SJS (3). This allele should be screened for in individuals of Asian descent prior to instituting treatment with standard AEDs including carbamazepine, phenytoin, valproate, or lamotrigine. Continued work on HLA alleles in other populations will ultimately lead to discoveries of similarly high impact and, in the long term, better understanding of the mechanism underlying these hypersensitivity reactions will help in the design of safer medications.

The other area of major clinical relevance for AED pharmacogenetics is polymorphic drug metabolism. There are numerous polymorphisms in gene families for both phase 1 and phase 2 biotransformation enzymes that have functional effects, and there is strong evidence that several of these have a measurable influence on pharmacokinetics of specific AEDs. In some cases, this information has been translated into dosing guidelines (145); however, these are not firmly established. CYP2C9 and CYP2C19 encode polymorphic cytochrome P450 oxidase isoforms that are well documented to metabolize several conventional AEDs and low-activity variants (i.e., "poor metabolizers"), while exhibiting significant ethnic differences in frequency, are not uncommon. Nonetheless, the relatively modest overall effect of these variants likely contributes to the fact that alleles of this polymorphic enzyme system are not regarded as validated biomarkers for the effects of AEDs (3).

Whereas the metabolic enzymes for many AEDs have been established, the role of ABC transporter proteins is less clear. Thus, not only are the reported effects of genetic variation in the genes ABCB1 and ABCC2 highly tentative, role of ABC transporters themselves in the absorption, distribution, and elimination of AEDs remains to be fully elucidated. For this reason and others, variant alleles of genes encoding ABC transporter proteins are not considered to be validated biomarkers for AED treatment (3). New approaches using human brain imaging promise to allow greater insight into the role of P-glycoprotein transport of AEDs and may lead to discoveries that could eventually inform routine treatment decisions.

Whereas pharmacokinetic aspects of AED therapy have shown a number of promising genetic leads with regards to refinement of treatment protocols, only the SCN1A gene has shown the potential to provide similarly useful information from a pharmacodynamic perspective. However, even in the case of SCN1A, the validity of the intronic polymorphism IVS5-91G>A as a biomarker for treatment response remains to be established. Recent functional evidence for an effect of this variant in human brain as determined by imaging will fortify resolve to further study this variant and document, or disprove, its clinical relevance. Currently, there are no other major AED targets known whose genetic variability has a significant impact on treatment regimens.

Overall, while there is clear evidence that genetic variation can have a significant influence on the effects of AEDs, the perceived value and use of genetic testing in routine therapy is currently limited; however, this is not different than the situation for many other therapeutic classes of drugs. Drug response is a complex trait determined by many diverse factors in the genome (and the environment), and although each is likely to have only a minor effect individually, they have a cumulative impact and contribute to interpatient variability, offering insight into ways to refine therapy. Considering the extent to which therapeutic responses are determined by plasma levels, a rational approach seems to develop algorithms based on combinations of variants that can predict AED CD ratios and other pharmacokinetic parameters. In one study, integrated analysis of polymorphisms in several candidate genes using logistic regression revealed that variants in CYP2C9 and ABCB1 explained 15% of the variability in phenytoin plasma levels in a group of healthy

individuals and also had predictive value in a clinical practice setting involving epilepsy patients (240). Building additional validated genetic influences into such regression models and using other newer methods of statistical analysis will permit better clinical control of critical factors that can be modulated to optimize treatment plans for every patient individually. This is the ultimate goal of pharmacogenetics, but one that still remains at a considerable distance.

CHAPTER 50 BENZODIAZEPINES

L. JOHN GREENFIELD, JR., KINSHUK SAHAYA, BASHIR SHIHABUDDIN, ELIZABETH I. TIETZ, AND HOWARD C. ROSENBERG

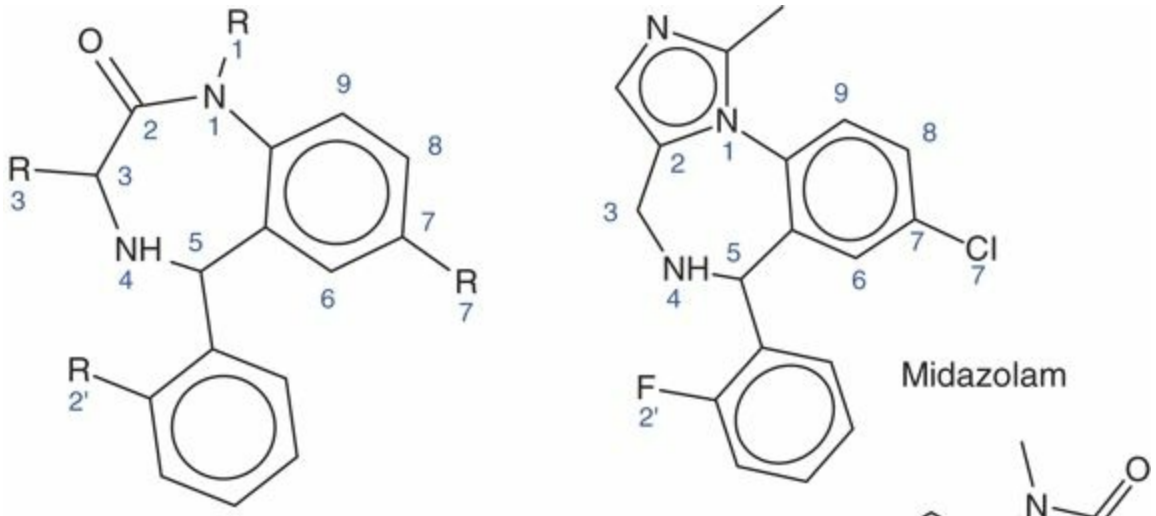
INTRODUCTION

Benzodiazepines (BZs) were developed in the 1950s from a class of heterocyclic compounds known since 1933 (1,2). Chlordiazepoxide was introduced as an anxiolytic agent in 1960, followed by diazepam (3) and nitrazepam (4). The BZs soon became the most widely prescribed drugs in the United States. Gastaut et al. (5) first used diazepam to treat status epilepticus in humans in 1965. Clonazepam was introduced in the 1970s primarily as an antiseizure drug (ASD) (6), and clobazam, a 1,5-BZ, was later developed as an ASD with reduced sedative effects (7). However, only a few BZs have been approved for acute or chronic use as ASDs in the United States.

The site of action of the BZs was clarified by the discovery of high-affinity, saturable BZ binding to a central nervous system (CNS) receptor (8,9). The BZs were also shown to enhance inhibitory neurotransmission mediated by γ-aminobutyric acid (GABA), the major inhibitory neurotransmitter of the mammalian brain (10). Subsequent studies confirmed that the brain BZ receptor was in fact a binding site on the $GABA_A$ receptor, where the BZs act as positive allosteric modulators (11).

CHEMISTRY AND MECHANISM OF ACTION

The BZ structure is based on a benzene ring fused to a seven- member ring containing two nitrogens, usually in the 1 and 4 positions (1,4 BZs), commonly with an aryl group attached at the 5 position (Fig. 50.1). An exception to this pattern is clobazam, a 1,5-BZ with antiepileptic properties and fewer sedative effects (7,12). Some agents (e.g., midazolam and flumazenil) have fused R1 and R2 substituents, creating further ring complexity.



Drug	R1	R3	R7	R2'
Diazepam	CH_3	H_2	Cl	H
Lorazepam	H	H, OH	Cl	Cl
Clonazepam	H	H_2	NO_2	Cl
Nitrazepam	H	H_2	NO_2	H
Clorazepate	H	COOH	Cl	H

Figure 50.1. Structure of the 1,4-benzodiazepines. Substituents at the named sites are given in the table for diazepam, lorazepam, clonazepam, nitrazepam, and clorazepate. Midazolam with its fused R1 ring is shown separately. Clobazam is a 1,5 benzodiazepine.

BZ potency correlates with binding affinity at the BZ site on neuronal $GABA_A$ receptors (Table 50.1) (14,15). An electron-withdrawing group at the 7 position increases receptor-binding affinity (Table 16) and potency, and all useful anticonvulsant BZs have this feature. A methyl group on the position-1 nitrogen (as in diazepam and clobazam) increases binding affinity and potency, as does a halogen at the 2′ position on the aryl group. A hydroxyl group at position 3 (as in lorazepam) decreases potency and binding affinity.

Table 50.1 Antiseizure Activity, Motor Impairment, and Receptor Binding of Some BZs

BZ	ED_{50} to suppress clonus in kindled rats, mg/kg[a]	ED_{50} for ataxia, mg/kg[a]	IC_{50} to inhibit [^{3}H] flunitrazepam-specific binding, nM[b]
Clobazam	2.8	13.2	870
Diazepam	0.4	1.5	78
Clonazepam	0.09	0.9	16
7-amino-clonazepam	>40	—	195

[a]Dose required to inhibit forelimb clonus or to cause ataxia in 50% of amygdala-kindled rats (data from Tietz EI, Rosenberg HC, Chiu TH. A comparison of the anticonvulsant effects of 1,4- and 1,5-benzodiazepines in the amygdala-kindled rat and their effects on motor function. Epilepsy Res. 1989;3:31–40.; (13), except 7-amino-clonazepam data (HC Rosenberg, EI Tietz, and TH Chiu; unpublished data, 1987).

[b]Concentration required to displace 50% of 2 nM [^{3}H]flunitrazepam specifically bound to rat cerebral cortical membranes (EI Tietz, TH Chiu, and HC Rosenberg; unpublished data, 1990).

BZ activity at the $GABA_A$ receptor is a function of the drug's affinity for the BZ binding site and

its intrinsic allosteric effect on the $GABA_A$ receptor. The efficacy of individual compounds varies widely. Most BZ ASDs are full agonists that maximally enhance $GABA_A$ receptor activity. Competitive antagonists bind to the BZ site but do not affect $GABA_A$ receptor function. The BZ antagonist, flumazenil, is used to reverse sedation induced by BZs in anesthesia (17,18) and to treat BZ overdose (19). Several "partial agonists" at the BZ binding site have been characterized, including abecarnil (20), imidazenil (21), and bretazenil (22). Although less effective than full agonists like diazepam, these drugs have demonstrated anticonvulsant efficacy in animal models and appear less prone to the development of tolerance (23,24). Still other compounds, notably the beta-carbolines, behave as "inverse agonists" at the BZ site and inhibit GABA binding or GABA-evoked currents (25). These agents can induce convulsive seizures or anxiety (25,26) and have no clinical utility.

Anticonvulsant Activity

BZs are effective against most experimental seizure types, but there are large differences between individual drugs in their potency, efficacy, and other clinical effects (27). BZs are particularly effective against seizures induced by pentylenetetrazol (28) but are less effective against tonic seizures in the maximal electroshock model (29). BZs also slow the development of kindling (30). The dose ratio between clinical efficacy and adverse effects varies between specific agents. For example, the diazepam dose for blocking pentylenetetrazol seizures is 1% of that necessary to abolish the righting response; for clonazepam, the ratio is <0.02%, suggesting a wider therapeutic window.

BZ Actions at the $GABA_A$ Receptor

In 1977, a high-affinity, saturable binding site for BZs was discovered on CNS neuronal membranes (8,9,14). BZ receptor binding was "coupled" to GABA binding (31), which led to the idea of a "$GABA_A$ receptor complex" incorporating binding sites for GABA, the BZs, and barbiturates and a ligand-gated chloride channel. Later, it became clear that BZs and GABA bind to sites on a single pentameric channel. Electrophysiologic studies demonstrated that BZs increased the amplitude of GABA-mediated inhibitory postsynaptic potentials (IPSPs) (10) by increasing the opening frequency of the GABA-gated chloride channel (32); this was later confirmed with single-channel studies (33).

In whole-cell patch clamp recordings of isolated CNS neurons, BZs alone produce no $GABA_A$ receptor current. Increasing BZ concentrations enhance GABA currents evoked by a low GABA concentration (Fig. 50.2A, C). This enhancement results from an effect of BZs to increase the affinity of GABA at the GABA binding site, which produces a leftward shift of the concentration–response curve for GABA (34) (Fig. 50.2B). There is no change in the kinetics of channel gating (33). The BZs increase the current produced by low GABA concentrations but not by high (millimolar) synaptic concentrations at which receptor binding is saturated (35). Thus, BZs do not usually increase the amplitude of miniature inhibitory postsynaptic currents (mIPSCs) from individual synapses. So, how do they increase GABA currents? By increasing the binding affinity of GABA for the receptor (see Fig. 50.2B), BZs slow the dissociation of GABA from the receptor, which prolongs the mIPSC decay phase (36,37). Prolongation of the mIPSC increases the likelihood of temporal and spatial summation of multiple synaptic inputs, which in turn increases the amplitude of stimulus-evoked polysynaptic IPSCs (Fig. 50.2D). The BZs thus increase the inhibitory "tone" of GABA-ergic synapses, which

reduces the hypersynchronous firing of neuron populations that underlies seizures (38).

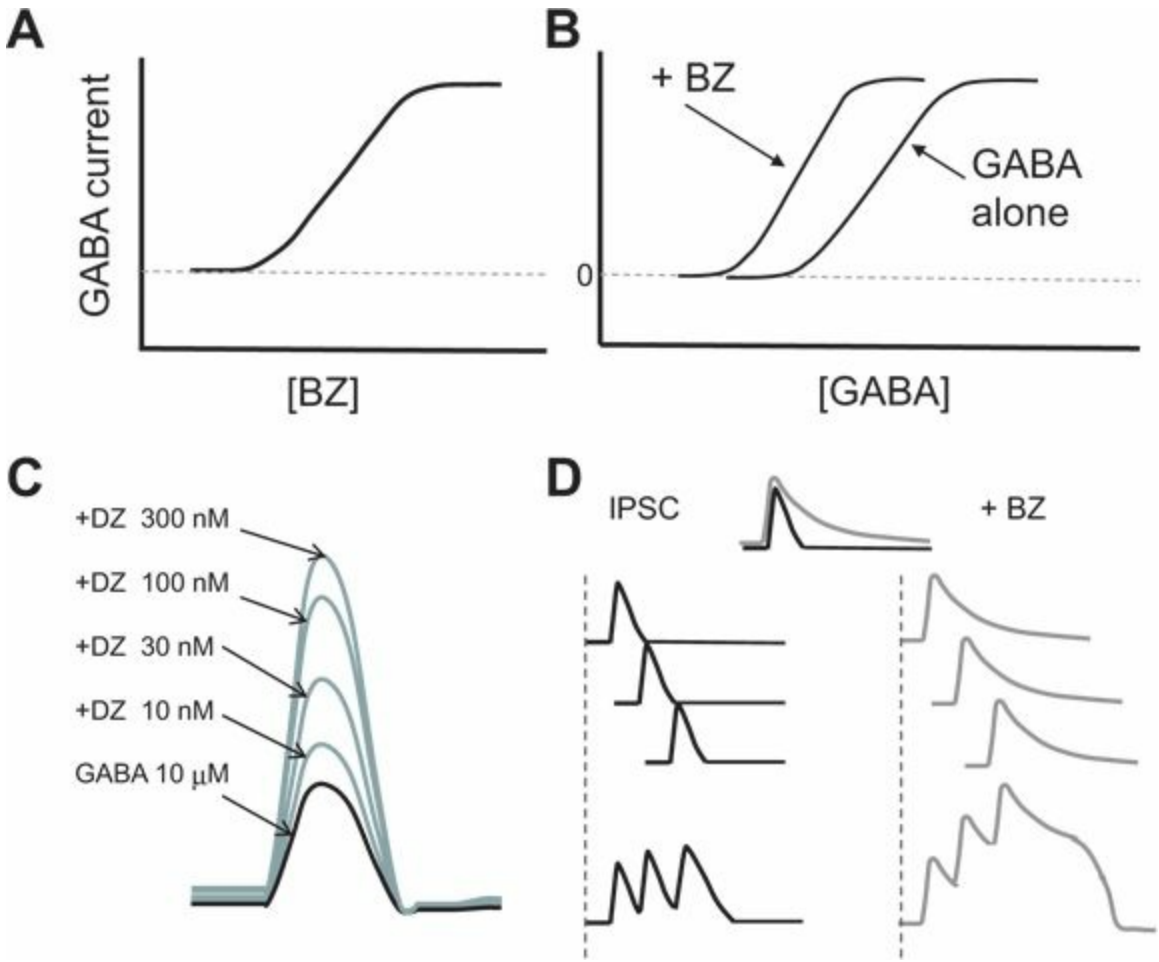


Figure 50.2. Effects of BZs on $GABA_A$ receptor currents. **A:** Increasing BZ concentration with a single low concentration of GABA evokes progressively larger currents, as shown in **(C)** for increasing diazepam (DZ) concentrations (mock data). **B:** Addition of a single BZ concentration to increasing GABA concentrations shifts the concentration–response curve for GABA to the left, indicating increased affinity for GABA at the receptor but no increase in maximal current. The BZs have no effect in the absence of GABA. **D:** The increased GABA affinity prolongs the IPSC decay phase (gray), resulting in increased temporal and spatial summation to produce larger polysynaptic currents (mock data).

Molecular Biology of $GABA_A$ Receptors

$GABA_A$ receptors are pharmacologically complex, with binding sites for BZs; barbiturates; neurosteroids; general anesthetics; the novel anticonvulsant, loreclezole; and the convulsant toxins, picrotoxin and bicuculline. Protein subunits from seven different subunit families (39) assemble to form pentameric (40) transmembrane chloride channels (Fig. 50.3). In mammals, 16 subunit subtypes have been cloned, including 6 α, 3 β, and 3 γ subtypes, as well as δ, π , ε, and θ, and there are alternatively spliced variants of the β2 and γ2 subtypes (39). Though thousands of subunit compositions are possible, expression is regulated by region and cell type (41) and also developmentally controlled (42), reducing the number of possible isoforms in specific brain regions and individual neurons. The most common $GABA_A$ receptor has a presumed stoichiometry of two α1, two β2, and a single γ2 subunit; the δ subunit may in some cases substitute for γ, particularly when receptors are expressed extrasynaptically. The subunits are arranged around a central water-filled pore, which opens to conduct Cl^- ions when GABA is bound (see Fig. 50.3). Studies of recombinant receptors have shown that individual subunit subtypes confer different sensitivities to $GABA_A$

receptor modulators, including BZs (43), loreclezole (44), and zinc ions (45).

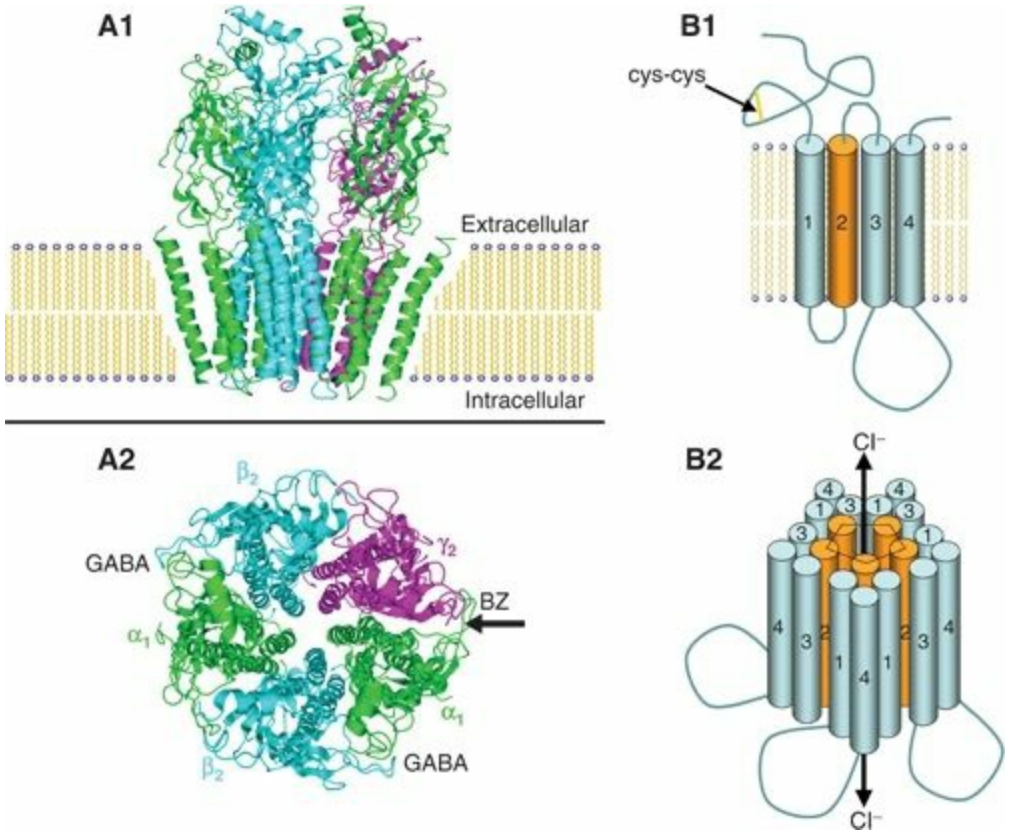

Figure 50.3. Model of a $GABA_A$ receptor in the plasma membrane. **A:** A space-filling model of the pentamer in side view (**A1**) and top view (**A2**) based on the high sequence homology with the nicotinic acetylcholine receptor. There are with two binding sites for GABA, between α and β subunits, and one for BZs, between the alpha and gamma subunits (arrow). **B:** A schematic view shows the topology of each subunit with a large extracellular loop containing a cysteine loop (**B1**) and four transmembrane domains from which the second forms the lining of the chloride ion channel. Binding of GABA allows the channel to open and conduct Cl^- ions **(B2)**, resulting in the fast inhibitory postsynaptic potential (IPSP)

$GABA_A$ Receptor Subunits and BZ Pharmacology

BZ augmentation of $GABA_A$ receptor currents requires a γ subunit, and the selectivity of BZ responsiveness is determined by which α subunits are present (46). The BZ binding site is located in a cleft between the extracellular amino termini of these two subunits. The α1 subunit results in a receptor with high affinity for the hypnotic, zolpidem, defining the "BZ-1" (or Ω1) receptor type (47). The α2 and α3 subunits result in receptors with moderate zolpidem affinity, termed BZ-2 receptors. $GABA_A$ receptors with the α5 subunit and/or the γ3 subunit are sensitive to diazepam, but far less so to zolpidem, and are termed BZ-3 receptors. $GABA_A$ receptors with the α4 or α6 subunits are insensitive to most BZs (46).

The $GABA_A$ receptor subunit composition determines not only the affinity for particular BZs but also the clinical/behavioral effects of the BZ at that specific receptor subtype. The role of the α subunits in BZ pharmacology was revealed by the discovery of a single histidine (H) residue found in all BZ-sensitive α subunits (H101 in the rat α1 subunit) but not in the BZ-insensitive α4 or α6 subunits, which instead have a charged arginine (R) residue. This H residue was discovered in a strain of "alcohol-nontolerant" rats, which were found to have a spontaneous point mutation in the α6 subunit (R100Q) that made their α6-containing $GABA_A$Rs (found mostly in the cerebellum) diazepam

sensitive. Since alcohol appears to enhance $GABA_AR$ function via the BZ site (39), the abnormally BZ-responsive receptors in the cerebellum resulted in ataxia and intolerance to these agents (48). Mutation of R100 to H in α6 dramatically increased BZ binding in this normally insensitive subunit, while mutation of H101 to R in α1 reduced BZ sensitivity (49). BZ-insensitive α subunit mutations were subsequently "knocked in" to identify BZ actions at receptors containing that subunit. In homozygous α1(H101R) knock-in mice, the anxiolytic effect was intact, but BZs were not protective against pentylenetetrazol-induced convulsions and did not produce sedation or amnesia, suggesting that binding to the (wild type) α1 subunit is responsible for sedative, amnestic, and antiseizure actions (50). Moreover, the α1-selective sedative–hypnotic, zolpidem, showed no sedative effect in α1(H101R) mice (51). Unfortunately, these findings underscore the association between sedation and antiseizure efficacy at α1-containing $GABA_ARs$. Similarly, the anxiolytic (52) and myorelaxant (53) properties of BZs appear to derive from α2- and α3-containing $GABA_ARs$, while the α5 subunit was critical for amnestic effects (54). BZs may also have a true analgesic effect independent of their sedative and anxiolytic actions, associated with the α2 and α3 more than α5 subunits (55). Since there is no evidence of biophysically distinct effects of BZs on receptors composed of different α subunits, the different behavioral effects are likely due to the brain regions and neuronal populations expressing specific $GABA_AR$ isoforms. New α2/α3 subunit–selective BZs appear to have anxiolytic activity without causing sedation (56). Development of nonsedating antiseizure BZs that do not induce tolerance (57) may also be possible.

$GABA_A$ Receptors and Epilepsy

The anticonvulsant properties of BZs are likely related to the prominent role of $GABA_A$ receptors in epilepsy. The evidence linking epilepsy with dysfunction of GABA-ergic inhibition is substantial (38). $GABA_A$ receptors are the target not only of the BZs but of other ASDs including the barbiturates and, indirectly, of two agents that increase GABA concentration at the synapse, tiagabine and vigabatrin (38). Several animal models of epilepsy have demonstrated altered $GABA_A$ receptor number or function (38,58). Moreover, genetic or acquired changes in the composition or structure of the transmembrane protein subunits that make up $GABA_A$ receptors can result in epilepsy. $GABA_A$ receptor subunit expression is altered in the hippocampi of experimental animals with recurrent seizures (59) and in patients with temporal lobe epilepsy (60,61). Reduced expression of the $GABA_AR$ γ2 subunit in rats using an antisense oligonucleotide to block translation of endogenous γ2 mRNA led to spontaneous electrographic seizures that evolved into limbic status epilepticus (62). In humans, Angelman syndrome, a neurodevelopmental disorder associated with severe mental retardation and epilepsy, is linked to a deletion mutation on chromosome 15q11-13 (63) in a region encoding the $GABA_A$ receptor β3 subunit (64). In addition, two mutations in the γ2 subunit that impair $GABA_A$ receptor function (65), K289M (66) and R43Q (67), have been linked to a human syndrome of childhood absence epilepsy and febrile seizures, and a loss-of-function mutation in the α1 subunit was found in a family with autosomal dominant juvenile myoclonic epilepsy (68). The R43Q mutation in the γ2 subunit reduces BZ sensitivity (69) by altering $GABA_A$ receptor assembly (70) and trapping the receptor in the endoplasmic reticulum (71). The relative positions of these and several other epilepsy-causing mutations are shown schematically on a "generic" $GABA_A$ receptor subunit in Fig. 50.4, along with the sites of action for several $GABA_A$ receptor subunit–associated

ASDs (72).

Other BZ Actions

With a few caveats (26), the BZs derive their anticonvulsant properties from their specific interaction with $GABA_A$ receptors. At doses used to treat status epilepticus, BZs can also inhibit voltage-gated sodium (73) and calcium channels (74) and can increase GABA levels in cerebrospinal fluid (75). However, it should be noted that the BZs have no interaction with the G protein–linked $GABA_B$ receptor, which can either suppress voltage-gated Ca^{2+} channels or activate inward rectifying K^+ channels (76).

The BZs also bind to the "peripheral BZ receptor" (PBR) (77), an 18-kDa protein in the outer mitochondrial membrane that functions as part of the mitochondrial permeability transition pore involved in cholesterol transport (77), apoptosis, and regulation of mitochondrial function (78). Although the PBR is widely expressed throughout the body, its expression in the CNS is restricted to ependymal cells and glia (79); hence, it is unlikely that the PBR is involved in the antiseizure properties of the BZs, though it may explain the neuroprotective properties of some BZs (80,81).

Excitatory $GABA_A$ Currents

BZ enhancement of $GABA_A$ receptor function may not always be anticonvulsant or even inhibitory. Early in CNS development, neurons express the $Na^+/K^+/Cl^-$ cotransporter, NKCC1, rather than the K^+/Cl^- cotransporter, KCC2, which is expressed in adult neurons. NKCC1 increases intracellular Cl^- resulting in a depolarizing Cl^- reversal potential, while KCC2 exports Cl^- yielding the hyperpolarizing Cl^- reversal potential found in adult neurons (82). As a result, activation of $GABA_A$ receptor channels can be excitatory during early development (83) and play a trophic role in neuronal migration and connectivity (84,85), but this may also contribute to epileptogenesis (86). In fact, endogenous GABA appears to be proconvulsant in early postnatal rat hippocampal slices, as $GABA_A$ antagonists blocked epileptiform activity induced by depolarization with high external $[K^+]$ (87). However, BZ anticonvulsant efficacy appears to be intact, likely because persistent opening of GABA channels (in the presence of BZs) may reduce the depolarizing chloride reversal potential, resulting in "shunt" inhibition, or alternatively, subthreshold GABA-evoked depolarization may inactivate sodium channels and prevent action potential firing (88). The current through $GABA_A$ receptor channels can also be altered by changes in intracellular bicarbonate, $[HCO_3^-]$ (82), which, like Cl^-, can flow through the channel (89). Changes in $[HCO_3^-]$ may underlie reduced synaptic GABA currents during development of BZ tolerance (90). Depolarizing $GABA_A$ currents may also be a source of interictal spike activity, as observed in epileptic subiculum neurons in brain slices of hippocampi removed from patients with temporal lobe epilepsy (91). Changes in the GABA current reversal potential might also explain why diazepam may be less effective in children with epileptic encephalopathies (92) and rarely can cause status epilepticus in patients with the Lennox–Gastaut syndrome (93).

ABSORPTION, DISTRIBUTION, AND

METABOLISM

The major anticonvulsant role of the BZs is in the treatment of status epilepticus (SE) and seizure clusters, for which they represent first-line therapy, preferably administered intravenously (IV) (94). In very young children, this may be difficult or impossible, necessitating administration via rectal (95–100), intraosseous (101), buccal (102,103), or nasal (104–106) routes. With IV administration, the main factor in a drug's effectiveness for SE is the rate at which it crosses the blood–brain barrier (BBB). The BZs are highly lipophilic and cross the BBB rapidly (107), though this varies more than 50-fold between agents (108) and is fastest for the most lipophilic agents, such as diazepam. Protein binding also correlates with lipophilicity and is high for most BZs, up to nearly 99% for diazepam. The BZs are fully absorbed after oral ingestion.

Despite generally long plasma half-lives, most BZs are relatively "short-acting" after administration of a single dose due to a similarly rapid distribution from the brain and vascular compartments to peripheral tissues (109,110). BZ pharmacokinetics are best fit by a two-compartment model: high levels occur rapidly in the brain and other well-perfused organs and then decline rapidly with an initial brief half-life due to distribution into peripheral tissues and lipid stores, followed by a much slower elimination half-life related to enzymatic metabolism and excretion. For example, the elimination half-life of diazepam ranges from 20 to 54 hours (111), but the duration of action after a single IV injection is only 1 hour, with peak brain concentrations present for only 20 to 30 minutes (112).

The BZs are metabolized in the liver by cytochrome P450 enzymes, particularly CYP3A4 and CYP2C19, with relatively little enzyme induction. The presence of biologically active metabolites (e.g., nordazepam, a metabolite of diazepam) can significantly prolong the biologic half-lives of some BZs. Elimination may be prolonged by enterohepatic circulation, particularly in the elderly. Most BZs cross the placenta and are secreted into breast milk. A schematic of BZ metabolic pathways is shown in Figure 50.5. The biotransformation and pharmacokinetics of the BZs have been extensively reviewed (115–117) and will be presented in more detail for the individual agents below.

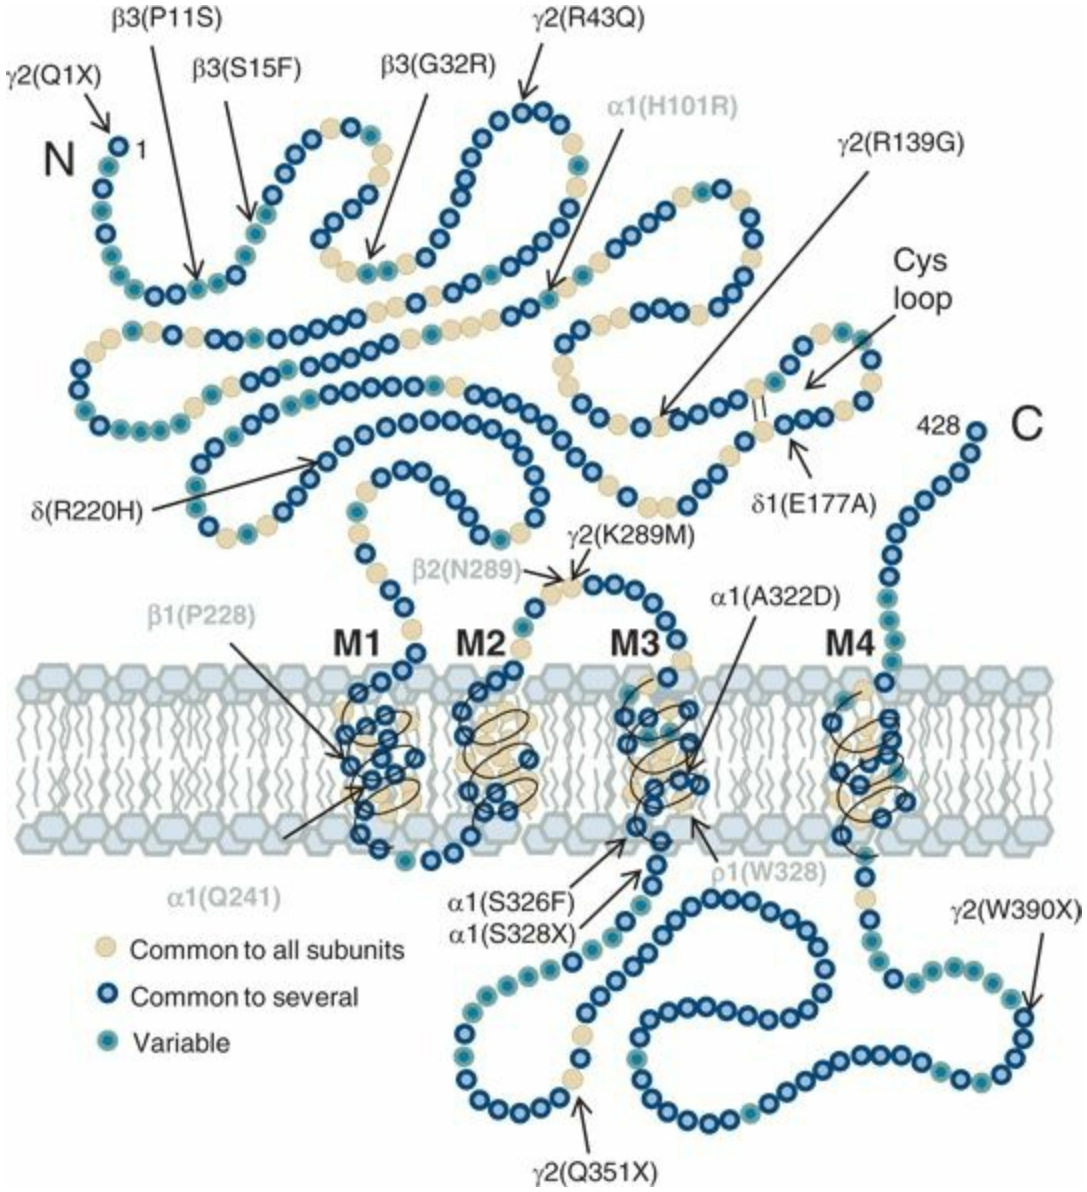

Figure 50.4. Model of a prototype $GABA_AR$ subunit (based on α1 subunit diagram from Olsen RW, Tobin AJ. Molecular biology of GABAA receptors. FASEB J. 1990;4:1469–1480.) showing approximate locations of point mutations associated with generalized epilepsies (see also Macdonald RL, Kang JQ, Gallagher MJ. GABAA receptor subunit mutations and genetic epilepsies. In: Noebels JL, Avoli MB, Rogawski MA, Olsen RW, Delgado-Escueta AV, editors. Jasper's Basic Mechanisms of the Epilepsies [Internet]. 4th edition. Bethesda (MD): 2012) in black and point mutations associated with ASD sites of action (see text for details).

DRUG INTERACTIONS

BZs interact with other drugs more prominently through pharmacodynamic than pharmacokinetic mechanisms. They do not significantly affect plasma protein binding or metabolism of other drugs. CNS depression is increased when BZs are given in conjunction with other CNS-depressant drugs (118). Pharmacokinetic interactions with other anticonvulsants are infrequent and inconsistent, with the exception of phenobarbital. Diazepam enhances phenobarbital elimination (119), and phenobarbital increases clearance (120) and lowers plasma levels of clonazepam (121). Clobazam increases the 10,11-epoxide metabolite of carbamazepine (122). Valproate reduces diazepam protein binding, increasing free drug levels (123), and enhances diazepam's CNS effects (119). Other ASDs may augment metabolism and clearance of N-desmethyldiazepam derived from clorazepate (124). Inhibitors of CYP3A4, including erythromycin, clarithromycin, ritonavir, itraconazole, ketoconazole, nefazodone, and grapefruit juice, can slow BZ metabolism (125). Cimetidine decreases the clearance

of diazepam (126,127) and nitrazepam (128). Rifampin increases the clearance and shortens the half-life of nitrazepam (129). Lorazepam half-life is markedly increased by probenecid (130).

ANTISEIZURE EFFICACY

Status Epilepticus

Status epilepticus is associated with significant morbidity and mortality (131,132) and requires emergent medical treatment to avoid neuronal damage and its neurologic consequences (133,134). The BZs have become agents of choice for initial therapy due to their rapid onset, proven efficacy (135), and lower risk of cardiotoxicity or respiratory depression compared to the barbiturates (136). The role of BZs in status epilepticus has been confirmed in several well-controlled clinical trials, including the multicenter, double-blind VA Cooperative Status Epilepticus Trial (137).

Lorazepam and diazepam were compared for treatment of status epilepticus in a double-blind study of 78 adults with epilepsy (135). Intravenous lorazepam (4 mg) stopped status epilepticus in 78% of patients and diazepam (10 mg) in 58% after the first injection; both had similar efficacy (89% and 76%, respectively) after the second injection. An open-label, prospective, randomized trial compared lorazepam (0.05 to 0.1 mg/kg) and diazepam (0.3 to 0.4 mg/kg) in children with acute convulsions, including convulsive status epilepticus (138). Lorazepam was more effective ($P < 0.01$) after the first dose and apparently safer than diazepam. A meta-analysis of 11 randomized controlled trials with 2017 participants found that lorazepam was better than either diazepam or phenytoin alone for reducing risk of seizure continuation (139). A population-based study of 182 children with convulsive status epilepticus showed that IV lorazepam was 3.7 times more likely than rectal diazepam to terminate seizures (140). Lorazepam's superiority may be due to its longer duration of action, based on a longer distribution half-life (see Lorazepam: Pharmacokinetics).

Lorazepam has largely replaced diazepam as the agent of choice for prehospital treatment of status epilepticus. A prehospital trial of lorazepam and diazepam found that status epilepticus had terminated by arrival at the emergency department in 59.1% of patients treated with lorazepam (2 mg), compared to 42.6% of patients treated with diazepam (5 mg) and 21.1% of patients given placebo (141). Rates of circulatory or ventilatory complications for lorazepam and diazepam were similar (10.6% and 10.3%, respectively) and lower than that of placebo (22.5%), confirming the safety of BZ treatment in this setting. However, patients treated with >30% more than the standard therapeutic BZ doses were more likely to require intubation for airway protection and had significantly longer hospitalizations (2 weeks vs. 1 week) (142).

Early treatment of status epilepticus increases the probability of seizure termination (141), likely because prolonged seizures lower $GABA_A$ receptor sensitivity to BZs (143). Reduction in $GABA_A$ receptor BZ sensitivity can occur within minutes in status epilepticus (144,145) and may be responsible in part for both the persistent epileptic state and its refractoriness to treatment. Refractoriness to BZs may be mediated by N-methyl-D-aspartate (NMDA) receptor mechanisms, as NMDA antagonists improve the response to diazepam in late pilocarpine-induced status epilepticus (146). These findings suggest a possible strategy for treatment of late, BZ-refractory status epilepticus with combinations of a BZ and an NMDA receptor antagonist such as the dissociative general anesthetic, ketamine. Efficacy of combined diazepam and ketamine has been demonstrated in a rat model of status epilepticus (147). A recent nonrandomized trial of oral ketamine for refractory

nonconvulsive status epilepticus in children showed efficacy in five of five cases (148). Treatment protocols involving NMDA antagonists have been suggested (149,150), but such approaches will require validation in controlled clinical trials.

Both lorazepam and diazepam have been approved by the U.S. Food and Drug Administration (USFDA) for treatment of status epilepticus in adults; diazepam has also been approved in children older than 30 days. Parenteral preparations of other BZs, including midazolam, flunitrazepam, and clonazepam, expand the possibilities for BZ treatment of status epilepticus. However, parenteral clonazepam is currently available only in Germany and the UK, and flunitrazepam is not available in the USA. Alternative routes of administration, including intramuscular (IM) injection and intranasal (104,105), buccal (102), endotracheal (151,152), or rectal (100,153,154) instillation, also rapidly produce therapeutic levels and have demonstrated efficacy against status epilepticus or seizure clusters.

Acute Repetitive Seizures

The availability of alternative methods of BZ administration increases the therapeutic options for treatment of acute repetitive seizures. Individual agents can be selected for specific clinical situations. For example, repeated seizures in a patient rapidly tapered off anticonvulsants for inpatient epilepsy monitoring could be treated with diazepam (rather than lorazepam) since its shorter peak duration of action may be less likely to suppress seizure activity needed later for localization of seizure onset. In the case of serial seizures, the need for high drug levels immediately is less urgent, and the ease of administration by family or allied health workers becomes important. Diazepam rectal gel is effective in preventing subsequent seizures during seizure clusters (153–155) and can reduce the frequency of emergency department visits (96). Buccal (156,157) and intranasal (158) routes may be equally effective and more acceptable (159). Table 50.2 compares the clinical and pharmacologic properties of the BZs used for acute seizures.

Table 50.2 Clinical Pharmacology of BZs Used for Acute Seizures

	Diazepam		Lorazepam		Midazolam		Clonazepam

Chronic Treatment of Epilepsy

Although the use of BZs in chronic treatment of epilepsy is limited by sedation and the development of tolerance, BZs may have specific therapeutic indications, such as adjunctive treatment of myoclonic and other generalized seizure types or in conjunction with comorbid anxiety disorders. For example, lorazepam improved control of seizures associated with psychological stressors (160). Intermittent use of BZs when seizure thresholds are transiently reduced may be the ideal strategy for these ASDs. Not only are they suited pharmacokinetically for such applications, but short-term use may avoid the development of tolerance. For example, catamenial seizures improved with intermittent administration of clobazam (161). ASD efficacy for specific indications will be discussed with the individual agents below.

TOLERANCE AND DEPENDENCE

BZ Tolerance

Chronic BZ treatment is associated with tolerance, a decrease in sedative or anticonvulsant properties, and dependence, the need for continued drug to prevent a withdrawal syndrome (162). The development of tolerance is a significant clinical problem, requiring escalation of drug doses and increasing the risk of withdrawal seizures. Chronic treatment with BZs can also reduce their subsequent effectiveness in acute conditions (163), rendering them less useful for treatment of status epilepticus. In animal studies, tolerance develops proportionally to agonist efficacy. BZ partial agonists develop much less tolerance than full agonists, and the antagonist flumazenil causes no tolerance-related changes in receptor number or function (24). Tolerance to one BZ with a particular regimen may not induce tolerance to a different BZ, suggesting drug-specific interactions of each agent at BZ receptor sites on specific $GABA_A$ receptor subunit combinations (164). The duration of tolerance also varies between BZs (165). Several studies of tolerance have noted changes in $GABA_A$ receptor subunit expression (166–168) as well as functional changes (169,170); however, such changes are dependent not only on the drug and dosage but also on the duration and method of drug administration, all of which contribute to chronic BZ receptor occupancy that predisposes to tolerance. Measurements of tolerance also depend on the animal seizure model and the behavioral tests used to assess BZ clinical properties (171).

Physical Dependence

Abrupt cessation of prolonged BZ therapy can result in withdrawal symptoms, including restlessness and agitation, anxiety, loss of appetite, nausea, lethargy, dizziness, headache, palpitations, irritability, confusion, and, in some cases, seizures. The short-acting antagonist, flumazenil, precipitated a withdrawal syndrome in subjects given chronic low-dose diazepam (mean dose 11.2 mg/day) for an average of 4.6 years (172). Four of 13 patients developed panic attacks. A short-lived withdrawal syndrome was elicited by IV flumazenil following 7, 14, or 28 days of oral diazepam (15 mg/70 kg) administration to healthy volunteers (173). There is debate whether withdrawal symptoms, such as heightened anxiety, might represent rebound of existing symptoms to a level greater than that before treatment and whether withdrawal anxiety can result in relapse to the previous state of anxiety (174). BZ prescription misuse has been ascribed to patients' efforts to alleviate withdrawal symptoms,

which can lead to a drug dependence syndrome (175,176). BZ self-administration is enhanced in long-term therapeutic users suddenly switched to placebo relative to those whose dose was tapered gradually (177).

Changes in $GABA_A$ receptors related to tolerance might be assumed to underlie withdrawal symptoms and physical dependence (178,179). Yet, evidence from animal models suggests that enhancement of excitatory systems in a variety of brain regions (180) may underlie anxiety behavior (181–183) and increased seizure activity (183). Enhanced glutamatergic neurotransmission involves a selective increase in GluR1-containing alpha-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) receptors (183–185), which correlates with increased anxiety-like behavior (181). Such neuroplastic changes in the hippocampus are similar to those found with long-term potentiation (LTP) (186). LTP depends on AMPA receptor–mediated depolarization and subsequent relief of the Mg^{2+} block from NMDA receptors, allowing Ca^{2+} entry, which in turn activates kinases resulting in persistent enhancement of GluA1 AMPA receptors. In contrast, for BZ withdrawal, the calcium signal that mediates enhancement of GluA1 AMPA receptors enters through voltage-gated calcium channels (VGCCs) (181,182). In fact, VGCC currents double during chronic BZ treatment and withdrawal, and anxiety can be alleviated by prior administration of the VGCC antagonist, nimodipine (182). The increased anxiety and other symptoms abate over time, associated with downregulation of NMDA receptors (181,187,188), which may serve as a natural brake on withdrawal symptoms.

ADVERSE EVENTS

With acute treatment of status epilepticus, the primary adverse effects are respiratory and cardiovascular depression (135,189). For IV infusions, the propylene glycol solvent contributes to toxicity (190). Other toxic effects such as sedation and amnesia are of relatively little consequence in this setting and difficult to distinguish from the effects of status epilepticus itself. However, sedation after termination of convulsive status epilepticus often necessitates EEG evaluation to ensure that convulsive seizures have not been converted to nonconvulsive status epilepticus. When BZs have been administered in conjunction with other CNS-active drugs such as phenobarbital, respiratory and cardiovascular toxicity may be enhanced (118). In patients with Lennox–Gastaut syndrome, parenterally administered BZs can induce tonic status epilepticus, though this is rare (191). Thrombophlebitis may occur (192), and intra-arterial injection may produce tissue necrosis (193).

With chronic use, all of the BZs induce similar untoward effects including sedation and drowsiness, lightheadedness, ataxia, cognitive slowing and confusion, and anterograde amnesia. Other effects include weakness, headache, blurred vision, vertigo, nausea and vomiting, GI distress, and diarrhea. Joint aches, chest pains, and incontinence occur more rarely (108). The risk of tolerance, dependence, and abuse is significant but low in patients prescribed these agents for appropriate indications (110,194). Abrupt withdrawal of the BZs has been associated with convulsions, worsening of insomnia, psychosis, and delirium tremens in nonepileptic individuals using diazepam, clonazepam, clorazepate, or nitrazepam (195,196). The incidence of allergic, hepatotoxic, or hematologic reactions to the BZs is extremely low. The BZs can sometimes increase the frequency of seizures in epileptic patients. Specific adverse effects will be discussed with the individual agents below.

INDIVIDUAL BZS

Diazepam, lorazepam, and midazolam are used predominantly for short-term indications including status epilepticus, serial seizures, and episodes of lower seizure threshold. Clonazepam, clorazepate, clobazam, and nitrazepam are used more commonly for treatment of chronic epilepsy.

Diazepam

Diazepam, the first BZ used in the treatment of epilepsy (5), became a standard initial therapy for status epilepticus in adults and children (135), though its primary role has been usurped by lorazepam (137,141). Diazepam is available in both oral and parenteral preparations. The classification of rectal diazepam as an orphan drug in 1993 allowed the development of rectal diazepam gel (Diastat).

Diazepam and other BZs induce an increase in β-frequency activity and slowing of the background on EEG, which can be quantified by spectral analysis (197). The pattern of EEG changes may be of prognostic value in seizure control; 88% of patients (29/33) whose EEG responded to diazepam with loss of abnormal activity or emergence of fast (β-frequency) activity had a good prognosis (seizure free or 50% seizure reduction) (198).

Absorption, Distribution, and Metabolism

Diazepam is highly lipophilic, which allows rapid entry into the brain but also results in rapid subsequent redistribution into peripheral tissues. It is extensively bound to plasma proteins (90% to 99%) (199). The volume of distribution is 1.1 L/kg. Plasma concentration declines rapidly during the distribution phase with an initial half-life ($t_{1/2\alpha}$) of 1 hour (200). Diazepam undergoes demethylation to desmethyldiazepam (DMD, nordazepam), a metabolite with anticonvulsant activity and a long half-life (>20 hours), followed by slow hydroxylation to oxazepam, which is also active (see Fig. 50.5) (201). Small amounts of temazepam are also formed by 3-hydroxylation of diazepam. The hydroxylated metabolites are conjugated with glucuronic acid in the liver (202) followed by renal excretion (201) with an elimination half-life ($t_{1/2\beta}$) of 24 to 48 hours (119,200). Diazepam treatment causes modest induction of cytochrome P450 type 2B (203). There is little evidence of enterohepatic circulation (204), but diazepam may be secreted in the gastric juices resulting in enterogastric circulation (205). Like most BZs, diazepam crosses the placenta and is excreted in breast milk (108,200).

Adverse Effects and Drug Interactions

Diazepam can produce respiratory depression (206), which may be exacerbated by postictal CNS depression and necessitate ventilatory support (207). Sedative effects, including inattention and drowsiness, occur at plasma levels of about 200 ng/mL (208), the same level needed to suppress spikes (209) and maintain control of status epilepticus in acute studies (119). Drowsiness, fatigue, amnesia, ataxia, and falls are more prominent in the elderly. Intravenous diazepam can cause thrombophlebitis and lactic acidosis (due to the propylene glycol vehicle) (192,210). Rare paradoxical responses include increased seizure frequency, muscle spasms, or status epilepticus (125). An idiosyncratic allergic interstitial nephritis has also been reported (211). Other rare adverse events include cardiac arrhythmias, hepatotoxicity, gynecomastia, blurred vision and diplopia, neutropenia or thrombocytopenia, rash and urticaria, and anaphylaxis (212). There is potential for abuse, though it is rare in patients prescribed diazepam for appropriate indications (110). The

teratogenicity of diazepam is uncertain, but diazepam taken during the first trimester has been associated with oral clefts (213). Diazepam may also amplify the teratogenic potential of valproic acid (214).

Diazepam enhances the elimination of phenobarbital (119), likely due to induction of cytochrome P450 (203). Valproic acid displaces diazepam bound to plasma proteins, leading to increased free diazepam and associated increased sedation (123).

Clinical Applications

Status Epilepticus.

Diazepam is effective initial therapy in both convulsive and nonconvulsive status epilepticus (137). It may be particularly effective in generalized absence status epilepticus, with 93% of patients initially controlled (215). In the same early study, diazepam also controlled 89% of generalized convulsions, 88% of simple motor seizures, and 75% of complex partial status epilepticus. These numbers are higher than those observed in the VA Cooperative Status Epilepticus Trial (137), possibly due to differences in patient populations.

Diazepam is typically administered initially as a single IV bolus of 10 to 20 mg (119). A 20-mg bolus given at a rate of 2 mg/minute stopped convulsions in 33% of patients within 3 minutes and in 80% within 5 minutes (216), but a single injection often does not produce lasting control, due to its short duration of action, and may be less effective when status results from acute CNS disease or structural brain lesions (115). Strategies to avoid this problem have included giving subsequent 5 to 10 mg IV doses every few hours, following diazepam with a longer-lasting anticonvulsant (e.g., phenytoin (137)), or continuous IV diazepam. Repeated dosing results in a decrease in apparent volume of distribution and clearance; hence, subsequent doses should be tapered to prevent toxicity (217). Diazepam (100 mg in 500 mL of 5% dextrose in water) infused at 40 mL/hour delivers 20 mg/hour (94) and may be suitable to obtain a serum level in the range of 200 to 800 ng/mL; 500 ng/mL appears to be effective for termination of status epilepticus (119,218). Complete suppression of 3 Hz spike and wave required 600 to 2000 ng/mL (219). Continuous infusion has been used in patients hypersensitive to anticonvulsants (220). Diazepam is absorbed onto polyvinyl chloride bags, with a reduction in bioavailability of 50% after 8 hours (221), which should be taken into account if a chronic infusion of diazepam for status epilepticus is contemplated. As noted above, the efficacy of BZs decreases with duration of status epilepticus (143); hence, higher levels or alternative treatments may be necessary if seizures are refractory.

Pediatric Status Epilepticus.

The initial recommended IV diazepam dose in children is 0.1 to 0.3 mg/kg IV by slow bolus (<5 mg/minute) repeating every 15 minutes for two doses, with a maximum of 5 mg in infants and 15 mg in older children (222). If IV administration is not possible, a diazepam solution (0.5 to 1 mg/kg), placed 3 to 6 cm into the rectum, has been effective (97). Continuous IV diazepam infusion (0.01 to 0.03 mg/kg/min) controlled seizures in 86% of pediatric patients in status epilepticus (49/57) within an average of 40 minutes (223). Hypotension occurred in 1 patient (2%), respiratory depression in 6 patients (12%), and death in 7 patients (14%). A meta-analysis of 111 pediatric patients (1 month to 18 years) with refractory generalized convulsive status epilepticus, treated with diazepam, midazolam, thiopental, pentobarbital, or isoflurane, suggested that diazepam was less effective as

continuous therapy than the other agents (86% vs. 100%) after stratifying for etiology of status epilepticus (224). However, all of the patients receiving diazepam were from one region (India), and none received continuous EEG monitoring, suggesting that differences in location or details of care may have been contributory. Mortality was 20% in symptomatic cases and 4% in idiopathic cases and was less frequent in midazolam-treated patients.

Although IV administration is preferable, rectal administration of diazepam rapidly produces effective drug levels (225) and safely aborts status epilepticus in pediatric patients (95,99). In children found to be in electrographic status epilepticus during EEG monitoring, rectal diazepam stopped paroxysmal activity in 58% of cases (226). Rectal diazepam was particularly effective in patients with electrical status epilepticus during sleep and less effective in patients with hypsarrhythmia. Intraosseous injection is a viable alternative in children of suitable age when IV access is not available (101).

Febrile Convulsions.

Rectal diazepam is effective in aborting febrile and nonfebrile seizures in the home setting (96). While the concept of chronic prophylaxis for childhood febrile convulsions has long been in disrepute, it has not been clear whether there was benefit to short-term seizure prophylaxis during fever. A prospective trial randomized 289 children in Denmark to intermittent prophylaxis (diazepam at fever) or no prophylaxis (diazepam at seizure) and assessed neurologic outcome; motor, cognitive, and scholastic achievement; and likelihood of future seizures 12 years later (227). There were no differences in these measures, suggesting that short-term prophylaxis is probably not necessary. Moreover, the incidence of respiratory depression in children treated with IV and/or rectal diazepam is fairly high, with 9% showing decreased respiratory rate or oxygen saturation in one study (207).

Acute Repetitive Seizures.

In a large-scale multicenter open- label trial of rectal diazepam gel (Diastat) in 149 patients older than 2 years, 77% of diazepam administrations resulted in no further seizures for the ensuing 12 hours (154). There was no loss of effectiveness with more frequent (>8) doses, suggesting that tolerance did not reduce the effectiveness of diazepam under these conditions. Sedation occurred in 17%. Diazepam rectal gel was also useful against serial seizures in adult patients with refractory epilepsy (100,153), with 0.5 mg/kg found to be an effective dose (98). Intramuscular diazepam injection may also be suitable for prophylaxis of serial seizures, but absorption is not rapid enough to be effective against status epilepticus. Intranasal diazepam administration is another alternative in this setting. In healthy human volunteers, peak serum concentrations of diazepam (2 mg) after intranasal administration occurred after 18 ± 11 minutes with bioavailability of about 50% (104). A pharmacodynamic effect was seen at 5 minutes.

Chronic Epilepsies.

Periodic courses of diazepam have been proposed as therapy for several chronic conditions, including West syndrome, Lennox–Gastaut syndrome, Landau–Kleffner syndrome, and electrical status epilepticus during sleep (228). Oral diazepam (0.5 to 0.75 mg/kg/d) administered in cycles of 3 weeks duration was beneficial in interrupting electrical status epilepticus and improved neuropsychological function in some cases.

Lorazepam

Lorazepam (see Fig. 50.1) has greater potency and a longer duration of action than diazepam and has become the agent of choice for initial treatment of status epilepticus in adults (132). Lorazepam is also less likely to produce significant respiratory depression (138). It is available in both oral and parenteral preparations.

Pharmacokinetics

Lorazepam is rapidly absorbed but less bioavailable after oral administration due to first-pass biotransformation in the liver (229). Peak plasma levels occur 90 to 120 minutes after oral dosing (230). Lorazepam is about 90% protein bound, with CSF levels approximately equivalent to free serum levels (231). Sleep spindles in EEG recordings were observed within 30 seconds to 4 minutes after IV lorazepam (232), though peak brain concentrations and maximal EEG effect did not occur until 30 minutes (233). The volume of distribution is about 1.8 L/kg (233). After a single IV injection, plasma levels decrease initially due to tissue distribution with a half-life ($t_{1/2\alpha}$) of 2 to 3 hours. The minimal effective plasma concentration for control of status epilepticus was 30 ng/mL (234); after IV injection of 5 mg, plasma levels remain above that level for about 18 hours (235). Sedation, amnesia, and anxiolysis occur at plasma levels between 10 and 30 ng/mL (230).

Lorazepam is metabolized in the liver via glucuronidation at the 3-hydroxy group (236) and then excreted by the kidneys (237) (see Fig. 50.4). The half-life for elimination ($t_{1/2\beta}$) is in the 8 to 25 hours range (mean 15 hours) and is the same for oral administration (238).

Adverse Effects and Drug Interactions

Sedation, dizziness, vertigo, weakness, and unsteadiness are relatively common, with disorientation, depression, headache, sleep disturbances, agitation or restlessness, emotional disturbances, hallucinations, and delirium less common (239). Psychomotor impairment, dysarthria, and anterograde amnesia have also been observed. Lorazepam (0.2 mg orally) impaired driving more than a blood alcohol level of 0.5 mg% (240). Mild respiratory depression sometimes occurs, particularly with the first IV dose (241). Rare adverse events include neutropenia. A paradoxical effect was observed in a patient with Lennox–Gastaut syndrome in which lorazepam precipitated tonic seizures (242). Abuse liability is relatively low. Although lorazepam is in USFDA pregnancy category D, of unknown teratogenic potential, short-term use in treatment of status epilepticus may be of lifesaving benefit and likely to outweigh the uncertain risks. Sudden discontinuation after chronic use has caused withdrawal seizures (243).

Valproic acid increased plasma concentrations of lorazepam (244) and decreased lorazepam clearance by 40% (245), apparently by inhibiting hepatic glucuronidation. Lorazepam does not affect valproic acid levels (244). Probenecid increased the half-life of lorazepam by inhibiting glucuronidation, resulting in toxicity in patients on long-term therapy (130).

Clinical Applications

Status Epilepticus.

The recommended IV dose of lorazepam for status epilepticus is 0.1 mg/kg (up to a maximum of 4

mg) administered at 2 mg/minute, with repeat doses after 10 to 15 minutes if necessary (137). Although lorazepam is less lipophilic than diazepam, it crosses the BBB readily. Onset of action occurred within 3 minutes, with control of status epilepticus in 89% of episodes within 10 minutes (135). In another study, all 10 patients with generalized convulsive status epilepticus had seizures controlled with IV lorazepam (mean 4 mg), but 9 of 11 patients with complex partial status epilepticus experienced problems, including respiratory depression (246). Other studies have shown response rates of 80% (115) and 92% (241). Similar success rates were achieved with simple partial status epilepticus (163,241). As noted above, the VA Cooperative Status Epilepticus Trial demonstrated superiority of lorazepam (0.1 mg/kg) over phenytoin (18 mg/kg) in response rate to initial therapy (64.9% vs. 43.6%), with slightly better results for lorazepam than diazepam (0.15 mg/kg) (137). Intravenous lorazepam (4 mg) was effective against post–anoxic myoclonic status epilepticus after cardiac arrest in six patients (247). However, continuous EEG monitoring during lorazepam treatment is advisable, as electroclinical dissociation (electrographic seizures despite cessation of convulsive activity) has been observed.

Pediatric Status Epilepticus.

The usual IV lorazepam dose in pediatric status epilepticus is 0.05 mg/kg, repeated twice at intervals of 15 to 20 minutes (138,163). This regimen terminated seizure activity in 81% of 31 children aged 2 to 18 (241). In a prospective randomized trial of 178 children, lorazepam (0.1 mg/kg) had the same efficacy (100%) as diazepam (0.2 mg/kg) plus phenytoin (18 mg/kg), with similar rates of respiratory depression (about 5%) (248). A retrospective study found that lorazepam (0.1 mg/kg in children and 0.07 mg/kg in adolescents) was most effective in partial status epilepticus, terminating seizures in 90% of cases (163). Prior treatment of status epilepticus with phenytoin, phenobarbital, or diazepam did not alter the effectiveness of lorazepam, though chronic BZ treatment with clonazepam or clorazepate significantly reduced the effectiveness of lorazepam in status epilepticus (163), indicating tolerance. Respiratory depression, when observed, occurred after the first injection.

Lorazepam was effective in neonatal seizures refractory to phenobarbital and/or phenytoin in several small studies. In seven neonates (gestational ages 30 to 43 weeks) treated with IV lorazepam (0.05 mg/kg), seizures were controlled within 5 minutes in all seven patients, with no recurrence in five, and at least 8 hours of control in the remaining two patients (249). No respiratory depression or other adverse effects were reported. In another small series, status epilepticus in six of seven neonates was terminated with lorazepam (0.05 to 0.14 mg/kg) (250).

Pediatric Serial Seizures.

Sublingual lorazepam (1 to 4 mg) was effective against serial seizures in 80% (8/10) and partially effective in 20% (2/10) of children, with onset of clinical effect within 15 minutes in most cases (251).

Alcohol Withdrawal Seizures.

Lorazepam (2 mg) administered after a witnessed ethanol withdrawal seizure prevented a second seizure better than placebo (3% vs. 24%) and may be the agent of choice in this setting (252). Duration of withdrawal symptoms was shorter with lorazepam than with chlordiazepoxide (253).

Chronic Epilepsy.

Lorazepam was effective as adjunctive treatment of complex partial seizures, with an optimal dose of 5 mg/day after slow upward titration from 1 mg twice daily (189). Therapeutic levels were in the range of 20 to 30 ng/mL. However, long-term treatment with lorazepam is likely to result in tolerance and is not generally recommended (254).

Midazolam

Midazolam (see Fig. 50.1) is widely used for induction of anesthesia and as a preanesthetic agent. It is three to four times as potent as diazepam. Midazolam has gained popularity in acute treatment of status epilepticus by either IV or IM use, though its short duration of action necessitates continuous IV maintenance or subsequent therapy with an additional anticonvulsant. Midazolam (10 mg) IM injection reduced interictal spike frequency in EEG recordings as well as IV diazepam (20 mg) (255), and this route provides a valuable alternative when IV access is unavailable.

Pharmacokinetics

Midazolam is water soluble, but at physiologic pH, a conformational change in the BZ ring makes it lipid soluble (256). Serum midazolam levels after IV administration were best fit by a two-compartment model, with an initial tissue distribution phase ($t_{1/2\alpha}$ of 5.7 minutes) and an elimination phase ($t_{1/2\beta}$ of 1.9 hour) (200). After IV administration in eight healthy adult volunteers, mean plasma concentration for a half-maximal increase in β-frequency activity on EEG recording was 276 μmol/L (257). With an IM injection, peak serum concentration occurred after 25 minutes (258). After oral administration, 44% of the dose was bioavailable (200), while intranasal midazolam bioavailability ranged from 50% (259) to 83% (260). Bioavailability after rectal administration was 52% (261) and 74.5% after buccal administration (102). Midazolam is 95% protein bound, with a volume of distribution of 1.1 L/kg and a half-life in the range of 1.9 (200,262) to 2.8 hours (258). The clearance rate was 6.6 mL/min/kg, with 56% urinary excretion. The pharmacokinetics of midazolam is altered in children and critically ill patients. In children aged 1 to 5 years, administration of midazolam (0.2 mg/kg) by intranasal or IV route resulted in a similar elimination half-life, 2.2 hours for intranasal and 2.4 hours for IV administration (263). In critically ill neonates, the elimination half-life after IV administration was 12.0 hours (264). In adult ICU patients, the volume of distribution (3.1 L/kg) and elimination half-life (5.4 hours) were significantly greater than in healthy volunteers (0.9 L/kg and 2.3 hours, respectively) (265) though clearance was not significantly different (6.3 vs. 4.9 mL/min/kg for patients and volunteers, respectively).

Midazolam is metabolized rapidly by α-hydroxylation of the methyl group on the fused imidazo ring (Figs. 50.1 and 50.5) (256). This metabolite is biologically active but is eliminated by hepatic glucuronidation, with an elimination half-life of about 1 hour (266).

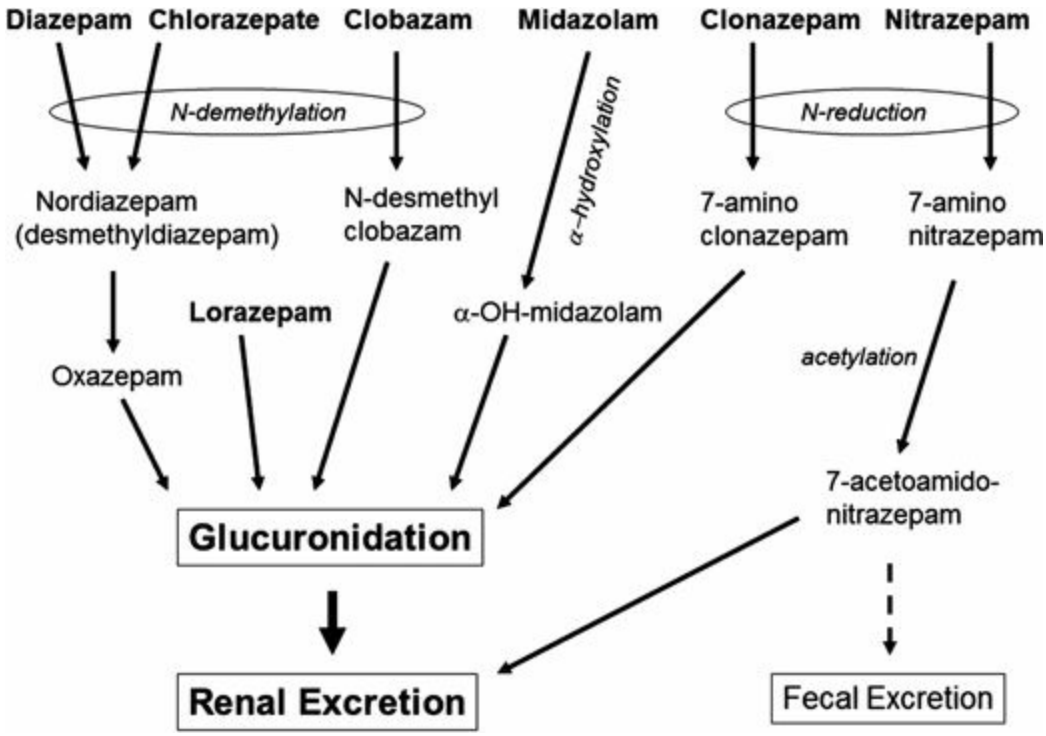

Figure 50.5. Hepatic metabolism of the antiseizure BZs.

Adverse Effects and Drug Interactions

Dose-dependent sedation with midazolam may be prolonged after continuous infusion despite its short half-life (267). Retrograde amnesia, euphoria, confusion, and dysarthria also occur. Midazolam syrup has been associated with respiratory depression and arrest and should only be given where resuscitative drugs, equipment, and experienced personnel are immediately available. Paradoxical reactions (agitation, tremor, involuntary movements, hyperactivity, combativeness) occur in about 2%, and seizures and nystagmus in about 1%. Midazolam syrup is associated with nausea (8%) and vomiting (4%), but these are far less common with IV administration. Hypotension and decreased cardiac output likely result from peripheral vasodilatation (256). Sudden discontinuation after long-term use can result in withdrawal seizures (268). Midazolam is in USFDA pregnancy risk category D.

Erythromycin prolongs the half-life of midazolam to 10 to 20 hours (269). Phenytoin and carbamazepine reduce the bioavailability of oral midazolam by inducing cytochrome P450, which enhances first-pass hepatic metabolism (270).

