CHAPTER 64 VALPROATE

ANGELA K. BIRNBAUM AND SUSAN E. MARINO

HISTORICAL BACKGROUND

For more than 40 years (1), valproic acid or valproate (VPA) has been used in the treatment of epilepsy. Prior to 1990, it was regarded as one of the major antiepilepsy drugs (AEDs), distinguished from previous agents by its broad spectrum of activity against many seizure types in both children and adults (2,3) as well as by its relatively low sedative effect. In addition to being the first agent to be highly effective against several primarily generalized seizure types, such as absence, myoclonic, and tonic–clonic seizures, VPA was found to be effective in the treatment of partial seizures, Lennox–Gastaut syndrome, infantile spasms, neonatal seizures, and febrile seizures (4,5). Although VPA is also used for the treatment of conditions other than seizures, these indications will not be included in the present discussion. For the purpose of this chapter, epilepsy seizure nomenclature will be used according to the study cited and may not reflect the newer naming nomenclature.

CHEMISTRY AND MECHANISM OF ACTION

Valproic acid (MW 144.21; Fig. 64.1), a short-chain, branched fatty acid, is a colorless liquid with low solubility in water. Other forms include (i) sodium valproate (MW 166.19), a highly water-soluble, hygroscopic white, crystalline powder, and (ii) divalproex sodium, a complex composed of equal parts of VPA and sodium valproate (Fig. 64.1). The antiepileptic activity of VPA, demonstrated in several animal models (6,7), includes protection against maximal electroshock-induced seizures; seizures induced chemically by pentylenetetrazol, bicuculline, glutamic acid, kainic acid, strychnine, ouabain, nicotine, and intramuscular penicillin; and seizures induced by kindling (8). This broad spectrum of efficacy of VPA in animal models suggests that the agent is effective in both preventing the spread and raising the threshold of seizures. Although several effects of VPA have been demonstrated at the cellular level, the precise mechanism underlying its antiepilepsy effect has not been fully elucidated. Identified mechanisms include potentiation of γ-aminobutyric acid (GABA)ergic function, inhibition of γ-hydroxybutyric acid formation (9), inhibition of voltage-sensitive sodium channels (10), antagonism of NMDA receptor–mediated neural excitation (5,11), and inhibition of histone deacetylase (HDAC) (12) that may act to induce the GABA synthetic enzyme, glutamate decarboxylase (13,14). It is not known to what extent any of these actions contribute to clinical seizure protection by VPA.

ABSORPTION, DISTRIBUTION, AND METABOLISM

The main pharmacokinetic parameters of VPA are summarized in Chapter 44, Table 44.1. Different preparations of VPA are available, although not all are available in any given country. Oral preparations of VPA include VPA capsules, tablets, and syrup (immediate-release); enteric-coated tablets of sodium valproate or sodium hydrogen divalproate (divalproex sodium); divalproex sodium enteric-coated sprinkles; slow-release oral preparations; and valpromide (the amide of VPA). A parenteral formulation of sodium valproate for intravenous (IV) use is also available.

The bioavailability of oral preparations of VPA is virtually complete compared with that of the IV route (15). The purpose of the enteric coating of tablets is to prevent gastric irritation associated with release of VPA in the stomach. The rate of absorption of VPA after oral administration is variable, depending on the formulation. Administration of syrup or uncoated regular tablets or capsules is followed by rapid absorption and peak levels within 2 hours. Absorption from enteric-coated tablets is delayed but rapid. The onset of absorption varies as a function of the state of gastric emptying at the time of ingestion, and peak levels may be reached only 3 to 8 hours after oral ingestion of enteric-coated tablets (16–18) (Chapter 44, Figure 44.1). Therefore, in patients treated chronically with enteric-coated VPA, the trough level may occur later than after administration of non–enteric-coated formulations. The bioavailability of enteric-coated sprinkles of divalproex sodium was compared with that of VPA syrup in 12 children, with no difference noted between the two formulations (19). However, the average time to maximal VPA concentrations was longer for sprinkles (4.2 hours) than for syrup (0.9 hours). Diurnal variation in VPA concentrations of particular VPA formulations has been observed with the enteric-coated tablets resulting in nighttime drug concentrations of 30% to 40% of daytime values (20–26). The extended-release divalproex formulation does not seem to exhibit this variation after administration to healthy volunteers (27). Rectal preparations from the syrup and capsule formulations can be prepared and have been given to patients (28,29).

The volume of distribution of VPA is relatively small (0.13 to 0.19 L/kg in adults and 0.20 to

0.30 L/kg in children). VPA is highly bound to serum proteins; this binding appears to be saturable at therapeutic concentrations, with the free fraction of VPA increasing as the total concentration increases (30): 7% at 50 mg/L, 9% at 75 mg/L, 15% at 100 mg/L, 22% at 125 mg/L, and 30% at 150 mg/L. VPA unbound fraction decreases from 15% at maximum concentration to 9% at 45 mg/L when rapid infusion (infusions of VPA administered in <60 minutes) of IV VPA is given (31). Several factors including induction status, albumin concentration, and infusion rate can significantly affect VPA pharmacokinetics. Infusion of VPA at a rate up to 3 mg/kg/min produces predictable total VPA concentrations when hepatic induction status and albumin levels are considered. Unpredictable protein binding can also be seen in critically ill patients and after rapid administration of VPA. Four hospitalized children receiving doses of 8.3 to 15.4 mg/kg in <15 minutes had a fraction unbound of 45% (32). Monitoring of unbound drug concentration may be useful when protein-binding alterations are suspected.

The elimination half-life of VPA varies as a function of comedication. In the absence of inducing drugs, the half-life in adults is 13 to 16 hours (16,33), whereas in adults receiving polytherapy with inducing drugs, the average half-life is 9 hours (15). In children, the half-life is slightly shorter. Cloyd et al. (26) reported an average half-life of 11.6 hours in children receiving monotherapy and 7.0 hours in those receiving polytherapy. Newborns eliminate VPA slowly; the half-life in this population is longer than 20 hours (24). In vitro studies from human liver microsomes show no difference in the rates of valproate–glucuronide formation in microsomes from young versus elderly (>65 years of age) livers (34). Approximately 55% of elderly nursing home residents are maintained at total VPA concentrations below the adult therapeutic range for epilepsy of 50 to 100 mg/mL regardless of indication (35,36). The population clearance from a study of 146 (405 VPA concentrations) elderly nursing home residents (average age 78.5 years ±8.0 [SD]) was 0.843 L/hour (37). Apparent oral clearances in elderly nursing home residents are reported to be 27% lower in female residents, even after adjusting for weight, and 25% greater in residents using the nonsyrup formulation (37). Approximately 20% of elderly nursing home residents take VPA syrup (35). The lower clearances seen with the syrup formulation may be a function of the patient's pathophysiology rather than a difference in the bioavailability of the syrup formulation. There can be considerable variability in VPA concentrations within an elderly nursing home patient even when receiving the same dose; therefore, the interpretation of a single drug measurement needs to be used with caution (38).

Several enzymes (UDP-glucuronosyltransferases: UGTs, β-oxidation, and cytochrome P450: CYP) are predominantly involved in the metabolism of VPA. The most abundant metabolites of VPA are glucuronide and 3-oxo-VPA, which represent about 40% and 33%, respectively, of the urinary excretion of a VPA dose (23). Several UGTs—UGT1A3, UGT1A4, UGT1A6, UGT1A8, UGT1A9, and UGT1A10—have been identified in vitro to be involved in forming the acyl glucuronide conjugate (34,39–41). Two desaturated metabolites of VPA, 2-ene-VPA and 4-ene-VPA, have anticonvulsant activity that is similar in potency to that of VPA itself (22). Because there is delayed but significant accumulation of 2-ene-VPA in the brain and because it is cleared more slowly than VPA (21), the formation of 2-ene-VPA provides a possible explanation for the discrepancy between the time courses of VPA concentrations and antiepilepsy activity (20). It appears that 2-ene-VPA does not have the pronounced embryotoxicity (42) and hepatotoxicity (43) of 4-ene-VPA. Both are produced by the action of cytochrome P450 enzymes, which are induced by certain other AEDs (23,44). This may explain the increased risk for hepatotoxicity in patients receiving VPA concomitantly with these agents (45). However, elevation of 4-ene-VPA levels has not yet been found in patients with VPA hepatotoxicity, short-term adverse effects, or hyperammonemia (46).

Cytochrome CYP2C9*1 is the predominant catalyst in the formation of 4-ene-VPA, 4-OH-VPA, and 5-OH-VPA metabolites (75% to 80%) with CYP2A6 and CYP2B6 being responsible for the remainder of these reactions. CYP2A6 is involved in approximately 50% of the formation of 3-OH-VPA (47). Population pharmacokinetic studies indicate that knowledge of a patient's CYP2C9 and CYP2C19 genotype may aid in predicting a patient's response to VPA (48).

DRUG INTERACTIONS

Pharmacokinetic interactions with VPA fall into three categories, based on the following features: (i) the metabolism of VPA is sensitive to enzymatic induction; (ii) VPA itself can inhibit the metabolism of other agents; and (iii) VPA has a high affinity for serum proteins and can displace other agents or be displaced from proteins (49–51). Concomitant administration of enzyme-inducing drugs has been repeatedly shown to lower VPA levels relative to the dose (52). Carbamazepine (53–55) and phenytoin (55) lower VPA levels by one-third to one-half, or even more in children (56–58). When children receiving polytherapy discontinued treatment with other agents, VPA levels increased 122% after withdrawal of phenytoin, 67% after withdrawal of phenobarbital, and 50% after withdrawal of carbamazepine (59). In elderly nursing home residents, VPA clearance is increased to 41% in residents who are also taking phenytoin or carbamazepine (37). In contrast, levels of VPA are increased by coadministration of felbamate: 28% with felbamate 1200 mg/day and 54% with felbamate 2400 mg/day (60,61).

VPA affects the kinetics of other drugs either by enzymatic inhibition or by displacement from serum proteins. Phenobarbital levels have been found to increase from 57% (62) to 81% (63) after the addition of VPA. Levels of ethosuximide can also be raised by the addition of VPA, mostly in the presence of additional AEDs (64). Although VPA does not increase levels of carbamazepine itself, levels of the active metabolite carbamazepine-10,11-epoxide may double (65,66). Elimination of lamotrigine is markedly inhibited by VPA, resulting in a two- to threefold prolongation of the lamotrigine half-life (67). Although this is a competitive interaction that is likely to be rapidly reversible upon discontinuation of VPA, the inhibition seems to persist even at low VPA concentrations (68,69). A pharmacokinetic interaction occurs between VPA and phenytoin, partly because both agents have a high affinity for serum proteins. Displacement of one highly protein-bound drug by a second highly protein-bound drug can cause a reduction in total but not unbound drug concentrations and does not necessarily require a dose change (25). However, VPA also interferes with the metabolism of phenytoin resulting in a decrease in total and an increase in unbound phenytoin concentrations (i.e., VPA increases the free fraction of phenytoin) (70,71). Thus, in the presence of VPA, total phenytoin concentrations in the usual therapeutic range may be associated with clinical toxicity. In contrast to inducing AEDs, VPA is not associated with oral contraceptive failure (72); however, oral contraceptives may decrease VPA levels in women taking both compounds (73).

EFFICACY

VPA is a highly effective first-line agent for the treatment of generalized seizures, such as generalized absence, tonic–clonic, and myoclonic seizures (74). The indication for VPA when it was first released in North America in 1978 was for treatment of absence seizures. In patients with typical and atypical absence seizures, a reduction of spike-and-wave discharges was demonstrated (75–78). In two studies, comparison of VPA and ethosuximide for the treatment of absence seizures showed equal

efficacy for the two agents (79,80). It appears that absence seizures are more likely to be fully controlled when they occur alone than when they are mixed with another seizure type (59,81). Overall, VPA appears to be somewhat less effective against atypical or "complex" absence seizures than against simple absences (82,83). VPA can also be used effectively in patients with recurrent absence status (84).

VPA was found to be effective in the treatment of certain generalized convulsive seizures (85–88). Among 42 patients with intractable seizures, generalized tonic–clonic seizures were fully controlled in 14 patients by add-on VPA therapy (59). VPA was compared with phenytoin in 61 previously untreated patients with generalized tonic–clonic, clonic, or tonic seizures, and seizures were controlled in 82% of VPA-treated patients versus 76% of those treated with phenytoin (89). In another randomized comparison of VPA and phenytoin in patients with previously untreated tonic–clonic seizures, a 2-year remission was achieved in 27 of 37 patients receiving VPA and in 22 of 39 patients receiving phenytoin (88). Monotherapy with VPA was assessed in two studies of patients with primary (or idiopathic) generalized epilepsies (81). Among patients who had generalized tonic–clonic seizures only, complete seizure control was achieved in 51 of 70 patients (90) and in 39 of 44 patients (81), respectively. VPA monotherapy in children with generalized tonic–clonic seizures was also found to be highly effective (91).

VPA is often a first choice for most myoclonic seizures, particularly for those occurring in patients with primary or idiopathic generalized epilepsies (81,82,90). In a study of VPA monotherapy for primary generalized epilepsies, 22 patients had myoclonic seizures and 20 of the 22 had at least one other seizure type, either absence or tonic–clonic. The myoclonic seizures were controlled by VPA monotherapy in 18 of the 22 patients (81). Patients with juvenile myoclonic epilepsy have an excellent response to VPA (92), which remains an agent of first choice for this condition unless you are a woman of child-bearing potential. Benign myoclonic epilepsy of infancy also responds well to treatment with VPA (91). Some success has been achieved with VPA in patients with postanoxic intention myoclonus (92,93). A combination of VPA and clonazepam is often used to treat the myoclonic and tonic–clonic seizures associated with severe progressive myoclonus epilepsy (94).

Like all other AEDs, VPA is less effective in the treatment of generalized encephalopathic epilepsies of infancy and childhood, such as infantile spasms and Lennox–Gastaut syndrome. In a series of 38 patients with myoclonic astatic epilepsy, seven patients became and remained seizure free with VPA therapy and 50% to 80% improvement was achieved in one-third of patients (82).

Reports on the use of VPA for the treatment of infantile spasms include a small number of patients or patients receiving corticotropin and VPA simultaneously (95–97). Overall, there was a trend toward a better response with corticotropin, but the incidence and severity of side effects was lower with VPA. A retrospective study of VPA monotherapy in 30 patients with simple partial and complex partial seizures in whom previous drugs had failed showed a remarkable response (98). Seizure control was achieved in 12 patients, a >50% seizure reduction occurred in 10 patients, and only 9 patients showed no improvement. Comparison of VPA with carbamazepine or phenytoin showed little difference (99,100).

Mattson et al. (101) reported the most comprehensive controlled comparison of VPA and carbamazepine monotherapy for the treatment of partial and secondarily generalized seizures. Several seizure indicators, as well as neurotoxicity and systemic neurotoxicity, were assessed quantitatively. Four of five efficacy indicators for partial seizures were significantly in favor of carbamazepine, and a combined composite score for efficacy and toxicity was higher for carbamazepine than for VPA at 12 months, but not at 24 months. Outcomes for secondarily generalized seizures did not differ

between the two agents. Two studies—one comparing VPA and carbamazepine (102) and the other comparing VPA, carbamazepine, phenytoin, and phenobarbital (103)—were conducted in children. Equal efficacy against generalized and partial seizures was reported with all agents. Unacceptable side effects necessitating withdrawal occurred in patients receiving phenobarbital, which was prematurely eliminated from the study. VPA was also evaluated in 143 adult patients with poorly controlled partial epilepsy randomized to VPA monotherapy at low plasma levels (25 to 50 mg/L) or high plasma levels (80 to 150 mg/L) (104). The reduction in frequency of both complex partial and secondarily generalized tonic–clonic seizures was significantly higher among patients in the high-level group.

Several studies have demonstrated the efficacy of VPA in the prevention of febrile seizures (105–111). Based on risk–benefit ratio considerations, VPA cannot be recommended for this indication. A small group of newborns with seizures have also been treated with VPA administered rectally (112) or orally (24). Results were favorable overall. In newborns treated with VPA, a long elimination half-life (26.4 hours) and high levels of ammonia were reported (24).

ADVERSE EFFECTS

Neurologic Effects

A dose-related tremor is relatively common in patients treated with VPA. If it does not improve sufficiently with dosage reduction, propranolol may be tried (113). Drowsiness, lethargy, and confusional states are uncommon with VPA, but may occur in some patients, usually at levels >100 mg/L. There have also been case reports of reversible dementia and pseudoatrophy of the brain (114–116). Treatment with VPA has been associated with a somewhat specific and unique adverse effect, characterized by an acute mental change that can progress to stupor or coma (117,118). It is usually associated with generalized delta slowing in the electroencephalographic tracing. The mechanism is not known with certainty, but it is probably not caused by hyperammonemia or carnitine deficiency. This encephalopathic picture is more likely to occur when VPA is added to another AED, and it is usually reversible within 2 to 3 days upon discontinuation of VPA or the other AED. In addition, when compared with other AEDs, VPA can significantly lower, in a dose-related fashion, the IQ of children 3 years of age who have been exposed to VPA in utero (119). These findings have been extended to 6-year-old children who continued to demonstrate reduced cognitive abilities across a range of domains after exposure to VPA in utero (119). A population-based study of Danish children found that maternal use of VPA during pregnancy is also associated with increased risks of autism and autism spectrum disorder (120). Therefore, it is strongly recommended that VPA be avoided in women of child-bearing potential especially if they desire to become pregnant.

Gastrointestinal Effects

The most common gastrointestinal (GI) adverse effects associated with VPA use are nausea, vomiting, GI distress, and anorexia. These effects may be due, in part, to direct gastric irritation by VPA; the incidence is lower with enteric-coated tablets. Excessive weight gain is another common problem (121,122). This is not entirely attributable to increased appetite, and decreased β-oxidation of fatty acids has been postulated as a mechanism (123). Excessive weight gain seems to be less of a problem in children, and a recent report suggests that VPA is not associated with greater weight gain,

compared with carbamazepine, in children (83).

Fatal hepatotoxicity remains the most feared adverse effect of VPA (21,124–127). Two main risk factors have been clearly identified: young age and polytherapy (124). The risk for fatal hepatotoxicity in patients receiving VPA polytherapy is approximately 1:600 at younger than 3 years of age, 1:8000 from 3 to 10 years, 1:10000 from 11 to 20 years, 1:31000 from 21 to 40 years, and 1:107000 at older than 41 years of age. The risk is much lower in patients receiving monotherapy; it varies between 1:16000 (3 to 10 years of age) and 1:230000 (21 to 40 years of age) (124). No fatalities in patients receiving VPA monotherapy have been reported in certain age groups (0 to 2 years, 11 to 20 years, and older than 40 years of age) (124). Because a benign elevation of liver enzymes is common during VPA therapy and because severe hepatotoxicity is not preceded by a progressive elevation of liver enzymes, laboratory monitoring is of little value despite the fact that it is often performed routinely. The diagnosis of VPA-associated hepatotoxicity depends mostly on recognition of the clinical features, which include nausea, vomiting, anorexia, lethargy, and, at times, loss of seizure control, jaundice, or edema. One study indicates a possible protective effect of L-carnitine administration in cases of established VPA-induced hepatotoxicity (128). Among 92 patients with severe, symptomatic VPA-induced hepatotoxicity, 48% of the 42 patients treated with L-carnitine survived, as opposed to 10% of the 50 patients receiving similar supportive treatment without L-carnitine. The results suggested better survival with IV, rather than enteral, L-carnitine (128).

Another serious complication of VPA treatment is the development of acute hemorrhagic pancreatitis (129–133). Suspicion should be raised by the occurrence of vomiting and abdominal pain. Serum amylase and lipase are the most helpful diagnostic tests, and abdominal ultrasonography may also be considered.

Hematologic Effects

Hematologic alterations are relatively common with VPA therapy, but they seldom lead to discontinuation of treatment (134,135). Thrombocytopenia (134,136) can fluctuate and tends to improve with dosage reduction. In conjunction with altered platelet function (137,138) and other VPA-mediated disturbances of hemostasis (139,140), it may cause excessive bleeding. Therefore, the common practice of withdrawing VPA before elective surgery may be recommended despite the fact that several reports found no objective evidence of excessive operative bleeding in patients maintained on VPA therapy (141–143).

Hyperammonemia

Mild hyperammonemia is a very common finding in asymptomatic patients receiving chronic VPA therapy, particularly in those taking VPA along with an enzyme-inducing AED (144,145), and routine monitoring of ammonium levels is not warranted. Although hyperammonemia can be reduced with L-carnitine supplementation (146), there is no documentation that this is necessary or clinically beneficial (147). Chronic treatment with VPA, especially in polytherapy, tends to lower carnitine levels (148,149); however, a role for carnitine deficiency in the development of severe adverse effects of VPA has not been established. A beneficial effect of L-carnitine supplementation in acute VPA overdoses has been suggested (150,151), and a panel of pediatric neurologists has made recommendations for routine supplementation with L-carnitine in a subgroup of pediatric patients

being treated with VPA (152).