Clinical Applications

Status Epilepticus.

For refractory status epilepticus, IV midazolam 0.2 mg/kg by slow bolus injection followed by 0.75 to 10 μg/kg/min maintenance infusion has been recommended (132,271). Midazolam suppresses respiratory drive, so patients must be intubated and mechanically ventilated. Typically, infusion is maintained for 24 hours and then slowly tapered during continuous EEG monitoring; if seizure activity returns, midazolam infusion is resumed for additional 12-hour periods. Tolerance may develop, and doses up to 2 mg/kg/h have been required for seizure control (270). Advantages of midazolam over other BZs include rapid onset of action, ease of administration and titration (with the possibility of initial IM injection (272)), good efficacy, and lack of serious adverse effects (271).

Continuous IV infusion of midazolam was effective for treatment of refractory status epilepticus, terminating seizures within 100 seconds in seven patients who had failed treatment with diazepam, lorazepam, and phenytoin with or without phenobarbital (273). Intramuscular midazolam has been used successfully for status epilepticus in several small series, with an effective dose of 0.2 mg/kg (272,274).

Pediatric Status Epilepticus.

Midazolam is also safe and effective in pediatric status epilepticus. In a retrospective study of unprovoked refractory convulsive status epilepticus in epileptic children 1 to 15 years old, repeated bolus midazolam (0.1 mg/kg every 5 minutes) controlled 89% of the episodes after three doses, with infrequent adverse events (respiratory depression, 13%) (275). In another study, midazolam (0.15 mg/kg bolus followed by 1 to 5 μg/kg/min infusion), either alone or with concomitant phenytoin or phenobarbital, controlled status epilepticus in 19 of 20 children (mean age 4 years) (276). In a series of 8 pediatric patients (age 17 days to 16 years) with refractory status epilepticus treated with prolonged (>48 hours) midazolam coma, the average dose for seizure cessation was 14 μg/kg/min and mean duration of therapy was 192 hours; one patient could not be successfully weaned and died after 4 weeks (277). In a similar series of 20 children (mean age 4 years), midazolam was well tolerated and stopped seizures in 95% of patients (278). Intravenous midazolam was safe and effective as first-line therapy in 15 of 16 episodes of status epilepticus in 10 children (20 months to 16 years), using a loading dose of 0.1 to 0.3 mg/kg followed by average infusion of 2.7 μg/kg/min for 12 hours to 6 days (279). It was also effective as a second-, third-, or fourth-line drug, with seizure control in 34 of 38 status epilepticus episodes. In neonates (1 to 9 days, 30 to 41 weeks gestational age), midazolam (0.1 to 0.4 mg/kg/h) controlled overt seizures refractory to high-dose phenobarbital in six patients within 1 hour (280); electrographic seizures continued in two of the six for another 12 hours. Midazolam was tolerated well by neonates, with no change in pulse or blood pressure and no adverse reactions.

Febrile Seizures.

In a prospective, randomized study of 47 children, intranasal midazolam was as effective as IV diazepam for controlling prolonged febrile convulsions, with shorter mean time to starting treatment and shorter time for controlling seizures (3.5 vs. 5.5 minutes) (106).

Pediatric Acute Repetitive Seizures.

A study comparing IM midazolam to IV diazepam in children with seizures lasting longer than 10 minutes found similar efficacy between these agents, though patients in the midazolam group received medication sooner and seizures ended sooner (281). Intranasal midazolam was rapidly effective (158,282), and parents preferred it over rectal diazepam due to faster action and the ability to give it in public (158). In a prospective randomized trial comparing rectal diazepam (0.3 mg/kg) to intranasal midazolam (0.2 mg/kg), mean time from drug administration to cessation of seizure was less in the midazolam group, and mean respiratory rate and oxygen saturation were lower in the diazepam group (159). A randomized trial in children (aged 5 to 19 years) with the Lennox–Gastaut syndrome or other symptomatic generalized epilepsies showed that midazolam (10 mg in 2 mL) administered to the buccal mucosa stopped 75% of seizures, compared to 59% of seizures stopped by rectal diazepam (10 mg) (103). The time to end of seizure was not different between groups, and no

cardiorespiratory adverse events occurred. Intrabuccal and intranasal midazolam are thus viable routes of administration in this patient population. A randomized, double-blind, placebo-controlled trial of intranasal midazolam for seizure clusters in children over age 14 and adults to age 65 (ARTEMIS I, Upsher-Smith, NCT01390220) is in progress.

Clonazepam

Clonazepam (see Fig. 50.1) is used primarily as an anticonvulsant for treatment of both acute seizures and chronic epilepsy. It is effective in several types of status epilepticus (283), but in the United States, clonazepam is available only as an oral preparation.

Pharmacokinetics

The initial distribution half-life after IV injection has not been studied. Clonazepam is 81% to 98% absorbed after oral administration, with peak plasma levels occurring in 1 to 4 hours (6). It is highly lipid soluble with somewhat lower plasma protein binding (86%) than diazepam (108). The volume of distribution is 1.5 to 4.4 L/kg (6), which is greater than that of diazepam or lorazepam. Clonazepam is primarily metabolized to an inactive product, 7-amino-clonazepam, which is conjugated to glucuronide and excreted by the kidneys (6) (see Fig. 50.5). Plasma half-lives were similar in single- and multiple-dose studies, with ranges of 18.7 to 39 hours and 31 to 42 hours, respectively, suggesting relatively little hepatic enzyme induction (6). An intranasal formulation with superior delivery of drug to brain has been developed (284).

Adverse Effects and Drug Interactions

Drowsiness and lethargy occur in about 50% of adult patients initially, but tolerance to these symptoms develops with continued administration (285). Drowsiness was seen in up to 85% of children treated with clonazepam and, along with other side effects, necessitated termination of the drug in 27% of patients (6). Respiratory and cardiovascular depression can occur with IV use. Nystagmus is fairly common; incoordination, ataxia, hypotonia, dysarthria, and dizziness are less frequent. Behavior disturbances including aggression, hyperactivity, and paranoia can be seen in up to 12% of children (286). Seizure frequency is sometimes increased by clonazepam, and seizures (287) or status epilepticus (288) can occur upon abrupt withdrawal. Increased salivary and bronchial secretions, anorexia, or hyperphagia can also occur. A “burning mouth syndrome” with painful oral dysesthesias has been described (289).

Clinical Applications

Status Epilepticus.

Intravenous injection of 0.01 to 0.09 mg/kg terminates status epilepticus in most cases (6). A single 1 mg dose controlled various types of status epilepticus in 80% of adult patients (290). Both IV and oral clonazepam were effective treatments for status epilepticus in children (283,291). The minimum effective plasma level of clonazepam for control of convulsive status epilepticus was 30 ng/mL (115). In children and adults with absence status epilepticus, clonazepam (1 to 4 mg) was effective in 83.3% (292). Dissolving clonazepam into a droplet of propylene glycol followed by buccal

administration achieved therapeutic levels in 10 to 15 minutes and might be a strategy for treating serial seizures (293). An open label study comparing clonazepam and lorazepam for status epilepticus in 50 adults with various epilepsies found similar efficacy (68% and 69%) (294). A single site retrospective study in Germany found clonazepam more effective in terminating generalized convulsive status epilepticus than other ASDs (295). However, neither diazepam nor clonazepam was found to be effective for status epilepticus in another study of 55 patients with symptomatic generalized epilepsy, primarily Lennox–Gastaut syndrome (290).

Pediatric Status Epilepticus.

An IV 0.25 mg bolus of clonazepam, repeated as needed up to 0.75 mg, terminated status epilepticus in 17 of 17 children (2 weeks to 15 years old) (283). Doses ranged from 0.01 to 0.09 mg/kg; the mean clonazepam level was 185 ng/mL at 10 minutes after seizure termination and 43 ng/mL at 30 minutes.

Chronic Epilepsy.

The dose for chronic therapy in children is 0.01 to 0.02 mg/kg/d; in adults, it may range up to 8 mg/day in two to three divided doses. Good control of absence seizures was obtained at plasma levels of 13 to 72 ng/mL (291). However, correlation between plasma clonazepam levels and efficacy is relatively poor (6,296) due to the development of tolerance to antiseizure effects (297). Children require relatively higher doses than adults due to a higher clearance rate. Because of rapid absorption and elimination, children should receive the total daily dose in thirds (6). Clonazepam can be safely discontinued with dosage reduction of 0.04 mg/kg/wk (298).

Severe Childhood Epilepsies.

Although clonazepam is effective against a wide variety of seizure types, side effects limit its use to the most difficult epileptic conditions. Clonazepam produced lasting improvement in 5 of 24 patients with infantile spasms and in 3 of 13 patients with Lennox–Gastaut syndrome at doses of 0.1 to 0.3 mg/kg/d (299). Similarly, complete seizure control was achieved in about one-third of 42 cases of infantile spasms and 37 cases of Lennox–Gastaut syndrome (300).

Myoclonic Seizures.

Clonazepam is effective in various myoclonic seizure disorders including myoclonic–atonic seizures (301), myoclonic seizures (302), Unverricht–Lundborg myoclonic epilepsy (303), and intention myoclonus (304). Other conditions reported to respond to clonazepam include hyperekplexia (305), acute intermittent porphyria (306), epilepsy with continuous spike and wave during slow-wave sleep (307), and neonatal seizures (308).

Clorazepate

Clorazepate (see Fig. 50.1) is used as adjunctive treatment of seizure disorders, anxiety, and alcohol withdrawal. Its role in epilepsy is limited to adjunctive therapy of refractory generalized or partial seizure disorders, particularly in the setting of comorbid anxiety disorders.

Pharmacokinetics

Clorazepate is a prodrug for nordiazepam (N-desmethyldiazepam, DMD), the major active metabolite of diazepam (see Fig. 50.5). Nonenzymatic decarboxylation at position 3 occurs at gastric pH, with 90% of clorazepate converted to DMD in <10 minutes. Decarboxylation of absorbed clorazepate continues more slowly in the blood. DMD is responsible for most of clorazepate's antiseizure effect. Clorazepate is 100% bioavailable by the IM route (309) and 91% (as DMD) by oral ingestion (310). Clorazepate and DMD are 97% to 98% protein bound. The time to peak DMD concentration is 0.7 to 1.5 hours, with peak response in 1 to 2.5 hours (311). Volume of distribution ranged from 0.9 to 1.5 L/kg and was greater in the elderly and in obese subjects (312). The elimination half-life of clorazepate is 2.3 hours, but the half-life of DMD is about 46 hours (313), longer in elderly males and neonates (314). DMD is then hydroxylated to oxazepam (see Fig. 50.5), which is then conjugated to glucuronic acid in the liver (202) and excreted by the kidneys with an elimination half-life of 1 to 2 days (119). As with diazepam, drugs and conditions that alter hepatic metabolism can dramatically affect the metabolism and clearance of clorazepate, DMD, and oxazepam.

Adverse Effects and Drug Interactions

Clorazepate is reportedly less sedating than other BZ anticonvulsants, although sedation is still its most common side effect (315). Dizziness, ataxia, nervousness, and confusion are less commonly seen. Memory problems, difficulty in concentration, irritability, and depression also occur, particularly in association with primidone (316). Paradoxical akathisia has been reported in two patients with history of head trauma and seizure disorders (317). Personality changes with aggressive behavior, irritability, rage, or depression have been described (318), though some have attributed these changes to the underlying temporal lobe epilepsy (319). Hepatotoxicity (320) and transient skin rashes have also been reported. Withdrawal symptoms after chronic use include nervousness, insomnia, irritability, diarrhea, muscle aches, and memory impairment. Clorazepate is in USFDA pregnancy category D; major malformations were reported in one infant born to a mother who took clorazepate during the first trimester (321).

Clinical Applications

The recommended initial dose for adjunctive treatment is 7.5 mg three times daily (0.3 mg/kg/d), with slow increases as required, to a maximal daily dose of 90 mg (about 1 mg/kg/d) in adults and up to 3 mg/kg/d in children (315). Rapid absorption and conversion to DMD require divided dosing to avoid toxicity, despite the long elimination half-life (124). A sustained release preparation delivers 22.5 mg in a single daily dose (Tranxene-SD). Plasma DMD levels of 0.5 to 1.9 mg/mL may represent the therapeutic range (200).

Clorazepate has been used primarily as add-on therapy. It was ineffective as monotherapy but improved seizure control as adjunctive therapy in 59 patients with various seizure disorders (322). Other studies have found limited effectiveness (323) or drowsiness at effective doses (324). Clorazepate was no more effective than phenobarbital as an adjunct to phenytoin treatment, but patients preferred clorazepate (325). Clorazepate controlled refractory generalized seizures in 11 children (age 3 to 17 years), though seizures recurred in 3, likely due to tolerance (326). However, clorazepate's long half-life, slow-release formulation, and slow induction of tolerance may make it more useful than some other BZs for chronic treatment of epilepsy (254).

Clobazam

Despite the possible development of tolerance, clobazam (8-chloro-5-methyl-1-phenyl-1,5-benzodiazepine-2,4-dione) has become the most widely used BZ for the long-term treatment of epilepsy because of its effectiveness and relatively low tendency to produce sedation (327). In post–temporal lobectomy patients, clobazam is the third most common anticonvulsant employed after carbamazepine and phenytoin (328). Clobazam has primarily been used as add-on therapy, though the Canadian Study Group for Childhood Epilepsy (329) has found it effective as monotherapy in children. In 2011, it was approved in the United States for adjunctive treatment of seizures associated with Lennox–Gastaut syndrome.

Pharmacokinetics

Clobazam is the only 1,5-BZ in clinical use as an anticonvulsant. Clobazam has a relatively low binding affinity and a correspondingly low potency (see Table 50.1). It is well absorbed, with peak concentrations in 1 to 4 hours, highly lipid soluble, and 85% protein bound. N-desmethylclobazam, the major metabolite, is the primary anticonvulsant component in patients undergoing long-term therapy. The mean elimination half-life is 18 hours for clobazam and 42 hours for N-desmethylclobazam. Clobazam induces hepatic enzymes, leading to more rapid conversion to N-desmethylclobazam with long-term treatment (330). Plasma levels of clobazam and N-desmethylclobazam correlated with both therapeutic effect and toxicity, but therapeutic levels have not been established, likely due to presence of the active metabolite and the development of tolerance (331).

Adverse Effects and Drug Interactions

Clobazam may have fewer or milder side effects than other BZs at equipotent doses (7,332,333). Levels of the metabolite, N-desmethylclobazam, correlated with side effects (334). In epileptic patients, the predominant side effects of clobazam are drowsiness and fatigue (330). Of 23 open-label studies of clobazam, ataxia was described in 4, dizziness in 19, and vertigo in 2 studies (330). Memory disturbance, aggressiveness, dysphoria, and illusional and psychotic symptoms occur relatively infrequently. Clobazam has been associated with blurred vision. Negative myoclonus (asterixis, sudden brief loss of tone) has been observed when clobazam was added to carbamazepine (335). Tolerance occurred in 48% of Lennox–Gastaut syndrome patients treated with clobazam (336) as seen with the 1,4-BZs (57). Increased seizure activity can occur with discontinuation of the drug (337).

Clinical Applications

Clobazam doses range from 10 to 50 mg/day, with most studies using 10 to 30 mg/day in one or two doses. In the Canadian Clobazam Cooperative Group trial of 877 patients, the average dose in adults was 30.8 mg, while the average dose for children was 0.86 mg/kg (338).

Clobazam is effective against all seizure types (339), but the benefits may be short-lived. In the Canadian Clobazam Cooperative Study, more than 40% of patients with a single seizure type had a 50% or greater reduction in seizure frequency, and 60% of patients with multiple seizure types had improvement in at least one type of seizure (338). About a third developed drowsiness as a side

effect, but this was severe enough to cause discontinuation in only 11%. About 9% discontinued due to recurrence of seizures, which was thought to represent tolerance. In a randomized, double-blind study of clobazam as adjunctive therapy for drop seizures in Lennox–Gastaut syndrome, clobazam provided a significant, dose-related reduction in drop seizure rates, with non–drop seizures also reduced; adverse effects were rare and mild (340). Clobazam may be particularly effective in the Lennox–Gastaut syndrome (327), but tolerance prevents it from being the drug of first choice for most epilepsies (330). In a large prospective US study of 251 refractory patients prescribed adjunctive clobazam (5 to 60 mg/day, mean 23.9 mg/day), 7 patients (11.3%) became seizure free for at least 6 months after introduction of clobazam, and the 1-year retention rate was 61% (341). An indirect comparison of clobazam to other ASDs found that clobazam had greater efficacy for seizures of all types and drop attacks (atonic seizures) (336). An economic analysis found that clobazam was cost-effective due to the reduction in emergency care needed for drop attacks (342). Clobazam was effective when used intermittently in catamenial epilepsy, as tolerance to the anticonvulsant effect was apparently avoided (161). It has also been shown safe and effective in the treatment of epileptic encephalopathies of childhood (343) though its ability to suppress EEG spike-and-wave activity has caused confusion in the diagnosis of electrical status epilepticus during sleep (344).

Despite reports of rapid development of tolerance, the Canadian Clobazam Cooperative Study (338) reported that 40% to 50% of patients remained on clobazam for 4 years or longer. Patients who had a seizure reduction exceeding 75% when clobazam was added were likely to sustain this response if their epilepsy was not long-standing and had a known cause (345).

Nitrazepam

Nitrazepam (see Fig. 50.1) has been used as a hypnotic and anticonvulsant, with benefit against infantile spasms, and as adjunctive therapy for severe generalized epilepsies of childhood. Nitrazepam may be particularly effective against myoclonic seizures.

Pharmacokinetics

Oral bioavailability is about 78% (346), with peak concentration occurring in 1.4 hours (347). Nitrazepam is 85% to 88% protein bound (348) and has a volume of distribution of 2.4 L/kg in healthy young adults, higher in the elderly and in women (346). Nitrazepam is metabolized in the liver to an inactive product (see Fig. 50.5) (349). It does not induce its own metabolism. A portion is apparently bound in tissues for prolonged periods (350). Metabolism is slowed in patients with hypothyroidism (351) and obesity (352).

Adverse Effects and Drug Interactions

Like other BZs, nitrazepam can produce disorientation, confusion, and drowsiness, particularly in elderly patients (348). Vivid nightmares have occurred at the onset of therapy (353). Drooling and aspiration have occurred in children (354,355), apparently caused by impaired swallowing (355), though this did not occur at doses <0.8 mg/kg/d (355). Respiratory depression has occurred in elderly patients (356). Increased seizure frequency and new seizure types are sometimes seen (357). Tolerance can develop with chronic use, and withdrawal symptoms have occurred (195,358,359).

Nitrazepam is in USFDA pregnancy category C. Infants born to mothers on nitrazepam late in pregnancy have been somnolent, floppy, poorly responsive, and required tube feeding but recovered

in several days (360). Among 43 pregnant women who took overdoses of nitrazepam in suicide attempts, 30% of births were associated with congenital abnormalities (361). Like other BZs, nitrazepam is associated with increased teratogenic risk, particularly oral clefts (213).

Nitrazepam therapy increased the risk of death in young patients with intractable epilepsy. In a retrospective analysis of 302 patients treated with nitrazepam, 21 patients died, 14 of whom were taking nitrazepam at time of death (362). In patients younger than 3.4 years, the death rate was 3.98 per 100 patient-years, compared with 0.26 deaths per 100 patient-years in patients not taking nitrazepam. Nitrazepam had a slight protective effect in patients older than 3.4 years. It should therefore be used with extreme caution if at all in children younger than 4 years.

Clinical Applications

Nitrazepam is not available for clinical use in the United States. The usual daily dose is 1 mg/kg for children and 0.5 mg/kg for adults. Initial doses of 1 to 6 mg daily, with gradual increases up to 60 mg daily, have been used in treatment of pediatric seizure disorders (363–365). In children, satisfactory seizure control was associated with a mean plasma concentration of 114 ng/mL (348); levels above 220 ng/mL were more likely to be toxic. Nitrazepam (0.25 to 0.5 mg/kg/d, in t.i.d. dosing during fever) was effective in prophylaxis of febrile convulsions (366).

Nitrazepam was particularly effective for infantile spasms, myoclonic seizures, and the Lennox–Gastaut syndrome (363,365,367). In 52 patients (1 to 24 months) with infantile spasms and hypsarrhythmia on EEG, nitrazepam (0.2 to 0.4 mg/kg/d in two divided doses) and adrenocorticotrophic hormone (ACTH, 40 U IM daily) were similar in efficacy and incidence of adverse effects (368). Both regimens resulted in 75% to 100% reduction in seizure frequency in 50% to 60% of patients. Twenty children (4 to 28 months) with infantile spasms or early Lennox–Gastaut syndrome were treated with nitrazepam (median dose 1.5 mg/kg/d); of these, five had complete cessation of seizures, seven had >50% seizure reduction, and eight had no response (369). Twelve children experienced pooling of oral secretions and 6 developed sedation, but no serious side effects were reported.

Flumazenil: Potential Uses in Epilepsy

The BZ antagonist, flumazenil, has been used primarily to reverse BZ-induced sedation (17,18) but may also have benefit in reversing hepatic coma (370,371) in patients who had no prior exposure to BZs. Ammonia and manganese activate mitochondrial benzodiazepine receptors leading to increased production of neuroactive steroids, some of which (e.g., allopregnanolone, THDOC) enhance inhibitory neurotransmission via allosteric modulation of the $GABA_A$ receptor (372,373). The reversal of hepatic coma has bolstered arguments for an endogenous BZ ligand or "endozepine," which could be displaced by flumazenil (374,375). An endogenous "diazepam-binding inhibitor" (DBI) peptide has been characterized (376), though its role in inhibitory neurotransmission remains unclear. Endogenous potentiation of GABA-ergic synaptic transmission and responses to GABA uncaging in thalamic reticular nucleus (nRT) neurons was absent in nm1054 mice, in which the DBI gene is deleted (377). Viral transduction of DBI into nRT was sufficient to rescue the endogenous potentiation of GABA-ergic transmission in these mice. Hence, DBI may function as an endogenous inhibitory neuromodulator, possibly increased in the setting of hepatic encephalopathy.

Flumazenil may be of use in epilepsy by reversing tolerance and may also have intrinsic

antiepileptic effects. Brief exposure to flumazenil can reverse tolerance-related changes in $GABA_A$ receptor function (378,379) and subunit expression (380). Flumazenil has been used with modest success to treat BZ dependence (381). The concept of using intermittent low doses of flumazenil to reverse BZ anticonvulsant tolerance has been explored in humans (382). Three patients with daily seizures who had become tolerant to clonazepam (1 mg b.i.d.) were treated with a single IV dose of flumazenil (1.5 mg, corresponding to 55% receptor occupancy), resulting in a mild withdrawal syndrome (shivering) lasting 30 minutes, followed by seizure freedom for 6 to 21 days (mean 13 days). Refinement of this approach may allow more extensive use of the BZs in the chronic treatment of epilepsy. Curiously, flumazenil itself has shown anticonvulsant efficacy in some animal models, possibly due to partial agonism at high doses (383,384) or antagonism of an endogenous proconvulsant (382). Flumazenil also reduced epileptiform discharges in rat hippocampal slices (385) and slowed the development of kindling (386). Flumazenil (0.75 to 15 mg) suppressed focal epileptiform activity in six patients with partial (temporal lobe) seizures but had no effect on generalized spike-and-wave activity in six patients with generalized seizures (387). Several small studies have suggested possible benefit as an ASD in humans (387,388). In 9 of 11 previously untreated patients with epilepsy, oral flumazenil (10 mg one to three times daily) caused a 50% to 75% reduction in seizure frequency, and 9 of 16 patients experienced 50% to 75% reduction in seizure frequency when flumazenil was added as an adjunctive anticonvulsant (389). Flumazenil's ability to prevent interictal epileptiform discharges on EEG was similar to that of diazepam (382,390).

Flumazenil can precipitate seizures, particularly in the setting of hepatic encephalopathy, in BZ-dependent patients, or in patients who have ingested multiple agents in overdose (e.g., tricyclic antidepressants) (391). The ability of flumazenil to induce seizures in patients previously treated with BZs has been used to precipitate partial seizures during inpatient epilepsy monitoring to localize seizure onset (392), though that practice is controversial. In addition, [^{11}C]flumazenil has been used diagnostically in positron emission tomography studies to demonstrate regions of neuronal loss associated with epilepsy (393–395) and may be useful in localizing the seizure focus in patients with dual pathology (396) and to define the epileptogenic zone (397).

FUTURE DIRECTIONS: NEW STRATEGIES FOR THE BZS

Partial BZ agonists (abecarnil, bretazenil, imidazenil) may retain anticonvulsant efficacy but be less prone to the development of tolerance. The utility of these agents in human epilepsy has not been adequately explored. Combination therapy using a full agonist with a partial agonist or antagonist (flumazenil), or intermittent use during periods of higher seizure risk (e.g., catamenial epilepsy), might prevent the development of tolerance and provide new strategies for BZ use. Novel routes of administration via the nasal, buccal, or rectal mucosa provide less invasive means to use BZs acutely in the outpatient setting. Another novel approach involves using BZs in a device capable of detecting seizure discharges and injecting the drug at the onset of seizure activity, locally onto the epileptic focus, into the cerebral ventricles, or systemically. A model for this type of device in rats showed a decrease in seizure frequency and duration when diazepam rather than vehicle was injected onto a bicuculline-created seizure focus (398). Such approaches may increase the future role of BZs in the treatment of status epilepticus, serial seizures, and epilepsy.

CHAPTER 51 CARBAMAZEPINE, OXCARBAZEPINE, AND ESLICARBAZEPINE

CARLOS A.M. GUERREIRO, MARILISA M. GUERREIRO, AND SCOTT MINTZER

Carbamazepine (CBZ) is one of the most often prescribed drugs worldwide for the treatment of neurologic disorders. CBZ is considered an efficacious agent for the treatment of focal and generalized tonic–clonic seizures in children and adults, with an excellent side effect profile (1).

Oxcarbazepine (OXC), the 10-keto analog of CBZ, has been used largely as an alternative for CBZ because of its more favorable pharmacologic and adverse event profiles. It is effectively a prodrug for licarbazepine, which exhibits effects similar to CBZ but avoids metabolism into carbamazepine-10,11-epoxide, which is believed to add to the toxicity of CBZ.

It was felt that there might still be room for improvement, however, since licarbazepine exists in two enantiomeric forms, yet only the S-enantiomer appears to contribute to anticonvulsant activity. This prompted the development of eslicarbazepine acetate (ESL), which is metabolized directly to S-licarbazepine, without loss to the R-enantiomer.

CHEMISTRY AND MECHANISM OF ACTION

CBZ is an iminodibenzyl derivative. Both CBZ and OXC are tricyclic anticonvulsant agents that are structurally similar to antidepressants. However, unlike the tricyclic antidepressants, CBZ and OXC are neutral substances because of their carbamoyl side chains (Fig. 51.1).

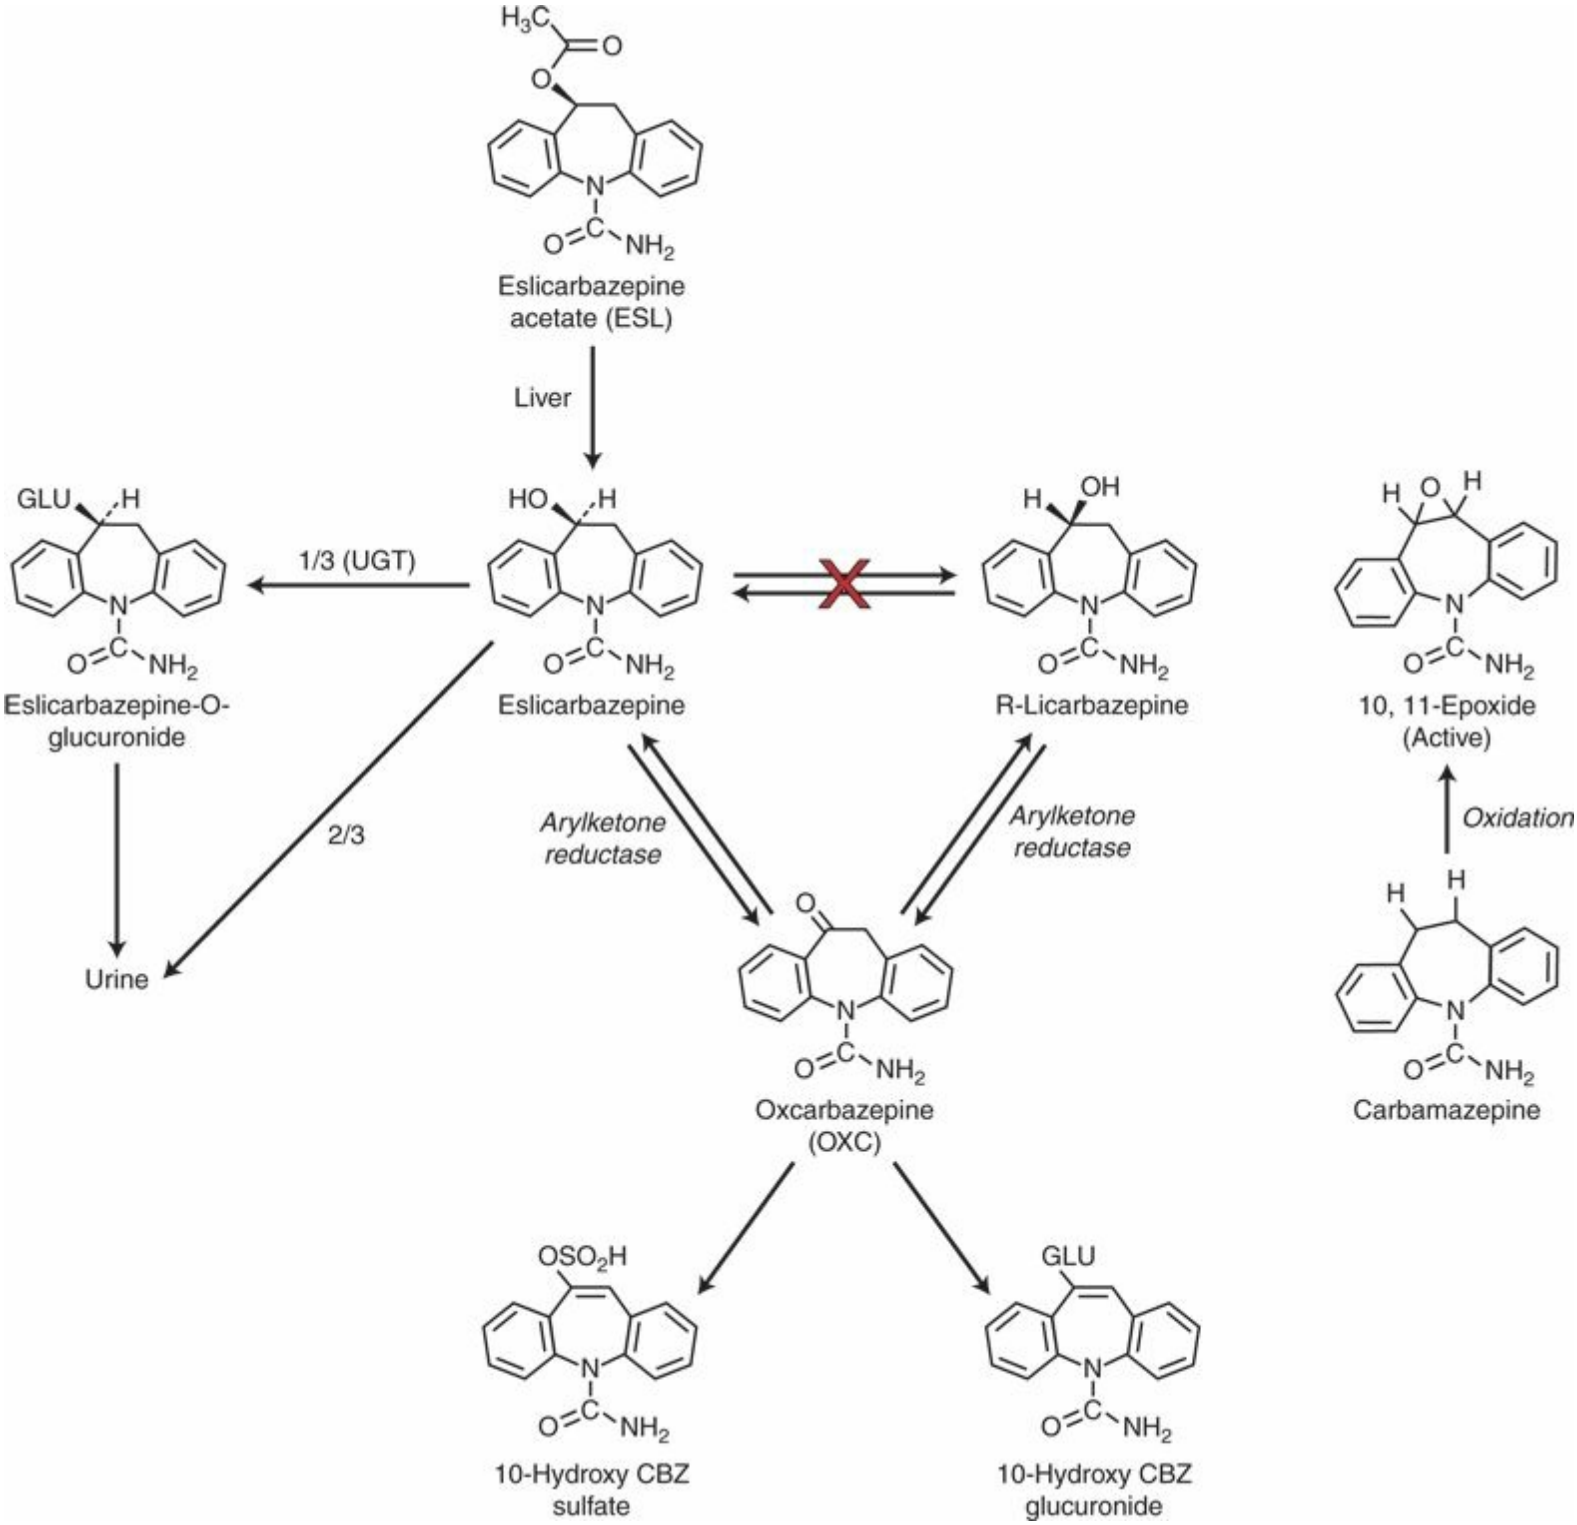

Figure 51.1. Chemical structure and main first-step metabolic pathways of oxcarbazepine and carbamazepine, and their active metabolites, MHD and CBZ-10,11-eproxide (CBZ-E).

OXC as a prodrug is rapidly and completely metabolized to R- and S-licarbazepine, which together are sometimes referred to as the monohydroxy derivative of oxcarbazepine (MHD). CBZ and OXC (and also their active metabolites—CBZ epoxide and MHD) share many known actions of antiepileptic drugs (AEDs). They produce blockade of voltage-dependent ionic membrane conductance (especially sodium, potassium, and calcium), resulting in stabilization of hyperexcited neural membranes and synaptic actions of such neurotransmitters as γ-aminobutyric acid (GABA), glutamate, purine, monoamine, N-methyl-D-aspartate, and acetylcholine receptors; the effect is diminution of propagation of synaptic impulses (2). There are subtle differences in the mechanisms of

action of CBZ and OXC. For instance, MHD blocks N-type calcium channels, whereas CBZ blocks L-type (3). ESL, being converted into the active enantiomer of MHD (S-licarbazepine), is presumed to act in the same manner as does OXC. One recent study found that ESL maintains its effect on Na^+-channel currents even in mice who lack the B subunit of the channel, in sharp contrast to CBZ; this effect is also seen with lacosamide, and raises the possibility that ESL may have at least some effects that are distinct from CBZ (4).

Circulating MHD exists as a racemic mixture composed of S-licarbazepine and R-licarbazepine. There appear to be potentially important differences in pharmacologic activity between these two enantiomers. For example, the affinity of R-licarbazepine appears to be about fourfold greater for voltage-gated sodium channels when in the resting state (vs. inactive state) as compared to S-licarbazepine. In addition, R-licarbazepine may block voltage-gated potassium channels (Kv7.2 currents), whereas S-licarbazepine does not. Finally, administration of eslicarbazepine was shown to inhibit acquisition of kindling in mice, whereas R-licarbazepine administration did not (5).

CARBAMAZEPINE

Absorption and Distribution

CBZ is absorbed from the gastrointestinal tract slowly, with an estimated bioavailability of about 80% to 90%. The bioavailability of the agent is similar for all formulations—that is, tablets, solution, oral suspension, chewable tablets, and extended-release tablets/capsules. However, some studies have demonstrated the advantages in reducing serum level fluctuation with controlled-release forms of CBZ. Peak plasma concentration with chronic dosing is 3 to 4 hours. CBZ is a lipophilic compound that crosses the blood–brain barrier readily and is rapidly distributed to various organs, including fetal tissues and amniotic fluid as well as breast milk (6). Pharmacokinetic parameters are shown in Table 51.1 (7–9).

Table 51.1 Pharmacokinetic Parameters of CBZ, OXC, and MHD (7–9)

	F (%)	T_{max} (h)	V_d (L/kg)	Protein binding (%)	$t_{1/2}$ (h)	T_{ss} (d)	Therapeutic range (μg/L)	Dose (mg/kg/d)
CBZ	75–85	4–12	0.8–1.9	70–80	5–20	20–30	3–12	10–30
OXC	>95	1–2	—	—	2	—	—	10–50
MHD	—	3–5	0.75	40	8–15	2	8–20	—

CBZ, carbamazepine; OXC, oxcarbazepine; MHD, monohydroxy derivative; F, bioavailability; T_{max}, time interval between ingestion and maximum serum concentration; V_d, volume of distribution; protein binding, fraction to serum protein; $t_{1/2}$, elimination half-life; T_{SS}, steady state; therapeutic range, therapeutic range of serum concentration.

Metabolism

CBZ clearance is accomplished almost entirely via hepatic metabolism (9). The major pathways of CBZ biotransformation, consecutively or as parallel reactions, are the epoxide–diol pathway, aromatic hydroxylation, and conjugation. Metabolites from these major routes account for 80% to 90% of total urinary radioactivity. The main metabolites found in urine are due 40% to oxidation of the 10,11 double bond of the azepine rings, 25% to hydroxylation of the six-membered aromatic rings,

15% to direct N-glucuronidation at the carbamoyl side chain, and 5% to substitution of the six-membered rings with sulfur-containing groups. CBZ is oxidized by the cytochrome P450 system (CYP3A4 and CYP2C8 isoforms) to CBZ-10,11-epoxide (CBZ-E), which is considered the most important product of CBZ metabolism (see Fig. 51.1). CBZ-E is an active metabolite that may contribute to rash and other side effects associated with CBZ use. CBZ induces the activity of CYP3A4, with the metabolic clearance of CBZ-E nearly doubled in induced patients (6).

CBZ leads to autoinduction, which increases clearance (double in monotherapy), shortens serum half-life, and decreases serum concentrations. This process takes approximately 2 to 6 weeks to occur (6).

CBZ-E is hydrolyzed via the microsomal enzyme epoxide hydrolase to trans-10,11-dihydroxy-10,11-dihydrocarbamazepine (trans-CBZ-diol). The diol is excreted in the urine and accounts for 35% of a CBZ dose and is considered to be inactive. Another, somewhat less important metabolic pathway of CBZ is the hydroxylation at different positions of the six-membered aromatic rings. The third most important step in CBZ biotransformation is conjugation reactions. CBZ may be directly conjugated with glucuronic acid. Direct N-glucuronidation of CBZ and its metabolites depends on microsomal uridine diphosphate glucuronosyltransferase (UDPGT). Additionally, CBZ and its phenolic metabolites can be conjugated with sulfuric acid (6).

Drug Interactions

CBZ has a narrow therapeutic range, and plasma concentrations are often maximized to the upper limit of tolerance. As a low-clearance drug, CBZ is sensitive to enzyme induction or inhibition, especially by the large number of agents that induce or inhibit CYP3A4 isoenzymes. Drugs that inhibit CYPA34 increase plasma concentrations of CBZ.

CBZ, like phenytoin (PHT) and phenobarbital (PB), is a broad and potent inducer of the CYP450 isozyme system including CYP3A4, CYP2C9, CYP2C19, and CYP1A2 as well as UDP-glucuronyl transferase (UGT). As a result, the metabolism of other agents, including both AEDs, and numerous other non-AED medications is increased (10). Polytherapy with CBZ can therefore result in unpredictable plasma concentrations and, potentially, clinical effect of other medications. Pharmacokinetic interactions among CBZ, OXC, and AEDs are shown in Table 51.2 (7,11).

Table 51.2 Pharmacokinetic Interactions Among CBZ, OXC, and other AEDs (7,11)

	Effects of the addition of						
On levels of	CBZ	PHT	PB	PRM	VPA	OXC	ZNS
CBZ	↓	↓	↓	↓	↑E	↑E	↑E
OXC	↓	↓	↓	↓			

Note: Ethosuximide, felbamate, lamotrigine, gabapentin, tiagabine, pregabalin, levetiracetam, and vigabatrin addition do not affect level of OXC.

CBZ, carbamazepine; OXC, oxcarbazepine; PHT, phenytoin; PB, phenobarbital; PRM, primidone; VPA, valproate; ZNS, zonisamide; E, CBZ epoxide.

While neurologists tend to pay most attention to the effect of CBZ on other AEDs, the number of other drugs whose metabolism is induced by CBZ is vast; these include cancer chemotherapy, psychotropics, antibiotics, antithrombotic agents, antihypertensives, HMG-CoA reductase inhibitors,

immunosuppressants, and many more besides (11). The number of these is so extensive, in fact, that a full discussion of these is beyond the scope of this chapter, and the reader is referred to other sources for more detail (9).

These interactions can have a profound effect on the care of other health conditions aside from the patient's epilepsy, some of which are worth highlighting. The effectiveness of hormonal contraceptives, independent of preparation (oral, subcutaneous, intrauterine, implant, or injectable), is reduced by CBZ administration. Midcycle spotting or bleeding is a sign that ovulation has not been suppressed (10). Some practitioners believe that oral contraceptives should contain ≥50 μg of estrogen in the setting of CBZ treatment to overcome the induction, but there is a lack of good evidence to support this, so in view of the potential consequences, others take the view that OCP and CBZ should simply not be used together. Agents used for HIV infection are significantly reduced in level, and likely in efficacy, by concomitant use of enzyme-inducing AEDs, including CBZ; this is of such importance that it has generated a formal recommendation that the inducing drugs should be avoided when possible in HIV-infected patient (13). Warfarin metabolism is substantially induced by CBZ treatment, necessitating higher doses. With warfarin, and indeed all other concomitant hepatically metabolized drugs, discontinuation of CBZ will result in higher circulating levels of the other agent due to deinduction; this may result in drug toxicity. Factors pertaining to drug interaction constitute a major issue with CBZ treatment and need to be kept in mind whenever it is prescribed; the use of newer agents without such interactions avoids such complications and may be preferable in a wide range of clinical circumstances.

Efficacy

The efficacy of CBZ in patients with epilepsy was first demonstrated in the early 1960s (14). The agent continues to be a first-line treatment for patients with focal seizures.

Randomized, Monotherapy, Controlled Trials: CBZ Versus Other Agents

Most studies have demonstrated no difference in efficacy between CBZ and PHT as monotherapy for adults and children with epilepsy (14). No difference in efficacy was reported in trials comparing CBZ and PB in children. The second Veterans Administration (VA) Cooperative Study (15), a multicenter, randomized, double-blind, parallel-group trial, compared CBZ with valproate (VPA) for the treatment of 480 adults with complex partial (n = 206) or secondarily generalized (n = 274) seizures. The patient population comprised recently diagnosed, AED-naïve patients with epilepsy, as well as those who were being suboptimally treated. In patients with tonic–clonic seizures, there was no difference in efficacy between the two agents. However, CBZ appeared more efficacious than VPA for the treatment of patients with partial seizures, according to several outcome measures: number of seizures, seizure rate, seizure score, and time to first seizure. Other studies did not reveal any significant differences between CBZ and VPA in adults or children (14).

Large Trials Comparing Several AEDs with CBZ

The first VA study was a double-blind, comparative study of monotherapy with PB, PHT, primidone (PRM), and CBZ in 622 adults with partial and secondarily generalized tonic–clonic seizures (16). CBZ was found to be similarly as effective as PB, PHT, and PRM in controlling secondarily generalized tonic–clonic seizures. However, CBZ was more effective than barbiturates for the

treatment of partial seizures, whether simple or complex. No difference was found between CBZ and PHT.

Other studies in the United Kingdom (14) did not demonstrate any difference between CBZ and PB, PHT, or VPA. However, the patients from the United Kingdom had been recently diagnosed with epilepsy, whereas half of the patients in the VA trials had been previously treated. Nevertheless, the large number of patients with complex partial seizures in the VA studies may provide the power to detect statistically significant differences. Because of the above-mentioned data, CBZ has been considered a first-line AED for the treatment of focal and generalized tonic–clonic seizures and is used as an active control in trials of all new compounds.

A multicentric class I study (17) of 593 elderly subjects with newly diagnosed seizures, comparing gabapentin (GBP), lamotrigine (LTG), and CBZ, concluded that there were no significant differences in the seizure-free rate at 12 months, but the main limiting factor in patient retention was adverse drug reactions. Patients taking LTG or GBP did better than those taking CBZ. Seizure control was similar among the groups. Based on the findings, the authors proposed that LTG and GBP should be considered as initial therapy for older patients with newly diagnosed seizures.

CBZ has been tested against almost all new AEDs in monotherapy trials. The majority of these studies have shown no difference in efficacy between CBZ and LTG in adults, adolescents, and children, OXC (14), or topiramate (TPM) in children and adults (18). CBZ was significantly more efficacious than were vigabatrin (VGB) (19), remacemide (20), and probably GBP (21). Some studies have suggested that GBP, LTG, VGB, and OXC are better tolerated than is CBZ.

There are several methodologic limitations in many trials, with some satisfying regulatory agencies but not necessarily guaranteeing clinical use. Most studies are either undertaken with insufficient numbers of patients to demonstrate significant differences, or else the follow-up is relatively short, considering the seizure-free period, for a true improvement in quality of life to be realized.

An important study comparing CBZ and levetiracetam did not show difference in the efficacy and effectiveness between these AEDs (22).

The available data suggest that CBZ is as effective as any of the other AEDs that have been investigated. More studies that assess the economic impact of epilepsy treatment are warranted to compare several therapies.

According to the evidence-based analysis of the AED efficacy and effectiveness as initial monotherapy for adults with focal seizures, CBZ was considered a level A recommendation (23). Based on the same guidelines, CBZ is not a level A, but a level C recommendation for elderly patients with focal epilepsy.

Adverse Events

Accurate determination of adverse events has been a limitation in several AED trials. Systematic active questioning of patients has revealed a completely different picture of a spontaneously self-reporting adverse event. Although up to 50% of patients treated with CBZ experience adverse events, only 5% to 10% need to discontinue therapy (24,25).

Neurotoxicity

Most adverse events associated with CBZ use involve the central nervous system (CNS) and are mild, transient, and dose related; severe idiosyncratic reactions occur rarely. The most common

adverse events are nausea, gastrointestinal discomfort, headache, dizziness, incoordination, vertigo, sedation, diplopia or blurred vision, nystagmus, tremor, and ataxia. Adverse events are similar in children and more common in elderly patients (24,25).

As with most AEDs, CBZ may cause several psychic disturbances, including asthenia, restlessness, insomnia, agitation, anxiety, and psychotic reactions. Neuropsychological adverse events associated with nontoxic, chronic CBZ use are generally minimal. Some investigators believe that the use of a sustained-release preparation may be advantageous in both children and adults (25).

Movement disorders, including dystonia, choreoathetosis, and tics, are associated with the use of CBZ, possibly with toxic plasma levels of the agent.

Hypersensitivity Reactions

The incidence of rash with CBZ use is approximately 10% (16,26). CBZ causes the anticonvulsant hypersensitivity syndrome (AHS), characterized by fever, skin rash, and internal organ involvement (26,27). AHS is associated with the aromatic AEDs—that is, PHT, PB, PRM, CBZ, and LTG. AHS begins within 2 to 8 weeks after AED therapy initiation; the reaction usually starts with low- or high-grade fever, and over the next 1 or 2 days, a cutaneous reaction, lymphadenopathy, and pharyngitis may develop. Involvement of various internal organs may occur, resulting in hepatic, hematologic, renal, or pulmonary impairment. The most prominent manifestations are hepatitis, eosinophilia, blood dyscrasias, and nephritis. The most common cutaneous manifestation is an exanthema with or without pruritus. Rarely, severe skin reactions may occur, such as erythema multiforme, Stevens–Johnson syndrome, and toxic epidermal necrolysis (26). It is important for the management of the patient to be aware of acute cross-reactivity, which may be as high as 70% to 80% among CBZ, PHT, and PB (25,27). VPA is considered a safe, acute alternative for the treatment of patients with AHS. Systemic corticosteroids are usually required for full recovery (27).

Systemic lupus erythematosus may be induced by CBZ. Symptoms generally appear 6 to 12 months after initiation of therapy. Discontinuation of CBZ usually leads to disappearance of the symptoms. Hair loss associated with CBZ use has been reported. Myocarditis has been described as a manifestation of CBZ hypersensitivity (25).

Hematologic and Hepatic Effects

Transient leukopenia occurs within the first 3 months of treatment in 10% to 20% of patients taking CBZ. Persistent leukopenia, which is seen in 2% of patients, reverses with discontinuation of CBZ treatment (25). In the VA study, only one patient had a transient, clinically significant neutropenia (<1000 cells/mm^3) associated with CBZ use, and the treatment was not discontinued (16). Isolated thrombocytopenia associated with CBZ treatment has been described at a rate of 0.9 per 100,000. Aplastic anemia and agranulocytosis have been reported in association with the use of CBZ (9,24). Data from a population-based case–control study demonstrated that the risk of developing these reactions is five to eight times greater than in the general population (9).

Hepatic enzymes may be elevated in patients receiving CBZ treatment—mostly mild elevations with no clinical significance. Rarely, CBZ hepatotoxicity can be a serious adverse event that leads to death. Cases in pediatric patients are probably less common than in adults (24). Cardiac arrhythmias have also been associated with CBZ use (25).

Metabolic Effects

Because of its potent enzyme-inducing properties, CBZ has extensive effects upon metabolism owing to the involvement of CYP450 and other similar enzymes in many endogenous metabolic processes (28). CBZ is well established to increase serum cholesterol by an average of about 25 mg/dL; it also substantially increases lipoprotein(a), doubles C-reactive protein, and may increase homocysteine as well (29–31). All of these would be expected to increase the risk of ischemic vascular disease.

Over the past several years, bone health impairment and increased risk of fractures have been associated with epilepsy and AEDs, including CBZ, both in children and in adults. There is clear evidence that CBZ decreases 25-hydroxyvitamin D levels by about 25% to 30%, accompanied by increases in markers of bone turnover (12). Because of this, many authors recommend vitamin D and calcium supplementation. Nevertheless, there is no evidence-based guidance about the efficacy of dietary supplements or the appropriate amount to be used (32,33). It is also unclear whether CBZ actually reduces bone density or increases fracture risk, with the evidence being mixed on that score (34–37).

The effect of CBZ on metabolism of testosterone, pituitary responsiveness to gonadotropin-releasing hormones, prolactin, follicle-stimulating hormone, and luteinizing hormone have been studied, although the clinical relevance of the findings has not been thoroughly elucidated (25,38). CBZ has been repeatedly shown to reduce bioactive testosterone, but not total testosterone, apparently via induction of sex hormone–binding globulin. While sizable, the clinical impact of this testosterone decrease is uncertain, with contradictory evidence regarding its effects on male sexual function (39).

Although thyroid function tests may be abnormal due to CBZ use, treated patients remain clinically euthyroid. Because of the induction effect of CBZ on the metabolism of thyroid hormones, hypothyroid patients may require higher doses of T_4 to maintain euthyroid states (25).

Hyponatremia is an adverse event seen commonly by CBZ treatment. The risk for hyponatremia increases in proportion to the dose CBZ and age of the patient; it is unusual in children (25). Clinical significant hyponatremia, usually defined as sodium ≤125, is quite rare.

Weight gain is an occasional side effect associated with the use of CBZ, although it is nowhere near as pronounced as with VPA use (25)—typically in the range of 2 to 4 kg.

Teratogenic and Postnatal Effects

As with other established AEDs, CBZ exhibits teratogenic effects. CBZ exposure has also been associated with neural tube defects and major congenital malformations in monotherapy (40). Polytherapy with two or more agents significantly elevates the teratogenic risk. Despite uncertainty about the efficacy of periconceptional folate supplementation in women with epilepsy, most authors recommend its use at the same dosage as that recommended for the general population: 0.4 to 0.6 mg/day. Women taking CBZ should have prenatal diagnostic ultrasonography to detect any congenital malformations. The overall risk for CBZ causing major congenital malformation appears relatively low. Breast-feeding is considered safe for women being treated with CBZ.

A fetal AED exposure study revealed that CBZ is safer than VPA when cognitive outcomes at age 6 years are concerned (41). The North American AED Pregnancy Registry (40) assessed the safety of AEDs during pregnancy. The risk of major malformations was 3.0% for CBZ and 2.0% for lamotrigine, showing that CBZ is one of the safest AEDs during pregnancy (40). Nevertheless, when

efficacy is concerned, pregnancies exposed to lamotrigine were less likely to be seizure free than were pregnancies exposed to CBZ (42).

Clinical Use

CBZ is one of the agents of choice for the treatment of structural–metabolic and unknown cause focal epilepsies, as well as for generalized tonic–clonic seizures. CBZ is available as 100-mg chewable tablets; 200-mg tablets; and 100-mg, 200-mg, and 400-mg extended-release tablets for oral administration. CBZ is also available as a 100-mg/5 mL (60 mg/mL) oral suspension (9). Doses must be adjusted individually because of great variability in different epileptic syndromes and intra- and interindividual responses.

CBZ treatment should be initiated with 100 to 200 mg/day in adults and children >12 years of age. Increments up to an initial target dose of 400 to 800 mg (10 mg/kg) in adults (60 to 80 kg) (14,15,22) and changes at weekly intervals are preferred. Risk for AHS or rash is higher with rapid titration. Newly diagnosed patients usually require lower doses than those with chronic epilepsy.

For children under 6 years of age, CBZ treatment should be initiated with 10 to 20 mg/kg/day, with a twice-daily or thrice-daily regimen. Doses can be increased at weekly intervals to achieve doses below 35 mg/kg. If a satisfactory clinical response has not been achieved, plasma levels should be measured to determine whether or not they are in the therapeutic range (9).

Maintenance dosage should be adjusted to the minimum effective level, usually 400 to 1200 mg daily in adults. Dosage generally should not exceed 1000 mg daily in children 12 to 15 years of age and 1200 mg daily in patients above 15 years of age. Doses up to 1600 mg daily have been used in adults in rare instances (9). If seizures cannot be controlled, doses should be gradually increased by 100- or 200-mg increments until either control is achieved or unacceptable adverse events appear.

Although plasma level monitoring is a useful tool for the clinician, it has no definitive value. It is necessary to push the CBZ dose to the maximum clinically tolerated dose, independent of plasma level, in uncontrolled patients. Plasma level monitoring may be useful in the range of 4 to 12 mg/L (14). The dosage interval depends both on the severity of the epilepsy and on the difficulty with control. Most responsive patients, such as those newly diagnosed, need modest doses twice daily. If higher doses are necessary, however, toxicity may be avoided by taking CBZ three times per day. Two or three times per day provides similar levels, with fluctuations of 57% ± 20% and 56% ± 29%, respectively. In children, the interdose variation was 21% for patients receiving CBZ sustained-release and 41% for those treated with standard CBZ preparation. Children metabolize CBZ faster than do adults and thus may need higher doses. Elderly patients retain their sensitivity to dose-dependent autoinduction and heteroinduction by CBZ, but their metabolism rates remain considerably lower than those observed in matched controls. As a result, elderly individuals will require a lower dosage to achieve serum concentrations comparable to those found in nonelderly adults (14). In patients receiving doses that approximate the maximal tolerated doses, the use of sustained-release formulations of CBZ twice daily may minimize dose fluctuations and may help to adequately control seizures (25). On the other hand, a recent review does not confirm or refute the superiority of the sustained-release formulation with respect of seizure frequency in patients with newly diagnosed epilepsy. This study showed a trend for sustained-release CBZ to be associated with fewer adverse events when compared to immediate-release CBZ (43).

Precautions and Contraindications

CBZ should not be used in patients with a known hypersensitivity to any tricyclic antidepressant or to OXC. Use of CBZ can worsen some epileptic conditions by aggravating preexisting seizures or by leading to new seizure types, particularly absence and myoclonic seizures. An increase in the number of generalized seizures has been documented in children (14).

Serious and sometimes fatal dermatologic reactions, including toxic epidermal necrolysis and Stevens–Johnson syndrome, have been reported with CBZ treatment. The risk of these events is higher in patients with a particular human leukocyte antigen (HLA) allele: HLA-B* 1502. This allele occurs almost exclusively in patients with Asian ancestry. The U.S. FDA (44) has recommended genetic screening for the HLA-B* 1502 allele in patients of Asian ethnicity before starting CBZ therapy.

Aplastic anemia and agranulocytosis have been reported in association with CBZ treatment. Patient with history of adverse hematologic reaction to any drug may be particularly at risk of bone marrow depression (9).

OXCARBAZEPINE

Absorption, Distribution, and Metabolism

Orally administered OXC is rapidly and almost completely absorbed, with absorption being largely unaffected by food. As discussed earlier, the pharmacologic effect of OXC in humans is exerted predominantly through its main metabolite, MHD, which is a racemic mixture of R(-) and S(+) enantiomers. This metabolic pathway accounts for its unique pharmacokinetic and pharmacodynamic profile (45,46) (see Fig. 51.1). OXC undergoes rapid and extensive metabolism via ketoreduction to MHD. Oral absorption of OXC is extensive (>95%) and rapid. At steady state, peak concentrations of MHD are seen within about 2 to 4 hours following drug ingestion. The half-life of OXC is 1 to 3.7 hours, and the half-life of MHD is 8 to 10 hours. As a lipophilic compound, MHD is widely distributed throughout the body and easily crosses the blood–brain barrier (47). The plasma protein binding of MHD is approximately 40%, which is less than that of CBZ (70% to 90%). Steady state is achieved after three to four doses. At steady state, the pharmacokinetics of OXC is linear over the dose range of 300 to 2400 mg/day (48). After oral administration of ^{14}C-labeled MHD, most of the dose is excreted in the urine within 6 days after dosing, <1% as unchanged drug (46). As with most AEDs, placental transfer of OXC appears to occur.

Drug Interactions

OXC exhibits no enzyme autoinduction and has a moderate potential for heteroinduction. Induction of the cytochrome P450 system is less pronounced with OXC than with CBZ (46,48). Therefore, polytherapy is much simpler with OXC. Levels of the MHD are not significantly modified by felbamate, LTG, PHT, or VPA (49). CBZ and PB may decrease levels of MHD, so dosage adjustments may be necessary (48).

Whereas CBZ induces many cytochrome P450 isoenzymes (CYP1A2, CYP2C9, CYP2C19, and CYP3A4), OXC is a weak inhibitor of CYP2C19 and a weak inducer of CYP3A4. Since CYP2C19 is involved in PHT metabolism, OXC may increase plasma levels of PHT. As the CYP3A subfamily is responsible for the metabolism of estrogens, oral contraceptive levels may be lower in patients receiving OXC therapy (49). The same precautions used with CBZ therapy apply to OXC therapy,

relative to coadministration with hormonal contraceptives.

Efficacy

Monotherapy

Most studies found OXC to be efficacious as monotherapy for patients with focal and generalized tonic–clonic seizures. OXC has a similar efficacy to CBZ, but with a more favorable tolerability profile (50).

In two large, similarly designed trials of previously untreated patients with recently diagnosed epilepsy, OXC was as effective as PHT (51) and VPA (52). A total of 287 adult patients with either focal or generalized tonic–clonic seizures were randomized in a double-blind, parallel-group comparison of OXC and PHT (51). In the efficacy analyses, no statistically significant differences were found between the treatment groups. Seventy patients (59.3%) in the OXC group and 69 (58%) in the PHT group were seizure free during the 48-week maintenance period (47). In the comparison of OXC and VPA (52), 249 adult patients with either focal or generalized seizures were randomized. As with OXC and PHT, no statistically significant differences were found between the treatment groups in the efficacy analyses. Sixty patients (56.6%) in the OXC group and 57 (53.8%) in the VPA group were seizure free during the 48 weeks of maintenance treatment (52).

A multicenter, double-blind, randomized, parallel-group trial compared the efficacy of two different doses of OXC as monotherapy in a refractory epilepsy patient population. In the intent-to-treat analysis, 12% of patients in the higher-dose (2400 mg/day) OXC group were seizure free, compared with 0% in the lower-dose (300 mg/day) OXC group (53).

In another monotherapy trial, OXC was compared with placebo in a double-blind, randomized, two-arm, and parallel-group design in hospitalized patients with refractory focal and generalized seizures. Both primary and secondary efficacy variables showed a statistically significant effect in favor of OXC (54).

In children and adolescents with newly diagnosed epilepsy, a double-blind, controlled clinical trial of OXC versus PHT showed that OXC was comparable to PHT in terms of efficacy, but had significant advantages over PHT in terms of tolerability and treatment retention (55). A total of 193 patients 5 to 18 years of age with either focal or generalized tonic–clonic seizures were enrolled. In the efficacy analyses, no statistically significant differences were found between the treatment groups. Forty-nine patients (61%) in the OXC group and 46 (60%) in the PHT group were seizure free during the 48-week maintenance period (55).

A long-term extension phase of two multicenter, randomized, double-blind, controlled trials (51,55) showed that the estimated seizure-free rate after 52 weeks on open follow-up was 67.2% with OXC and 62.2% with PHT. These 2-year studies revealed that the majority of patients were seizure free, suggesting an improvement in seizure control during the 2nd year of OXC monotherapy.

Adjunctive Therapy

Several adjunctive studies have shown that patients treated with OXC experienced a significantly greater reduction in focal seizure frequency than those treated with placebo (48).

Adverse Events

Monotherapy

The main adverse events associated with OXC treatment are CNS-related effects, gastrointestinal symptoms, and idiosyncratic reactions (50–56). The most common adverse events are somnolence, headache, dizziness, diplopia, fatigue, nausea, vomiting, ataxia, abnormal vision, abdominal pain, tremor, dyspepsia, abnormal gait, and rash.

When OXC was compared with placebo (54), most adverse events with OXC were mild or moderate in intensity and similar to those with placebo. Adverse events reported at some time during the trial by ≥5% of all treated patients were headache, nausea, dizziness, pruritus, somnolence, diplopia, vomiting, fatigue, constipation, dyspepsia, and insomnia. Each of these adverse events occurred with greater frequency in the OXC treatment group. Three patients in the OXC group discontinued treatment prematurely—one for a transient rash, one for postictal psychosis, and one for an administrative reason. Two patients discontinued prematurely from the placebo group, both for administrative reasons.

The trial that compared OXC with PHT (51) showed that the number of premature discontinuations due to adverse experiences with OXC was significantly lower than that with PHT. Five of 143 patients in the OXC group discontinued treatment because of tolerability reasons—rash in one case, pregnancy in one case, an astrocytoma not previously diagnosed in one case, a suicide attempt with OXC intoxication in one case, and gastrointestinal discomfort combined with depression/anxiety in one case. Sixteen of 144 patients in the PHT group discontinued treatment because of tolerability reasons—rash in 10 cases, hirsutism/gum hypertrophy in 5 cases, and cerebellar symptoms/sedation in the last case. Somnolence, headache, dizziness, nausea, and rash occurred in ≥10% of the patients in both groups. Gum hyperplasia, tremor, diplopia, acne, nervousness, and nystagmus occurred in <10% of the patients in both groups (51). When differences in the incidence of adverse events were apparent between the groups, these were nearly all in favor of OXC therapy.

The comparison of OXC and VPA in 249 adults revealed no statistically significant difference between treatment groups with respect to the total number of premature discontinuations or those due to adverse events. The most frequent reason for withdrawal due to adverse events in the OXC group was allergic reaction with skin symptoms (6 patients); in the VPA group, it was hair loss (4 patients). The most common adverse events considered to have a causal relationship to the trial treatment were somnolence, weight increase, fatigue, headache, alopecia, dizziness, nausea, tremor, abdominal pain, impaired concentration, increased appetite, and diarrhea. When differences in incidence existed between the groups, these generally favored OXC treatment. Abnormally low plasma sodium levels were reported in two OXC-treated patients. Both patients were asymptomatic with respect to their low plasma sodium levels, and neither discontinued treatment prematurely (52).

In another study of OXC monotherapy for focal seizures, most of the adverse events were transient and rated as mild to moderate in intensity (53).

The trial that compared the efficacy and safety of OXC with that of PHT in 193 children and adolescents (55) found that two patients in the OXC group and 14 patients in the PHT group discontinued treatment prematurely for tolerability reasons. The number of premature discontinuations due to adverse events was statistically significantly lower in the OXC group than in the PHT group. Moreover, the odds of an individual discontinuing prematurely were almost twice as high in the PHT group. Based on the findings of this trial, the authors concluded that OXC has significant advantages

over PHT in terms of tolerability and treatment retention.

OXC therapy in elderly patients (≥65 years of age) seems as safe as treatment in younger adults. The four most common adverse events experienced by elderly patients were vomiting (19%), dizziness (17%), nausea (17%), and somnolence (15%). Three of 52 patients developed an asymptomatic hyponatremia, with at least one patient's serum sodium level <125 mequiv./L (56).

Adjunctive Therapy

The study that evaluated the safety of a broad OXC dosage as adjunctive therapy in patients with uncontrolled focal seizures (56) found that the most common adverse events were related to the nervous and digestive systems. Rapid and fixed titration to high doses was associated with an increased risk for adverse events, which could potentially be reduced by adjusting concomitant AEDs and using a slower, flexible OXC titration schedule.

The trial that compared the safety of OXC with placebo as adjunctive therapy in children with inadequately controlled focal seizures (56) found that 91% of the OXC group and 82% of the placebo group reported at least one adverse event. Vomiting, somnolence, dizziness, and nausea occurred more frequently in the OXC-treated group. The majority of these adverse events were mild to moderate in severity. The incidence of rash was 4% in the OXC group and 5% in the placebo group. Fourteen patients (10%) in the OXC group and 4 patients (3%) in the placebo group discontinued treatment prematurely because of adverse events. The most common reasons for discontinuation in the OXC group were adverse events involving the digestive system (primarily nausea and vomiting), which occurred in 5 patients, and rash (maculopapular and erythematous), which occurred in 4 patients.

Hyponatremia

Hyponatremia is usually defined as a serum sodium level <135 mequiv./L. Clinically significant hyponatremia (sodium level <125 mequiv./L) has been observed in 2.5% of OXC-treated patients in 14 controlled trials (48). Acute symptoms of hyponatremia include headache, nausea, vomiting, tremor, delirium, seizures, and decerebrate posturing, whereas chronic symptoms include anorexia, cramps, personality changes, gait disturbance, stupor, nausea, and vomiting (48). The 14 trials that evaluated 1966 patients showed that hyponatremia increased with age, from 0% at <6 years and 0.5% at <18 years to 3.4% between 18 and 64 years and 7.3% at >65 years (48,56,57). OXC-induced hyponatremia has not been attributable to the syndrome of inappropriate secretion of antidiuretic hormone. Possible mechanisms include a direct effect of OXC on the renal collecting tubules or an enhancement of their responsiveness to circulating antidiuretic hormone. Although hyponatremia has been reported, it is only rarely accompanied by clinical symptomatology and rarely leads to OXC discontinuation. The degree of hyponatremia seems to be related to the dose of OXC. Rapid titration may be another risk factor (57).

Other Potential Adverse Events

An analysis of 29 trials involving 2191 patients treated with OXC for up to 11.5 months showed no clinically significant weight changes in the OXC group compared with the placebo group (58). However, the authors have seen patients with weight gain that reversed with OXC substitution. This information is also described in very few other clinical trials (48).

OXC in monotherapy or combination therapy has no effect on blood pressure and electrocardiograms (48).

A few studies have evaluated the teratogenicity of OXC. The risk associated with OXC monotherapy in a recent study was 2.2% (40).

OXC does not appear to affect cognitive function in healthy volunteers or adults with newly diagnosed epilepsy. The cognitive effects of the agent in children and adolescents have not been systematically studied (59).

OXC, like CBZ, has been reported to aggravate some seizures in children (60). Clinical and EEG monitoring may be important, especially in patients who do not show adequate response to OXC.

Clinical Use

OXC is indicated for use as monotherapy or adjunctive therapy in the treatment of focal and generalized tonic–clonic seizures in adults and children 4 to 16 years of age and as adjunctive therapy in the treatment of focal seizures in children 2 to 16 years of age. OXC is available as 150-mg, 300-mg, and 600-mg film-coated tablets for oral administration. OXC is also available as a 300-mg/5 mL (60 mg/mL) oral suspension (48). It can be taken with or without food. An extended-release once-daily oral preparation became available in 2013 with 150-mg, 300-mg, and 600-mg tablets (61).

In adults, treatment with OXC monotherapy should be initiated at a dose of 300 to 600 mg/day. Increases at weekly intervals are advisable and titration should be planned according to the clinical condition of the patient, since slow and gradual initiation of therapy minimizes side effects. In the case of frequent seizures, the interval may be shortened (e.g., every 2nd day). Another option to achieve rapid therapeutic level of MHD can be a single loading dosage of 30 mg/kg (62). This study showed that oral loading of OXC is an effective and well-tolerated method for rapidly achieving therapeutic level of MHD.

The recommended monotherapy dosage is 600 to 1200 mg/day in two divided doses. OXC dosages range from 600 to 3000 mg/day. As adjunctive therapy, treatment with OXC should be initiated at a dose of 600 mg/day, administered as a twice-daily regimen. The recommended dosage for adjunctive therapy is 1200 mg/day or higher, if needed, which may be increased at weekly intervals. In controlled trials, most patients were not able to tolerate a 2400 mg/day dose, mainly due to CNS side effects (48).

In children, treatment should be initiated at a daily dose of 8 to 10 mg/kg administered as a twice-daily regimen. The target maintenance dose of OXC should be achieved over 2 weeks and is dependent upon the patient's weight (900 mg/day for 20 to 29 kg, 1200 mg/day for 29.1 to 39 kg, and 1800 mg/day for >39 kg). For patients under 20 kg, a starting dose of 16 to 20 mg/kg may be considered. The maximum maintenance dose should be achieved over 2 to 4 weeks and should not exceed 60 mg/kg/day in a twice-a-day regimen (48). The pharmacokinetics of OXC are similar in older children (>13 years of age) and adults. However, younger children (<13 years of age) have an increased clearance compared with older children and adults. Therefore, the OXC dose per body weight may be up to twice that of adults for children 2 to <4 years of age and 50% higher than the adult dose for children 4 to <12 years of age (48).

A multicentric study has shown improvement in the quality of life in patients with focal seizures after conversion to OXC monotherapy (63).

Therapeutic drug monitoring is claimed to be of little or no value with OXC because of the linear pharmacokinetics of the agent, although measuring drug levels is undoubtedly useful for

individualization of treatment in selected cases in a particular clinical setting. The plasma concentration associated with antiepileptic effect was reported to be 5 to 50 mg/L (46).

It is believed that there is no need to monitor sodium levels regularly in asymptomatic patients, unless there are special risks, such as in patients taking high doses or diuretics and in the elderly individuals. OXC is not a drug of first choice for the elderly patients (57).

ESLICARBAZEPINE

Pharmacology

In the acetate form in which it is marketed, ESL is essentially completely converted from the acetate form to eslicarbazepine proper by first-pass hydrolysis, with oral bioavailability of over 90% and peak plasma concentrations occurring 1 to 4 hours post dose. As discussed previously, it is the S-enantiomer that is believed to be primarily responsible for the anticonvulsant activity of either OXC or ESL. Protein binding of ESL is under 40%. The drug exhibits linear pharmacokinetics throughout the clinical dose range. The apparent volume of distribution for an average (70 kg) person was calculated as 61 L. Metabolites, including glucuronides of OXC and R-licarbazepine, account for only 9% of systemic exposure. Unlike CBZ, there is no autoinduction of metabolism, with elimination half-life ranging from 13 to 20 hours and remaining stable with chronic dosing. Excretion is renal, with eslicarbazepine and its glucuronide accounting for 90% of this and minor metabolites for the remainder.

The pharmacokinetics of ESL are similar in the elderly to the younger population, and the drug is not affected by mild or moderate hepatic dysfunction. Renal function has a substantial impact, however, with exposure increasing 60% to 100% and 150% for mild, moderate, and severe renal failure, respectively, leading to a formal recommendation that doses for the latter two groups should be halved.

Efficacy

A preliminary trial to assess the most appropriate dosing regimen for ESL (64) arrived at a very surprising result: not only was once-daily dosing fully effective, but twice-daily dosing (between 200 and 600 mg BID) failed to separate from placebo using the primary outcome measure.

As a consequence of this, the subsequent pivotal phase III adjunctive therapy trials were all done using once-daily dosing of ESL in adult patients with focal epilepsy. The first of these tested doses of 400, 800, and 1200 mg daily, with the result that the low dose did not separate from placebo, while the middle and higher doses were clearly effective in reducing seizure frequency; using the primary outcome measure, percentage reduction in seizures, there was essentially no difference in efficacy between those two doses (65). A second study, also using the same three doses in a once-daily fashion, produced very similar results, with the 400-mg dose not significantly effective and the 800-mg and 1200-mg doses significantly and equally effective (66). The third study utilized only the two higher doses, each of which resulted in a significant decrease in seizure frequency of about 40% (compared to 17% in the placebo group) (67).

Interestingly, the most common concomitant AED used in the population in these three studies was CBZ, and in at least two of the trials, analyses suggested no difference in efficacy when comparing patients taking ESL with CBZ to those taking ESL with other AEDs (65,66). All trials excluded

patients taking OXC. As is typical of regulatory trials, all of these were of relatively short duration (12 weeks); open-label extensions were performed, though those are uncontrolled and thus of uncertain value. A metaanalysis of these four trials found that the responder rate (chance of achieving a ≥50% reduction in seizures) was 36%, nearly double the rate in the placebo group, while the chance of seizure freedom over the trial was about 7%, three times higher than the placebo group (68).

Adverse Effects

Similar to OXC, side effects with ESL are almost entirely CNS-related: symptoms such as dizziness, somnolence, headache, diplopia, vertigo, and cognitive impairment were those most commonly reported in studies. The aforementioned metaanalysis of ESL trials found that the three adverse effects seen with drug significantly more often than with placebo were dizziness, nausea, and diplopia, each occurring about three times more commonly with ESL treatment than with placebo. Based upon the drug's mechanism of action, and clinical experience, one would expect that these effects would be more common when ESL is used with another sodium channel–blocking agent (e.g., CBZ, PHT, lamotrigine, lacosamide). Like all newer-generation AEDs, ESL carries a warning regarding suicidal thoughts and behavior based upon an FDA metaanalysis that clinicians in the field consider dubious at best.

Hyponatremia, seen sometimes with CBZ and frequently with OXC, occurs more rarely during ESL treatment, with clinically significant hyponatremia ($Na^+ \leq 125$) occurring in only 1% to 1.5% of patients. Elevations of liver function tests have been reported, though not hepatic failure. Again, like its cousins, ESL can cause serious allergic reactions, including Stevens–Johnson syndrome, drug rash with eosinophilia and systemic symptoms (DRESS), and angioedema with anaphylaxis. Patients who have had an allergic reaction to CBZ or OXC should not be treated with ESL owing to the great similarity in structure between these agents and the potential for a dangerous reaction.

Total ESL exposure, as measured by the area under the time–concentration curve (AUC), is reduced by about a third in the presence of the enzyme-inducing AEDs PHT, CBZ, or PB. This is presumably due to induction of the UGT enzymes, which mediate glucuronidation of ESL. A higher dose of ESL may be necessary as a consequence (bearing in mind, with the former two agents, the potential for synergistic toxicity due to sodium channel blockade).

ESL appears to inhibit CYP2C19, which is prominently involved in the metabolism of PHT. PHT peak concentrations (C_{max}) and area under the curve (AUC) increased by about a third when ESL was given concomitantly. This may necessitate a PHT dose decrease; monitor levels and adjust accordingly. The drug reduces the AUC for topiramate by a modest amount (15% to 20%), but this may not be clinically important. The drug has no effect on other AEDs studied, including CBZ, PHT, PB, VPA, gabapentin, levetiracetam, lamotrigine, or clobazam.

As with its cousins CBZ and OXC, the potential for induction of CYP450 and other metabolic enzymes led to drug interaction studies. The good news is that ESL has no effect on metformin, digoxin, or warfarin (based upon coagulation parameters in the treated patients). The bad news is that, like its aforementioned relatives, ESL appears to significantly increase metabolism of the active components of oral contraceptives in a dose-dependent fashion, with the estrogen affected at the 800 mg ESL dose (decrease in AUC by 30%) and both the estrogen and progestin impacted at the 1200-mg ESL dose (AUC decrease by about 40%) (69). While some have advocated for the use of higher-dose contraceptive pills to overcome what is presumably due to CYP450 enzyme induction, there is

no convincing evidence for this, and in view of the serious potential consequences, this author's policy has always been to insist that a patient obtain either a new AED or a new contraceptive method.

There is somewhat more mixed news in the form of ESL's interaction with simvastatin. Plasma exposure to simvastatin is reduced by 50% to 60% in the presence of ESL, and the active metabolite of the simvastatin is reduced by 40% to 50%, presumably due to induction of CYP3A4 (69). However, a recent abstract suggested that, despite this, there seemed to be no effect on patients' lipid levels (70). Thus, the clinical impact of this interaction remains to be determined.

Clinical Use

ESL is presently approved for add-on treatment of focal epilepsy in patients age 18 and older. There are virtually no data regarding its use in children. Its similarity to CBZ and OXC would suggest that it is unlikely to be effective for generalized epilepsies and in fact could exacerbate them, as CBZ is known to do. The drug is not indicated to be used in combination with OXC because the studies did not include any OXC-treated patients.

The drug is manufactured in 200-mg, 400-mg, 600-mg, and 800-mg tablets, with all but the 400-mg tablet being scored. The formally approved titration schedule entails simply starting at 400 mg once daily and increasing to 800 mg daily in a week. As the 400-mg dose was not demonstrated effective in the trials, and 1200-mg showed little to no increased efficacy over the 800-mg dose (and a higher incidence of adverse effects), a dose of 800 mg daily seems the only reasonable target. Increase to 1200 mg daily may be considered if efficacy is inadequate and there are no tolerability issues, though it will take time to amass the clinical experience to determine if this is worthwhile.

Use of the drug is not affected by mild to moderate hepatic impairment (severe hepatic disease has not been studied). Renal insufficiency does have an impact, however, and both the initial and target doses should be halved in patients with moderate to severe renal impairment.

Pending more extensive clinical experience, it would seem prudent to prioritize the use of ESL with drugs that do not act on the sodium channel rather, as this might reduce the incidence of side effects. Further time and clinical data will be needed to ascertain this, as well as to ascertain whether the drug might have a place as early monotherapy for focal epilepsy.

CARBAMAZEPINE VERSUS OXCARBAZEPINE VERSUS ESLICARBAZEPINE

CBZ and OXC are among the most efficacious AEDs available. The literature suggests that CBZ and OXC do not differ in terms of seizure control efficacy. However, OXC has a better safety profile, including its association with fewer severe adverse events, such as idiosyncratic reactions, aplastic anemia, and agranulocytosis. Except for sodium monitoring under special circumstances with OXC treatment, laboratory monitoring of drug levels is not necessary. The OXC pharmacokinetic profile is also better than that of CBZ, with lack of autoinduction, low protein binding, and minimal drug interactions, except with contraceptive use. OXC does not appear to change endogenous hormonal levels—though it likely induces the metabolism of vitamin D (71)—and OXC also does not appear to affect serum lipids (72). These considerations suggest OXC should be considered one of the first-line treatment options for patients with focal seizures. According to the ILAE guidelines, OXC was considered a level A recommendation for efficacy and effectiveness as initial monotherapy for

children with focal seizures (23).

In some cases, a decision may be made to switch a patient from CBZ to OXC. This can either be done gradually or with a more abrupt changeover. Typically, the conversion ratio for similar efficacy is on the order of 1:1.5.

ESL is quite new as of this writing, and more clinical study and clinical experience will be needed to determine its appropriate place in epilepsy treatment algorithms. Both its efficacy and its tolerability relative to CBZ or OXC remain unassessed. ESL seems not to affect serum lipids [Sunovion, data on file], and it may have the more limited drug interaction profile of OXC, thus representing an improvement over CBZ with its diffuse metabolic effects. When comparing ESL to OXC, the former's once-daily dosing surely represents an advance with regard to convenience and compliance, and the reduced incidence of hyponatremia relative to OXC is also a clear improvement. Whether this or other considerations are sufficient to justify the difference in cost between patented ESL and generically available OXC remains to be determined. The imminent availability of once-daily sustained-release forms of OXC makes this calculus even more complex.

CHAPTER 52 ETHOSUXIMIDE

ANDRES M. KANNER AND RAMSES RIBOT

INTRODUCTION

Ethosuximide (ETS) is one of the first-generation antiepileptic drugs (AEDs) that, despite the advent of several new AEDs, continues to maintain its position as a first-line treatment of absence seizures. Its narrow therapeutic profile has limited its use to the treatment of childhood absence epilepsy. Some studies have also suggested a potential therapeutic effect in epileptic negative myoclonus (1) and encephalopathy with status epilepticus during sleep (ESES) (2,3). In addition, data from several experimental animal models of pain suggest that ETS may have potential analgesic properties. Despite its 52-year existence in the market, additional research continues to further elucidate the mechanisms of action of this AED. The purpose of this chapter is to review the latest experimental and clinical data of ETS.

HISTORICAL BACKGROUND

The development of ETS was a response to the need in the 1950s to develop a more effective, safer, and better-tolerated anticonvulsant for the treatment of absence seizures (4). Introduced in the 1940s, trimethadione and its analog paramethadione were the first anticonvulsants to demonstrate efficacy against absence seizures, but they were associated with significant toxicity (5– 8). These toxicity issues spurred the discovery and testing in the 1950s of the succinimide family of anticonvulsants (ETS, methsuximide, and phensuximide) (8). Of the succinimides, ETS had the greatest efficacy and least toxicity when used against absence seizures (8). Because of this combination of efficacy and safety, ETS has been considered as first-line therapy for absence seizures since its introduction in 1958 (9,10).

CHEMISTRY

ETS (2-ethyl-2-methylsuccinimide), with a molecular mass of 141.2, is a chiral compound containing a five-member ring, with two negatively charged carbonyl oxygen atoms with a ring nitrogen between them and one asymmetric carbon atom (11,12) (Fig. 52.1). Its chemical characteristics include a melting point of 64°C to 65°C, a weakly acidic pK_a of 9.3, and a partition coefficient of 9 (chloroform-to-water; pH 7) (12). ETS is freely soluble in ethanol and water (solubility, 190 mg/5 mL) (10). Being a white crystalline material, ETS is used clinically as a racemate and is commercially available in 250-mg capsules or 250 mg/5 mL of syrup (9,11).

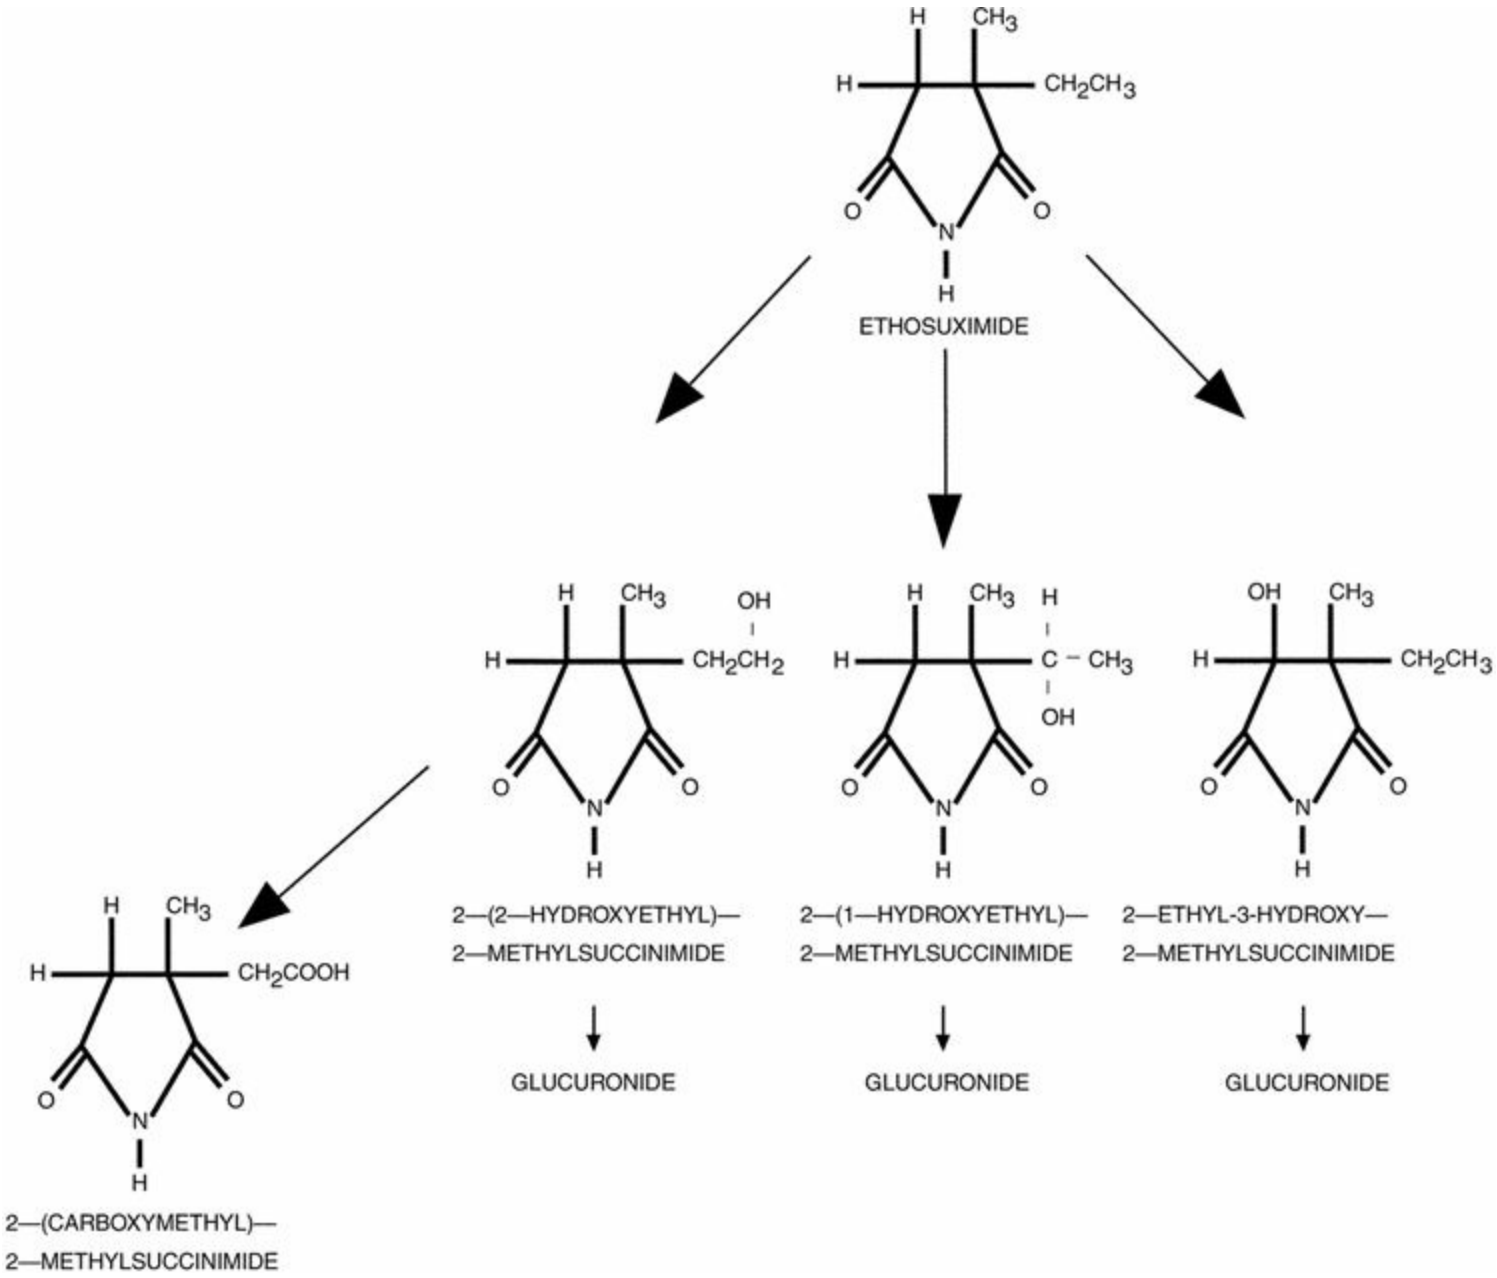

Figure 52.1. Structure and biotransformation pathways of ethosuximide. (From Pisani F, Meir B. Ethosuximide: chemistry biotransformation. In: Levy R, Mattson R, Meldrum B, eds. Antiepileptic Drugs. 4th ed. New York : Raven Press; 1995:655–658, with permission.)

MECHANISM OF ACTION

As stated above, in addition to its antiepileptic effect, ETS appears to have an analgesic effect.

Antiepileptic Effects

The presumed mechanism of action against absence seizures is reduction of low-threshold T-type calcium currents in thalamic neurons (13,14). The spontaneous pacemaker oscillatory activity of thalamocortical neurons involves low-threshold T-type calcium currents (15). These oscillatory currents are considered to be the generators of the 3-Hz spike-and-wave rhythms in patients with absence epilepsy (15). Voltage-dependent blockade of the low-threshold, T-type calcium current was demonstrated at clinically relevant ETS concentrations in thalamic neurons isolated from rats and guinea pigs (13,14,16). ETS does not alter gating of these T-type Ca^{2+} channels (8,14). Combining

these findings, it is proposed that ETS's effect on low-threshold, T-type calcium currents in thalamocortical neurons prevents the "synchronized firing associated with spike–wave discharges" (13).

In addition to the effects on voltage-dependent Ca^{2+} currents of the thalamus, studies have investigated the impact of ETS on GABA, on persistent Na^+ and sustained K^+ currents in cortical and thalamic neurons, and on G protein–activated inwardly rectifying K^+ channels. Here are some of the data.

The genetic absence epilepsy rats from Strasbourg (GAERS) have been identified as one of the ideal animal models of absence epilepsy (17). In this animal model, the frequency of spike-and-wave discharges is high with one-third of recorded EEG presenting as seizure activity. The use of ETS has been effective in stopping such epileptic activity (18). On this model, Polack and Sharpier conducted simultaneous in vivo electrocorticographic and intracellular recordings from the cortical focus of the GAER in which ETS had been administered at therapeutic concentration. The cessation of seizures mediated by ETS correlated with a recovery, in the hyperactive focus neurons, of physiologic values of membrane potential, firing rate, and pattern, thus converting the ictogenic cortical neurons into normal neurons (19). The impact of ETS on GABA was also investigated in this animal model by various investigators all of who recognize a pivotal pathogenic role of excess GABA in absence epilepsy (20). In one study, ETS was shown to reduce GABA concentration in the primary motor cortex of GAERS (21), confirming the findings from a previous study (18). The antiabsence effect of ETS has also been associated with an enhancement of synaptic inhibition of glutamate and GABA release (22).

Using a different animal model of absence epilepsy (WAG/Rij rats), investigators demonstrated the initiation of epileptic activity in the somatosensory cortex (23). Furthermore, the effect of infusion of ETS into thalamic nuclei (ventrobasal and reticular nuclei) was significantly lower than that seen with its infusion in the somatosensory cortex. The potential effect of ETS on GABA was also suggested in a study using a mouse with a mutation in the gamma2 subunit of the GABA receptor. Such mutation has been identified in childhood absence epilepsy and febrile seizures. Tan et al. developed a mouse model with a gamma2-subunit point mutation (R43Q) in a large Australian family. ETS blocked the 6- to 7-Hz spike-and-wave discharges and clinical events consisting of behavioral arrest recorded in mice heterogeneous for the mutation (24).

In cortical tissue, at concentrations significantly greater than those used for anticonvulsant effect, ETS inhibits Na^+, K^+-adenosine triphosphatase (Na^+, K^+-ATPase) activity (25– 29). Yet, one in vitro study suggested that ETS lowers the persistent Na^+- and Ca^{2+}-activated K^+ currents of layer V cortical pyramidal and thalamic relay neurons of rats and cats, but has no effect on the transient Na^+ current (30).

G protein–activated inwardly rectifying K^+ channels (GIRK) have been found to play an important role in the regulation of neuronal excitability (31). Using the Xenopus oocyte expression assay, Kobayashi et al. (31) demonstrated that ETS inhibited GIRK at clinically relevant concentrations and in a concentration- and time-dependent manner, but such inhibition was voltage independent during each voltage pulse.

Blumenfeld et al. demonstrated that an early treatment with ETS suppressed the development of absence seizures in WAG/Rij rats, through the blockade of changes in the expression of ion channels Nav1.1, Nav1.6, and HCN1. More importantly, ETS prevented seizure occurrence during its administration from age p21 to 5 months and even after its discontinuation (up to the age 8 months).

This model illustrates how early treatment during development may provide a new strategy for preventing epilepsy in susceptible animals (32). Similar findings were published by Russo et al., who used ETS or levetiracetam (LEV) in WAG/Rij rats approximately 3.5 months, starting before seizure onset (at age 1.5 months). In that study, both drugs reduced the development of absence seizures, thus exhibiting antiepileptogenic effects in this specific animal model. This antiepileptogenic effect of ETS is thought to be possibly linked to changes in Na^+ and HCN1 channel expression (33). In the GAERS model, Dezsi et al. randomized these rats to chronic therapy with either ETS or water from 3 to 22 weeks of age, followed by tap water for all rats for an additional 12 weeks. These investigators assessed the impact of ETS on the expression of key components of the epigenetic molecular machinery, the DNA methyltransferase enzymes. GAERS randomized to ETS exhibited a significant reduction in seizure occurrence during the treatment phase and for a 12-week posttreatment period. In addition, ETS treatment was associated with increased expression of DNA methyltransferase enzyme messenger RNA in the cortex. These data again suggest that chronic treatment with ETS can yield disease-modifying effects in the GAERS model of GGE, with antiepileptogenic effects against absence seizures through epigenetic modifications of cellular mechanism of this type of epilepsy (34).

Analgesic Effects

T-type Ca^{2+} channels appear to be important targets for treating persistent pain syndromes. Accordingly, various animal models of pain have suggested a potential analgesic effect of ETS (see section Efficacy).

Other Calcium Channel Antagonistic Properties

Based on the postulated idea that T-type calcium channel antagonists may effectively suppress tremor, Handforth et al. (35) found that five T-type calcium antagonists, including ETS, suppress tremor in two animal tremor models. It is possible that ethosuxamide's action on Na and K channel may have contributed to this effect. These findings open the possibility of ETS as a suitable target for developing new therapeutic strategies for treating tremor. However, this antitremor effect was not replicated in the parkinsonian tremor model in rats. No clear explanation was found for this finding given antitremor effect of similar calcium channel blockers with high transitivity to the brain such as zonisamide (36).

PHARMACOKINETICS

Implications of Racemic Mixture

ETS has always been used clinically as a racemate. It is theoretically possible that the two enantiomers could demonstrate different pharmacokinetic parameters or anticonvulsant effects. In rats, ETS's disposition is nonstereoselective (12). In chiral gas chromatographic analysis of enantiomer concentrations in plasma samples obtained for routine monitoring, 33 patients demonstrated that the enantiomer ratio was close to unity, and there was little interindividual variability (37). This implies that the disposition of ETS in humans is nonstereoselective and that measurement of total ETS for therapeutic monitoring is reasonable and appropriate (12,38). A small study (three pregnancies in two women taking ETS) demonstrated that the nonstereoselective

disposition was unaffected by pregnancy, placental transfer, or passage into breast milk (38).

ABSORPTION

In rats, dogs, and monkeys, absorption is rapid, with nearly complete oral bioavailability in dogs (88% to 95%) and monkeys (93% to 97.5%) (39–44). In children and adults, absorption is considered to be rapid and nearly complete (90% to 95%), even though no intravenous formulation can be used as a reference standard to determine absolute bioavailability in humans (4,43,45,46). Absorption is reported to remain efficient over multiple administrations (43). In two single-dose capsule administration studies, three volunteers given a single 1-g oral dose and four healthy adults given a 0.5-g oral dose, peak ETS plasma concentrations were reached between 1 and 4 hours after administration (44,46,47). A separate study with five institutionalized children that compared capsules and syrup demonstrated peak plasma concentrations within 3 to 7 hours with either formulation (10,43–45,48). The syrup had a faster absorption rate than the capsules, but the two formulations were bioequivalent (9,10,43–45,48).

DISTRIBUTION

Tissue Distribution

In rats, ETS distributes evenly to the brain, plasma, and other tissues, except for adipose tissue (in which steady-state concentrations are approximately one-third of those reached in plasma) (43). ETS crosses the placenta in rats (44,49) and, in dog and rat studies, readily passed through the blood–brain barrier (39,44). In dogs, the plasma–to–cerebrospinal fluid (CSF) ratio was 1.01 ± 0.15, with an estimated half-life of entry into the CSF at about 4 to 5 minutes (39,43,44,50). In one study in rats, the whole brain to plasma ETS concentrations ratio was near unity, whereas a second study in rats found uniform distribution in four discrete brain areas (cerebral cortex, cerebellum, midbrain, and pons medulla) (42,44). However, a third study in rats receiving a single intraperitoneal (I.P.) dose of 50 mg/kg found a decrease in brain-to-plasma concentrations over time, suggesting that ETS may be actively transported out of the rat brain (43,51).

In humans, ETS homogeneously distributes throughout the body (9). Saliva, tears, and CSF concentrations are similar to plasma concentrations (43,44,52–57). In three studies (involving 6, 15, and 19 patients), the respective correlations between saliva and serum concentrations were R = 0.99, R = 0.99, and R = 0.74 (55–57). A fourth study, which examined concentrations in paired parotid saliva and plasma samples from 10 patients, showed the average saliva-to-plasma ratio to be 1.04, which appeared constant over the measured time intervals (54). In light of these results, multiple studies have concluded that saliva can be used in lieu of plasma for therapeutic monitoring of ETS (44,52,54–58).

ETS crosses the placenta in humans and has been detected in cord serum and amniotic fluid at concentrations of 104% and 111% of maternal serum concentrations, respectively (9,59). In two separate reports, ETS was detected in either the urine or plasma of a newborn of a woman receiving long-term therapy (44,60,61). The serum concentration in the newborn was similar to that in the mother (43,61). ETS is excreted in the breast milk of mothers receiving long-term therapy (43). In multiple studies, the average breast milk–to–maternal serum concentration ratio ranged from 0.8 to

0.94 (43,61–64). The ETS serum concentration of breast-feeding infants of mothers given long-term therapy was 30% to 50% of their mothers' serum concentration (43,63,64). The American Academy of Pediatrics, however, considers ETS to be usually compatible with breast-feeding (65).

Volume of Distribution and Protein Building

The apparent volume of distribution in rats, dogs, and rhesus monkeys ranges from 0.7 to 0.8 L/kg (39,40,43,66). In humans, ETS's apparent volume of distribution is 0.62 to 0.65 L/kg in adults and 0.69 L/kg in children, implying distribution through total body water (9,43,45,46,53).

ETS protein binding is 0% to 10% in humans, dogs, and rats (37,43,45,48,52,67).

METABOLISM AND EXCRETION

Animals

Metabolism is the main method of ETS elimination in animals. In rhesus monkeys and rats, the drug and its metabolites are excreted predominantly by the kidney, with only a small proportion recovered in the feces (43,49). Unchanged ETS accounts for only 12% of urinary recovery in rats (68).

In rats, biotransformation is catalyzed predominantly by hepatic cytochrome P450 (CYP)3A isoenzymes, with possible minor contributions by CYP2E, CYP2B, and CYP2C isoenzymes (12,43,65,69,70,71). These CYP enzymes are inducible, and autoinduction has been reported in rats (43,65). The major metabolite in rats and monkeys is 2-(1-hydroxyethyl)-2-methylsuccinimide, and the two minor metabolites are 2-ethyl-3-hydroxy-2-methyl-succinimide and 2-(2-hydroxyethyl)-2-methylsuccinimide (43,72). ETS provided complete protection against pentylenetetrazol-induced clonic seizures in mice at a dose of 125 mg/kg; in contrast, the major metabolite demonstrated "no significant anticonvulsant activity" (72).

Elimination appears to follow first-order kinetics in animals, except in dogs, in which Michaelis–Menten kinetics may apply (39,43,72). Studies of single- and multiple-dose ETS administration in monkeys have demonstrated comparable elimination half-life and total body clearance (9,40,41). In animals, elimination half-lives range from 1 hour in mice to 9 to 26 hours in rats and 11 to 25 hours in dogs (39,43,72). Steady-state plasma concentrations are significantly higher in the morning than in the evening in rhesus monkeys receiving intravenous ETS at a constant rate. These fluctuations may result from circadian changes in ETS-metabolizing enzymes (43,72,73).

Humans

As in animals, metabolism is the main method of ETS elimination in humans. ETS undergoes extensive hepatic oxidative biotransformation (80% to 90%) to pharmacologically inactive metabolites. Although most of the remaining drug is excreted unchanged in the urine, small amounts of unchanged ETS can be recovered from bile and feces (74). ETS oxidation is catalyzed mainly by enzymes of the CYP3A subfamily (9). In vitro studies with humanized heterologous CYP microsomal systems showed that ETS is primarily oxidized by CYP3A4, with CYP2E1 playing a minor role in its metabolism (75).

The major metabolite recovered from human urine in patients receiving ETS is 2-(1-hydroxyethyl)-2-methylsuccinimide, of which at least 40% is excreted as a glucuronide conjugate

(12,75). Two other metabolites recovered (often as a glucuronide conjugate) from human urine are 2-ethyl-3-hydroxy-2-methylsuccinimide and 2-(2-hydroxyethyl)-2-methylsuccinimide. The latter metabolite can undergo subsequent metabolism by the hepatic mixed-function oxidase system to form the fourth major metabolite, 2-carboxymethyl- 2-methylsuccinimide (12,72,75) (see Fig. 52.1).

In humans, ETS's elimination follows first-order kinetics. Total body clearance in adults averages 0.01 L/kg/h (46) and in two children was 0.016 and 0.013 L/kg/h (45). This is significantly lower than hepatic plasma flow (0.9 L/kg/h) implying that ETS does not undergo a significant first-pass effect and that drug clearance is not blood flow limited (43,44). Total body clearance has been reported to decrease slightly after repeated dosing (43). ETS does not induce hepatic microsomal CYP enzymes or the uridine diphosphate glucuronosyltransferase (UDPGT) system (67,76,77). In humans, in contrast to rats, autoinduction does not occur (77,78).

In general, ETS has a long elimination half-life that varies with age. Its mean half-life in adults reportedly ranges from 40 to 60 hours, compared with 30 to 40 hours in children (45–47,53,72,78–81). Large variations have been observed in pediatric studies, with half-lives ranging from 15 to 68 hours (44,72,79). In neonates, half-lives ranging from 32 to 41 hours have been reported (61,63). The time to reach steady-state concentration after a dosage change is 6 to 7 days for children and 12 days for adults (9,82). ETS clearance is reported to be lower in women than men (83). Dose size and repeated dosing do not affect the elimination half-life (53,79).

The effects of liver and renal disease on ETS elimination have not been formally studied (43). It would seem that liver disease would impair ETS elimination because of the drug's substantial hepatic oxidative metabolism, whereas renal disease would have much less impact on ETS elimination (43). Hemodialysis can readily remove ETS. One report estimated that approximately 50% of the body's ETS was removed over a 6-hour dialysis interval and that the drug's half-life dropped to 3 to 4 hours during dialysis (43,84). In a separate case report, peritoneal dialysis decreased ETS concentrations in a child taking ETS and phenobarbital (85).

DRUG INTERACTIONS

Interactions with Other Antiepileptic Drugs

ETS's lack of effect on either the hepatic microsomal CYP enzymes or the UDPGT system, along with negligible protein binding, indicates a low potential for drug interactions (67,82). Most investigators conclude that ETS therapy does not have a clinically significant effect on the pharmacokinetics of phenytoin, phenobarbital, or carbamazepine, despite scattered reports of some changes in phenytoin or phenobarbital concentrations when ETS is used in combination with phenytoin or primidone (9,86–93). There is no alteration in the plasma protein binding of carbamazepine or phenytoin when ETS is used concomitantly, nor is there a change in the formation of phenobarbital from primidone (94). One study reported a significant decrease in valproic acid (VPA) serum concentration after the addition of ETS (120.0 ± 20.1 μg/mL before ETS vs. 87.0 ± 13.1 μg/mL during cotherapy with ETS; $P < 0.01$). After cessation of ETS, VPA levels rose to 36.7%. The mechanism underlying this observed effect is unknown (95).

In a review of the available literature, Czuczwar et al. (96) suggested a potential anticonvulsant synergy between ETS and valproic acid. In another study that investigated the interactions between several AEDs in suppressing pentylenetetrazole-induced clonic seizures in mice by the use of type II

isobolographic analysis, the combinations of VPA and ETS with LEV at the fixed ratio of 1:2 were found to have a supra-additive (synergistic) effect in suppressing seizures, while VPA and ETS with LEV (1:1, 2:1, and 4:1) were additive. Of note, ETS was found to significantly reduce brain LEV concentrations, and ETS and LEV have been suggested by some authors (97).

In contrast, because of ETS's extensive hepatic oxidative metabolism by CYP isoenzymes, concomitant therapy with enzyme-inducing AEDs would be predicted to increase ETS's total clearance (93). ETS's clearance is significantly accelerated (leading to a drop in the serum concentration) when the drug is used concurrently with phenobarbital, phenytoin, or carbamazepine (67,93,98–101). In one study, discontinuation of concomitant carbamazepine therapy increased ETS plasma concentrations by 48% (102). The magnitude of this effect may vary considerably among patients (98).

The effect of concomitant therapy with VPA on the pharmacokinetics of ETS is variable, with studies showing increases, decreases, or no change in ETS clearance (67,78,81,90,103–105). Some investigators postulate that VPA may inhibit the metabolism of ETS, leading to an increase in the plasma ETS concentration (106).

Whenever an AED–ETS interaction could occur, serum concentration and clinical response of both AEDs should be monitored. No formal pharmacokinetic interaction studies have examined potential ETS interactions with felbamate, gabapentin, lamotrigine (LTG), tiagabine, topiramate, oxcarbazepine, levetiracetam, or zonisamide.

Interactions with Nonantiepileptic Drugs

The clearance of ETS is substantially increased when it is used in combination with rifampin, an inducer of CYP3A isoenzymes (100). In contrast, concomitant use with isoniazid, a potent inhibitor of CYP isoenzymes, resulted in increased ETS serum concentrations and psychotic behaviors (107).

EFFICACY

Antiepileptic Effects

Animal Models

ETS exhibits very different efficacy profiles in the two major traditional animal models of epilepsy—the maximal electroshock test (MES) and the pentylenetetrazol seizure test. The MES is used to identify agents able to prevent the spread of seizures and has been hypothesized to identify agents effective against partial-onset and generalized tonic–clonic seizures (8,108). ETS was ineffective against MES-induced tonic seizures, except at anesthetic doses (8,108–110), but ETS blocked clonic seizures produced by subcutaneously administered pentylenetetrazol or bicuculline (8,108,110,111). These chemically induced seizure models are hypothesized to identify agents that raise the seizure threshold and may be effective against absence seizures. ETS's activity profile suggests that the drug exerts its anticonvulsant effects by raising the seizure threshold rather than by blocking the spread of seizures, and it predicts efficacy against absence rather than partial-onset or generalized tonic–clonic seizures.

ETS demonstrated activity against spontaneously occurring absence seizures in three other animal

models (mutant tottering mice, Wistar rats, and spontaneously epileptic rats) (112–114), as well as activity against spike–wave seizures induced by systemic administration of α-hydroxybutyrate (108,115,116).

Humans

Monotherapy Trials.

The efficacy of ETS as an effective monotherapy against childhood absence epilepsy had been taken for granted for many years, following two studies conducted in the 1970s strongly suggesting the efficacy of ETS in childhood absence epilepsy (117,118). Efficacy against typical partial seizures was examined in a study with a well-constructed method for patient selection and assessment. Each patient's absence seizure was required to meet a predetermined clinical definition and be witnessed by the principal investigator. Seizure frequency was then assessed by five separate measures: the ward's staff observation, trained observer's observation, mother's observation, physician's observation (including during patient hyperventilation), and standardized video-electroencephalographic (video-EEG) recording. These measures were combined into a "seizure index" (117). Thirty-seven patients were enrolled. By the eighth week of treatment, 19% (7 of 37 patients) were seizure free, with a 100% reduction in seizure index. Overall, during ETS therapy, 49% (18 of 37) of patients demonstrated at least a 90% reduction in seizures, and 95% (35 of 37) had a 50% or more reduction. The full antiabsence effect occurred within a week for any given ETS dose. Plasma ETS concentrations ranged from 16.6 to 104.0 μg/mL (doses of 6.5 to 36.7 mg/kg) and, on the basis of the seizure index, the investigators suggest that the optimal ETS plasma concentrations in this study were 40 to 100 μg/mL (117).

The second major study was a prospective, longitudinal, open-label investigation that used therapeutic drug monitoring to maximize clinical response (118). Seventy patients were enrolled; 54% (38 of 70) were female, with ages ranging from 4 to 28 years (median, 12 years). Thirty-eight patients (54%) had only absence seizures. The remaining patients had either absence seizures with tonic–clonic seizures (30%) or absence seizures, and one or more other generalized seizure types (16%). Approximately 50% of the patients were taking other AEDs in addition to ETS. Patients received between 9.4 and 73.5 mg/kg/d of ETS and were evaluated at 6-month intervals. Introduction of ETS therapy completely controlled seizures in 47% (33 of 70) of the patients. None of these patients had plasma ETS concentrations below 30 μg/mL; only 9% were below 40 μg/mL (119). During the next 2.5 years, attempts were made to achieve plasma ETS concentrations above 40 μg/mL in the remaining 53% (37 of 70) of patients with uncontrolled absence seizures. Improved compliance and higher dosages led to significantly higher ETS plasma concentrations in 19 patients, 10 of whom became seizure free. At the 2.5-year follow-up, 61% (43 of 70) of the group was seizure-free. In these patients, ETS's effectiveness persisted over the next 2.5 years of follow-up (total, 5 years). In contrast, ETS was not able to control absence seizures in patients with both absence seizures and tonic–clonic seizures who were receiving combination AED therapy (118).

Three randomized, controlled, prospective trials have compared ETS and VPA as monotherapy for absence seizures (119–121), and a Cochrane Review reexamined the results (122). A parallel, open study enrolled 28 drug-naive patients, between 4 and 15 years of age, who had typical absence seizures, and followed them up for a mean of 3 years (range, 18 months to 4 years) (119). The relative risk (RR) estimate with 95% confidence interval (CI) for seizure freedom (RR < 1 favors

ETS) was 0.70 (95% CI, 0.32 to 1.51); the RR estimate for 50% or more reduction in seizure frequency was 1.02 (95% CI, 0.70 to 1.48). The outcomes were confirmed by 6-hour telemetry and clinical observation. Although no difference was apparent for either outcome, the CIs were wide; the possibility of important differences could not be excluded, and equivalence of ETS and VPA could not be inferred (119,122).

Another trial of similar design enrolled 20 patients between 5 and 8 years of age whose simple absence seizures had begun <6 months before (120). Follow-up lasted for 1 to 2 years, and outcomes were confirmed by clinical observation and EEG. Again, wide CIs and the possibility of important differences precluded confirmation of equivalence of ETS and VPA. All patients achieved at least a 50% reduction in seizure frequency (120,122).

A double-blind, crossover study used a complex response–conditional design and recruited 45 patients between 4 and 18 years of age (123). The enrollment included both treatment-naive patients and those with drug-resistant disease. Some had only absence seizures; others had other seizure types as well. In the first phase of this trial, patients were assigned to receive either ETS with placebo VPA or VPA with placebo ETS for 6 weeks. Responders continued with the randomized drug for a further 6 weeks. This group included treatment-naive patients who became seizure free and previously treated patients who had an 80% or more reduction in seizure frequency. Nonresponders and those with adverse effects were crossed over to the alternative treatment and followed up for another 6 weeks. No differences emerged between therapies, but the CIs were wide, and equivalence could not be inferred. The reduction in seizure frequency, determined by a 12-hour video-EEG telemetry, was 100% for the drug-naive group and 80% for the drug-resistant group.

Yet, the efficacy of ETS as a "first-line treatment" was demonstrated in an initial 16- to 20-week, multicenter, randomized, double-blind, controlled study that compared the efficacy and tolerability of ETS, VPA, and LTG given as monotherapy in 446 children with Childhood Absence Epilepsy (123). At the end of the 16- to 20-week period, ETS and VPA yielded comparable seizure freedom rates (53% and 58%, respectively) compared to 29% for LTG. Yet, attentional problems were more frequent with VPA (49%) than ETS (33%). On the other hand, discontinuation related to adverse events failed to differ among the three AEDs.

The study was continued for 12 months, by which time 37% of all enrolled subjects were free from treatment failure (no seizures, no significant adverse event leading to discontinuation), with rates for ETS and VPA continuing to be comparable (45% and 44%, respectively) and higher than that for LTG (21%) (124). More children on LTG discontinued because of poor efficacy, while 42% of the 115 children discontinuing due to adverse events was among those on VPA. The higher rate of attentional dysfunction identified at 16 to 20 weeks in children on VPA compared with those on ETS and LTG continued to be present at 12 months. The last new AED guidelines of the International League Against Epilepsy recognized that the data proving efficacy/effectiveness evidence as initial monotherapy for CAE met the criterion for a level A evidence (125).

In a retrospectively study of 128 children with CAE at the Seoul National University Hospital, investigators compared the seizure-free rate and the retention rate observed during 2 years of treatment (126). After 3 months, children on ETS were more likely to achieve seizure freedom (84%) than those on VPA (62%) and LTG (53%), but this difference disappeared at 9 and 12 months (ETS, 77%; VPA, 83%; and LTG, 64%). Furthermore, the drug AEDs failed to differ in retention rate throughout the whole treatment period and adverse event rates (ETS, 25%; VPA, 29%; and LTG, 14%); this study suggested that the onset of efficacy was faster for ETS compared with VPA or LTG.

ETS in Polytherapy.

Combination therapy with ETS and VPA for absence seizures resistant to either drug alone was reported in one open-label study of five patients (127), and many investigators subsequently recommended this combination for patients with absence seizures resistant to monotherapy (10,48,82,128). Similarly, ETS in patients with both absence and tonic–clonic seizures should be combined with another AED effective against tonic–clonic seizures, such as VPA, carbamazepine, or phenytoin (10,82,128). Despite being reported as "highly effective" against atypical absence seizures (82,128), ETS is almost always used as part of combination therapy for patients with atypical absence seizures because of the high incidence of coexisting seizure types (10).

ETS has been found to be useful in the prevention and treatment of absence status epilepticus at serum concentrations >120 μg/mL (129,130), and there are anecdotal reports of effectiveness in severe myoclonic epilepsy in infancy (131), childhood epileptic encephalopathy (Lennox–Gastaut syndrome) (7,132), juvenile myoclonic epilepsy (133,134), epilepsy with myoclonic absences (134), eyelid myoclonia with absences (134), photosensitive seizures (135), gelastic seizures (48,136), frontal absence seizures (137), epilepsy in Angelman syndrome (138), nonconvulsive status epilepticus in mucopolysaccharidosis type II (139), and nonconvulsive seizures after brain injury (140). No controlled studies have investigated ETS's effectiveness against simple partial, complex partial, or partial secondarily generalized tonic–clonic seizures.

Epileptic negative myoclonus consists of an interruption of tonic muscle activity, which is time locked to an epileptic EEG abnormality, without evidence of an antecedent positive myoclonia in the agonist–antagonist muscles (1). It can be identified in various types of seizure disorders, including idiopathic, cryptogenic, and symptomatic epileptic disorders. It has been suggested that ETS may be effective in epileptic negative myoclonus associated with childhood idiopathic partial epilepsy. Capovilla et al. (141) reported a remission of the motor disorder in nine patients after the addition of ETS to other AEDs. Furthermore, Oguni et al. (142) reported total remission of epileptic negative myoclonus in 6 of 10 patients with the use of ETS.

ETS has been used in the treatment of encephalopathy with status ESES or continuous spikes and waves during slow sleep syndrome. In a recent retrospective study with these syndromes, ETS was reported to yield a favorable response when given in combination with other drugs and steroids (2,3). Accordingly, these findings remain equivocal.

Analgesic Effects

Animal Models

Barton et al. (143) investigated the effect of ETS in acute and persistent nociceptive tests in the rat. Intraperitoneal administration of ETS reversed capsaicin-induced mechanical hyperalgesia in a dose-dependent manner. In addition, ETS produced antinociceptive effects in the rat tail-flick reflex test and displayed significant analgesic effects in both early- and late-phase formalin-induced behaviors. Similar findings were reported by Shannon et al. (144). Of note, in this study, ETS increased the doses of pentylenetetrazol required to produce both first twitch and clonic seizures, thus showing that the analgesic effects can be obtained at doses that yield an anticonvulsant effect.

Todorovic et al. injected ETS intradermally into peripheral receptive fields of sensory neurons in the hind paws of adult rats and studied pain perception using the model of acute thermal nociception;

ETS induced dose-dependent analgesia in the injected paw but not in the contralateral (noninjected) paw (145). These findings suggest an analgesic effect mediated at peripheral nerve endings of rat sensory neurons.

Flatters and Bennett demonstrated the analgesic properties of ETS in an animal model using male Sprague Dawley rats, to which four I.P. injections of 2 mg/kg paclitaxel were administered on alternate days (146). Paclitaxel is a chemotherapeutic agent known to produce neuropathic pain and sensory abnormalities in patients treated with this agent both during therapy and after its discontinuation. The development of mechanical and cold allodynia/hyperalgesia was demonstrated with behavioral assessment using von Frey filaments and acetone. ETS administered by I.P. route at doses of 450 mg/kg yielded a near complete remission of mechanical allodynia/hyperalgesia. No tolerance of the analgesic effect was found following repetitive dosing with I.P. ETS at doses of 100 or 300 mg/kg daily for 3 days. Furthermore, I.P. administration of ETS at doses of 300 mg/kg also reversed paclitaxel-induced cold allodynia and vincristine-induced mechanical allodynia/hyperalgesia. Of note, paclitaxel-induced pain was resistant to opioid therapy. Similar results were suggested by Hamidi et al. (147) also in the Sprague Dawley rats, using the chronic constriction injury model of neuropathic pain with ETS blocking tactile and thermal hypersensitivity and potentiating the analgesic effects of morphine in neuropathic pain conditions and behavioral responses.

Finally, Wang and Thompson demonstrated an analgesic effect of ETS in an animal model of central pain syndrome (148). These investigators created unilateral electrolytic or demyelinating lesions in the spinothalamic tract of the spinal cord of rats resulting in thermal hyperalgesia and mechanical allodynia in all four paws that were attenuated significantly with the administration of ETS. Clearly, ETS appears to have analgesic properties in various animal models of pain.

Human Studies

There have been no open or controlled studies that have investigated the analgesic efficacy of ETS in humans.

ADVERSE EFFECTS

Effects That Depend on Concentration

The incidence of adverse effects due to ETS in initial published reports in 1952, 1958, and 1961 was very low, ranging from 1% to 9%; subsequent studies have indicated an incidence ranging from 31% to 44% (118,149–155). Most adverse effects depend on concentration and are related to the primary and secondary pharmacologic effects of the drug. These reactions are usually predictable, dose dependent, and host independent; they resolve with dose reduction (156,157).

The most common ETS concentration-dependent adverse effects involve the gastrointestinal system and include nausea (the most common), abdominal discomfort, anorexia, vomiting, and diarrhea (4,10,48,149,150,158). Between 20% and 33% of children experience these symptoms, usually at the onset of therapy (48,158). Symptoms are considered mild and respond promptly to dose reduction (48,149,150,158). Techniques to reduce the symptoms include dividing the total daily dose and administering the smaller doses at mealtime (9).

Central nervous system (CNS)-related adverse events (e.g., drowsiness) are the second most

common form of ETS concentration-dependent adverse events. Drowsiness usually occurs at the onset of therapy and responds promptly to dose reduction (9,149,150,158). Other CNS-related adverse events include insomnia, nervousness (12% of children), dizziness, hiccups, lethargy, fatigue, ataxia, and behavior changes (e.g., aggression, euphoria, irritability, hyperactivity) (10,158). A direct relationship between ETS therapy and these reported behavioral changes is not certain, because poor methodology (e.g., lack of reliable methods for objectively measuring behavior changes, confounding variable of polypharmacy, and lack of serum AED measurements) makes analysis of existing reports difficult at best (149,150).

Few trials have examined the potential cognitive effects of ETS in a controlled fashion, accounting for confounding variables such as plasma concentrations, underlying mental retardation, concomitant AEDs, or seizure type. In one early report, psychometric testing of 25 children receiving ETS for various seizure types revealed memory, speech, and emotional disturbances (159). However, no plasma concentrations were measured, all the patients were also taking barbiturates; 60% of the cohort had intelligence quotient (IQ) scores below 83; and no matched control group was used (159). In a cohort of children without epilepsy but with learning disorders, and 14- and 6-Hz positive spikes on EEG recording, administration of ETS significantly improved verbal and full-scale IQ scores, without changing motor performance or personality test scores (160).

In a well-designed study, psychometric performance improved significantly over 8 weeks of ETS therapy in 17 (46%) of 37 children with absence seizures (119). This improvement was significantly greater than that of a control group tested in the same fashion over the same interval. Only 25% of the study group had IQ scores below 83, and only 32% were receiving other AEDs.

Dreifuss (149,150) reported a probable dose-dependent, ETS-related granulocytopenia that often resolves with dose reduction without the need to terminate therapy. Distinction between this probable adverse event and ETS-associated idiosyncratic bone marrow depression (see section Idiosyncratic Reactions) is critical. Careful clinical and laboratory monitoring are essential in making this decision.

Effects That Do Not Depend on Concentration

Some ETS adverse effects do not appear to be concentration dependent, but are also not idiosyncratic reactions in the usual sense. Headaches, reported in 14% of children, may not respond to dose reduction and may persist (9,149,150,158,161).

Episodes of psychotic behavior (i.e., anxiety, depression, visual hallucinations, auditory hallucinations, intermittent impairment of consciousness, and mania) have been noted with ETS (149,162–166) and are most likely in young adults with a history of mental disorders (9,149). The acute psychotic episodes appeared after ETS-induced seizure control with associated EEG improvement, and they resolved when ETS was stopped and seizures returned, illustrating the phenomenon of forced normalization (9,149). Psychotic symptoms have recurred when ETS was restarted in patients with previous ETS-related psychotic episodes (149). This forced normalization reaction is not dose dependent and, among all antiabsence AEDs, occurs with highest frequency with ETS (9,167).

Most studies find no evidence of ETS-associated seizure exacerbation (118,149,153,168,169); however, scattered reports describe exacerbation of myoclonic and absence seizures and transformation of absence into “grand mal” seizures in patients receiving ETS (149,151,170). Dreifuss considered this exacerbation effect to be a consequence of the high incidence of generalized

tonic–clonic seizures in patients with absences seizures, coupled with ETS's lack of efficacy against generalized tonic–clonic seizures (149). Furthermore, Anyanwu et al. reported a case of conversion of typical absence to Rolandic spikes after treatment with ETS. However, it is not clear if this represents the simultaneous presence of these two common childhood idiopathic epilepsies as a continuum or a drug-induced conversion (171).

Calcium channel blockers, including ETS, have been shown to negatively affect spermatogenesis and steroidogenesis in the prepubertal mouse testis. Lee et al. showed a significant reduction in body weight, testis size/weight, and sperm production when feeding ETS and nifedipine to prepubertal male mice for 20 days at dosages below maximum tolerated. The authors suggest these drugs must be used with caution due to its potential adverse side effects on male infertility (172). There have been no human studies or reports, however.

Idiosyncratic Reactions

Idiosyncratic drug reactions are unpredictable, dose-independent, host-dependent reactions that are not associated with the known pharmacologic effects of the drug; they can be serious and life threatening. Preclinical animal toxicologic testing may not detect these reactions, and often they cannot be reproduced in animal models (156,157). In general, the skin is the most commonly affected site, followed by the formed elements of the blood and liver and, to a lesser extent, the nervous system and kidneys (156,173). These reactions may be organ specific or may manifest with generalized nonspecific symptoms, such as lymphadenopathy, arthralgias, eosinophilia, and fever (156,174). Idiosyncratic reactions are believed to result from toxic metabolites that cause injury directly or indirectly (i.e., through an immunologic response or free radical-mediated process) (175).

ETS has been associated to various degrees with a wide array of idiosyncratic reactions (149,150,158,176), including allergic dermatitis, rash, erythema multiforme, Stevens–Johnson syndrome (177), systemic lupus erythematosus (178–180), lupus–scleroderma syndrome (181), a lupus-like syndrome (182), blood dyscrasias (aplastic anemia, agranulocytosis) (118,155,168,183–190), dyskinesia (191,192), akathisia (191), autoimmune thyroiditis (193), and diminished renal allograft survival (194).

Mild cutaneous reactions, including allergic dermatitis and rash, are the most common ETS-associated idiosyncratic reactions. They frequently resolve with withdrawal of the drug, but some patients may require steroid therapy. Patients who develop Stevens–Johnson syndrome, a potentially life-threatening condition, require more aggressive in-hospital therapy.

The symptoms of the lupus-like syndrome are described as fever, malar rash, arthritis, lymphadenopathy and, on occasion, pleural effusions, myocarditis, and pericarditis (149). After discontinuation of ETS, these patients usually fully recover, but the recovery may be prolonged (149).

The manifestations of ETS-associated blood dyscrasias range from thrombocytopenia to pancytopenia and aplastic anemia (118,155,168,183–188). Between 1958 and 1994, only eight cases of ETS-associated aplastic anemia were reported, with onsets of 6 weeks to 8 months after initiation of therapy (187). Six patients were receiving polypharmacy; five were taking phenytoin or ethotoin in combination with ETS (187). Despite therapy, five of the eight patients died (118,155,168,183–188).

Long-Term Effects

Adverse effects resulting from long-term therapy are related to the cumulative dose (156,157). Severe

bradykinesia and parkinsonian syndrome have been reported after several years of ETS treatment (154,195).

Delayed Effects

In mice, ETS exhibits considerably less teratogenic effect than carbamazepine, phenytoin, phenobarbital, or primidone (196). In humans, because ETS is predominantly indicated for absence seizures, which frequently remit before child-bearing years, little is known about the risks that maternal use poses to the fetus (149). Not enough data are available to accurately assess the teratogenic effect of ETS in humans.

CLINICAL USE

Indications

ETS is regarded as effective first-line monotherapy against typical absence seizures. ETS may be the first choice in children younger than 10 years old with absence epilepsy, but as adolescence approaches and the risk of generalized tonic–clonic seizures increases, VPA clearly becomes the drug of choice in males (197). Because of the potential serious teratogenic effects of VPA and its negative impact on reproduction functions, LTG should be considered as an alternative in woman. In addition, ETS as adjunctive therapy may be beneficial for patients whose absence seizures are not controlled by VPA or LTG monotherapy, patients with both absence and tonic–clonic seizures, and patients with atypical absence seizures (10,48,82,125,197). No evidence supports a role for ETS as monotherapy or adjunctive therapy in patients with only simple partial, complex partial, or partial secondarily generalized tonic–clonic seizures.

Starting and Stopping

A common starting dosage for children is 10 to 15 mg/kg/d with subsequent titration to clinical response (9,10). Maintenance dosages frequently range from 15 to 40 mg/kg/d (82). In older children and adults, therapy can begin at 250 mg/day and increase by 250-mg increments until the desired clinical response is reached. The interval between dosage changes for older children and adults varies from 3 days (10) to every 12 to 15 days (9). Common maintenance doses for older children and in adults are 750 to 1500 mg/day (9,10). In elderly patients, titration should involve smaller increments with longer intervals between changes (10). After a dosage change, steady-state concentration is reached in 6 to 7 days in children and 12 days in adults (9,82). ETS can be administered once, twice, or even thrice daily (with meals) for maximum seizure control with minimum adverse effects (9,10).

If intolerable side effects without seizure control or 2 or more years' freedom from absence seizures occur, discontinuation may be warranted, with gradual reduction over 4 to 8 weeks (9,10). If necessary, abrupt discontinuation is probably safe because of ETS's long half-life (10).

Monitoring

ETS should always be titrated to maximal seizure control with minimal side effects. The generally

accepted therapeutic range is 40 to 100 µg/mL (9,10); some patients with refractory seizures or absence status may need serum concentrations up to 150 µg/mL (10). Monitoring ETS's serum concentration may help to identify noncompliance and aid in maximizing seizure control (119).

There is no evidence that monitoring of blood count values during therapy anticipates the drug's idiosyncratic hematologic reactions. Patients must alert their physicians immediately if fever, sore throat, and cutaneous or other hemorrhages occur (149). However, one recommendation for monitoring is that "periodic blood counts be performed at no greater than monthly intervals for the duration of treatment with ETS and that the dosage be reduced or the drug discontinued should the total white blood cell count fall below 3500 or the proportion of granulocytes below 25% of the total white blood cell count" (149).

CHAPTER 53 EZOGABINE (RETIGABINE)

SCOTT MINTZER

INTRODUCTION

Ezogabine was first developed as a new agent for the treatment of focal seizures under the name retigabine, and then the appellation was changed in the United States to avoid confusion with the antiparkinsonian agent rotigotine. As an allosteric modulator of KCNQ2-5 potassium channels, ezogabine is believed to take advantage of a mechanism of action that had not previously been leveraged by other antiepileptic medications.

PHARMACOLOGY

Ezogabine is a structurally novel compound (Fig. 53.1) consisting of two aromatic rings—one with a fluorine atom and the other with a carbamic acid ethyl ester side chain, linked by an amino group between them, carrying the chemical name N-[2-amino-4-(4-fluorobenzylamino)-phenyl] carbamic acid ethyl ester. It is a white, odorless, tasteless powder, insoluble in water at room temperature except in highly acidic environments, but somewhat more soluble in organic solvents.

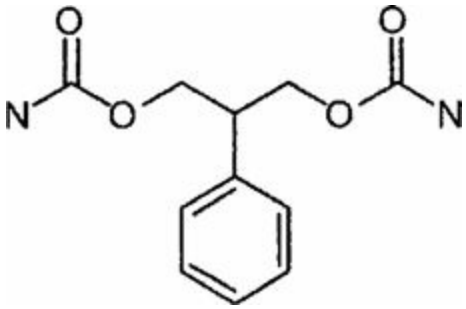

Figure 53.1. Chemical structure of ezogabine/retigabine.

Interest in the drug began with a compound called flupirtine, developed in Europe as an analgesic but demonstrating some modest anticonvulsant activity (1). An attempt was made to modify this molecule to maximize the latter effect, resulting in the development of retigabine/ezogabine. Early evidence of preclinical efficacy in animal models of epilepsy was rapidly followed by mechanistic studies that first excluded traditional epilepsy pharmacologic targets as sites of action and then revealed evidence that the drug acted as an opener of neuronal potassium channels (2,3). The discovery and cloning of the KCNQ-type potassium channels and their link to epilepsy (4) led subsequently to the discovery that ezogabine has potent effects on this channel family (2) and thus recognition that the compound was clearly acting via a heretofore undescribed mechanism. While one may establish that a compound reduces seizures and that it has certain pharmacologic properties, there may still be no definitive basis to connect the latter to the former. In the case of ezogabine, both the physiologic activity of the drug and the connection to seizure predisposition are clear enough that

it is widely believed that its true mechanism of anticonvulsant action is established.

Ezogabine's primary activity is as an allosteric modulator of KCNQ2-5 potassium channels. This type of channel is assembled from four subunits, which may be the same type or two different types. The predominant type of KCNQ channel in the brain includes both subunits 2 and 3, called KCNQ 2/3, and ezogabine has greater affinity for this one than it does for channels that include KCNQ4 or KCNQ5 subunits. KCNQ channels are also present in nonneurologic tissues, but ezogabine has no effect on KCNQ1, the type found in cardiac tissue, which presumably explains the drug's lack of cardiac effects (2). When it binds to the allosteric modulation site on the channel, it reduces the threshold for the channel to open and keeps the channel open three to four times longer, resulting in greater potassium efflux from the neuron and more negative membrane potential (i.e., hyperpolarization), which reduces action potential generation and retards the development of synchronous electrical discharges (i.e., seizures).

Confirmation of the importance of KCNQ2/3 in epilepsy comes from the observations that loss-of-function mutations in the genes coding for these subunits are strongly associated with the syndrome of benign familial neonatal convulsions (4) and that even modest reductions in the expression of these genes results in an epileptic diathesis (5). These findings, the impact of potassium channel opening on neuronal physiology, and the lack of effect on other molecular targets of epilepsy at physiologic doses all make it likely that the allosteric modulation of brain potassium channels is the true source of ezogabine's anticonvulsant activity.

PHARMACOKINETICS AND DRUG INTERACTIONS

Ezogabine is rapidly absorbed, with peak plasma concentrations being reached in about 1.5 hours, and has an oral bioavailability of about 60% (6). High-fat foods delay absorption somewhat and can increase the maximum concentration reached just over a third but do not affect overall extent of absorption, so that the drug can be given without respect to meals. Concomitant ingestion with alcohol may increase ezogabine peak concentrations and overall systemic exposure by 20% to 30%. Ezogabine is 80% protein bound in serum, with a volume of distribution of 2 to 3 L/kg. Ezogabine has an elimination half-life of about 7 hours in patients with normal renal function.

About 60% of a dose of ezogabine is metabolized, mainly by hepatic glucuronidation and to a lesser extent by acetylation, mostly to inactive metabolites but also to an N-acetyl metabolite (called NAMR, where the R stands for retigabine) that possesses some modest antiepileptic activity. Ezogabine is metabolized by UGT1A1 and UGT1A9 to form two distinct N-glucuronides. Multiple UDP-glucuronosyltransferases appear to be involved in the metabolism of ezogabine and include UGT1A1, 1A4, and 1A9, while acetylation is mediated by NAT2 (7). The cytochrome P450 isozyme system does not participate in its metabolism. Renal excretion accounts for about 36% of an oral dose of the parent molecule and 18% of NAMR.

Ezogabine neither inhibits nor induces the major CYP450 enzymes involved in drug metabolism, so as expected, it has no effect on the metabolism of other antiepileptic drugs (AEDs) with the exception that it causes an increase of approximately 20% in lamotrigine clearance; both the mechanism for, and the clinical significance of, this effect remain unknown. The drug has no effect on oral contraceptives (or vice versa). Coadministration of carbamazepine or phenytoin results in about a one-third increase in clearance and a corresponding one-third decrease in the area under the curve

for ezogabine, engendering a formal recommendation that a higher dose should be considered in this clinical circumstance. Curiously, phenobarbital, which like the two aforementioned agents is a potent UDP-glucuronyltransferase (UGT) inducer, does not affect ezogabine at all nor do any other anticonvulsants, including valproate.

Ezogabine is neither a substrate for nor an inhibitor of P-glycoprotein, although renal clearance of digoxin (a P-glycoprotein substrate) was reduced by NAMR in a concentration-dependent manner, suggesting that this metabolite is a modest P-glycoprotein inhibitor.

EFFICACY

Demonstration of ezogabine's efficacy has come in the form of three pivotal trials, each done for adjunctive treatment of focal epilepsy in a randomized, double-blind, placebo-controlled fashion. The first of these was a dose-finding study in patients aged 16 years and over, with three different treatment arms consisting of ezogabine at total daily doses of 600, 900, or 1200 mg (8). The lower dose did not separate from placebo, while the 900- and 1200-mg doses did, using either the Food and Drug Administration–preferred percent seizure reduction or the European Medicines Agency–requested 50% responder rate as the outcome. The former measure showed a steady increase with increasing dose (−13.1% for placebo vs. −23.4%, −29.3%, and −35.2%, respectively), while the latter measure showed no real change between the 900- and 1200-mg doses (31.6% and 33.0%, respectively, vs. 15.6% in the placebo group).

Two further placebo-controlled trials were performed in comparable populations, one comparing the 600- and 900-mg doses to placebo and one comparing the 1200-mg dose to placebo. The former study (9) showed dose–response efficacy, this time with both doses significantly superior to placebo using either percent seizure reduction (−27.9% and −39.9%, respectively, vs. −15.9% with placebo) or 50% responder rate (38.6% and 47.0%, respectively, vs. 18.9% with placebo). The latter study had similar placebo outcome rates, and outcomes with 1200 mg daily were comparable to those seen using 900 mg in the other trial (44.3% seizure reduction, 44.4% responder rate) (10). These results are in the range seen with other compounds in phase III trials for focal epilepsy. Seizure-free rates in all arms of both of these trials were minimal (2% to 4.7%), likewise in keeping with results seen with other drugs in the highly treatment-resistant clinical epilepsy trial population.

A combined analysis of the data from all three of the aforementioned trials was subsequently published (11), confirming that all three doses were effective, there was a moderate increase in efficacy with the step-up in dose from 600 to 900 mg, and that there was only modest evidence of further efficacy at 1200 mg when compared to 900 mg. The difference between the higher two doses was greater when efficacy was examined during the maintenance phase, rather than throughout the entire double-blind phase, suggesting that a gradual titration period exhibiting less efficacy may have contributed to obscuring some of the difference between the higher doses. None of the pivotal studies performed subanalyses of different seizure types, so extant data must be assumed to apply broadly to the category of focal seizures with or without secondary generalization.