Reproductive Issues

In women, VPA has been reported to cause menstrual irregularities, hormonal changes such as hyperandrogenism and hyperinsulinism, polycystic ovaries, and pubertal arrest (153–157). An additional concern has been the possible association of VPA therapy, polycystic ovaries, and elevated testosterone levels (153–155,158). In a comparison of women treated with VPA, 21 with phenobarbital, 23 with carbamazepine, and 20 healthy untreated women, polycystic ovary prevalence, ovary volumes, and hirsutism scores did not differ among the groups (159). Epilepsy itself, other AEDs, and additional factors may be involved in the development of polycystic ovary syndrome (160,161). Treatment with VPA during the first trimester of pregnancy has been found to be associated with an estimated 1% to 2% risk of neural tube defect (159,162,163); a pharmacogenetic susceptibility has been suggested (164). Folate supplementation appears to reduce the risk (165), and a daily dose of at least 1 mg should be considered in all female patients of child-bearing age who are taking VPA. Further, a recent study from the European Surveillance of Congenital Anomalies reports that the use of VPA monotherapy during the first trimester was associated with significantly increased risks for six specific malformations: spina bifida, atrial septal defect, cleft palate, hypospadias, polydactyly, and craniosynostosis (166). Taken together with the finding that by age 3, children who have been exposed to VPA in utero are cognitively impaired compared to children who had fetal exposure to other AEDs supports the recommendation by Meador et al. that "VPA not be used as a first-choice drug in women of childbearing potential" (119).

Miscellaneous Effects

Excessive hair loss may be seen during treatment with VPA, and although the hair tends to grow back, it may become different in texture (167) or color (168). Facial and limb edema can occur in the absence of VPA-induced hepatic injury (169). Children may develop secondary nocturnal enuresis after initiation of VPA therapy (99,122,170–172). Hyponatremia (173) has been reported in one patient. The occurrence of rash with VPA therapy is very rare (174).

CLINICAL USE

An initial VPA dosage of approximately 15 mg/kg/d is recommended, with subsequent increases, as necessary and tolerated, of 5 to 10 mg/kg/d at weekly intervals. The optimal VPA dose or concentration may vary according to a patient's seizure type (175). Daily doses between 10 and 20 mg/kg are often sufficient for VPA monotherapy in patients with primary generalized epilepsies (59,81,89,90); children may require higher doses (63,82), whereas elderly nursing home residents may require lower doses (35). Dosages of 30 to 60 mg/kg/d (in children, >100 mg/kg/d) may be necessary to achieve adequate VPA levels in patients being treated concomitantly with enzyme-inducing agents. If therapeutic levels of VPA are to be achieved rapidly or if patients are unable to take VPA orally, the agent can be administered intravenously (176). This route has also been suggested for the treatment of patients with status epilepticus, with an initial dose of 15 mg/kg (at 20 mg/minute) followed by 1 mg/kg/h (177). A more rapid loading with an initial dose of 20 mg/kg has also been advocated, given at a rate of 33.3 to 555 mg/min (178) or ≤6 mg/kg/min. Rapid IV VPA

loading seems to be well tolerated (179).

Because of the short half-life of VPA, it is common to divide the total daily dose into two or three doses. However, the pharmacodynamic profile of VPA may explain why equally good results have been achieved with a single daily dose (82,180,181). In addition, the availability of an extended-release divalproex formulation makes once-a-day dosing even more appealing. The value of monitoring serum levels of VPA is limited. First, there is a considerable fluctuation in VPA levels because of the short half-life and variable absorption rate of the agent. Second, there seems to be a poor correlation between VPA serum levels and clinical effect, and the pharmacodynamic effect of VPA may lag behind its blood concentrations (81,182–185). Although the usual therapeutic range for VPA serum levels is 50 to 100 mg/L (350 to 700 μmol/L), levels up to 150 mg/L may be both necessary and well tolerated. In selected cases, and particularly during combination therapy with enzyme-inducing agents, VPA serum levels can be valuable, but a single measurement must be interpreted cautiously (186). Routine monitoring of liver enzymes and complete blood count with platelets is a common practice, but may be of little value. It may be more useful to perform these tests if unusual bruising or bleeding occurs or if there are any symptoms or signs of liver failure.

CHAPTER 65 VIGABATRIN

KELLY G. KNUPP AND ELIZABETH A. THIELE

HISTORICAL BACKGROUND

Vigabatrin (VGB) was initially synthesized in 1977 by Jung et al. (1), designed as a specific inhibitor of gamma-aminobutyric acid (GABA)-transaminase (GABA-T), the enzyme responsible for metabolizing GABA at the synapse. It was hypothesized that inhibiting GABA-T would then increase whole-brain levels of GABA, making it more available to its receptor site, thus increasing GABAergic inhibition. For decades prior to this, the role of GABA in seizure activity had been proposed by the apparent proconvulsant properties of compounds either inhibiting GABA synthesis or blocking its postsynaptic action, by the ability of drugs enhancing GABA-mediated inhibition to act as anticonvulsants in many animal models, and by the identification of abnormalities in the GABA receptor in certain genetically determined epilepsy animal models. Although several compounds have been developed over the last 30 years that function to modulate GABA-A–mediated inhibition via various mechanisms, VGB is the only drug that does so by specifically inhibiting GABA-T.

VGB was initially approved and marketed in the United Kingdom in 1989. Although the initial NDA for VGB in the United States was submitted in 1994 for adult patients with complex partial seizures (CPS), the medication was only approved for use in 2009. Since initial approval in 1989, over 1.5 million have been treated with VGB. Multiple clinical studies conducted around the world, including the United States, have established the efficacy of VGB in the treatment of refractory CPS and infantile spasms (IS).

GENERAL CHARACTERISTICS

VGB (4-amino-5-hexenoic acid or gamma-vinyl-GABA) is a structural analogue of GABA that contains a vinyl appendage (Fig. 65.1). It was designed to specifically and irreversibly inhibit GABA-T and is the only currently available drug with this mechanism of action. It may also stimulate GABA release (2). VGB is highly water soluble, only slightly soluble in ethanol and methanol, and insoluble in hexane and toluene. VGB is a white to off-white crystalline solid, with a molecular mass of 129.16 and a melting point of 171°C to 117°C. It exists as a racemic mixture of R(−) and S(+) isomers, which occur in equal proportions, and has no optical activity. The pharmacologic activity is thought to be associated only with the S(+) enantiomer, and the R(−) enantiomer is thought to be entirely inactive (3,4). The major pharmacologic effects are determined by effects of VGB on GABA-T half-life and activity rather than the drug itself.

PHARMACOKINETICS

Administration

Current formulations of VGB include 500-mg tablets and 500-mg powder packets or sachets. Following oral administration, VGB is almost completely absorbed, with peak VGB concentrations reached within 2 hours of administration of doses ranging from 0.5 to 3 g (3,5,6). VGB can be given at or between meals, as the presence or type of food does not have a significant effect on absorption and therefore should not influence clinical response.

Distribution

VGB is widely distributed throughout the body with a volume of distribution at steady state of 1.1 L/kg (7) and a half-life of distribution of 1 to 2 hours. Concentrations of VGB in the CSF are approximately 10% of blood levels (8). VGB has pharmacokinetics that is dose proportional and linear following single and repeated dosing (9,10). VGB does not bind to plasma proteins and does not cause hepatic induction of hepatic cytochrome P450–dependent enzymes (5,11). Passage of VGB across the human placenta occurs at a low level, comparable to other alpha-amino acids; the maximum amount of VGB that a nursing infant would be exposed to each day is approximately 3.6% of the R(−) and 1% of the S(+) enantiomer of the maternal VGB dose (12).

VGB has been shown to have minimal drug–drug interactions with other AEDs, ethanol, and oral contraceptive agents (13,14). VGB plasma levels are not affected by CBZ, clorazepate, primidone, or valproic acid. A modest reduction of about 20% in phenytoin plasma levels has been reported.

Metabolism

VGB is not metabolized, and is eliminated primarily as the parent drug by renal excretion. The half-life of VGB is approximately 5 to 8 hours, although it is thought that plasma levels do not correlate with clinical effect (7). Children have a lower AUC than do adults following VGB dosing, although renal clearance is similar. Therefore, children may require higher doses of VGB to achieve the same clinical effect as seen in adults.

SPECIAL POPULATIONS

Age

The renal clearance of VGB in healthy elderly patients (>65 years of age) was 36% less than that observed in healthy younger patients (10). The VGB half-life in elderly patients with reduced creatinine clearance is approximately twice that of normal healthy volunteers.

Gender

No gender-specific differences for the pharmacokinetics parameters of VGB have been observed.

Race

Limited data are available regarding race-specific variability in pharmacokinetics of VGB. A single report compared the pharmacokinetic parameters of Caucasian and Japanese patients; all parameters were similar except for mean renal clearance of VGB, which was slightly higher among the Caucasians.

Renal Impairment

As VGB is renally excreted, its pharmacokinetics is affected in the setting of renal impairment. Mean AUC values were found to increase 32% and 253% and $t_{1/2}$ increase 4.0 and 15.3 hours, respectively, in patients with mild to moderate (creatinine clearance of 40 to 79 mL/minute) and severe (creatinine clearance of 10 to 39 mL/minute) renal impairment (5).

EFFICACY

Now in clinical use for over 20 years, the efficacy of VGB in the treatment of partial-onset seizures and IS is well recognized.

Complex Partial Seizures

Numerous single-blind and double-blind studies have shown that VGB is effective in the treatment of intractable partial- onset seizures. A meta-analysis of the first 10 single-blind studies of VGB, which included a total of 352 patients, showed a 55.8% responder rate (patients with a >50% seizure reduction) (8,15–19).

Several European-conducted, double-blind, placebo- controlled, crossover studies also found VGB to be effective in the treatment of refractory partial-onset seizures. With doses ranging from 2 to 3 g/day as add-on treatment, the studies reported responder rates between 33% and 64%, with between 0% and 7% of patients becoming seizure free. In addition, two U.S. studies showed VGB to be effective as adjunctive treatment for intractable or refractory CPS. Both U.S. studies were placebo controlled and enrolled patients between 18 and 60 years of age; over 50% of patients in both studies were on two or more concomitant anticonvulsant medications at time of enrollment and had on average an over 20-year history of epilepsy, the majority having been treated with over three anticonvulsant medications. The first U.S. study, which included 182 patients, showed a 43% responder rate (compared to 19% placebo responder rate), including 5.4% of VGB-treated patients

who became seizure free (20). The second U.S. study, which enrolled 174 patients, evaluated doses of 1, 3, or 6 g/day of VGB, with significant reductions in seizure frequency seen in the two higher doses with a 51% responder rate in the VGB 3 g/day group and 54% responder rate in the VGB 6 g/day group (21). During the last 8 weeks of the study, 9.3% and 12.2% of patients in the 3 and 6 g/day groups, respectively, were seizure free, compared with no patients in the placebo-controlled or the VGB 1 g/day groups. Efficacy was also seen relatively early in the study, with a significant reduction in seizures seen after 14 days of treatment.

Open-label trials of VGB in children with mixed seizure types have shown similar efficacy of VGB in CPS as the adult studies (22,23), myoclonic seizures appeared to be exacerbated.

Infantile Spasms

The efficacy of VGB in the treatment of IS has been appreciated for over 20 years. The initial report of an uncontrolled study of VGB in 70 patients with IS in 1991 showed a 68% responder rate in infants with refractory IS with 71% of those with IS due to tuberous sclerosis complex (TSC) becoming seizure free (24). The effectiveness of VGB as a monotherapy treatment for IS was established in three controlled studies, including one conducted in the United States and two outside the United States, one of which was restricted to the treatment of IS due to TSC (25–27). In all three studies, cessation of IS was observed, with onset of efficacy between 2 and 4 weeks. The U.S. study, which was the largest study with 221 infants completing the study, found VGB effective across etiologies of IS and found that doses of >100 mg/kg/d were more effective than lower doses (25). In addition, several uncontrolled studies have examined the efficacy of VGB in IS, finding between 38% and 76% of infants having cessation of spasms (28–31). The UK Infantile Spasm Study (UKISS) compared the efficacy of VGB to prednisolone and ACTH in IS due to etiologies other than TSC; at 2 weeks of treatment, 54% of those on VGB had experienced cessation of spasms compared to 73% receiving hormonal treatment (30). On follow-up analysis at 12 to 14 months, 75% of those treated with VGB continued to be spasm free compared to 76% receiving hormonal treatment (31). An American Academy of Neurology practice parameter published in 2012 found that VGB "may be useful for short-term treatment of IS" (32). A meta-analysis of 11 randomized controlled trials in IS found VGB to be as effective as other treatments, namely ACTH and steroids, in the treatment of IS (33).

SAFETY

Adverse Events

Overall, VGB is well tolerated but can be associated with adverse events (AEs). The most frequently noted AEs in clinical trials for CPS and in clinical use included fatigue and somnolence; dizziness, nystagmus, tremor, headache, weight increase, blurred vision, diarrhea, and irritability can also be seen. Serious AEs were also noted in the controlled trials and included visual field defects (VFDs) (discussed below), status epilepticus, and psychiatric complaints including most commonly depression, but also confusion, aggression, insomnia, irritability, suicidal ideation, and suicide attempt. In clinical trials for IS, most common AEs included upper respiratory tract infection, otitis media, pyrexia, viral infection, irritability, somnolence, sedation, vomiting, constipation, pneumonia, diarrhea, insomnia, and rash. Serious AEs also were seen in the IS studies, most commonly status

epilepticus and pneumonia.

Chronic Toxicity

Intramyelinic Edema

Studies in animals revealed that treatment with VGB could be associated with intramyelinic edema (IME), or edema occurring within the myelin sheath (34,35). This finding, observed in rats and dogs but not monkeys, is characterized histopathologically by microvacuolation of specific regions of the brain, predominantly within the white matter.

IME was found to develop within several weeks of VGB treatment, stabilize without further progression, and resolve within 12 to 16 weeks after drug discontinuation. No residual histopathology was observed following drug discontinuation in dogs; however, rats retained swollen axons as well as foci of microscopic mineralization in the cerebellum. Further characterization of VGB-related IME identified both evoked potentials as well as MRI as sensitive noninvasive techniques to diagnose IME in rats and dogs. These studies also were used to support the absence of IME in monkeys and humans. Monkeys were treated with VGB at doses up to 300 mg/kg/d, which provided maximal plasma concentrations of 38 μg/mL, for up to 6 years to characterize possible toxicities; evaluation after 16 months of treatment did not yield conclusive evidence of IME. This dosing and plasma levels were consistent with that of infants and young children at a dosing of 50 mg/kg/d (36).

Additional studies to further characterize VGB-related IME in rodents included a juvenile toxicity study to evaluate the effects of VGB treatment on the physical and behavioral development of rats compared to controls (37). Microscopic evaluation of animals revealed mild vacuolar changes within the neuropil in select brain regions following VGB treatment at 50 mg/kg/d. Most affected brain regions included gray matter in the midbrain tegmentum, substantia nigra, dorsal subiculum, deep cerebellar nuclei, posterior thalamus, basal forebrain, and medulla oblongata. Additional although significantly less abundant vacuoles were also seen in some white matter tracks, including the medial longitudinal fasciculus and the medial forebrain bundle. Although it was not possible to determine which cell type was vacuolated, it was felt that the neuronal cell bodies, blood vessel endothelium, and perivascular astrocytic end processes were not affected. The authors felt that although the morphologic appearance was consistent with IME seen in older rodents, the distribution of involvement was different in the younger animals as it was found predominantly in subcortical gray matter. The behavior and development of these animals were evaluated by a variety of observational and standardized testing; there was no evidence of significant adverse developmental effects of these pathologic findings. Reproductive and ocular development were also assessed and not found to be significantly affected by the pathologic changes; however, the VGB-treated animals receiving higher doses of VGB (15 and 50 mg/kg/d) were found to have significant reductions in food intake and growth.

Subsequently, ultrastructural characterizations of these changes were performed using electron microscopy that showed an evolution of vacuoles, which were found to begin as splits of myelin sheaths along the intraperiod line (38). These initial splits in the myelin sheaths then expanded and evolved into large, fluid-filled, membrane-rich vacuoles. Lesions in the cerebellum were found to appear prior to those in the reticular formation and more rostral brain regions. The distribution of changes appeared to vary with age, species, and possibly timing and duration of treatment, although

the process appeared limited to myelinated nerve fibers or axons. Changes in adult rats were characterized by vacuoles in large white matter regions of the brain; neonatal and juvenile rats instead had lesions in white matter fibers traversing in or near the gray matter.

Following these observations, significant efforts were made to see if VGB treatment–related IME occurred in humans. Studies involved review of data obtained during several VGB clinical trials over a 15-year period of time, including review of effects of VGB treatment on brain MRI and evoked potentials. In addition, surgical brain and autopsy samples of VGB-treated patients were evaluated histopathologically for evidence of IME. In an estimated 350,000 patients' years of VGB exposure (correlating to approximately 175,000 patients treated for 2 years at an average daily dose of 2 g), no definite evidence of VGB-related IME was identified (39).

However, Pearl et al. (40) reported the initial observation of MRI T2 signal abnormalities involving the deep gray nuclei in 3/15 young children treated with VGB. Subsequent reports describe similar findings occurring in 20% to 30% of infants treated with VGB for IS (41–43). The characteristic MRI T2 signal changes seen involve the basal ganglia, thalamus, dentate nucleus, brain stem, and cerebellum. On diffusion-weighted imaging, apparent diffusion coefficient maps also suggested restricted diffusion in these regions. These changes appeared to resolve following drug discontinuation, dosage reduction, and also with continuation of drug. Risk factors for developing these MRI signal changes during VGB therapy are thought to include age (since observed during treatment for IS but not seen in older children or adults) and VGB dose (since changes are more frequently seen in infants on VGB doses of 150 mg/kg/d and higher). There are isolated case reports suggesting extrapyramidal symptoms in rare patients with these MRI findings (44), but further work is required to establish a clear association. It is unclear how these signal changes relate histopathologically to VGB-related IME well characterized in animal models, but they are thought to likely represent similar mechanisms.

Visual Field Defects

VGB treatment is associated with possible development of a VFD, typically characterized by a bilateral, concentric constriction of the peripheral visual fields. First reported in 1997 (45), this VGB-related VFD has now been well characterized by numerous studies providing understanding regarding the pathophysiology of the VFD as well as incidence, prevalence, and functional impact of the VFD as well as most effective methods to diagnose and monitor the VFD (46–49). The VGB-related VFD has been described as typically a slowly progressive bilateral concentric peripheral constriction of visual fields, which many studies have found to be more marked nasally than temporally. Central vision and color vision are spared.

Pathophysiology.

The retina has been identified as the site of injury in VGB-related VFD via nonclinical studies as well as electroretinography (ERG) studies in humans (50). Visual evoked potentials and brain imaging have demonstrated that the optic nerve and central visual pathways are not involved. ERG studies in humans have suggested that the postreceptor cone responses of the inner retina are most affected by VGB treatment, which has been supported by ophthalmoscopic identification of nerve fiber atrophy in some VGB-treated patients and abnormal nerve fiber layer thickness measurements by optical coherence tomography (OCT) (51,52). However, a single postmortem examination of human retina following VGB treatment showed cell loss in all retinal layers (53).

The pathophysiologic mechanisms of these changes and the related VFD are unknown, although several hypotheses have been proposed. One hypothesis suggested that since VGB is more effectively transported into the retina than the brain, the resulting levels of GABA could contribute to the retinal toxicity (54). Subsequent studies have suggested a possible role for aberrant protein kinase C-alpha activity (PKC-alpha) after identifying VGB dose–related changes in translocation of the enzyme in rod bipolar cells as well as a significant decrease in the number of PKC-alpha–labeled rod bipolar cells in VGB-treated animals (55). Most recently, the effects of VGB on taurine levels were investigated given the VFD similarities between VGB treatment and those characterized with taurine deficiency (56). The authors found significant reductions in taurine levels in VGB-treated animals compared to controls as well as in VGB-treated infants. Taurine supplementation led to diminished retinal toxicity in both rats and mice. Human clinical trials are currently underway to explore the possible role of taurine supplementation to reduce the risk for retinal toxicity.

Clinical Features.

The actual prevalence and incidence of VGB-related VFD are difficult to determine due to limited data sets and study design; however, they are thought to be influenced by age of the patient and extent of exposure to VGB (including dose and duration of treatment or cumulative VGB exposure). There is a likely 25% to 50% prevalence of VFD in adults, a 15% prevalence in children, and a range of 15% to 31% prevalence in infants (57). It is believed that the VGB-related VFD most likely occurs with more prolonged drug treatment, although there are limited prospective data. The earliest identification of a VFD in adults is after 9 months of treatment, with a mean time to onset of 4.8 years. The earliest identification of a VFD in children is after 11 months of treatment, with a mean time of onset of 5.5 years. In infants, the earliest onset of a presumed VGB-related retinal abnormal detected by ERG is 3.1 months. There are rare case reports of VGB-related VFD occurring in adults with <6 months of treatment. The literature also has varying estimates of the severity of the VGB-associated VFD, although most agree that it is usually mild and asymptomatic. However, severe visual peripheral field constrictions (defined as <30 degrees of retained temporal field or <60 degrees of binocular field) can occur (“tunnel vision”), and occur in 2% to 40% of patients. Although it is possible that the VFD can progress, it typically remains stable and may improve, although not normalize following drug discontinuation. Progression of the VFD following drug discontinuation cannot be ruled out, but available evidence suggests that it is unlikely for this to occur.

Clinical Assessment.