ADVERSE EFFECTS

Most of the adverse effects of ezogabine that emerged from clinical trials were central nervous system related (11). The most common of these were dizziness, somnolence, fatigue, ataxia, dysarthria, and confusion (along with other forms of cognitive impairment). All of these showed a

clear and continuous increase in incidence with increasing dose, indicating that they were true effects of the drug. Tremor was also seen at higher doses, and this was observed consistently in the pivotal trials. There was no evidence of adverse behavioral effects. There may be a modest and dose-dependent tendency to produce some weight gain, with significant (≥7% of body weight) gain seen in 11% (low or medium dose) and 18% (high dose) of patients (compared to 1% in the placebo group). Like all newer-generation AEDs, ezogabine carries a warning regarding the risk of suicidal thoughts and behavior derived from the results of an FDA meta-analysis.

Ezogabine has been associated with two serious adverse effects, including urinary retention and retinal and cutaneous discoloration. Researchers were alerted to the possibility of urinary complications during clinical trials, because the KCNQ2/3-type potassium channel, the type most commonly found in the brain and impacted by the drug, is also found quite prominently in the bladder. In the placebo-controlled trials, urinary complications were categorized as urinary retention, urinary hesitation, and dysuria, and they occurred in 0.9%, 2.2%, and 2.3% of ezogabine-treated patients, respectively (compared to 0.5%, 0.9%, and 0.7% of patients on placebo). When data from the placebo-controlled trials and the open-label extensions were combined, 29 of 1365 patients, or 2.1%, developed urinary retention, generally within the first 6 months of treatment but sometimes later. Five of these 29 patients required bladder catheterization, and 2 of them developed hydronephrosis, with 1 of these developing renal failure with spontaneous resolution following drug withdrawal. Of the five, one had spontaneous resolution of the urinary retention, but one patient continued to require intermittent self-catheterization even after discontinuation of ezogabine; of note, this patient had a prior history of drug-induced urinary retention. Ezogabine-induced urinary retention showed no gender bias, and the relative risk for urinary side effects relative to placebo was elevated only for those taking the 1200-mg dose, with no apparent increased risk for those taking 900 or 600 mg daily (12).

As an accessory urinary issue, crystals of an unknown, bilirubin-like substance were observed in 15% of ezogabine-treated patients in clinical trials, but they were not actually made of bilirubin, and there is no clear evidence that the drug is associated with nephrolithiasis at present.

The other serious adverse effect, described in a “black box” warning on the label, is that of retinal and cutaneous discoloration. This was publicly documented by the FDA in April 2013, 1 year after the drug was released to the market. This adverse effect may be divided into two forms. The first consists of skin discoloration, usually bluish in color, most commonly of the lips or nail beds, but also seen less often in the eyes (sclera, conjunctiva, eyelids), the face, the palate, or the legs. It was found in 6.3% of 605 patients as of the FDA’s original report. The second form, the subject of the formal warning, consists of pigmentary deposits on the retina. This is assumed to be related to the skin deposits, though they are not always seen together. The retinal abnormality resembles that seen in retinal pigment dystrophies—conditions that cause functional retinal damage—and the first patients observed to have this were thought to have retinal dystrophy until subsequent spontaneous reports made it apparent that this was an adverse drug reaction. Some of the patients with these deposits had less than normal visual acuity, but none of these had acuity documented prior to initiation of ezogabine therapy, and given the high prevalence of abnormal vision, it remains unclear whether or not the deposits were themselves productive of visual compromise.

The large majority of patients with discoloration of the skin or retina had been on ezogabine for 2 years or more, and in a group of patients taking ezogabine for about 4 years, one-third of those who had ophthalmic examinations were found to have retinal deposits. However, at least one patient developed skin discoloration after only 10 months’ exposure to the drug. Because the functional

impact of the retinal findings is unclear, and because it is unclear whether the retinal (or skin) changes are reversible with discontinuation of the drug, the FDA has formally recommended that patients should undergo ophthalmologic screening before starting ezogabine and subsequently every 6 months.

CLINICAL USE

Ezogabine is indicated for adjunctive treatment of focal seizures in patients aged 18 years and over. Because of concerns over the potential impact of retinal pigment deposits, its indication is specifically for those patients who have failed to respond sufficiently to other agents.

The drug comes in 50-, 200-, 300-, and 400-mg tablets; the former should be used for initial titration and the larger sizes for maintenance therapy at the target dose. Ezogabine must be dosed on a TID schedule (13). It is initiated at 100 mg TID, with weekly increases of 50 mg TID up to the target dose of 200 to 300 mg TID. It is formally approved for dosing up to 400 mg TID, but given only moderate evidence of increased efficacy at that dose, with a clear-cut worsening in tolerability, this dose should probably not be an initial therapeutic target. For those with moderate or severe renal or hepatic impairment, and for the elderly, a modified dosing regimen is recommended, beginning with 50 mg TID and increasing by 50 mg TID each week to a maximum of 200 to 250 mg TID. There is no information on the drug in pregnancy.

Ezogabine was given a designation as a Schedule V–controlled substance due to the occurrence of euphoric mood in a minority of substance abusers who were given the drug in testing. This designation is shared by pregabalin and lacosamide, drugs that some clinicians believe to have low abuse potential.

As mentioned previously, baseline and semiannual ophthalmic exams are now mandated when using the drug, and because of concerns about potential retinal toxicity, it is formally recommended that the drug be discontinued if there is insufficient benefit from its use. These recommendations are reminiscent of those for vigabatrin, which also may cause visual toxicity but can be effective for children with infantile spasms (14). If it is found that the retinal toxicity from ezogabine adheres to a certain subgroup that could be screened prior to initiation of treatment, then this would also be advantageous.

CHAPTER 54 FELBAMATE

EDWARD FAUGHT

HISTORICAL BACKGROUND

Felbamate (FBM) is historically significant as the first of a new generation of antiepileptic drugs (AEDs) introduced in the 1990s. It was synthesized in the 1950s as one of a series of dicarbamates. Meprobamate, another drug in this series, was marketed as one of the first nonbarbiturate tranquilizers. FBM has no tranquilizing action and found no immediate clinical use. In the 1970s, it was submitted to the National Institutes of Health (NIH) AED-screening program. After impressive results in animal seizure models (1), FBM entered human clinical trials in 1985 (2–6). It was only modestly effective as adjunctive therapy for refractory partial-onset (focal) seizures, but results of later monotherapy trials were very positive (7,8). In the United States, FBM was approved for both adjunctive and monotherapy use for partial-onset seizures in 1993. Dangerous side effects were not anticipated based on the experience of 2100 patients enrolled in clinical trials, but in 1994, FBM was linked to cases of aplastic anemia and liver failure (9), and prescription numbers plummeted. FBM remains available for patients with refractory seizures who respond poorly to other medications. Patients on long-term therapy are often quite loyal to the drug, citing its nonsedating quality. An estimated 6000 to 10,000 patients are currently taking FBM in the United States (Gever L, personal communication, 2013).

CHEMISTRY AND MECHANISMS OF ACTION

Chemistry

FBM (2 phenyl-1,3-propanediol dicarbamate, molecular weight 238.24) differs from meprobamate by having a phenyl group, rather than an aliphatic chain, at the 2-carbon position (Fig. 54.1). It is lipophilic and relatively insoluble in water (10).

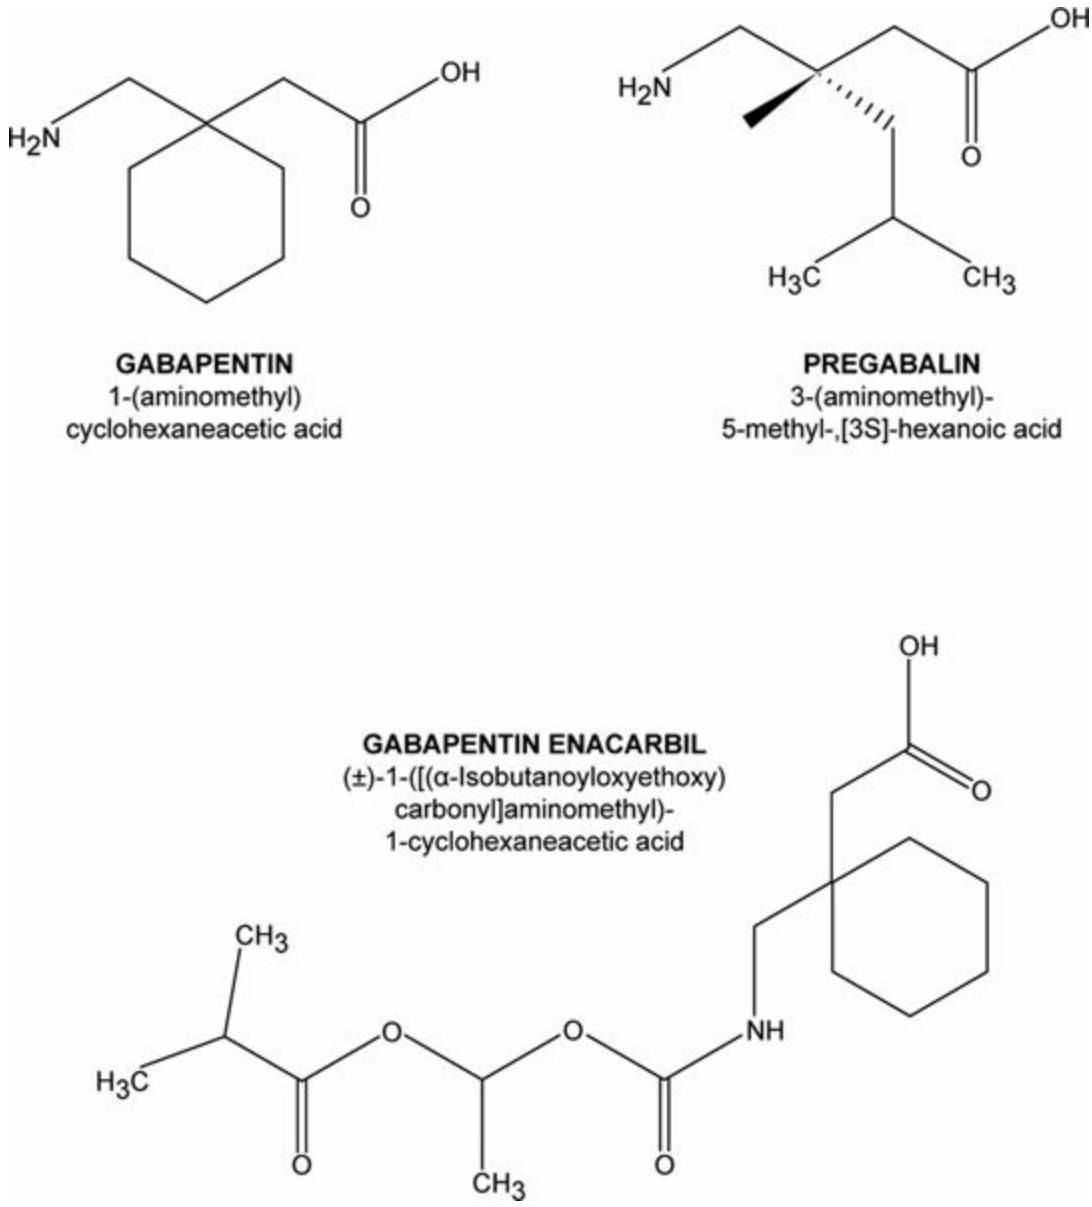

Figure 54.1. Structure of felbamate.

Antiepileptic Profile in Animals

FBM displayed high protective indices (toxic $dose_{50}$/effective $dose_{50}$) against the tonic phase of both maximal electroshock seizures (MES) and subcutaneous pentylenetetrazol-induced seizures in rodents (1). It is effective in amygdala-kindled, phenytoin (PHT)-resistant rats (11).

Mechanisms of Action

FBM binds to open ion channels of the N-methyl-D-aspartate (NMDA) subtype of the glutamate receptor (12) and may also modulate NMDA receptor function by binding to an associated strychnine-insensitive glycine receptor (13). These actions inhibit sodium and calcium excitatory currents. The NMDA effect of FBM is unique among available AEDs. Binding is more specific to receptors containing the N2RB subunit of the glutamate receptor (14,15). Subtype specificity may account for the lack of serious neurobehavioral complications and impairment of learning, which might be expected of NMDA receptor blockers (16).

FBM may also affect non–NMDA-type glutamate channels (17), voltage-gated sodium channels

(17), high-threshold voltage-sensitive calcium currents (18), and GABA-mediated chloride current inhibition (19).

The antiglutamatergic mechanism may imply neuroprotective effects: FBM reduced neuronal damage in a rat model of hypoxia–ischemia (20), protected CA1 hippocampal neurons from apoptosis in a gerbil ischemia model (21), and exhibited neuroprotective effects in a rat model of status epilepticus (22).

ABSORPTION, DISTRIBUTION, AND METABOLISM

FBM is well absorbed; more than 90% of ^{14}C-labeled FBM, or its metabolites, is recovered in urine and feces after oral administration (23). The rate and extent of absorption are not affected by food or antacids (24). Protein binding in human plasma is low, 22% to 25% (23). FBM readily crosses the blood–brain barrier (25).

Of the absorbed FBM dose, 30% to 50% is excreted in the urine unchanged (23). The remainder —more if there is renal insufficiency—is metabolized by the liver, utilizing CYP3A4 and CYP2E1 isozymes (23). Clearance in children is up to 40% higher in comparison to adults (26) but does not decrease significantly in the elderly (27).

In humans, FBM exhibits linear first-order kinetics over a dose range of 1200 to 6000 mg/day (28). Peak plasma concentration is reached 3 hours after an oral dose (23). Monotherapy with FBM 3600 mg/day produced a mean trough plasma level of 78.4 μg/mL (range, 23.7 to 136.6 μg/mL) in one study (7) and a mean (±standard deviation) level of 65 (±23) μg/mL after 112 days in another (8).

The mean terminal elimination half-life of 20 hours (range, 13 to 23 hours) in monotherapy decreases to 13 to 14 hours in the presence of phenytoin (PHT) or carbamazepine (CBZ) (3). The apparent volume of distribution is 0.8 L/kg (3,29). Steady-state plasma levels are achieved in 4 days (29).

EFFICACY

FBM is approved for use in the United States as either adjunctive therapy or monotherapy for patients older than 14 years of age with partial seizures, with or without generalization, and as adjunctive therapy for patients of any age with Lennox–Gastaut syndrome and its component seizure types (29).

Partial-Onset Seizures

Early clinical studies of FBM employed standard adjunctive trial designs. Adding FBM to CBZ (4,5) or to PHT (4) in outpatient trials produced modest reductions in seizure frequency. An adjunctive therapy trial among patients in an inpatient seizure monitoring unit produced a more encouraging result (6). The primary end point was time to occurrence of a fourth seizure or 29 days, whichever came first. Of patients randomized to adjunctive placebo, 88% had a fourth seizure, compared to 46% taking adjunctive FBM ($P = 0.03$) (6). Nevertheless, the authors of a Cochrane review concluded that there is “no reliable evidence to support the use of FBM as an add-on therapy in patients with refractory partial-onset epilepsy” (30). A flaw in this conclusion is that CBZ and PHT strongly induce the metabolism of FBM, and it is possible that suboptimal FBM concentrations were achieved

in those three trials (4–6). The efficacy of FBM when added to newer non–enzyme-inducing drugs has not been tested in humans, although a synergistic effect with levetiracetam was shown in a mouse MES model (31).

In 1988, new monotherapy designs for AED trials were proposed in a workshop sponsored by the NIH (32). Clinical investigators of FBM were the first to use these designs. The presurgical design was repeated as a monotherapy trial, and results suggested good efficacy (33). In two outpatient monotherapy trials, standard therapy was withdrawn over 28 days, while FBM 3600 mg/day or valproate (VPA) 15 mg/kg/day was substituted (7,8). The VPA control requires explanation: it was a compromise between a placebo control, considered unsafe, and a flexible dose active control, which could have reduced the chance of detecting a difference (34). This design has been criticized as violating the concept of equipoise, but 15 mg/kg/day is the recommended starting dose for VPA. Therefore, patients were randomized to a drug with unknown efficacy—FBM—or to the recommended initial dose of a drug with proven efficacy for their seizure type—VPA. The end point, "escape" (treatment failure), was defined individually for each patient according to predetermined criteria, including doubling of seizure frequency during any 2-day or 30-day period compared to the pretreatment baseline. Patients were removed from the trial at once if one of the end points were met. Patients taking low-dose VPA met escape criteria more often than did FBM-treated patients (86% vs. 14%, respectively, of 42 patients in the single-center study (7); 78% vs. 40%, respectively, of 95 patients in the multicenter study (8). Experience with partial-onset seizures in children is limited.

Lennox–Gastaut Syndrome and Other Seizure Types

FBM 45 mg/kg/day was used as adjunctive therapy, most often as an adjunct to valproate, in a multicenter, double-blind, controlled trial of 73 patients with a diagnosis of Lennox–Gastaut syndrome (35). Atonic seizures (drop attacks) were reduced by 34% and all seizures by 19%, versus a 9% decrease and a 4% increase, respectively, with placebo. During a 12-month, open-label follow-up, seizure frequency decreased by 50% with adjunctive FBM, compared to 15% with adjunctive placebo (36).

Infantile spasms may respond (37). Among 38 children with severe intractable epilepsies (22 Lennox–Gastaut syndrome, 6 Doose syndrome, and 10 other syndromes), FBM rendered 16% seizure free and 63% experienced a reduction of >50% in seizure frequency (38). Children younger than 4 years of age with various seizure types have sometimes responded well (39).

DRUG INTERACTIONS

Skillful use of FBM requires knowledge of several drug interactions. Primary references for these interactions are available from a review article (40). Clinically significant interactions are summarized in Table 54.1. FBM often acts as an enzyme inhibitor, especially of the cytochrome P450 2C19 isozyme. FBM therefore increases serum levels of many other drugs, including phenobarbital, PHT, and warfarin. FBM raises VPA levels by inhibiting its beta oxidation. Typical clinical toxicities of concomitant drugs, such as ataxia with PHT, may occur when FBM is added. The FBM/CBZ interaction is unusual: when FBM is added to CBZ, levels of CBZ decrease by 20% to 30%, but CBZ epoxide (CBZ-E) levels increase by 50% to 60%. The increase in CBZ-E can cause clinical toxicity such as dizziness, diplopia, or headache.

Table 54.1 Interactions of Felbamate with Other AEDS

	Effect of felbamate on other AEDs		Effect of other AEDs on felbamate
	AED change in concentration (%)	Recommended dose adjustment (%)	Change in concentration (%)
Phenytoin	↑ (30–50)	↓ (20–33)	↓ (32)
Carbamazepine (total)	↓ (30)	↓ (20–33)	↓ (38)
Carbamazepine (epoxide)	↑ (50–60)	—	—
Valproate	↑ (25–50)	↓ (20–33)	↔ (Variable, 53)
Phenobarbital	↑ (24)	↓ (25)	↓ (27)
Gabapentin	—	—	↑ (37)

AEDs, antiepileptic drugs.

In contrast, enzyme-inducing drugs may lower effective FBM serum levels by enhancing its metabolism via CYP2E1 and CYP3A4 pathways. This effect is pronounced for PB, CBZ, and PHT, which lower FBM levels by 27%, 32%, and 38%, respectively (40).

Oddly, CYP3A4 inhibitors such as erythromycin have little effect on FBM metabolism. VPA, however, does inhibit the metabolism of FBM, though the extent is not clear from the limited data. A nonmetabolic effect of gabapentin (GPN) in raising FBM serum levels is thought to be due to an interaction at the renal excretion level: GPN can increase FBM elimination half-life by 46% (40).

ADVERSE EFFECTS

Common Adverse Effects

The overall dropout rate attributed to adverse effects in clinical trials was 12% (29), a figure not dissimilar to that seen in clinical trials of other new AEDs. Gastrointestinal disturbances, headache, anorexia, and insomnia are common (7,8,29). Weight loss is most likely over the first year of use, then may stabilize (29). Dizziness, diplopia, and ataxia were more common in adjunctive therapy than with monotherapy (4,5,7,8) and thus may have been related to pharmacokinetic elevations in PHT and CBZ-E levels.

Monotherapy is better tolerated. Among 366 adults receiving monotherapy, 4.1% experienced nausea, 3.6% insomnia, 3% anorexia, 2% to 5% dizziness, and 2% weight loss (7,8,33). Administering FBM in three daily doses after meals may reduce stomachache.

FBM has a stimulant effect in many patients. This is a major advantage in comparison to other AEDs, but it may be associated with insomnia, irritability, and behavioral changes. Giving the largest dose in the morning may help insomnia. At 3% to 4%, the incidence of rash was no higher than placebo in clinical trials (29). Two children experienced involuntary dyskinetic movements (41). There is one report of a kidney stone (42).

Dose-Limiting Effects

Doses in clinical trials were limited to 3600 mg/day for adults and 45 mg/kg/day for children. Some patients cannot achieve these doses without side effects, especially in adjunctive therapy. Higher doses are sometimes well tolerated: among 50 patients stabilized on 3600 mg/day whose dose was raised to 4200 to 7200 mg/day (mean 5412 mg/day, mean serum concentration 110 mg/L), 32%

developed new or increased side effects, but only 15% required dose reductions (43). The most common dose-limiting effects in this group were dizziness, ataxia, and nausea.

Aplastic Anemia

FBM can cause aplastic anemia. In 1994, 33 cases were reported to the FDA (9,44,45). Another case was reported in 2000 and a questionable one in 2007 (29). There have been 14 fatalities. Detailed review of the first 31 cases according to International Agranulocytosis and Aplastic Anemia Study criteria revealed that 23 (74%) met criteria for a diagnosis of aplastic anemia (44). Six others had preexisting blood dyscrasias or systemic lupus erythematosus. Of the 23 confirmed cases, FBM was implicated as the most likely cause in 14; others had other plausible causes, usually other medications known to cause aplastic anemia.

Based on a 1997 estimate of 110,000 patients exposed, this yields a most probable incidence of 127 per million (1/8000 cases), compared with a population rate of 2 per million per year, with a worse-case incidence of 300 per million (44). By comparison, estimates for CBZ range from 5 to 39 per million per year (44). All FBM-related aplastic anemia cases were diagnosed within 1 year of starting the drug, two-thirds within 6 months (45). This suggests that the risk drops substantially after 1 year.

Patients developing aplastic anemia were more likely to have histories of blood dyscrasias, especially cytopenia, autoimmune disorders, and rashes, or significant toxicities with previous drugs (45,46). It seems best to avoid FBM in such patients. FBM may be safer for children; only one child, a postpubescent 14-year-old, has been affected (29).

Liver Failure

Among patients taking FBM for 25 to 959 days, 18 reported cases of liver failure resulted in 9 fatalities (45,46). Of these 18, 8 cases may have been caused by other factor: 5 with status epilepticus and 1 case each of hepatitis A, acetaminophen poisoning, and severe hypotension. Using population exposure estimates, this implies a risk of about 1 per 10,000 patient exposures.

Mechanisms of Toxicity

The mechanism by which FBM causes bone marrow and liver toxicity is unknown, but the formation of a toxic metabolite that triggers an immune reaction is suspected. The second step in FBM metabolism is formation of 3-carbamoyl-2-phenylpropionaldehyde (CBMA) (47). CBMA is then metabolized by three competing pathways, one of which leads to the formation of 2-phenylpropenal, also known as atropaldehyde (47). Atropaldehyde is cytotoxic and immunogenic, and it may be that individuals who form more of this compound on a genetic basis are more at risk. The aldehyde undergoes beta-elimination to 2-phenylpropenal, another known toxic compound (48). Since atropaldehyde is detoxified by glutathione, and glutathione stores are depleted by acetaminophen, it seems prudent to advise patients on FBM therapy not to take acetaminophen, although this notion is theoretical. There may be other mechanisms for blood toxicity. Both FBM and metabolites can cause apoptosis of bone marrow progenitor cells in vitro (49). Fluorofelbamate, a potent antiepileptic compound that is not metabolized to atropaldehyde, has been proposed as a safer alternative to FBM (50), and other carbamate derivatives of FBM show promise as anticonvulsant agents (51). However, it will be difficult to conduct human trials of these drugs without very thorough reassurance from

animal safety studies.

CLINICAL USE

Patient Selection

Because of the low but definite risk of serious blood or liver reactions, FBM should not be used as initial therapy or when an effective alternative can be found. Patients with focal seizures refractory to several drugs, especially with both severe epilepsy and drug sedative side effects, may be considered for treatment. A Quality Standards Subcommittee of the American Academy of Neurology and the American Epilepsy Society have formulated practice guidelines (52) (Table 54.2). All patients or their caretakers must be able to report side effects reliably, comply with blood testing, and understand potential risks and benefits.

Table 54.2 Recommendations for Use of Felbamate

A. Patients for whom risk-to-benefit ratio supports use because there is class I evidence of benefit
   1. Patients with Lennox–Gastaut syndrome >4 y of age who are unresponsive to primary AEDs
   2. Intractable partial seizures in patients >18 y of age who have failed standard AEDs at therapeutic levels (monotherapy data indicate a better risk-to-benefit ratio for FBM used as monotherapy)
   3. Patients taking FBM >18 mo

B. Patients for whom the current risk-to-benefit assessment does not support the use of FBM
   1. New-onset epilepsy in adults or children
   2. Patients who have experienced significant prior hematologic adverse events
   3. Patients in whom follow-up and compliance will not allow careful monitoring
   4. Patients unable to discuss risks to benefits (i.e., those with mental retardation, developmental disability) and for whom no parent or legal guardian is available to provide consent

C. Patients in whom risk-to-benefit ratio is unclear and based on case reports and expert opinion (class III) only, but under certain circumstances, depending on the nature and severity of the patient's seizure disorder, FBM use may be appropriate
   1. Children with intractable partial epilepsy
   2. Patients with other generalized epilepsies unresponsive to primary agents
   3. Patients who experience unacceptable sedative or cognitive side effects with traditional AEDs
   4. Patients with Lennox–Gastaut syndrome <4 y of age who are unresponsive to other AEDs

Adapted from French J, Smith M, Faught E, et al. Practice advisory: the use of felbamate in the treatment of patients with intractable epilepsy. Report of the Quality Standards Subcommittee of the American Academy of Neurology and the American Epilepsy Society . Neurology. 1999;52:1540–1546, with permission.

Dosage

Both children and adults may be started on FBM 15 mg/kg/day in three divided doses, taken after meals, with increases to 30 mg/kg/day and 45 mg/kg/day at 2-week intervals (29). Therefore, the starting dose for adults is about 600 mg twice a day. However, starting with 300 to 400 mg twice a day (one 400-mg tablet or half 600-mg tablet) is better tolerated, then doses can be increased more slowly at about 10 mg/kg/day every 2 weeks. It is important to remember that FBM is generally an enzyme inhibitor and doses of other drugs may need to be decreased to avoid toxicity. For example, ataxia when it is added to PHT and headache and dizziness when it is added to CBZ are to be expected, and the proper course of action is to reduce the baseline drug. This effect can be verified by measuring levels of the baseline drug or CBZ epoxide in the case of CBZ. FBM is more effective and better tolerated as monotherapy, and if initial encouraging results are obtained, consideration should be given to reduction or withdrawal of concomitant drugs. Nevertheless, if seizure freedom without

toxicity is achieved with polytherapy, it is certainly reasonable to defer further dose changes. The target adult dose is 3600 mg/day; the target pediatric dose is 45 mg/kg/day. If no definite improvement is seen at this dose, FBM should be tapered back down gradually over 4 to 6 weeks and stopped. There is no reason to expose a patient to therapy longer than a few months in the absence of benefit, since shorter therapy durations, at least up to a year, may reduce the risk of dangerous side effects. Higher mg per kg doses may be necessary for younger children, in whom clearance is increased (26). Because of the many drug interactions, FBM serum levels during polytherapy may also be useful. The average therapeutic range for FBM is reported to be 50 to 110 mg/L, similar to valproate (53).

Monitoring for Adverse Effects

Patients with aplastic anemia from any cause may have symptoms before laboratory confirmation (54). Patients should be advised to watch for early symptoms, especially unusual fatigue, pallor, dyspnea, easy bruising, or bleeding. Nausea, vomiting, or jaundice may be indicative of hepatic problems. The manufacturer recommends blood counts and liver function tests, but the frequency is not mandated (29). However, neither patient surveillance nor periodic blood testing may detect adverse events early enough to prevent serious illness or death. A reasonable schedule is a baseline blood count and liver function panel before FBM is started, followed by monthly testing for the first 6 months then every 2 months for the second 6 months. Experience has shown that patients comply poorly with more frequent blood tests. The diminishing risk after 1 year implies that less frequent testing is acceptable, perhaps every 3 months during the second year, then only if symptoms develop thereafter. There is no evidence that lower doses are safer. Since most serious reactions began 3 to 12 months after initiation of FBM, consideration should be given to withdrawing it if no benefit occurs after a few months (44). There are no published guidelines for how much change in blood parameters should mandate FBM discontinuation. FBM should be withdrawn at once if a precipitous drop in white or red blood cells or platelets occurs, or perhaps if two of the three cell lines drops below the laboratory lower limit of normal. It may be acceptable to monitor a drop of a single cell line, perhaps with weekly blood counts, so long as the cell count itself is within a safe range. It is even harder to know what change in liver function parameters should lead to discontinuation. It is probably reasonable for the clinician to follow his or her usual practice for other hepatically metabolized drugs. Of course, a steady trend downward in blood counts or upward trend in liver function tests even within the normal range may be enough to support a decision to stop.

Managing Adverse Effects

The first question to ask is whether adverse effects are from FBM itself or from the pharmacokinetic or pharmacodynamic effects on the concomitant drugs. Common FBM-specific effects may include insomnia, gastrointestinal distress, weight loss, and headache. Insomnia can be moderated by giving a larger dose earlier in the day, or giving a dose right at bedtime, so that the maximal concentration occurs after sleep is achieved. An hypnotic may be necessary. Otherwise FBM should be given after meals to reduce GI effects. Weight loss is usually only a problem in thin individuals, especially in patients with cognitive problems who cannot increase their caloric intake voluntarily. Headache usually requires an FBM dose reduction.

Withdrawal from Felbamate

Dramatic increases in seizure frequency and even status epilepticus can occur with rapid withdrawal from FBM (55). Remember that as the dose of FBM is reduced, levels of PHT, PB, and valproate will also decrease. Surveillance for hematologic and hepatic effects should be continued for 6 months after FBM therapy ends, because damage to bone marrow stem cells may not be manifested immediately in peripheral blood counts. If a quick reduction in FBM is necessary because of hematologic or hepatic concerns, then either a simultaneous increase in a concomitant AED or a bridge treatment with a benzodiazepine should be considered.

SUMMARY

FBM can be dramatically effective, especially as monotherapy for focal seizures. Many patients report improved alertness when switched from other drugs. Nevertheless, serious toxicities preclude its use except in those patients who do not achieve complete seizure control with safer agents. Safety may be improved by avoiding FBM use in patients with autoimmune diseases, previous histories of significant cytopenia, or serious drug reactions. The combined risk for serious bone marrow or hepatic toxicity is about 1 per 5000 patients, and for death perhaps 1 in 10,000, with nearly all of the risk coming during the first year. These dangers are almost certainly less than the dangers of poor seizure control.

CHAPTER 55 GABAPENTIN AND PREGABALIN

PIERO PERUCCA AND JOHN M. DOPP

Gabapentin (1-[aminomethyl]cyclohexaneacetic acid; Neurontin) and pregabalin (3-[aminomethyl]-5-methyl-,[3S]- hexanoic acid; Lyrica) are 3-substituted analogues of γ-aminobutyric acid (GABA), constituting a class of compounds known as "gabapentinoids" (Fig. 55.1). Related to this class is gabapentin enacarbil ((±)-1-([(α-isobutanoyloxyethoxy)carbonyl]aminomethyl)-1-cyclohexaneacetic acid; Horizant), an acyloxyalkylcarbamate analogue and a prodrug of gabapentin (see Fig. 55.1).

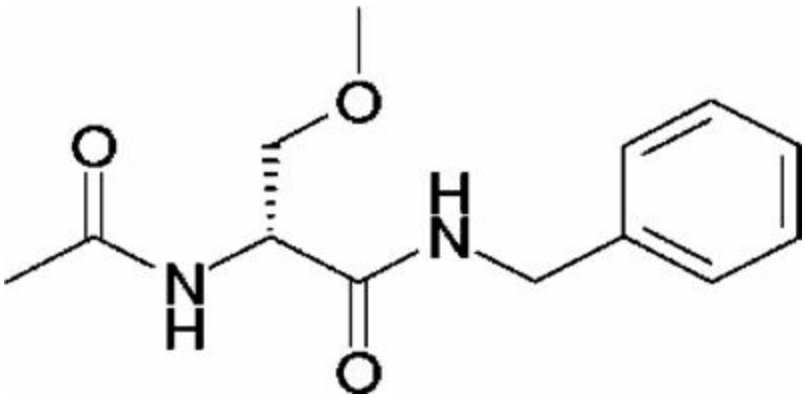

Figure 55.1. Chemical structure of gabapentin, pregabalin, and gabapentin enacarbil.

The mechanism of action of gabapentinoids differs from that of other antiepileptic drugs (AEDs). Contrary to initial belief, they do not interact with GABA receptors. Rather, compelling evidence suggests that they bind to the α_2-δ subunit of the P-, Q-, and N-type voltage-gated calcium channels (1,2). The binding affinity of pregabalin for the α_2-δ subunit is six times greater than that of gabapentin (3). The functional consequences of binding to this site are yet to be fully elucidated. These may involve allosteric modulation of calcium channels (4), or inhibition of trafficking and expression of calcium channels at the presynaptic membrane (5). In any case, the ensuing effect appears to be a decrease in presynaptic calcium influx, which leads to a reduction in calcium-dependent release of neurotransmitters, such as glutamate, noradrenaline, serotonin, acetylcholine, substance P, and calcitonin gene–related peptide, from nerve terminals (6).

GABAPENTIN

Chemistry

Gabapentin is a highly water-soluble, bitter-tasting, white crystalline substance with a molecular weight of 171.34 g/mol. At 25°C, it has two pK_a values at 3.68 and 10.70. At physiologic pH, it is a

zwitterion—a neutral molecule with both negative and positive charges (7). In this latter form, gabapentin is recognized by the L-amino acid transport system, which mediates its transport across the gut wall, the blood–brain barrier, and cell membranes (7,8).

Pharmacokinetics

Absorption

Gabapentin is absorbed predominantly in the small intestine, where the L-amino acid transport system is concentrated (9). Absorption in the colon is poor (10).

Gabapentin exhibits dose-dependent pharmacokinetics because its oral bioavailability decreases with increasing doses (11). Oral bioavailability is approximately 60% after a 300-mg dose, but only approximately 40% after a 600-mg dose and approximately 35% at a dose of 1600 mg t.i.d. at steady state (7). Peak serum concentrations typically occur 2 to 3 hours postdose (7,9), and steady state is achieved in 1to 2 days (7). Although in phase I pharmacokinetic studies serum concentrations of gabapentin increased linearly up 1800 mg/day (12), further rises in serum concentrations were less than dose proportional at doses between 1900 and 4800 mg/day (12). A nonlinear increase in serum concentrations of gabapentin with increasing doses was also noted in clinical trials (12). Overall, these findings are consistent with the saturability of the L-amino acid transport system involved in the gastrointestinal absorption of the drug (11,13).

Absorption of gabapentin varies considerably between patients (14), resulting in substantial interindividual variations in serum concentrations (13), which may contribute to differences in dose requirements. Within subjects, however, pharmacokinetic variability appears to be relatively low (13).

No dose adjustments are required when the drug is administered with food, as this has a negligible impact on gabapentin absorption (9).

Distribution

Gabapentin is not bound to plasma proteins (15). The volume of distribution is approximately 60 L or 0.65 to 1.04 L/kg (7). Gabapentin crosses the blood–brain barrier via the L-amino acid transport system. Cerebrospinal fluid (CSF) concentrations are 5% to 35% of that of plasma (15), and after a single dose continue to rise for hours after peak serum concentrations are attained.

Elimination

Gabapentin is not metabolized in humans and is eliminated unchanged in the urine (15,16). The elimination half-life of gabapentin is 5 to 9 hours in individuals with normal renal function (17). It is unknown whether gabapentin elimination is dependent on a tubular reabsorption process. However, cimetidine (an inhibitor of renal tubular secretion) decreases gabapentin clearance by approximately 12%, suggesting that a tubular secretion process could be involved in the elimination of the drug (18).

Special Populations

Gabapentin clearance is higher in children than in adults. It is greatest in younger children, with those under 5 years of age requiring approximately 30% higher doses than do children aged 5 to 12 years

(19). Gabapentin serum concentrations are higher in the elderly than in nonelderly adults receiving the same dose, a finding that is consistent with the physiologic decline in renal function (20).

Gabapentin clearance is decreased in patients with renal failure (especially in those requiring hemodialysis), potentially resulting in severe drug toxicity if appropriate dose adjustments are not made (21). Dose recommendations for different degrees of renal impairment are available in the drug information sheet (22).

New Formulations

To overcome the problems of gabapentin having a short half-life and a saturable mechanism of absorption, an extended- release formulation (Gralise) has been developed, which uses gastric-retentive technology to release gabapentin slowly over approximately 10 hours (23). This may attenuate the saturation of the L-amino acid transport system, thus enhancing and prolonging the absorption of the drug, particularly at higher doses, compared to the traditional formulation (24). Absorption of the extended-release formulation is substantially improved by food (23). Extended-release gabapentin has been found to be effective in the treatment of postherpetic neuralgia (23), but no controlled trials with this formulation have been reported as yet in patients with epilepsy.

Another agent developed to improve gabapentin absorption is gabapentin enacarbil, a prodrug of gabapentin (25). Gabapentin enacarbil is absorbed in the small and large intestine via the monocarboxylate transporter type 1 and the sodium-dependent multivitamin transporter (25). Absorption of gabapentin enacarbil is not saturable nor dose dependent, and it is improved by food. Gabapentin enacarbil is rapidly converted to gabapentin by nonspecific carboxylesterases in enterocytes and, to a lesser extent, in the liver (25). Serum concentrations of the intact prodrug are transient and represent ≤2% of those of gabapentin. The disposition of gabapentin derived from gabapentin enacarbil is similar to that of gabapentin administered as such. Gabapentin enacarbil is effective in the treatment of moderate–severe primary restless legs syndrome and postherpetic neuralgia, but no controlled studies with this agent have been reported as yet in patients with epilepsy.

Drug Interactions

Gabapentin has not been reported to cause or be a target for clinically relevant drug interactions. This is attributable to the fact that gabapentin is not bound to plasma proteins, is not metabolized, and does not induce or inhibit enzymes involved in the metabolism of other drugs (7,9).

Antacids containing aluminum or magnesium can reduce gabapentin bioavailability by approximately 20% (7), but the clinical relevance of this interaction is uncertain (7). In any case, it is generally recommended that administration of antacids and gabapentin be separated by ≥2 hours.

Efficacy

Adjunctive Therapy in Epilepsy

Adults.

Five randomized, double-blind, placebo-controlled trials demonstrated the efficacy of gabapentin as

adjunctive therapy in adults with refractory partial seizures (26–30) (Table 55.1). In these studies, 600 to 1800 mg/day of gabapentin (in three divided doses) were investigated over approximately 3 months. Titration was 2 to 3 days, except for one study (26) in which the target dose was reached over a 2-week period. The proportion of patients attaining a ≥50% reduction in seizure frequency compared to baseline (responder rates) varied between 12.5% and 33% (vs. 6.7% and 16.7% with placebo), with higher doses being associated with higher responder rates. Open-label studies (31–33) and case series (34,35) have suggested additional benefit at even higher doses (up to 6400 mg/day).

[a]All studies consisted of a 12-wk baseline period, followed by a 12-wk treatment period. The only exception was the UK Gabapentin study group (26), in which the 12-week baseline was followed by a 14-week treatment period.[b]In three divided doses.
*P < 0.05,**P < 0.01 and ***P < 0.001 for comparisons with placebo.
n/r, not reported; R Ratio = (T − B)/(T + B), where T is the seizure frequency during treatment and B is the seizure frequency during baseline. Therefore, negative values indicate a reduction in the number of seizures during treatment, whereas positive values indicate an increase; Responder rate, proportion of patients with ≥50% reduction in seizure frequency.

A 14-week, double-blind, placebo-controlled trial evaluated the efficacy of gabapentin as add-on therapy for refractory generalized seizures in patients with idiopathic or symptomatic generalized epilepsy (37). A total of 129 patients with a mean age of approximately 30 years (range: 13 to 62) were randomized to placebo or 1200 mg/day of gabapentin. No significant differences were found between the two groups in terms of seizure outcome. The lack of effect on seizure outcome may be a result of the relatively low dose of gabapentin used in the study.

Children.

A 12-week, randomized, double-blind, placebo- controlled trial of 247 patients provided evidence for the efficacy of gabapentin as adjunctive therapy for refractory partial seizures in children aged 3

to 12 years (38). The target dose was 25 to 35 mg/kg/day. Children receiving gabapentin had a median reduction of 35% in the frequency of complex partial seizures (vs. 12% in the placebo group) and 28% in the frequency of secondarily generalized seizures (vs. a 13% increase in the placebo group). Higher daily doses (up to 78 mg/kg/day) have been used in open-label studies, but do not appear to be associated with increased efficacy (39).

The efficacy of gabapentin (40 mg/kg/day) as add-on treatment for refractory partial seizures in very young patients has been investigated in a 3-day, randomized, double-blind, placebo-controlled trial in 76 patients aged 1 to 36 months (40). Although there was a reduction in seizure frequency in the gabapentin arm versus a worsening in patients receiving placebo, differences did not reach statistical significance.

Monotherapy in Epilepsy

Adults.

The efficacy of gabapentin as monotherapy for refractory partial seizures has been evaluated in two randomized double-blind trials (41,42). One study compared 300 and 3600 mg/day over an 8-day period in 82 hospitalized patients whose medications had been discontinued for seizure monitoring (41). Time to meet exit criteria primarily related to lack of efficacy (the primary outcome variable) was significantly longer and completion rate was significantly higher in the 3600 mg/day arm. In the second study, 275 patients were randomized to 600, 1200, or 2400 mg/day and then underwent gradual discontinuation of their concomitant AEDs (42). Duration of the double-blind treatment phase was 26 weeks (2 weeks of gabapentin add-on therapy; 8 weeks of gradual discontinuation of concomitant AEDs; and 16 weeks of gabapentin monotherapy). Outcome measures, including time to exit, completion rate, and mean time on monotherapy, did not differ across the three groups. Overall, completion rate was only 20%.

Several studies assessed the efficacy of gabapentin monotherapy in adults with newly diagnosed seizures. Chadwick et al. (43) randomized 275 patients with newly diagnosed epilepsy to one of three masked doses of gabapentin (300, 900 or 1800 mg/day) or an open-label fixed dose of immediate-release carbamazepine (600 mg/day). After titration (7 days for gabapentin, 21 days for carbamazepine), patients entered a 24-week evaluation phase. Completion rate was 37% in the carbamazepine arm and 25%, 39% and 38% in patients receiving 300, 900 and 1800 mg/day, respectively. Although the completion rate for 900 and 1800 mg/day of gabapentin was similar to that of carbamazepine, more patients in the two gabapentin groups (40% and 43%, respectively) exited the study due to seizure occurrence compared to the carbamazepine group (30%). Conversely, the withdrawal rate because of adverse events was higher with carbamazepine compared to gabapentin 900 and 1800 mg/day (24% vs. 4% and 14%, respectively). In a 30-week, randomized, double-blind study, Brodie et al. (44) compared 1200 to 3600 mg/day of gabapentin to 100 to 300 mg/day of lamotrigine in 309 patients with newly diagnosed partial or generalized epilepsy. No between-group differences were found across several outcome measures. However, since many patients had only a few seizures in the ≥12 months prior to enrollment (median seizure number at study entry: 3 for the gabapentin group and 4 for the lamotrigine group), a period >30 weeks would have been desirable to obtain a more robust assessment of comparative efficacy. In an open-label trial (45), 1721 patients for whom carbamazepine was deemed to be preferable to valproate as initial treatment were randomized to carbamazepine (100 to 2000 mg/day), gabapentin (300 to 4800 mg/day), lamotrigine

(20 to 800 mg/day), topiramate (25 to 600 mg/day), and oxcarbazepine (300 to 2850 mg/day), and followed for up to 6 years. Most patients (82%) had newly diagnosed seizures, but patients who had previously received suboptimal treatment or who had relapsed after discontinuation of effective therapy were also included. Time to treatment failure, one of two primary endpoints, was significantly better with lamotrigine compared to gabapentin (hazard ratio 0.65 [95% CI 0.52–0.80]). Time to 12-month remission, the other primary endpoint, significantly favored carbamazepine over gabapentin (0.75 [0.63–0.90]).

A randomized, double-blind, parallel study compared gabapentin (target dose: 1500 mg/day), lamotrigine (150 mg/day), and immediate-release carbamazepine (600 mg/day) in 593 elderly patients (mean age 72 years) with newly diagnosed seizures (36). Patients were followed for up to 2 years. Doses could be optimized on the basis of clinical response. Although carbamazepine was the most efficacious agent, significantly more patients in the lamotrigine and gabapentin groups (55.8% and 49%, respectively) remained in the trial for 12 months, the primary outcome measure, compared to the carbamazepine group (35.5%; $P < 0.0001$ for lamotrigine and $P = 0.008$ for gabapentin vs. carbamazepine). This was largely attributable to the fact that carbamazepine was associated with higher withdrawal rates due to adverse events (31% vs. 12.6% for lamotrigine and 21.6% for gabapentin; $P = 0.001$).

Children.

The efficacy of gabapentin (9.7 to 19.1 mg/kg/day) in newly diagnosed childhood absence epilepsy has been investigated in two identical 2-week, randomized, double-blind, placebo-controlled trials including 33 children aged 4 to 12 years (46). Gabapentin did not significantly improve or worsen seizure frequency compared to placebo.

A double-blind study suggested that gabapentin monotherapy may be efficacious in benign childhood epilepsy with centrotemporal spikes (47). A total of 225 patients aged 4 to 13 years were randomized to gabapentin (30 mg/kg/day) or placebo for 34 weeks. In preliminary analyses, time to treatment failure was significantly longer with gabapentin compared to placebo. The estimated completion rate was 57% in the gabapentin arm and 44% in the placebo arm. These preliminary data, however, have not been followed by a final report.

Nonepilepsy Indications

There is evidence from randomized, double-blind, placebo- controlled trials that gabapentin is effective in the treatment of neuropathic pain disorders, particularly postherpetic neuralgia (48). Other conditions for which gabapentin may be useful include restless legs syndrome, anxiety disorders, and postoperative pain (49–51).

Adverse Effects

Gabapentin is generally well tolerated. In early trials, dropout rates due to adverse events were <10% in patients receiving gabapentin. Its adverse effects typically involve the central nervous system (CNS), such as drowsiness, fatigue, dizziness and ataxia (Table 55.2), tend to be mild to moderate in severity, often appear in the first few days of therapy, and may resolve within 2 to 3 weeks (13). These effects do not display a clear dose–response relationship (31,33) (see Table 55.2), with some individuals not tolerating even small doses of the drug (33).

Table 55.2 Most Common Treatment-Emergent Adverse Events in a Placebo-Controlled Trial of Gabapentin Versus a Placebo-Controlled Trial of Pregabalin

	US Gabapentin study group (1993) (28)				French et al. (2003) (52)				
		Gabapentin (mg/day)				Pregabalin (mg/day)			
Adverse event	Placebo (n = 98)	600 (n = 53)	1200 (n = 101)	1800 (n = 54)	Placebo (n = 100)	50 (n = 88)	150 (n = 86)	300 (n = 90)	600 (n = 89)
Somnolence	12.2%	7.5%	35.6%	20.4%	11%	10.2%	17.4%	17.8%	28.1%
Dizziness	9.2%	24.5%	24.8%	18.5%	9%	9.1%	16.3%	31.1%	42.7%
Ataxia	11.2%	11.3%	25.7%	18.5%	3%	3.4%	10.5%	10.0%	14.6%
Accidental injury	—	—	—	—	5%	14.8%	5.8%	11.1%	12.4%
Nystagmus	13.3%	9.4%	16.8%	16.7%	—	—	—	—	—
Asthenia	—	—	—	—	8%	5.7%	8.1%	12.2%	10.1%
Headache	12.2%	18.9%	8.9%	20.4%	13%	6.8%	9.3%	5.6%	5.6%
Tremor	9.2%	7.5%	14.9%	13%	3%	3.4%	3.5%	6.7%	11.2%
Fatigue	7.1%	11.3%	10.9%	13%	—	—	—	—	—
Withdrawal due to adverse events	1%	5.7%	2%	3.7%	5%	6.8%	1.2%	14.4%	23.6%

Note that, for both gabapentin and pregabalin, adverse events mainly involve the CNS. However, while gabapentin adverse events do not clearly display a dose-dependent relationship, those emerging during pregabalin therapy appear to be largely dose related.

A relatively common complication of gabapentin therapy is weight gain. DeToledo et al. (53) reviewed changes in body weight in 44 patients with refractory seizures receiving gabapentin for ≥12 months. Twenty-eight patients were taking doses of >3000 mg/day. Overall, 10 patients gained >10% of their initial weight, 15 patients gained 5% to 10%, 16 patients had no change, and 3 patients lost 5% to 10%. Gabapentin-induced weight gain appears to be dose related. In a 6-month open-label study of gabapentin add-on therapy for refractory partial seizures, weight gain was observed in 8%, 6.3%, 9.7%, and 15.2% of patients receiving 1200, 1600, 2000, and 2400 mg/day, respectively (31).

Gabapentin can cause peripheral edema, particularly at higher doses. In a pooled analysis of three randomized, double-blind, placebo-controlled studies of gabapentin in postherpetic neuralgia, the incidence of peripheral edema was 1.6%, 1.4%, and 7.5% in patients receiving placebo (n = 245), <1800 mg/day (n = 358), and ≥1800 mg/day (n = 321) of gabapentin, respectively (54). The edema resolves with discontinuation of therapy.

Movement disorders have been observed with gabapentin (55). There are several reports of gabapentin-induced myoclonus, for which individuals with preexisting myoclonus, severe chronic static encephalopathy, or renal failure appear to be at higher risk (56,57).

A few reports suggest that, in children and individuals with intellectual disabilities, gabapentin may induce behavioral problems, such as hyperactivity and aggression (51).

Serious idiosyncratic reactions are extremely uncommon during gabapentin therapy, and the potential for causing hypersensitivity reactions is much lower with gabapentin compared to some other AEDs, such as carbamazepine, phenytoin, and lamotrigine (58,59). Of note, three reports suggested that gabapentin may cause rhabdomyolysis (60–62).

There is sparse information on the fetal risks in gabapentin-exposed pregnancies (Table 55.3). As reflected by the large confidence intervals in Table 55.3, the number of exposed cases in each study is too small to allow meaningful conclusions about the teratogenic potential of gabapentin. In a recent prospective study (63), rates of major malformations in the offspring were 4.1% among 223 pregnancies exposed to gabapentin compared to 2.5% among 223 pregnancies exposed to agents considered nonteratogenic (e.g., acetaminophen or antibiotics). Gabapentin-exposed pregnancies were associated with lower rates of live births (76.2% vs. 90%, P < 0.001), and higher rates of therapeutic abortions (13% vs. 2.2%, P < 0.001), preterm births (10.5% vs. 3.9%, P = 0.019), low

birth weight (8.1% vs. 4%, P = 0.033), and admissions to neonatal intensive care unit/special care nursery (38% vs. 2.9%, P < 0.001). However, because no distinction was made between monotherapy and polytherapy, and pregnancy outcomes with other AEDs for comparison are missing, these findings are difficult to interpret.

Table 55.3 Rates of Major Congenital Malformations After Exposure to Gabapentin Monotherapy in Different Prospective Studies

Study	Number of exposed pregnancies	Number of malformations	Rate (95% CI)
Montouris (2003) (64)	17	1	5.9% (1.0%–26.7%)
Morrow et al. (2006) (65)	31	1	3.2% (0.6%–16.2%)
Tomson et al. (2011) (66)	23	0	—
Hernandez-Diaz et al. (2012) (67)	145	1	0.7% (0.1%–3.8%)
Fujii et al. (2013) (63)	36	0	—
Total	*252*	*3*	*1.2% (0.4%–4.3%)*

Inclusion criteria and methods of assessment (including duration of follow-up postnatally) differed across studies.
CI, confidence interval.

Place in Current Therapy

Gabapentin has been approved in several countries for adjunctive therapy and monotherapy use in partial seizures, as well as for the treatment of neuropathic pain. In the United States, it has received Food and Drug Administration (FDA) approval for adjunctive therapy in the treatment of partial seizures in patients aged ≥3 years, and for the management of postherpetic neuralgia in adults.

In the Neurontin U.S. Physician Prescribing Information (68), the recommended starting dose for patients with epilepsy aged >12 years is 300 mg t.i.d. However, if a rapid response is required, starting doses up to 3600 mg/day can be well tolerated. The effective dose range of Neurontin is given as 900 to 1800 mg/day (68). However, postmarketing experience suggests additional benefit with further dose increases, up to 3600 mg/day.

In children with epilepsy aged 3 to 12 years, the recommended starting dose is 10 to 15 mg/kg/day in three divided doses, which can be increased to the effective dose over a period of approximately 3 days (68). The effective dose of Neurontin is stated as 25 to 35 mg/kg/day in children aged 5 to 12 years, and 40 mg/kg/day in children aged 3 and 4 years (68).

Neither the extended-release formulation of gabapentin nor gabapentin enacarbil is indicated for the treatment of epilepsy. Extended-release gabapentin has received FDA approval for the treatment of postherpetic neuralgia in adults. Gabapentin enacarbil is FDA approved for the treatment of moderate–severe primary restless legs syndrome in adults, and postherpetic neuralgia in adults.

In the Gralise Prescribing Information (69), the recommended starting dose of extended-release gabapentin is 300 mg once daily, which should be increased to a 1800-mg once-daily dose over 15 days (69). Extended-release gabapentin should be taken with the evening meal. In the Horizant Prescribing Information (25), the recommended dose of gabapentin enacarbil is 600 mg once daily at 5 PM for the treatment of restless legs syndrome. For the treatment of postherpetic neuralgia, the recommended dose is 600 mg once daily for 3 days, which should be increased to 600 mg twice daily

beginning on day 4 (25). When discontinuing gabapentin enacarbil, tapering is not necessary in patients taking ≤600 mg/day (25). In patients with postherpetic neuralgia taking 600 mg twice daily, the dose of gabapentin enacarbil should be reduced to 600 mg once daily for 1 week prior to discontinuation to reduce the risk of withdrawal seizure (25).

In summary, gabapentin is a safe and well-tolerated agent, which displays a wide therapeutic window and no clinically relevant drug interactions. It is also suitable for rapid titration, with little or no significant risk for serious toxicity. Although well-designed head-to-head comparative studies are lacking, gabapentin is generally considered less efficacious than other AEDs for the treatment of partial seizures, possibly due to incomplete bioavailability especially at the high doses. There is no evidence of gabapentin being efficacious in generalized epilepsies. The extended-release formulations of gabapentin and gabapentin enacarbil have yet to be investigated in patients with epilepsy.

PREGABALIN

Chemistry

Pregabalin is a white to off-white crystalline substance with a molecular weight of 159.23 g/mol. It has two pK_a, 4.2 and 10.6, corresponding to the carboxylic acid and the amine groups, respectively (see Fig. 55.1). It is freely soluble in water and in basic and acidic aqueous solutions (70).

Pharmacokinetics

Absorption

Like gabapentin, pregabalin is absorbed in the small intestine by the L-amino acid transport system (9,71). Unlike gabapentin, which shows dose-dependent pharmacokinetics due to saturable absorption, pregabalin exhibits linear absorption pharmacokinetics within the therapeutic dose range (9,70). This can be explained by the fact that pregabalin is used clinically at much lower doses compared to gabapentin, and also by differences in regional distribution and sodium dependence between the pregabalin and gabapentin carriers (72). In addition, mechanisms other than the L-amino acid transport system may be involved in the absorption of pregabalin, and contribute to the >90% oral bioavailability across the effective dose range (9). Peak serum concentrations occur approximately 1 hour after oral intake, and steady state is achieved 1 to 2 days after repeated dosing. Food delays peak serum concentrations but does not affect total drug absorption (73).

Distribution

Pregabalin does not bind to plasma proteins, and it has a volume of distribution of approximately 0.5 L/kg. Pregabalin crosses the blood–brain barrier via the L-amino acid transport system. Peak CSF concentrations occur 8 hours postdose, and decrease at a slower rate compared to plasma (9).

Elimination

Pregabalin undergoes negligible metabolism (<2% of the dose) and is eliminated virtually unchanged

in the urine (70,71). Its elimination half-life is 5 to 7 hours in people with normal renal function (70). Pregabalin renal clearance (67.0 to 80.9 mL/min) has been found to be lower than the glomerular filtration rate, suggesting that tubular reabsorption may be involved in the renal clearance of the drug (9).

Special Populations

Pregabalin clearance is decreased in patients with impaired renal function. This decrease is directly proportional to the reduction in creatinine clearance (CL_{Cr}) (71). A 50% reduction in pregabalin daily dose is recommended in patients with CL_{Cr} between 30 and 60 mL/min compared to those with CL_{Cr} greater than 60 mL/min. Daily doses should be further reduced by 50% for each additional 50% decrease in CL_{Cr} (74). Since pregabalin is highly cleared by hemodialysis, supplemental doses may be required for patients on chronic hemodialysis treatment after each dialysis session to maintain unaltered drug serum concentrations (74).

Preliminary observations suggest that pregabalin clearance may be also reduced in the elderly (75), a finding that can be explained by the physiologic age-related decline in renal function (76).

Drug Interactions

Since pregabalin is not bound to plasma proteins, does not influence the activity of drug metabolizing enzymes, and is not itself significantly metabolized (71), its potential for clinically relevant drug interactions is very low. In regulatory trials, pregabalin did not alter serum concentrations of concomitantly administered carbamazepine, lamotrigine, phenobarbital, phenytoin, tiagabine, topiramate, and valproic acid (77). Evidence also exists that pregabalin pharmacokinetics are not affected by several comedications, including other AEDs, oral contraceptives, oral hypoglycemics, diuretics, and insulin (78). In one study, however, comedication with enzyme-inducing AEDs was associated with moderately lower pregabalin serum concentrations compared to comedication with noninducers (75).

Pregabalin may worsen the cognitive and motor dysfunction caused by oxycodone, and potentiate the CNS effects of ethanol and lorazepam (79).

Efficacy

Adjunctive Therapy in Epilepsy

Adults.

Six randomized, double-blind, placebo-controlled trials involving 2009 patients demonstrated the efficacy of pregabalin as adjunctive therapy in adults with refractory partial seizures (52,80–84) (Table 55.4). In these studies, pregabalin doses of 50 to 600 mg/day were investigated over 12 to 17 weeks; titration was 1 to 8 days, except for one study (82) in which the target dose was reached over a 2-week period. The first three studies were designed to assess dose–response relationships by using a fixed-dose regimen (52,80,81). Doses of 150, 300, and 600 mg/day were found to be superior to placebo in reducing seizure frequency, whereas 50 mg/day was not effective (see Table 55.4). Twice-daily and three times daily dosing schedules displayed similar effectiveness. The fourth and

fifth studies differed from the earlier trials in that they tested a flexible-dose regimen of 150 to 600 mg/day (82,83). In both studies, pregabalin therapy was associated with a significantly greater reduction in seizure frequency compared to placebo (see Table 55.4). The sixth study randomized 434 patients to pregabalin (300/600 mg/day), lamotrigine (300/400 mg/day), or placebo for 17 weeks of double-blind treatment divided in two phases (84). Phase I consisted of 11 weeks starting with titration (1-week for pregabalin, 5-week for lamotrigine) and concluding with doses of both AEDs fixed at 300 mg/day. Phase II was an additional 6 weeks in which patients who had seizures during phase I received a higher dose of their assigned AED (pregabalin: 600 mg/day, up-titrated over 1 week; lamotrigine: 400 mg/day, no titration). Patients who were seizure free during phase I were maintained on their assigned AED at the original dose. During phase I, there were no significant differences in efficacy measures across the three groups. Over the entire 17-week treatment period, however, pregabalin was associated with a greater reduction in seizure frequency and higher responder rates compared to placebo. Responder rates, but not seizure frequency reduction, also significantly favored pregabalin over lamotrigine (see Table 55.4).

[a]Three studies [French et al. (52), Arroyo et al. (80), Beydoun et al. (81)] consisted of a 8-wk baseline period, followed by a 12-wk treatment period. Two studies [Elger et al. (82), Lee et al. (83)] consisted of a 6-wk baseline, followed by a 12-wk treatment period. The study by Baulac et al. (84) was characterized by a 6-wk baseline, followed by a 17-wk treatment period.[b]In two divided doses.[c]In three divided doses.[d]$P < 0.05$ for comparisons with lamotrigine.*$P < 0.05$, **$P < 0.01$ and ***$P < 0.001$ for comparisons with placebo. n/r, not reported; R Ratio = $[(T - B)/(T + B)] \times 100$, where T is the seizure frequency during treatment and B is the seizure frequency during baseline. Therefore, negative values indicate a reduction in the number of seizures during treatment, whereas positive values indicate an increase; Responder rate, proportion of patients with ≥50% reduction in seizure frequency.

Open-label studies suggest that the clinical response to pregabalin is sustained over time (70,85). In a pooled analysis of six long-term, open-label, adjunctive therapy studies involving 2061 patients, the mean percentage reduction in 28-day seizure frequency remained relatively stable over time (25% to 40%), with 43% of all patients exhibiting a ≥50% reduction in seizure frequency during the last 3 months of treatment (85). However, these results must be interpreted with caution due to the high number of patients who discontinued treatment (n = 1304), with responders being more likely to remain in the study than nonresponders. These studies also allowed for changes in concomitant agents, which might have contributed to the apparent sustained effect of pregabalin on seizure control.

Children.

A prospective, open-label, uncontrolled study evaluated the efficacy and safety of pregabalin (150 to 300 mg/day) as adjunctive therapy in 19 children aged 4 to 15 years with severe refractory epilepsy (86). Over a follow-up of 3 to 6 months, one patient became seizure free, and seven attained a >50% reduction in seizure frequency. Of note, pregabalin was withdrawn in five patients due to lack of efficacy, and in two due to worsening of myoclonic seizures.

Large company-sponsored trials assessing the effectiveness of pregabalin as add-on therapy in pediatric patients with partial and generalized seizures are currently under way.

Monotherapy in Epilepsy

Adults.

The efficacy of pregabalin as monotherapy for refractory partial seizures has been evaluated in two randomized double-blind trials (87,88). One study compared 600 mg/day of pregabalin and 300 mg/day of gabapentin over an 8-day period in 93 hospitalized patients whose AEDs had been discontinued for seizure monitoring (87). There was a nonsignificant trend towards a longer median time to meet exit criteria primarily related to lack of efficacy (primary outcome variable) in the pregabalin group compared to the gabapentin group (191 hours vs. 88 hours, P = 0.08). Completion rate was higher in the pregabalin arm (57.7% vs. 23.5%, P = 0.003). The second study was based on a historical-controlled conversion to monotherapy design (88). Pregabalin doses of 150 and 600 mg/day were compared over a 20-week double-blind phase, comprising an 8-week conversion period (during which the pregabalin dose was escalated and the concomitant AEDs discontinued) and a 12-week monotherapy period. The trial was stopped early after an interim analysis on 134 patients showed that efficacy in the 600 mg/day group (primary study endpoint) could already be established based on predefined exit criteria.

In a recent randomized, double-blind, noninferiority trial, Kwan et al. (89) compared pregabalin and lamotrigine monotherapy in 660 patients with newly diagnosed partial seizures. Initial target doses were 150 mg/day for pregabalin and 100 mg/day for lamotrigine, which could be increased as needed during a 52-week assessment period to a maximum of 600 and 500 mg/day, respectively. Fewer patients became seizure free for ≥6 continuous months (primary study endpoint) with pregabalin compared to lamotrigine (52% vs. 68%; differences in proportion: −0.16 [95% CI −0.24 to −0.09]). Secondary efficacy endpoints, including time to exit due to lack of efficacy, time to first seizure, and time to 6-month seizure freedom, also favored lamotrigine over pregabalin. The authors speculated that these findings might have been at least in part attributable to the choice of the initial target dose of pregabalin (150 mg/day), possibly too low for this type of epilepsy population.

Children.

There are no data on the efficacy of pregabalin monotherapy in children with epilepsy.

Nonepilepsy Indications

Data from randomized, double-blind, placebo-controlled trials indicate that pregabalin is effective in neuropathic pain disorders (90), particularly postherpetic neuralgia and painful diabetic neuropathy (91). Pregabalin has also shown efficacy in fibromyalgia (92), generalized anxiety disorder, and social anxiety disorder (51).

Adverse Effects

Similarly to gabapentin, adverse effects of pregabalin typically involve the CNS, such as dizziness, ataxia, and drowsiness; usually appear in the first days of treatment; are generally mild to moderate in severity; and may abate with continued therapy (2 to 7 weeks). As opposed to gabapentin, these effects exhibit a definite dose-dependent relationship (see Table 55.2) (93). In a pooled analysis of four randomized, double-blind, placebo- controlled studies of pregabalin in refractory partial seizures (94), discontinuation rates due to adverse events were 6.9%, 5.9%, 14.4%, and 24.2% in patients receiving 50 mg/day (n = 88), 150 mg/day (n = 187), 300 mg/day (n = 90), and 600 mg/day (n = 321) of pregabalin, respectively (vs. 6.3% in 294 patients receiving placebo).

Weight gain is also a common complication of pregabalin therapy. In regulatory trials, an increase of ≥7% over baseline body weight was found in 9% of patients taking pregabalin and 2% of patients receiving placebo (95). Weight gain appeared to be dose related. The proportion of patients experiencing a ≥7% increase in body weight was 4.9% at 150 mg/day, 6.7% at 300 mg/day, and 20.4% at 600 mg/day (70). Very few patients (0.3%) discontinued pregabalin due to weight gain (95). In a pooled analysis of six long-term, open-label, adjunctive therapy studies involving 2061 patients, the estimated weight gain at 1 year from starting pregabalin treatment was 5.2 kg (85). In a randomized controlled trial, extended clinical counseling was found to be ineffective in preventing pregabalin-induced weight gain (96).

Peripheral edema may occur in up 20% of patients taking pregabalin (97), and appears to be more common in neuropathic pain compared to epilepsy (94). Sexual dysfunction, including erectile dysfunction, decreased libido, and anorgasmia, has been associated with pregabalin therapy (98). A few reports suggest that pregabalin may induce myoclonus (99).

Pregabalin has been associated with negative effects on mood. In a recent single-center study, 24 of 402 (6%) patients treated with pregabalin discontinued the drug because of psychiatric adverse events, including depression, low mood, and mood swings (100).

A number of reports have suggested that pregabalin might have a potential for abuse and addiction, with individuals with a previous history of substance dependence being at higher risk (95).

To date, there is no adequate information on the teratogenic potential of pregabalin in women with epilepsy. Pregabalin has teratogenic effects in rats at very high doses (1250 to 2500 mg/kg), which are much higher than those used in humans (94).

Place in Current Therapy

Pregabalin has received FDA approval as adjunctive therapy in adults with partial seizures. It has

also been approved for the treatment of fibromyalgia, postherpetic neuralgia, and neuropathic pain associated with diabetic peripheral neuropathy and spinal cord injury. In other countries, pregabalin is also indicated for the management of generalized anxiety disorder (9). Because of its potential for abuse, pregabalin has been classified as a Schedule V controlled substance by the U.S. Drug Enforcement Administration (95).

In the Lyrica U.S. Physician Prescribing Information (95), the recommended starting dose for adults with partial seizures is 150 mg/day (75 mg b.i.d. or 50 mg t.i.d). However, clinical experience suggests that, in patients prone to developing AED-related CNS toxicity, a starting dose of 50 to 75 mg/day may be preferable, with up-titration to 150 mg/day over a period of 2 to 4 weeks (94). The effective dose range of Lyrica is given as 150 to 600 mg/day.

In summary, like gabapentin, pregabalin displays absence of hepatic metabolism, minimal potential for clinically relevant drug interactions, protective activity against partial-onset seizures, and efficacy in some nonepilepsy indications, including neuropathic pain. Unlike gabapentin, however, pregabalin exhibits linear pharmacokinetics and complete bioavailability at all clinically used doses, resulting in perceived greater antiseizure efficacy but also greater propensity to cause adverse effects at the upper portion of the approved dose range. The value of pregabalin relative to other AEDs remains to be elucidated in well-designed head-to-head comparative trials.