Standard methods for assessing visual fields in adults and older children include Goldmann kinetic perimetry and Humphrey’s static automated perimetry. Both are sensitive and specific enough to establish baseline visual field function and to monitor for possible treatment-related effects on peripheral function. Kinetic perimetry is less reliable in children <9 years of age and in the neurologically impaired population.

ERG is an electrophysiologic measurement of retinal function that can also be used to assess for possible VFD, especially in infants, young children, and others not able to cooperate with visual perimetry testing. Testing often requires sedation or anesthesia in infants, young children, and impaired individuals, which dramatically limits access. The 30-Hz flicker response component of the ERG is thought to be the most predictive of the presence and degree of severity of VGB-induced VFD (58,59). Other measures, namely b-cone amplitude, are also thought to be measures of VGB toxicity.

However, the exact relationship between these ERG findings in infants and subsequent visual field abnormalities has not firmly been established.

OCT is a recently developed technology that shows great promise for monitoring for possible VGB-induced VFD, although further studies are needed to better characterize its sensitivity and specificity.

Teratogenicity

Limited data are available on the teratogenic effects of VGB therapy in animals, except for a possible increased incidence of cleft palate in rabbits receiving a high dose, and possible mandibular and maxillary hypoplasia, arched palate, cleft palate, limb defects, and exophthalmia in the TO mouse after receiving high doses (300 to 450 mg/kg) (60). Similar to other AEDs, VGB has a class warning against use in pregnancy due to inadequate evidence of possible human teratogenic effects.

CLINICAL USE

Administration

The daily adult dose of VGB used in most clinical trials and reports is between 2 and 3 g/day, with 3 g accepted as an optimal adult dose. Higher doses can improve efficacy, such as the U.S. double-blind study that employed 6 g/day; however, higher doses have also been shown to be associated with increased side effects (21). If clinical response is not achieved at a dose of 3 g/day, consideration should be given to discontinuation of the medication, particularly given the risk of VGB-related VFD. In infants and children, dosing of VGB is similar to other medications, and calculated on a mg/kg/day basis. VGB is frequently titrated up to 100 to 150 mg/day in b.i.d. dosing as needed for seizure control. Although higher doses may be effective in some infants being treated for IS, caution should be used given the probable increased risk both of VGB-related VFD as well as VGB-related MRI T2 signal changes.

Titration

In order to minimize side effects, particularly psychiatric or behavioral difficulties, gradual titration of the medication is suggested for both adults and infants and children.

Discontinuation

Efficacy of VGB is usually seen within the first 3 months of treatment, earlier for IS. Should the medication not prove effective or tolerated, it should be discontinued. VGB should be tapered slowly to minimize possibility of rebound seizures, including status epilepticus, and of significant behavioral abnormalities. Discontinuing VGB over a period of 1 to 2 months is usually well tolerated.

The optimal duration of VGB treatment if effective is not clear, particularly given the possibility that VGB-related VFD increases with cumulative VGB exposure. Typically, infants being treated for IS have continued on the medication for 1 year; currently, the long-term efficacy of shorter duration treatment is being evaluated.

Laboratory Monitoring

Although assays to measure VGB levels in blood and CSF are available, they are not felt to be clinically useful as blood level has not been shown to correlate with clinical effectiveness. Routine blood monitoring of blood counts and hepatic enzyme levels are not recommended as VGB has not been shown to have a significant effect on these values. Due to limited drug–drug interactions with other AEDs, routine AED levels are also not recommended unless clinically indicated.

Clinical Monitoring

Due to the risk of VGB-related VFD, clinical monitoring of visual function is important. In adults, visual field perimetry should ideally be obtained at baseline and subsequently at regular intervals throughout the duration of treatment. Should abnormalities appear, consideration should be given to discontinue VGB treatment based on a risk–benefit assessment with the patient. In infants, young children, and those who are neurologically impaired and not able to cooperate with perimetry, visual fields should be assessed at baseline by confrontational testing. Repeat confrontational testing should be performed at 3-month intervals for the duration of treatment. Ideally, infants should also be followed by experienced pediatric ophthalmologists and by ERG, although access to these services is not always readily available, and should not delay treatment. Should abnormalities appear, consideration of discontinuation of VGB should also be considered, with careful risk–benefit assessment of continued treatment, especially in the context of VGB treatment for IS. In the United States, all patients are mandated to enter a patient registry as a requirement of FDA approval that established a Risk Evaluation and Mitigation Strategy to reduce the risk of vision problems and assess risk–benefit analysis for different populations. As part of this registry, ophthalmologic evaluation is required at 3-month intervals throughout the duration of VGB treatment in infants and adults due to the risks of retinal toxicity.

CONCLUSION

VGB has been shown to be an effective AED in a wide variety of seizure types affecting both adults and children, particularly refractory CPS and IS. It has a unique mechanism of action from other available AEDs and is generally well tolerated. However, VGB-related VFD is a possible and possibly significant side effect of the medication. Therefore, patients started on VGB should be closely monitored for visual field changes. VGB appears to be particularly effective in the treatment of IS, a catastrophic pediatric epilepsy syndrome with limited effective treatments available. In this setting, the use of VGB should be strongly considered, as the risks of the impact of uncontrolled IS on subsequent neurocognitive development may outweigh the risks of possible VGB-related VFD. The MRI T2 signal changes seen in infants treated with VGB are another possible risk of the medication. However, no significant clinical changes have been seen with these changes, and further studies are needed to understand any possible significance that could affect continuation of VGB treatment.

CHAPTER 66 Zonisamide

TIMOTHY E. WELTY

Zonisamide was first synthesized in Japan. In the early 1980s, clinical trials of zonisamide were initiated in the United States. Due to reports of nephrolithiasis in patients receiving active drug, further development in the United States was halted. Development of zonisamide continued in Japan, and the drug was approved for marketing in Japan in 1989. Additional studies in Europe and the United States were initiated with approval for marketing granted in the United States in 2000. Zonisamide is an antiepileptic drug (AED) that appears to have broad activity in various seizure types and epilepsy syndromes.

CHEMISTRY

Zonisamide is classified as a sulfonamide AED that is a 1,2-benzisoxazole derivative and is the first compound from this group of chemicals to be developed as an AED. It is unrelated chemically to other AEDs (Fig. 66.1). It is moderately soluble in water (0.8 mg/mL) and has a pK_a of 10.2. Zonisamide is a white powder and has a molecular weight of 212.23.

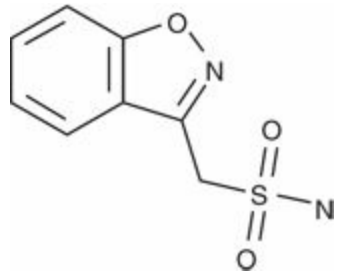

Figure 66.1. Zonisamide.

MECHANISM OF ACTION

There are several pharmacologic effects of zonisamide that may be responsible for its activity as an AED. Results from several studies demonstrate the most likely mechanism of action for zonisamide to be through blockade of T-type calcium channels, inhibition of slow sodium channels, and possibly inhibition of glutamate release (1–5). Zonisamide differs from ethosuximide in that zonisamide does not inhibit G protein–activated inwardly rectifying K^+ channels (6). Zonisamide does have activity as a carbonic anhydrase inhibitor, but this is not responsible for its antiepileptic activity (7). In animal models, zonisamide demonstrates broad spectrum as an AED (8–11). Beside its antiepileptic activity, zonisamide has some effect as a neuroprotective agent in ischemia (12,13). Additionally, other pharmacologic activities may make zonisamide useful in the treatment of Parkinson disease and essential tremor (14,15).

PHARMACOKINETICS

Absorption

Zonisamide is rapidly absorbed following oral administration with maximum concentrations achieved within 2 to 5 hours (16). The absolute bioavailability in humans is unknown, due to the lack of a parenteral product. Nagatomi et al. (17) measured the absolute bioavailability of orally administered zonisamide at 81% in rats. In the same study, the bioavailability of zonisamide in a rectal preparation was 96%. Zonisamide is metabolized by cytochrome P450 3A4 (CYP 3A4) (18). Intestinal CYP 3A4 may account for decreased bioavailability of the oral preparation.

Distribution and Protein Binding

Like many sulfonamide drugs, zonisamide has a dose-dependent decrease in volume of distribution (V_d/F) (19). The volume of distribution for a 200-mg dose is 1.8 L/kg and for an 800-mg dose is 1.2 L/kg. Saturable binding to erythrocytes, especially to intracellular carbonic anhydrase, is the most likely explanation for this phenomenon (20–22). Additionally, 40% to 60% of zonisamide is bound to plasma proteins, especially albumin (22,23).

Therefore, zonisamide is concentrated in the erythrocytes compared to plasma. With saturable binding to erythrocytes, the whole blood zonisamide concentration is nonlinear as the dosage increases. However, the plasma zonisamide concentration is linear with increased doses (16). Care must be taken in laboratory analysis and interpretation of zonisamide concentrations. Results should be identified as coming from whole blood or plasma.

Metabolism and Clearance

Following oral administration, the half-life ($t_{1/2}$) of zonisamide is estimated at 50 to 69 hours (16,24). Apparent oral clearance (Cl/F) following single and repeated oral doses is 0.6 to 0.71 L/hour (24). Less than 30% of zonisamide is eliminated unchanged in the urine, and most of the drug undergoes extensive hepatic metabolism (25). The relatively long $t_{1/2}$ and slow clearance allow for once-daily dosing of zonisamide.

Early studies of the pharmacokinetics of zonisamide suggested that concentrations increased in a nonlinear relationship to doses (19,26). Following an 800-mg dose, zonisamide clearance was 22% lower than clearance estimates following 200- and 400-mg doses. Clearance estimates at steady state with doses ranging from 400 to 1200 mg daily were 40% lower than those seen following a single 400-mg dose (16,27). One study showed steady-state zonisamide concentrations to be higher than predicted from single-dose data, but steady-state plasma concentrations did increase in a linear relationship to daily dose (28). These observations were considered to be related to the saturable, preferential binding of zonisamide to erythrocytes. However, an analysis of zonisamide doses and concentrations in children using a nonlinear mixed- effects model and population pharmacokinetic methodology demonstrated dose-dependent, Michaelis–Menten pharmacokinetics of zonisamide with a mean V_{max} of 27.6 mg/d/kg and K_m of 45.9 µg/mL (29). Because the V_{max} is well above the typical range of daily zonisamide doses, it is unlikely that the nonlinear nature of zonisamide clearance will profoundly impact clinical practice.

The major metabolite of zonisamide is 2-sulfamoylacetylphenol (SMAP), formed under anaerobic conditions by liver microsomal enzymes (18,30,31). The formation of SMAP appears to be primarily through cytochrome P450 3A4 (CYP 3A4) (18,30). In these studies, metabolism of zonisamide to SMAP was inhibited by cimetidine and ketoconazole, known CYP 3A4 inhibitors. Zonisamide is metabolized to a much lesser extent by CYP 2C19 and CYP 3A5 (32). Studies of the effect of genetic polymorphisms on zonisamide metabolism have shown a 16% to 30% reduction in clearance in individuals who were CYP 2C19 heterozygous extensive metabolizers or homozygous poor metabolizers compared to homozygous extensive metabolizers (33). The clinical implications of this observation are unclear.

Serum Concentrations and Doses

The manufacturer's recommended dose for adults is 300 to 400 mg daily, but doses of 600 mg daily have been used in clinical trials (34). Doses above 400 mg have not consistently been associated with increased efficacy. The recommended doses of zonisamide are typically associated with steady-state plasma concentrations of 10 to 38 µg/mL (24,29,35). However, a relationship between concentration and response has not been established. Other investigators have suggested that concentrations >30 µg/mL are associated with increased adverse effects (19,28). Therefore, it may be advisable to maintain zonisamide concentrations <30 to 40 µg/mL. The pharmacokinetics and dosing of zonisamide are summarized in Table 66.1.

Table 66.1 Summary of Zonisamide Pharmacokinetics and Dosing

Parameter	Value
Oral bioavailability	81%[a]

[b]Volume of distribution is inversely related to dose, due to saturable binding to erythrocytes.

[c]Additionally, zonisamide is highly and preferentially bound to erythrocytes.

[d]These are typical concentrations observed with usual doses. A relationship between concentrations and response has not been established.

[e]Higher doses have been used in clinical trials.

Special Populations

Pediatrics

No formal pharmacokinetic studies have been done in children. In a study of zonisamide for infantile spasms by Suzuki et al. (36), daily doses of 4 to 5 mg/kg yielded plasma concentrations of 5.2 to 16.3 µg/mL. Additional work by this group substantiated these findings with zonisamide doses of 4 to 12 mg/kg/d producing plasma concentrations of 5.2 to 30 µg/mL (37). Table 66.2 summarizes typical

mean plasma concentrations related to dose and age. A comparison of pharmacokinetic parameters derived from population data in children and adults shows a similar volume of distribution but more rapid clearance of zonisamide in children (29,39). Thus, children appear to require larger doses of zonisamide, based on body weight, to achieve plasma concentration similar to those seen in adults (40).

Table 66.2 Mean Zonisamide Plasma Concentrations Related to Age and Daily Dose (38)

Age (years)	Mean daily dose (mg/kg)	Mean plasma concentration (µg/mL)
>16	5.9	20.0
7–15	7.1	20.7
2–6	8.8	19.9
≤1	8.6	19.6

Three case reports have provided some documentation regarding transfer of zonisamide across the placenta and into breast milk. Kawada et al. (41) measured zonisamide concentrations in umbilical cord blood, infant blood, and maternal blood of two infants born to mothers taking zonisamide for epilepsy. In these infants, zonisamide concentrations were 92% of that in maternal blood. Kawada et al. also measured zonisamide concentrations in the breast milk of these mothers, showing these concentrations to be 41% to 57% of maternal plasma concentrations. In a separate case, evaluating zonisamide concentrations in breast milk to 30 days postpartum, Shimoyama et al. (42) observed breast milk concentrations to range from 81% to 100% of maternal plasma concentrations. It appears that zonisamide readily crosses the placenta. Zonisamide also appears in breast milk at concentrations similar to maternal plasma concentrations. No clinically important adverse effects related to zonisamide were documented in these case reports.

Pregnancy

A study of clearance of multiple AED, including zonisamide, in pregnant women demonstrated that changes in clearance are highly variable between women and between pregnancies. In general, doses increased during pregnancy. It is recommended that serum concentrations of zonisamide be closely monitored during pregnancy and appropriate dosage adjustments made (43).

Renal Failure

A single-dose study of zonisamide in individuals with moderate renal failure (creatinine clearance >0.6 L/hour) did not demonstrate any difference in pharmacokinetic parameters compared to normal individuals (44). Studies in severe renal dysfunction and multiple-dose studies in renal failure have not been reported.

DRUG INTERACTIONS

Because zonisamide is primarily metabolized through CYP 3A4 and to a lesser extent by CYP 2C19, it is potentially prone to drug–drug interactions involving these enzyme systems. Several interactions have been studied in animals and in humans (Table 66.3). However, the exact clinical implications of

these interactions are poorly documented.

Table 66.3 Drug Interactions with Zonisamide

Reduce zonisamide metabolism	Increase zonisamide metabolism	Variable effect on zonisamide metabolism
Cyclosporin A	Phenytoin	Carbamazepine
Ketoconazole	Phenobarbital	
Dihydroergotamine	Primidone	
Triazolam		
Diazepam		
Erythromycin		

Influence of Other Drugs on Zonisamide

Using in vitro studies of the CYP 3A system, Nakasa et al. (32) showed that cyclosporin A, ketoconazole, dihydroergotamine, and triazolam profoundly inhibit zonisamide metabolism. These drugs reduced zonisamide metabolism by 85% to 95% compared to control. Other known inhibitors of CYP 3A, diazepam, terfenadine, erythromycin, and lidocaine did not produce a marked reduction in metabolism. The percent reduction in metabolism with these agents ranged from 35% to 45%. Clinical correlates to these findings have not been documented, so recommendations for dosage adjustments in patient care are not available. However, patients receiving known inhibitors of CYP 3A may require lower doses of zonisamide to reduce the risk of adverse events.

Inducers of CYP 3A have been shown to increase the metabolism of zonisamide (32). Phenytoin and carbamazepine have been shown to induce zonisamide metabolism, with phenytoin possibly having a greater influence than did carbamazepine (45,46). In a study of 12 patients receiving phenytoin or carbamazepine concomitantly with zonisamide, the mean oral clearance (Cl/F) of zonisamide was 33.9 mL/h/kg with phenytoin and 20.6 mL/h/kg with carbamazepine (45). However, some researchers have observed inhibition of zonisamide metabolism by carbamazepine (32). Other known inducers of hepatic metabolism, especially phenobarbital and primidone, can also increase the metabolism of zonisamide (16). When zonisamide is used in combination with known CYP 3A inducers, doses of zonisamide may need to be increased to achieve seizure control. In the case of carbamazepine, care must be taken to determine if induction or inhibition is predominant in a given patient and zonisamide doses adjusted accordingly.

Zonisamide Influence on Other Drugs

Studies with zonisamide have shown that it does not induce or inhibit hepatic enzymes (47,48). A study of zonisamide's effects on ethinyl estradiol–norethindrone oral contraceptives demonstrated no alteration of hormonal effect or loss of contraceptive efficacy (49). A survey of interactions between zonisamide and cancer chemotherapy agents demonstrated no known interactions (50). It appears that zonisamide does not cause clinically significant alteration of the pharmacokinetic disposition of other drugs.

Drug–Food Interactions with Zonisamide

As a substrate for CYP 3A4, zonisamide is a candidate for drug–food interactions. Within the intestinal wall, are high concentrations of CYP 3A4 that can metabolize drugs before they are absorbed into systemic circulation. Several foods, especially grapefruit juice, lime juice, and Seville orange juice, contain substances that inhibit the activity of intestinal CYP 3A4. When these foods are eaten with drugs that are metabolized by CYP 3A4, there is increased absorption of the drug and a potential for adverse effects. Although this potential interaction with zonisamide has not been documented, it should be of concern. In a study of rectal administration (a route that bypasses intestinal CYP 3A4) of zonisamide, Nagatomi et al. (17) consistently demonstrated increased bioavailability and absorption of zonisamide.

CLINICAL TRIALS

Clinical studies of zonisamide have evaluated its use in several different types of epilepsy and epilepsy syndromes. Additionally, zonisamide has been used extensively in Japan and has gained increasing use in the remainder of the world. Despite this history, there have been no direct comparisons of zonisamide to other AEDs in specific seizure types. The best published comparison has been in two meta-analyses of clinical trials of other newer AEDs, including zonisamide (51,52).

Focal-Onset Epilepsies/Partial Seizures

Clinical studies of zonisamide have evaluated its use in several different types of epilepsy and epilepsy syndromes. The best published comparisons are in meta-analyses of clinical trials of other newer AEDs, including zonisamide (51–54). In the first study, Marson et al. (51) evaluated the odds ratio of zonisamide producing a ≥50% reduction in seizure frequency compared to placebo. Combining data from two clinical trials, zonisamide was shown to be significantly better than was placebo in controlling seizures. In a second meta-analysis, Marson et al. (52) identified the five most common adverse effects patients on zonisamide experienced. In a study designed to compare intention to treat to last observation carried forward methodology, zonisamide had a 3% seizure-free rate compared to 0.8%, 2.6%, 7.1%, and 1.4% for lamotrigine, oxcarbazepine, levetiracetam, and pregabalin, respectively (53). A Cochrane review of zonisamide for refractory partial epilepsy concluded that it is effective as adjunctive therapy in patients who have failed other pharmacotherapy (54).

Several clinical trials of zonisamide for partial seizures have been published (27,28,55–59). Each of these studies demonstrated that zonisamide was significantly more effective than was placebo in reducing seizures. For adults, a reduction in seizures occurs with doses ranging from 100 to 500 mg/day, and increasing doses in this range increases the number of patients who respond.

A summary of Japanese studies using zonisamide in pediatric patients with partial seizures estimated that 34% of children responded to zonisamide (39). Guerrini et al. (60) reported a randomized clinical trial of adjunctive zonisamide in 207 children, aged 6 to 17 years. Responder rates were 50% for zonisamide compared to 31% for placebo, a statistically significant difference. There was no difference in the incidence of adverse events between zonisamide and placebo treatments. Decreased appetite, weight loss, somnolence, vomiting, and diarrhea were more frequently associated with zonisamide. In a safety study of zonisamide in 107 patients, there was a significant reduction in all seizure types, with 7 patients discontinuing therapy due to serious adverse events (61).

Generalized Epilepsies

A small clinical trial suggested that zonisamide decreases cortical excitability in patients with idiopathic generalize epilepsies (62). Henry et al. (63) report two cases of progressive myoclonic epilepsy where zonisamide use was associated with reduced seizure frequency and improved functioning. A case series of patients with juvenile myoclonic epilepsy indicated that zonisamide was well tolerated and associated with reduced seizures compared to valproate (64). A similar retrospective study of juvenile myoclonic epilepsy indicated that zonisamide was easily titrated and had a rapid onset of action (65).

More extensive evaluation of zonisamide in primary generalized epilepsies has been done in children. In children with newly diagnosed infantile spasms, Suzuki et al. (36) used 3 to 10 mg/kg/d of zonisamide in an open-label trial. Of the children who started on zonisamide, four had complete seizure control and cessation of hypsarrhythmia with doses of 4 to 5 mg/kg/d. Kishi et al. (66) reported their experience with zonisamide in children with hypsarrhythmia. In three patients, zonisamide resulted in elimination of hypsarrhythmia and seizures. A larger study in 54 patients, newly diagnosed with West syndrome, was done (37). Zonisamide doses ranged from 4 to 14 mg/kg/d with a mean dose and serum concentration of 7.2 mg/kg/d and 15.3 μg/mL, respectively. Eleven infants had complete elimination of seizures and hypsarrhythmia, 7 children had >50% reduction in seizure frequency, and 14 with cryptogenic West syndrome responded. Of those who the authors categorized as not responding, 4 were seizure free transiently, 6 had a <50% reduction in seizure frequency, and 33 had no change in seizure frequency. The 11 individuals in this study who had elimination of seizures and hypsarrhythmia were entered into a long-term follow-up study, evaluating their response out to 79 months (mean duration of 53 months) (67). Seven of the infants who had an initial cessation of seizures continued to be seizure free. Presence of epileptiform activity on the EEG at the end of 3 weeks was predictive of recurrence of seizures. Yanagaki et al. (68) studied the use of zonisamide starting at 10 mg/kg/d, demonstrating this scheme was well tolerated in children with West syndrome.

Although case series reports and open-label studies suggest that zonisamide may be effective in patients with generalized epilepsies, it has not been well studied in this patient population. The most extensive information on zonisamide use in generalized epilepsies is in children with West syndrome and suggests that zonisamide may be an alternative treatment.

Monotherapy

Few clinical trials have evaluated the use of zonisamide in monotherapy for the treatment of epilepsy. The most extensive studies have been in children with West syndrome (36,67). Additionally, Kumagai et al. (69) studied zonisamide as a single agent in 44 children with epilepsy. In this open-label trial, 30 children with various seizure types became seizure free, and 6 children had to discontinue the drug due to adverse effects. A systematic review of adjunctive and monotherapy for partial seizures in children concluded that there was insufficient evidence to support zonisamide monotherapy (70).

The only published study of zonisamide monotherapy in adults was done by Wilensky et al. (28). Eight adults with partial seizures and receiving phenytoin were randomized to carbamazepine or zonisamide and then crossed over in an open-label design. Two subjects had improved seizure control with zonisamide compared to carbamazepine, and a third individual had a similar response but had to discontinue zonisamide due to the development of Stevens–Johnson syndrome.

The limited available data on zonisamide monotherapy treatment indicate that zonisamide may be effective as a single agent for epilepsy. However, larger, double-blind clinical trials must be done before zonisamide monotherapy can be recommended.

Nonepilepsy Indications

Preliminary clinical trials of zonisamide in disorders other than epilepsy indicate that it may be useful for other indications. One study of zonisamide in patients with mania and acute psychotic conditions indicated that 71% responded at least moderately to treatment (71). In an open-label trial of zonisamide in 35 patients with neuropathic pain, mean pain scores showed little or no improvement after 8 weeks of therapy (72). A trial in nine patients with Parkinson disease demonstrated that seven of the nine patients had improvement in their symptoms, especially wearing-off phenomenon, when zonisamide was added to their other medications (73). Preliminary data suggest that zonisamide is at least as effective as is propranolol in patients with head tremor or essential tremor (14,74).

ADVERSE EFFECTS

Common Adverse Effects

In the initial and major clinical trials of zonisamide as adjunctive therapy, several adverse effects were commonly reported (Table 66.4) (27,28,55–57). Schmidt et al. (55) reported the statistical evaluation of adverse events reported in their trial. Dizziness, somnolence, anorexia, abnormal thinking, ataxia, and confusion were more common with zonisamide compared to placebo. A meta-analysis showed that patients on zonisamide were more likely to experience anorexia, ataxia, dizziness, and fatigue compared to patients receiving placebo (52). These adverse events and their frequency are similar to those reported with other new AEDs.

Table 66.4 Most Frequently Reported Adverse Effects in Clinical Trials

Adverse event	Percent reporting range
Fatigue	3.3%–22.5%
Ataxia	3.3%–11.3%
Nausea/vomiting	4.2%–15%
Headache	5%–15.9%
Somnolence	5.2%–18.3%
Rhinitis	5.2%–14.4%
Confusion	5.6%–10.6%
Anorexia	6.7%–15%
Dizziness	6.9%–16.9%
Nervousness	8.8%–9.9%
Thinking abnormal	9.7%–11.3%

Adverse events in children appear to be similar to those in adults. The adverse events that are reported in >10% of children on zonisamide in combination with other AEDs are somnolence, anorexia, ataxia, fatigue, dizziness, cognitive impairment, irritability, and exanthema (39). Monotherapy of zonisamide in pediatrics has been more extensively studied than in adults. When zonisamide is used by itself in children, the only adverse effect that occurs in >10% of individuals is

somnolence (39). Thus, common adverse events, especially in children, may be limited by decreasing or eliminating other AEDs.

Zonisamide appears to produce a mild to moderate weight loss. A post hoc analysis of data from the major clinical trials demonstrated that significantly more patients on zonisamide (21.6%) lost >5 pounds compared to patients on placebo (57). A retrospective analysis of patients from European and American clinical trials (55–57) showed that 28.9% of individuals receiving zonisamide lost >5 pounds compared to 8.4% receiving placebo, a significant difference (75). The mean weight loss for all patients on zonisamide was 4.3 pounds. A double-blind, placebo-controlled study of 60 obese nonepileptic patients demonstrated a mean weight loss of 9.2 kg with zonisamide compared to a mean weight loss of 1.5 kg in those receiving placebo (76). A second study compared diet alone to diet and zonisamide in obese women (77). Women who took zonisamide had an additional 5 pounds weight loss compared to those only on a diet. Patients who are obese or have experienced weight gain associated with the use of other AEDs may benefit from the addition of zonisamide to their regimen.

Rare Adverse Effects

Early in the clinical trials of zonisamide, the formation of renal calculi was observed in some patients (56). Four patients of the 113 enrolled in this study had kidney stones form during the study. Kubota et al. (78) reported three cases of nephrolithiasis in patients receiving zonisamide, and Miyamoto et al. (79) reported the case of a 10-year-old girl with a kidney stone after starting zonisamide. Zonisamide is an extremely weak carbonic anhydrase inhibitor, but this does not fully explain the incidence of renal calculi (78). All published reports of renal calculi with zonisamide are in individuals who were taking other AEDs. Zonisamide is not contraindicated with patients with a history of kidney stones, but care should be taken when using zonisamide in these patients. Prudent management of patients on zonisamide should include adequate hydration to maintain good urine flow.

Allergic reactions to zonisamide are rare but did occur in the clinical trials. Rash was the predominant allergic type reaction reported, with at least four individuals (one with Stevens–Johnson syndrome) in these studies being discontinued due to dermatologic reactions. A mild, relative neutropenia was also observed in several individuals. A study by Hirsch et al. (80) demonstrates that there is no cross-reactivity with other AEDs. Because zonisamide is chemically related to sulfonamide drugs, caution should be taken when using zonisamide in patients who note a prior allergic reaction to these agents. The exact cross-reactivity in patients known to be allergic to sulfonamides has not been determined.

Oligohidrosis can occur with zonisamide and is marked by decreased sweating and hyperthermia. Postmarketing surveillance indicates that oligohidrosis occurs primarily in children, with all reported cases in individuals ≤18 years of age. The estimated rate of incidence is approximately 1 cases per 10,000 patient-years (81). When zonisamide is used in children, parents should be instructed to carefully monitor for decreased sweating and increased body temperature. Children on zonisamide should not be exposed for prolonged periods of time to extreme heat.

As with other AEDs that possess carbonic anhydrase inhibition activity, zonisamide can produce a metabolic acidosis. Individuals with impaired pulmonary or renal function are especially at risk for this side effect, and serum electrolytes should be monitored.

The cognitive effects of zonisamide were studied early in its development. Berent et al. (82) studied 11 patients who were on stable regimens of two to three other AEDs. When plasma concentrations of zonisamide exceeded 30 μg/mL, the acquisition and consolidation of new

information, especially verbal learning, were impaired. Miyamoto et al. (83) reviewed 74 reported cases of psychosis associated with zonisamide use, and only 14 of these cases exhibited symptoms of true psychosis. There were significantly more men than women with psychosis, and this group was younger than the general population of patients with epilepsy. Hirai et al. (84) reported on 27 children in a prospective clinical trial of zonisamide monotherapy, and 2 displayed behavioral disturbances. As with other AEDs, zonisamide may alter cognition and behavior in some individuals. It is difficult to truly assess the incidence of these effects, because none of the reports accounted for the number of individuals taking zonisamide. Additionally, most of the reports of cognitive or behavioral problems were in patients taking multiple AEDs.

Few data are available on the teratogenic effects of zonisamide. Kondo et al. (85) surveyed 381 hospitals in Japan during June 1989 regarding pregnancies in women using AEDs. Only two women exposed to zonisamide during pregnancy bore children with major malformations. In both of these cases, multiple AEDs were taken by the mothers. The authors conclude that zonisamide is associated with no greater risk of teratogenicity than are other AEDs.

SUMMARY

Clinical studies have proven the effectiveness of zonisamide as adjunctive therapy for partial seizures. Zonisamide has been used in a variety of age groups, seizure types, and as monotherapy. However, clinical study data outside of the primary indication are lacking. Current evidence suggests that zonisamide has broad utility as an AED in children and adults. The adverse effect and pharmacokinetic profile of zonisamide are favorable with few severe adverse effects reported and a long half-life that allows once-daily dosing.

Zonisamide should be considered an alternative adjunctive agent when typical AEDs have failed in treating partial seizures. It may also be useful in patients with other seizure types and in monotherapy. Individuals who are concerned about weight gain or desire to lose weight may benefit from zonisamide therapy. Care should be exercised when using zonisamide in patients with a history of renal calculi and true sulfa allergies. However, these items do not constitute absolute contraindications to zonisamide use. Zonisamide has been used safely and effectively in pediatrics, but children need to be monitored carefully for oligohidrosis.

CHAPTER 67 ADRENOCORTICOTROPIN AND STEROIDS

CRISTINA GO AND O. CARTER SNEAD III

HISTORICAL BACKGROUND

In 1950, Klein and Livingston (1) reported on the efficacy of adrenocorticotropin (ACTH) therapy for childhood seizures after observing its benefits in various types of intractable generalized seizures. Eight years later, Sorel and Dusaucy-Bauloye (2) reported control of seizures and an improvement in electroencephalographic (EEG) findings for children with infantile spasms treated with the drug. The benefit of oral steroids in this condition was established soon after that of ACTH (3–7), and since then, both drugs have been used in a number of other epilepsy syndromes, including Ohtahara syndrome, Lennox–Gastaut syndrome, other myoclonic epilepsies, and Landau–Kleffner syndrome.

ACTH and steroid therapy appear to have a unique beneficial effect upon epilepsy syndromes that have an age-related onset during a critical period of brain development that can cause a characteristic regression or plateau of acquired developmental milestones at seizure onset and subsequent long-term cognitive impairment. For some of these patients, ACTH or steroids, or both, can improve the short-term developmental trajectory and the long-term prognosis for language and cognitive development, in addition to the beneficial effects on the convulsive state (8–13).

INFANTILE SPASMS

General Considerations

In 1841, Dr. William West (14) wrote a letter to Lancet in which he described an unusual condition affecting his 4-month-old son, James, as a peculiar form of infantile convulsions. He went on to describe a reduction in developmental trajectory in his child who was normal prior to the onset of the event. This letter, now over 160 years old, remains the most eloquent clinical description of what we now know as infantile spasms.

In 1952, Gibbs and Gibbs (15) described the classical interictal EEG pattern associated with this condition, called hypsarrhythmia, which is characterized by high-voltage chaotic slowing with multifocal spikes and marked asynchrony. The term West syndrome refers to an age-related triad of epileptic spasms, developmental regression, and hypsarrhythmia on EEG. Although this term has been used synonymously with infantile spasms, the latter should refer strictly to the massive myoclonus because infantile spasms may occur in the absence of either mental retardation or the hypsarrhythmia EEG pattern.

Published studies on the efficacy of ACTH and corticosteroids in infantile spasms display considerable variability in design, complicating the establishment of evidence-based recommendations for optimal treatment (16–18). There is general consensus on a few observations,

however. The cumulative spontaneous remission rate over the first 12 months of seizures is about 25% (19). Seizures are almost always intractable to treatment with traditional anticonvulsant drugs. ACTH or oral steroid therapy should significantly reduce seizures in 50% to 75% of patients, but ACTH protocols, particularly those employing high-dose, long-acting synthetic formulations, are associated with a significantly high rate of side effects (20,21). The best chance for a treatment response is probably between 4 and 12 months of age in children who are neurologically normal when spasms begin that have no demonstrable cause (11,12,20,22–24). The ultimate prognosis is dismal for most patients and depends heavily upon the cause of the spasms, preexisting neurologic and developmental status, the presence or absence of other seizures concomitant with the spasms, and the patient's age at seizure onset (8,12,20,25–28).

The controversies surrounding the management of infantile spasms continue to outnumber the areas of agreement. Which is the most effective therapy: ACTH or steroids; other medical treatment including the ketogenic diet; other anticonvulsants such as vigabatrin (VGB), valproic acid, benzodiazepines, topiramate, zonisamide, or levetiracetam; pyridoxine; or some or all of these in combination? What is the impact of treatment with ACTH compared with other forms of steroids, the ketogenic diet, or anticonvulsants on the long-term outcome in recurrence of spasms, evolution into other forms of intractable epilepsy, and cognitive or behavioral function? Does treatment change the outcome for a patient with preexisting impairment in cognition and a structurally abnormal brain? What is the optimal dosage of these drugs, and how long should the treatment last? Does the ultimate outcome depend on timing of treatment or dose of steroid employed? Does the efficacy of ACTH depend on the formulation (natural vs. synthetic, sustained release vs. short acting)? More than 160 years after this syndrome was described by Dr. West, most of these questions remain unanswered.

Mechanisms of Action

The pathogenesis of infantile spasms and therefore the mechanisms of action of ACTH and steroids in this condition are unknown, principally because of a paucity of valid animal models for this disorder (29–34). However, this void has begun to disappear with the recent description of several animal models that bear phenotypic similarity to one or more critical features of infantile spasms.

Infantile spasms are epileptic syndrome that begins in infancy within a narrow range of ages, with initial onset mostly between 3 and 7 months of life in more than 50% of cases. A number of abnormalities have been causally linked (symptomatic cases) to infantile spasms including an ever-increasing number of bewildering metabolic and genetic etiologies (35); however, infantile spasms may also occur without apparent cause (idiopathic and cryptogenic cases). The effect of ACTH and corticosteroids is frequently all or nothing, and the steroid-induced seizure-free state is often sustainable even after drug withdrawal. These observations support the theory that the developing brain experiences a significant stress response to various etiologies that results in this age-dependent epileptic encephalopathy. Within this very narrow developmental window, ACTH and steroids may be able to reset the deranged homeostatic mechanisms of the brain, thereby reducing the convulsive tendency and improving the developmental trajectory.

The Brain–Adrenal Axis

Evidence suggests that the effects of ACTH on infantile spasms may be independent of steroidogenesis (36,37). Efficacy studies have demonstrated the superiority of ACTH to

corticosteroids in treating infantile spasms and its efficacy in adrenal-suppressed patients (38–41). Substantial physiologic and pharmacologic data indicate that ACTH has direct effects on brain function: increasing dendrite outsprouting in immature animals (42); stimulating myelination (43); regulating the synthesis, release, uptake, and metabolism of dopamine, norepinephrine, acetylcholine, serotonin, and γ-aminobutyric acid; regulating the binding at glutamatergic, serotonergic, muscarinic type 1, opiate, and dopaminergic receptors (44,45); and altering neuronal membrane lipid fluidity, permeability, and signal transduction (42). These neurobiologic effects can influence synaptic function and neurotransmission and may reside in fragments of the peptide devoid of corticotropic activity.

Baram et al. (40,46,47) proposed the important role of corticotropin-releasing hormone (CRH) in the pathogenesis of infantile spasms as well as its response to ACTH. The hypothesis is that diverse etiologies resulting in infantile spasms cause activation of the brain's stress response, leading to excessive release of CRH. CRH is an excitatory neuromodulator, with potent age-specific convulsant effects demonstrated in animal models. In immature brains, CRH can cause neuronal hyperexcitability, seizures, and neuronal death in the amygdala and hippocampus (48,49). High brain CRH levels can decrease ACTH levels due to desensitization of CRH receptors after chronic activation, which then decreases ACTH release. Low ACTH levels have been found in the cerebrospinal fluid of children with infantile spasms (48,50).

ACTH has a down-regulatory effect on CRH by reducing CRH gene expression in specific brain regions, an effect demonstrated in the absence of adrenal steroids and achieved with the use of only the 4 to 10 fragment of ACTH, which does not release adrenal steroids (40). Melanocortin receptor antagonists blocked this effect, suggesting that these are the targets of ACTH action (40).

By suppressing CRH expression, possibly through the action of peptide fragments of ACTH on melanocortin receptors, neuronal hyperexcitability may be reduced, ameliorating infantile spasms (33,34). Indirect evidence to support this hypothesis was reported recently by Liu et al. (51), who found that genetic variants in the central melanocortin-4-receptor promoter are associated with the development of infantile spasms and influence treatment response to ACTH in children with infantile spasms. Clinical trials of ACTH fragments without activity on adrenals have yielded disappointing results (52,53), but these studies used the 4 to 9 rather than the 4 to 10 peptide fragment studied in animal models (40).

Efficacy and Dosage

Table 67.1 lists the different preparations of depot corticotrophin. The biologic activity, expressed in international units (IU), permits a comparison of potency but represents the relative ability of the peptide to stimulate the adrenals and may not reflect its ability to affect brain function. The biologic activity of natural ACTH in the brain may differ from that of synthetic ACTH (12) as a result of ACTH fragments and possibly other pituitary hormones with neurobiologic activity in the brain that are present in the pituitary extracts. These compounds could enhance the therapeutic efficacy of natural ACTH (54). Any differences in the biologic effects of sustained ACTH levels provided by the depot formulations, as opposed to those of the short-acting preparations, are unknown. Given in high doses, however, long-acting depot preparations are associated with an increased incidence of severe side effects, including death from overwhelming infection (21).

Although most efficacy studies of ACTH and steroids are retrospective, an expanding body of prospective data is available (12,18,27,55–65). Most published literature supports the hypothesis that the natural ACTH 1 to 39 peptide (p-ACTH) is superior to oral steroids. In randomized, controlled trials, spasms ceased in 42% to 87% of children treated with ACTH, compared with 29% to 33% of children treated with prednisone (49,50). In these studies, the relapse rates were 15% to 31% for ACTH and 29% to 33% for prednisone. The United Kingdom infantile spasms study (UKISS) compared a high-dose oral prednisolone protocol of 40 to 60 mg/day with IM synthetic ACTH, which showed spasms responder rates of 70% for prednisolone and 76% for ACTH with neither agents showing significant difference in EEG response rate at 14 days, $P = 0.61$ (18); however, further prospective studies are needed to confirm this finding.

Most institutions have their own treatment protocol for infantile spasms, with a wide variety of dose and duration (66–68). The most effective dose and duration of treatment with p-ACTH for remission of infantile spasms continues to be a controversial issue. Compared to prednisone, no major advantage was demonstrated by low doses of ACTH, whereas high doses were superior (58,59). High-dose p-ACTH at 60 IU/day or 150 IU/m^2/day has produced excellent short-term response rates of 87% to 93% in prospective studies (58,63). In the only randomized, prospective comparison of p-ACTH, however, Hrachovy et al. (60) found no difference between high-dose and low-dose therapy. A prospective study using synthetic ACTH (62) by Yanagaki et al. compared very-low-dose (0.2 IU/kg/day) and low-dose (1 IU/kg/day) ACTH and found equivalent efficacy, with response and relapse rates comparable to those in other studies. Describing a stepwise increase in dosage, Heiskala et al. (65) demonstrated that while some patients can be controlled on lower doses of carboxymethylcellulose ACTH (3 IU/kg/day), others required high doses (12 IU/kg/day). Spasms were controlled initially in 65% of patients, but the relapse rate was high.

While some evidence supports high-dose ACTH over low-dose ACTH or oral steroids in cognitive outcome (9,11), the data are contradictory and not class I. Glaze et al. (55) found no difference between low-dose p-ACTH (20 to 30 IU/day) and prednisone (2 mg/kg/day). In a comparison of high-dose p-ACTH (110 IU/m^2/day) and steroids, however, Lombroso (12) showed a higher rate of normal cognitive outcome in cryptogenic patients treated with ACTH than in those treated with prednisone alone (55% vs. 17%). In a retrospective comparison of different ACTH

dosage regimens (69), Ito et al. also noted a positive correlation between dose and developmental outcome.

Although some data support high-dose ACTH as being more effective than low-dose ACTH, the precise dosage and duration are undetermined. The optimal dose may lie between 20 and 200 IU/m^2/day. Doses of 400 IU/m^2/day or higher are contraindicated because of a high incidence of life-threatening side effects (20,21,60,69).