CHAPTER 56 LACOSAMIDE

RAJ D. SHETH

HISTORICAL BACKGROUND

Lacosamide (Vimpat; previously harkoseride) is the R-enantiomer of 2-acetamido N-benzyl-3-methoxypropionamide (Fig. 56.1). Lacosamide is a recently approved antiepileptic medication for adjunctive therapy for patients 17 years and older with partial complex seizures. Formulations as a tablet, a syrup, and an intravenous injection are available. The drug was initially developed by Harris LLC with preclinical trials conducted by Schwartz Pharma and subsequently acquired by UCB Pharma. Although it was specifically synthesized as an antiepileptic medication, as with many newer agents, it was found to have additional pharmacologic properties including a role in the alleviation of pain associated with diabetic neuropathy. Preclinical development suggests neuroprotection in animal models of seizures as well as in status epilepticus models. Most studies have examined activity in the maximal electroshock-induced seizure test used in rodents. Human randomized controlled trials have shown lacosamide to have efficacy as an adjunctive therapy in patients 17 years and older with partial-onset seizures; however, efficacy in other epilepsy syndromes is being investigated.

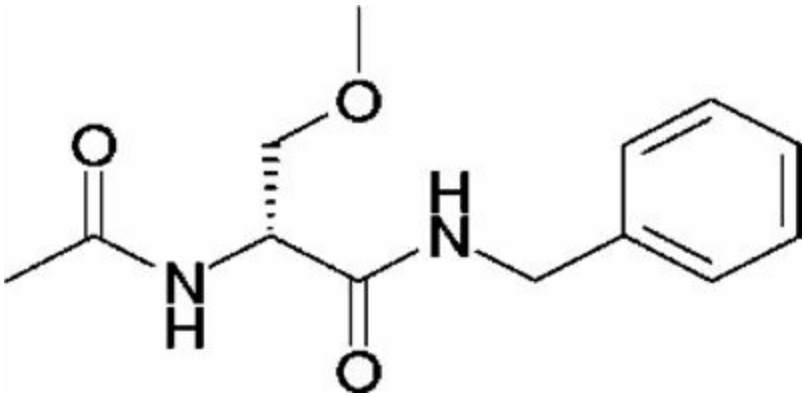

Figure 56.1. Structure of lacosamide ($C_{13}H_{18}N_2O_3$).

GENERAL CHARACTERISTICS

Lacosamide belongs to a class of functionalized amino acids that were specifically designed to have potential anticonvulsant properties (see Fig. 56.1). It is a light yellow crystalline powder that is soluble in phosphate-buffered saline (pH of 7.5 at 25°C) and has a chemical formula of $C_{13}H_{18}N_2O_3$.

METABOLISM

Almost 40% of lacosamide is excreted unchanged in the urine. A further 30% is metabolized by demethylation to the pharmacologically inactive O-desmethyl metabolite that is excreted in the urine (1). In addition, a polar fraction (approximately 20% of the dose) is also excreted into urine after

both oral and intravenous administration. Small amounts of further metabolites representing 0.5% to 2% of the dose are also found in urine. Cytochrome P450 (CYP) 2C19 is involved in the demethylation of lacosamide. The relative contribution of other CYP isoforms to lacosamide metabolism is currently not clear.

Given the large portion that is renally excreted, adjustment with moderate-to-severe renal failure is needed. With mild-to-moderate renal impairment, there is no need for dosage adjustment. It should be noted that hemodialysis clears over half of serum lacosamide. Accordingly, dose supplementation after hemodialysis should be considered (2). In patients with mild-to-moderate renal impairment dosage adjustment does not appear to be needed.

This study examined, population-based pharmacokinetics of lacosamide in adults with partial-onset seizures. A total of 2370 lacosamide plasma concentrations were examined using nonlinear mixed-effect modeling in two phase 3, double-blind, multicenter, randomized, parallel-group, placebo-controlled trials where subjects received 200, 400, or 600 mg/day lacosamide in divided doses twice daily (3). As a class, inducer antiepileptic medications increased clearance by approximately 36%. Individually, coadministration of the CYP inducers carbamazepine or phenytoin resulted in an approximate decrease in area under the curve by 20%, and coadministration of phenobarbital yielded an approximate 30% decrease. The observed effect of inducer antiepileptic medications on lacosamide exposure was modest. Accordingly, this finding result is unlikely to be clinically significant when adding lacosamide to an existing treatment regimen. Furthermore, no significant change in lacosamide PK was seen in CYP2C19 poor metabolizers or following comedication with omeprazole.

MECHANISM OF ACTION

Animal Models

Lacosamide has a dual mechanism of action, both of which appear novel and operational across a wide variety of animal seizure models when administered intraperitoneally in a dosage range of 1 to 30 mg/kg (4). Animal models where lacosamide has had antiseizure activity demonstrated include mice with audiogenic seizures and maximal electroshock and N-methly-D-aspartate–induced seizures (5).

Lacosamide appears to have two main mechanisms of actions. The primary mechanism of action appears to be selective enhancing the slow inactivation of voltage-gated sodium channels without interfering with fast inactivation. Slow inactivation of sodium channels is an endogenous mechanism whereby neurons reduce ectopic hyperactivity and may represent an effective mechanism to selectively reduce ictal hyperactivity without altering physiologic function (6). Lacosamide, unlike carbamazepine, lamotrigine, and phenytoin, did not produce frequency-dependent facilitation of block of 3 seconds, 10-Hz pulse stimulation train. The slow inactivation voltage curve was shifted in the hyperpolarizing direction and significantly promoted the shift of channels to the slow inactivated state without impairing rate of recovery. Such modulation of neuronal activity may underlie lacosamide's therapeutic activity in the management of pain (5).

Lacosamide is highly potent in acute status epilepticus models. In rats, it has been shown to have the potential for disease modification that may be CRMP-2 dependent (7). Inhibition of CRMP-2 was thought to render the medication effective both as a traditional antiepileptogenic agent and having

efficacy in acute seizures. However, lacosamide binding to CRMP-2 has been questioned (8).

Early preclinical electrophysiologic studies have demonstrated that lacosamide targets voltage-gated sodium channels and acts by specifically enhancing slow inactivation without affecting fast inactivation of the channel (9). Initial preclinical investigations (8,10) suggested that lacosamide might have an additional mode of action by binding to the collapsin response mediator protein 2 (CRMP-2). However, Wolff et al. (8) demonstrated that there is currently no experimental evidence to support direct binding between lacosamide and CRMP-2.

Male rats rendered in self-sustaining EEG and clinical status epilepticus treated with early (10 minutes) or delayed (40 minutes) lacosamide showed dose-dependent and potent reduction in both the frequency of seizures and the cumulative duration of seizures. Early treatment with lacosamide resulted in a dose-dependent reduction of the number of spontaneous recurrent seizures of up to 70%. Late treatment with lacosamide resulted in a 50% reduction in the frequency of spontaneous recurrence. The number of seizure-free animals increased from 0% in the untreated group to 65% in the highest-dose groups. Protection of hippocampal structures within 72 hours following induction of status epilepticus was greatly enhanced. It is not clear if this mechanism is operational in humans.

Lacosamide was also evaluated in a comprehensive preclinical toxicology and pharmacology program (10) conducted in mice, rats, rabbits, and dogs. These studies found lacosamide to be well tolerated; either no or only minor side effects were observed in safety studies involving the central nervous, respiratory, gastrointestinal, and renal systems, and in three animal models, there was no indication of abuse liability. Long-term, repeated-dose toxicity studies demonstrated that after either IV or oral lacosamide administration, adverse events were reversible and consisted mostly of exaggerated pharmacodynamic effects on the central nervous system. No genotoxic or carcinogenic effects were observed in vivo, and lacosamide showed a favorable profile in reproductive and developmental animal studies (11).

CLINICAL STUDIES

Lacosamide has been studied in two clinical settings: (i) in patients 17 years or older with partial seizures as an adjunctive agent and (ii) in pain associated with diabetic neuropathy. Dose ranges that were tested in these situations are between 200 and 600 mg/day (Table 56.1), following indications from initial trials of efficacy between 100 and 600 mg/day.

Table 56.1 Change in Seizure Frequency per 28 Days During the First 2 Weeks of Lacosamide Exposure

Randomized treatment group	Reduction over placebo (%)	*P*-value
First week of exposure to LCM (LCM 100 mg/day)		
LCM 200-mg/day group	17.6	0.031
LCM 400-mg/day group	21.2	0.002
Second week of exposure to LCM (LCM 200 mg/day)		
LCM 200-mg/day group	25.3	0.001
LCM 400-mg/day group	18.3	0.007

RANDOMIZED CONTROLLED TRIALS IN

EPILEPSY

A total of three randomized controlled trials in adults with partial complex epilepsy where lacosamide was used as an adjunctive have been completed to date. All three used similar randomization with double-blind parallel-group design in a 12-week dose escalation with target 100 mg/day increments followed by a 12-week maintenance period.

Ben-Menachem et al. (12,13) in a multicenter, international, double-blind, placebo-controlled, randomized, dose–response study, involving 418 adults with refractory partial epilepsy, demonstrated significant efficacy at doses of 400 and 600 mg/day. At these dosages, compared to placebo, median seizure frequency was reduced 40%, with 49% of patients experiencing a 50% or greater reduction in seizure frequency. A dose–adverse effects relationship was seen with doses of 600 mg/day most consistently associated with the highest adverse event rate. In these studies, adverse effects included common neurologic symptoms, including nausea, headache, ataxia, fatigue, and diplopia. Serious adverse effects resulting in medication withdrawal occurred in <1% of all patients. Adverse effects resulting in withdrawal most frequently consisted of exacerbation of convulsive seizures and intolerable dizziness. Lacosamide appeared to be neutral on its effect on body weight. Importantly, there was no change in the serum concentrations of coadministered anticonvulsants. When lacosamide is added to other sodium channel agents, there is an additive effect on experienced adverse effects (14,15). Furthermore, rapid titration to high doses of lacosamide with simultaneous tapering of other sodium channel AEDs was associated with a marked reduction in adverse events when compared to that reported for fixed doses of concomitant AEDs (14,15).

Dose-Range Study

Dose-finding studies are critically important in the clinical development of a new drug. They help define the no-effect, mean effective, and maximal effective doses and determine a potentially optimal therapeutic dose range. In a pooled post hoc review of 1294 patients treated in three placebo-controlled, double-blind, international clinical trials evaluating the efficacy and safety of adjunctive lacosamide (200 to 600 mg/day) in adults ≥17 years with partial-onset seizures with or without secondary generalization, Chung et al. (16) found consistent seizure reduction for lacosamide dosages 400 and 600 mg/day. Dosage with 200 mg/day produced a variable effect, although pooled data suggested that 200 mg/day was efficacious compared to placebo. Lacosamide 400 mg/day added to between 1 and 3 other antiepileptic medications in 466 patients with intractable epilepsy in phases 2 and 3 double-blind placebo-controlled studies was examined to understand medication efficacy (17). Lacosamide was added to carbamazepine (33%), lamotrigine (33%), levetiracetam (30%), valproate (23%), topiramate (23%), and oxcarbazepine (17%). Median percent reduction over 28 days in seizure frequency from baseline was 36.8% for lacosamide 400 mg/day versus 18.4% for placebo. Lacosamide showed a similar magnitude of reduction versus placebo regardless of which combination of antiepileptic medication regimens it was added to. Importantly, efficacy was demonstrated whether lacosamide was added to a sodium channel–blocking AED or to an AED with other mechanisms of action. This suggests an independent additive efficacy in excess of that provided by preexisting antiepileptic medication to which lacosamide was added.

The time of onset of efficacy is an important consideration in the choice of antiepileptic medication. Lacosamide appears to have an early onset of efficacy against seizures. Secondary analysis of lacosamide in a pooled analysis of three Phase 2 and Phase 3 trials demonstrated efficacy

in the early weeks after addition (18).

Lacosamide in fixed doses of 200, 400, or 600 mg/day was used in these pooled data. Titration was started at 100 mg/day during the initial week of lacosamide exposure, followed by weekly titration in 100 mg increments to the assigned target dose. After the first week of lacosamide exposure to 100 mg/day, the percent reduction of seizures over placebo was 17.9% ($P < 0.01$) and only slightly improved to 20.4% by the second week when patients were receiving 200 mg/day. Post hoc pooled analysis showed an early onset of efficacy starting at a dose of 100 mg/day in the first week and increasingly modestly after that for patients where lacosamide was added to their antiepileptic medication regimen. Thus, efficacy can be expected in the first week or two following initiation of adjunctive lacosamide. Prospective trials are required to confirm these findings.

Clinical use suggest that lacosamide be initiated as an adjunctive at 50 mg twice daily with subsequent dose increases on a weekly basis to a target dose of 200 to 400 mg/day in adults with partial epilepsy. The availability of a parenteral formulation has the potential to be useful in the management of acute seizures, although studies in status epilepticus are still to be performed. Studies in other populations, including pediatrics and the elderly, are needed to further define the therapeutic spectrum of lacosamide.

Recently, 5-year open-label long-term safety and efficacy follow-up has been studied. Efficacy based on retention of lacosamide exposure was reported for >1, >2, >3, or >4 years as being 75%, 63%, 54%, and 29%, respectively. Primary reasons for discontinuation were lack of efficacy (26%) and adverse events (11%). Common treatment-emergent adverse effects were similar to currently reported adverse effects with dizziness, headache, contusion, nausea, convulsion, nasopharyngitis, fall, vomiting, and diplopia being most common. Of patients exposed to lacosamide ≥2 years, 3.1% remained seizure-free for a period ≥2 years (23).

Studies in Diabetic Neuropathy

At least three randomized placebo-controlled double-blind trials have been completed to test the efficacy of lacosamide in diabetic neuropathy–related pain. Lacosamide appears to be effective in doses up to 400 mg/day. However, doses of 600 mg/day were not associated with further increments in efficacy and were generally less well tolerated (20).

ABSORPTION, DISTRIBUTION, AND METABOLISM

The pharmacokinetic properties of lacosamide include a fast rate of absorption, little metabolism with cytochrome P450 isoenzymes with about 20% metabolized via CYP2C19, limited effect of age and gender on plasma levels, and low potential for drug–drug interactions (21).

Oral administration of lacosamide results in rapid and near complete absorption with minimal first-pass effects (22). Bioavailability after oral administration approaches 100%, with peak plasma concentration being reached after 30 minutes to 4 hours following oral administration. Dose to plasma concentrations are linear with low intra- and intersubject variability. Food appears to have a no influence on lacosamide's absorption with oral bioavailability reaching 100% (23). Escalating dose administration orally results in near linear increases in serum concentration. Lacosamide administered in a 300-mg single dose following consumption of a high fat diet did not influence its serum concentration. Lacosamide has an apparent volume of distribution of about 40 to 60 L (0.5 to

0.8 L/kg) and has a low plasma protein binding, with <15% of serum lacosamide being bound to plasma protein. Distribution in placenta and breast milk and distribution in children have not been examined.

INTERACTIONS WITH OTHER DRUGS

Given the pharmacokinetic properties, the probability of drug–drug interactions with lacosamide treatment is likely to be low (13,24). When used at therapeutic concentrations, lacosamide did not have a significant effect on the cytochrome P450 enzyme system. Human hepatocyte showed no potential to induce cytochrome P450 isoforms including 1A2, 2B6, 2C9, 2C19, and 3A4. At 30 times higher than "therapeutic" human plasma concentrations, lacosamide exerted a 60% inhibition of CYP2C19 function. The dosage at which this inhibition would be expected is unlikely to be routinely achieved in the treatment of human epilepsy.

Twenty-three patients had a baseline median of 4 seizures per month with persisting partial-onset seizures, despite previous treatment with an average of 6.8 AEDs. Mean decreases in monthly seizure frequency were as follows: 3 months, 49.9% ($P = 0.011$); 6 months, 55.4% ($P = 0.010$); 9 months, 60.8% ($P = 0.002$); and 12 months, 58.2% ($P = 0.011$). Most adverse events were mild CNS-related symptoms and occurred transiently only during titration—there was no significant relationship ($\chi^2 < 1.5$, $P > 0.1$) between lacosamide dose and the presence of side effects at 3, 6, 9, or 12 months. Drug-resistant patients rapidly titrated to high doses of lacosamide with simultaneous tapering of traditional sodium channel AEDs had marked reduction in CNS-related adverse events compared with patients treated in three previous pivotal trials that used fixed doses of concomitant AEDs.

Coadministration of lacosamide 400 mg/day did not alter the pharmacokinetics of warfarin 25 mg or anticoagulation. These results suggest that there is no need for dose adjustment of warfarin when coadministered with lacosamide (14,15).

ADVERSE EFFECTS

Animal Toxicology

Single as well as 3-, 6-, and 12-month repeated-dose studies in mice, rats, and dogs did not demonstrate adverse effects that persisted after discontinuation of lacosamide. Signs of dose-related toxicity, typically seen with other antiepileptic medication, including ataxia, tremor, and reduced motility, occurred. At high doses, paradoxical convulsions were observed. This supratherapeutic effect was similar to that described for phenytoin, gabapentin, and carbamazepine.

Clinical Adverse Effects

Adverse events were evaluated in 944 subjects randomized to receive either lacosamide 200 mg/day (n = 270), 400 mg/day (n = 471), or 600 mg/day (n = 203) or placebo (n = 364) (10). A dose–adverse effect relationship was seen for frequently reported nervous system and gastrointestinal adverse effects. All patients were on between 1 and 3 other concomitantly administered antiepileptic drugs, including carbamazepine (35%), lamotrigine (31%), levetiracetam (29%), valproate (24%), topiramate (22%), oxcarbazepine (18%), and phenytoin (14%).

Frequently reported treatment-emergent adverse events are shown in Table 56.2. Other adverse

events including peripheral edema (1%), weight gain (1%), memory impairment (2%), pancreatitis (0.1%), and psychotic disorders (0.2%) were low and generally similar to placebo. Clinically relevant changes in observed laboratory parameters, ECGs, vital signs, or body weight measurements were not seen, although there was a small, dose-related increase in PR interval. Generally, lacosamide was well tolerated when combined with up to three concomitant antiepileptic medications. Lacosamide has been FDA approved in the United States as a class V controlled substance. All AEDs have a labeling from the FDA as class V agents since 2008. The increased risk of suicidal thoughts or behavior was generally consistent among antiepileptic medication despite varying mechanisms of action and across a range of indications including epilepsy. Accordingly, the Federal Drug Administration has required that all AEDs carry the label warning of the risk used for any indication.

Table 56.2 Most Common Treatment-Emergent Adverse Effects (≥2%) Resulting in Early Discontinuation

Adverse effects	Placebo (n = 364) (%)	LCM 200 mg/day (n = 270) (%)	LCM 400 mg/day (n = 471) (%)
Dizziness	0.3	0.4	4.2
Vomiting	0.3	0.4	2.3
Diplopia	0.3	1.5	2.1

Cardiac conduction disturbances, including atrial fibrillation and atrioventricular block, have been reported in patients receiving lacosamide for epilepsy. This is a particular concern when lacosamide used to treat diabetic neuropathy due to the higher cardiac comorbidity associated with diabetes (25).

Intravenous Administration

Intravenous administration of lacosamide was studied in a multicenter, double-blind, double-dummy, randomized, inpatient trial evaluating the safety, tolerability, and pharmacokinetics as replacement for oral lacosamide (9). This study utilized patients from an open-label extension trial of oral lacosamide and randomized to either intravenous lacosamide and oral placebo or intravenous placebo and oral lacosamide. Infusions occurred over either 30- or 60-minute time periods. Treatment-emergent adverse events were mild and included dizziness, headache, back pain, somnolence, and injection site pain and were similar to oral lacosamide. There were no significant cardiac/hemodynamic adverse effects noted, and there does not appear to be the need for special monitoring of cardiovascular function. Efficacy of the intravenous formulation in partial complex seizures or status epilepticus has not been studied. There have not been clinical trials evaluating lacosamide for status epilepticus. This is not surprising given the very recent availability of an intravenous formulation. Given lacosamide's pharmacokinetic profile, a 1:1 substitution of intravenous to oral dosage has been approved by the Federal Drug Administration. Optimum effective dosage in adults is 200 to 400 mg/day suggesting similar-type dosages for intravenous formulation. Case reports of usage in adults with status epilepticus have reported the use of 200 mg administered intravenously over 30 minutes with a subsequent repeat in 30 minutes. However, such recommendations need to be substantiated by carefully designed clinical studies.

Recent studies (26) have safely administered 200 and 300 mg of lacosamide intravenously over 15 minutes in patients with partial-onset seizures.

Infusion with 400 mg loading was less well tolerated due to a higher frequency of adverse events that were similar to that for oral dosing.

CONCLUSIONS

Lacosamide is a novel anticonvulsant with a favorable pharmacokinetic profile including low protein binding, a long half-life, and good bioavailability that is not affected by food intake. Furthermore, the lack of induction or inhibition of the hepatocyte CYP family renders a low potential for clinically significant drug–drug interactions. Weight neutrality and absent skin rashes, at least in limited studies, are favorable features. Efficacy from pooled analysis indicates target doses of 200 to 400 mg/day are likely to have optimum effect with an acceptable and low adverse effect rate. Clinical use in adults with partial epilepsy suggests that lacosamide be initiated as an adjunctive at 50 mg twice daily with subsequent dose increases on a weekly basis to a target dose of 200 mg/day. Dizziness is the most common adverse event, followed by gastrointestinal disturbances such as nausea and vomiting. The availability of a parenteral formulation has the potential to be useful in the management of acute seizures, although studies in status epilepticus are still to be performed. Studies in other populations, including pediatrics and the elderly, are also needed to further define the therapeutic spectrum of lacosamide in these populations.

CHAPTER 57 LAMOTRIGINE

BARRY E. GIDAL AND JOHN M. STERN

CHEMISTRY AND MECHANISM OF ACTION

Lamotrigine is a phenyltriazine, tertiary amine derivative (3,5-diamino-6-(2,3-dichlorophenyl)-1,2,4-triazine, MW = 256.09), which is poorly soluble in water or alcohol. A primary cellular mechanism of action for lamotrigine is voltage- and use-dependent blockade of neuronal sodium channels, that is, greater blockade during repetitive activation (1–7). Lamotrigine blockade of sodium channels activated from depolarized membrane potentials occurs at lower concentrations than those required to elicit blockade from a hyperpolarized membrane and occurs at clinically achievable concentrations (6). A potential binding site within the sodium channel pore has been identified, and lamotrigine appears to stabilize the inactivated state of the sodium channel (8).

In addition to sodium channels, lamotrigine produces dose-dependent inhibition of high-voltage–activated Ca^{++} currents, possibly through inhibition of presynaptic N- and P/Q-type calcium channels (9,10). Despite its apparent clinical activity in human absence seizures, lamotrigine does not appear to inhibit low-voltage currents mediated by T-type calcium channels. Although these actions are mechanistically similar to those of phenytoin, important differences do exist between these agents. Veratrine-evoked release of both glutamate and GABA is inhibited by phenytoin. At similar concentrations, however, lamotrigine is twice as effective in inhibiting the release of glutamate as compared to GABA (11). Release of excitatory amino acid neurotransmitters such as glutamate and aspartate is blocked during sustained repetitive firing. Animal models also suggest that lamotrigine inhibits ischemia-induced release of excitatory neurotransmitters (12–15). Inhibition of nitric oxide release (16) and serotonin uptake (17) may also modestly contribute to lamotrigine's action in both epilepsy and affective disorders. Lamotrigine appears to display only modest inhibition of potassium channels. Similarly, lamotrigine is only a weak inhibitor of 5-HT uptake in humans or rodents (17). Lamotrigine is not an N-methyl-D-aspartate receptor antagonist (18), nor does it displace other ligands for this receptor complex (CNQX, CGS, TCHP). Furthermore, lamotrigine does not appear to alter either plasma or brain GABA concentrations in humans (19,20). Most likely, the antiepileptic actions and clinical spectrum of lamotrigine can be predominantly explained by the combination of both sodium and calcium (N, P/Q) channel inhibition.

Lamotrigine is effective in preventing maximal electroshock seizures in mice with potency and duration that are similar to phenytoin and carbamazepine (21). In contrast to its clinical efficacy for absence seizures, lamotrigine does not prevent pentylenetetrazole-induced clonus, which is a model of absence seizures (21). Lamotrigine is active in suppressing photically evoked after-discharges and photoconvulsive responses (22) and has demonstrated activity in the genetic epilepsy-prone rat (23). Lamotrigine has also demonstrated efficacy in the electrically induced electroencephalogram after-discharge model (24). While lamotrigine does not prevent the development of cortical kindling in rats, it does attenuate kindled seizures in a dose-dependent manner (24–26).

ABSORPTION, DISTRIBUTION, AND METABOLISM

Lamotrigine is an orally administered drug and is available in a variety of dosage strengths, and also including dispersible tablets and extended-release tablets. Bioequivalence has been established between these various product formulations. Lamotrigine is completely absorbed, with a bioavailability of 98% (27,28). Peak serum concentrations are achieved within 1 to 3 hours following oral administration (29–31). Lamotrigine displays linear oral absorption, with proportionality observed following doses up to 700 mg (32–34). A secondary peak in serum concentration may occur between 4 to 6 hours following either oral or parenteral administration, suggesting enterohepatic recycling. Food does not significantly affect drug absorption (35).

The extended-release formulation of lamotrigine that is marketed as Lamictal XR has an enteric coating and a modified-release core. A small aperture is drilled through the coating, allowing for a gradual dissolution rate over approximately 12 to 15 hours. Pharmacokinetic studies in patients with epilepsy (36) have demonstrated that this extended-release formulation is bioequivalent to the immediate-release brand product, when patients are converted from twice-daily branded lamotrigine (Lamictal) to once-daily Lamictal XR. In this study, peak-to-trough fluctuations for once-daily Lamictal XR were less than twice-daily immediate-release Lamictal, particularly in those patients receiving a concomitant enzyme-inducing antiepileptic drug (AED). Simulation studies suggest that lamotrigine serum concentrations may remain more stable following a missed dose with the XR, once-daily formulation as compared to twice-daily administration of the IR product in the same setting. This same study suggested that doubling the dose after a missed dose for either XR or IR formulation would not be expected to result in excessively high peak serum concentrations (37).

Lamotrigine is also systemically absorbed following rectal administration, although mean AUC (area under plasma concentration-time curve) are approximately 50% of corresponding oral administration values (38,39).

Lamotrigine is only moderately bound to plasma proteins with approximately 56% bound, and this is constant over a concentration range of at least 1 to 10 μg/mL (32). In vitro studies have demonstrated that lamotrigine protein binding is unaffected by phenytoin, phenobarbital, carbamazepine, and valproate (32). Lamotrigine volume of distribution is independent of dose and ranges between 0.9 and 1.2 L/kg in healthy volunteers (14,40). Recent data suggest that lamotrigine distribution into the brain may be mediated, at least in part by a specific influx transporter, OCT1. Whether this may result in clinically meaningful drug interactions (i.e., inhibitors of OCT1) is still unclear (41). In contrast, lamotrigine does not appear to be a substrate for multidrug resistance–associated proteins that have been implicated in treatment-resistant epilepsy (42).

In humans, lamotrigine is extensively hepatically metabolized by UDP-glucuronyltransferase (UGT 1A4, UGT 2B7) (43). Glucuronide conjugation can occur at both heterocyclic nitrogen atoms to form a quaternary amine glucuronide (44). In healthy volunteers, 70% of a single dose was recovered in the urine (32), with the 5-N and 2-N-glucuronide metabolite accounting for 90% of the recovered dose. This glucuronide metabolite is pharmacologically inactive. Genetic polymorphisms in one or both of these UGT isozymes may contribute to the observed interindividual variability seen with this agent (45,46). Renal elimination of unchanged drug accounts for a minor fraction of administered dose (<10%).

When given as monotherapy in adults, lamotrigine elimination half-life is approximately 24 to 29

hours. Oral clearance averages 0.35 to 0.59 mL/min/kg (47). Lamotrigine clearance is higher in children and lower in the elderly as compared to young adults. The concentration/dose ratio of lamotrigine was approximately 30% to 50% lower in young children (3 to 6 years) versus that seen in older children (7 to 15 years) or young adults (48). Mean lamotrigine oral clearance was 0.64 mL/kg/min and elimination half-life was 32 hours, in 12 children (ages 4 to 11 years) receiving monotherapy (49). Advancing age has modest effects upon lamotrigine clearance and half-life. In a group of elderly volunteers (ages 65 to 76 years), lamotrigine clearance was 37% lower than a group of young adults (ages 26 to 38 years) (31). In another study, lamotrigine clearance in older adults (55 to 92 years) was been found to be 22% lower than in younger adults (16 to 36 years) (50).

Evidence demonstrates that lamotrigine undergoes autoinduction. Population analysis of sparse data obtained retrospectively from 163 monotherapy patients demonstrates a 17% increase in clearance over a 48-week period (51). As lamotrigine initiation usually involves gradual dose escalation, this modest degree of autoinduction is not clinically meaningful.

Hepatic disease, depending upon severity, can influence lamotrigine pharmacokinetics, and patients with Child–Pugh scores of 5 to 6 (B) or 7 to 9 (C) requiring dosage reductions of 50% to 75%, respectively (52). No significant differences in the plasma clearance of lamotrigine have been noted in patients with chronic renal failure (53). Approximately 17% of a lamotrigine dose may be removed by hemodialysis, with a corresponding reduction in half-life to about 13 hours (54).

The apparent oral clearance of lamotrigine does not appear to significantly differ between men and women overall (51). However, the magnitude of alterations in lamotrigine concentrations exceeds that described for many of the older AEDs, perhaps due to sex hormone–mediated activation of UDP-glucuronyltransferase (55,56). Supporting this possibility is the observation that lamotrigine clearance may transiently decrease during menopause (57). Moreover, lamotrigine oral clearance may be markedly (>65%) increased during pregnancy, with changes being most evident during the second and third trimester.

In association with this change, women treated with lamotrigine may experience increased seizure frequency due to decreased serum concentrations. Data from Pennell et al. (58) indicated that lamotrigine total and unbound oral clearance were increased during all three trimesters, with peaks of 94% (total) and 89% (unbound) in the third trimester. In this study population, seizure frequency significantly increased when the lamotrigine serum concentration decreased to 65% of the individualized, preconceptional value. Lamotrigine oral clearance appears to return to baseline values during the early postpartum period, which necessitates further dose modifications soon after delivery (59). In that, these changes in oral clearance may result in reduced serum concentrations and possibly increased seizures during pregnancy, monitoring lamotrigine serum concentrations before, during, and immediately after pregnancy is clearly prudent (60).

A well-defined serum concentration–effect range for lamotrigine has yet to be conclusively established (61), and individual patients may respond to a wide range of concentrations. A target range of 4 to 14 μg/mL has been suggested by some investigators for patients with epilepsy (62,63). Use of serum concentration data may aid in the interpretation of drug interactions and adherence issues. Given ongoing concerns regarding the interchangeability of various generic formulations of this drug (64,65), additional monitoring of serum concentrations both before and following generic substitution would also seem prudent.

DRUG INTERACTIONS

Effect of Other Drugs on Lamotrigine

Comedication with Hepatic Enzyme–Inducing AEDs

Lamotrigine displays substantial interpatient variability in plasma clearance; a phenomenon that can largely be explained by the presence or absence of concomitant drug therapy (66,67). Lamotrigine elimination half-life is reduced by approximately 50% ($t_{1/2}$ about 12 to 15 hours) in the presence of UGT-inducing drugs, such as carbamazepine, phenobarbital, primidone, and phenytoin (22). While the effect of adding an enzyme inducer to a regimen containing lamotrigine is well recognized, an important clinical question involves deinduction, following the removal of a concomitant inducer such as phenytoin or carbamazepine. In a recent pharmacokinetic analysis of lamotrigine serum concentration data derived from the pivotal conversion-to-monotherapy trial (68), Anderson et al. found that mean lamotrigine serum concentrations increased by approximately 100% following the withdrawal of concomitant phenytoin treatment, the increase was only 50% to 75% following the withdrawal of concomitant carbamazepine treatment. Importantly, these data suggested that lamotrigine concentrations did not significantly change (increase) until the concomitant enzyme-inducing drug was completely removed, and concentrations of either phenytoin or carbamazepine approached zero (69).

There do not appear to be any significant interactions between lamotrigine and newer AEDs such as topiramate, felbamate, gabapentin, pregabalin, zonisamide, vigabatrin, or levetiracetam, lacosamide or perampanel. Modest reductions (approximately 30%) in lamotrigine serum concentrations have been noted in patients receiving concomitant oxcarbazepine (70–73) and eslicarbazepine (approximately 14%) (74). Comedication with ezogabine (retigabine) also seems to result in a modest 20% reduction in lamotrigine serum concentrations (75).

Comedication with Valproate

As lamotrigine does not undergo cytochrome P450–dependent metabolism, only drugs that inhibit UGTs, such as valproate, will decrease lamotrigine clearance and result in increased serum concentrations. Valproate can markedly reduce lamotrigine clearance and prolong elimination half-life by about 60 hours (76). Pharmacokinetic studies in adult volunteers have suggested that the maximal theoretical inhibition of lamotrigine clearance by valproate is approximately 65%, with 50% of maximal inhibition occurring at valproate plasma concentrations of approximately 5 to 6 μg/mL. Maximal theoretical inhibition appears to occur at valproate concentrations of approximately 50 μg/mL. These data suggest that valproate-mediated inhibition of lamotrigine begins at very low valproate doses (e.g., 125 to 250 mg/day), with maximal inhibition occurring at valproate doses of approximately 500 mg/day (77).

While earlier studies suggested that concurrent treatment with lamotrigine may result in modestly decreased valproate serum concentrations, this is unlikely to be of clinical significance (78,79).

Effect of Lamotrigine upon Other Drugs

Lamotrigine does not induce or inhibit the mixed-function oxidase system (cytochrome P450 isozymes). In addition, lamotrigine is not extensively bound to plasma proteins. These properties would predict lamotrigine to have a low incidence of causing pharmacokinetic interactions. Addition

of lamotrigine does not alter serum concentrations of phenytoin, phenobarbital, primidone, carbamazepine, or carbamazepine epoxide (47,54,80,81). Lamotrigine does not appear to significantly alter hormone concentrations in female volunteers taking oral contraceptives (OCs) (82).

Effect of NonAEDs on Lamotrigine

Daily doses of acetaminophen, a drug that is 55% eliminated by glucuronide conjugation, but not an inducer of UGT, unexpectedly increased lamotrigine clearance. Occasional use of acetaminophen would not be expected to alter lamotrigine pharmacokinetics (83). One anecdotal report has suggested a potential interaction between the serotonin-selective reuptake inhibitor sertraline and lamotrigine, with lamotrigine serum concentrations increasing following the addition of the antidepressant (84); however, changes in lamotrigine concentrations are likely to be modest and are unlikely to be relevant in most patients (85).

While lamotrigine does not alter the pharmacokinetics of OC medications, clinical reports have indicated that concomitant treatment with combined OCs may decrease lamotrigine serum concentrations, possibly due to induction of UGT by ethinyl estradiol (86–88). The addition of an OC-containing ethinyl estradiol may decrease lamotrigine serum concentrations by as much as 30% to 50%. Importantly, this interaction dissipates quite rapidly during the pill-free week and within 1 week following discontinuation of OC.

EFFICACY

Lamotrigine is indicated by the United States Food and Drug Administration (FDA) as adjunctive therapy for patients ≥2 years of age with

- Partial seizures
- Primary generalized tonic–clonic (PGTC) seizures
- Generalized seizures of Lennox–Gastaut syndrome

Lamotrigine is indicated by the FDA for conversion to monotherapy for patients ≥16 years of age with partial seizures who are receiving treatment with carbamazepine, phenobarbital, phenytoin, primidone, or valproate as a single AED. Although data from several clinical trials suggest utility, lamotrigine has not yet received FDA approval as initial monotherapy.

The extended-release formulation of lamotrigine is indicated by the FDA for patients ≥13 years as

- Adjunctive therapy for PGTC seizures and partial-onset seizures with or without secondary generalization
- Conversion to monotherapy for partial seizures being treated with a single AED

Adjunctive Therapy for Partial Seizures

Seven premarketing multicenter, double-blind, placebo-controlled add-on trials supported the efficacy of lamotrigine as adjunctive treatment for partial seizures in adults (89). The study with the highest dose (500 mg) (90) demonstrated a mean reduction in seizure frequency of 36% compared to baseline. Seizure frequency was reduced by greater than 50% in about one-quarter of these patients. The placebo group had an 8% reduction in seizure frequency relative to baseline. These studies

supported the initial approval for the indication of lamotrigine as adjunctive therapy for partial seizures in persons 16 years and older. A subsequent pediatric trial demonstrated efficacy over placebo in 201 children from 40 sites in the United States and France and supported an FDA indication for children who are at least 2 years old (91).

Naritoku et al. (92) confirmed that once-daily, extended- release lamotrigine was effective as adjunctive treatment in patients (13 years and older) with partial seizures, many of whom had tried multiple other AEDs without seizure control. In this study, the percentage of patients with at least a 50% reduction in seizure frequency was significantly greater than placebo (42% vs. 24%, $P = 0.0037$).

Monotherapy for Partial Seizures

Efficacy as monotherapy in partial seizures has been shown by several trials, including a multicenter, double-blind randomized trial comparing 500 mg of lamotrigine to an active control of 1000 mg of valproate (68) and a conversion-to-monotherapy study using an historical control group (93). The primary end point for the active control study was proportion of patients exiting the trial according to a criterion of doubling of greatest 2-day or 1-month seizure rates observed in the baseline period. With this primary end point, 56% of patients taking lamotrigine completed the trial compared to 20% receiving low-dose valproate. In the historical control study, exit rates for participants were less than the aggregated exit rates for pseudoplacebo groups in eight completed conversion-to-monotherapy trials. Lamotrigine has been shown to have equivalent efficacy to immediate-release carbamazepine (94) and phenytoin (95) in double-blind, randomized clinical studies of recent-onset epilepsy in adults. Similarly, lamotrigine was shown to have comparable effectiveness when compared to controlled- release carbamazepine in newly diagnosed elderly patients with epilepsy (96).

The SANAD trial (97), which was an unblinded, randomized effectiveness trial conducted in the United Kingdom, suggested that lamotrigine was at least as effective as carbamazepine in patients with newly diagnosed partial seizures. Patients treated with lamotrigine were found to have a significantly longer time to treatment failure than either gabapentin or topiramate.

Lennox–Gastaut Syndrome in Children

A large ($n = 169$) multicenter, double-blind, randomized add-on trial of lamotrigine demonstrated efficacy of lamotrigine for the treatment of major motor seizures in children and young adults with Lennox–Gastaut syndrome (98). The age range for the study was 2 to 25 years. The target dose of lamotrigine was 15 mg/kg for patients not taking valproate and 5 mg/kg for those taking valproate. Major motor seizures, defined as atonic, tonic, major myoclonic, and tonic–clinic, were reduced by 32% compared to baseline. The placebo group had only a 9% reduction in major motor seizures. This study supported the FDA indication for major motor seizures in Lennox–Gastaut syndrome in adults and children. Other studies have supported the efficacy of lamotrigine in Lennox–Gastaut syndrome (99–101).

Other Generalized Epilepsy Syndromes

Although lamotrigine has not received FDA approval for the indication of treatment of childhood absence epilepsy and juvenile myoclonic epilepsy, several studies have identified effectiveness for the seizures of these syndromes (102–106). A double-blind, randomized, placebo-controlled

"responder- enriched" study of recently diagnosed typical absence seizures that confirmed seizure frequency by 24-hour EEG and hyperventilation EEG found that 62% of patients were seizure free compared to 21% in the placebo group (106). Glauser et al. (107), however, have reported that in children with newly diagnosed childhood absence, treatment with either valproate or ethosuximide was more efficacious when compared to treatment with lamotrigine. This result was obtained at both 16 weeks and 12 months of treatment (108). Another double-blind, placebo-controlled, add-on crossover study of treatment-resistant generalized epilepsy demonstrated that lamotrigine significantly reduced seizures that had not been controlled by other AEDs; 25% of the sample became seizure free (102). A small case series suggested that myoclonus may worsen with lamotrigine treatment in some patients with generalized epilepsy (109).

Data from Biton et al (110) suggest that lamotrigine is effective as adjunctive therapy for PGTC seizures. In a double-blind placebo-controlled trial, where lamotrigine was added to patients with recurrent PGTC seizures and concurrently receiving one or two background AEDs, seizure frequency was reduced by approximately 66% (vs. 34% in the placebo arm). Seventy-two percent of patients treated with lamotrigine (vs. 49% of placebo) experienced a 50% reduction in seizures. Importantly, no serious adverse events, nor aggravation of other seizure types, was noted. Efficacy and tolerability of once-daily adjunctive administration of the XR formulation has also been demonstrated, with statistical separation from placebo occurring as early as 1 week (111).

In an unblinded, randomized effectiveness trial, Marson et al. (112) found that in patients with idiopathic generalized seizures, initial treatment with valproate was significantly better with respect to time to 12-month remission than with lamotrigine; however, no significant differences were seen for time to treatment failure between these two treatments. Similarly, long-term seizure freedom in patients with juvenile myoclonic epilepsy has been reported to be comparable in patients randomized to receive lamotrigine or valproate (113). While these data are certainly useful, the decision as to which agent should be considered drug of the first choice will likely still depend on patient-specific characteristics, such as gender, pregnancy, weight gain, etc.

SAFETY AND TOLERABILITY

Similar to efficacy, the safety profile of lamotrigine has been defined by numerous clinical studies. Of the adverse effects reported with lamotrigine, rash has received the most attention (114,115). The pathologic mechanism is not known, but a genetic basis and an association between certain HLA alleles are suspected, but not as of yet confirmed (116–118). A cross-reactivity for rash with other antiepileptic medications, especially carbamazepine and phenytoin, appears to be present (119).

The incidence of serious rash associated with hospitalization and discontinuation of lamotrigine in the pediatric population was assessed in a prospectively followed cohort of pediatric patients (2 to 16 years of age) with epilepsy receiving adjunctive therapy. In these patients, the incidence of serious rash was approximately 0.8%. In the adult population, serious rash associated with lamotrigine occurred in 0.3%. Interestingly, the clinical trials of lamotrigine for adults with bipolar disorder identified a rash rate of 0.08% in those receiving lamotrigine as initial monotherapy and 0.13% in those who receiving lamotrigine as adjunctive therapy. When compared to either carbamazepine or phenytoin as monotherapy for new-onset epilepsy, lamotrigine monotherapy for new-onset epilepsy had an equivalent rash rate (94,95).

In general, the risk for serious rash appears to be increased either when lamotrigine is initiated at a high starting dose or when the dosage is rapidly escalated (115). Attention and adherence to FDA-

approved dosage and titration schedules are clearly warranted. There is also evidence that the combination of valproate and lamotrigine may increase the risk of serious rash in both pediatric and adult patients.

The most common central nervous system and systemic adverse effects reported with lamotrigine conversion and monotherapy are shown in Table 57.1. Some adverse events are related to pharmacodynamic interactions, which occur most commonly with carbamazepine. Several double-blind, randomized monotherapy studies indicate that lamotrigine causes significantly less sedation or cognitive adverse effects than several other AEDs (68,94,95,120). Steiner et al. (95) reported that 28% of patients reported sleepiness while taking phenytoin, compared to 7% ($P < 0.05$) with lamotrigine. Brodie et al. (94) also found less sedation compared to carbamazepine (12% vs. 22%, $P < 0.05$), and more patients withdrew from the study due to adverse events on carbamazepine (15% vs. 27%). However, a randomized, double-blind comparison study of lamotrigine and carbamazepine for new-onset epilepsy in the elderly (aged 65 to 90 years old) found no significant difference in most quality of life and adverse effects measures (121). The one significant difference was a decrease in dysphoria for those taking lamotrigine. When compared to levetiracetam, lamotrigine did not have a significant difference in efficacy or tolerability in a prospective, randomized, open-label monotherapy study of patients with newly diagnosed focal or generalized epilepsy (122).

Table 57.1 Most Common Adverse Events in Pivotal Trial (n = 156) of Lamotrigine (500 mg/d) as Monotherapy Compared to Active Control Valproate (1000 mg/d) (82)

	Transition phase		Monotherapy phase	
	Lamotrigine (500 mg)	Low-dose valproate	Lamotrigine	Low-dose valproate
Dizziness	20%	23%	7%	0%
Nausea	16%	19%	7%	2%
Headache	13%	13%	7%	14%
Asthenia	12%	13%	2%	0%
Coordination abnormality	12%	0%	7%	0%
Vomiting	11%	9%	9%	0%
Rash	11%	8%	2%	2%
Somnolence	8%	14%	0%	2%
Tremor	7%	10%	5%	7%
Dyspepsia	0%	14%	7%	2%

Other studies have also suggested that lamotrigine has a favorable psychotropic profile and may improve mood in some patients (123–125). This observation is potentially confounded by decreased sedations and improved concentration after converting from less well-tolerated antiepileptic medications (126), but available evidence supports that lamotrigine can improve mood or even protect against adverse mood effects of other medications. For example, Mula et al. reported that concomitant treatment with lamotrigine was associated with reduced rates of adverse psychiatric reactions to levetiracetam (127) or topiramate (128).

Recently, an association between lamotrigine use and aseptic meningitis has been reported. While the mechanism underlying this relatively rare adverse effect is unclear, clinicians should consider this is cases of culture-negative meningitis (129).

Teratogenicity is another consideration in an assessment of safety. Data derived from rodents as well as human ex vivo placental perfusion studies suggest that lamotrigine easily and rapidly crosses

the placenta (40). Comparison of lamotrigine serum concentration in maternal and umbilical cord blood has identified a median infant-to-mother concentration ratio of 0.9 (SD 0.2) (130). A direct comparison of the effect of lamotrigine on the fetus has been found to be lower than valproate and similar to carbamazepine with an odds ratio of 1.48 (95% CI 0.47, 4.69) (131). Data from the Australian Pregnancy Registry suggest a malformation rate of 5.2% in women receiving lamotrigine monotherapy and, further, failed to find dose-dependent increase in risk (132). A large population-based registry identified a 2.2% major congenital malformation rate from a first-trimester exposure group that included 1558 women (133). This registry lacked an internal control group, which precludes an odds ratio calculation, but the rate is similar to the general population. This registry also failed to detect an increased frequency of major malformations with increased lamotrigine dose. However, a higher rate of 3.2% also has been observed, and lamotrigine has not been found to be without teratogenic potential (134,135). Lamotrigine is present in maternal milk at potentially clinically significant concentrations (136).

CHAPTER 58 LEVETIRACETAM

JOSEPH I. SIRVEN, KATHERINE H. NOE, AND MATTHEW T. HOERTH

Levetiracetam (LEV) is a novel antiepileptic drug (AED) approved in 2000 by the U.S. Food and Drug Administration (FDA) as adjunctive therapy for patients with partial epilepsy, myoclonic seizures, and primary generalized tonic–clonic seizures. The compound was developed as a derivative of the nosotropic agent piracetam, with a wide spectrum of anticonvulsant effects in animal models of various types of epileptic seizures (1). It is chemically unrelated to existing AEDs. In addition to its unique chemical structure, LEV has a distinct mechanism of action and a favorable pharmacokinetic and safety profile, making it an attractive therapy for seizure management.

CHEMISTRY

LEV is a single enantiomer (−)-(S)-α-ethyl-2-oxo-1-pyrrolidine acetamide with a molecular weight of 170.21 (1,2). The structural formula of the agent is shown in Figure 58.1. The drug is a white to off-white crystalline powder with a faint odor and bitter taste. It is very soluble in water (104.0 g/100 mL), freely soluble in chloroform and in methanol, and soluble in ethanol. It is much less soluble to insoluble in acetonitrile and n-hexane. LEV tablets contain LEV and the inactive ingredients silicon dioxide, cornstarch, methylcellulose, magnesium stearate, polyethylene glycol 4000, and coloring agents. LEV is supplied for clinical use in regular and extended-release tablets and as an oral and intravenous solution (2).

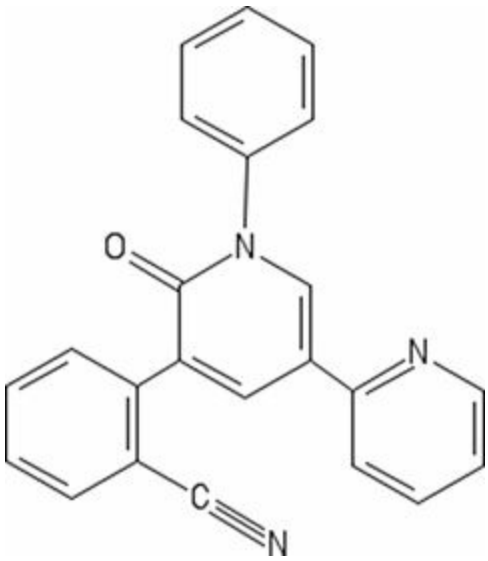

Figure 58.1. The chemical structure of LEV.

MECHANISM OF ACTION

Prior to undergoing standardized AED testing by the National Institutes of Health, LEV was found to

have antiepileptic properties. In contrast to previously approved AEDs, LEV lacked conventional modulation of the acute seizure model (maximum electroshock seizure test and pentylenetetrazol), suggesting a novel mechanism of action (3–5). Moreover, LEV displays unique potent protection against kindled seizures in both mice and rats during kindling models (3,4). In comparative tests with established AEDs in a number of animal models of epileptic seizures, LEV displays potent protection in a broad range of animal models of chronic epilepsy, including partial and primary generalized seizures (5).

The mechanisms by which LEV exerts its AED effect are still not fully defined. Initial investigations of classic AED targets such as neuronal voltage-gated sodium, T-type calcium currents, or gamma-aminobutyric acid A receptors did not demonstrate sufficient action to account for the effectiveness of the drug (6,7). Subsequently, LEV was determined to have a unique central nervous system–binding site, synaptic vesicle protein 2A (SV2A) (8,9). SV2A is a component of secretory vesicle membranes and has been shown to mediate calcium-dependent vesicular neurotransmitter release (10–12). Binding affinity for SV2A has been shown to correlate with antiepileptic potency in animal models of audiogenic, partial, and generalized seizures (9,13). However, the mechanism by which binding of LEV to SV2A results in antiseizure activity is not yet known. This is a focus of ongoing research, given the potential importance of SV2A as a target for development of new antiepileptic agents.

ABSORPTION, DISTRIBUTION, AND METABOLISM

Overview

LEV is rapidly and almost completely absorbed following oral administration. The pharmacokinetics is linear and time invariant, with low individual variability (14). LEV is not protein bound (<10%), and its volume of distribution is close to the volume of intracellular and extracellular water (14,15). Sixty-six percent of the dose is unchanged as it is excreted renally (14). The major metabolic profile of LEV is an enzymatic hydrolysis of the acetamide group (14,15). LEV is not liver cytochrome P450 dependent (14). Its metabolites have no known pharmacologic activity and are renally excreted. The plasma half-life of LEV across studies is approximately 6 to 8 hours. The effects of the agent are increased in the elderly (primarily due to impaired renal clearance) and in patients with renal impairment (14,15).

Absorption and Distribution

Absorption of LEV is rapid, with peak plasma concentrations occurring about 1 hour following oral administration. Oral bioavailability is 100%, with no effect from ingestion of food. Linear pharmacokinetics characterizes LEV over a dose range of 500 to 5000 mg. Steady state is achieved after 2 days of multiple twice-daily dosing. LEV is <10% bound to plasma proteins; clinically significant interactions with other drugs through competition for protein-binding sites are unlikely (14,15).

Metabolism and Elimination

LEV is not extensively metabolized in humans with the major metabolic pathway of enzymatic hydrolysis of the acetamide group, which produces the pharmacologically inactive carboxylic acid metabolite. There is no dependency on P450 cytochrome liver metabolism (14,15).

LEV is eliminated by renal excretion as unchanged drug, which represents 66% of the administered dose (14). The total body clearance is 0.96 mL/min/kg, and the renal clearance is 0.6 mL/min/kg (14,15). The mechanism of excretion is glomerular filtration with subsequent partial tubular reabsorption. Elimination is correlated with creatinine clearance (CrCl) (14).

Special Populations

Pediatrics

The pharmacokinetics of LEV has been evaluated in children 6 to 12 years of age following single 20-mg/kg doses. The apparent clearance of LEV was approximately 40% higher in children than in adults. The half-life in children is 4 to 8 hours, compared with approximately 7 hours in adults. The maximum concentration of drug (C_{max}) and area under the curve (AUC) values are comparable to those in adults. There is no correlation between age and clearance among pediatric patients (15).

Elderly

In older adults, total body clearance decreased by 38%, and the half-life was 2.5 hours longer compared with healthy adults (14).

Renal Impairment

Total body clearance of LEV is reduced in patients with impaired renal function by 40% in those with mild renal impairment (CrCl 50 to 80 mL/min), 50% in those with moderate impairment (CrCl 30 to 50 mL/min), and 60% in those with severe renal impairment (CrCl < 30 mL/min). In patients with end-stage renal disease, total body clearance decreased by 70% compared with those with normal renal function. About 50% of LEV is removed during a standard 4-hour hemodialysis procedure. Thus, dosage should be reduced in patients with impaired renal function, and supplemental doses should be given after hemodialysis (14).

Hepatic Impairment

The pharmacokinetics of LEV is unchanged in individuals with hepatic impairment. No dose adjustment is needed in patients with hepatic impairment (14).

DRUG INTERACTIONS

In vitro data on metabolic interactions indicate that LEV is unlikely to produce or be affected by pharmacokinetic interactions. Minimal plasma protein binding makes interactions due to competition for protein-binding sites unlikely (16). Potential pharmacokinetic interactions were assessed, but none were reported in clinical pharmacokinetic studies with phenytoin, warfarin, digoxin, and oral

contraceptives (17–20). Analysis of Phase 3 studies also revealed no pharmacokinetic interactions with other AEDs, such as phenytoin, carbamazepine, valproic acid, and phenobarbital (17,21).

EFFICACY

Partial-Onset Seizures

The effectiveness of LEV as adjunctive therapy in adults was established in three multicenter, randomized, double-blind, placebo-controlled clinical trials in patients with refractory partial-onset seizures with or without secondary generalization (22–24). Patients (N = 904) were randomized to one of four treatment arms: placebo, LEV 1000 mg, LEV 2000 mg, or LEV 3000 mg/day. Responder rates (50% or more reduction in seizure frequency compared with baseline) of 37.1% and 20.8%, respectively, were reported for 1000-mg/day doses for studies 1 and 2. At 2000 mg/day, a responder rate of 35.2% was reported; responder rates of 39.6% and 39.4%, respectively, were noted for 3000 mg/day (22–24). All of the response rates were statistically significant when all three LEV treatment arms were compared with placebo. Complete seizure freedom was reported to be 2% at 1000 mg and 6.7% at 3000 mg/day (22–24).

An interesting finding in study 1 was the rapid onset of efficacy of LEV (22). A significant reduction in weekly seizure frequency compared with that of the baseline period was observed during the first 2 weeks of the titration period, indicating that the agent has a rapid clinical effect at an initial dose (22). Open-label community trials confirmed the results noted in the pivotal trials, with efficacy achieved in patients at a dose of only 500 mg b.i.d. (25).

Four published studies have demonstrated the sustained efficacy of LEV as add-on epilepsy therapy for a period of at least 12 months and for as long as 54 months. The long-term tolerability of the agent is similar to that seen in the short-term, placebo-controlled trials (26–31).

Myoclonic Seizures

The effectiveness of LEV as adjunctive therapy in patients 12 years of age or older with juvenile myoclonic epilepsy (JME) experiencing myoclonic seizures was established after one multicenter, randomized, double-blind, placebo-controlled study (32). One hundred twenty-two patients were randomized to either placebo or LEV at a target dose of 3000 mg/day. A total of 58.3% of the LEV group responded (>50% reduction from baseline in myoclonic seizure days per week) versus 23.3% of those in the placebo arm; 25% of those treated with LEV were seizure free.

Primary Generalized Tonic–Clonic Seizures

LEV was evaluated for efficacy as adjunctive therapy in patients with idiopathic generalized epilepsy experiencing primary generalized tonic–clonic seizures by one randomized controlled multicenter trial (33). One hundred sixty-four subjects aged 4 to 65 years were randomized to either placebo or a LEV dose of 3000 mg/day or 60 mg/kg/day for children, added to one or two baseline AEDs. 77.2% of the LEV-treated group had a >50% reduction in GTC frequency versus 45.2% in the placebo arm. More subjects in the LEV arm were also seizure free (34.2% vs. 10.7%) during the evaluation period.

Monotherapy

Individuals with refractory partial epilepsy who completed a multicenter, double-blind, placebo-controlled parallel group with LEV 3000 mg/day were eligible for a monotherapy trial (24). Forty-nine patients entered the monotherapy arm. The median percent reduction in partial seizures was 73.8%, with a 50% responder rate of 59.2%. Nine patients (18.4%) remained seizure free on monotherapy (24).

In a multicenter, noninferiority comparison trial conducted in newly diagnosed patients with epilepsy, LEV was compared to controlled-release carbamazepine as initial treatment. At 1 year, seizure outcomes were similar, with 56.6% of patients randomized to LEV (N = 288) and 58.5% of patients receiving controlled-release carbamazepine (N = 291) were seizure free. Withdrawal rates due to treatment-emergent adverse events were 14.4% with LEV and 19.2% for those treated with controlled-release carbamazepine (34). LEV is not currently FDA approved as initial monotherapy.

Pediatrics

LEV has been evaluated in partial-onset seizures in children with epilepsy. One randomized, double-blind, placebo-controlled study was performed in North America with 60 sites and 198 pediatric patients between the ages of 4 to 16 years of age (35). Patients were randomized to placebo or to a dose of 20 mg/kg/day in two divided doses to a target dose of 60 mg/kg/day. The results showed a responder rate of 44.6% and a 26.8% reduction in weekly partial-onset seizures. A comparative trial was recently performed comparing LEV versus carbamazepine monotherapy for partial epilepsy in children <16 years of age. LEV was shown to have equal efficacy to carbamazepine (36).

Two open-label trials have been conducted to assess the efficacy and safety of LEV in children with partial seizures (15,37). Twenty-three children 6 to 12 years of age with treatment-resistant partial-onset seizures who were receiving one standard AED were eligible (32). Seizure frequency in these children was evaluated and compared with a 4-week baseline seizure frequency, using a 6-week titration to a target dose of 40 mg/kg/day. Twelve children (52%) responded (50% seizure reduction), with two patients remaining seizure free during the entire study period (37).

A small randomized trial of LEV versus placebo for children and adolescents with newly diagnosed absence epilepsy found no statistically significant response with short-term use (38).

Status Epilepticus

The availability of an intravenous formulation of LEV that can be infused relatively quickly without hemodynamic side effect has led to multiple case series reported in the literature. Ten of the highest quality studies were identified and systematically reviewed, which included a total of 334 patients. Of the patients reported, 279 were treated with LEV after the administration of a benzodiazepine, while the remaining 55 were treated as initial therapy. The definition of efficacy varied between the reviewed studies and ranged between 44% and 94%. No serious adverse effects were reported. The most common side effect noted was somnolence in up to 40%. Caution should be used when attempting to generalize these data, since none of these studies were controlled trials and 8 of the 10 studies were retrospective. Also, due to the design of these studies, many of these patients had relative contraindications to traditional therapies (39).

Subsequent to the systematic review, a larger randomized prospective open label trial of 79 patients in convulsive status epilepticus was published comparing LEV 20 mg/kg infused over 15

minutes to lorazepam and 0.1 mg/kg over 2 to 3 minutes. Primary end point was the cessation of seizure activity by 30 minutes. There was no statistical difference between the two groups for first-line therapy (LEV 79.8% vs. lorazepam 78.2%). Also, there was no statistical difference in response when crossed over to second-line therapy, seizure recurrence in 24 hours, and seizure freedom at 24 hours (40). From these initial data, a prospective randomized multicenter trials are planned to determine the effectiveness of LEV and other therapies in benzodiazepine refractory status epilepticus (41). LEV is not currently FDA approved for the indication of status epilepticus.

ADVERSE EVENTS

Central Nervous System

Three main types of CNS adverse effects are associated with LEV use: fatigue, coordination difficulties, and behavioral problems (22–24,37). In the three pivotal clinical trials, 14.7% of patients reported fatigue, whereas 3.4% had coordination problems. Coordination difficulties included ataxia, abnormal gait, and incoordination. Dose reduction improved these symptoms. Fatigue and coordination problems occurred most frequently within the first 4 weeks of treatment. Of patients treated with LEV, 13% reported such behavioral symptoms as agitation, hostility, anxiety, apathy, emotional lability, depersonalization, and depression (Table 58.1). Most of these symptoms occurred within 4 weeks of drug initiation (22–24). Dose reduction was associated with improvement in these behavioral problems, with only 0.8% of treated patients requiring hospitalization. In the open-label trial of children, there were no differences between adverse events reported in this population and those reported in adults (42).

Table 58.1 Neurologic and Psychiatric Adverse Effects of LEV

Neurologic effect	Reported incidence in placebo-controlled trials in adults
Somnolence	14.8%
Vertigo	3%
Agitation	6% (pediatric trials)
Nervousness	4%
Depression	6.7%
Irritability	7%
Suicidal ideation	0.5%
Anxiety	2%

Other Systemic Adverse Events

Table 58.2 illustrates systemic adverse effects that have been reported in clinical trials with LEV. The most frequently reported adverse events included asthenia, somnolence, and dizziness, which occurred predominantly during the first 4 weeks of treatment. In 15% of patients treated with LEV, somnolence was most often associated with discontinuation or dose reduction, followed by breakthrough seizures or dizziness (22–24).

Table 58.2 Adverse Effects of LEV: Systemic

Body system	Adverse effects
Cardiac	No effect
Dermatologic	Minimal rash potential
Gastrointestinal	No significant effect
Hematologic	Minor decreases in hemoglobin, red blood cell count, and white blood cell (WBC) count No patients required treatment discontinuation because of these effects
Hepatic	No meaningful changes in liver function tests
Infectious	Pharyngitis, rhinitis with no relationship to WBC count
Pulmonary	No effect

Pregnancy

Data from prospective observational pregnancy registries to date suggest that use of monotherapy LEV during the first trimester of pregnancy carries a relatively low risk for major congenital malformations (43–46). To date, in utero exposure to LEV has not been shown to adversely impact early-life cognitive development (46). Maternal serum LEV levels can fall significantly during pregnancy, so that monitoring of blood levels to guide dosing during gestation and in the postpartum period should be considered (47). LEV is excreted into breast milk, but serum drug levels in a small sample of breast-fed infants were shown to be low (47).

CLINICAL USE

The recommended dosage of LEV is between 1000 and 3000 mg/day in two divided doses (2). Although in some studies there was a tendency toward greater response with higher doses, a consistent increase in response with increased dose has not been reported. Indeed, some older adults may respond to a dose as low as 500 mg/day (48). Dosage should guide titration to clinical response.

LEV should be introduced gradually at 250 to 500 mg b.i.d. in adults, in order to reduce the potential for side effects and to identify the minimum effective dose. Increases of 250 to 500 mg/day at 1- to 2-week intervals are recommended. If behavioral symptoms occur, reducing the dose may be beneficial. Although LEV has a rapid onset of effect, dose escalation that is too rapid could lead to adverse effects. A therapeutic serum concentration has not been established for LEV. Dosage should be guided by clinical response. LEV may be ideally suited for individuals with seizures who are hepatically compromised or are taking multiple medications.

For adjunctive treatment of partial-onset seizures and primary generalized seizures, children from age 4 to 16 years should be initiated with a daily dose of 20 mg/kg in two divided doses (2). The daily dose can be increased every 2 weeks by increments of 20 mg/kg to a target dose of 60 mg/kg/day. In children 12 years of age or older with myoclonic seizures, treatment should be initiated with a dose of 1000 mg/day given as b.i.d. doses. The target maximum dose is 3000 mg/day (2).

OTHER PREPARATIONS

Extended-Release Formulation

There is an extended-release preparation of oral LEV based on matrix pill technology available. The bioavailability of Keppra XR tablets is similar to that of immediate-release LEV. Similarly, no differences exist between extended-release formulations and immediate-release LEV with regard to metabolism or renal excretion. Extended-release LEV is different than immediate-release LEV in that the time to peak plasma concentrations is about 3 hours longer with extended-release LEV than with immediate-release LEV. Single administration of two 500-mg extended-release LEV tablets once a day produces comparable maximal plasma concentration and AUC plots as one 500-mg immediate-release LEV taken twice daily. There are no tablet skeletons/shells seen in the stool.

Extended-release LEV was evaluated for efficacy as adjunctive therapy in one multicenter, double-blind, randomized, placebo-controlled study in patients with refractory partial seizures (49). Patients were randomized to placebo versus two 500-mg tablets of extended-release LEV. When compared to placebo, median reduction in seizure frequency for the extended-release group was 46.1% versus 33.4% ($P = 0.038$) for placebo during the 12-week treatment period. A subsequent meta-analysis of 555 patients over 16 years old comparing side effects from extended and immediate-release formulations demonstrated statistically significant less headaches favoring those treated with extended-release LEV. Trends toward less somnolence, dizziness, nervousness, anxiety, and depression were also reported but not statistically significant (50). The manufacturer suggests that treatment should be initiated as adjunctive therapy for partial seizures with a dose of 1000 mg once daily with dosage adjusted in increments of 1000 mg every 2 weeks to a maximum recommended dose of 3000 mg/day. There are no data for the use of extended-release LEV in myoclonic seizures, primary generalized epilepsy, and children. This formulation can be taken with or without food but must be swallowed whole and should not be crushed or chewed.

Intravenous Preparation

An intravenous formulation of LEV is available for adult patients 16 years and older when oral administration is temporarily not feasible (51–53). This preparation does not have an indication for seizure emergencies (2). Intravenous LEV and oral LEV result in equivalent pharmacokinetic parameters when IV LEV is administered as a 15-minute infusion. Its distribution, metabolism, and elimination are no different than oral LEV. In fact, intravenous LEV is almost interchangeable with oral LEV. In switching from oral LEV to intravenous LEV, the total daily dosage of medication should be equivalent. The manufacturer suggests that the total daily dose of LEV be administered as a 15-minute infusion following dilution in 100 mL of a compatible diluent. There is no evidence to suggest that a loading dose is necessary. Compatible diluents include sodium chloride (0.9%), lactated Ringer solution, and dextrose (5%).

CONCLUSION

LEV is a highly efficacious broad spectrum agent that can be used for a number of seizure types including partial seizures, myoclonic seizures of JME, and generalized tonic–clonic seizures of primary generalized epilepsy in both adults and children. LEV has linear and predictable pharmacokinetics, renal metabolism with few drug interactions, and multiple dosing preparations. These pharmacologic characteristics reduce the need for frequent serum therapeutic monitoring and allow the agent to be utilized in a variety of clinical settings. Although LEV has few adverse effects,

its main drawback is concerns relating to its behavioral side effects. These effects can be mitigated by patient education and surveillance.

CHAPTER 59 PERAMPANEL

GREGORY L. KRAUSS AND BARRY E. GIDAL

Perampanel is a selective, noncompetitive AMPA receptor antagonist that has recently been approved in both Europe and the United States as adjunctive treatment of localization-related epilepsy (Fig. 59.1) (1,2).

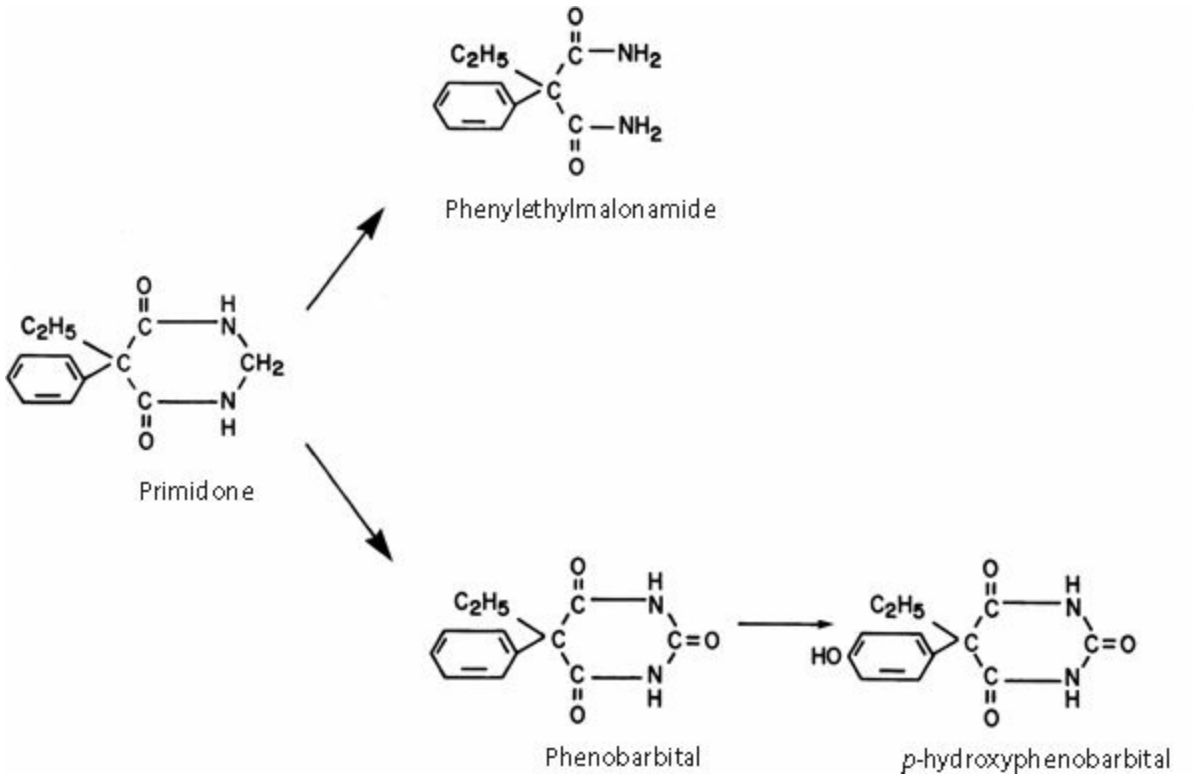

Figure 59.1. 2-(2-oxo-1-phenyl-5-pyridin-2-yl-1,2-dihydropyridin-3-yl) benzonitrile hydrate, M.W. 349.38 (perampanel).