There are some data suggesting that a good response to ACTH appears to be associated with better long-term outcome (24,70) in children with cryptogenic infantile spasms.

Based on these and other data, the current American Academy of Neurology Evidence–based guideline for the medical treatment of infantile spasms has concluded that low-dose ACTH should be considered for treatment of infantile spasms. ACTH or VGB may be useful for short-term treatment of infantile spasms, with ACTH considered preferentially over VGB. Hormonal therapy (ACTH or prednisolone) may be considered for use in preference to VGB in infants with cryptogenic infantile spasms, to possibly improve developmental outcome. A shorter lag time to treatment of infantile spasms with either hormonal therapy or VGB possibly improves long-term developmental outcomes (71).

Adverse Effects

ACTH and steroids, particularly at the high doses recommended for infantile spasms, can produce dangerous side effects. These are more frequent and more pronounced with ACTH. In prospective controlled trials, cushingoid features and extreme irritability were seen frequently; hypertension, while less common, was associated with higher doses (59–62). Vigilance is required for signs of sepsis, pneumonia, glucosuria, metabolic abnormalities involving the electrolytes calcium and phosphorus (72–74), and congestive heart failure (75,76). Of five deaths reported in prospective studies, at least two were directly attributable to ACTH (12,64).

Cerebral ventriculomegaly (59,77–81), which is not always reversible (55), can lead to subdural hematoma (82,83). The cause of the apparent cerebral atrophy is obscure, but its existence emphasizes the importance of diagnostic neuroimaging before initiation of ACTH.

Because hypothalamic–pituitary or adrenocortical dysfunction can result from ACTH therapy (84,85), morning levels of cortisol should be monitored during a taper and any medical stress treated with high-dose steroids (86). Treatment with ACTH or steroids can also be immunosuppressant and associated with infectious complications, perhaps as a result of impaired function of polymorphonuclear leukocytes (87). Both agents are therefore contraindicated in the face of serious bacterial or viral infection such as varicella or cytomegalovirus. Because of the high rate of fatal Pneumocystis pneumonia as an infectious complication of ACTH therapy (20,88–90), prophylaxis with trimethoprim–sulfamethoxazole, accompanied by folate supplementation and frequent blood counts, may be prudent in infants older than 2 months of age. In rare cases, ACTH also has been reported to exacerbate seizures (91,92).

Vigabatrin Versus Adrenocorticotropin

The 2004 American Academy of Neurology Practice Parameter for the medical treatment of infantile spasms has concluded that VGB is possibly an effective agent in the short-term treatment of infantile spasms (16). The 2012 American Academy of Neurology updated evidence-based guidelines for the

medical treatment of infantile spasms concluded that while either ACTH (level B) or VGB (level C) could be offered for short-term treatment of infantile spasms, the evidence suggests that ACTH may be offered over VGB (level C) (71). Based on data from randomized controlled trials, from 23% to 65% of children treated with VGB achieve short-term remission of infantile spasms, with relapse rates of 4% to 20% (18,61,70,93,94).

Although VGB is thought to be particularly effective against infantile spasms associated with tuberous sclerosis (61,95,96) and is frequently advocated as a first-line therapy for this disorder, the data supporting this are retrospective (16). The mammalian target of rapamycin (mTOR) pathway is a key signaling pathway that is dysregulated in TSC. Animal studies have shown that VGB partially inhibited mTOR pathway activity and glial proliferation in the knockout mice in vitro as well as reduced mTOR pathway activation in cultured astrocytes from both knockout and control mice. This may account for the unique efficacy of VGB in TSC (97).

Limiting its use is the characteristic concentric constriction of visual fields. This effect does occur in childhood, and the risk may be cumulative with longer duration of therapy (98–102). The incidence in very young children is not known, and perimetric testing is often impossible in this group. Electrophysiologic studies in infants, although not as sensitive as perimetry, have confirmed VGB-associated abnormalities (101–104). In 22% to 32% of infantile spasms patients treated with VGB, reversible abnormal MRI signal intensity or restricted diffusion-weighted imaging in the thalamus, basal ganglia, dentate nucleus, and the brainstem have been reported. Although the clinical significance of these MRI changes is unknown, there is concern that the changes reflect a medication-related neurotoxic effect (105,106). VGB may have a place as a short-term treatment, although its long-term safety remains uncertain.

Other Agents in Infantile Spasms

Valproate (107,108), nitrazepam (109), pyridoxine (110), felbamate (111), intravenous immunoglobulin (112), topiramate (113), zonisamide (114), ganaxolone (115), levetiracetam (116), and the ketogenic diet (117,118) have been studied in small uncontrolled trials. However, there is insufficient evidence of efficacy and safety to recommend any of these therapies at this time (16,71).

Recommended Protocols for Adrenocorticotropin

In our center, the standardized therapy for new-onset infantile spasms, regardless of the etiology or lack thereof is to use VGB as first-line therapy. The reason for the use of VGB is its ease of use and relative lack of side effects compared to ACTH. We require complete resolution of spasms and hypsarrhythmia on EEG to continue VGB alone for a full 6-month course. Failing that, ACTH is begun as described below. This protocol has been shown to achieve seizure freedom in 96% of children so treated (119).

The optimal dose of ACTH required to enhance short-term response and long-term cognitive outcome is unknown; however, relatively high doses given early in the disease, accompanied by a second course in the event of relapse, appear warranted. The following high-dose ACTH regimen that has been used successfully in more than 500 children (58,63,120) is recommended (Table 67.2). A suggested protocol using Synacthen (cosyntropin or tetracosactide) based on the study done by Snead et al. (63) with 0.25 mg of Synacthen equivalent to 25 units of corticotropin is also included. The initial dose of ACTH is 150 IU/m^2/day of ACTH gel, 80 IU/mL, intramuscularly in two divided doses

for 1 week. In the second week, 75 IU/m^2/day is given, followed by 75 IU/m^2 every other day in the third week. Over the next 6 weeks, the dose is gradually tapered. The lot number of the ACTH gel is carefully recorded. Usually, a response is seen within the first 7 days; if within 2 weeks no response is noted or a steroid effect is evident, the lot is changed.

Table 67.2 Protocol for ACTH Therapy for Infantile Spasms

Initial assessment before therapy begins

History and physical examination including Wood light
EEG with pyridoxine injection
Blood counts, routine blood chemical analysis, urinalysis including glucose, and thyroid and adrenal function tests
Electrocardiogram
Magnetic resonance imaging of the brain
Family counseling and education for administration and monitoring of side effects

Clinical monitoring during ACTH therapy

Blood pressure and urine dipstick for glucose: daily first week, then thrice weekly
Blood counts, routine blood chemical analysis weekly first month, then fortnightly
EEG once during and after therapy and as indicated
Provide the family with a letter describing treatment and prompting urgent assessment in case of fever or other signs of infection

High-dose schedule for natural ACTH

Week 1	150 IU/m²/d IM, two divided doses
Week 2	75 IU/m²/d IM, single daily dose
Reassess	If spasms stop and hypsarrhythmia resolves, continue with taper; if no clinical or EEG response, change ACTH lot or select alternative therapy and taper ACTH as appropriate
Week 3	75 IU/m²/d IM, alternate days
Week 4	60 IU/m²/d IM, alternate days
Week 5	50 IU/m²/d IM, alternate days
Week 6	40 IU/m²/d IM, alternate days
Week 7	30 IU/m²/d IM, alternate days
Week 8	20 IU/m²/d IM, alternate days
Week 9	10 IU/m²/d IM, alternate days
Week 10	5 IU/m²/d IM, alternate days, then stop ACTH

Lower-dose schedule for ACTH[a]

Weeks 1 and 2	20 IU/d

If response is complete: taper ACTH over 1-week period
If response is incomplete: increase 30 IU/d for 4 weeks then taper to zero over a 1-week period
If response remains incomplete: taper ACTH and try other medications

Suggested schedule for Synacthen (cosyntropin) in infantile spasms[b]

Week number	Date of injection	Dose given intramuscularly
Week 1	Day 1	1.9 mg/m²
	Day 3	1.9 mg/m²
	Day 5	1.9 mg/m²
	Day 7	1.9 mg/m²
Week 2	Day 9	0.94 mg/m²
	Day 11	0.94 mg/m²
	Day 13	0.94 mg/m²
Reassess after 2 weeks; responders will finish protocol on the following taper schedule		
If no clinical and EEG response, select alternative therapy and taper ACTH as appropriate		
Week 3	Day 15	0.75 mg/m²
	Day 17	0.75 mg/m²
	Day 19	0.75 mg/m²
	Day 21	0.63 mg/m²
Week 4	Day 23	0.63 mg/m²
	Day 25	0.5 mg/m²
	Day 27	0.5 mg/m²
Week 5	Day 29	0.38 mg/m²
	Day 31	0.38 mg/m²

High dose, long duration vs. low dose, short duration corticotropin therapy in infantile spasms. J Pediatr. 1994;124:803–806.

[b]This 6-week Synacthen protocol developed and used at the Hospital for Sick Children, Toronto, Ontario.

A low-dose ACTH protocol based on two studies by Hrachovy et al. (59,60) showed clinical and EEG response rates of >40% in children with infantile spasms and provided evidence suggesting that low-dose ACTH is probably as effective as high-dose ACTH for the short-term treatment of infantile spasms. Patients receive 20 U/day for 2 weeks. If response was documented, the dose of ACTH was tapered to zero over a 1-week period. If a response was not documented, ACTH was increased to 30 U/day for 4 weeks and then tapered to zero during a 1-week period.

Once the decision is made to embark upon a course of ACTH therapy, the child is admitted to a day care unit for initiation therapy. Parents are taught to administer the injection, measure urine glucose three times daily with Chemstix, and recognize spasms so as to keep an accurate seizure calendar. Any diagnostic workup indicated by clinical circumstances is also performed, including screening for occult infections. Before ACTH is started, an endocrine profile, complete blood count, urinalysis, electrolyte panel, baseline renal function tests, and calcium, phosphorus, and serum glucose levels are obtained. Blood pressure is measured and an electrocardiogram performed. The drug is not given if any of these studies show abnormal results. Diagnostic neuroimaging is indicated before initiation of ACTH or steroids because of the association with ventriculomegaly.

Blood pressure must be measured daily at home during the first week and three times weekly thereafter. Control of hypertension is attempted with salt restriction and amlodipine therapy rather than discontinuation of ACTH. The patient is monitored in the outpatient clinic weekly for the first month and then biweekly, with appropriate blood work at each visit. Waking and sleeping EEG patterns are obtained during and after the start of ACTH to assess treatment response. Because a response is usually noted within a week or two of initiating ACTH (57–59), positive results are suggested when properly trained parents report no seizures in a child whose waking and sleeping EEG patterns are normal.

If relapse occurs, the dose may be increased to the previously effective dose for 2 weeks and another tapering begun. If seizures continue, the dose may be increased to 150 IU/m^2/day and the regimen restarted.

Recommended Protocols for Prednisone and Prednisolone

If prednisone is chosen because of its oral formulation and lower incidence of serious side effects, the pretreatment laboratory evaluation described earlier is performed. The initial dose is 3 mg/kg/day in four divided doses for 2 weeks, followed by a 10-week taper (115). A multiple daily dose regimen of high-dose ACTH therapy is recommended to produce sustained elevations of plasma cortisol (57,63).

The UKISS by Lux et al. (18) used the following high-dose oral prednisolone regimen: initial dose is 10 mg four times a day for 2 weeks, increasing to 20 mg three times a day after 1 week if spasms continued, followed by taper of 10 mg every 5 days or, if on the higher-dose treatment, 40 mg daily, then 20 mg, then 10 mg for 5-day periods.

OTHER SEIZURE DISORDERS

Ohtahara and Lennox–Gastaut syndromes are believed to represent earlier and later manifestations, respectively, of a spectrum of infantile epileptic encephalopathies that include infantile spasms

(121–124). These conditions respond poorly to traditional anticonvulsant drug therapies but are sometimes improved by the antiepileptic drugs used in infantile spasms: ACTH, steroids, benzodiazepines, and valproic acid. ACTH of steroids also may be beneficial in Landau–Kleffner syndrome.

Ohtahara Syndrome

Also known as early infantile epileptic encephalopathy, Ohtahara syndrome is characterized by spasms beginning within the first 3 months of life associated with persistent burst suppression on the EEG in all stages of the sleep–wake cycle (121). Despite reports of improvement after ACTH (121,125), VGB (126), and zonisamide (121), the long-term prognosis usually is unchanged by any treatment (121,123) and involves high mortality and severely handicapped survivors. If used, ACTH should be administered as described for infantile spasms.

Lennox–Gastaut Syndrome and Other Myoclonic Disorders

ACTH and steroids have been found useful in younger children with various combinations of severe and intractable seizures, particularly atypical absence, myoclonic, tonic, and atonic seizures (1,38,120,127–132). This group includes patients with Lennox–Gastaut syndrome, a disorder characterized by mental retardation, generalized slow spike-and-wave discharges, intractable atypical absence, myoclonus, and frequent ictal falls. Several uncontrolled, retrospective studies suggest that ACTH is superior to oral steroids against these seizure types (121,127,129,130), and the regimen described in this chapter for ACTH or prednisone is recommended. Nevertheless, ACTH and steroids should be reserved for the most severe and intractable disease. Usually, the best result is temporary relief, because 70% to 90% of patients with multiple seizure types suffer a relapse during the ACTH taper (120).

In another age-dependent disorder first described by Doose (133), myoclonic astatic seizures begin between 7 months and 6 years of age in a previously normal child and are associated with generalized discharges on the EEG (134). This disorder is resistant to most conventional antiepileptic drugs; however, a retrospective study has reported response to the ketogenic diet, ACTH, and ethosuximide (134).

Landau–Kleffner Syndrome and Related Disorders

Described in 1957 (135), Landau–Kleffner syndrome, also known as acquired epileptic aphasia, is characterized by regression in receptive and expressive language associated with epileptic seizures. The usual presentation occurs between the ages of 2 and 8 years. Clinical seizures may precede, be coincident with, or develop after the onset of language deterioration, and up to 25% of patients with language loss and epileptiform EEG patterns never experience clinical seizures (136,137). Behavioral disturbances are frequent, ranging from hyperactivity and aggressiveness to autism and global cognitive deterioration. Some children display sustained agnosia and mutism; others show a waxing and waning course that parallels the EEG changes; still others demonstrate spontaneous resolution (137). The EEG typically shows 1- to 3-Hz high-amplitude spike and slow waves; these may be unilateral, bilateral, unifocal, or multifocal but often include the temporal region, with or without parietal and occipital involvement, and are activated in sleep (138).

Valproate and benzodiazepines may control the syndrome's clinical seizures but have only a

partial and transient effect on the EEG abnormalities (10,139). In 1974, McKinney and McGreal (140) described the beneficial effect of ACTH on the characteristic seizures, language regression, and behavioral change. Since then, although no controlled prospective trials of ACTH or steroids have been published, case reports and retrospective series have demonstrated improvements in seizure control and language in children treated with varying ACTH or corticosteroid regimens (10,137–139,141–143).

The use of ACTH or corticosteroids in patients with Landau–Kleffner syndrome appears justified; however, further study of dose and duration of therapy is warranted, as is exploration of new anticonvulsants. High-dose ACTH or prednisone, as described in this chapter for infantile spasms, may be useful, with a longer tapering schedule and concomitant use of valproic acid.

CHAPTER 68 ANTIEPILEPTIC DRUGS IN CLINICAL DEVELOPMENT

DEANA M. GAZZOLA, NORMAN DELANTY, AND JACQUELINE A. FRENCH

Despite advances in epilepsy treatment, there remains a continuing need for the development of new medications (1–4). Multiple new agents have been introduced in recent years, some of which are products of the Antiepileptic Drug Development Program sponsored by the U.S. National Institutes of Health (5). Many novel compounds with antiepileptic drug (AED) potential are currently in various stages of development (Tables 68.1 and 68.2) (6–10); however, not all of these compounds will complete the development cycle and be approved for use.

Table 68.1 Chemistry and Possible Mechanisms of Action of Some New AEDs

Drug	Chemistry	Possible mechanism of action
Eslicarbazepine acetate	*S-(–)-10-Acetoxy-10,11-dihydro-5H-dibenz/b,flazepine-5-carboxamide*; shares the dibenzazepine nucleus bearing the 5-carboxamide substitute with carbamazepine	Stabilizes the inactivated state of voltage-gated sodium channels
Brivaracetam	Pyrrolidone derivative in the same class as levetiracetam and piracetam	Binds to the SV2A like its parent compound levetiracetam, but with higher affinity; also inhibits sodium channel currents
PID	Chiral isomer of valpromide	(*R*)-Enantiomer is more potent; mechanism of action unknown
Carisbamate	*S-2-O-carbamoyl-1-o-chlorophenyl-ethanol*	Inhibits voltage-gated sodium channels; modest inhibition of high-voltage activated calcium channels
Ganaxolone	*3α-Hydroxy-3β-methyl-5α-pregnan-20-one*	Positive allosteric modulator of the $GABA_A$ receptor
Huperzine A	Sesquiterpene lycopodium alkaloid	*N*-Methyl-D-aspartate receptor and acetylcholinesterase inhibitor
JZP-4	3-(2,3,5-Trichloro-phenyl)-pyrazine-2,6-*diamine*; structurally related to lamotrigine	Sodium- and calcium-channel blocker
NAX 5055	Analog of the endogenous neuropeptide galanin	Agonist of galanin receptor subtypes GalR1 and GalR2; this is thought to decrease glutamate release
Retigabine	Carbamacic acid ethyl ester	*Opens inward rectifying K^+ channels; GABA potentiation*
Stiripentol	Aromatic allylic alcohol	Inhibits synaptosomal GABA uptake; enhances GABAergic transmission; inhibits hepatic cytochrome P450 enzymes
YKP3089	Unknown	Unknown

Table 68.2 Important Pharmacokinetic Parameters of New Antiepileptic Compounds in Humans

Drug	T_{max} (h)	Protein binding (%)	Half-life (h)	Excretion
Eslicarbazepine acetate	2–3	30	20–24	Renal
Brivaracetam	1–2	Weak	8	Renal
PID	Unknown	Unknown	Unknown	Unknown
Carisbamate	1–3	44	12	Renal
Ganaxolone	1.5–2	99	35–40	Hepatic
Huperzine A	Unknown	Unknown	Unknown	Unknown
JZP-4	Unknown	Unknown	10	Renal
NAX-5055	Unknown	Unknown	Unknown	Unknown
Retigabine	1–2	<80	8–10	Renal
Stiripentol	1.5	99	Nonlinear pharmacokinetics (Michaelis–Menten)	Unknown
YKP3089	1.5–3.5	Unknown	30–75	Unknown

In the fifth edition of this textbook, this chapter discussed 11 anticonvulsant drugs (11). Information on brivaracetam, carisbamate, ganaxolone, stiripentol, huperzine A, and YKP3089 has been updated. Nax 5055, JZP-4, and propylisopropyl acetate (PID) will not be discussed in this chapter as the interval development of these agents has stalled or ceased. Compounds newly developed as potential AEDs since the writing of the last edition have been added.

The chapter has also been reorganized; drugs whose chemical structures are related to preexisting parent compounds are discussed first under the derivative compound section, followed by neurosteroids (NS), anti-inflammatory agents, and other structurally novel compounds.

DERIVATIVE COMPOUNDS

Levetiracetam Derivatives: Brivaracetam

Brivaracetam (UCB 34714) is a pyrrolidone derivative in the same class as levetiracetam and piracetam. Like levetiracetam, it binds to the synaptic vesicle protein 2A (SV2A), but with higher affinity. In contrast to levetiracetam, brivaracetam also inhibits sodium channel currents as demonstrated in rat cortical neurons in vitro (12). It exhibits superior activity against secondarily generalized motor seizures in corneally kindled mice and prevents clonic convulsions in audiogenic-susceptible mice (13). Brivaracetam suppresses spike-and-wave discharges in Generalized Absence Epilepsy Rat from Strasbourg (GAERS) rats and also suppresses both motor seizure severity and after-discharge duration in amygdala-kindled rats (13). Brivaracetam was developed with the hope that it would (i) be more potent than levetiracetam due to its higher affinity binding, (ii) provide benefit to a larger percent of patients because of its additional impact on sodium channels, or (iii) have a more favorable behavioral side effect profile. None of these potential benefits have yet been proven.

Brivaracetam is rapidly absorbed following oral administration, displays linear pharmacokinetics, binds weakly to plasma proteins, and has an approximately 8-hour half-life (14,15). Inactive metabolites are primarily renally cleared (15). In contrast to levetiracetam, brivaracetam has been demonstrated in vitro to have some impact on metabolizing enzymes; it inhibits epoxide hydrolase and to a lesser extent CYP3A4 and 2C19 and is a weak inducer of CYP3A4 (16). Brivaracetam slightly reduces carbamazepine concentrations, while slightly increasing levels of carbamazepine-10,11-epoxide. Brivaracetam has equivocal effects on phenytoin, possibly lowering

serum concentrations, and has no effect on the concentrations of lamotrigine, levetiracetam, oxcarbazepine, topiramate, and valproic acid (6,17). High doses of brivaracetam have been shown to moderately reduce the estrogen and progesterone components of oral contraceptives, but this has not been shown to impact ovulation (6,16). However, a dose of 100 mg/day did not modify the pharmacokinetics of oral contraceptive steroid components (30 g ethinyl estradiol and 150 g levonorgestrel) (18). Enzyme-inducing AEDs increase brivaracetam clearance, leading to a 30% reduction of AUC (7). There is no change in exposure in elderly and renally impaired patients, indicating that no dose adjustments should be necessary (19). However, severe hepatic impairment will increase exposure by about 50% (7,18).

Tolerability is good overall; the majority of treatment- emergent adverse events (TEAEs) reported in Phase III trials were mild to moderate (8), the most common being headache, somnolence, dizziness, and fatigue (8,20). Cardiac repolarization in healthy subjects is not affected with doses of 75 and 400 mg BID (21).

Three Phase III clinical trials (Study N01252, N01253, and N01254) utilizing the primary efficacy end point of percent reduction in baseline-adjusted partial-onset seizure frequency have been conducted. Patients were randomized to a variety of drug doses (20, 50, and 100 mg/day in Study N01252; 5, 20, and 50 mg/day in Study N01253; and 20 mg/day with variable stepwise increases up to a maximum of 150 mg/day in Study N01254). In Study N01253, statistical significance was reached for the primary efficacy end point with the 50 mg/day dose versus placebo ($P = 0.02$) (22); this was not achieved for the 50 mg dose in Study N01252, but was at 100 mg/day dosing ($P = 0.05$) (22). In clinical trial N01254 (23), median percent reduction from baseline in partial-onset seizure frequency/week was 26.9% for brivaracetam versus 18.9% for placebo ($P = 0.070$), while 50% responder rates were 30.3% for brivaracetam versus 16.7% for placebo ($P = 0.006$) (23). Preliminary data also suggest possible efficacy of brivaracetam as an add-on agent in adults with generalized epilepsy (consisting of a combination of idiopathic, cryptogenic, symptomatic, and unknown, with 34/36 patients completing the treatment period) (23). The median generalized seizure days/week decreased to 0.63 on brivaracetam compared to placebo (1.26); median percentage reductions from baseline and ≥50% responder rates in generalized seizure days/week also favored brivaracetam treatment (42.6% and 44.4%, respectively) over placebo (20.7% and 15.4%, respectively) (23).

Multiple additional Phase III studies as well as multicenter open-label trials are ongoing at the time of writing of this chapter, including studies in children.

Vigabatrin Derivatives: CPP-115

Vigabatrin increases levels of γ-aminobutyric acid (GABA) in the brain by inhibiting its degradation through inactivation of the enzyme GABA-aminotransferase (GABA-AT) (24). Derivatives of vigabatrin have been created; strengthening the molecular structure of the drug has led to the development of a more potent analog with stronger binding capacity to the target enzyme GABA-AT (25). The molecule (1S,3S)-3-amino-4-difluoromethylenecyclopentanecarboxylic acid, a conformationally rigid vigabatrin analog, is a potent inactivator of GABA-AT and approximately 186 times more potent than is S-vigabatrin in vitro (25). However, the latter molecule possesses relatively low lipophilicity, which could limit permeability across the blood–brain barrier (25). The tetrazole analog (1S,3S)-3-amino-4-difluoromethylenyl-cyclopentanoic acid (CPP-115) is more highly lipophilic (25). In addition, CPP-115 is a time- and concentration-dependent inhibitor of

GABA-AT (25), less potent than is its parent compound, but more potent in vitro than is vigabatrin (25). CPP-115 was over 100 times more effective in the treatment of infantile spasms in a rat model, and efficacy against drug addiction in rat models was also demonstrated (26). And importantly, much less retinal damage has been observed at high doses of CPP-115 compared to effective doses of vigabatrin (26). CPP-115 has been licensed to Catalyst Pharmaceutical Partners, Inc., which has begun Phase I clinical trials at the time of writing of this chapter.

NEUROSTEROIDS

Étienne-Émile Baulieu (27) first defined NS as steroids synthesized de novo in the nervous system from cholesterol independent of the peripheral endocrine glands. This definition was expanded by Paul and Purdy (28) who further characterized "neuroactive steroids" as including "natural or synthetic steroids" that alter neuronal excitability. $GABA_A$ receptors are primary NS targets; at low concentrations, NS potentiate the action of GABA, and at higher concentrations, they directly activate the receptor at sites distinct from benzodiazepine and barbiturate modulatory sites (29), and anticonvulsant tolerance to NS has not been seen (30,31). NS exhibit broad-spectrum anticonvulsant effects in animal models, showing efficacy against Pentylene Tetrazole (PTZ), bicuculline, pilocarpine, and kindling-induced seizures (32). Similar to other GABA agents, however, NS may exacerbate generalized absence seizures (33,34). Ganaxolone is the only synthetic NS-based compound currently in development and is discussed below.

GANAXOLONE

Ganaxolone (3α-hydroxy-3β-methyl-5α-pregnan-20-one) is the 3-β-methyl analog of the NS allopregnanolone (7). It is a positive allosteric modulator of the $GABA_A$ receptor and is similar to its natural analog allopregnanolone in potency and efficacy (35). Ganaxolone has protective antiepileptic activity in multiple seizure models (35–38). It is highly protein bound (>99%) (7), is rapidly absorbed, and is primarily hepatically metabolized via CYP3A4/3A5 enzymes (7). In vitro studies have failed to show significant interactions between ganaxolone and other AEDs (39). Ganaxolone is not a CYP3A4 inhibitor and has shown low or no potential to induce CYP3A4 metabolism, although concomitantly administered strong CYP3A4 inducers (carbamazepine and phenytoin) can increase ganaxolone's clearance (8). Ganaxolone has a 10-hour effective half-life and a terminal elimination half-life of 35 to 40 hours (7). Metabolites are eliminated in urine (25%) and feces (69%) (32). Plasma values are 5 to 15 times higher when taken with food, compared to fasting values; thus, several unique formulations have been created including two solid capsule forms, one immediate-release and the other pH-sensitive delayed-release. Ganaxolone possesses a favorable safety and toxicity profile in animals and is safe and well tolerated in humans (8). The most common TEAEs are headache, dizziness, fatigue, and somnolence (8,40). The 3β-methyl component of ganaxolone eliminates back conversion to the hormonally active intermediate dihydroprogesterone, potentially avoiding hormonal side effects (41).

In one Phase II clinical trial, 1500 mg/day of ganaxolone resulted in an 18% decrease of mean weekly seizure frequency, compared with a 2% increase in the placebo group over a 10-week treatment period ($P = 0.014$) (8). Twenty-six percent of subjects treated with ganaxolone versus 13% of those treated with placebo ($P = 0.057$) experienced >50% reduction in seizures during the maintenance phase (8). Sustained efficacy was demonstrated in a 104-week open-label extension of a

10-week double-blind randomized study, with no new safety concerns identified (8). Three Phase II open-label, adjunctive therapy studies have been performed in the pediatric population. The largest enrolled a total of 45 patients with partial or generalized refractory seizures, ages 2 to 15 years. A maximum dose of 12 mg/kg three times daily was administered for an 8-week maintenance period. Twenty-seven patients (60%) completed the entire study and 12 patients (27%) experienced a >50% reduction in seizure frequency (39). Ganaxolone is currently in Phase III development for epilepsy (8).

ANTI-INFLAMMATORY AGENTS

Targeting hyperexcitability and inflammation is another potential approach to seizure control (42). Evidence suggests that glia-mediated inflammation plays a role in the pathogenesis of seizures and epilepsy; one proposed mechanism is glial effects on the IL1β cascade, which ultimately leads to NMDA-mediated enhancement of Ca^{2+} influx, which in turn promotes excitability and excitotoxicity (43,44). Using therapies that target the inflammatory cascade particularly for those patients severely resistant to standard AED treatment may be helpful; results from animal studies are promising (45).

HE3286 (Triolex)

The orally active HE3286 is a synthetic derivative of the anti-inflammatory dehydroepiandrosterone (DHEA) metabolite, androstene-3β,7β,17β-triol (βAET) (46). While anti- inflammatory, HE3286 is not immunosuppressive (47); it is thought to have an anti-inflammatory mechanism of action distinct from corticosteroids and other agents (48). HE3286 has been used to treat collagen-induced arthritis, where it has been associated with various immune-related changes including the reduction of proinflammatory cytokines tumor necrosis factor-α, IL-6, IL-1β, and IL-23 (48).

Thus far, HE3286 demonstrates low potential for direct or indirect toxicity and possesses suitable pharmacokinetics for clinical development (47). It possesses a terminal half-life slightly longer in males than in females ($T_{1/2}$: 8.2 and 5.4 hours, respectively) (47). HE3286 readily permeates the blood–brain barrier in mice (47). It is extensively metabolized, and some of the various metabolites have been found to interact with CYP enzymes (47). Pharmacokinetic evaluations are ongoing. Toxicology studies in rats revealed no systemic or neurotoxicity at daily doses of up to 400 mg/kg in 4-week studies; doses of 200 mg/kg and 30 mg/kg in 13- and 26-week studies, respectively, also resulted in no toxicity (47). Dose-dependent, generally mild, estrogenic effects were observed in both sexes (47).

At the time of writing of this chapter, HE3286 was in preclinical development for use in refractory epilepsy using a chronic seizure mouse model at the Mario Negri Institute for Pharmacological Research, Milan, Italy.

VX-765

VX-765 ((S)-1-((S)-2-{(1-(4-amino-3-chloro-phenyl)-methanoyl)-amino}-3,3-dimethyl-butanoyl)-pyrrolidine-2-carboxylic acid ((2R,3S)-2-ethoxy-5-oxo-tetrahydro-furan-3-yl)-amide) is a selective and reversible inhibitor of interleukin converting enzyme, also known as caspase 1 (8,49). By this mechanism, it is able to reduce the production of IL-1β, which is thought to inhibit neuronal hyperexcitability.

Two small Phase IIA clinical trials have been completed. The first was a 6-week trial in which subjects were randomized 4:1 to VX-765 900 mg three times daily (TID) (n = 48), or placebo (n = 12). There was no long-term extension phase, but patients continued to count seizures for 6 weeks after drug was discontinued. The most common side effect was dizziness, and no serious side effects attributable to VX-765 emerged. 18.8% of subjects in the VX-765 group had a 50% reduction in seizures versus 8.3% in the placebo group (P = NS). However, in a post hoc analysis, seizure frequency appeared to diminish further in a "hybrid" period consisting of the last 2 weeks of treatment and the first 2 weeks of the posttreatment period, consistent with a delayed onset of treatment seen in animal studies (8,50). Subsequently, a 13-week dose-ranging study was initiated. Patients were randomized (1:1:1:1:1) before the first dose of study drug on day 1 to receive placebo or VX-765 300 mg, 600 mg, 900 mg, or 1200 mg TID. The study was initially designed to enroll 500 patients. It was stopped administratively due to a decision by the company not to pursue development, when only 55 patients had been randomized. At present, the fate of the molecule is uncertain (51).

OTHER STRUCTURALLY NOVEL COMPOUNDS

2-Deoxy-D-Glucose

2-Deoxy-D-glucose was discovered during studies exploring the possible molecular mechanisms underlying the anticonvulsant effect of the ketogenic diet (8). 2-Deoxy-D-glucose is a nonmetabolizable glucose analog that inhibits glycolysis and that has been shown to have beneficial acute and chronic antiepileptic effects in a number of in vitro and rat models of seizures (52). A recent report suggests that it may exert its anticonvulsant properties by up-regulation of the potassium receptor subunits Kir6.1 and Kir6.2 (53). There have been some concerns about its safety in animal models with report of cardiac muscle vacuolization and increased mortality in rats (54). The significance and reversibility of these findings are currently under investigation. An intriguing aspect of this compound is that it may be preferentially taken up at the site of active seizure focus and thus may have a specific role in the treatment of acute repetitive seizures and status epilepticus. Phase 11 studies in humans have been planned, including studies of use in status epilepticus.

Cannabinoids

There is a lot of current interest in the medical use of marijuana and its constituent compounds for the treatment of epilepsy. There are hundreds of unique compounds in marijuana (cannabis), and the ones that are unique to the plant are called cannabinoids. Two neuroactive compounds in marijuana (cannabis) are tetrahydrocannabinol (Δ^9-tetrahydro-cannabinol (Δ^9-THC), a psychoactive compound) and cannabidiol (non-psychoactive). Sativex, a derivative containing both constituents, has recently been approved in a number of countries for the treatment of pain and spasticity in multiple sclerosis (55). In the day-to-day practice of epileptology, some patients have reported that the use of marijuana has beneficial effects on seizure control, and indeed, the use of cannabis has a long history of use for the control of seizures in human epilepsy. Both THC and cannabidiol have been tested in animal models of epilepsy, but recently, there has been more focus on cannabidiol. Notably, while THC engages the endocannabinoid system, cannabidiol does not. However, cannabidiol does engage a number of other targets and is considered to be antioxidant. Its mechanism of action is currently unknown (56). It has been tested in animal models of epilepsy and is effective in the 6 Hz and

maximal electroshock model (57). CBD exerted anticonvulsant effects against PTZ-induced acute generalized seizures, pilocarpine-induced temporal lobe convulsions, and penicillin- induced partial seizures in Wistar-Kyoto rats (58,59).

Cannabidivarin, a propyl analog of cannabidiol, acting on the CB_2 cannabinoid receptor, has been shown to be anticonvulsant in mouse and rat models of seizures, including the maximum electroshock model, and the audiogenic seizure model in mice, and pentylenetetrazole model in rats (60). These effects were seen at doses that did not impair motor function.

Epidiolex is a natural plant-based form of cannabidiol delivered in an oil-based capsule that is in development for Dravet syndrome. Cannabidiol (Epidiolex) has been designated orphan drug status for the treatment of Dravet syndrome by the FDA. It is available in several expanded access programs. At the time of this writing, GBH Pharma is conducting an open-label dose-ranging trial in children with severe epilepsy. It is likely that cannabidivarin and other phytocannabinoids will be further investigated for specific use in human epilepsy.

Carisbamate

Carisbamate (S-2-O-carbamoyl-1-o-chlorophenyl-ethanol, formerly RWJ-333369) is a novel molecule in the carbamate class that has exhibited potent and broad activity in rodent seizure models including audiogenic seizure models and seizures induced by MES (Maximal Electroshock), PTZ, BIC (bicuculline), and picrotoxin, as well as in corneal-kindled rats (6). Carisbamate also suppressed the duration of spike-and-wave discharges in the GAERS model (61) and has shown efficacy in additional rat models. Approximately 44% of the drug is protein bound, and primary routes of metabolism include O-glucuronidation and carbamate ester hydrolysis followed by oxidation of the aliphatic side chain (62). Unlike felbamate, there is low likelihood of conversion to the reactive metabolite mercapturic acid or its conjugates (63). This is important as presence of mercapturic acid has been suggested as a potential cause of some of felbamate's serious idiosyncratic reactions. Carisbamate has a 12-hour half-life allowing for twice daily dosing and follows linear pharmacokinetics (64). Maximum concentrations (C_{max}) occur 1 to 3 hours after dosing. Oral (metabolic) clearance is low. It is primarily renally excreted. Carisbamate has minimal impact on CYP450 hepatic enzymes and only slightly increases valproic acid and lamotrigine clearance (63). While carisbamate has no effect on carbamazepine pharmacokinetics, the C_{max} of carisbamate is reduced by approximately 30% when administered with carbamazepine (65). Carisbamate plasma concentration is reduced to a lesser extent when administered with an oral contraceptive (63). A randomized, double-blind, placebo-controlled, dose-ranging Phase IIb study for adjunctive use in partial-onset seizures has recently been completed (66). At carisbamate doses of 300, 800, and 1600 mg/day, patients experienced a reduced seizure frequency of 24% ($P = 0.001$), 21% ($P = 0.006$), and 29% ($P < 0.001$), respectively, compared to a 6% reduction in the placebo group. The most common adverse events in patients were CNS related (headaches, dizziness, somnolence) and led to drug discontinuation in 6%, 12%, and 19% in each of the respective carisbamate-treated groups (vs. 8% in the placebo group). However, two other identical randomized placebo-controlled trials revealed that patients treated with carisbamate 400 mg/day had significant improvement ($P < 0.01$) in percent reduction of seizure frequency compared to placebo in one study, but not the other (67). Carisbamate 200 mg/day did not differ statistically from placebo in either study (67).

Johnson and Johnson filed a new drug application (NDA) to the FDA in 2008. After initial approval, the conflicting results from the completed studies led the FDA to not give marketing

approval in 2009, and development was suspended. This compound has recently been acquired by SK Life Science; it is presently unclear if it will continue in development for epilepsy. It may be useful to explore its use further in refractory idiopathic generalized epilepsy with photosensitivity.

Everolimus

Everolimus is an exciting new advance in the therapy of tuberous sclerosis complex and opens the way for more specific biologic therapies as advances in genetics and genomics uncover more specific molecular mechanisms underlying the epilepsies. Tuberous sclerosis complex is frequently associated with treatment resistant epilepsy and is the prototypic "mTORopathy" which also includes a proportion of other disorders associated with epilepsy including focal cortical dysplasia, ganglioglioma, and hemimegancephaly (68). The mTOR pathway is critical in the control of cell growth and proliferation in the development of the cerebral cortex. Aberrant control of the mTOR pathway due to pathogenic mutations in mTOR complex 1 (mTORC1) and other genes involved in the mTOR pathway may allow for abnormal cell growth and differentiation. Everolimus is a rapamycin analog (a "rapalog") with a superior pharmacokinetic profile to that of rapamycin. It has been shown to be effective and safe in the treatment of patients with tuberous sclerosis complex and associated subependymal giant cell astrocytomas (69). The recent EXIST-1 trial (70), involving 117 patients aged between 0 and 65 years, demonstrated a >50% reduction in the volume of subependymal giant cell astrocytomas in 35% of patients on active treatment, suggesting a clear disease-modifying effect of everolimus in tuberous sclerosis complex. Adverse effects include stomatitis and mouth ulceration and were mild and did not lead to treatment discontinuation in the EXIST-1 trial. Mean duration of active treatment was 41.9 weeks. Anecdotal reports have described the beneficial effects on seizure control in patients with refractory epilepsy associated with tuberous sclerosis complex (71); trials are now in progress or planned to test this exciting prospect more formally. If this is proven, then it may be that individuals with epilepsy associated with genetic defects involving the mTOR pathway more broadly may benefit from everolimus therapy.

Huperzine A

Huperzine A, an N-methyl-D-aspartate (NMDA) receptor and acetylcholinesterase inhibitor, is a sesquiterpene lycopodium alkaloid isolated from the Chinese club moss Huperzia serrata, traditionally used in China for swelling, fever and inflammation, blood disorders, and schizophrenia (7,72,73). Huperzine A is approved for use in China for Alzheimer disease and is considered a dietary supplement by the U.S. FDA, available in health food stores. A recent Cochrane Review of use of huperzine A in mild cognitive impairment failed to identify suitable randomized placebo-controlled trials (74). While huperzine A has not been shown to protect against seizures in the MES-induced seizure model, it has been found to be protective against subcutaneous PTZ-induced seizures in mice and NMDA-induced seizures and status epilepticus in rats (75). A maximum protection was observed at three doses of 1, 2, and 4 mg/kg in mice; however, rotarod test impairment was observed in a majority of mice at doses of 2 and 4 mg/kg (76). Given its mechanism of action, it has been speculated that huperzine A may be effective in the management of organophosphate poisoning, which is associated with acute symptomatic seizures (75). A trial is underway in patients with Alzheimer disease using doses of 200 and 400 g twice daily. A case report has described the apparent beneficial effect of huperzine A lasting over 6 months in a Bernese mountain dog with frequent complex partial

seizures (77). Further preclinical studies to better understand its mechanism of action and pharmacologic profile are underway with a view toward further clinical trials in epilepsy.

NAX 810-2 and Other Galanin Receptor-2-Based Therapies

Galanin is a neuropeptide with anticonvulsant properties, acting on galanin (Gal) receptor subtypes 1 and 2. Systemic administration of galanin leads to poor penetration across the blood–brain barrier and activation of peripheral GalR1, which leads to inhibition of insulin release and thus hyperglycemia. NAX 810-2 is the lead compound in a series of galanin analog with preferential binding to GalR2; it is safer and leads to less hyperglycemia. NAX 810-2 is active in a wide variety of animal models of epilepsy, including the mouse 6 Hz seizure model. It also appears to be effective in animal models of pain. Further preclinical studies are ongoing.

Propofol Hemi-Succinate

Propofol hemisuccinate (PHS), a water-soluble prodrug form of the anesthetic agent propofol, is delivered via nebulizer to the lung. The onset of action of PHS compared to propofol in proof-of-principle animal studies is delayed, which suggests conversion of PHS to propofol might occur (78). In mice, intraperitoneal PHS (60 to 80 mg/kg) elevated seizure thresholds in PTZ, bicuculline, picrotoxin, and kainic acid seizure models (78); however, intratracheal administration was more potent, elevating seizure threshold at lower doses (10 to 15 mg/kg). Onset of PHS activity in the PTZ mouse threshold model was at 5 minutes, maximal activity at 10 minutes, and loss of activity at 20 minutes (78). These findings suggest that intratracheal PHS administration provides potent seizure protection of rapid onset and brief duration (78). Intrapulmonary PHS is not known to cause pulmonary damage or inflammation. Human safety and efficacy studies of nebulized PHS are planned.