PERAMPANEL PHARMACOLOGY

Glutamate is the major excitatory neurotransmitter in the CNS. Fast glutaminergic transmission is mediated predominantly by NMDA and AMPA receptors within the CNS. In vitro studies suggest that selective blockade of NMDA receptors has only minimal effect on hippocampal epileptiform activity, while AMPA receptors are quite important in initiating epileptiform discharges and mediating epileptic synchronization (3). AMPA receptors are glutamate-gated ion channels that are formed as tetramers of protein subunits. These receptors are widely distributed throughout the CNS and are found both in the postsynaptic membrane of excitatory neurons and in inhibitory interneurons as well.

Glutamate receptor antagonists have been evaluated to treat a variety of neurologic disorders, including hypoxic injury, amyotrophic lateral sclerosis, Parkinson disease, and epilepsy. NMDA receptor antagonists, however, produced unacceptable CNS depression. NMDA receptor gating is also necessary for induction of long-term potentiation, which is likely an important cellular process in memory formation. Blockade of NMDA receptors can abolish long-term potentiation and has been

found to impair memory formation. In contrast, selective blockade of AMPA receptors does not appear to interfere with long-term potentiation, and animal studies suggest no impairment in memory formation, even at higher doses (4).

Based upon the growing understanding of the importance of AMPA receptors, a number of early competitive antagonists were developed. The quinoxalinediones such as CNQX demonstrated poor in vivo response due to lack of penetration across the blood–brain barrier. Subsequent analogs such as NBQX showed improved permeability and demonstrated in vivo anticonvulsant response in a number of seizure models.

Talampanel, a 2,3-benzodiazepine, is a selective noncompetitive AMPA antagonist that demonstrated good CNS penetration but only had modest potency. Although showing initial promise for treating localization-related epilepsy and ALS, this compound was not effective for treating malignant gliomas and was not further developed (5).

Perampanel—2-(2-oxo-1-phenyl-5-pyridin-2-yl-1,2 dihydropyridin-3-yl)benzonitrile hydrate (4:3) or benzonitrile, 2-(1′,6′-dihydro-6′-oxo-1′-phenyl[2,3′-bipyridin]-5′-yl)—was discovered via high-throughput screening program using [3H]AMPA-binding assay to find selective competitive displacers at the glutamate recognition site in rat cortical neurons (3,6,7). Perampanel was shown to inhibit AMPA-induced responses in a noncompetitive manner in cultured rat neurons, with little to no inhibition of NMDA receptors (6).

In keeping with in vitro observations, perampanel demonstrated efficacy in a variety of animal seizure models, including audiogenic seizures in DBA/2 mice, as well as maximal electroshock, pentylenetetrazol, and 6-Hz tests (7). Interestingly, this spectrum of efficacy across diverse seizure models differentiates perampanel (from a mechanistic perspective) from more traditional sodium channel–blocking AEDs, which are relatively inactive in 6 Hz or pentylenetetrazole models (6). Perampanel was not active, however, in the WAG/Rij rodent model of absence seizures (7).

PERAMPANEL PHARMACOKINETICS AND DRUG INTERACTIONS

Perampanel pharmacokinetics in humans has been delineated in 14 phase I studies in single doses ranging from 0.2 to 12 mg and in chronic once-daily doses ranging between 1 and 12 mg/day (8). Following oral administration, perampanel is rapidly and essentially completely absorbed with a median time to maximal peak concentration of 0.75 hours (0.5 to 1 hours). Perampanel does not appear to be a substrate for xenobiotic efflux transporters such as P-glycoprotein or breast cancer resistance protein (6). When given with food, perampanel absorption is slowed (t_{max} 3 hours later in fed vs. fasted state), and resulting maximal peak concentrations are reduced by about 28%, but the overall extent of drug absorption is not significantly altered. Perampanel absorption is linear, and plasma concentrations are dose proportional. Perampanel is approximately 95% bound to plasma proteins, and its binding appears to be linear. Following oral administration, perampanel displays an initial decline in plasma concentrations over 12 hours, with a long elimination phase. Perampanel terminal elimination half-life has been reported to range between 53 and 136 hours, with an average half-life of about 100 hours in the noninduced subject.

Perampanel is extensively metabolized via CYP3A4, with the main metabolic pathway being oxidation at the pyridine, benzene, or benzonitrile rings and subsequent glucuronide conjugation. Although several metabolites have some activity at AMPA receptors, their potency is much weaker

than the parent molecule, and their contributions to clinical activity in patients are likely minimal (6).

Consistent with its long elimination half-life, accumulation was evident with multiple-dose administration, and perampanel concentrations at steady state were substantially higher than after a single dose. Renal elimination of perampanel is minimal, with <0.12% of an administered dose eliminated unchanged in urine. In subjects with mild (Child–Pugh A) and moderate (Child–Pugh B) hepatic impairment, unbound systemic exposure was 1.8- to 3.3-fold higher, and half-life of perampanel was approximately twofold longer than that in healthy subjects.

Perampanel oral clearance is significantly influenced by the presence of concomitant enzyme inducing AEDs, such as phenytoin, oxcarbazepine, or carbamazepine, which can increase perampanel oral clearance by about two- to threefold. While concomitant administration will reduce perampanel elimination half-life, it is still sufficiently long enough to support once-daily dosing. Pharmacokinetic/pharmacodynamic analyses showed that increased steady-state perampanel plasma concentrations were related to decreased seizure frequency and increased probability of achieving ≥50% reduction in seizure frequency (9). This association between plasma concentration and improved clinical response was seen in patients enrolled in the clinical trials irrespective of whether or not they were receiving an enzyme-inducing AED (10). Although there was no apparent effect of enzyme inducers on the concentration–response curve, the dose–response curve may be shifted due to patients receiving concomitant enzyme-inducing medications having lower perampanel concentrations. Patients receiving inducing medications may require higher maintenance doses of perampanel than do noninduced patients.

Perampanel has few other pharmacokinetic interactions. Data derived from the clinical trials suggest that topiramate concentrations may be increased by 20% and oxcarbazepine concentrations increased by 35% (9). Perampanel 12 mg/day decreased levonorgestrel concentrations by 40%, and patients may require additional nonhormonal forms of contraception while taking perampanel. In that perampanel is extensively metabolized by CYP3A4, it is likely that inhibition of this isozyme will result in potentially meaningful changes in perampanel pharmacokinetics. Given its long elimination half-life, however, changes in perampanel plasma concentration in the presence of a strong CYP3A4 inhibitor, such as ketoconazole, are not likely to be evident in the short term but might develop slowly after chronic administration (11). Therapeutic plasma concentrations have not been established for perampanel, though the effective dose range of 4 to 12 mg/day was associated with a range in plasma concentrations of approximately 200 to 800 ng/mL (9). A pharmacokinetic/efficacy model of phase III study data showed expected effects of AED inducers in reducing median perampanel concentration (median Cavss approximately 200 and 300 ng/mL for perampanel 8 and 12 mg/day doses with inducers and 550 and 700 ng/mL for 8 and 12 mg/day perampanel doses without inducers). Predicted reductions in seizure frequency corresponded to increasing concentrations across these concentration ranges (12). Similarly, data are still insufficient to determine a “toxic” plasma level; however, analysis of the phase 3 data suggests that the incidence of certain adverse effects such as dizziness, somnolence, euphoric mood, irritability, gait disturbance, dysarthria, and weight increase did appear to increase at higher perampanel plasma concentrations (9).

CLINICAL EFFICACY

Perampanel was not effective in treating multiple sclerosis, Parkinson disease, or migraine prophylaxis when tested at low 0.5- to 4-mg/day doses. Two phase IIa studies showed, however, that most patients with localization-related seizures tolerated much higher doses of perampanel, and

clinical development was done using 2- to 12-mg/day doses. A placebo-controlled "maximum tolerated dose" trial showed that nearly all patients with epilepsy tolerated 4-mg/day doses when given once a day or divided twice a day. In a subsequent dose-escalation trial, the majority of patients tolerated perampanel 8 mg/day; dose-limiting side effects—usually dizziness and somnolence—became more common at perampanel doses of 10 to 12 mg/day (13).

Subsequent epilepsy trials evaluated perampanel doses of 2 to 12 mg/day (compared with placebo), with the largest number of patients treated with 8-mg/day doses. The efficacy, safety, and tolerability of perampanel for treating localization-related seizures were evaluated in three large global trials and in several extension studies (Fig. 59.2) (14–18). Patients were adults and adolescents (≥12 years) with highly treatment-resistant epilepsy (≥4 or more seizures per month despite >80% taking two or three concomitant AEDs). In these pivotal dose-ranging trials, treatment with perampanel 4 mg/day, but not 2 mg/day, was effective and established the lower effective dose range for the medication. Doses of 8 and 12 mg/day were effective compared with placebo, but patients had only small increases in efficacy with 12 mg/day compared with 8 mg/day. A large proportion of patients treated with 12 mg/day had CNS-related adverse events, demonstrating an upper effective dose range. Responder rates (>50% seizure reduction) in the three pooled pivotal trials were 28.5% for 4-mg/day, 35.3% for 8-mg/day, and 35.0% for 12-mg/day doses (compared with placebo, 19.3%) (18). Reductions in patients' median seizure frequency were similar: 23.3% for 4-mg, 28.8% for 8-mg, and 27.2% for 12-mg dose groups. One of the pivotal trials included several study sites in Latin America with unusually high placebo responses (15). The results from these sites were included in the primary efficacy analysis but were removed for several of the sensitivity analyses. Perampanel was tested in a large number of countries and ethnicities (Europe, the Middle East, South Africa, Southeast Asia, China, and North and South America), with similar overall treatment responses across various regions and ethnicities.

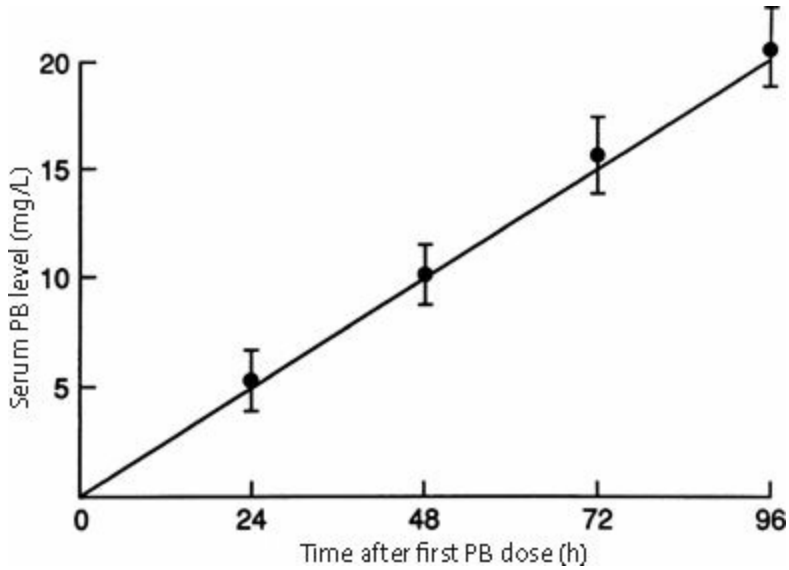

Figure 59.2. Efficacy of perampanel: proportions of 50%, 75%, and 100% responders (ITT analysis of pooled data for all partial seizure types). (Data from Steinhoff BJ, Ben-Menachem E, Ryvlin P, et al. Efficacy and safety of adjunctive perampanel for the treatment of refractory partial seizures: a pooled analysis of three phase III studies [published online ahead of print May 10, 2013]. Epilepsia. 2013;54(8):1481–1489.)

Important secondary efficacy end points showed possible benefits for some patients taking the higher 8- to 12-mg/day doses. The proportion of patients with ≥75% reduction in seizure frequency during perampanel treatment was 12.2% for 4 mg/day, 17.4% for 8 mg/day, and 16.9% for 12-

mg/day. The proportion of seizure-free patients for study completers in the pooled pivotal trial data was 1% for placebo compared to 4.4%, 3.5%, and 4.1% for 4-, 8-, and 12-mg doses, respectively (18). Secondary generalized seizures (for patients with this seizure type) decreased by 62.9% during treatment with 8 mg/day and 53.3% with 12-mg/day treatment (18). During 1 to 4 years of open treatment and follow-up, slightly more than 50% of patients continued perampanel treatment, with few patients discontinuing due to adverse events (3.9% dizziness and 1.3% irritability). Patients' continuing treatment appeared to have stable treatment responses appeared to be sustained (17). Early postmarketing experience using perampanel in Germany has shown similar responses (19).

TOLERABILITY AND SAFETY OF PERAMPANEL

Postdose sedation with perampanel coincides with brief plasma concentration peaks that occur 0.5 to 2 hours after dosing (t_{max}); symptoms of somnolence, however, were successfully alleviated in clinical trials by bedtime dosing with the once-a-day medication. The most common adverse events in adjunctive treatment trials were CNS-related symptoms similar to other AEDs—dizziness, drowsiness, blurred vision, and imbalance (Table 59.1). These symptoms were more common at higher doses, for example, 16% of patients reported dizziness with 4-mg/day treatment compared with 32% with 8-mg/day and 43% with 12-mg/day treatment (18). These symptoms were often transient during dose titration, and most patients successfully tolerated forced titration to 8- to 12-mg/day doses (median 10 mg/day) during conversion to open treatment in extension trials (17,20).

Table 59.1 Incidence of Common Side Effects (>5% of Patients) During Adjunctive Perampanel Treatment: Pooled Analysis

		Perampanel treatment groups			
Adverse event, *n* (%)	Placebo (*n* = 442)	2 mg (*n* = 180)	4 mg (*n* = 172)	8 mg (*n* = 431)	12 mg (*n* = 255)

Balance disorder	2 (0.5)	0 (0.0)	0 (0.0)	22 (5.1)	8 (3.1)

Data derived from Steinhoff BJ, Ben-Menachem E, Ryvlin P, et al. Efficacy and safety of adjunctive perampanel for the treatment of refractory partial seizures: a pooled analysis of three phase III studies [published online ahead of print May 10, 2013]. Epilepsia. 2013;54(8):1481–1489.

Special adverse events reported during clinical trials were unexplained falling, particularly in the elderly and psychiatric symptoms. Perampanel labeling includes a warning for possible psychiatric symptoms: aggression, hostility, unusual changes in mood, personality, or behavior, and other behavioral symptoms such as homicidal ideation and threats. Overall, serious psychiatric symptoms occurred in 1.2% of patients taking perampanel during controlled studies (compared to 0.9% during

placebo treatment) and in 3.9% of patients during long-term open treatment. The incidence for serious adverse events of homicidal ideation and/or threat was <0.1% (6 out of 4368 perampanel-treated patients); symptoms were usually associated with lethargy and somnolence, and most patients had prior histories of homicidal thoughts or mood or behavioral disorders. Aggression was reported in 1.6% of patients treated with perampanel and 0.5% receiving placebo. Psychiatric symptoms such as anger and irritability were most common during titration to high doses (10 to 12 mg/day) and generally occurred within 6 weeks of treatment. Several patients had these symptoms when perampanel was combined with alcohol. This suggests patients should be monitored for psychiatric symptoms, such as anger and irritability, during dose titration and particularly when perampanel is increased to high doses.

Systemic complications of perampanel treatment were rare and not increased compared with placebo. Patients experienced a small increase in weight (mean 1.1 kg compared with 0.3 kg with placebo treatment) though 46% of all patients were overweight or obese at study entry. No unusual laboratory changes or safety concerns were observed during 1 to 4 years of exposure in extension trials (17,20). Perampanel treatment did not produce significant ECG change with no QTc interval changes during treatment with up to 12 mg/day. Rashes were uncommon, occurring in 1.8% of patients treated with perampanel compared with 0.9% to 2.2% for placebo; three patients had AED-hypersensitivity reactions (1). Perampanel studies evaluated patients aged 12 to 77 years; only 28 patients were aged >65 years (1,21). Patients from a large number of regions and ethnicities were exposed with similar efficacy and safety findings during treatment.

Abuse Potential of Perampanel

Regulatory agencies in the United States have recently listed a number of newer AEDs as having possible abuse potential based on studies in drug-seeking individuals coupled with supportive evidence from clinical trial adverse event reporting and rodent reinforcement data. Clobazam and lacosamide received Schedule IV registration similar to alprazolam; while perampanel has a Schedule III listing similar to ketamine. Perampanel abuse potential studies tested therapeutic (8 mg) and supratherapeutic (24 and 36 mg) doses; drug-seeking individuals reported higher positive and sedative effects with these doses than placebo (22). Perampanel 24- and 36-mg doses were associated with drug "liking" scores similar to alprazolam and ketamine. The U.S. DEA concluded that abuse of perampanel could lead to moderate or low physical dependence or high psychological dependence. There has been, however, no evidence of psychological or physician dependence in patients enrolled in perampanel clinical trials for treatment of epilepsy (1).

PERAMPANEL DOSING

Currently, European and U.S. regulatory agencies recommend two approaches to manage the initial dosing, and dose escalation for patients receiving perampanel, based upon the presence or absence of concomitant enzyme-inducing AEDs. FDA prescribing information recommends a starting dosage of 2 mg/day (preferentially given at bedtime) for those taking a non–enzyme-inducing AED and 4 mg/day for patients taking enzyme-inducing AEDs (EIAEDs). Perampanel doses should be increased gradually, in 2 mg/day weekly increments, to a maximum dose of 4 to 12 mg/day based on clinical response and tolerability. In elderly patients, dosage increases should be slower still, with increases no more frequently than every 2 weeks. In Europe, the EMA recommends initiation of treatment with

PER at 2 mg/day, irrespective of concomitant EIAEDs.

In most patients, perampanel doses should be titrated based on clinical response and tolerability to a maintenance dose of 4 to 8 mg/day. Depending on an individual's clinical response and tolerability at a dose of 8 mg/day, some patients may require 12 mg/day. Again, consideration should be given as to the potential pharmacokinetic impact of enzyme-inducing medications.

In addition to drug-interaction considerations when initiating perampanel, patients need to be monitored for "deinduction" effects and potential rise in perampanel concentrations upon discontinuation of enzyme-inducing medications.

Perampanel was markedly effective in reducing primary generalized tonic clonic seizures in a recent placebo-controlled adjunctive therapy trial of 164 patients aged 12 years and older. In this treatment-resistant group of patients, perampanel decreased tonic clonic seizure frequency and improved responder rates. The safety profile was similar to previous trials; though, psychiatric adverse effects were similar across perampanel and placebo treatment groups. An exploratory analysis of perampanel effects on absence seizures is planned.

CONCLUSION

Perampanel is a first-in-class, selective noncompetitive AMPA receptor antagonist shown to be effective as adjunctive treatment for partial-onset seizures and for treating primary generalized tonic clonic seizures. Additional studies are examining efficacy and tolerability for treating children with localization-related epilepsy and effectiveness for treating seizures in patients with Lennox–Gastaut Syndrome.

CHAPTER 60 PHENOBARBITAL AND PRIMIDONE

MARK C. SPITZ, JACQUELYN L. BAINBRIDGE, AND PEI SHIEEN WONG

HISTORICAL BACKGROUND

Although its use has been decreasing, phenobarbital (PB) is still a major antiepileptic drug (AED). PB has been prescribed for the treatment of epilepsy since 1912, following serendipitous findings of seizure improvement in epilepsy patients by a German psychiatrist, Alfred Hauptmann, who originally intended it for sedative purposes (1). At the 10th European Congress on Epileptology in 2012, a special Centenary Symposium was held to commemorate the first 100 years of PB (2). Interestingly, in the 20th century, PB was prescribed using a weight-based measurement, the grain (gr), which was referenced to a "grain of wheat." When a prescription was written for PB, it would be in grains. One grain was equivalent to approximately 65 mg of PB (or by today's standards, one 60 mg tablet = 1 gr). Although PB is associated with more sedative and behavioral side effects than are most other AEDs, it has relatively low systemic toxicity, a conveniently long half-life, can be administered intravenously and intramuscularly, is effective in patients with status epilepticus and in neonates, and is inexpensive.

Primidone (PRM) has been in clinical use since its synthesis in 1952 (3). Often referred to as a barbiturate, PRM does not strictly belong in this class; its pyrimidine ring contains only two carbonyl groups, compared with the three groups of barbituric acid (Fig. 60.1). The remainder of its structure is identical to that of PB. Therapeutically, however, PRM is appropriately considered a barbiturate, as its effect can be attributed predominantly to PB derived through hepatic biotransformation. This metabolic transformation has made it impossible to establish whether therapy with PRM differs clinically from that with PB or whether PRM is a PB prodrug. Complicating this issue is the experimental demonstration of independent antiepileptic activity for the other main metabolite of PRM, phenylethylmalonamide (PEMA) (see Fig. 60.1), as well as the clinical benefits derived from PRM in essential tremor not seen with PB.

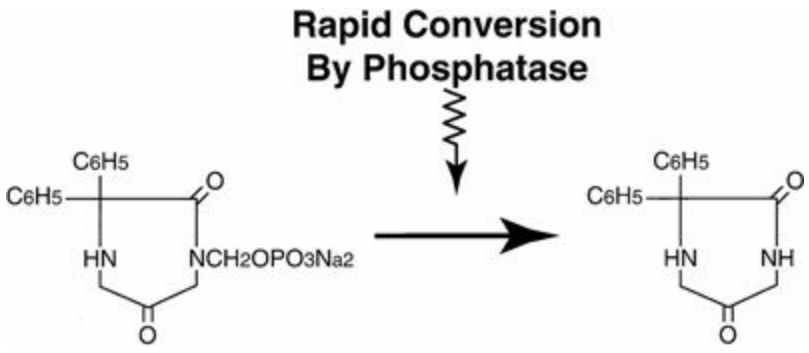

Figure 60.1. Structural formulas of PRM and its main metabolites.

CHEMISTRY AND MECHANISM OF ACTION

Phenobarbital

Chemically, PB is 5-ethyl-5-phenylbarbituric acid (see Fig. 60.1). The molecular weight is 232.23, and the conversion factor from milligrams to micromoles is 4.31 (1 mg/L = 4.31 μmol/L). The sodium salt of PB is water soluble. PB in its free acid form is a white crystalline powder soluble in organic solvents, but with limited water and lipid solubility; it is a weak acid with a pK_a of 7.3.

Many actions of PB at the cellular level have been described. Although it is not certain which are responsible for seizure protection, the available evidence seems to favor enhancement of γ-aminobutyric acid (GABA) inhibition (4). In animal models, PB protects against electroshock-induced seizures. Unlike phenytoin, carbamazepine, and PRM, PB also protects against seizures induced by chemical convulsants, such as pentylenetetrazol. In normal animals, PB raises the threshold and shortens the duration of afterdischarges elicited by electrical stimulation (5). Like other barbiturates, PB enhances postsynaptic $GABA_A$ receptor–mediated chloride (Cl^-) currents by prolonging the opening of the Cl^- ionophore (6). Increased flow of Cl^- into the cell decreases excitability. Presynaptically, PB can cause a concentration-dependent reduction of calcium (Ca^{2+})-dependent action potentials (7), which may contribute to seizure protection at higher therapeutic levels and, especially, to sedative and anesthetic effects.

Primidone

Chemically, PRM is 5-ethyldihydro-5-phenyl-4,6(1-H,5H) pyrimidinedione. The molecular weight is 218.264, and the conversion factor from milligrams to micromoles is 4.59 (1 mg/L = 4.59 μmol/L). PRM is very poorly soluble in water, somewhat soluble in ethanol, and virtually insoluble in organic solvents.

The basic anticonvulsant action of PRM has been studied in mouse neurons in cell culture (8). PRM was compared with PB for its effect on amino acid responses and on sustained, high-frequency firing. In contrast to PB, PRM had no effect on postsynaptic GABA and glutamate responses at concentrations up to 50 μg/mL. However, both agents limited sustained, high-frequency, repetitive firing at relatively high concentrations (>50 μg/mL). Together, PRM and PB limited sustained high-frequency, repetitive firing at clinically relevant concentrations (12 and 20 μg/mL, respectively). The authors concluded that PRM and PB may act synergistically to reduce sustained, high-frequency, repetitive firing.

All the evidence regarding the individual antiepileptic properties of PRM and PB has been demonstrated in experiments with animals whose seizures were provoked (9–12). Because the metabolites accumulate a few hours after administration of the first dose, possible long-term protection by PRM alone against spontaneously occurring seizures cannot be assessed in humans. The anticonvulsant potency of PRM against maximal electroshock-induced seizures is similar to that of PB, but unlike PB, PRM was ineffective against chemically induced seizures caused by pentylenetetrazol or bicuculline (11). Thus, the experimental anticonvulsant spectrum of PRM differs from that of PB and is similar to that of carbamazepine and phenytoin. Therefore, PRM and PB may be two different AEDs with different mechanisms of action.

On the basis of brain concentrations in mice, PRM appears to be 2.5 times less neurotoxic than

PB, with a superior therapeutic index (11). When PB and PRM were administered together in single-dose experiments in mice (13), their anticonvulsant activity was supra-additive (potentiated), and their neurotoxic effect was infra-additive. A PB–PRM brain concentration ratio of 1:1 provided the best therapeutic index. This ratio is not usually seen in patients, especially those taking PRM combined with enzyme-inducing drugs such as phenytoin or carbamazepine. If PRM is different from or even better than PB for the treatment of epilepsy, its different effect would be likely only when the PRM concentration equals or exceeds the PB concentration. Such a ratio is achieved only rarely with PRM monotherapy and almost never when PRM is added to phenytoin or carbamazepine, or combined with PB. The results of pharmacodynamic interactions between PRM and PB in mice were confirmed by experiments in amygdala-kindled rats. After single doses, the anticonvulsant effect of PB was potentiated by PRM, whereas side effects of PB, such as ataxia and muscle relaxation, were not increased by combined treatment with PRM (14).

In rats (15) and mice (11,12), PEMA had relatively weak anticonvulsant activity of its own. On the basis of brain concentrations in mice (11), PEMA was 16 times less potent than was PB in seizure protection and 8 times less potent in neurotoxic effects, but it potentiated the anticonvulsant (13,15) and neurotoxic effects (13) of PB. When this is interpreted together with the blood levels encountered in clinical practice, PEMA does not appear to significantly add to the antiepileptic effect or neurotoxicity of PRM therapy.

ABSORPTION, DISTRIBUTION, AND METABOLISM

Phenobarbital

Most formulations of PB contain sodium salt because of good aqueous solubility. The absolute bioavailability of oral preparations and intramuscular (IM) injection of PB is usually >90% (16,17). Accumulation half-life for the IM route (0.73 hours) was comparable to that to the oral route (0.64 hours). Time to peak concentration is usually 2 to 4 hours. In newborns, peak PB plasma levels after oral administration may be reached later than after IM administration (18). A parenteral solution of PB administered rectally has a bioavailability of 89%, compared with that of IM administration (19); average time to peak concentration was 4.4 hours.

PB is not highly bound to serum proteins (45%). Protein binding of PB is lower during pregnancy and in newborns, with a bound fraction between 30% and 40% in pregnant women and their infant offspring (20). Reported values for the volume of distribution vary. Following IV administration, average values were 0.54 L/kg in adult volunteers and 0.61 L/kg in adult patients with epilepsy (17), both well within the reported range. The volume of distribution of PB approached 1.0 L/kg in newborns (21).

PB is eliminated by both hepatic metabolism and renal excretion of the unchanged drug. An average of 20% to 25% of PB is eliminated unchanged by the kidneys in adults, with large interindividual variability (22,23). The two main metabolites of PB are p-hydroxyphenobarbital (PBOH) (see Fig. 60.1) and phenobarbital N-glucoside. At steady state, approximately 20% to 30% of the PB dose is transformed into PBOH by CYP2C9 (major), CYP2C19, and CYP2E1 (minor), approximately 50% of which is then conjugated to glucuronic acid (22–24). Nitrogen glucosidation, another relevant pathway of PB metabolism, accounts for 25% to 30% of total PB disposition (25).

Other identified metabolites of PB represent a very low percentage of the total elimination.

The elimination of PB from serum follows first-order kinetics. The half-life of PB is age dependent. It is usually well above 100 hours in newborns (26) and averages 148 hours in asphyxiated newborns (27). During the neonatal period, PB elimination accelerates markedly; thereafter, half-lives are very short, with average values of 63 hours during the first year of life and 69 hours between the ages of 1 and 5 years (28). Half-lives in adults range between 80 and 100 hours, and no evidence of autoinduction of PB metabolism has been demonstrated (17).

Primidone

PRM is supplied as 50- and 250-mg tablets and as syrup (1 mL = 50 mg); extremely low solubility precludes parenteral administration. After oral ingestion of tablets, the time to peak serum concentrations in adult patients with epilepsy was 2.7 (29) and 3.2 hours (30), respectively, and 4 to 6 hours after single-dose administration in children (31). In the same study, an average of 92% of the dose (range, 72% to 123%) was excreted in the urine as unchanged PRM and metabolites, probably indicating complete oral bioavailability. Concomitant administration of acetazolamide reduced the oral absorption of PRM (32). One generic preparation was found to have a lower bioavailability than did the trademark product (33).

The volume of distribution of PRM ranged from 0.54 L/kg following acute intoxication (34) to 0.86 L/kg (35). The volume of distribution of PEMA after its oral administration was 0.69 L/kg (36). In human plasma, protein binding of both PRM and PEMA was <10% (15,30,36). Brain concentrations of PRM were found to be lower than simultaneous plasma concentrations in mice (11,12) and in rats (10). In patients undergoing surgery for intractable epilepsy, one group of investigators found an average brain-to-plasma ratio of 87% (37). In another report (12) of six patients whose mean plasma PRM concentration was 6.3 μg/mL, brain concentrations ranged between nondetectable and 2.2 μg/g. Brain concentrations of PEMA in mice ranged between 77% and 93% of the plasma levels (11,12). In humans, the cerebrospinal fluid–plasma ratio for PRM ranged from 0.8 to 1.13 (30,37,38), which is similar to human saliva-to-plasma ratios (39) and which is consistent with the high free fraction of plasma PRM.

The elimination half-life of PRM varies, mainly because of enzymatic induction by comedication. In adults receiving long-term PRM monotherapy, the elimination half-life ranged from 10 to 15 hours (40–42). Therapy with additional AEDs was associated with values of 6.5 and 8.3 hours (29,30,41,42). In 12 children (4 treated with PRM monotherapy, 8 treated with PRM and phenytoin), half-lives ranged from 4.5 to 11 hours (mean, 8.7 hours) (31). In newborns, however, the average PRM half-life was 23 hours (range, 8 to 80 hours) (43), which was associated with a limited biotransformation to the metabolites (44).

After oral ingestion of PEMA itself, the half-life of PRM was 15.7 hours (36). The elimination rate of PEMA cannot be determined accurately in patients taking PRM because the liver produces PEMA as long as PRM is measurable in the blood.

Because two metabolites of PRM accumulate after repeated administration of the agent and because both have independent anticonvulsant activity, an understanding of the qualitative and quantitative aspects of PRM metabolism is needed before any rational clinical use of this drug can be undertaken. Although relative efficacy and relative toxicity of PRM and its metabolites have been studied acutely in animals (11,13), similar investigations are virtually impossible in humans because the three compounds are always present simultaneously during long-term therapy.

Figure 60.1 shows the relevant metabolic pathways for PRM. The first metabolite of PRM to be identified, PEMA was found initially in rats (45) and thereafter in every species studied. PB and PBOH were discovered only 4 years later, in 1956 (46), and toxic reactions attributed to the derived PB were first reported in 1958 (47). Other metabolites of PRM, with either negligible or nondetectable blood levels during long-term therapy, have no practical significance. Numerous clinical studies have discussed the quantitative aspects of the biotransformation of PRM to PB and PEMA. A comparison of the ratios of PB serum levels to dose during long-term PB therapy and during long-term PRM therapy in the same patients demonstrated that 24.5% of the PRM dose is converted to PB (48). This is in accordance with the report that average PRM doses (in mg/kg/day) required to maintain a given PB level are about five times higher than the equivalent PB doses (49). The extent of PRM biotransformation and the ratios of the blood levels of PRM and its metabolites are very sensitive to interactions with other AEDs and are discussed separately. (See Table 60.1 for a summary of pharmacokinetics of PB and PRM)

INTERACTIONS WITH OTHER AGENTS

Phenobarbital

Most of the interactions of PB reflect its status as an enzymatic inducer that accelerates the biotransformation of some AEDs, as well as other agents. No clinically significant interaction with PB has been reported that involves absorption. Significant interactions involving displacement from serum proteins do not occur as PB is only 55% protein bound in serum. Clinically, the most significant interaction affecting PB levels is the inhibition of PB elimination by valproate (50). Seen in the majority of patients, the extent of this interaction is variable. As a result, the increase in PB concentration can reach 100%, often necessitating dosage adjustments. The concentrations of PB derived from PRM are equally affected by valproate.

In the great majority of interactions, PB affects levels of other agents. Levels of valproate (51) and carbamazepine (52) are often reduced by the addition of PB. Levels of the active metabolite of carbamazepine, the 10,11-epoxide, are less affected or may even increase, and the epoxide–carbamazepine ratio is usually higher in the presence of PB. Relative to the metabolism of phenytoin, PB appears to cause both enzymatic induction and competitive inhibition. The two effects tend to balance out in patients, and dosage adjustments of phenytoin are seldom necessary (53). PB significantly increases the clearance of lamotrigine (54), as well as that of ethosuximide, felbamate, topiramate, zonisamide, tiagabine (55), and rufinamide (56). Clobazam clearance does not appear to be affected by PB (57). Those AEDs that are predominantly cleared by renal elimination (e.g., levetiracetam, pregabalin, lacosamide) do not appear to interact with PB.

PB induces the metabolism of many agents besides AEDs, which may require closer monitoring and dosage adjustments. Some examples of drugs susceptible to this interaction include theophylline (58), warfarin (59), and steroids, including those contained in oral contraceptives, leading to breakthrough bleeding and contraceptive failure (60). Combined oral contraceptive preparations containing at least 50 μg of ethinyl estradiol have been recommended for some women taking PB (61,62). Of note, preparations with this higher content of ethinyl estradiol are currently indicated only for use in emergency contraception. This should only be explored when other methods of birth control are not feasible. Alternatives can be considered, such as intrauterine devices or medroxyprogesterone

acetate injection, which is extensively metabolized on first pass through the liver, and concentrations are theoretically not affected by additional hepatic enzyme induction (63). However, as a conservative measure, the injection should be given more frequently (every 10 weeks instead of the usual 12 weeks) to ensure contraceptive efficacy. The use of the progesterone-only pill, progesterone implant, vaginal ring, and contraceptive patch are not recommended in women taking enzyme-inducing AEDs, unless combined with a barrier device. Regardless of which method is chosen, it is essential that the conversation between the patient and the practitioner, documenting a pregnancy or contraceptive plan, should appear frequently in the electronic medical records in women of childbearing potential.

Primidone

PRM is the cause, as well as the object, of numerous pharmacokinetic interactions (Table 60.1) (64). Because PB is invariably present during long-term PRM treatment, all of the effects of PB on other agents can be expected with PRM. The degree of enzymatic induction by other AEDs causes the extent of PRM biotransformation to vary among patients. Most reports describe enzymatic induction of the conversion of PRM to PB; some note inhibition. These interactions change not only the blood levels of PRM, PB, and PEMA relative to the PRM dose but also the ratios among the three substances. Phenytoin, a known potent inducer (41,65–67), causes the most extensive acceleration of PRM conversion, leading to a decrease in the PRM–PB serum concentration ratio. The rate of PRM biotransformation is slower with carbamazepine (41,64), which may also inhibit the conversion of PRM to PB, causing an increase in the PRM–PB serum concentration ratio (68). Table 60.2 summarizes the effect of comedication with phenytoin, carbamazepine, or both on the concentration-to-dose ratios and on the relative concentration ratios of PRM, PB, and PEMA (69). At the same daily dose of PRM, concomitant phenytoin or carbamazepine reduced the morning trough levels of PRM by about 50% and increased PB levels by about 160%. Thus, when patients receive concomitant phenytoin or carbamazepine, the average PRM dose required to maintain a given PB level is about 1.6 times lower than that with PRM monotherapy. Because derived PB is the product of enzymatic conversion and not the substrate, this difference is the opposite of what is usually seen with inducing interactions, which typically require an increased dose to maintain the same therapeutic drug level. With PRM, such an increase in metabolism often yields PB levels associated with toxic reactions.

Table 60.1 Pharmacokinetic Parameters of PB (17–21), PRM (29–31,34,35,40–42), and PEMA (36)

	F (%)	T_{max} (h)	Age group	V_d (L/kg)	Protein binding (%)	$T_{1/2}$ (h)	Cl (L/h/kg)

Table 60.2 also shows that the PB–PRM concentration ratio in a morning predose blood sample was more than three times higher in patients taking phenytoin or carbamazepine in addition to PRM (5.83 vs. 1.65, respectively). This means that at a PRM level of 10 mg/L, the corresponding average PB level would be 16.5 mg/L in a patient receiving PRM monotherapy, but 58.3 mg/L in a patient also taking phenytoin or carbamazepine.

Different effects of valproate on PRM kinetics have been described. In one study (70), transient elevations of PRM levels were observed after the addition of valproate; however, in general, no consistent changes in PRM or PB levels have been detected.

In all patients receiving long-term PRM therapy, the PB level is almost always higher than the PRM level. Attempts have been made to elevate the PRM level in relation to the PB level to obtain a greater therapeutic effect from PRM itself. Adding nicotinamide to the drug regimen (68) could achieve such a change in ratio, but the necessary doses may cause gastrointestinal side effects and hepatotoxic reactions. The antituberculosis drug isoniazid also markedly inhibits PRM biotransformation, producing relatively high PRM levels relative to PB levels (71).

EFFICACY

PB shows varying degree of efficacy against every seizure type, except absence seizures, but is used mainly for the treatment of generalized convulsive seizures and partial seizures. In a large-scale, controlled comparison of 622 adults with partial and secondarily generalized tonic–clonic seizures (72), phenytoin, carbamazepine, PB, and PRM were equally effective in achieving complete control. Compared to carbamazepine, PB and PRM controlled partial seizures in a lower percentage of patients. Evidence-based comparison of PB with phenytoin (73) and with carbamazepine (74) revealed no overall difference in seizure control, but PB was more likely to be withdrawn than the other two agents, presumably because of side effects. In children, PB was as effective as carbamazepine for up to 1 year in the treatment of partial seizures (39). In a randomized study of previously untreated children, PB, phenytoin, carbamazepine, and valproate were compared (75). After 6 of the first 10 children randomized to PB discontinued treatment mainly because of behavioral side effects, PB was eliminated from the study for ethical reasons. Generalized myoclonic seizures

and, in particular, juvenile myoclonic epilepsy (76) also respond to PB, although it is not an agent of first choice.

As a major agent in the treatment of patients with convulsive status epilepticus, PB is a reasonable next-line option if seizures persist following administration of a benzodiazepine and phenytoin (77,78). In patients with status epilepticus, PB was as effective as a combination of diazepam and phenytoin (79). The main disadvantages associated with its use are respiratory depression and hypotension. Very high doses of PB have been recommended for the treatment of refractory status epilepticus in children (80,81). This approach controlled seizures when no limits were imposed relative to maximum dose, and serum levels of 70 to 344 mg/L were achieved (80). In this series, most patients were initially intubated but recovered good spontaneous respiration despite persistently high PB levels; hypotension was uncommon.

PB is the agent of first choice in newborns with any type of seizure, with control achieved in about one-third of the infants (21,82,83). An efficacy rate of 85% against various neonatal seizures was noted with loading doses of up to 40 mg/kg (84). In a recent study, newborns with seizures were randomized to initial treatment with PB or phenytoin (85). There was no difference in the percentage of neonates in whom seizure control was achieved with PB (43%) and with phenytoin (45%).

PB has been the most widely used agent for chronic prophylaxis of febrile seizures, with efficacy demonstrated at levels higher than 15 mg/L (86,87). Failure of prophylaxis was often due to noncompliance with the regimen and subtherapeutic levels at the time of seizure recurrence. However, such treatment is now rarely considered, for several reasons: improved understanding of the benign nature of simple febrile seizures; the efficacy of intermittent short-term use of rectal or oral diazepam therapy (88–90); and reservations about the possible detrimental effect on cognitive function (91,92).

Neurologic side effects have prevented PRM from becoming an agent of first choice for the treatment of any seizure type. Indications are similar to those for PB, except for the treatment of status epilepticus and neonatal seizures (PRM is not available in a parenteral formulation). PRM is effective against generalized tonic–clonic seizures and juvenile myoclonic epilepsy (93,94). However, other agents such as levetiracetam, lamotrigine, topiramate, zonisamide, and valproate have demonstrated efficacy and tolerability as first-line therapy (95) for the latter condition. The clinical efficacy of PRM and PB has been compared in various studies. Several demonstrated no superiority of PRM but did establish noninferiority (48,95,96). In one crossover study (97), the efficacy of PRM and PB was compared sequentially in the same patients. Similar PB levels were maintained during both therapies, and PRM was found to be slightly more effective than PB against generalized tonic–clonic seizures.

In partial and secondarily generalized seizures, PRM use was associated with the same degree of seizure control as PB, phenytoin or carbamazepine (98,99); however, the percentage of treatment failures was highest with PRM because of an increased incidence of side effects early on in treatment (72). PRM is rarely indicated for management of any type of seizure other than partial and secondarily generalized seizures. In particular, the agent has little or no place in the treatment of generalized epilepsies encountered in childhood, such as absence epilepsy and Lennox–Gastaut syndrome. Although some potential use has been demonstrated in the treatment of neonatal seizures (44), PRM is rarely used for this indication. PRM is contraindicated in any patient with a previous allergic, severe idiosyncratic reaction to PRM or to PB, and patients with hepatic porphyria. If indicated, the choice between PB and PRM may depend on individual factors. After PB has failed, PRM may still be tried. However, selecting PRM before PB may save one therapeutic step, based on

the assumption that PB is unlikely to be effective if maximal tolerated doses of PRM have not controlled seizures.

ADVERSE EFFECTS

Among AEDs, PB and PRM are more likely to cause dose-related neurotoxic reactions, yet serious systemic side effects are rare. These agents invariably produce sedation and drowsiness at high doses in adults, whereas children often experience paradoxical behavioral side effects, mainly hyperactivity, aggressiveness, and insomnia, even at levels in the therapeutic range (<15 mg/L) (87). Sedation, usually present at relatively low levels during the first few days of treatment, subsides over time as tolerance to this effect develops. Sedation or somnolence reappears only at high therapeutic or supratherapeutic levels, usually >30 mg/L. As dose levels increase further, neurologic toxicity appears, characterized by dysarthria, ataxia, incoordination, and nystagmus. Movement disorders, such as dyskinesia, may be induced by PB, but they are rare (100). Like other AEDs, PB can exacerbate seizures or induce de novo seizures (101).

Depression has been attributed to both PB (102,103) and PRM therapy (104). Although its effect may have been overemphasized, double-blind, controlled studies have confirmed that PB affects cognitive abilities even at levels in the therapeutic range. Children treated with PB had lower memory and concentration scores than those receiving placebo, and these differences correlated significantly with plasma levels (105). Double-blind comparisons of PB-treated children versus untreated children (91,106) or valproate-treated children (107) demonstrated subtle but significantly lower intelligence quotient (IQ) scores in the PB groups. In an intention-to-treat analysis comparing children treated with PB or placebo for febrile seizures, the average IQ score was 8.4 points lower with PB (91) and remained 5.2 points lower 6 months after discontinuation of PB. Some differences persisted 3 to 5 years later (92).

Allergic rashes and hypersensitivity reactions are relatively rare with PB and PRM treatment (108), but cross-reactivity with CBZ and PHY has been established (109). Hematologic toxicity is quite rare with PB or with PRM (110,111). Like phenytoin and carbamazepine, PB can exacerbate acute intermittent porphyria (112) and cause osteoporosis, decreased bone mineral density, and increased risk of fracture, presumably through accelerated vitamin D metabolism (113–115). Vitamin K–deficient hemorrhagic disease in newborns of mothers treated with PB (116) can be prevented by administration of vitamin K to the mother before delivery. Connective tissue disorders associated with long-term PB therapy are well known (117) and have recently received renewed attention. These include Dupuytren contractures, plantar fibromatosis, heel and knuckle pads, frozen shoulder, and diffuse joint pain (118). Connective tissue disorders are an unusual side effect in children.

Like every AED, PB has been known to increase the risk for minor and major malformations in the offspring of mothers who were chronically exposed during pregnancy. Assessment of the specific risk for a given agent in clinical studies has been complicated by polytherapy and the underlying risk for malformation due to maternal epilepsy (119). A recent study using data from the North American AED Pregnancy Registry evaluated the relative safety of different AEDs used as monotherapy in pregnant women during the first trimester. PB was reported to be associated with a higher risk of major malformation when compared to lamotrigine (RR 2.9, 95% CI 1.4–5.8). It was also associated with a higher risk of cardiac defects and oral clefts (120). Like valproate and phenytoin, PB may be associated with reduced cognitive outcome in the child (121). Folic acid supplementation taken at 5 to 12 weeks of amenorrhea may decrease the risk of anomalies (122). Evidence that PB increases the

risk for any type of tumor development in humans is lacking (123).

Acute and chronic toxic PRM reactions can be distinguished clearly from one another, but long-term PRM side effects are difficult to separate from those associated with derived PB. Because the ratio of PRM to PB varies, toxic side effects may occur at different PRM concentrations. Reliable evidence that long-term PRM side effects and potential teratogenic effects differ from those with comparable PB therapy is lacking. Ventriculoseptal defects, microcephaly, and poor somatic development (124) have been described in the offspring of women taking PRM, although no specific teratogenic pattern has been attributed to the agent.

The acute initial toxicity clearly differentiates PRM from PB. Even after a low initial dose of PRM, some patients experience transient side effects—usually drowsiness, dizziness, ataxia, nausea, and vomiting (71)—that are so debilitating they may be reluctant to take a second dose. Because this acute toxic reaction occurs before PB or PEMA is detected in the blood, it must be associated with PRM itself. Much larger doses of PRM are later tolerated by the same patients during long-term therapy, arguing for the development of tolerance to PRM probably within hours to days. The ratio of clinical toxicity score to serum PRM levels, determined in a group of patients receiving their first PRM dose (125), decreased significantly as early as 6 hours after the ingestion of drug. PB probably produces a cross-tolerance to this acute PRM toxicity and possibly to the anti-seizure activity, because patients on long-term PB therapy are less likely to experience the same degree of toxicity on first exposure to PRM (125–127).

CLINICAL USE

On the basis of its relative efficacy and toxicity profile, PB is no longer used as a first-line treatment for any seizure type, except for neonatal seizures. PB remains an agent of second or third choice for the treatment of generalized convulsive seizures and partial seizures at any age and is prescribed widely for infants because it is easier to use and is associated with less systemic toxicity than several other AEDs.

In adults, the daily maintenance dose of PB, between 1.5 and 4 mg/kg, achieves steady-state levels within the recommended therapeutic range of 15 to 40 mg/L. Because of its long elimination half-life and slow accumulation, the full maintenance dose can be administered on the first treatment day. Steady-state plasma level is attained only after 2 to 3 weeks. The daily maintenance dose of PB in children varies between 2 and 8 mg/kg; doses >8 mg/kg may be necessary in some infants to achieve high therapeutic levels. The dose is roughly inversely proportional to the child's age: 2 months to 1 year, 4 to 11 mg/kg/day; 1 to 3 years, 3 to 7 mg/kg/day; and 3 to 6 years, 2 to 5 mg/kg/day (128). Given the long half-life of PB, dividing the daily dose of the agent into two or more doses appears unnecessary, even in children (129). Close monitoring of plasma levels and dosage reductions may be necessary in patients with advanced renal disease (130) and cirrhosis (131).

The IV loading dose of PB for the treatment of status epilepticus varies between 10 and 30 mg/kg; 15 to 20 mg/kg is most common. The rate of administration should not exceed 100 mg/min (2 mg/kg/min in children weighing <40 kg). PB penetrates the brain relatively slowly. Although full equilibrium is not reached for as long as 1 hour, therapeutic brain concentrations are reached within 3 minutes (132). The initial loading dose of 15 to 20 mg/kg in newborns is similar to the dose in children and adults and will achieve a plasma level of about 20 mg/L. This level can usually be maintained in newborns with a dose of 3 to 4 mg/kg/day (133). However, loading doses up to 40 mg/kg have been used in some situations (84).

PRM should be used alone or in combination with a noninducing drug, such as gabapentin, lamotrigine, topiramate, tiagabine, zonisamide, levetiracetam, vigabatrin, or a benzodiazepine. An inducing drug will shift the PRM–PB ratio to such an extent that the clinically effective component is solely PB. Similarly, prescribing PRM and PB simultaneously for the same patient is not justified. A low starting dose is more important with PRM than with most other AEDs because of the occurrence of transient, but severe, neurotoxic reactions. A first dose of one-half tablet (125 mg) at bedtime is often well-tolerated, but some patients initially need as little as one-quarter tablet (62.5 mg). The dose can then be increased every 3 days as tolerated, to a final daily maintenance dose of 10 to 20 mg/kg. Maintenance doses are 15 to 25 mg/kg/day in newborns, 10 to 25 mg/kg/day in infants, and 10 to 20 mg/kg/day in children.

A schedule that allows rapid advancement to the full maintenance dose of PRM was devised (134) based on the idea that PB produces cross-tolerance to the effects of PRM. After initial administration of PB, the dose is titrated as rapidly as tolerated to achieve a serum level up to 20 mg/L; abrupt switch to the full maintenance dose of PRM follows. Experimentation revealed that most adult patients tolerate the following regimen: 3 mg/kg of PB orally on day 1 (two doses of 1.5 mg/kg each, 12 hours apart); 3.5 mg/kg on day 2; 4 mg/kg on day 3; and 5 mg/kg on day 4 (Fig. 60.2). On day 5, the patient can receive a full PRM maintenance dose of 12.5 to 20 mg/kg, without significant toxicity. This beneficial effect of PB pretreatment on initial PRM toxicity has been confirmed in a more recent study (135).

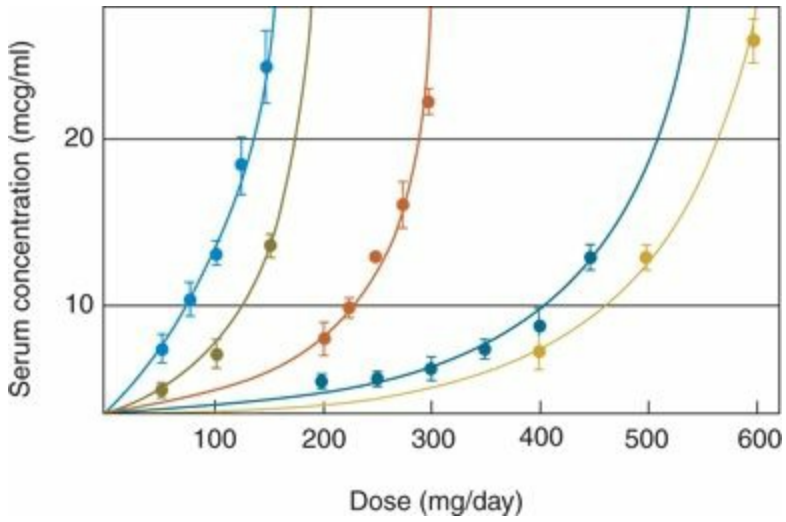

Figure 60.2. Phenobarbital (PB) loading dose over 4 days for rapid introduction of PRM. The PB values represent the average of 11 patients with standard deviation (vertical bars). The solid straight line connects the corresponding predicted values (5, 10, 15, and 20 mg/L). (Courtesy of Bourgeois BFD, unpublished data, 1991.)

PRM monotherapy at a daily dose of 20 mg/kg will achieve PB levels of 30 mg/L (see Table 60.2). Steady-state PB levels will be reached only after 2 to 3 weeks at the same PRM dose. In patients comedicated with carbamazepine or phenytoin, the same PB level will be achieved with an average PRM dose of 10 to 15 mg/kg/day. As with most AEDs, average dosage requirements may be higher in children and lower in the elderly. Because of the relatively short half-life of PRM, usual recommendations call for dividing the daily dose into three doses, although the need to do so has never been documented. If blood levels are used to adjust the PRM dose, then PB rather than PRM levels are preferred, because at the usual concentration ratios, the side effects from a high PB level are more likely to limit further dosage increases. Although a therapeutic range of 3 to 12 mg/L has been suggested for PRM (136), monitoring PRM levels or PEMA is of little help in clinical practice.

After long-term administration, PB and PRM should always be discontinued gradually over several weeks. Barbiturates and benzodiazepines are the AEDs most commonly associated with withdrawal seizures on rapid discontinuation. This phenomenon is due to pharmacodynamic mechanisms that cause a state of rebound hyperexcitability when the amount of the drug decreases in the brain, resulting in a lower seizure threshold, and predisposing the patient to more severe than usual seizures or even to status epilepticus. The phenomenon is unrelated to pharmacokinetics, and the fact that PB has a long elimination half-life does not preclude the need for very gradual withdrawal. Since patients treated with PRM are also chronically exposed to PB, the same caution should be exercised when discontinuing PRM therapy. Unless there is a specific reason to proceed faster, it is appropriate to taper the PB or PRM dose linearly over 3 to 6 months, with reductions each month.

CHAPTER 61 PHENYTOIN AND FOSPHENYTOIN

JEANNINE M. CONWAY, DIEGO A. MORITA, AND TRACY A. GLAUSER

HISTORICAL BACKGROUND

Phenytoin

From the second half of the 19th century until 1938, the antiepileptic effect of commonly used medications (bromides and phenobarbital) was attributed to their sedative effects (1). The landmark work of Merritt and Putnam in 1937 and 1938 demonstrated that the antiepileptic potential of drugs could be tested in animals, the anticonvulsant effect and sedative effects could be separated, and anticonvulsant activity could be achieved without sedation (2,3). Phenytoin (compared with bromides and phenobarbital) showed the greatest anticonvulsant potency with the least hypnotic activity in the cat model they devised, which compared a drug's ability to change the seizure threshold with its sedative effects.

In a subsequent series of articles, Merritt and Putnam (4) demonstrated that phenytoin was effective in humans; the first clinical trial of phenytoin in epilepsy documented freedom from seizures in 50% of 142 patients with refractory disease. This trial showed, for the first time, that a drug effective against seizures in experimental animals could be successfully used in humans. In fact, Merritt and Putnam's electroconvulsive test in animals remains the most reliable experimental indicator of antiepileptic drug (AED) efficacy in tonic–clonic and partial seizures in humans. A follow-up study described effectiveness in complex partial seizures, with or without secondarily generalized tonic–clonic seizures, but not in absence seizures (5). Today, phenytoin remains one of the world's most widely prescribed AEDs and is on the WHO essential medicines list (6).

Fosphenytoin

Because phenytoin is poorly soluble in water, parenteral phenytoin sodium has been formulated as an aqueous vehicle containing propylene glycol, ethanol, and sodium hydroxide, adjusted to a pH of 12. Unfortunately, parenteral phenytoin sodium is associated with cardiovascular complications and phlebitis (7,8). First synthesized in 1973, fosphenytoin was developed as a water-soluble phenytoin prodrug that might reduce the risks of the cardiovascular complications and phlebitis from parenteral phenytoin administration (9).

CHEMISTRY AND MECHANISM OF ACTION

Phenytoin

Phenytoin is commercially available as the free acid and the sodium salt. The molecular weight is 252.26 for the free acid and 274.25 for the sodium salt. A weak organic acid, phenytoin is poorly soluble in water. The apparent dissociation constant (pK_a) ranges from 8.1 to 9.2 and requires an alkaline solution to achieve solubility in high concentrations. As a result, parenteral phenytoin sodium must be formulated as an aqueous vehicle containing 40% propylene glycol and 10% ethanol in water for injection, adjusted to a pH of 12 with sodium hydroxide (9–11).

Phenytoin affects ion conductance, sodium–potassium adenosine triphosphatase activity, various enzyme systems, synaptic transmission, posttetanic potentiation, neurotransmitter release, and cyclic nucleotide metabolism (12). Despite these numerous sites of action, the major anticonvulsant mechanism of action is believed to be the drug's effect on the sodium channel. Phenytoin blocks membrane channels through which sodium moves from the outside to the inside of the neuron during depolarization, suppressing the sustained repetitive firing that results from presynaptic stimulation (12–14).

Fosphenytoin

Fosphenytoin, a phenytoin prodrug, is the disodium phosphate ester of 3-hydroxymethyl-5,5-diphenylhydantoin (molecular weight 406.24) (Fig. 61.1). Following conversion, 1.5 mg of fosphenytoin sodium yields 1 mg of phenytoin sodium. To avoid confusion, fosphenytoin (Cerebyx) is packaged as milligram phenytoin sodium equivalents (mg PE). Thus, 100 mg of parenteral phenytoin sodium (Dilantin) and 100 mg PE of parenteral fosphenytoin sodium (Cerebyx) have equal molar amounts of phenytoin sodium.

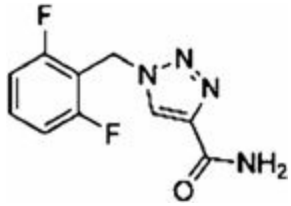

Figure 62.1. Structural formulas of fosphenytoin (**left**) and phenytoin (**right**).

Fosphenytoin's phosphate ester group on the basic phenytoin molecule significantly increases solubility. The water solubility of fosphenytoin at 37°C is 75,000 µg/mL, compared with 20.5 µg/mL for phenytoin (9). Thus, fosphenytoin is freely soluble in aqueous solutions and can be formulated without organic solvents (15). Fosphenytoin is formulated as a ready-mix solution of 50 mg PE/mL in water for injection, USP, and tromethamine, USP (Tris) buffer adjusted to pH 8.6 to 9.0 with either hydrochloric acid, NF, or sodium hydroxide, NF (16). Fosphenytoin itself has no known anticonvulsant activity and derives its utility from its rapid and total conversion to phenytoin (15,16).

ABSORPTION, DISTRIBUTION, METABOLISM, AND EXCRETION

Phenytoin

Absorption

Phenytoin is available in various formulations for both oral and parenteral use (Table 61.1) as phenytoin sodium or phenytoin acid. Both the rate and extent of absorption may differ among the formulations, leading to clinically significant alterations in serum concentrations when switching among products. The chewable tablet and liquid suspension are phenytoin acid and contain 100% phenytoin, whereas all other formulations are phenytoin sodium and only contain 92% phenytoin. Switching between formulations can result in significant changes in pharmacokinetics.

Table 61.1 Formulations of Phenytoin and Fosphenytoin

Formulation	Preparation	Strength	Acid or salt	Amount of drug	Prompt or extended
Dilantin Kapseals	Capsule	30 mg	Sodium salt	27.6 mg	Extended
Dilantin Kapseals	Capsule	100 mg	Sodium salt	92 mg	Extended
Dilantin Infatabs	Chewable tablet	50 mg	Free acid	50 mg	Prompt
Dilantin-125 suspension	Suspension	125 mg/5 mL	Free acid	125 mg/mL	Prompt
Phenytek	Capsule	200 mg	Sodium salt	184 mg	Extended
Phenytek	Capsule	300 mg	Sodium salt	276 mg	Extended
Phenytoin (generic)	Capsule	30 mg	Sodium salt	27.6 mg	Prompt and extended
Phenytoin (generic)[a]	Capsule	100 mg	Sodium salt	92 mg	Prompt and extended
Phenytoin (generic)	Suspension	125 mg/5 mL	Free acid	125 mg/mL	Prompt
Phenytoin (generic)	Injectable solution	50 mg/mL	Sodium salt	46 mg/mL	
Fosphenytoin	Injectable solution	50 mg PE/mL	Disodium salt	46 mg PE/mL	

[a]The prompt-release generic phenytoin 100-mg capsules are not bioequivalent to Dilantin 100-mg Kapseals. The extended-release generic phenytoin 100-mg capsules are considered bioequivalent. The prescriber should be cautious when writing prescriptions.

The rate and extent of absorption of phenytoin from its site of entrance depends on pK_a and lipid solubility, the pH of the medium in which it is dissolved, solubility in the medium, and concentration. These factors are frequently altered by the presence of foods or drugs in the intestinal tract and by the formulations. Little phenytoin is absorbed in the stomach because the drug is insoluble in the acidic pH of gastric juice (about 2.0), even though it is in its nonionized form in the stomach. Absorption occurs primarily in the duodenum, where the higher pH increases the solubility of phenytoin. Absorption from the jejunum and ileum is slower than from the duodenum and is poor from the colon (17,18).

In humans, the rate of absorption is variable and prolonged (19,20) and significantly influenced by the rate of elimination (21). Because dissolution is the rate-limiting process in the absorption of phenytoin, any factor that affects dissolution or solubility will affect absorption. After oral administration of a single dose, peak blood drug levels are generally reached between 4 and 8 hours later (range, 3 to 12 hours) (22,23). In patients ingesting massive amounts of phenytoin, absorption may continue for as long as 60 hours (24). Relative bioavailability increases with age, suggesting an age-dependent effect on drug absorption (25). In newborns and infants up to 3 months old, phenytoin is absorbed slowly and incompletely after both oral and intramuscular administration (26); absorption in older infants and children is similar to that in adults. Stable isotope tracer doses have been used to assess the bioavailability of phenytoin (27,28).

After intramuscular administration, phenytoin is absorbed slowly, as poor water solubility leads to precipitation of drug at the injection site, forming almost a depot repository (20). This prolonged absorption and pain on administration mandate use of the intravenous route if parenteral administration is required.

The reported bioavailability of rectally administered phenytoin sodium is approximately 25% (29).

Absorption of Generic Preparations

Several generic phenytoin preparations have been approved by the Food and Drug Administration and are available in the United States; however, they are not equivalent owing to differences in their rate of absorption. Most of the generic products are not rated as bioequivalent to brand name Dilantin because of their rapid ("prompt") absorption profile. Steady-state concentrations of the prompt formulation have been found to be higher than those of the brand extended-release form (30), lower (31,32), or not different (33). Thus, when stable concentrations are desirable, an extended-release profile is preferred. In 1998, a 100-mg generic extended-release product (manufactured by Mylan Pharmaceuticals) was approved as bioequivalent to Dilantin Kapseals 100 mg.

In contrast, the generic prompt-release formulation is useful when rapid serum concentrations are desired, such as with an oral loading dose. Prompt-release phenytoin administered in three divided doses of 6 mg/kg every 3 hours reaches maximal concentrations almost 4 hours sooner than does the brand name extended-release form given according to the same regimen (34).

Distribution

Protein Binding.

Phenytoin is approximately 90% bound to plasma proteins, primarily albumin, in most healthy, ambulatory patients. Only the unbound (free) portion is pharmacologically active because protein-bound drug cannot cross the blood–brain barrier. Because unbound phenytoin distributes passively between plasma and cerebrospinal fluid, concentrations are the same in both sites (35), and the unbound plasma concentration can be used to estimate the cerebrospinal fluid concentration (18).

The percentage of binding (70% to 95%) depends on albumin concentration and coexisting medications or illnesses. Low serum albumin, renal failure, or concomitant medications that displace phenytoin from protein-binding sites increase the risk for changes in protein binding. Both exogenous (other highly protein-bound medications) and endogenous (increased bilirubin) substances can compete for binding sites and increase unbound phenytoin concentrations. Valproic acid significantly alters phenytoin binding to serum albumin, whereas phenobarbital, ethosuximide, diazepam, carbamazepine, and folic acid do not (36). Binding is decreased in uremia (84.2%), hepatic disease, and acquired immunodeficiency syndrome (18); in renal dysfunction, it is most apparent at creatinine clearances below 25 mL/min (37). In patients with uremia who undergo renal transplantation, binding returns to normal when renal function recovers (38).

Volume of Distribution.

Phenytoin is distributed freely in the body with an average volume of distribution in humans of 0.78 L/kg (18). The volume of distribution after single intravenous doses (9.4 to 21.3 mg/kg) in children declines with age and ranges from 1 to 1.5 L/kg below the age of 5 years and from 0.6 to 0.8 L/kg above the age of 8 years (39). At the pH of plasma, phenytoin exists predominantly in the nonionized form, thus allowing rapid movement across cell membranes by nonionic diffusion. The volume of distribution, which correlates with body weight (40), is larger in morbidly obese patients, who may

require large loading doses to achieve therapeutic concentrations (41,42).

Metabolism

In humans, the major pathway of phenytoin elimination (approximately 80%) is 4′-hydroxylation to form 5-(4′-hydroxyphenyl)-5-phenylhydantoin (4′-HPPH). This reaction is mediated mainly by the cytochrome P450 (CYP) enzyme CYP2C9 and to a lesser extent by CYP2C19 (43,44). Approximately 10% of phenytoin is eliminated to a dihydrodiol, and another 10% is metabolized to 5-(3-hydroxyphenyl)-5-phenylhydantoin (3′,4′-diHPPH) (10,43,45). An arene oxide, which precedes the formation of these compounds, has been implicated in the toxicity and teratogenicity of phenytoin; however, its transient presence in patients with normally functioning arene oxide detoxification systems is unlikely to account for many of the toxic reactions (46,47).

Because phenytoin has nonlinear pharmacokinetics, a narrow therapeutic index, and a concentration-related toxicity profile, small changes in CYP2C9 activity may be clinically significant. Of the more than 50 CYP2C9 alleles identified to date, the most common, designated as CYP2C9*1A, is considered the wild-type allele (48,49). Individuals homozygous for the wild-type allele are called extensive metabolizers. Studies in various populations demonstrated that the CYP2C9*2, CYP2C9*3, CYP2C9*4, and CYP2C9*6 alleles are important in vivo determinants of phenytoin disposition (50–59). Individuals with at least one of these variant alleles are called poor metabolizers and have a reduced ability to metabolize phenytoin. They may require lower-than-average phenytoin doses to decrease the incidence of concentration-dependent adverse effects (54,60).

While two-thirds of Caucasians possess the wild-type allele, one-third are heterozygous for the CYP2C9*2 or CYP2C9*3 allele (61). These two variant alleles are much less prevalent in African Americans and Asians, with more than 95% of these groups expressing the wild-type genotype (61). A study in a Black Beninese population demonstrated that CYP2C9 alleles *5, *6, *8, and *11 were associated with decreased phenytoin metabolism (62). The allele CYP2C9*13 was identified in the Chinese population and found to be associated with reduced plasma clearance of drugs that are substrates for CYP2C9 (63). A clear association between the newer discovered alleles and an altered phenytoin metabolism has not yet been demonstrated. Odani et al. (50) observed a decrease of approximately 30% in the maximal rate of phenytoin elimination in Japanese heterozygous for CYP2C9*3 compared with those homozygous for the wild-type allele. Moreover, the mean phenytoin maintenance dose leading to a therapeutic serum concentration was significantly lower in patients with CYP2C9 allelic variants (199 ± 42.5 mg/day) than in those with the wild-type allele (314 ± 61.2 mg/day; $P < 0.01$) (54). A case report of a heterozygous CYP2C9*3 allele carrier described excessive phenytoin concentrations relative to the doses taken; a toxic level (32.6 μg/mL) was reached despite a modest dose (187.5 mg/day). The patient showed signs of central nervous system intoxication, ataxia, and diplopia (55).

The activity of CYP2C9 alone, however, does not fully explain the large interindividual variability in the clinical pharmacokinetics and reported drug interactions of phenytoin (64). More than 30 CYP2C19 alleles have been described to date (48). CYP2C19*2 to CYP2C19*8 are inactive and are responsible for the poor metabolizer phenotype. The CYP2C19*17 variant has been associated with ultrarapid drug metabolism for two of its substrates, omeprazole and escitalopram, which might imply increased risk of therapeutic failure (65,66).

The majority of all populations studied have the CYP2C19 extensive metabolizer phenotype

involving the wild-type CYP2C19*1 allele. The frequency of CYP2C19 poor metabolizers is much higher in Asians (13% to 23%) than in Caucasians and African Americans (1% to 6%) (67). The CYP2C19*2 and CYP2C19*3 mutations are responsible for most of the CYP2C19 poor metabolizers. CYP2C19*2, the main defective allele, occurs with a frequency of 30% in the Chinese population, approximately 15% in Caucasians, and approximately 17% in African Americans. The CYP2C19*3 variant affects approximately 5% of Chinese, and is almost nonexistent in Caucasians (68). Together, the CYP2C19*2 and CYP2C19*3 alleles can explain all Asian and approximately 80% of Caucasian poor metabolizers (69).