Stiripentol

Stiripentol (4,4 dimethyl-1-(3,4-methylenedioxyphenyl)- 1-penten-3-ol) is a structurally novel molecule belonging to the aromatic allylic alcohol family. It has been used in France and Canada for over 15 years, but only recently began development for use in the United States. Animal studies have shown that stiripentol both inhibits synaptosomal GABA uptake and also enhances GABAergic transmission in CA3 pyramidal neurons of immature rats (79,80). In addition, stiripentol inhibits the hepatic cytochrome P450 enzymes, which likely also contributes to the drug's antiepileptogenic properties when it is combined with other AEDs, as serum concentrations of many concomitant AEDs will rise (81). This feature of stiripentol has made it difficult to study clinically. Patients with refractory epilepsy are often on concomitant AEDs, making it difficult to attribute any observed therapeutic effects purely to stiripentol. Specifically, stiripentol inhibits CYP3A4, CYP2C19, and CYP1A2. The coadministration of stiripentol with carbamazepine significantly increases the ratio of carbamazepine to carbamazepine epoxide. Stiripentol also inhibits the hydroxylation of the active metabolite of clobazam, desmethylclobazam. These interactions underscore the need to reduce the dose of carbamazepine and clobazam when stiripentol is added as adjunctive therapy. Because of its broad inhibition of the CYP system, stiripentol has the propensity to cause many other drug–drug interactions, including the elevation of theophylline and caffeine through CYP1A2 inhibition. Stiripentol is 99% protein bound and demonstrates nonlinear pharmacokinetics, decreasing in clearance as drug dose increases (82).

Since 1995, studies in adults have been discontinued due to lack of efficacy; however, results in children have been more promising. The first trial was an open-label adjunctive therapy study, which included children with partial-onset epilepsy, as well as children with Dravet syndrome (severe myoclonic epilepsy in infants) (83). Two-thirds of the children with partial epilepsy treated with stiripentol were responders to drug, and 20% became seizure free. In addition, 10 out of 20 children with Dravet syndrome were responders, and three became seizure free. Given these findings, two additional small add-on trials were performed, one in France and one in Italy. Children 3 to 18 years of age with Dravet syndrome were enrolled. Stiripentol significantly reduced clonic and tonic–clonic seizure frequency and led to complete seizure freedom in 9/21 patients and 3/12 patients in the two respective trials (84). Whether these results are purely attributable to stiripentol alone, or to secondary increases in concomitant AEDs, remains to be determined. Adverse effects of stiripentol are fairly common, but can be minimized by adjusting doses of coadministered drugs. The most frequently observed adverse effects include drowsiness, slowing of mental function, ataxia, diplopia, loss of appetite causing weight loss, nausea, abdominal pain, and occasionally asymptomatic neutropenia (85). Currently, stiripentol is available from some hospitals in France and has been granted orphan drug status by the European Union for use in Dravet syndrome. In a recently published retrospective study in 82 children with Dravet syndrome in the United States, stiripentol use reduced seizure frequency, prolonged seizure occurrence, rescue medication use, and emergency room visits (86).

Tonabersat

Tonabersat is a novel benzoylamino benzopyran compound developed by SmithKline Beecham for the treatment of migraine and epilepsy (8). It binds to a site distinct from other CNS drugs and possesses a novel mechanism of action that possibly relates to uncoupling of neuronal gap junctions (8). Findings in rats suggest gap junctions play a role in the expression, duration, and propagation of seizures; in one study, blockade of gap junctions with carbenoxolone shortened seizure duration and decreased ictal discharge amplitude, while opening of gap junctions with trimethylamine increased ictal duration and amplitude and facilitated secondary epileptogenesis (87). Tonabersat has been tested in multiple animal models in preclinical studies; in vivo tonabersat demonstrated low toxicity with a TD50 > 250 mg/kg in mice and > 500 mg/kg in rats (8). Time- and dose-dependent inhibition of tonic extension seizures was observed in the rat MES model, and efficacy against audiogenic seizures has also been appreciated (8). Tonabersat was not effective against 6 Hz or picrotoxin-/bicuculline-induced clonic seizures (8). It also failed to inhibit seizures in either hippocampal or lamotrigine-resistant kindled rats (8). Tonabersat is currently undergoing Phase 1 clinical studies for epilepsy.

YKP3089

YKP3089 is a novel tetrazole-derived compound now in Phase 11 clinical development (8). It has been effective in a wide variety of epilepsy and seizure animal models, suggesting its potential use as a broad-spectrum AED (7). It also has efficacy in rodent models of anxiety. Its mechanism of action is currently unknown. Phase I clinical trials have documented linear pharmacokinetics over a single dose range of 5 to 750 mg and a half-life of 30 to 75 hours (7). Single dose studies have shown the drug to be well tolerated, with a low incidence of CNS-related adverse effects. The compound was

effective in a photosensitivity study. In this study, 12 patients were given a single dose of either placebo or 100, 250, or 400 mg of YKP 3089. The best response was seen at the highest dose of 400 mg. The 400 mg dose level of YKP3089 produced complete suppression of intermittent photic sensitivity in 1 out of 4 (25%) patients and partial suppression in 2 out of 4 (50%) patients in at least one eye condition (88).

A recently completed Phase II study demonstrated good efficacy. Patients with partial-onset seizures were randomized to placebo or to adjunctive 200 mg YKP3089 over a 6-week titration period followed by a 6-week maintenance period. There was a 50% responder rate of 50% in patients randomized to YKP versus 22% on placebo $P < 0.0001$. Twenty-eight percent of patients on active drug were seizure free during the maintenance phase versus 9% on placebo (88). A larger dose-ranging trial was ongoing at the time of this writing.

CONCLUSIONS AND FUTURE DIRECTIONS

The choice of clinically effective novel anticonvulsant compounds will likely expand and help more patients with epilepsy live with fewer seizures and side effects. However, with now over 20 AEDs available, the practicalities and logistics of performing the old type of trial designs in investigating new compounds is now a very significant challenge; new innovative trial designs are needed. As new drugs are released onto market, continued vigilance will be needed to detect rare idiosyncratic side effects, and this should include the use of postmarketing surveillance studies. Interest will grow in the elucidation of optimal combination therapies using the available and upcoming drugs. Improvements in drug delivery systems and an increased choice of parenteral formulations are other reasonable expectations. The identification of compounds with antiepileptogenic and neuroprotective properties remains a priority. Advances in our understanding of the genomic underpinnings of many of the epilepsies and continued pharmacogenomics research will help pave the way for tailored biologic therapies and more individualized drug prescribing.

CHAPTER 69 LESS COMMONLY USED ANTIEPILEPTIC DRUGS

ROBERT T. WECHSLER AND BASIM M. UTHMAN

The AEDs are generally divided broadly into the first-generation and second-generation agents, with the first generation consisting of those agents that became available prior to the mid-1980s and the second generation consisting of those agents that became available after 1992. Some go further and consider agents that emerged after 2000 as possibly making up a third generation of AEDs. The generations are largely differentiated from each other on the basis of tolerability differences rather than differences in efficacy, with newer agents generally considered less likely to be associated with toxic, dose-dependent side effects. There is little evidence of substantial and consistent superiority between different AEDs, although some may work better than others in an individual patient or in specific syndromes. While the newer agents have supplanted the older ones in many circumstances, older agents are still sometimes used when newer agents are not available or have failed to yield an adequate clinical response.

This chapter focuses on some of the older and less frequently encountered AEDs that are still in use in some parts of the world, albeit infrequently. Some of these agents are no longer available in the United States. They are presented in chronologic order of their development for the treatment of epilepsy: bromides, mephobarbital, acetazolamide, pyridoxine, ethotoin, and methsuximide.

BROMIDES

Historical Background

In 1857, at a time when seizures were linked to hysteria and masturbation, bromides were thought to have antiaphrodisiac properties and were introduced for the treatment of epilepsy (1). They remained the principal AED until phenobarbital became available in 1912 and are rarely used in the modern era.

Chemistry and Mechanism of Action

The anticonvulsant mechanism of bromides is thought to be related to hyperpolarization of postsynaptic membranes. Bromide has a smaller hydrated diameter than does chloride, crosses cell membranes faster, and tends to hyperpolarize postsynaptic membranes activated by inhibitory neurotransmitters (2).

Absorption, Distribution, and Metabolism

Bromide salts are rapidly absorbed from the GI tract and have nearly complete bioavailability, with a

volume of distribution similar to that of chloride ions (3). Tissues do not distinguish between these two anions, so their concentration in extracellular fluids depends on their relative intake and excretion. Bromides have a half-life of approximately 12 days after oral administration (3). Excretion by the kidneys occurs slowly and depends on concomitant chloride intake. A high chloride load increases the excretion of bromides and shortens the half-life. Conversely, a salt-deficient diet reduces bromide clearance and prolongs the half-life (3).

Efficacy and Clinical Use

Bromides are usually administered as triple bromide elixir (a combination of sodium, potassium, and ammonium bromide salts) containing 240 mg/mL of bromide salt. The usual dosage in children younger than 6 years of age ranges from 300 mg twice daily to 600 mg three times daily. For children older than 6 years of age, 300 to 1000 mg is administered three times daily (4). The therapeutic plasma concentration (3) ranges from 750 to 1250 μg/mL. The therapeutic window for bromides is narrow, with potential toxicity at plasma concentrations in the range of 1500 μg/mL. Careful monitoring is thus required, and a steady dietary salt intake should be maintained during treatment.

Interactions with Other Agents and Adverse Effects

Interactions between bromides and other agents have not been reported. Sedation is the most frequently encountered side effect, usually a result of chronic toxicity (bromism), which can also cause weakness, fatigue, headaches, irritability, confusion, restlessness, psychosis, and sometimes coma (5). Dermatologic manifestations include rash, nodular or pustular lesions, and ulcerations. Anorexia, constipation, and GI distress may also occur. Rare cases of acute intoxication with nephrotoxicity and ototoxicity have been reported. Bromism is treated by the administration of a large quantity of sodium chloride and a chloruretic agent. Hemodialysis or peritoneal dialysis can be used to lower bromide levels rapidly (6).

MEPHOBARBITAL

Historical Background

Hundreds of barbiturate compounds have been synthesized since barbituric acid was first produced in 1864, but only a few have been licensed by the U.S. Food and Drug Administration as hypnotics, anesthetics, or anticonvulsants (7). Three barbiturate agents have commonly been marketed as AEDs: phenobarbital, primidone, and mephobarbital (methylphenobarbital). Phenobarbital was introduced in 1912 and remains a major AED in use worldwide for a variety seizure types, most often for refractory status epilepticus in the United States. Primidone is a deoxybarbiturate that is metabolized to phenobarbital and phenylethylmalonamide. Phenobarbital and primidone are discussed in detail in other chapters. Mephobarbital is considered here.

Chemistry and Mechanism of Action

Mephobarbital is structurally similar to phenobarbital, with the addition of a methyl group at the 3 N position. All commercially available hypnotic barbiturates exhibit anticonvulsant activity at

anesthetic doses and inhibit epileptic seizures induced by electroshock, tetanus, strychnine, or pentylenetetrazol. This anticonvulsant activity is distinct from sedative or anesthetic effects and is not diminished by the concurrent administration of agents that counteract sedation (7). Barbiturates prolong and potentiate the action of GABA at $GABA_A$ receptors (8).

Absorption, Distribution, and Metabolism

Mephobarbital is highly soluble in lipids, is easily absorbed, and readily crosses biologic membranes. It is widely distributed in the body, with higher concentrations in adipose tissue and brain. It is metabolized to phenobarbital by demethylation in the liver, is affected by the cytochrome P450 system, and is partly excreted in human urine as a p-hydroxyphenyl glucuronide derivative of the parent drug (9). Phenobarbital is a hepatic enzyme inducer, possibly responsible for the gradual decrease in mephobarbital elimination half-life from approximately 50 hours initially to 12 to 24 hours during long-term therapy.

Efficacy and Clinical Use

Clinical use of mephobarbital began in 1932 (10). One might reasonably expect its efficacy and safety to be similar to that of its metabolite, phenobarbital, although well-controlled studies comparing it with other AEDs for the treatment of epilepsy have not been conducted. The therapeutic range of mephobarbital is expressed in terms of plasma phenobarbital concentrations because of the metabolite's slower metabolism. Usual therapeutic plasma levels of phenobarbital range from 10 to 40 μg/mL and steady-state plasma phenobarbital levels correlate closely with mephobarbital dose. Mephobarbital dosages of 3 to 4 mg/kg/day produce mean plasma phenobarbital levels of 15 μg/mL; a dosage of 5 mg/kg/day produces mean levels of 20 μg/mL (11). At higher mephobarbital doses, proportionately lower phenobarbital plasma levels are seen. This may suggest a rate-limited metabolism at high plasma mephobarbital concentrations (11).

Interactions with Other Agents and Adverse Effects

Any interaction that is known to occur with phenobarbital is also likely to happen with mephobarbital. The most common adverse effects with both agents include cognitive impairment, hypnotic effects, irritability, hyperactivity, and alterations in sleep patterns (7). Thus, when other, safer AEDs have failed and phenobarbital or mephobarbital must be used, patients should be treated with the lowest dose that effects adequate seizure control.

Another set of side effects of phenobarbital that are sometimes unintentionally minimized by both patients and physicians are impotence and decreased libido. In a Veterans Administration Cooperative study, Mattson and colleagues (12) found that 15% of patients complained of decreased potency, decreased libido, or both. Of 56 patients who took phenobarbital for 1 year, 14% reported a transient or continuous decrease in sexual function. The problem usually disappeared when phenytoin or carbamazepine was substituted for phenobarbital but not when phenobarbital was changed to another barbiturate.

ACETAZOLAMIDE

Historical Background

Carbonic anhydrase activity was first demonstrated in red blood cells in the early 1930s and has subsequently been found in many tissues, including the pancreas, gastric mucosa, renal cortex, eye, and the CNS. Inhibition of carbonic anhydrase activity was observed when sulfanilamide was introduced as a chemotherapeutic agent. A large number of sulfonamides have been synthesized and tested as carbonic anhydrase inhibitors and potential diuretics. Acetazolamide was first introduced in 1952 (13) and is still in limited use in the present day. It can be effective in several seizure types but has limited long-term utility because tolerance develops rapidly (14).

Chemistry and Mechanism of Action

Acetazolamide (N-(5-sulfamoyl-1,3,4-thiadiazol-2-yl-)acetamide) is a weak acid that acts through inhibition of carbonic anhydrase, causing accumulation of carbon dioxide that is thought to be responsible for its anticonvulsant properties (15). Blocking carbonic anhydrase in other tissues, particularly red blood cells, causes even greater retention of carbon dioxide in the brain (15). Accumulation of carbon dioxide is thought to result in blockade of anion transport, disrupting seizure propagation as measured by prevention of maximal electroshock-induced seizures, which correlates with the degree of inhibition of brain carbonic anhydrase (16,17). The drug also alters choroid plexus function through its effect on carbonic anhydrase, decreasing production of CSF by limiting chloride and bicarbonate transport across the plexus, resulting in subsequent increased carbonic anhydrase synthesis in glial cells and glial proliferation, which may be a reason for the development of tolerance (14).

Absorption, Distribution, and Metabolism

Acetazolamide is rapidly absorbed from the GI tract, and peak plasma levels occur 2 to 4 hours after a single oral dose (14). In humans, the agent is 90% protein bound, so concentrations are lower in CSF than in plasma. The greatest concentration of acetazolamide is in red blood cells. After distribution to various tissues, it binds to carbonic anhydrase and remains in a relatively stable carbonic anhydrase–acetazolamide complex. The plasma half-life of acetazolamide is 2 to 4 days. It is eliminated in the urine unchanged. Increasing urinary pH increases excretion. Acetazolamide is also excreted in the bile and is resorbed from the intestinal tract.

Efficacy and Clinical Use

Acetazolamide is effective against multiple seizure types, but tolerance develops within weeks of continuous treatment (14). For this reason, it is primarily used on an intermittent basis to treat periodic seizure exacerbations. Perhaps the most common application of acetazolamide is in catamenial epilepsy (18). The drug can be started prior to the expected onset of menses in each cycle and continued through the period of increased seizure risk. Steady-state plasma levels occur 5 to 7 days after the initial dose, and adequate levels continue for 3 to 5 days after the agent is discontinued. The recommended daily dosage of acetazolamide is 10 mg/kg given in a single dose or in two or three divided doses. Usual effective therapeutic plasma levels range from 8 to 14 μg/mL. Acetazolamide is available in 125- and 250-mg scored tablets as well as delayed-release 500-mg tablets.

Interactions with Other Agents and Adverse Effects

Acetazolamide is a relatively benign agent, with only a few known adverse effects. Lethargy, paresthesias, rashes, abdominal distention, and cyanosis have been reported with its use. It can alter taste sensation in up to 90% of patients, giving a false flat taste to carbonated beverages (19). Renal calculi have been reported after long-term use. Patients who have been taking phenytoin, barbiturates, and/or acetazolamide for 5 years or more show decreased bone mineral density compared with healthy controls (20). Elimination of acetazolamide may decrease and its half-life may increase with the concomitant use of probenecid, which blocks renal tubular secretion of acids. The absorption of salicylate may be increased and that of amphetamine may be delayed when these drugs are taken with acetazolamide.

PYRIDOXINE

Historical Background

The role of pyridoxine (vitamin B_6) in neonatal seizures was first recognized in the mid-1950s. Two types of pyridoxine-related seizure syndromes occur in the newborn: that caused by pyridoxine deficiency (21) and that caused by pyridoxine dependency (22). These rare conditions carry a poor prognosis for mental development if prompt treatment is not rendered. Pyridoxine deficiency is a nutritional disorder in which vitamin B_6 levels are reduced, whereas they tend to be normal in pyridoxine dependency. Pyridoxine dependency is an autosomal recessive disorder that typically manifests in neonates, although onset has been reported up to the age of 19 months (23). Supplemental vitamin B_6 is the only effective treatment for both syndromes. In pyridoxine deficiency, a single dose is sufficient, whereas pyridoxine dependency requires continued vitamin B_6 administration.

Chemistry and Mechanism of Action

Pyridoxal phosphate, the active metabolite of vitamin B_6, is the coenzyme for glutamic acid decarboxylase and GABA transaminase, the enzymes necessary for the production and metabolism of CNS GABA. In pyridoxine-dependent and -deficient states, GABA levels in CSF are significantly reduced (24). Supplementation of vitamin B_6 reverses this deficit.

Efficacy and Clinical Use

Pyridoxine Dependency

The diagnosis is established by remission of seizures (generalized seizures or status epilepticus) with vitamin B_6 and relapse without treatment. Pyridoxine hydrochloride stops seizures within minutes when given parenterally at doses in the range of 50 to 100 mg (25). In pyridoxine dependency, lifelong supplementation with vitamin B_6 is needed. Withdrawal of pyridoxine even after several years of effective therapy causes seizures to recur within days or weeks (25). Untreated patients develop intractable epilepsy, and most die within days or months (26). Psychomotor retardation and

progressive neurologic deterioration result when therapy is delayed, so early diagnosis and treatment are important for stopping the seizures and preventing a chronic encephalopathy.

Pyridoxine-dependent seizures rarely may involve prolonged seizure-free periods with conventional AEDs before pyridoxine treatment (25). Bass and coworkers (27) reported other atypical features in a child whose seizures stopped only after repeated trials of pyridoxine. The investigators warned of the possibility of decreased levels of consciousness with intravenous pyridoxine and of the need to have resuscitative equipment available.

Recommended daily oral maintenance dosages range from 2 to 300 mg, corresponding to doses from 0.2 to 30 mg/kg/day (25,26), with most patients becoming seizure free with doses between 20 and 100 mg/day. To prevent psychomotor retardation in patients with this condition, adjustments in the vitamin B_6 dosage should be based on seizure control and on normalization of glutamate concentration in the CSF (28).

Pyridoxine-Responsive Epilepsy

The finding that CSF levels of GABA were lower in patients with infantile spasms than in controls led to efforts to treat this syndrome with vitamin B_6. In the first and largest trial, 13% of children became seizure free within 2 weeks of initiation of daily treatment with vitamin B_6 at doses of 30 to 400 mg (29). However, when vitamin B_6 was assessed in comparison to valproic acid in another study, no statistically significant difference was identified between patients treated with either in monotherapy, the two in combination appeared to be more effective than either alone, and corticotropin was more effective than was vitamin B_6 both as monotherapy and in combination with valproic acid, although seizures eventually recurred in many of those patients (30). Of note, Wang and Kuo (31) suggest using pyridoxal phosphate (PLP), the active form of vitamin B_6, instead of pyridoxine in pediatric epilepsy. They reason that PLP is as inexpensive as pyridoxine is and patients with one of the four inborn errors of vitamin B_6 metabolism, pyridoxine phosphate oxidase deficiency, respond to PLP and not to pyridoxine.

It has been reported that supplementation with vitamin B_6 may help to correct the behavioral disturbance seen in children who have levetiracetam-induced behavioral side effects (32). It is unclear whether this phenomenon is related to relative pyridoxine deficiency.

Adverse Effects

After IV vitamin B_6 administration, apnea, lethargy, pallor, decreased responsiveness, and hypotonia may occur immediately and persist for several hours (26,27). Perhaps the most well-recognized consequence of long-term pyridoxine use is the development of peripheral neuropathy (33).