Because the contribution of CYP2C19 to the metabolism of phenytoin increases with an increase in drug concentration, CYP2C19 may be important when CYP2C9 is saturated. The reported differences in K_m values for CYP2C9-catalyzed and CYP2C19-catalyzed phenytoin hydroxylation (5.5 μmol/L vs. 71.4 μmol/L) suggest that CYP2C9 is likely to become saturated at phenytoin therapeutic concentrations of 10 to 20 μg/mL (40 to 80 μmol/L) (70). This mechanism explains the increased risk of toxic reactions with the coadministration of CYP2C19 inhibitors such as ticlopidine or isoniazid. The 1% to 2% of Caucasian poor metabolizers for both CYP2C9 and CYP2C19 are particularly susceptible to phenytoin's adverse effects (71). Dosage adjustments based on the CYP2C9 and CYP2C19 genotypes may decrease the risk of concentration-dependent adverse effects in allelic variant carriers, particularly at the beginning of therapy.

A Japanese epilepsy study (50) noted an approximate decrease of 14% in the maximum metabolic rate in patients with CYP2C19 variants compared with those with the extensive metabolizer phenotype. In another Japanese study (51), the predicted plasma concentrations with a phenytoin dose of 5 mg/kg/day were 18.7, 22.8, and 28.8 μg/mL in CYP2C19 homozygous extensive metabolizers, heterozygous extensive metabolizers, and poor metabolizers, respectively. Although the effect of CYP2C polymorphisms on the pharmacokinetic parameters has been reported, caution is advised when estimating the usefulness of genotyping the CYP2C subfamily for the determination of phenytoin dosage regimens. There are other factors, such as concurrent drug treatment and many environmental factors, that may overwhelm the significance of genotyping in clinical practice (72,73).

Enzyme saturation kinetics lead to phenytoin plasma concentrations increasing nonproportionally with changes in dose (Fig. 61.2) (74). The relationship between dose and concentration can be expressed by the Michaelis–Menten equation:

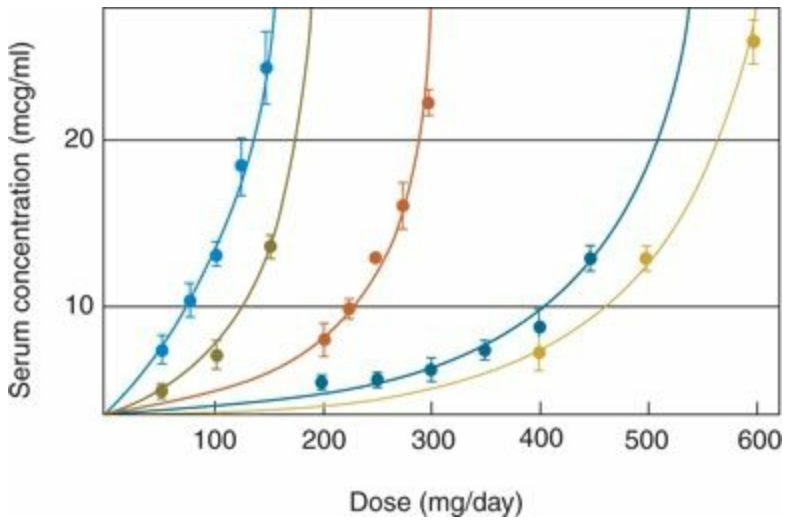

Figure 61.2. Relationship between serum phenytoin concentration and daily dose in five patients. Each point represents the mean (±SD) of three to eight measurements at steady state. The curves were fitted by computer through use of the Michaelis–Menten

equation. (From Richens A, Dunlop A. Serum phenytoin levels in the management of epilepsy. Lancet. 1975;2:247–248.)

$$\text{Dose}(\text{mg}/\text{day}) = \frac{V_{max} C_{ss}}{K_m + C_{ss}}$$

where V_{max} is the maximal rate of drug metabolism, C_{ss} the steady-state serum concentration, and K_m the concentration at which V_{max} is half-maximal. The mean apparent phenytoin K_m in adults 20 to 39 years old is 5.7 µg/mL (range, 1.5 to 20.7 µg/mL); the mean V_{max} is 7.5 mg/kg/day (75). In most patients, phenytoin exhibits nonlinear pharmacokinetics because the usual therapeutic plasma concentrations exceed the usual K_m. Concomitant illnesses (76) or medications, pregnancy (77,78), genetic makeup (79–81), and age can significantly affect V_{max} or K_m (or both). Children have higher V_{max} values, but similar K_m values, compared with adults (82–84); elderly individuals have lower V_{max} values (mean, 6.0 mg/kg/day) (75).

Excretion

Up to 95% of phenytoin is excreted in urine and feces as metabolites, with 5% or less of unchanged phenytoin excreted in urine. Phenytoin is also excreted in breast milk (85). Some investigators have suggested that phenytoin enhances its own elimination through enzyme induction (86).

Fosphenytoin

Absorption and Bioavailability

Fosphenytoin can be administered either intravenously or intramuscularly. The values for the area under the plasma total phenytoin and free phenytoin concentration versus time curves, after either intravenous or intramuscular administration of fosphenytoin, are almost identical to that for intravenous phenytoin sodium, indicating complete bioavailability by either route (9). These findings are based on studies involving single-dose intravenous and intramuscular administration to drug-free volunteers and single-dose intravenous administration to patients with therapeutic plasma phenytoin concentrations (9,87,88).

Because oral absorption of phenytoin can be erratic and unpredictable, switching to intravenous dosing can result in increased concentrations due to all medication being systemically available. Dosage adjustment is not usually necessary when fosphenytoin is used for up to 1 week, although a phenytoin plasma concentration should be checked after longer periods of administration.

Distribution

Protein Binding.

Fosphenytoin is highly bound (95% to 99%) to serum albumin in a nonlinear fashion (9). This protein binding is not affected by prior diazepam administration (89). However, in the presence of fosphenytoin, phenytoin is displaced from binding sites, rapidly increasing unbound phenytoin concentrations as a function of plasma fosphenytoin concentration. This displacement is accentuated by fosphenytoin doses of at least 15 mg PE/kg delivered at rates of 50 to 150 mg PE/min. As plasma

fosphenytoin concentrations decline, phenytoin protein binding returns to normal. There is little displacement of phenytoin after intramuscular administration of fosphenytoin (9).

Volume of Distribution.

Fosphenytoin's volume of distribution is reported to be 0.13 L/kg in patients receiving 1200 mg PE fosphenytoin at 150 mg PE/minute. At lower doses and slower infusion rates, the volume of distribution is lower, 2.6 L, or approximately 0.04 L/kg for a 70-kg human (9,87,90). Fosphenytoin, a very polar molecule, achieves a rapid equilibrium between plasma and associated tissues (90).

Metabolism

After intravenous or intramuscular administration, the phosphate group of fosphenytoin is cleaved by ubiquitous nonspecific phosphatases to produce active phenytoin. The half-life of this conversion is approximately 8 to 18 minutes, is complete in a little more than an hour, and is independent of age, dose, or infusion rate (9,16,91–93). The tissue phosphatases responsible for this conversion are present at all ages; age, plasma phenytoin or fosphenytoin concentrations, and other medications do not alter their activity. The conversion of fosphenytoin to phenytoin is slightly faster in patients with hepatic or renal disease, consistent with decreased binding of fosphenytoin to plasma proteins and increased fraction of unbound fosphenytoin resulting from hypoproteinemia in these diseases (91). In addition, fosphenytoin's phosphate load of 0.0037 mmol phosphate/mg PE fosphenytoin should be considered in patients with severe renal impairment (16).

Excretion

A clinically insignificant amount of fosphenytoin (0% to 4% of a dose) is excreted renally (93).

PLASMA DRUG CONCENTRATIONS

Phenytoin

Most laboratories and textbooks assume a therapeutic range for phenytoin of 10 to 20 μg/mL, which clinical experience and literature have called into question. Seizures have been controlled with concentrations lower than 10 μg/mL (94), although at times, more than 20 μg/mL is needed (95). This variability in seizure control may be due to the underlying disorder, the seizure type, or genetic determinants (95). In one study (96), 51% of patients achieved complete control at concentrations either below or above that range. No significant association was evident between the serum phenytoin concentration and any measures of efficacy or toxicity.

The generally established therapeutic range for phenytoin of 10 to 20 μg/mL includes both bound and unbound drugs. As 10% is normally unbound, the equivalent unbound therapeutic range is 1 to 2 μg/mL. The extent of protein binding varies little with phenytoin plasma concentration. Total phenytoin concentrations that are below the normal range can be associated with unbound phenytoin concentrations in the therapeutic range. For example, if a patient has a subtherapeutic total phenytoin concentration of 5 μg/mL but an unbound fraction of 20%, the equivalent unbound phenytoin concentration is 1 μg/mL, which is in the "therapeutic" range. Thus, patients at high risk for altered protein binding may respond to clinically subtherapeutic total concentrations and may not tolerate

total serum concentrations within the therapeutic range. If such patients experience toxic reactions despite therapeutic concentrations, measurement of unbound concentrations may be warranted. Total phenytoin concentrations may be a misleading test in developing countries, where hypoalbuminemia is highly prevalent (97).

Among the methods that predict total phenytoin concentrations in the face of reduced albumin levels, the best documented is the Sheiner–Tozer method (98,99):

$$C_n = C_o / (0.2 \quad \text{Alb} + 0.1)$$

where C_o is the measured total phenytoin concentration (milligrams/liter), Alb is albumin concentration (grams/deciliter), and C_n is the total phenytoin concentration that would have been observed with normal albumin concentrations.

Fosphenytoin

Measurement of fosphenytoin levels does not provide clinically useful information for patient care but rather has been utilized only in clinical research settings. Fosphenytoin may interfere with the ability of common laboratory immunoanalytic techniques, such as TDx/TDxFLx (fluorescence polarization) and Emit 2000 (enzyme multiplication), to measure phenytoin levels, because of cross-reactivity resulting in an artificially elevated phenytoin concentration value. Waiting until all of the fosphenytoin to phenytoin conversion has occurred (approximately 2 hours after intravenous fosphenytoin administration or 4 hours after intramuscular fosphenytoin administration) before attempting to measure a patient's phenytoin concentrations is recommended (9).

A pharmacokinetic meta-analysis of plasma total and free phenytoin concentration from seven clinical trials involving neurosurgical patients, patients with status epilepticus, patients with stroke, and healthy volunteers demonstrated that fosphenytoin loading doses of 15 to 20 mg PE/kg administered either intravenously or intramuscularly consistently resulted in total phenytoin plasma concentrations of 10 μg/mL or more and free phenytoin concentrations of 1 μg/mL or more. These therapeutic plasma phenytoin concentrations were reached in most subjects within 10 minutes, if rapid intravenous fosphenytoin dosing (≥100 mg PE/min) was used, or within 30 minutes, if slower intravenous (<100 mg PE/min) or intramuscular fosphenytoin dosing was used (100).

DRUG INTERACTIONS

Phenytoin

Phenytoin can affect, and be affected by, a number of medications (Table 61.2) (101). Because new medications are regularly being approved for patient use, it is important to regularly utilize drug interaction databases to identify and design a plan to monitor potential interactions. Although these drug interactions do not preclude concomitant administration, they signal the need for more frequent determination of serum concentrations, increased monitoring for the appearance of side effects, and, if appropriate, changes in dose. Patient-specific factors, such as genetic makeup, previous exposure to other compounds, and susceptibility to the clinical outcomes of the interaction, govern the extent and clinical significance of any drug interaction. In addition, a drug may act as an inhibitor in one patient and an inducer in another (e.g., phenobarbital's effect on phenytoin).

Table 61.2 Bidirectional Interactions Between Phenytoin and Other AEDs

Specific drug	Effect of AED on phenytoin concentration	Mechanism of AED effect	Effect of phenytoin on AED concentration	Mechanism of phenytoin effect
Carbamazepine	↑↓	CYP2C19 induction	↓↓	CYP3A4 induction
Ethosuximide	«		↓↓	CYP3A4 induction
Eslicarbazepine	↑	CYP2C19 inhibition	↓	UDPGT induction
Ezogabine	«		↓	Unknown
Felbamate	↑↑	CYP2C19 inhibition	↓↓	CYP3A4 induction
Fosphenytoin	↑ Free phenytoin	Protein-binding displacement	«	
Gabapentin	«		«	
Lacosamide	«		«	
Lamotrigine	«		↓↓	UDPGT induction
Levetiracetam	«		«	
Oxcarbazepine	↑	CYP2C19 inhibition	↓ MHD	Unknown
Perampanel	«		↓↓	CYP3A4 induction
Phenobarbital	↑↓	CYP2C9 and CYP2C19 induction	↑	Unclear
Pregabalin	«		«	
Rufinamide	↑	Unknown	↓	Unknown
Stiripentol	↑	CYP2C9 and 2C19 inhibition	↓	Unclear
Topiramate	↑	CYP2C19 inhibition	↓↓	Unknown
Tiagabine	«		↓↓	CYP3A4 induction
Valproic acid	↓/« or ↑ Free phenytoin	Protein-binding displacement and CYP2C9 inhibition	↓↓	CYP2C9 and CYP2C19 induction
Vigabatrin	↓	Unknown	«	
Zonisamide	«		↓↓	CYP3A4 induction

↑↓, Variable; ↑, minor increase; ↓, minor decrease; ↑↑, important increase; ↓↓, important decrease; «, no change; MHD, monohydroxy derivative; UDPGT, uridine diphosphate glucuronyltransferase.

Interactions can affect any of the four primary pharmacokinetic phases. A drug that affects absorption most likely will decrease phenytoin serum concentration. For example, administration of phenytoin with a continuous high-calorie, liquid complete-nutrition formula through nasogastric tube feedings causes a decrease in phenytoin serum concentrations from a mean of 9.8 to 2.72 µg/mL at the same dose (102).

Drugs that affect protein binding increase the percentage of unbound phenytoin, usually with no change in the unbound concentration and with a decrease in the total concentration. Valproic acid displaces phenytoin from protein-binding sites. When valproic acid is added to a phenytoin regimen, total phenytoin concentrations decrease, free fraction increases, and free concentrations either stay the same or increase slightly. The following equation may be used to measure unbound phenytoin concentration in a patient receiving this combination (103,104):

$$\text{Free PHT} = \left[0.095 + 0.001(\text{VPA})\right]\text{PHT}$$

where PHT is phenytoin and VPA is valproic acid. Metabolic interactions usually cause either enzyme induction or inhibition. Phenytoin is a significant liver enzyme inducer and is highly likely to cause many drug interactions (105). Addition of an inducer decreases phenytoin concentrations; addition of an inhibitor increases them. The order of addition or deletion is important. An inducer added to another compound may lead to decrease in the serum concentration of the preexisting drug; however, if that same drug is added to the inducer, the interaction would have a less noticeable clinical significance because nothing has changed—the added drug would simply require a higher dose. When an enzyme-inducing drug is removed from a regimen, the concentration of the remaining compound is likely to increase (106).

Fosphenytoin

As described above, in the presence of fosphenytoin, phenytoin is displaced from binding sites, rapidly increasing unbound phenytoin concentrations as a function of plasma fosphenytoin concentration (9).

EFFICACY AND CLINICAL USE

Phenytoin

Phenytoin is effective in the abortive treatment of acute seizures (including acute repetitive seizures and status epilepticus) or as chronic maintenance therapy to prevent seizure recurrence. Phenytoin is considered effective against partial-onset seizures and primary generalized tonic–clonic seizures (107,108); however, there is no convincing evidence that it is effective against absence, clonic, myoclonic, tonic, or atonic seizures. Phenytoin is not recommended for infantile spasms, Lennox–Gastaut syndrome, or primary generalized epilepsy syndromes such as childhood absence or juvenile myoclonic epilepsy.

Acute Seizures (Acute Repetitive Seizures and Status Epilepticus)

Multiple open-label series have indicated that patients with acute repetitive seizures or status epilepticus respond promptly to intravenous administration of phenytoin (109). In 60% to 80% of patients, a response was noted within 20 minutes after the initiation of an infusion (110,111). In one pediatric study (112), loading doses produced a complete or partial effect in 30 of 35 patients. The youngest children had lower concentrations and responded less favorably than did the older children.

For rapid increase in drug concentration, phenytoin doses of 15 to 20 mg/kg are used (113,114). Doses of 18 mg/kg increase phenytoin serum concentrations by approximately 23 μg/mL in adults being treated for acute seizures (115); in children with status epilepticus, similar or higher doses have been administered (112). The intravenous route is used during status epilepticus. In less acute situations, oral administration is appropriate, but the loading dose is divided into three or four doses, given 2 to 3 hours apart to improve bioavailability and rate of absorption (116–118).

When given intravenously to adults, phenytoin should be diluted in normal saline (not in dextrose 5% in water); the infusion should not exceed 50 mg/min and should be injected directly into a large vein through a large-gauge needle or intravenous catheter. The intramuscular route is not recommended owing to the drugs slow and erratic absorption, as well as painful local reactions likely associated with crystallization at the injection site. If, however, no other routes of administration are available, intramuscular doses 50% higher than oral doses may be needed to maintain plasma concentrations (119–121). Adjustments in dosage and monitoring of serum levels may be necessary on switching from one route to another. Therapeutic levels of phenytoin administered rectally have not been maintained in patients with seizures (122).

Partial-Onset and Generalized Tonic–Clonic Seizures

Multiple studies have compared the efficacy and tolerability of phenytoin with those of other AEDs

(including carbamazepine, phenobarbital, primidone, valproic acid, lamotrigine, topiramate, and oxcarbazepine) in the treatment of partial-onset and generalized tonic–clonic seizures.

In the first Veterans Administration Cooperative Study (123), 622 adults were randomly assigned to treatment with phenytoin, carbamazepine, phenobarbital, or primidone and remained on therapy unless unacceptable toxic reactions or lack of efficacy was evident. Carbamazepine and phenytoin were more effective and had greater tolerability over time compared with primidone and phenobarbital in the treatment of complex partial seizures. All four AEDs were equally effective as monotherapy for generalized tonic–clonic seizures. Carbamazepine and phenytoin produced the highest rates of success, as defined by retention in the study (Fig. 61.3), and were recommended as "drugs of first-choice for single-drug therapy of adults with partial or generalized tonic–clonic seizures or with both."

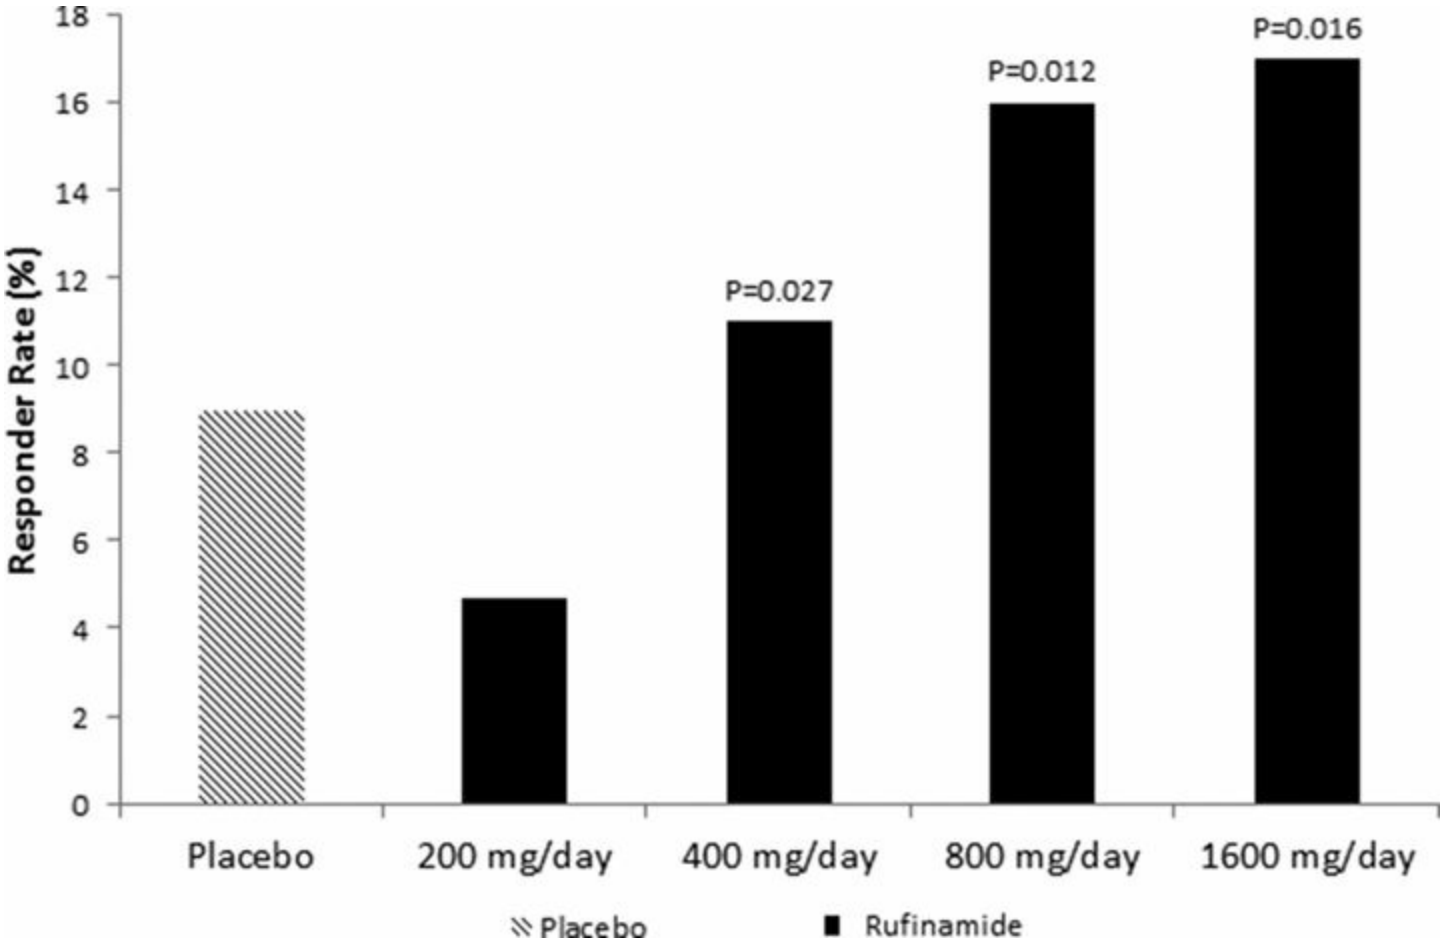

Figure 61.3. Cumulative percentage of patients remaining in the study during 36 months of follow-up. There were 275 patients at 12 months, 164 at 24 months, and 97 at 36 months. (From Mattson RH, Cramer JA, Collins JF, et al. Comparison of carbamazepine, phenobarbital, phenytoin, and primidone in partial and secondarily generalized tonic-clonic seizures. N Engl J Med. 1985;313:145–151.)

In several other comparative trials, phenytoin was as effective as carbamazepine and valproic acid, with similar potential to cause major side effects (108,124–126). No significant differences in efficacy were found among the four drugs at 1, 2, or 3 years of follow-up. The incidence of unacceptable side effects necessitating withdrawal from treatment was 10% (127).

In children, one study compared the efficacy and toxicity of phenytoin, phenobarbital, carbamazepine, and valproate as monotherapy in children with newly diagnosed epilepsy (128). There were no differences in efficacy between the drugs. Nine percent of the children had adverse effects requiring withdrawal. Patients on phenobarbital were more likely to withdraw because of

intolerable side effects, compared to those on the other drugs. There was no significant difference in the rate of withdrawal between the other drugs (128).

A number of studies comparing phenytoin to newer AEDs have been conducted. Two studies compared the efficacy and tolerability of oxcarbazepine and phenytoin monotherapy in patients with recent-onset partial seizures or generalized tonic–clonic seizures (129,130). The first study (129) involved 287 adults and adolescents, aged 15 to 91 years, demonstrated no difference in the proportion of seizure-free patients during the 48 weeks of maintenance between the oxcarbazepine group (59%) and the phenytoin group (58%). The second trial (130), in 193 children and adolescents, aged 5 to 17 years, also showed no difference in the proportion of seizure-free patients during the 48-week maintenance period between the oxcarbazepine group (61%) and the phenytoin group (60%). Lamotrigine and phenytoin monotherapy were compared in a study of patients with newly diagnosed untreated partial-onset seizures or generalized tonic–clonic seizures (131). No between-treatment difference in efficacy was detected on the basis of percentages of patients remaining on each treatment arm, those remaining seizure free during the last 24 and 40 weeks of the study, and times to first seizure after the initial 6 weeks of treatment (dose-titration period). Topiramate and phenytoin monotherapy were compared in a study of patients with new-onset epilepsy or epilepsy relapse (132). The duration of the study was short (28 days), and there was no statistical difference to time to first seizure between medications. The rate of side effects was similar, but the rate of study discontinuation due to side effects was higher in the phenytoin arm.

No monotherapy trials have compared phenytoin with felbamate, gabapentin, tiagabine, zonisamide, or levetiracetam in the treatment of partial-onset or generalized tonic–clonic seizures.

The International League Against Epilepsy elaborated an evidence-based guideline for AED efficacy and effectiveness as initial monotherapy for different epileptic seizures and syndromes (133). The guideline concluded that based on available efficacy and effectiveness evidence alone, phenytoin and carbamazepine were efficacious or effective as initial monotherapy for adults with newly diagnosed or untreated partial-onset seizures (with the highest level of evidence, level A). The findings in children was not that robust, and therefore, based on available efficacy and effectiveness evidence alone, phenytoin, carbamazepine, phenobarbital, topiramate, and valproate were possibly efficacious or effective as initial monotherapy for children with newly diagnosed or untreated partial-onset seizures (level C). Similarly, phenytoin, carbamazepine, phenobarbital, oxcarbazepine, lamotrigine, topiramate, and valproate were found to be possibly efficacious or effective as initial monotherapy for adults with generalized tonic–clonic seizures (level C). In children with generalized tonic–clonic seizures, phenytoin, carbamazepine, phenobarbital, topiramate, and valproate were possibly efficacious or effective (level C).

For phenytoin maintenance therapy, the nonlinear pharmacokinetics and wide interindividual variability in metabolism and absorption necessitate individualized regimens. The typical initial dose of 300 mg/day results in concentrations between 10 and 20 μg/mL in fewer than 30% of patients, and more than 57% will achieve concentrations below 10 μg/mL (99). Doses of 6 to 8 mg/kg will produce concentrations between 10 and 20 μg/mL in approximately 45% of otherwise healthy patients, less than 10 μg/mL in 35%, and more than 20 μg/mL in 20% (99). Thereafter, adjustments should be based on clinical response, increasing dosage for lack of seizure control or lowering dosage for concentration-dependent toxic reactions.

Privitera (134) proposed the following guidelines based on initial plasma concentration: increase dosage by 100 mg/day for an initial plasma concentration of less than 7 μg/mL; increase dosage by 50 mg/day for concentrations from 7 to 12 μg/mL; increase dosage by 30 mg/day for concentrations

greater than 12 μg/mL. This formula was tested in 129 dosage increases of 50 or 100 mg in 77 patients. All 53 increases that were within the guidelines produced plasma concentrations less than 25 μg/mL, whereas 36% of the increases that exceeded the guidelines produced plasma concentrations greater than 25 μg/mL (134).

Accurate predictions of phenytoin plasma concentrations cannot be accomplished with the Michaelis–Menten equation unless patient-specific values for V_{max} and K_m are obtainable, which is rarely possible in clinical situations. When at least some clinical data are available, numerous methods can assist in estimating an individual patient's dose (135–138) to achieve predetermined serum concentrations (139,140). The nonlinear pharmacokinetics of phenytoin not only leads to nonproportional changes in serum concentration with changes in dose but also increase the apparent elimination half-life with higher concentrations. Thus, patients with "high" concentrations exhibit smaller peak–trough variability and require a longer time to achieve steady state. For most patients whose concentrations are within the therapeutic range, the peak–trough remains relatively unaffected, and steady state is reached in approximately 1 to 2 weeks. Thus, any changes in dose will require 1 to 2 weeks to achieve maximum effect. Patients receiving prompt-release phenytoin products and those with low serum concentrations and rapid phenytoin metabolism (e.g., children or patients with relatively high dose requirements) are at high risk for large peak–trough variability and often need multiple daily doses to prevent wide fluctuations in clinical response.

Children require higher milligrams per kilogram daily doses, whereas the elderly should be started on 2 to 3 mg/kg/day and doses increased carefully. Elderly patients have demonstrated fluctuating concentrations despite no change in dose or other medications. An adjustment of dose may not be necessary if the patient is tolerating their current dose and is not having seizures (141). Concomitant illnesses can alter phenytoin pharmacokinetics and, consequently, dosage requirements. Critically ill patients may require plasmapheresis, continuous ambulatory peritoneal dialysis, or hemofiltration. Plasmapheresis does not appear to remove a significant amount of phenytoin (142); continuous ambulatory peritoneal dialysis may not either (143). In contrast, continuous hemofiltration at a high ultrafiltration rate may remove significant amounts of phenytoin in patients with renal failure with significant protein-binding changes (144). Pregnancy may necessitate an increase in phenytoin dose, especially during the third trimester (77,78).

Neonatal Seizures

Phenytoin and phenobarbital monotherapy were compared in a randomized trial of 59 neonates with seizures confirmed by electroencephalography (145). Seizures were controlled in 43% of the phenobarbital group and in 45% of the phenytoin group. Monotherapy or subsequent duotherapy controlled seizures in 59% of the neonates. The authors concluded that both drugs were "equally but incompletely effective as anticonvulsants in neonates."

In a sample of practice in major U.S. pediatric hospitals, 6099 infants with neonatal seizures were identified over 62 months. As expected, the most common treatment for neonatal seizures was phenobarbital, which was given to 76% of all infants in the study (range, 56% to 89%, $P < 0.001$) and 97% of the infants who received a nonbenzodiazepine AED (range, 92% to 100%). Overall, 80% of the neonates treated with phenobarbital did not receive any other nonbenzodiazepine AEDs. Phenytoin was the second most commonly used nonbenzodiazepine AED, but it was usually used in combination with another AED. It was used to treat 16% of all neonates diagnosed with neonatal seizures (range, 8% to 36%, $P < 0.001$) and 20% of the neonates who received a nonbenzodiazepine

AED (range, 12% to 42%, P < 0.001). Phenytoin was used without phenobarbital in only 11% of these neonates and was used without any other nonbenzodiazepine AEDs in only 83 infants overall (8%). Phenytoin was started at least 1 day after phenobarbital 46% of the time, started on the same day as phenobarbital 32% of the time, and started at least 1 day before phenobarbital 11% of the time (146).

Prophylaxis

Phenytoin is often used following neurosurgical procedures and cerebrovascular accidents. A randomized, double-blind trial compared the efficacy, tolerability, and impact on quality of life and cognitive functioning of anticonvulsant prophylaxis with phenytoin versus valproate in 100 patients following craniotomy (147). Fourteen patients (seven in each group) experienced postoperative seizures. No major between-treatment differences emerged in efficacy, tolerability, impact on quality of life, or cognitive functioning (147). A double-blind comparison of phenytoin or carbamazepine with no treatment after supratentorial craniotomy noted no significant differences but a higher incidence of side effects in the treated group (148). Thus, prophylactic anticonvulsants cannot be recommended routinely after this type of procedure.

The efficacy of phenytoin in the prevention of posttraumatic seizures was studied in a randomized, double-blind trial of 404 patients with serious head trauma (149). Patients received a phenytoin-loading dose within 24 hours of injury; free phenytoin serum levels were maintained in a range from 0.75 to 1.5 μg/mL. From the time of drug loading to day 7, significantly fewer seizures occurred in the phenytoin group than in the placebo group (3.6% vs. 14.2%, P < 0.001). No benefit was seen in the phenytoin group after day 8, however, leading to the conclusion that phenytoin had an early suppressive effect, but not a true prophylactic effect, on seizures, and that it reduced the incidence of seizures only during the first week after injury. In a secondary analysis of this study (150), no significant difference in mortality was found between patients assigned to phenytoin and those assigned to placebo. In a randomized, double-blind, placebo-controlled trial in children with moderate to severe blunt head injury, phenytoin did not prevent posttraumatic seizures within 48 hours of the trauma (151).

Fosphenytoin

Fosphenytoin itself has no known anticonvulsant activity; it derives its utility from its rapid and total conversion to phenytoin (15,16).

The two main situations in which fosphenytoin are used are during status epilepticus, or as a temporary substitute for oral phenytoin in a nonemergency hospital situation, such as in a patient undergoing a neurosurgical procedure. Fosphenytoin can be diluted in a variety of vehicles, such as dextrose 5% and 10%, lactated Ringer solution, and mannitol 20% (152).

Fosphenytoin (rather than phenytoin) has become part of the standard-of-care treatment protocols for convulsive status epilepticus in adults and children in many U.S. hospitals. It is preferred to phenytoin because of better tolerability at the infusion site, lack of cardiovascular complications, and overall ease of administration (153). For the treatment of convulsive status epilepticus, a fosphenytoin "loading dose" of 15 to 20 mg PE/kg can be given intravenously, with an infusion rate of at least 100 mg PE/min and up to 150 mg PE/min. The dose should be adjusted in patients who have hepatic impairment or hypoalbuminemia. For the prophylaxis of seizures in neurosurgical patients, a single nonemergency loading dose is given either intravenously or intramuscularly. The dose is

usually 10 to 20 mg PE/kg, with an intravenous infusion rate of up to 150 mg PE/min.

Fosphenytoin (given either intravenously or intramuscularly) is useful as a temporary substitute for oral phenytoin when the patient is unable to take oral medications. In this situation, the fosphenytoin dose and frequency would be the same as the patient's oral phenytoin dose and frequency.

Although now generic, fosphenytoin is more expensive than phenytoin (154). A number of studies and editorials have reported pharmacoeconomic comparisons between fosphenytoin and intravenous phenytoin (117,154–156). The overall cost of patient care with intravenous fosphenytoin was less than with intravenous phenytoin in an emergency department setting (156). Substitution of intravenous fosphenytoin for intravenous phenytoin was associated with reduced "adverse events at a reasonable increase in total hospital costs" in a second study (155). An editorial suggested that pharmacoeconomic decisions should be based on outcome cost, not acquisition costs (154). Overall, in terms of cost-effectiveness, studies in the past decade showed that despite higher acquisition cost, use of intravenous fosphenytoin appeared to be at least equivalent to, if not better than, intravenous phenytoin. However, two studies (117,157) have challenged this impression. The administration of intravenous fosphenytoin to adults in an emergency department did not significantly decrease the incidence of drug-related adverse effects or decrease the length of stay in the emergency department compared with the use of intravenous phenytoin. This result suggests that intravenous fosphenytoin may not be more cost-effective than is intravenous phenytoin.

ADVERSE EFFECTS

Phenytoin

Concentration-Dependent Effects

The most common concentration-dependent phenytoin side effects are related to the central nervous system and consist of nystagmus, ataxia, incoordination (158,159), diplopia (vestibulo-oculo-cerebellar syndrome), and drowsiness. Some patients may experience prominent side effects at concentrations in the lower end of the therapeutic range, while others may be free of complaints despite elevated drug concentrations. These effects are reversible with appropriate adjustments in dose. Although small decreases may completely alleviate complaints, significant dose alterations may dramatically decrease serum concentrations, leading to a recurrence of seizures. Nausea, vomiting, and epigastric pain are often improved by dividing the dose or taking it with meals (or both).

Symptoms noted at serum phenytoin concentrations higher than 30 μg/mL include dysarthria, far-lateral nystagmus, movement disorders (usually choreoathetosis and orofacial dyskinesia), exacerbation of seizures, external ophthalmoplegia, or encephalopathy (including lethargy, delirium, "psychosis," stupor, and coma) (93,159–164).

Reports of the effect of phenytoin on cognitive function vary, depending on the type of patients, presence or absence of concomitant AEDs, measurement instruments, and comparative drugs. In general, however, effects appear modest when serum concentrations are kept within standard therapeutic ranges, and polypharmacy is avoided (165,166). Unfortunately, patients taking phenytoin may suffer from cognitive side effects even when these guidelines are followed (167).

Idiosyncratic Reactions

Phenytoin's idiosyncratic reactions are proposed to result from the formation of a reactive metabolite (an arene oxide) that either directly (owing to deficiencies in detoxification resulting from inadequate epoxide hydrolase activity) or indirectly (through an immune response or free radical–mediated injury) causes cell, tissue, or organ injury and, at times, death (168).

The most common idiosyncratic reaction is rash, which may occur in up to 8.5% of patients, particularly children and adolescents (169–171). The in vivo and in vitro cross-reactivity between phenytoin, phenobarbital, and carbamazepine is as high as 70% to 80% (172). A recent study on cross-sensitivity of skin rashes among commonly used AEDs (n = 1875) found evidence of specific cross-sensitivity between carbamazepine and phenytoin (173). The phenytoin rash rate in patients who also had a rash to carbamazepine (n = 59) was 57.6%, which was significantly higher compared to the phenytoin rash rate in patients with rashes to any other AEDs (38.8%; $P < 0.0016$) (173). The rate of cross-sensitivity between phenytoin and other AEDs (phenobarbital, lamotrigine, oxcarbazepine, and zonisamide) was not as high as with carbamazepine (173). A more severe dermatologic idiosyncratic reaction is the "hypersensitivity syndrome" (172). In a series of 38 affected patients, the most common manifestations were rash, fever, lymphadenopathy, eosinophilia, abnormal liver function test results, blood dyscrasias, serum sickness, renal failure, and polymyositis. Symptoms usually occur within the first 3 months of therapy (174).

Other reported idiosyncratic reactions include Stevens–Johnson syndrome (SJS), toxic epidermal necrolysis, aplastic anemia, hepatitis, pseudolymphoma, and a lupus-like reaction (159). Recent data suggest a possible association between HLA-B*1052 and phenytoin-induced SJS (175,176). The human leukocyte antigen allele, HLA-B*1502, occurs almost exclusively in patients with ancestry across broad areas of Asia, including Han Chinese, Filipinos, Malaysians, South Asian Indians, and Thais. A study from Hong Kong reported that HLA-B*1052 was associated with SJS in a patient who started phenytoin within 8 weeks prior to the development of the cutaneous reaction, and in whom no other causes for the reaction were found (175). More recently, a Thai study reported a significant association between HLA-B*1052 and SJS in four patients on phenytoin ($P = 0.005$). One of the four patients, who developed phenytoin-induced SJS, was tolerant to carbamazepine. The authors concluded that while HLA-B*1052 may be necessary, it is not sufficient to cause SJS from phenytoin in the Thai population (176).

Adverse Effects with Long-Term Therapy

Long-term administration of phenytoin has been associated with gingival hyperplasia (177,178), hirsutism, acne, and rash. The exact incidence of gingival hyperplasia attributable to phenytoin is not known (178); reports range from 13% of patients attending general medical practices (179) to about 40% of patients taking phenytoin long term in a community-based cross-sectional study in Ferrara, Northern Italy (180). In the latter report, younger age and poorer oral hygiene seemed to predispose to the severest level of gingival involvement (180). Hyperplasia regresses after discontinuation of phenytoin (181,182).

Cerebellar atrophy has been reported after long-term (183,184) and acute use (185) of high doses, although whether the true etiologic agent was phenytoin or the seizures is unclear (186,187); single photon emission computed tomography scans may be a means for early detection (186).

Among other effects of long-term phenytoin therapy are alterations in laboratory values, including reduction in bone mineral density (188), low folate levels (93), macrocytosis (93), and decreases in

levels of carnitine (189), low-density lipoprotein cholesterol, and apolipoprotein B (190). Levels of prolactin (191) and apolipoprotein A and A1 (190) increase, as does high-density lipoprotein cholesterol, although at doses of 100 mg/day, this lipid fraction was unchanged (192). Phenytoin may decrease levels of free testosterone and enhance its conversion to estradiol (193).

Changes in thyroid hormones have been reported (194). The thyroxine (T_4) and free T_4 index, total T_4 and triiodothyronine (T_3), free T_4, and free T_3 all decrease. Increases in serum levels of thyroid-stimulating hormone (195,196) may involve protein-binding displacement and induction of cellular metabolism (197). Phenytoin therapy may suppress immunoglobulin (Ig) production, leading to decreases in IgG (198,199) and IgA (198,200). Panhypoglobulinemia was reported in one patient infected with the human immunodeficiency virus (201). It is unclear whether these changes are a direct result of phenytoin or epilepsy (198) or if they occur with any drug with arene oxide intermediates (198,202).

Teratogenicity

"Fetal hydantoin syndrome" was described in 1975 and consisted of growth retardation, microcephaly, mental retardation, and numerous "minor" congenital anomalies (171,203). However, "fetal anticonvulsant syndrome" has replaced this term because the malformations are seen in children of mothers taking a wide variety of AEDs. Although there is agreement that anticonvulsant polypharmacy and folic acid deficiency increase the risk of malformation (204), the absolute and relative teratogenicity of phenytoin is not completely known. One study showed an increased risk for cleft palate in the offspring with phenytoin use during pregnancy (205).

Four recent studies described the pregnancy outcomes of women with epilepsy taking AEDs; one focused on fetal malformations (206) and the other three on the neurocognitive outcome for AED exposure in utero (207–209). The North American AED Pregnancy Registry reported the risk of major malformations in infants exposed to phenytoin monotherapy in the first trimester based on 416 infants as compared to 1562 infants exposed to lamotrigine. The risk was not significantly increased (206). The Neurodevelopmental Effect of Antiepileptic Drugs (NEAD) study is an ongoing prospective observational study that recently reported on the cognitive outcome at ages 3 (207), 4.5 (208), and 6 years (209), in 311 children born to mothers who were taking a single AED during pregnancy. The age 6 study included 225 children, and on average, the IQ of children exposed to phenytoin (n = 40) was 11 points better than the ones exposed to valproate (95% CI, 5 to 16; P = 0.0004) but not different than the ones exposed to carbamazepine or lamotrigine (P = 0.99) (209).

Intravenous Administration

Administration of parenteral phenytoin solution is associated with local reactions, including pain and burning at the infusion site, phlebitis, and vessel cording (7,11,210). Extravasation can lead to phlebitis, chemical cellulitis, or frank necrosis (8). A unique effect of unknown etiology, purple glove syndrome (211,212), begins with discoloration and progresses to a petechial rash; severe cases may require surgical intervention. In one report (213), 9 of 152 patients (5.9%) receiving intravenous phenytoin developed purple glove syndrome.

Intravenously administered phenytoin can also lead to cardiovascular complications, such as hypotension, atrial and ventricular conduction depression, and ventricular fibrillation (7). The major risk factors for these complications include preexisting disease, advanced age, and rapid infusion

(7,210). In patients without cardiovascular disease, phenytoin can be administered at 40 to 50 mg/min (214). Rates should not exceed 25 mg/min in patients with arteriosclerotic cardiovascular disease (215).

Fosphenytoin

Concentration-Dependent Effects

Intravenous fosphenytoin infusion has a favorable side effect profile (11,216,217). The local reactions associated with administration of parenteral phenytoin solution (infusion site pain, phlebitis, and vessel cording) occur significantly less often with fosphenytoin (11). Pain at the site of fosphenytoin infusion is rare, but 48.9% of patients reported pruritus or tingling (without rash) in the perianal region, elsewhere on the trunk, or on the back of the head (217). Pruritus or tingling appears soon after an infusion starts, abates rapidly when the infusion stops, and can be reduced or abolished by slowing the infusion. Decreases in systolic and diastolic blood pressure have been observed, but the changes were judged to be clinically insignificant and did not require cessation of the infusion (218). Cardiac arrhythmias have not been noted (218). Dizziness, somnolence, and ataxia were observed with a frequency similar to that after phenytoin infusion (218).

Adverse effects have been even less notable after intramuscular fosphenytoin injection (219–221). Mild local irritation occurred in only 5% of 60 patients who received intramuscular loading doses, even though the volume of injected solution was usually 15 to 20 mL (mean, 17.8 mg/PE/kg or 1359.8 mg PE total) (220).

Idiosyncratic Reactions, Long-Term Adverse Reactions, Teratogenicity

No idiosyncratic reactions are associated specifically with fosphenytoin. As fosphenytoin is used only on a short-term basis, data about long-term adverse reactions are lacking. There are also no data on possible teratogenic effects with fosphenytoin.

CHAPTER 62 RUFINAMIDE

GREGORY L. KRAUSS AND RAMA K. MAGANTI

INTRODUCTION

Rufinamide was identified as a potential antiepilepsy drug (AED) by Ciba-Geigy in Europe and was initially developed by Novartis Pharmaceuticals, but had modest effects in treating medically resistant partial-onset seizures in adults and children. Eisai Pharmaceuticals subsequently obtained development rights and in 2008 obtained regulatory approval in Europe and the United States for using rufinamide to treat seizures in patients with Lennox–Gastaut syndrome. The drug is marketed in the United States with FDA approval as an orphan drug "Banzel" and in Europe as "Inovelon." Rufinamide has an orphan drug indication for treating tonic–atonic seizures in Lennox–Gastaut syndrome and has been used to treat other epileptic encephalopathies.

CHEMISTRY

Rufinamide (1-[2,6-difluorobenzyl]-1H-1,2,3-triazole-4-carboxamide) is a triazole ($C_2H_3N_3$) ring structure, which is structurally dissimilar to other AEDs (lamotrigine has a "triazine" two-ring structure) (Fig. 62.1).

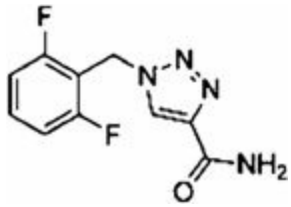

Figure 62.1. Rufinamide. MW 238.2, ($C_{10}H_8F_2N_4O$).

Rufinamide is nearly insoluble in water and slightly soluble in methanol and ethanol. This would make it difficult to prepare an intravenous formulation. Solubility in water and gastric fluid is approximately 40 to 70 mg/L at 37°C. Dissolution is the rate-limiting step for absorption. Rufinamide forms a white crystalline powder and is compacted into scored film tabs of 100-, 200-, and 400-mg tablets.

MECHANISMS OF ACTION

Rufinamide modulates voltage-dependent neuronal sodium channels; however, it also inhibits seizures triggered by γ-aminobutyric acid (GABA) antagonists, and its anticonvulsant mechanisms in humans are unknown. The drug interacts with sodium channels in cultured rodent cortical neurons, prolongs inactivation of voltage-dependent sodium channels in spinal cord neurons, and acts to reduce repetitive firing of sodium-channel dependent neurons (1). The drug does not interact,

however, with several subtypes of rodent and human voltage-gated sodium channels: rat $Na_v1.2a$, rat $Na_v1.8$, and human $Na_v1.5$ (2). Interactions with sodium channel isoforms, such as human $Na_v1.2$, involved in familial epilepsy syndromes have not been evaluated.

Rufinamide's effects in prolonging inactivation of voltage-dependent sodium channels are consistent with its potent inhibition of maximal electroshock–triggered seizures in rodents (oral ED50 = 4 to 24 mg/kg) (3). Rufinamide's inhibition of maximal electroshock seizures (MES) was additive with other AEDs, but it did not potentiate or reduce the effects of other AEDs (4). Rufinamide also prevents clonic seizures induced by injected (s.c. and i.p.) pentylenetetrazole (PTZ) in mice, but did not prevent seizures caused by oral PTZ treatment. Rufinamide caused behavioral toxicity on the rotarod test only at extremely high doses; consequently, rufinamide's protective indexes for MES and PTZ tests are much higher than traditional AEDs (e.g., phenytoin in MES model, valproic acid in PTZ model) (3).

Rufinamide inhibits seizures induced by the GABA-A antagonists bicuculline and picrotoxin, with less effect on strychnine-induced seizures. Rufinamide does not inhibit seizures in the WAG/Rij rat, however, which is a genetic model of absence epilepsy with GABA-A receptor abnormalities (5). Rufinamide also does not interact directly with GABA receptors or modulators. This suggests rufinamide's influences on cortical inhibition are indirect, possibly mediated by modulation of voltage-dependent sodium channels in cortical interneurons.

Rufinamide has mixed effects on chronic seizure models: it delayed the development of electrically kindled afterdischarges in the cat, but not in the rat. It markedly reduced recurring motor seizures induced by aluminum hydroxide placed on monkey cortex (6). Overall, these studies suggest that rufinamide modulation of voltage-dependent sodium channels may indirectly influence seizures via effects on cortical inhibition. However, associations between these mechanisms and effects on seizures associated with Lennox–Gastaut syndrome are unknown.

ABSORPTION, METABOLISM, AND DRUG INTERACTIONS

The pharmacologic profile for rufinamide is summarized in Table 62.1.

Table 62.1 Pharmacokinetic Properties of Rufinamide

Half-life	Mean 9.5 h (range 8–12 h)
T_{max}	Fed 6 h; fasted 8 h
Bioavailability	Fed 70%, fasted 49%
Protein binding	34%
Mean C_{max}	3.03 μg/mL (400 mg dose in healthy adult male volunteers)
V_d	Range: 50–80 L

Rufinamide is well absorbed orally in the fed state (≥85% absorption in healthy volunteers) with a slow rate of absorption; absorption decreases slightly at high doses (7). The relative extent of absorption of rufinamide was lower at a dose of 1600 mg/day compared to 200 to 800 mg/day in a large pharmacokinetic study (8). Bioavailability of single doses of rufinamide is increased by food; however, food effects were not seen with chronic dosing (9). Patients received rufinamide only with

food in clinical trials, and it is approved to be dosed with food. Peak rufinamide concentrations (T_{max}) occur approximately 6 hours after dosing when taken with food and approximately 8 hours when dosed while fasting (10). Rufinamide has relatively low (34%) protein binding—mostly to albumin—and is distributed in the bloodstream equally between erythrocytes and plasma (7). Rufinamide's apparent volume of distribution (V_d) is approximately 50 L at a 3200 mg/day dose and increases slightly with very high doses and high body surface area (11).

Rufinamide is eliminated via hydrolysis into an inactive carboxylic acid metabolite (CGP 47292), which is renally excreted. Less than 2% of rufinamide is recovered in the urine (4). A small fraction of metabolite is glucuronidated and subsequently excreted. Rufinamide is hydrolyzed by a carboxylesterase, which is concentrated in the liver, but is present in brain and other tissues (7). Rufinamide does not induce carboxylesterase and its metabolism is not dependent on cytochromes; thus, major drug–drug interactions are unlikely (7). With the exception of a valproic acid interaction in children, the overall pharmacokinetics for rufinamide are similar in children and in adults, including the elderly, with clearance proportionate to dose and body surface area (12). However, in one study in children, apparent clearance of rufinamide was higher in younger children than older children even when concomitant valproic acid was taken into account. Similar to that of other studies, concomitant enzyme inducing medications increased clearance in all age groups, particularly so in younger children (13). Moreover, human carboxylesterase 1, which is mainly involved in metabolism of rufinamide, has been shown to be inhibited by valproate or its metabolite valproyl-CoA in vitro, and thus, patients on concomitant valproate may need lower doses of rufinamide (14).

While no studies formally examined the relationship between serum concentrations and clinical response/efficacy of rufinamide, in one pediatric study of patients with epileptic encephalopathies, rufinamide plasma concentrations were extremely variable and no correlation between serum concentration and clinical response could be demonstrated (15). One study reported that plasma concentrations above 15 mg/mL are "useful" although the study found no validated therapeutic range (16).

In clinical studies, rufinamide had only small effects on concentrations of several other AEDs (17): Phenytoin clearance was decreased slightly, with plasma levels increasing 7% to 21%; carbamazepine, lamotrigine and phenobarbital concentrations decreased 7% to 13%; and topiramate and valproate concentrations were unchanged. Patients taking valproic acid, especially children, had increases in rufinamide concentrations (18). Valproic acid caused average increase in rufinamide concentrations of 40% in children and 11% in adults (12). Small children (<30 kg) with very high valproic acid concentrations (e.g., 100 mg/L) had increases in rufinamide concentrations of up to 70%; however, this varied widely across patients (18). Rufinamide doses were not adjusted in clinical trials for patients receiving valproic acid; however, reduced dose reductions of 50% to 60% have been recommended for small children (<30 kg) taking valproic acid (14). European regulators have requested an additional pediatric monitoring study to evaluate this interaction further. Adolescents and adults receiving valproic acid had much smaller increases in rufinamide concentrations compared to children: ≤26% increases in adolescents and <16% increases in adults (18). Other AEDs were associated with variable small-to-moderate decreases in rufinamide concentrations: carbamazepine (19% to 26%), phenobarbital (25% to 46%), phenytoin (25% to 46%), and primidone (25% to 46%). Lamotrigine and topiramate did not alter rufinamide concentrations (6). One pediatric study did not show any significant effect of rufinamide on the kinetics of concomitant AEDs (13). Among adolescents and adults however, one study showed that only valproic acid had any significant effect on rufinamide clearance (decrease) with no other

concomitant medication showing any effect (19).

Rufinamide had a modest interaction with oral contraceptives: Repeated administration of 1600 mg/day of rufinamide decreased ethinyl estradiol concentrations by 22% and norethindrone by 14%. It is unclear whether higher doses of rufinamide might produce greater hormonal reductions and contraceptive failure (19). Triazolam clearance increased slightly with rufinamide treatment (4). Increased clearance is most likely caused by modest induction of CYP3A4 and is not believed to be clinically relevant (20).

Due to extensive metabolism, rufinamide elimination is not influenced by renal dysfunction, and no specific dosage changes are required for patients with renal impairments (11). No marked difference in rufinamide concentrations was found in patients experiencing severe renal impairment as compared to healthy individuals after a single 400-mg dose (18). During dialysis, area under the curve (AUC) was decreased by approximately 30%. Simulations over 1 week, however, estimate three 3-hour dialysis sessions would decrease total rufinamide exposure (AUC) by approximately 12%. This suggests that no specific dose adjustment of rufinamide is likely to be required for patients with renal failure undergoing hemodialysis (18).

CLINICAL STUDIES

Lennox–Gastaut Syndrome

Rufinamide is approved with an orphan drug indication for adjunctive treatment of Lennox–Gastaut syndrome in the United States and Europe. Patients with Lennox–Gastaut syndrome typically have multiple seizure types along with encephalopathies. Their most characteristic (and serious) seizure types are tonic and tonic–atonic "drop attacks," which cause sudden falls and injuries. Patients also have varying patterns of atypical absence, myoclonic, atonic, tonic–clonic, and complex motor seizures. Most patients have slow spike-and-wave discharges and generalized slowing on EEG. Effects of rufinamide in treating seizures in patients with Lennox–Gastaut syndrome were evaluated in a randomized, parallel-design, placebo-controlled study of children and adults >4 years (N = 138) (21). Seizures associated with falls (predominantly tonic and tonic–atonic seizures) and total seizures were assessed. Patients were treated with rufinamide 45 mg/kg, up to a maximum of 3200 mg/day, divided twice a day. Patients receiving rufinamide had a 42.5% median reduction in tonic–atonic seizures compared to a 1.4% increase in seizures for patients receiving placebo treatment (Fig. 62.2A). The patients' total seizure frequency was reduced 32.7% during rufinamide treatment compared to a median of 11.7% for placebo treatment. Seizure responder rates (proportions of patients with >50% seizure reduction) were also significantly higher for patients treated with rufinamide (42.5%) compared to placebo (16.7%) (Fig. 62.2B).

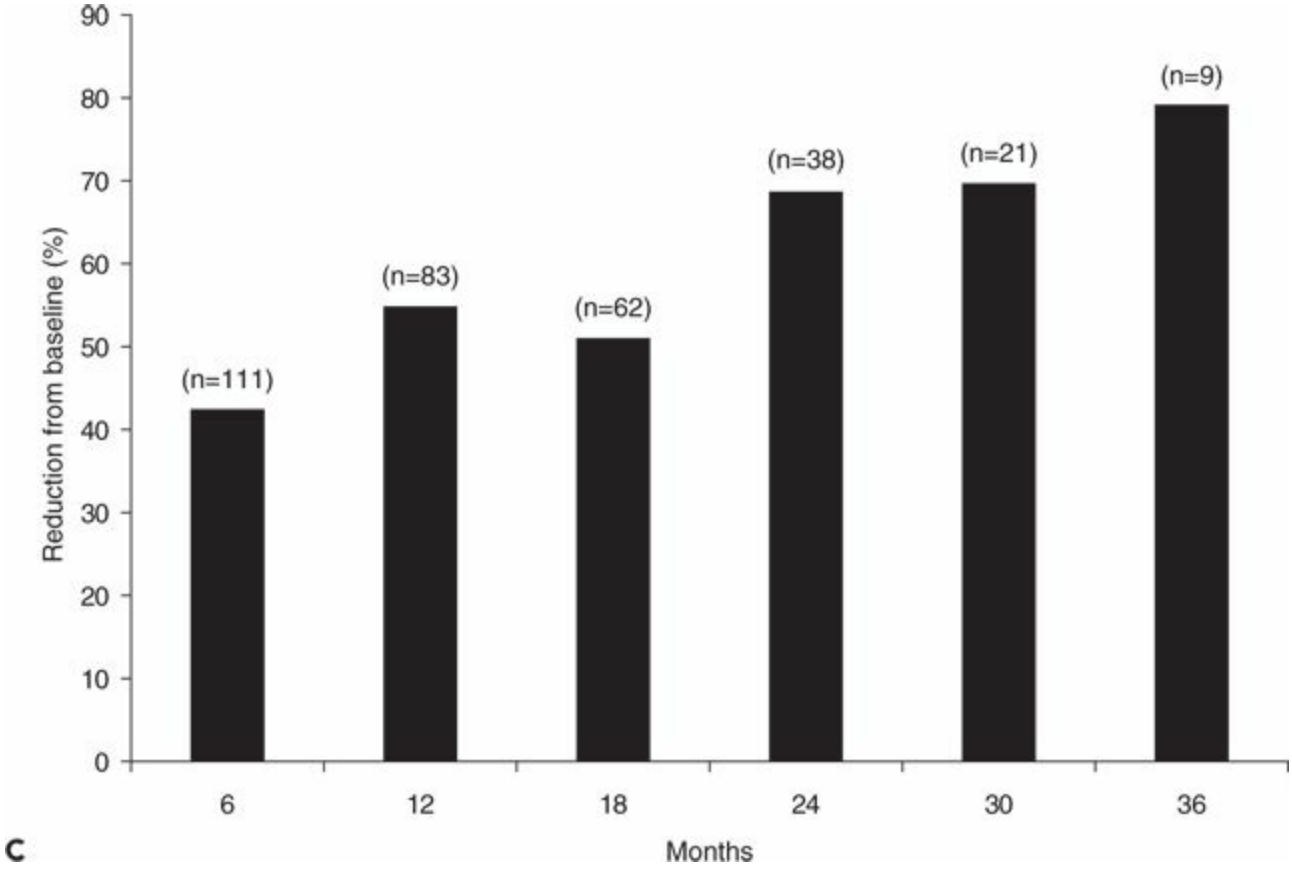

Figure 62.2. A: Median percentage reduction in total seizure frequency and tonic–atonic seizure frequency. **B:**Percentage of patients (responders) who experienced at least 50% reduction in tonic–atonic seizure frequency. **C:**Efficacy of adjunctive rufinamide therapy during long-term extension study treatment of patients with Lennox–Gastaut syndrome. (C, Data from Glauser T, Kluger G, Sachdeo R, et al. Open-label extension study of the efficacy and safety of rufinamide adjunctive therapy in patients with Lennox-Gastaut syndrome. Epilepsia. 2005;46(suppl 6):406.)

Efficacy was sustained during open-label extension treatment, with decreases in seizure frequency of 43% to 79% during 6 to 36 months of treatment; patients converting from placebo to rufinamide also had substantial reductions in seizures (Fig. 62.2C) (22). Responder rates for patients, during their most recent 6 months of therapy, were 45.1% for total seizures and 47.9% for tonic–atonic seizures. A total of 9.4% of patients were free of tonic–atonic seizures during their last 6 months of open-label treatment (23).

Most patients with Lennox–Gastaut syndrome tolerated rufinamide well, especially considering that treatment was combined with one to three concomitant AEDs (21) and titrated very rapidly. The most common adverse events (≥10%) seen in rufinamide-treated patients as compared to those receiving placebo were as follows: somnolence (24.3% vs. 12.5%), vomiting (21.6% vs. 6.3%), pyrexia (13.5% vs. 17.2%), and diarrhea (5.4% vs. 10.9%), respectively. Vomiting and somnolence were the only adverse events occurring at an incidence of 5% greater than placebo treatment. Of the 124 patients entering open-label extension treatment (median dose 1800 mg/day), 12 subsequently discontinued treatment due to adverse events (18). The most commonly reported adverse events during the uncontrolled extension treatment phase were vomiting (30.6%), pyrexia (25.8%), upper respiratory tract infection (21.8%), and somnolence (21.0%). Some of these symptoms appeared to be due to childhood viral illnesses rather than due to rufinamide treatment.

Rufinamide's effectiveness for treating seizures in Lennox–Gastaut syndrome was demonstrated in a single placebo-controlled study, but has generally been confirmed by the long-term extension treatment results and by several open treatment series: 41% of patients were >50% responders in a long-term open-label extension study (24). A multicenter prospective open treatment Italian series

reported 51% of children and adults with Lennox–Gastaut syndrome had ≥50% responses to rufinamide; 9.3% were seizure free over a mean follow-up of 12 months of treatment (25). During 12 weeks of maintenance treatment with rufinamide 20 to 40 mg/kg/day in a Korean study, 36% of patients were >50% responders and responders included patients with drop seizures, myoclonic seizures, and "epileptic spasms" (26). Similarly, in a single center Korean study of children and young adults, 35% of patients at 6 months were >50% responders (27).

Small retrospective series have reported some patients with other epileptic encephalopathies may respond to rufinamide treatment (28,29). In 38 patients (ages 17 months to 23 years) with "epileptic spasms," 53% of patients were >50% responders in one series (30). Other small retrospective series reported benefit in some children with Doose syndrome (myoclonic–astatic epilepsy), malignant migrating partial epilepsy of infancy, and epilepsy with myoclonic absences, with only a small proportion with Dravet syndrome responding to treatment (31).

In a small observational study from Europe, 8 patients with Doose syndrome were treated with rufinamide for 6 to 18 months: 6 out of 8 patients had a >75% reduction in their major seizure type (myoclonic–astatic seizures) immediately after initiation of adjunctive rufinamide; however, this efficacy was not sustained during long-term therapy (32). Another series noted greater rufinamide responses in patients with Lennox–Gastaut syndrome and epileptic spasms (with up to 40% of patients being 50% responders) compared to patients with Dravet syndrome and myoclonic seizures (29).

Partial-Onset Seizure Trials

Rufinamide consistently reduced the frequency of partial-onset seizures in adults in three large randomized, placebo-controlled, multicenter trials. Effect sizes were modest, though, and the drug was not submitted for regulatory approval for this indication. In a large (N = 357) placebo-controlled randomized trial of adults and adolescents (≥16 years) with difficult-to-control partial-onset seizures, rufinamide 3200 mg/day reduced median seizure frequency by 23.2% compared to a 9.8% decrease with placebo treatment (19). In another placebo-controlled randomized trial, rufinamide 3200 mg/day reduced median seizure frequency by 20.4% compared to a 1.6% increase during placebo treatment. Patients not receiving carbamazepine during rufinamide treatment in this study had a slightly higher median seizure reduction of 29% (33). A third large (N = 647) study in adults and adolescent (ages 15 to 65 years) with partial-onset seizures explored treatment with four doses of rufinamide 200, 400, 800, or 1600 mg/day (divided twice a day) and placebo. Patients had a significant linear trend in dose response across the four rufinamide doses (P = 0.003): 50% responder rates ranged from 9% with placebo to 4.7% with rufinamide 200 mg/day, 16% for 400 mg/day (P = 0.027), 12% for 800 mg/day dose (P = 0.012), and 14% with a 1600 mg/day dose (P = 0.016) (Fig. 62.3) (34).

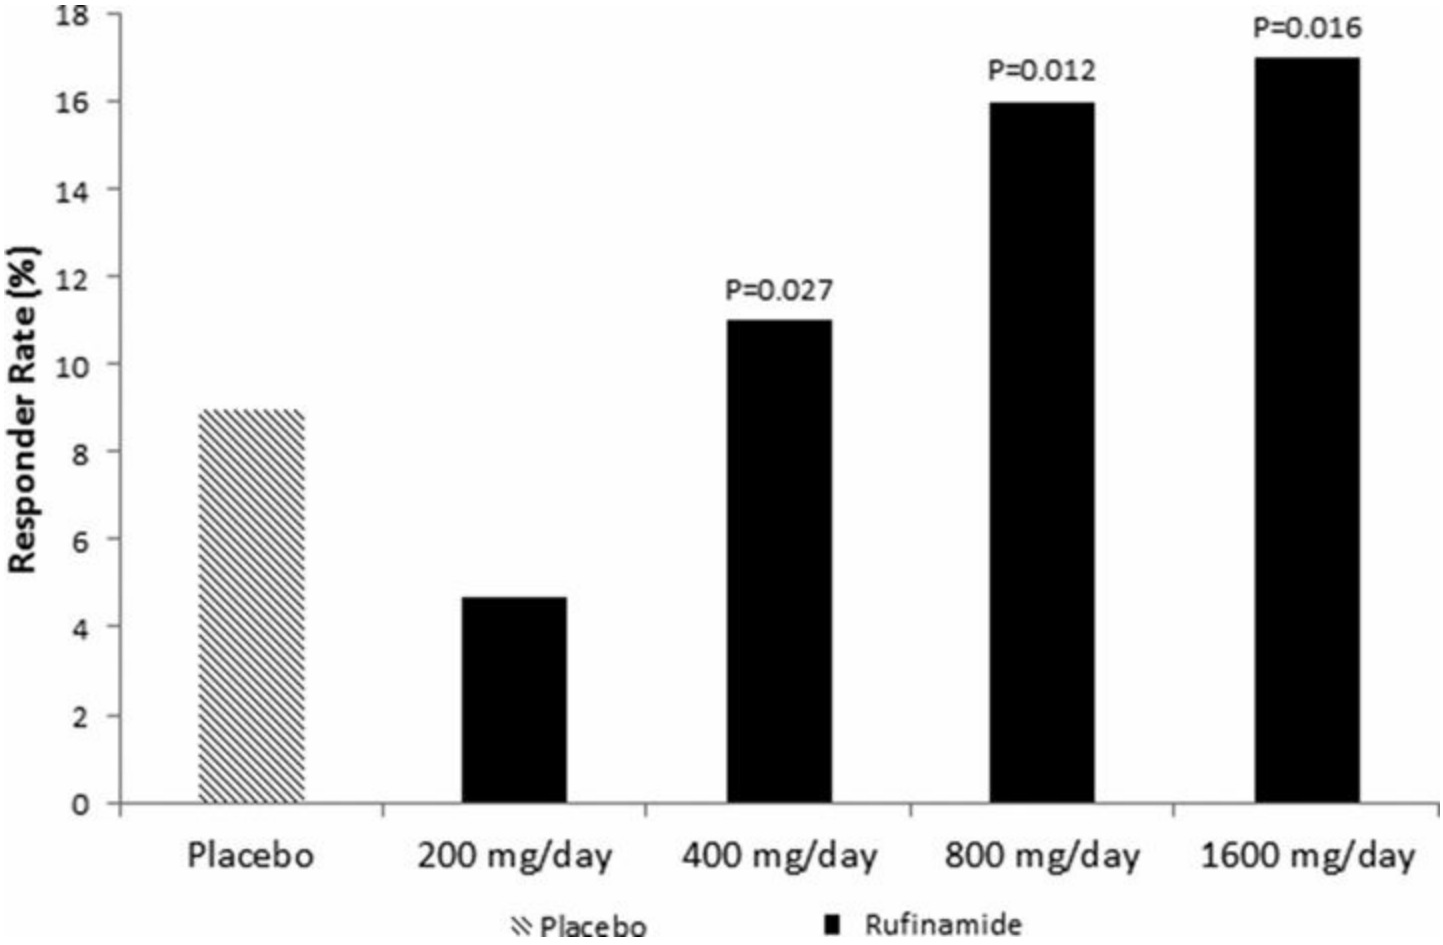

Figure 62.3. Greater than or equal to 50% responder rates for four doses of adjunctive rufinamide therapy compared to placebo treatment among adults and adolescents with partial-onset seizures. (Data from Elger CE, Stefan H, Mann A, et al. A 24-week multicenter, randomized, double-blind, parallel-group, dose-ranging study of rufinamide in adults and adolescents with inadequately controlled partial seizures. Epilepsy Res. 2010;88(2–3):255–263.)

Monotherapy Treatment for Partial Onset

Two clinical trials did not demonstrate the efficacy of rufinamide monotherapy treatment in adult and adolescent patients (>12 years of age) with medically resistant partial-onset seizures. One study (35) included patients (N = 104) with uncontrolled partial seizures completing an evaluation for epilepsy surgery. Patients were randomized to rufinamide 3200 mg (divided twice a day) or placebo with efficacy determined by time required for patients to reach an end point of four seizures. Although rufinamide treatment significantly increased patients' time to having one, two, or three seizures compared to placebo ($P < 0.04$), their times to reaching the primary end point of a fourth seizure was only slightly longer for patients treated with rufinamide ($P = 0.051$). The median times for patients to have second and third seizures, however, were more than twice as long for patients randomized to rufinamide monotherapy than for placebo-treated patients.

An additional outpatient high-versus-low-dose monotherapy study compared seizure recurrence in patients receiving rufinamide 3200 mg/day versus 300 mg/day (36). Efficacy end points were defined as proportions of patients reaching several exit criteria of recurring seizures. The number of patients meeting the exit criterion was not significantly different for the high-dose treatment (66.7%) and low-dose (72.5%) groups ($P = 0.44$). The median time to reach the exit criterion slightly favored high-dose rufinamide therapy (56 days) versus low-dose therapy (32 days) ($P = 0.097$).

Partial-Onset Pediatric Trials

A randomized, double-blind, placebo-controlled, adjunctive trial enrolled 269 pediatric patients between the ages of 4 to 15 years of age (37). Seizure frequencies for children treated with rufinamide (45 mg/kg/day) decreased by an average of only 7% compared to a 12.8% reduction with placebo treatment (P = 0.62). A number of children with very high seizure frequencies appeared to influence the assessment of seizure frequencies in this study. Children treated with rufinamide had slightly higher responder rates (>50% reduction in seizures) (27.2%) compared to those treated with placebo (18.3%), though this difference was not significant (P = 0.082).

Open treatment series have reported possible responses in some children treated with rufinamide. In an Italian observational study, children and adolescents (age range from 3 to 21 years old) received rufinamide 1000 to 3200 mg a day: 5.7% of patients became seizure free and 37.4% had >50% seizure reduction after 6 months of treatment with stable responses in patients continuing treatment for 12 months (38). In a recent open-label pediatric study of patients with refractory cryptogenic or symptomatic focal seizures, adjunctive rufinamide at doses of 1000 to 3200 mg a day (based on body weight), 30.9% of patients were ≥50% responders, while none became seizure free. Compared to other seizure types, frontal lobe seizures and secondarily generalized tonic–clonic seizures were most reduced with rufinamide. Patients taking one rather than multiple concomitant AEDs responded best to rufinamide treatment (39).

Generalized Epilepsy

The safety and efficacy of treating adult and adolescent patients (N = 153) with inadequately controlled, primary, generalized tonic–clonic seizures was evaluated in a multicenter, double-blind, placebo-controlled study using a relatively low 800 mg/day dose of rufinamide (40). Patients receiving rufinamide had only a modest, nonsignificant reduction in median frequency of generalized tonic–clonic seizures (36.4%) compared to placebo (25.6%) (P = 0.63); responses to higher doses have not been explored.

SAFETY AND TOLERABILITY

Rufinamide safety and tolerability were assessed in 11 double-blind, randomized, placebo-controlled studies; long-term safety was evaluated in 14 controlled and open-label extension studies. These included all patients receiving ≥1 dose of rufinamide. Overall, 98.2% of all patients with epilepsy received at least one concomitant AED, the most common medications being carbamazepine (52.9%), valproate (31.6%), phenytoin (22.9%), and clonazepam (19.7%).

Short-Term Therapy

Safety and tolerability were evaluated in patients receiving rufinamide treatment (N = 1317, with a mean age of 31.7 years) in controlled studies compared to those receiving placebo (N = 635, with a mean age of 28.6 years). The mean dose of rufinamide was 1373 mg/day with a median daily dose of 1000 mg/day. The most commonly reported adverse events associated with rufinamide treatment (compared to placebo) were headache, dizziness, fatigue, somnolence, and nausea (19,33,34) (Table 62.2). Other significant adverse events included rash (children 4%, adults <2%), AED hypersensitivity syndrome (three children), cognitive symptoms (mostly somnolence), psychiatric

symptoms, status epilepticus, and convulsions. The percentage of rufinamide-treated patients experiencing serious adverse events was slightly greater than for placebo-treated patients, especially at higher doses.

Table 62.2 Most Common Adverse Events Reported by Patients in Adjunctive Trials for Partial-Onset Epilepsy

	Rufinamide-treated patients	Placebo-treated patients
Short-term therapy (N = 1875)		
Headache	22.9%	18.9%
Dizziness	15.5%	9.4%
Fatigue	13.6%	9.0%
Somnolence	11.8%	9.1%
Nausea	11.4%	7.6%
Serious AEs	6.3%	3.9%
Long-term therapy (N = 1978)		
Headache	29.5%	
Dizziness	22.5%	
Fatigue	17.7%	
Serious AEs	13.2%	

Long-Term Therapy

Safety and tolerability during long-term rufinamide therapy were evaluated in 1978 patients (mean age of 31.3 years) in controlled and open studies lasting from <1 months to >4 years of exposure (41). The mean daily dose of rufinamide was 1700 mg/day with a median daily dose of 1600 mg/day. The most frequently reported adverse events were headache, dizziness, and fatigue. The majority of common adverse events appeared during the first 2 weeks of therapy, with few patients developing new adverse events during chronic therapy. Although most symptoms were mild to moderate in severity, at least one severe adverse event occurred in 20.8% of patients: 261 patients reported serious adverse events during treatment, most commonly convulsions, status epilepticus, and pneumonia. Additional single cases with hypersensitivity reactions (SJS and DRESS) and weight loss have been reported recently (42–44).

In extensive cardiac testing, rufinamide shortened QT intervals in ECG up to 20 ms in a large proportion (46%) of patients treated with recommended doses (2400 to 3200 mg/day) (11). Treatment, however, did not shorten QT intervals to a clinically significant range of <300 ms, which is associated with ventricular arrhythmias. There were no increased risks for sudden cardiac death or other cardiac abnormalities identified in clinical trials.

Pregnancy risks for women treated with rufinamide are unknown. Only 13 women (out of >2000 patients treated) in clinical trials had pregnancies: 6 had healthy babies, 3 had planned terminations, 1 had a spontaneous abortion, and 3 did not have pregnancy outcomes determined. A pregnancy registry has been established in Europe to monitor risks for pregnancy with rufinamide treatment; a U.S. AED registry monitors outcomes for patients treated with all AEDs. Due to a lack of outcome data, women of childbearing age receiving rufinamide are recommended to avoid pregnancies with careful contraceptive use. Patients becoming pregnant will require individual assessments of their risk–benefits for continuing rufinamide therapy.

Adverse Events Causing Discontinuation of Treatment

A larger proportion of patients discontinued rufinamide due to adverse events (N = 100; 8.1%) during double-blind studies than those receiving placebo (N = 27; 4.3%). The most common symptoms associated with patients discontinuing treatment were dizziness, fatigue, headache, nausea, and diplopia. The percentage of patients discontinuing treatment due to serious adverse events was also slightly increased for patients treated with rufinamide (6.3%) compared to placebo (3.9%)—"convulsions" were most commonly reported. During long-term extension treatment, 259 (13.1%) patients discontinued treatment due to adverse events; the most common symptoms were fatigue, headache, dizziness, and nausea. Emesis and drowsiness were most common adverse events among all pediatric studies.

CLINICAL USE

Rufinamide is approved in the United States and Europe with an orphan drug indication for adjunctive treatment of seizures in children (>4 years) and adults with Lennox–Gastaut syndrome. An extremely rapid 1-week titration schedule was used to initiate rufinamide treatment in the Lennox–Gastaut trial. This rapid schedule was approved for clinical use: in children, an initial rufinamide dose of approximately 10 mg/kg/day (divided twice a day), followed by an increase of 10 mg/kg every 2 days to a target dose of 45 mg/kg (or a maximum of 3200 mg/day), divided twice a day. These doses can be achieved using scored 200 and 400 mg tablets; an additional 100 mg tablet is available in Europe. The approved schedule for adults is similar: an initial dose of 400 to 800 mg/day (divided twice a day) followed by a 400 to 800 mg/day increase every 2 days to a maximum dose of 3200 mg/day, divided twice a day. Experience in regular clinical use, however, suggests that more gradual 2- to 3-week titration schedule may be better tolerated than rapid 1-week titration. Small children (<30 kg) adding rufinamide to valproic acid treatment may begin treatment at one-half these doses; this is particularly important when rufinamide is added to high doses of valproic acid in small children.

Therapeutic ranges for rufinamide blood concentrations are not established. Although, rufinamide blood concentrations are dose dependent, central nervous system (CNS)-related side effects and efficacy have not correlated well with blood concentrations during adjunctive treatment. Patients in the Lennox–Gastaut trial (target range of 45 mg/kg/day; maximum 3200 mg/day) had plasma concentration ranging from 5 to 48 mg/L. Infants treated with rufinamide (median dose 30 mg/kg/day) had higher mean steady-state concentrations (39 ± 24 mg/L) than children in the Lennox–Gastaut trial; however, side effects and efficacy also did not correlate well with plasma concentrations (45).

SUMMARY

Rufinamide is a unique AED, which prolongs inactivation of voltage-dependent sodium channels in neurons and has a very high protective index in animal seizure models, but also blocks seizures triggered by GABA-A receptor antagonists. Rufinamide was generally well tolerated in clinical trials with CNS-related side effects most common (headache, dizziness, fatigue, etc.). The drug was effective in a well-controlled clinical trial of Lennox–Gastaut syndrome and continues to be evaluated as adjunctive treatment of other forms of symptomatic epilepsy.

CHAPTER 63 TOPIRAMATE

WILLIAM E. ROSENFELD

HISTORICAL BACKGROUND

Topiramate (TPM) is a highly oxygenated sulfamate-substituted monosaccharide that is structurally distinct from other anticonvulsant medications. Available in the United States as Topamax (Ortho-McNeil Pharmaceutical), or as a generic formulation, it is a broad-spectrum agent that has been extensively studied in double-blind, randomized, controlled trials in adults and children. It was initially approved for use as adjunctive therapy in adults with partial-onset seizures. Subsequently, TPM was approved as adjunctive therapy in children and adults with partial-onset seizures, primary generalized tonic–clonic seizures, and multiple seizure types associated with Lennox–Gastaut syndrome from 2 years of age and older.

TPM is also approved in the United States for monotherapy in adults and children 2 years of age and older with partial- onset or primary generalized tonic–clonic seizures. TPM is indicated for adults for the prophylaxis of migraine headaches as well. The drug was originally discovered in a screening protocol using the standard maximal electroshock seizure (MES) test. Anticonvulsant effects were similar to phenytoin and carbamazepine (1). Most of the known benefits and side effects were noted for this medication from the first couple of 1000 patients (except narrow-angle glaucoma that is a much rarer phenomena). Efficacy was seen early (in blinded studies, family and friends often noted so much improvement they were often referring other friends). Side effects were also noted early due to not yet knowing the most effective dosages without side effects. Too high and too rapid titration often occurred, and the most common side effects noted were word-finding and mathematical difficulties, paresthesias, weight loss, and kidney stones. A 1.5% incidence of kidney stones was seen early and remained the same even despite millions of patients being on such (not necessarily dose or titration related).

CHEMISTRY

TPM (2,3:4,5-di-O-isopropylidene-β-D-fructopyranose sulfamate; Fig. 63.1) is a white crystalline powder that is freely soluble in acetone, chloroform, dimethyl sulfoxide, and ethanol. TPM is supplied as 25-, 50-, 100-, and 200-mg tablets and as 15- and 25-mg sprinkle capsules that can be opened and sprinkled onto soft food for children and for patients who may have difficulty swallowing tablets.

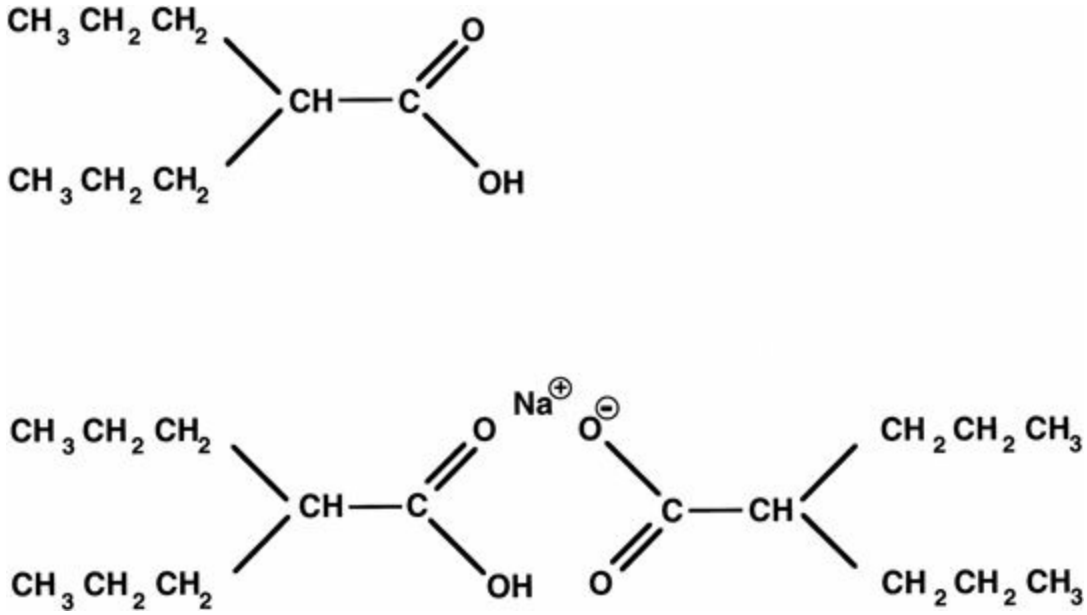

Figure 63.1. Topiramate (2,3:4,5-di-O-isopropylidene-β-D- fructopyranose sulfamate).

MECHANISMS OF ACTION

TPM has a unique combination of activities at various receptor sites and ion channels, which may account for its broad-spectrum profile in epilepsy and other neurologic disorders. It blocks the kainate/AMPA (α-amino-3-hydroxy-5-methylisoxazole-4-propionic acid) subtype of the glutamate receptor (2–5), with no direct effect on NMDA (N-methyl- D-aspartate) receptor activity; blocks voltage-activated sodium channels to limit sustained repetitive firing (6–10); enhances α-aminobutyric acid (GABA)–mediated chloride flux at $GABA_A$ receptors (11,12); reduces the amplitude of high-voltage–activated calcium currents (13,14); and activates potassium conductance (15,16). It has been hypothesized that effects of TPM on voltage-activated sodium channels, high-voltage–activated calcium channels, $GABA_A$ receptors, and AMPA/kainate receptors reflect a common modulator involving protein phosphorylation (17). TPM is also a weak inhibitor of carbonic anhydrase isoenzymes (CA II and CA IV), which may modulate pH-dependent activation of voltage- and receptor-gated ion channels (18); its inhibitory effect is less than acetazolamide.

ANIMAL MODELS

The anticonvulsant properties of TPM have been demonstrated in several animal models of epilepsy. TPM exhibited potent and long-lasting anticonvulsant activity when evaluated using the MES test in rodents with a median effective dose of 47.6 mg/kg in the mouse and 15.8 mg/kg in the rat (19). TPM inhibited chronic motor seizures and absence-like seizures when administered intraperitoneally (17). TPM blocked sound-induced clonic and tonic–clonic seizures (20). TPM effectively inhibited tonic, clonic, and wild running seizures in a postischemia model of epilepsy in rats, and its potency was similar to that of phenytoin for all three seizure types (21). TPM also produced a dose-related inhibition of amygdala-kindled seizures in rats (22). Experimental studies have shown that TPM reduced seizure-induced hippocampal neuronal injury (23) and prevented spontaneous seizures following status epilepticus (24). In an experimental model of neonatal hypoxia/ischemia, TPM suppressed acute seizures and reduced subsequent susceptibility to neuronal injury and seizures

induced by a second insult (kainate) (25).

PHARMACOKINETICS

Renal elimination, low protein binding, and a long half-life make TPM relatively easy to manage from a pharmacokinetic perspective (Table 63.1) (26,27).

Table 63.1 Pharmacokinetic Characteristics of TPM

Characteristic	Value
Elimination half-life (h)	19–23
Peak plasma concentration (mg/L)	1.7 (100-mg single dose) 7.7 (400-mg single dose) 28.7 (1200-mg single dose)
Time to maximum concentration (h)	1.8–4.3
Fraction of systemically available drug excreted unchanged into the urine (%)	70–97
Apparent oral clearance (mL/min)	22–36
Apparent volume of distribution (L/kg)	0.6–0.8

Absorption

TPM is rapidly absorbed with peak plasma concentrations occurring in 1 to 4 hours with TPM doses of 100 to 400 mg. Absorption is nearly complete with <80% of a 100-mg dose recovered in urine. Coadministration with food slightly delays absorption but does not decrease bioavailability (28). TPM exhibits linear kinetics; plasma concentrations increase in proportion to dose increases (29).

Distribution and Protein Binding

The apparent volume of distribution for TPM is 38.5 to 58 L (0.6 to 0.8 L/kg, weight normalized), consistent with distribution to total body water. Binding to plasma proteins is minimal (13% to 17%) and is not considered to be a major factor in dosing and drug interactions (29).

Metabolism and Excretion

In the absence of hepatic enzyme induction, approximately 20% of a TPM dose is metabolized. When TPM is coadministered with enzyme-inducing antiepileptic drugs (AEDs), up to 50% of the TPM dose may be metabolized. Hepatic metabolism appears to involve hydroxylation, hydrolysis, and glucuronidation; none of the metabolites constitutes >5% of an administered dose, and they are quickly cleared (29).

Elimination of TPM is primarily via renal excretion, with 50% to 80% being eliminated in the urine unchanged. The half-life of TPM in adults is 20 to 30 hours in the absence of enzyme induction, allowing steady-state plasma concentrations to be reached in 4 to 8 days. In the presence of enzyme induction, the TPM half-life in adults is 12 to 15 hours (29). In children 4 to 17 years of age, clearance is approximately 50% higher than in adults (30). Steady-state concentrations for the same mg/kg dose were correspondingly lower in children than in adults. Consistent with the higher clearance, the calculated half-life of TPM in children is approximately 15 hours without enzyme

induction and 7.5 hours with enzyme induction. In young children (younger than 4 years old), clearance rates were the same or slightly higher than in older children (31). In elderly patients (65 to 85 years of age), clearance decreases only to the extent that renal function itself is reduced by age; age alone does not alter clearance in adults (32).

TPM clearance is reduced by 40% to 50% in patients with moderate (creatinine clearance 30 to 69 mL/min) or severe (creatinine clearance, <30 mL/min) renal impairment compared to subjects with normal renal function (creatinine clearance, >70 mL/min) (29). One-half of the usual TPM dose is recommended in patients with moderate or severe renal impairment. TPM plasma concentrations fell by an average of 50.1% during hemodialysis. The mean hemodialysis plasma clearance of TPM has been reported to be approximately nine times higher than that found in subjects not receiving hemodialysis (33). Modest decreases in TPM clearance have been reported when comparing age- and sex-matched healthy controls to individuals with moderate to severe hepatic impairment; mean clearance was decreased to 26% (31.8 vs. 23.5 mL/minute) and half-life increased to 36% (25 vs. 34 hours), with parallel increases in plasma concentrations (29).

THERAPEUTIC DRUG MONITORING

Drug monitoring is of relatively little importance in initial titration of TPM. It is most important for compliance and also if utilizing higher-dose therapy. Steady-state plasma concentrations of TPM are generally linear, with dose- proportional increases in plasma concentration (29). Mean plasma concentrations achieved during maintenance in randomized, controlled trials of TPM monotherapy were as follows: 50 mg/day, 1.6 and 1.9 μg/mL; 97 mg/day, 3.8 μg/mL; 189 mg/day, 6.4 μg/mL; 313 mg/day, 11.7 μg/mL; and 367 mg/day, 12.4 μg/mL (34). Studies of TPM as monotherapy have provided the opportunity to examine the relationship between TPM plasma levels and clinical response. In a study comparing 50 and 500 mg/day TPM as monotherapy, plasma concentrations >9.91 μg/mL were associated with better seizure control compared with plasma concentrations of 1.77 to 9.91 μg/mL and ≤1.76 μg/mL (35). However, because of the intraindividual variations in blood levels associated with seizure control and side effects, a traditional "therapeutic range" cannot be identified. As expected, plasma concentrations are higher when TPM is administered as monotherapy (6.4 to 12.4 μg/mL with approximately 200 to 400 mg/day) versus its use as add-on to enzyme-inducing AEDs (1.4 to 5.3 μg/mL with approximately 200 to 400 mg/day). Despite the substantially higher plasma concentration with monotherapy, the incidence of central nervous system (CNS)-related adverse events, particularly cognitive effects, was substantially lower with TPM monotherapy than with adjunctive therapy. This finding underscores the contribution of pharmacodynamic interactions to the occurrence of adverse events during TPM polytherapy and the limited benefit of therapeutic drug monitoring in TPM-treated patients.

The relationship between TPM dose and plasma level was examined in children in whom TPM was titrated to clinical response or side effects (36). Among 21 children aged 6 to 12 years, TPM plasma levels were predictably related to dose (1:1 ratio). With monotherapy, a mean dose of 9.7 mg/kg/day (range, 5.5 to 16.5 mg/kg/day) resulted in a mean plasma level of 9.8 μg/mL (range, 3.4 to 16.6 μg/mL). For 20 younger children (younger than 6 years of age), however, higher monotherapy doses were needed (mean, 22.5 mg/kg/day; range, 11 to 35 mg/kg/day) to achieve seizure control; mean plasma level was 14.8 μg/mL (range, 6.1 to 23.7 μg/mL). When TPM was administered with an enzyme-inducing drug, the TPM dosage in younger children (mean, 14.2 mg/kg/day) was double than that in older children (7.0 mg/kg/day) (36).

Patients with levels close to 25 μg/mL or more rarely obtained additional benefit at higher dosages and side effects increased. Therapeutic ranges are often quoted in the 2 to 25 μg/mL range. It is this author's opinion that there are two ranges. Monotherapy patients who are relatively easy to control can often be controlled in the 2 to 6 μg/mL range, and those who are more intractable may need higher doses.

DRUG INTERACTIONS

Interaction studies were performed with the three leading AEDs (at time of initial release of TPM)—carbamazepine, phenytoin, and valproic acid and also later with lamotrigine. Similar study designs were utilized.

Topiramate and Carbamazepine

The steady-state pharmacokinetics of carbamazepine and TPM as adjunctive therapy and monotherapy were determined in 12 adults whose epilepsy was stabilized with carbamazepine 300 to 800 mg t.i.d. (37). No significant differences were observed in the pharmacokinetics of total or unbound carbamazepine or carbamazepine epoxide in the absence of TPM or with TPM 100 to 400 mg b.i.d. TPM AUC, C_{max}, average concentration, and minimum concentration levels were approximately 40% lower in the presence of carbamazepine than with TPM monotherapy (27).

Topiramate and Phenytoin

The steady-state pharmacokinetics of phenytoin and TPM were determined in 12 adults with partial epilepsy who were stabilized on phenytoin (38). During concomitant phenytoin therapy, TPM pharmacokinetics were proportional for dosages ranging from 100 to 400 mg. During TPM adjunctive therapy with phenytoin, TPM concentrations were reduced by approximately 50%. The investigators hypothesized that the increase in TPM clearance during concomitant phenytoin therapy was due to enzyme induction by phenytoin. In half the patients, TPM had no measurable effect on the pharmacokinetics of phenytoin; in the other patients, however, particularly those taking phenytoin twice a day, phenytoin concentrations were approximately 25% higher. No patients required adjustment of phenytoin or discontinued the trial. In clinical practice, patients receiving dosages in the higher therapeutic ranges of phenytoin should be observed carefully, because they may be more likely to require a downward adjustment of phenytoin dosage (27).

Topiramate and Valproic Acid

The steady-state pharmacokinetics of valproic acid and TPM were determined in 12 patients whose partial epilepsy was treated with valproic acid (39). TPM plasma concentrations were approximately 14% lower during adjunctive therapy with valproic acid. Valproic acid concentrations decrease by 11% when TPM 400 mg b.i.d. was added. The clinical significance of these changes is probably minimal (27).

Topiramate and Lamotrigine

An open-label, sequential, single-group, dose-escalating, PK study was performed in 13 patients with

epilepsy. No PK interactions were noted between TPM and lamotrigine at observed doses of 100 to 400 mg/day TPM (40).

Topiramate and Oral Contraceptives

Interaction studies evaluating the effect of TPM on combination oral contraceptives showed that TPM has no effect on the progestin (norethindrone 1.0 mg) component (41,42). At doses of ≤200 mg/day, TPM has no significant effect on estrogen (ethinyl estradiol 35 μg) concentrations (41,42). Initial studies showed the mean serum estradiol to be reduced by 18% at 200 mg/day, but repeat testing at the same 200 mg dosage showed only an 11% decrease. At higher doses (400 and 800 mg/day), TPM was associated with 21% and 30% reductions, respectively, in ethinyl estradiol concentrations, suggesting a modest induction of estrogen clearance (42). The level of induction is substantially less than that associated with potent enzyme-inducing agents such as carbamazepine (42% reduction in estrogen concentration) (41). The dose- related effect of TPM on estrogen clearance is consistent with the concentration-dependent induction of cytochrome P450 (CYP450) CYP3A4 activity measured in vitro (43). TPM induced CYP3A4 enzymes only at concentrations >50 μM, a concentration that is unlikely to be achieved with dosages up to 400 mg/day; enzyme induction was still less than that associated with known inducers (phenobarbital and rifampicin) used in this study.

Predominantly, renal elimination and low protein binding minimize the potential for drug interactions. Pharmacokinetic interactions between TPM and other AEDs are limited primarily to the effects of enzyme-inducing drugs on TPM. TPM plasma levels are approximately 50% lower when TPM is given with an enzyme-inducing AED (37–45) compared to TPM use alone or in combination with non–enzyme- inducing drugs (37–39,39–45). The addition of TPM does not significantly affect plasma concentrations of carbamazepine (37), valproate (39), phenobarbital/primidone (44), or lamotrigine (40). However, phenytoin plasma levels may be increased as much as 25% in some patients, particularly those in whom phenytoin metabolism may be at or near saturation (45). Studies of TPM in models designed to predict drug interactions related to the CYP450 enzyme system have shown inhibition of only the CYP2C19 isozyme, which may account for the potential interaction with phenytoin (46). Although pharmacokinetic interactions between TPM and other AEDs are limited, the lower incidence of adverse effects with TPM monotherapy (35,47,48) suggests that pharmacodynamic interactions may affect tolerability when TPM is added to existing therapy.

A slight decrease in digoxin clearance has been observed with the addition of TPM (49) but generally does not require dosage adjustments. Changes in metformin pharmacokinetics suggest that diabetic control should be monitored when TPM is added or withdrawn (50).

EFFICACY

Adjunctive Therapy

Partial-Onset Seizures

The effectiveness of TPM as adjunctive therapy across a wide range of doses (200 to 1000 mg/day) in adults with refractory partial-onset seizures has been well documented in randomized, double-blind, placebo-controlled trials (51–59). Similarity of trial design and patient populations allowed

pooled analysis of data from six of these trials (51–56). Among 743 adults (median baseline frequency, 12 seizures per month), median seizure reduction was 44% with TPM treatment versus 2% with placebo ($P \leq 0.001$); 43% of TPM-related patients (placebo, 12%; $P \leq 0.001$) achieved at least 50% seizure reduction (60). During 11 to 19 weeks of double-blind treatment, 5% of patients in the TPM group were seizure free, while no patients in the placebo group were seizure free ($P \leq 0.001$) (60). Initially, it was felt that dosages of 200 mg/day would be placebo-like, and therefore, 79% of the original patients were at dosages of 400 to 1000 mg/day. On initial review of the data, it appeared that there was a flattening of the efficacy curve at higher dosages. However, one must remember that this was intent to treat data. If a patient due to side effects did not make it to his assigned upper dosage (even if seizure free or significantly reduced in seizure frequency), the patient was considered as not succeeding at that dosage. Therefore, from an efficacy point of view, there was a dose–response curve. Although dosages as high as 1000 mg/day were evaluated, the most clinically useful adjunctive therapy dosages appear to be 200 to 400 mg/day. In a 12-week, double-blind trial to further evaluate the lower end of the presumed dosing range (59), 200 mg/day TPM was added to carbamazepine. Median seizure reduction in TPM-treated patients ($N = 168$) was 44% (vs. 20% with placebo, $N = 91$; $P < 0.001$); 45% of TPM-treated patients (placebo, 24%; $P = 0.001$) achieved at least 50% seizure reduction. After 2 weeks, median seizure reduction in patients receiving TPM 100 mg/day ($N = 84$) was 60% (placebo, 17%; $P < 0.001$), which suggests that 100 mg/day may be a target dose at which seizure control should be initially evaluated.

The initial overestimation of TPM dosage needs is evident from prospective, in-practice studies in which adults with refractory partial-onset seizures achieved good seizure control with 264 mg/day (48% of patients had 50% or more seizure reduction rate; 9% were seizure free) (61) and 323 mg/day (68% of patients had a 50% or more seizure reduction rate) (62). When titrating to response, patients with fewer baseline seizures (>4 per month) required lower TPM dosages (303 mg/day) than those with higher baseline seizure frequency (341 mg/day in patients with four or more seizures per month) (62). In a prospective study, 17% of refractory patients had at least 50% seizure reduction and 8% were seizure free with TPM dosages of 100 or less mg/day (63).

In treatment-resistant epilepsy patients treated at a tertiary epilepsy center, estimated long-term retention rates among 393 TPM-treated patients were 52% after 1 year, 42% at 2 years, 30% at 3 years, and 28% at 5 years (64,65). Although these rates were higher than those with another new-generation agent (lamotrigine), the low retention rate at 5 years reflects the limitations of medical therapy in patients with refractory epilepsy.

TPM was evaluated as adjunctive therapy in 86 children (2 to 16 years of age) with refractory partial-onset seizures (66). With a mean daily dose of 6 mg/kg (target dose, 5 to 9 mg/kg/day), median seizure reduction was 33% (placebo, 11%; $P = 0.03$). More TPM-treated children had at least 50% reduction in seizures (39% vs. 20% with placebo; $P = 0.08$); 5% of children receiving TPM had no seizures, while no placebo-treated children were seizure free.

All 83 children completing the double-blind phase entered the long-term, open-label extension in which the dosages of TPM and concomitant AEDs could be adjusted according to clinical response (67). Mean treatment duration was 15 months, with some children being treated as long as 2.5 years; the mean TPM dosage was 9 mg/kg/day (range, 4 to 22 mg/kg/day). Among children treated for at least 6 months, 64% had at least a 50% reduction in seizures; 14% were seizure free for a minimum of 6 months. During open-label in-practice studies in children with refractory partial-onset seizures (68–71), 4% to 20% of TPM-treated children were seizure free during treatment periods as long as 33 months.

Lennox–Gastaut Syndrome

TPM was evaluated as adjunctive therapy in 98 patients with Lennox–Gastaut syndrome confirmed by an electroencephalographic (EEG) pattern of slow spike-and-wave, multiple seizure types, including drop attacks, and a history of atypical absence episodes (72). At a maximum dose of 6 mg/kg/day, median reduction for drop attacks was 15% compared with a 5% increase with placebo; 28% of TPM-treated patients were responders (placebo 14%). A combined measure of drop attacks and tonic–clonic seizures showed a 26% reduction with TPM and a 5% increase with placebo ($P = 0.015$); respective responder rates were 33% and 8% ($P = 0.002$). These outcomes compared favorably with those reported for lamotrigine in this population (73). The placebo-adjusted responder rate for drop attacks was 14% for TPM and 15% for lamotrigine; respective rates for major motor seizures were 25% and 17% (72,73).

During the long-term, open-label extension in which the dosages of TPM and concomitant AEDs could be adjusted according to clinical response (74), 55% of the 82 children treated with TPM for more than 6 months had at least a 50% reduction in drop attacks during the last 6 months of treatment; 15% experienced no drop attacks. Two patients were free of all seizures. The mean duration of TPM treatment was 18 months, with treatment periods as long as 3.4 years. The mean TPM dosage was 10 mg/kg/day (range, 1 to 29 mg/kg/day). Among patients treated as long as 8 years, 21% to 40% of patients had at least 50% seizure reduction, with major motor seizures being the most responsive (75,76).

Generalized Tonic–Clonic Seizures of Nonfocal Origin

Two double-blind, placebo-controlled trials (77,78) evaluated TPM in the treatment of generalized, nonfocal tonic–clonic seizures (i.e., primary generalized tonic–clonic seizures). Inclusion criteria specified tonic–clonic seizures with or without other generalized seizure types and EEG or CCTV/EEG patterns consistent with generalized epilepsy (generalized, symmetric, synchronous spike–wave discharges, and normal background activity); patients with Lennox–Gastaut syndrome or partial-onset seizures were excluded. In the two trials, more than 70% of patients had primary generalized tonic–clonic seizures plus at least one other type of generalized seizure (i.e., absence, myoclonic, or tonic).

TPM was initiated as adjunctive therapy in adults and children (at least 4 years of age) with refractory generalized tonic–clonic seizures despite treatment with one or two AEDs. The target dose was 5 to 9 mg/kg/day, and the maximum daily dose was 400 mg. In one trial (77), baseline seizure frequency in the TPM-treated group ($N = 39$) was five generalized tonic–clonic seizures per month (placebo 4.5 generalized tonic–clonic seizures per month; $N = 41$). Median seizure reduction was 57% (placebo 9%; $P < 0.02$) for tonic–clonic seizures and 42% (placebo, 1%; $P = 0.003$) for all generalized seizures. Among TPM-treated patients, generalized tonic–clonic seizures and all generalized seizures were reduced at least 50% in 56% and 46%, respectively (respective placebo values: 20%, $P = 0.001$; 17%, $P = 0.003$). No generalized tonic–clonic seizures occurred during the 20-week study in 13% of TPM-treated patients (placebo 5%); 5% had no generalized seizures of any type (placebo 0% of patients).

Because the two trials were identically designed, data were pooled and analyzed. As had been observed in the single trial, TPM reduced the frequency of generalized tonic–clonic and all generalized seizures, with significantly more patients achieving 50% or greater reduction in generalized tonic–clonic (55% vs. 28% with placebo; $P \leq 0.001$) and all generalized seizures (43%

vs. 19% with placebo; P = 0.001). Although small sample sizes limited analysis, TPM was also more effective than placebo in reducing the frequency of tonic and myoclonic seizures and did not exacerbate absence seizures.

All 131 patients who completed the double-blind phase entered an open-label extension phase (79). During the last 6 months of treatment, 16% had no generalized tonic–clonic seizures and 7% were seizure free for at least 6 months. TPM was also effective against other generalized seizure types; during the last 6 months of treatment, 10% of patients with absence seizures, 33% of patients with myoclonic seizures, and 21% of patients with tonic seizures were seizure free for at least 6 months.

In a study evaluating EEG changes and seizure control in TPM-treated patients with primary generalized epilepsies (80), more than half of the patients showed reductions in epileptiform spike-wave activity, although TPM was less likely to suppress activity in patients with very high discharge frequencies at baseline. As with other broad-spectrum AEDs, seizure reduction (36% seizure free) did not correlate with EEG response, and no correlation was observed between clinical or EEG response and TPM blood levels.

Juvenile Myoclonic Epilepsy

In a pilot study, 15 patients who had previously failed valproic acid (one wanted off strictly due to weight gain and 5 wished to get off due to weight issues) were switched from valproic acid to TPM. Myoclonic seizures stopped in 60% of patients, 49% of generalized tonic–clonic seizure patients became seizure free of that type of seizure, and 25% of absence seizure patients stopped having this type of seizure (81).

A small subset of patients with juvenile myoclonic epilepsy (JME) was included in the controlled trials evaluating TPM in primary generalized tonic–clonic seizures (77,78). Among 11 patients with JME receiving TPM, primary generalized tonic–clonic seizures were reduced at least 50% in 73% (vs. 18% of patients receiving placebo, N = 11; P = 0.03) (82). In addition, the frequency of myoclonic seizures was reduced, and the number of weeks without absence seizures was increased in TPM-treated patients. In a randomized, open-label study in patients with JME (83), TPM and valproate were similarly effective (seizure-free rates following 12 weeks' treatment: 47% and 33%, respectively). The treatment groups were similar in neurotoxicity scores; however, TPM was associated with less systemic toxicity than valproate.

West Syndrome

Eleven children with refractory West syndrome participated in a pilot study of TPM (84). At a maximum daily dose of 24 mg/kg, the frequency of infantile spasms was reduced by at least 50% in nine children, including five (45%) who were completely controlled. Ancillary seizures responded in four of six children. After 18 months of TPM (mean dosage, 29 mg/kg/day), eight children (73%) continued on medication, four (50%) children were free of spasms, and seven (88%) children had spasms reduced by at least one-half (85).

Childhood Absence Epilepsy

Five children 4 to 11 years of age with EEG-documented absence seizures and childhood absence epilepsy were treated with open-label TPM (maximum dose, 12 mg/kg/day) (86). Three children

experienced a minimum reduction of 50% at daily dosages of 5 to 6 mg/kg; two children were seizure free. Frequency was unchanged in the remaining two children, even at the maximum dosage.

Severe Myoclonic Epilepsy in Infancy

During a prospective, multicenter, open-label study in 18 patients with severe myoclonic epilepsy in infancy and refractory seizures of different types, three patients became seizure free, six patients had >75% seizure reduction, and four patients had >50% seizure reduction with TPM treatment (87). Seizure frequency was unchanged in five patients; no patients experienced seizure worsening. Mean treatment duration was 12 months (range, 2 to 24 months); mean TPM dose was 5.4 mg/kg/day (range, 2.8 to 10 mg/kg/day).

Patients with Mental Retardation, Learning Disabilities, and/or Developmental Disabilities

Among 64 patients (16 to 65 years of age) with refractory epilepsy and learning disability treated with TPM in an open- label study, 16 patients became seizure free and 29 patients had at least a 50% seizure reduction (88). Many patients, including 63% of those who were seizure free and 66% of treatment responders, were receiving TPM dosages of ≤200 mg/day. In a study evaluating the effect of TPM in 20 adults (21 to 57 years of age) with intractable mixed seizures, mental retardation, and development disabilities, two patients became seizure free and 11 patients had at least a 50% seizure reduction with TPM treatment (89). In addition, the duration and/or severity of seizures were reduced in 44% of patients. The mean duration of treatment was 42 weeks (range, 20 to 54 weeks); the mean TPM dose was 189 mg/day (range, 50 to 350 mg/day).

Refractory Status Epilepticus

In six cases of refractory status epilepticus unresponsive to sequential trials of multiple agents, including one patient who had been in a prolonged pentobarbital coma, TPM (300 to 1600 mg/day) administered via nasogastric tube successfully terminated refractory status epilepticus (90). TPM was effective against both generalized convulsive and nonconvulsive status epilepticus. All patients were subsequently discharged from the hospital.

Monotherapy

The 1990s ushered in a new era—at least in the United States—for clinical studies in newly diagnosed, previously untreated epilepsy. The use of traditional AEDs (carbamazepine, phenytoin, valproate) as first-line monotherapy is largely based on landmark Veterans' Administration Cooperative trials (91,92) and similar open-label trials in the United Kingdom (93,94). However, the U.S. Food and Drug Administration (FDA) began requiring randomized, double-blind trials demonstrating a statistically significant difference between treatments as evidence of efficacy, generating considerable debate as to how to safely and ethically accomplish this goal. One such approach is an active-control conversion-to-monotherapy design in which patients are randomized to study drug or a minimally effective active-control, and preexisting AED therapy is gradually withdrawn (95). Such a design parallels the technique clinicians use to switch patients to a second trial of AED monotherapy when the first agent has failed because of ineffective seizure control or

intolerable side effects. Such a design was used as a proof-of-principle trial for TPM monotherapy (96).

Monotherapy trial design becomes particularly complex when evaluating new AEDs in patients with newly or recently diagnosed epilepsy. The use of a placebo control in untreated epilepsy patients remains controversial, and only one such trial has been conducted (97). Unlike their European counterparts, regulatory authorities in the United States are unwilling to accept monotherapy equivalence trials for AEDs already approved as adjunctive therapy (95). The argument is that a trial showing equivalence of two treatments could be interpreted as meaning that both treatments were equally ineffective or that the trial simply failed to detect existing differences (95,98). Given the responsiveness of patients with newly diagnosed epilepsy, some have doubted the possibility of demonstrating a treatment effect with active-control or dose-control trials. These trial types are also controversial in relation to ethical equipoise (99).

TPM has been evaluated as first-line monotherapy in adults and children with newly or recently diagnosed epilepsy in three multicenter, randomized, double-blind trials. Two trials were dose-controlled trials (35,48), and one trial used a novel trial design to simultaneously compare TPM with two standard AEDs (i.e., carbamazepine and valproate) (47).

In the first dose-controlled trial (35), 252 adults and children who had been diagnosed with epilepsy within 3 years of study entry and who had one to six partial-onset seizures during a 3-month retrospective baseline were randomized to 50 or 500 mg/day TPM (patients weighing ≤50 kg were randomized to 25 or 200 mg/day). Patients were untreated or had been treated for more than 1 month with one AED. The primary efficacy outcome was time to exit, which was time to second seizure in 96% of patients. Time to exit was longer in patients receiving TPM 200/500 mg/day (median 422 days vs. 293 days in patients receiving 25/50 mg/day), although the difference was not significant. When time to exit was analyzed using time to first seizure as a covariate, the difference between treatment groups was significant ($P = 0.01$). This finding reflected the higher seizure-free rate in patients receiving TPM 200/500 mg/day (54% vs. 39% with 25/50 mg/day; $P = 0.02$) as well as the longer interval before the first seizure (median 317 days vs. 108 days with 25/50 mg/day; $P = 0.06$). In this study, seizure-free rates with 50 mg/day (39%) and TPM 400 mg/day (54%) were at the lower and upper ends for the range of seizure-free rates (36% to 43%) reported with therapeutic dosages of other AEDs in double-blind studies (100,101). The mean dosage among patients randomized to TPM 500 mg/day was 366 mg/day. A significant difference between treatment groups was observed for patients with one or two seizures in the 3-month baseline, but not for patients with three or more seizures in the 3-month baseline. This finding suggested that higher seizure frequency may serve as an indicator of more treatment-resistant seizures in patients with untreated epilepsy and is consistent with other reports linking higher seizure frequency before initial treatment with refractory epilepsy (102).

Results from the first dose-controlled study (35) suggested that TPM 50 mg/day was an effective dose in some patients responsive to anticonvulsant therapy and could serve as an active control to treatment with TPM 400 mg/day. Moreover, patients with one or two seizures in a 3-month baseline may represent the population of patients with newly diagnosed epilepsy who are most likely to benefit from monotherapy and not require polytherapy because of drug-resistant epilepsy. In the second dose-controlled study (48), 470 adults and children (weighing at least 25 kg) were eligible if they had untreated epilepsy diagnosed within 3 months of study entry, or if epilepsy had relapsed while they were not receiving anticonvulsant therapy. Patients could have only one or two partial-onset or generalized tonic–clonic seizures during the 3-month retrospective baseline. The primary

efficacy end point was time to first seizure; seizure-free rates at 6 months and 1 year were secondary efficacy measures. Kaplan–Meier survival analyses for time to first seizure showed a significantly greater treatment effect with the 400 mg/day group versus the 50 mg/day group (P = 0.0002). The probability of being seizure free was 83% with the 400 mg/day group and 71% with the 50 mg/day group (P = 0.005) after 6 months treatment and 76% and 59% (P = 0.001) after 12 months. A difference between dose groups emerged within the first week after randomization when patients were receiving 25 or 50 mg/day; the between-group difference was significant after 2 weeks when patients were receiving 25 or 100 mg/day. The mean dosage achieved for each of these groups was 46 mg/day (in the so-called 50 mg/day group) and 275 mg/day (in the so-called 400 mg group). The reason that the numbers were <50 and 400 mg/day was that for example for the higher dosage patients, they had to be increased to at least 150 mg/day but not necessarily to 400 mg/day. Approximately half of the patients were not fully titrated to 400 mg/day and approximately half were titrated up to 400 mg/day (investigator discretion). Similarly, one could stop at 25 mg/day for the low-dosage group and did not have to increase to 50 mg/day.

The effectiveness of TPM 100 mg/day as initial monotherapy in patients with newly diagnosed epilepsy was established further with a randomized, double-blind trial comparing TPM, carbamazepine, and valproate in adults and children (N = 613) with newly diagnosed epilepsy (47). No seizure types/epilepsy syndromes were excluded. During this trial, investigators selected carbamazepine (600 mg/day) or valproate (1250 mg/day) as the preferred therapy according to each patient's clinical presentation. Patients were then assigned to the carbamazepine or valproate treatment branch. Within each branch, patients were randomized to double-blind treatment with the investigator's choice of traditional AED (carbamazepine or valproate), TPM 100 mg/day or TPM 200 mg/day. Patients continued double-blind treatment until exiting the study or until 6 months after the last patient was randomized.

The initial efficacy analysis compared time to first seizure for the two TPM dosages (100 and 200 mg/day). If TPM 200 mg/day was significantly more effective than TPM 100 mg/day, then 200 mg/day was to be compared with carbamazepine and valproate. If 200 mg/day was not significantly more effective, the protocol required TPM dosage groups to be pooled within each branch and compared with traditional therapy. For the comparison between TPM and traditional therapy, the primary efficacy measure was time to exit; secondary efficacy end points were time to first seizure and proportion of patients seizure free during the last 6 months of double-blind treatment.

No difference was observed for the initial efficacy analysis comparing the two TPM dosages groups. Therefore, the combined TPM groups were compared with carbamazepine and valproate treatment. In both the carbamazepine and valproate branches, time to exit did not differ between the combined TPM treatment groups and traditional therapy. Because the branches were homogeneous, pooled data across branches were used to calculate 95% confidence intervals (CIs) for treatment differences. Although retention rates were higher among patients receiving TPM compared with those receiving carbamazepine or valproate, 95% CIs included zero, which indicated that between-group differences were not statistically significant. Similar results were observed for time to first seizure. The proportion of patients with no seizures during the last 6 months of double-blind treatment was 49% among patients receiving TPM 100 mg/day and 44% in each of the other three treatment groups (i.e., TPM 200 mg/day, carbamazepine, and valproate). The 95% CIs were narrow and included zero, indicating no difference among the four treatment groups.

Results from two trials showing that TPM 100 mg/day is effective in adults and children with newly diagnosed epilepsy support clinical findings suggesting that only low to moderate dosages of

AEDs are required in patients with new-onset epilepsy that is responsive to treatment (103). Pharmacokinetic–pharmacodynamic (PK-PD) modeling and simulation bridging showed no difference in PK-PD of TPM between adult and pediatric patients. Monotherapy regimens were identified in children 2 < 10 years of age (104).

Intravenous Use

There is no intravenous formulation approved to date. The safety and pharmacokinetics following a single dose in patients with epilepsy or migraines taking oral TPM was however performed. A 25 mg single dose caused minimal infusion site or systemic adverse effects (105).

Other Clinical Uses

TPM is now indicated for adults for the prophylaxis for migraine headaches. Two randomized, double-blind, placebo- controlled trials evaluated the efficacy of TPM treatment (50, 100, and 200 mg/day) in 970 patients with migraine (106,107). The primary efficacy measure was change in mean monthly migraine frequency from baseline during double-blind treatment. Compared with placebo, significant reductions in monthly migraine frequency were reported with TPM dosages of 100 and 200 mg/day; migraine frequency was also reduced with 50 mg/day, although the difference from placebo was not statistically significant. The proportion of treatment responders with a 50% or more reduction in monthly migraine frequency was significantly greater in TPM-treated patients (36% to 54% vs. 23% with placebo) (104,105). TPM may also have favorable effects in patients with cluster headache; in a case series, cluster remission occurred in nine of 10 patients (108).

TPM may have a potential role in movement disorder treatment. In a double-blind, placebo-controlled, crossover trial in 62 patients with essential tremor, TPM was associated with significant improvements in tremor severity, motor task performance, and functional disability (109), findings that were consistent with those in an earlier pilot study (110). In a retrospective chart review, TPM seemed to be effective in reducing tics in children and adolescents with Tourette syndrome (111); 59% (19/32) of patients had at least 50% reduction in tic severity scores.

Several studies suggest that TPM may be effective in various impulse control disorders. In a randomized, double-blind, placebo-controlled trial in 150 patients with alcohol dependence, TPM-treated patients had significantly fewer drinks per day, drinks per drinking per day, and heavy drinking days and significantly more abstinent days compared with placebo (112). Plasma α-glutamyl transferase, an objective index of alcohol consumption, was also significantly lower in TPM-treated patients. Among 61 obese patients with binge-eating disorder who were participating in a randomized, double-blind, placebo-controlled trial, TPM treatment was associated with significantly greater reductions in binge frequency, binge per day frequency, body mass index (BMI), body weight, and obsessive–compulsive scores (113). Open-label treatment with TPM has been reported to improve behavior, mood, weight control, compulsive eating problems, and self-mutilating behavior (notably skin picking) associated with Prader–Willi syndrome (114,115).

The observation that TPM is associated with weight loss and expected improvement in metabolic parameters (e.g., lipids, blood pressure, glucose levels) (116) led to studies of TPM (64 to 384 mg/day) in obese patients (117). After 6 months, mean percent decrease in baseline body weight was significantly greater among TPM-treated patients (range, 4.8% to 6.3% depending on TPM dose; 2.6% with placebo). A similar pattern of weight loss was observed in patients with diabetes who

participated in three double-blind, placebo-controlled trials evaluating the efficacy of TPM in painful diabetic neuropathy (118). Moreover, in these trials, diabetic control, measured as HbA1c levels, improved significantly compared with placebo, with reductions in HbA1c occurring independent of weight loss. These findings are supported by data from an animal model of diabetes, in which TPM demonstrated dose- dependent decreases in blood glucose and plasma triglycerides without significant body weight changes (119).

In view of the role of glutamate and AMPA in the pathobiology of neuronal injury, attention has been focused on TPM because of its activity as an AMPA antagonist. Potential neuroprotective and disease-modifying effects of TPM have been observed in models of seizure-related neuronal injury (23), focal cerebral ischemia (120), and glutamate excitotoxicity (121). Preliminary data in patients with diabetic neuropathy suggest that TPM may improve or restore nerve function through preservation/regeneration of C-fibers, with associated improvement in functional parameters (122). Studies using a cerebral microdialysis technique in patients with traumatic brain injury showed that TPM reduced glutamate levels compared with historical controls (123). In a double-blind, placebo-controlled trial, high-dose TPM (800 mg/day) did not provide beneficial effects in patients with amyotrophic lateral sclerosis and may have accelerated the loss of arm muscle strength. In this study, TPM treatment was associated with an increased risk of side effects (124). These findings are useful for advancing our understanding of potential therapeutic targets.

A recent translational medicine research report using a computational approach to discover new drug therapies for inflammatory bowel disease (IBD) suggested the possibility that TPM might be helpful. They utilized a trinitrobenzenesulfonic acid–induced rodent model of IBD (125).

Use in Pregnancy

“In 2011, TPM was reclassified from a Pregnancy Category C to a Pregnancy Category D drug.” Data in humans suggested a link between the drug’s use in the first trimester of pregnancy and oral cleft formation in newborns. “Pregnancy Category D drugs are those with positive evidence of human fetal risk based on human data but still may be used in pregnant women in certain situations when its benefits are thought to outweigh potential risks. Previously, data suggesting fetal harm with TPM were available only with animal studies” (126). In animal studies, fetal abnormalities were similar to those observed with other carbonic anhydrase inhibitors such as acetazolamide, whose use has not been linked to teratogenic effects in humans. “The recent FDA action stemmed from inspection of data provided by the North American Antiepileptic Drug (NAAED) Pregnancy Registry. Upon review of these data, the agency found that newborns exposed to TPM monotherapy during the first trimester of pregnancy were more likely to develop an oral cleft compared to those who were not (RR = 21.3; 95% CI, 7.9–57.1). Similar conclusions were drawn from a review of the United Kingdom Epilepsy and Pregnancy Register (incidence of oral cleft: 3.2% vs. 0.2%, RR increase of approximately 16-fold). In their published safety communication, FDA agency officials stressed, ‘The benefits and the risks of TPM should be carefully weighed when prescribing this drug for women of childbearing age, particularly when TPM is considered for a condition not usually associated with permanent injury or death.” They continued, “Appropriate alternative treatment should be considered.” (126). One company sponsored study with 75 pregnancies with 29 monotherapy exposures revealed two malformations. The other 46 pregnancies in that study were exposed to at least one other AED; 7 infants had a malformation (127). Preliminary experience from the UK Epilepsy and Pregnancy Registry that is a prospective observational registry and follow-up study revealed 203 pregnancies

with 173 live births. There were 16 major congenital malformations (MCM) (9%). Of these 16 patients, 3 cases were on monotherapy (out of 70 monotherapy cases) (4.8%) and 13 were on polypharmacy (11.2%). Four MCMs were oral clefts (2.2%). There were four cases of hypospadias among 78 live male births. Two of these cases were classified as major malformations (128). Caution is advised due to sample size and wide CIs. Of additional note, approximately half of these patients were migraine patients and not all were epilepsy patients. In addition, much of the data were in polypharmacy. These are the first data we have had on TPM in pregnancy and while these findings are of potential concern, until we have more research from other pregnancy registries, they cannot be interpreted as definitive (129). Pregnancy registries in the United States and Europe are collecting information about the use of TPM and other AEDs during pregnancy. A progress report in 2009 from the North American Antiepileptic Drug Registry showed 8 total malformations out of 197 enrolled monotherapy pregnancies with TPM (prevalence 4.1%) (95% CIs 1.9 to 7.6%) (130). Identified malformations were eight separate, common birth defects and did not show an increase for any specific abnormality. (Data preliminary since predictions would be much more certain with a larger sample size—preferably >600 pregnancies.)

TPM is extensively excreted in human breast milk, and nursing infants are exposed to TPM (plasma concentrations in infants are 10% to 20% of maternal concentrations); the significance of this exposure is unknown (131).

EXTENDED-RELEASE FORMULATIONS

Two extended release formulations were recently released or are about to be released. Trokendi XR, the first once per day extended release formulation using Microtrol technology, was released in the third quarter 2013 by Supernus Pharmaceuticals and Qudexy XR, a proprietary formulation of coated bead technology to deliver consistent release of TPM over a 24-hour dosing interval by UpsherSmith Pharmaceuticals, is in the late stages of development. TrokendiXR was approved in 2014 for initial monotherapy for patients >10 years old with either partial onset or primary generalized tonic–clonic seizures, and as adjunct treatment in patients >2 years old with partial onset seizures, primary generalized tonic–clonic seizures, or seizures associated with Lennox–Gastaut syndrome. TrokendiXR was approved strictly based on bioequivalence with $AUC_{0–24}$ 97%, C_{max} 88%, and C_{min} 100% (132). The USL255 probable release will be based on an adjunctive therapy study in patients from 18 to 75 years of age. Pharmacokinetics have shown $AUC_{0–24}$ (90% CI: 98%–104%), C_{max} (90% CI: 86%–95%), and C_{min} (90% CI: 99%–104%) (133).

ADVERSE EFFECTS

Central Nervous System

As expected with anticonvulsants, CNS effects were the most commonly reported side effects in randomized, controlled trials with TPM. Their relatively high incidence in early double- blind, placebo-controlled trials was attributable in part to high starting doses, rapid dose escalation, and high drug load when supratherapeutic dosages of TPM were added to maximum tolerated dosages of one or more AEDs (60). Various studies showed that the incidence and severity of CNS effects, as well as premature discontinuations because of side effects, could be reduced with more gradual dose

escalation, lower target doses, and reductions in the dosages of concomitant AEDs as TPM was titrated to effect (62,134,135).

Although many of the CNS effects were nonspecific complaints seen with all AEDs (e.g., somnolence, fatigue, dizziness, ataxia, confusion), the early studies were characterized by a relatively high incidence of adverse events coded to the term "abnormal thinking" per WHOART (World Health Organization Adverse Reporting Terminology) (51,52). Subsequently, neurobehavioral adverse events were coded with an expanded adverse event term list that included psychomotor slowing, memory difficulty, concentration/attention difficulty, speech problems, language problems, and mood problems, among others. A double-blind study comparing TPM with carbamazepine and valproate as monotherapy in newly diagnosed epilepsy was the first in which the adverse events occurring with other AEDs were coded with the dictionary that is unique to TPM trials (47). The incidence of neurobehavioral side effects was low with all three medications. TPM 100 mg/day and carbamazepine 600 mg/day were indistinguishable in terms of most neurobehavioral side effects (concentration and attention difficulty, 4% in each group; psychomotor slowing, 4%; confusion, 3%; speech disorders, 2%), which occurred less frequently in patients receiving valproate 1250 mg/day (concentration and attention difficulty, 1%; psychomotor slowing, 1%; no reports of confusion or speech problems). Cognitive problems not otherwise specified, as well as memory difficulty, were slightly more common with TPM than with the other agents (cognitive problems not otherwise specified: TPM, 3%; carbamazepine and valproate, 1%; memory difficulty: TPM, 8%; valproate, 6%; carbamazepine, 5%), while language problems were somewhat more common with carbamazepine (carbamazepine, 6%; valproate, 4%; TPM, 3%).

Although TPM and carbamazepine have not been compared in terms of their effects on objective measures of cognitive function, two studies have compared TPM and valproate added to carbamazepine in patients with uncontrolled partial- onset seizures (136,137). In a double-blind study in which patients were followed for 20 weeks, 1 of 17 neuropsychometric variables (short-term verbal memory) showed a statistically significant difference between treatments (worsening of scores with TPM and improvement with valproate). Although the study did not include measures of language function, it used the titration schedule most commonly used in clinical practice when adding TPM to other AEDs (i.e., 25 mg/day starting dose increased weekly in 25-mg increments to a target dose of 200 to 400 mg/day). In a double-blind study using a more rapid escalation schedule (50 mg/day starting dose increased weekly in 50-mg increments to a target dose of 400 mg/day) to add TPM to carbamazepine, cognitive performance was significantly worse from baseline in seven of 24 variables at the end of the 8-week titration period but in only 2 of 24 variables (controlled oral word association and symbol digit modalities) after an additional 3 months of treatment (137). Compared with valproate added to carbamazepine, TPM scores during neuropsychometric testing were slightly worse overall. In this study, it appeared that a subset of patients was more sensitive to TPM and accounted for much of the worsening in cognitive function scores. Because pharmacodynamic interactions are a major factor in the neurobehavioral adverse events that have been reported with TPM polytherapy, neuropsychometric testing during TPM monotherapy would be a better indicator of the effects of TPM on cognitive function. However, no such study in patients with epilepsy has been published. A short-term study in healthy volunteers showed that a high starting dose (100 mg/day) and escalation to 400 mg/day in 4 weeks was associated with significant decreases from baseline on measures of attention and word fluency (138). However, the results of this study have little clinical relevance since the 400 mg/day dosage was four times higher than the recommended target dose of 100 mg/day in newly diagnosed epilepsy.

Although the comparative study of TPM, carbamazepine, and valproate as monotherapy showed that language and speech disorders were actually no more common with TPM, at least as monotherapy, than with carbamazepine, the occurrence of word-finding difficulty during TPM therapy has generated considerable interest, as evidenced by the studies using comprehensive neuropsychometric test batteries. In addition, investigators have sought potential risk factors for adverse cognitive effects with TPM. In a prospective study from a tertiary epilepsy center, left temporal lobe epilepsy and simple partial seizures were most strongly associated with the occurrence of word-finding difficulty in the 31 of 431 patients (7%) who developed word-finding difficulty during TPM therapy (139). As in the double-blind cognitive function study (132), it appeared that the word-finding difficulty in a small subset of patients reflected a biologic vulnerability.

The original double-masked placebo-controlled studies were all forced titration studies that increased each patient's dosage to a target dose, usually at weekly increments of 100 to 200 mg/day. The recommended titration rate (weekly increments of 50 mg/day or less) is slower and has clearly been associated with improved tolerability (27). TPM may be increased at 25 to 50 mg/week increments, and it is this author's opinion that 2-week intervals may be best. If TPM is titrated too quickly, patients may complain of agitation, anxiety, or nervousness as well as word-finding difficulties. This can often be ameliorated by slowing the rate of titration. Keeping TPM total dosage per day at no >200 mg by 6 to 8 weeks is often best. Reduction in the dose of concomitant AEDs can further decrease side effects. Particularly in patients with high valproic acid levels, reduction of the dose of valproate can improve cognitive side effects. Patients with thrombocytopenia while taking valproate may have a further reduction in platelet count with the addition of TPM (39). Platelet counts increase when the valproate dose is reduced. In most cases, side effects are manageable and do not require discontinuation of the drug (27).

Adverse Effects in the Elderly

Most studies of TPM involved mostly young adults with only a few exclusively involving the elderly. Studies have found deficits in working memory and verbal fluency (140–144). Gross effects of TPM on daily life have been evaluated by examining motor vehicle performance and decrease in driving ability (144,145). In the case of the elderly patient, it has been suggested that the patients avoid other sedative AEDs with TPM, and preferable choices according to these authors might include CBZ, GBP, LTG, and levetiracetam (146,147) (Starting at a lower dose, perhaps at 25 mg/day and no more rapidly than 25 mg/week, has been suggested (148).

Psychiatric

In 2008, the FDA posted an advisory in regard to suicidality in regards to epileptic drugs "stating that as a class, there is a possible risk between 11 such drugs, including TPM and suicidal ideation within 1 week of beginning treatment. This seems to occur to the same extent in both epilepsy and psychiatric patients. The FDA states that the risk is roughly twice that of placebo-treated patients (0.43% vs. 0.22%)" (148,149). "TPM-treated patients have a prevalence of suicidal ideation, attempts, and completed suicide of 0.5%, compared with 0.15% of placebo recipients, in randomized, double-blind clinical trials" (150).

Carbonic Anhydrase Inhibition

Side effects that can be linked to TPM inhibition of carbonic anhydrase isozymes (CA II and CA IV) are paresthesia, renal stones, and decreased serum bicarbonate. Paresthesias are often transient, resolve with continuing treatment, and rarely lead to drug discontinuation. Paresthesias are more common with TPM monotherapy (35,47,48) than as add-on treatment (60), which is likely caused by higher TPM plasma levels in the absence of hepatic enzyme–inducing AEDs.

As in the general population, renal stone formation in TPM clinical trials was more common in men. Other risk factors for renal stone formation include personal or family history of renal stones, chronic metabolic acidosis, and coadministration of other carbonic anhydrase inhibitors or the ketogenic diet. Although chronic metabolic acidosis may increase the risk of renal stone formation, serum bicarbonate levels are not reliable predictors of renal stone formation. Patients should maintain adequate hydration to increase urinary output and lower the concentration of stone-forming substances.

In some patients, carbonic anhydrase inhibition is associated with laboratory findings of reduced serum bicarbonate levels. In clinical trials, the mean serum bicarbonate reduction was 4 mEq/L. Although reductions in serum bicarbonate levels are usually asymptomatic, nonspecific symptoms may include fatigue, anorexia, nausea, and vomiting; no correlation between these symptoms and serum bicarbonate levels was observed in TPM-treated patients. Cases of metabolic acidosis marked by hyperventilation and acute changes in mental status have been reported in patients receiving TPM, primarily children (151–153), although most cases have been asymptomatic (154–156). Reductions in serum bicarbonate levels generally occur early in treatment and tend to stabilize without progression during continued treatment (nevertheless, more pronounced at higher doses). Conditions that increase bicarbonate loss (e.g., renal disease, diarrhea, other carbonic anhydrase inhibitors), interfere with carbon dioxide regulation via the lungs (e.g., severe respiratory disorders, surgery, status epilepticus), or alter acid–base balance (ketogenic diet) may have additive effects. It is prudent to monitor serum bicarbonate in patients with any of these potentially exacerbating conditions.

Due to the potential for untreated hyperchloremic normal anion gap, metabolic acidosis the potential for osteomalacia (rickets) with reduced growth rates in children has been raised as a hypothetical concern. The effect of these metabolic abnormalities on adult bone remain speculative.

Adverse Effects in Children

During controlled clinical trials with TPM adjunctive therapy, the incidence of CNS effects in children, including cognitive effects, was generally lower than that in adults, perhaps reflecting a more gradual dose-escalation schedule (60,66,72,77,78). The most common CNS effects in children were somnolence and decreased appetite. TPM did not negatively affect measures of mental status as evaluated by parents and guardians during double-blind treatment (66), although a formal study with neuropsychological testing has not been performed in children. Temporary slowing of weight gain or minor weight loss occurred with TPM treatment; however, weight gain resumed in most children with continued therapy (157). TPM does not adversely affect growth, measured as height, in children (158).

Pooled data from three randomized, double-blind trials (35,47,48) in which 245 children/adolescents as young as 3 years of age with newly or recently diagnosed epilepsy received 50 to 500 mg/day TPM as first-line monotherapy showed that the incidence of CNS effects, including neurobehavioral effects, was lower than with adjunctive therapy, even though the treatment periods were longer (median 8 months; treatment periods as long as 2.2 years) (159). The most common CNS

effects were headache, decreased appetite, and somnolence. In most children, body weight increased or did not change; among 13 patients who lost 10% or more of baseline body weight, 12 were adolescents (12 to 15 years old). No child/adolescent discontinued TPM monotherapy because of weight loss. As noted above, metabolic acidosis may be more likely to be symptomatic in children receiving TPM compared with adults.

Idiosyncratic Toxicity

No clinically significant abnormalities in hematologic or hepatic function were reported during clinical trials (60), and laboratory test values remained generally unchanged other than expected reductions in serum bicarbonate levels and increased chloride levels.

TPM has been associated with a rare ocular syndrome consisting of acute myopia with increased intraocular pressure (160). The syndrome occurs bilaterally and at any age, in contrast to primary narrow-angle closure, which is rarely bilateral and rare in individuals younger than 40 years of age. Symptoms occur early in TPM therapy (within the first month) and include acute (usually quite apparent) onset of blurred vision and/or ocular pain and/or red eyes. Ophthalmologic findings were bilateral and could include severe myopia, conjunctival hyperemia, shallowing of the anterior chambers, and increased intraocular pressure. Mydriasis was an inconsistent finding. Symptoms resolve upon prompt discontinuation of TPM treatment.

Decreased sweating (oligohidrosis) and an elevation in body temperature have been reported in association with TPM use; the majority of reports were in children. Most cases occurred after exposure to hot weather (161).

Weight Loss

Weight loss of 1.6 to 6.5 kg was reported in patients during the clinical trials. Patients who weighed most (>100 kg) before TPM therapy experienced the greatest weight loss (mean weight loss, 9.6 kg) compared with those who weighed least (<60 kg) before TPM treatment (mean weight loss, 1.3 kg). For patients receiving long-term TPM therapy, body weight reductions were most commonly noted during the first 3 months of treatment and peaked at 12 to 18 months. This was partially reversed in some patients who gained weight starting with the second year of therapy (27).

Pooled data from double-blind, placebo-controlled trials and open-label studies showed that 85% of 1319 adults with epilepsy receiving TPM as monotherapy or as adjunctive therapy lost weight; mean body weight change was 3.8 kg loss (4.6% of baseline body weight) (162). Weight loss was a function of baseline body weight, with greater losses occurring in patients with higher pretreatment weight. Weight loss was gradual, typically began during the initial 3 months of therapy, and peaked at 12 to 18 months. Weight loss was accompanied by positive changes in lipid profile, glycemic control, and blood pressure. In a prospective study evaluating weight changes associated with TPM treatment (116), more than 80% of adults lost weight without changes in diet or exercise; obese patients (BMI $\geq$ 30 kg/m^2) had the greatest degree of weight loss. Reduction of body fat mass represented 60% to 70% of the absolute weight loss. In these patients, weight loss was associated with improvements in glucose, insulin, and total cholesterol levels.

Weight loss has been observed in patients receiving TPM for conditions other than epilepsy. During two double-blind, placebo-controlled trials in patients with migraine (106,107), dose-related decreases in body weight were observed; the mean percent change in body weight compared with

placebo was significantly greater in patients receiving TPM. During three double-blind, placebo-controlled trials in patients with diabetic neuropathy, 18% to 40% had clinically significant weight loss (5% or more of baseline body weight) with TPM treatment (116). The observed improvement in diabetic control, measured as reduction in HbA1c levels, did not seem to correlate with TPM-induced weight loss.

CLINICAL USE

The initial randomized, controlled trials with TPM as adjunctive therapy identified TPM 200 to 400 mg/day as an appropriate target dose in adults with refractory epilepsy; subsequent studies have shown that many patients respond to TPM dosages of ≤200 mg/day. While gradual introduction improves tolerability, TPM can be added rapidly, if needed. Reducing the dose of concomitant AEDs as TPM is added also improves tolerability. In children receiving TPM as adjunctive therapy, the recommended daily dose is 5 to 9 mg/kg; the starting dose of 1 to 3 mg/kg/day can be increased in 1- to 3-mg/kg increments every 1 to 2 weeks.

As first-line monotherapy in adults with newly or recently diagnosed epilepsy, 100 mg/day is an appropriate target dose to initially assess patient response. It appears the optimal starting dose in adults is 25 to 50 mg/day, with weekly or biweekly increases of 25 to 50 mg/day. As initial monotherapy in children, the recommended dose is 3 to 6 mg/kg/day, using a starting dose of 0.5 to 1 mg/kg/day and incremental increases of 0.5 to 1 mg/kg at 1- or 2-week intervals.

ACKNOWLEDGMENTS

I would like to thank Michael D. Privitera, MD, Professor and Vice-Chair Neurology, Director, Cincinnati Epilepsy Center, Medical Director, UC Physicians—University of Cincinnati Medical Center, for his earlier excellent contributions to a previous-edition chapter. I would like to thank my wife, Susan M. Lippmann, MD, my partner in epilepsy and life for assisting with this publication. I would like to thank Caren Hein for her excellent administrative assistance.