ETHOTOIN

Historical Background

Phenobarbital was the agent of choice in the treatment of seizures in the United States until 1938, when phenytoin began to be marketed as an AED. Merritt and Putnam first reported on the

anticonvulsant properties of phenyl derivatives in animal studies and recommended clinical trials of phenytoin (5,5-diphenylhydantoin), demonstrating the superiority of the agent over phenobarbital due to its lack of significant hypnotic effects (34). Phenytoin soon became the world's most commonly used agent for the treatment of patients with generalized tonic–clonic and simple and complex partial seizures. Other hydantoins also were tested, but only ethotoin, which became available in 1956 (35), is still in use today—although it is no longer available in the United States.

Chemistry and Mechanism of Action

Ethotoin (3-ethyl-5-phenylhydantoin) is structurally similar to phenytoin, except for the deletion of one phenyl group from position 5 and the addition of an ethyl group in position 3 of the hydantoin ring. Ethotoin inhibits seizures induced by maximal electroshock and pentylenetetrazol. Hydantoins cause frequency-dependent suppression of the sodium-mediated action potential through enhanced inactivation of voltage- gated sodium channels (36).

Absorption, Distribution, and Metabolism

Ethotoin is slowly absorbed from the gastrointestinal tract. Absorption is dose dependent; the time to peak plasma concentration increases with increasing dose. This nonlinear profile may explain the poor correlation between daily dose and steady-state serum levels of ethotoin (37). Ethotoin is metabolized in the liver by hydroxylation and de-ethylation of the hydantoin ring.

Efficacy and Clinical Use

The clinical use of ethotoin has been primarily limited by its relatively short half-life of 6 to 9 hours (38), although lack of gingival hyperplasia and hirsutism, side effects commonly encountered with phenytoin, made ethotoin an attractive alternative. Because of its short half-life, ethotoin is given in four divided doses of 20 to 40 mg/kg/day. In a retrospective study of adults with medically refractory epilepsy, ethotoin as adjunctive therapy reduced overall seizure frequency, especially the frequency of tonic seizures (39). The efficacy of the agent, however, was reduced by one-half within 10 months, suggesting relatively rapid onset of tolerance. Ethotoin is ineffective in treating and may exacerbate absence seizures.

Interactions with Other Agents and Adverse Effects

No drug–drug interactions have been documented with ethotoin. Ethotoin can cause ataxia, diplopia, dizziness, insomnia, rash, GI distress, and rarely lymphadenopathy. Cleft lip, cleft palate, and other malformations have occurred in infants born to mothers taking ethotoin (40). Although ethotoin has been available for more than five decades, its efficacy and safety were not adequately established, and its use in the treatment of seizures and epilepsy has waned to the point that it is no longer available in the United States.

METHSUXIMIDE

Historical Background

Methsuximide belongs to the succinimide family, which also includes the more commonly used AED, ethosuximide. The latter is discussed separately. This group of agents emerged as effective for the treatment of absence seizures in the late 1950s and early 1960s. Methsuximide was introduced in 1957 for the treatment of refractory absence seizures but is also effective in the treatment of partial seizures (41). It is no longer used in the United States.

Chemistry and Mechanism of Action

Succinimides share a common heterocyclic ring. They can have either proconvulsant or anticonvulsant effects (42). This may be related to the substitution of different chemical groups in the succinimide ring (7). Methsuximide is a nonpolar chemical compound that is water soluble and slightly lipophilic. While its exact effects on excitable membranes are not known, its effectiveness against absence seizures suggests that it may block calcium currents similarly to ethosuximide (42).

Absorption, Distribution, and Metabolism

Methsuximide is quickly absorbed through the GI tract and is evenly distributed throughout the body, with peak plasma levels achieved within 2 to 4 hours. It has a mean half-life of 1.4 hours and is rapidly metabolized to N-desmethyl-methsuximide, which has a mean half-life of 38 hours and also has an anticonvulsant effect (43).

Efficacy and Clinical Use

Methsuximide is effective in a variety of seizure types, including absence seizures, myoclonic seizures, and focal-onset seizures (41,44). Tolerance to the anticonvulsant effect of methsuximide develops in approximately 50% of patients treated with maximal doses, and seizure frequency eventually returns to baseline. Rapid dose titration can be associated with toxicity that may lead to therapeutic failure, so dose should not be increased more often than every 2 weeks (45).

Interactions with Other Agents and Adverse Effects

Methsuximide interacts with other AEDs, necessitating close monitoring of serum levels and adjustment of concurrent AED dose, especially in the face of clinical toxicity (45). Methsuximide increases the mean serum concentration of phenobarbital by up to 37% and the mean serum concentration of phenytoin by up to 78% (46). Phenobarbital and phenytoin also increase serum levels of N-desmethyl-methsuximide compared with patients taking methsuximide alone (46). Methsuximide also decreased the mean serum concentrations of several other AEDs including carbamazepine (47), valproic acid (48), lamotrigine (49), and topiramate (50). Common side effects of methsuximide include GI disturbance, lethargy, somnolence, fatigue, headache, hiccups, irritability, ataxia, blurred vision, diplopia, inattention, and dysarthria (46).

CONCLUSION

Following the “Decade of the Brain” in the 1990s, there has been a dramatic increase in the number of therapeutic options available for the treatment of seizures in epilepsy, including new pharmacotherapies, neurostimulation, and other surgical innovations. We have come to accept that

mainstream, broad-spectrum AEDs—valproate, levetiracetam, lamotrigine, topiramate, zonisamide, and felbamate—can be effective in a variety of seizure types, whereas narrow-spectrum AEDs can exacerbate some primary generalized seizure types. We accept that the true role of some of the newest AEDs remains to be fully defined. However, within these broad generalizations, no AED has ever distinguished itself as being consistently superior in efficacy. Refractory epilepsy often remains refractory despite the advent of new therapies.

In striving to achieve seizure freedom without side effects in as many patients as possible, one is often required to keep an open mind to all therapeutic options, even older agents that have fallen out of broader use. While several of the agents discussed in this chapter are no longer available in the United States, they remain in use in some countries and remain appropriate therapeutic options in selected cases when more conventional therapies are unavailable. Finally, some innovations that first came to light decades ago still have practical significance today, such as the critical role of pyridoxine in some neonatal seizure syndromes and the potential role of acetazolamide in the treatment of periodic seizure exacerbations in catamenial epilepsy.

CHAPTER 70 DIETARY THERAPIES FOR EPILEPSY

ERIC H.W. KOSSOFF

HISTORY

Approximately 100 years ago, there were few anticonvulsants other than phenobarbital and bromides available for the treatment of epilepsy. In July 1921, the ketogenic diet (KD) was first reported as beneficial by Dr. Wilder and colleagues at the Mayo Clinic in Rochester, Minnesota (1). This treatment restricted carbohydrates, protein, calories, and fluids while significantly increasing fat intake to comprise approximately 90% of calories. Early reports described that half of all patients were responders, which is strikingly similar to more recent reports. Within several years, it became one of the most popular treatments for adults as well as children with epilepsy.

However, as new anticonvulsants such as phenytoin and carbamazepine were rapidly introduced, the popularity of the KD diminished. For several decades, it was only used at select pediatric academic medical institutions, and nearly only as a last resort. Very little research or interest existed until the creation of the Charlie Foundation parent support group in 1994 by the father of a toddler with intractable generalized seizures (www.charliefoundation.org).

In the 20 years since the Charlie Foundation was founded, dietary therapies for epilepsy have undergone a radical transformation in popularity. Every year, at least 100 new articles devoted to dietary therapy are being published by both clinical as well as basic scientists. Large international symposia solely focusing on dietary therapies have been held in Phoenix in 2008, Edinburgh in 2010, Chicago in 2012, and a fourth in Liverpool in October 2014. Results from two prospective controlled trials demonstrating efficacy of the KD are available since 2008 and 2009, respectively. Additionally, an International Consensus Statement guiding ideal use was published in 2009 (2–4). There are now four different KDs available to choose from: the traditional "classic" KD, the medium-chain triglyceride (MCT) diet, the modified Atkins diet (MAD), and the low glycemic index treatment (LGIT) (5–7). Diets are being used for adults, all over the world (including developing countries), earlier (even initially) in the treatment of epilepsy, and for neurologic conditions other than epilepsy such as Alzheimer disease, brain tumors, and autism (8–11).

Despite this recent progress, the KD is still vastly underutilized. Many patients and parents self-refer to KD centers as local neurologists are not universally encouraging of the KD. Although in one series 72% of parents received information about the KD from their child neurologists, who were typically viewed as highly supportive, the average time from epilepsy to KD onset was 2.8 years (12). Adults and children living in many regions of Central America, Africa, and Southeast Asia are not routinely offered ketogenic therapy (9).

ADMINISTRATION

The composition of the traditional "classic" KD has not changed significantly in the past 100 years since its introduction. The diet "prescription" includes a ratio of grams of fat to carbohydrate and protein combined, and 4:1 is the most common starting ratio (13). Lower ratios, usually 3:1 or 2:1, are utilized for infants, adolescents, and patients in whom higher protein or carbohydrate amounts are required due to either tolerability or side effects (13). Calories and fluid amounts are typically not restricted but are measured and calculated for each child. Examples of foods eaten include butter, bacon, heavy whipping cream, mayonnaise, oils, eggs, and cheese. However, fruits, vegetables, meats, fish, and nuts are often included as well. Breads, pastries, rice, candy, cake, and juices are significantly restricted. Computer programs such as KetoCalculator and EKM have improved the flexibility and variety of food items and meals that children are able to eat on the diet.

The KD is most commonly started in the hospital as part of a several-day admission during which parents are educated how to weigh and measure foods using gram scales (13). Fasting for 24 hours is a traditional method to start the diet. While fasting is not required for long-term benefit (14), quicker onset of ketosis may lead to faster improvement in seizure frequency (15). Vomiting, hypoglycemia, and acidosis may occur during the KD initiation week, but seizures may also rapidly decrease.

Recent years have seen a modification in the way the KD is started, not only via eliminating the fasting period but some centers have also started the KD outside the hospital (16). The MAD and the LGIT are typically taught to parents and patients during brief training sessions in outpatient clinics. E-mail administration has also been reported as a feasible alternative diet initiation and management option for adults and children in remote settings or developing countries (17). Cultural, social, and religious issues need to be considered on an individual basis, and the KD can be adapted for each family.

Anticonvulsants are typically left unchanged during the admission, other than being switched to tablet forms to avoid excess carbohydrates in liquid (13). One study determined that zonisamide may be beneficial for seizure control when used at the onset of the KD; phenobarbital may be detrimental (18). Many families start the KD with a secondary goal of anticonvulsant reduction, but this is not universally achieved (12).

The KD should not be started at home by a family; a neurologist and dietitian team are required for its maintenance. A KD-trained dietitian often adjusts the diet during periodic follow-up clinic visits every 1 to 3 months in order to optimize growth, nutrition, and efficacy (13). Side effects are consistently monitored and prevented through the use of supplements (more details to follow). An international group of 26 neurologists and dietitians, experts in the KD, published a Consensus Statement regarding ideal implementation and management in 2009 (4).

MECHANISMS OF ACTION

Twenty years ago, the KD was believed to have an unknown mechanism of action. Now it is accepted that there are multiple likely reasons for its benefits (19). The KD utilizes a high-fat, adequate-protein (1 g/kg), low-carbohydrate diet that produces metabolic changes often associated with the starvation state. Changes in plasma ketones, insulin, glucose, glucagon, and free fatty acids can occur within hours of starting the KD. Fasting appears to have an independent effect on seizure control, however, even before actual KD food is provided. Preliminary results from animal studies suggest that the effect of intermittent fasting is mediated by a distinct mechanism from the KD (20). Similarly, added benefits of fasting can be seen in children treated with the KD (21).

The name of the KD derives from the theory that ketone bodies (acetoacetate, acetone, and beta-

hydroxybutyrate), created in the liver from long- and medium-chain fatty acids, are directly anticonvulsant when crossing the blood–brain barrier. Urine and occasionally serum ketone levels are generally checked in patients on the KD to ensure that the diet is being managed correctly, in a manner analogous to anticonvulsant levels. However, it is unclear if ketosis is truly a mechanism of action or solely a marker that the body has made the metabolic shift to burn fat.

Increased mitochondrial biogenesis, oxidative phosphorylation, enhanced gamma aminobutyric acid levels, reduced neuronal excitability and firing, and stabilized synaptic function have been shown to occur in patients on the KD (19). While these may be induced by ketosis, alternative mechanisms proposed include elevated plasma free fatty acids (including polyunsaturated fatty acids), reduced glucose fluctuations, increased activation of ATP-sensitive potassium channels and adenosine, caloric restriction, and elevated brain amino acids (19).

EFFICACY

The KD is an effective treatment for patients with epilepsy, regardless of age, gender, or seizure type. A 2006 meta-analysis of 19 observational studies (1084 patients) found that after 6 months, approximately 50% to 60% of children started on the KD had a >50% seizure reduction, with 30% having >90% seizure reduction (22). Approximately 10% will become seizure free after 6 months of use. This meta-analysis and others provided further evidence for the use of the KD, but also demonstrated that no randomized, controlled studies exist to provide Class I evidence in support of its use (22,23).

This changed in 2008, following a study examining the MCT and classic KD, with a 4-week waiting period for each arm serving as its own control (2). Each arm was also subsequently randomized to an additional 12-week control period of continued anticonvulsants. After 4 months, the seizure frequency was significantly lower in the 54 children on the KD (38% decrease in seizures), compared to the 49 controls (37% increase in seizures) ($p < 0.0001$) (2). Additionally, no difference was seen in efficacy between the classical and MCT diets, the latter being also a randomized arm of this trial. Although this control group did not include a new treatment (e.g., an adjunctive anticonvulsant), the results clearly demonstrate that the KD is an effective epilepsy treatment leading to longitudinal improvement over time.

A randomized, double-blind, placebo-controlled trial of 20 patients (60 g daily glucose vs. saccharin solution given sequentially as a crossover during an initial fasting period) was published by our group at the Johns Hopkins Hospital the following year (3). This double-blinded placebo-controlled study was successful with parents and investigators being unaware of which solution the child was given or their level of ketosis. Only a strong trend toward statistical significance was identified in favor of the saccharin (treatment) group over the glucose (placebo) group, $p = 0.07$. Likely reasons for the study not to reach statistical significance include insufficient glucose (and persistent ketosis in the placebo group), the effects of fasting on immediate seizures in both groups, and too short a period allowed for a return to a baseline level of seizure frequency during the crossover between the treatment arms. There was overall a mean decrease of 34 seizures per day over the 12-day study period ($p = 0.003$) (3). This study demonstrates that the KD can be studied in a blinded manner.

The most recent randomized and controlled study followed the Neal protocol but studied the MAD (24). In this randomized, controlled trial in 102 children aged 2 to 14 years, the MAD was more likely to reduce seizures by 50% after 3 months than were continued anticonvulsants (52% vs.

11.5%, p < 0.001). The likelihood of >90% seizure reduction was also more likely with the MAD (30% vs. 7.7%, p = 0.005).

"ALTERNATIVE" DIETS

Although the KD is helpful for approximately 50% of children who try it, there are some adolescents, adults, busy families with multiple children, and patients with very high baseline carbohydrate intake (or fat aversion) who are concerned about the difficulty in changing their lifestyle to begin the KD. For these patients, "alternative" diets may be new options to successfully allow them to try this nonpharmacologic approach. Three alternative diets have been described, including the MCT diet, LGIT, and MAD (Table 70.1).

The MCT diet has been used since the 1970s. This diet provides large quantities of this highly ketogenic oil in order to free up more carbohydrates, and this in turn improves tolerability. The MCT diet was studied in a prospective, controlled, randomized manner by Dr. Neal and colleagues from London in 2008, and although the classic KD led to higher serum ketone levels, fatigue (at 3 months), and mineral deficiencies, there was no difference in growth, efficacy, and overall tolerability (5,25,26). There may be some benefit to dyslipidemia (27). The MCT diet is mostly used in the United Kingdom and Canada at this time.

The LGIT was first published by Dr. Thiele and colleagues from Boston in 2005, based on previously anecdotal reports of excessive carbohydrates (at times from cheating) leading to immediate seizure breakthroughs (28). This diet targets glucose by providing carbohydrates with glycemic indices <50 in order to maintain stable blood glucose levels (28). Although serum ketones do increase, changes are usually minimal. The LGIT is started as an outpatient without a fasting period. An update in 2009 from the same group includes 76 children, of which 50% of those remaining on the diet at 3 months had >50% seizure reduction (7). Nearly one-quarter found the LGIT restrictive and stopped this diet for that reason. Recent studies have described benefits for children with tuberous sclerosis complex and Angelman syndrome (29,30).

The fourth therapeutic diet, the MAD, was first published by our group in 2003 (31). The MAD is also started on an outpatient without a fast, but does not restrict calories, fluid, or protein (Table 70.2). Carbohydrates are restricted to 10 g/day (children) or 20 g/day (adults), and fats are strongly encouraged in order to maintain ketosis. When analyzed, the MAD mimics a 1:1 ketogenic ratio. To our knowledge, there are now 33 publications that detail the use of the MAD in children and adults,

with 207 (46%) of 452 total subjects having >50% seizure reduction after 6 months of which 108 (22%) had >90% improvement. These results are quite similar to findings in patients treated with the KD. One recent publication suggests that using one of the KD formulas (KetoCal) during the initial month may in fact boost the efficacy of the MAD by providing additional fat sources (6). Children can be switched from the MAD to the KD, with 30% of those switched having additional benefit, especially if their underlying condition was myoclonic astatic epilepsy (Doose syndrome) (32). Long-term outcomes on the MAD after 12 months appear similar to the short-term benefits as well (33). The MAD may also be especially useful for centers in developing countries with limited resources to implement the classic KD (34). At our center, the MAD has largely supplanted the KD for adolescents and adults nowadays.

- Copy of a carbohydrate counting guide (paperback), recipes, and Web sites provided.
- Complete blood count, liver and kidney functions, anticonvulsant levels, and fasting lipid profile at baseline, 3, and 6 months.
- Carbohydrates restricted to 10 g/day for the first month for children, 15 g/day for adolescents, 20 g/day for adults. Carbohydrates can be increased after 2 months in many patients.
- Fats (e.g., 36% heavy whipping cream, oils, butter, mayonnaise) strongly encouraged. KetoCal shake daily during the first month advised.
- Clear, carbohydrate-free fluids ad lib.
- Daily low-carbohydrate multivitamin and calcium supplementation.
- Urine ketones checked weekly for the first 2 months and weight checked weekly throughout dietary therapy.
- Medications left unchanged for at least the initial month, but reformulated if necessary to tablet or sprinkle (nonliquid) preparations.
- Discontinue the diet if ineffective after 2 months.

INDICATIONS

For many years, as evidence for its efficacy grew, the KD was solely indicated for "children with intractable epilepsy" in chapters such as this and review articles. There were no particular indications mentioned with the exception of GLUT-1 (glucose transporter-1) deficiency and pyruvate dehydrogenase deficiency. As studies have demonstrated the benefits of the KD for specific conditions, this concept has changed. The 2009 Consensus Statement focused on indications and provided a list of "indications" for the KD is available (Table 70.3) (4). These included myoclonic astatic epilepsy, tuberous sclerosis complex, Rett syndrome, infantile spasms, Dravet syndrome, and children receiving only formula (4). Since 2009, the data justifying the strong benefit of the KD for Dravet syndrome, myoclonic astatic epilepsy (Doose syndrome), and mitochondrial disorders have continued to increase (35–37).

Table 70.3 Potential Indications and Contraindications for Dietary Therapy

Probable benefit (at least two publications)
Glucose transporter protein 1 (GLUT-1) deficiency
Pyruvate dehydrogenase deficiency
Infantile spasms
Myoclonic astatic epilepsy (Doose syndrome)
Tuberous sclerosis complex
Rett syndrome
Lennox–Gastaut syndrome
Severe myoclonic epilepsy of infancy (Dravet syndrome)
Mitochondrial disorders
Children receiving only formula (infants or enterally fed patients)
Refractory status epilepticus (especially FIRES)
Suggestion of benefit (one case report or series)
Landau–Kleffner syndrome
Lafora body disease
Juvenile myoclonic epilepsy
Absence epilepsy
Hypothalamic hamartoma
Angelman syndrome
Combined use with vagus nerve stimulation
Combined use with zonisamide at KD onset
Children with recently worsened seizures in the past month
*Contraindications (*relative)*
Pyruvate carboxylase deficiency
Porphyria
Fatty acid oxidation defects
Primary carnitine deficiency
Carnitine translocase deficiency
Pancreatitis
Cardiomyopathy
Inadequate ability to maintain nutrition, or comply with the KD restrictions
Combined use with phenobarbital at KD onset*
Children with a clear focal and potentially resectable lesion*
Severe gastroesophageal reflux*
Concurrent propofol use*

Pediatric patients with infantile spasms may be the fastest growing population to be started on the KD, perhaps due to the combination of its efficacy as well as ease of use with myriad ketogenic formulas widely available worldwide. Several studies have been published on the use of the KD for infantile spasms since 2001. The largest to date included 104 infants, of which 64% had at least a >50% decrease in their spasms within 6 months of treatment, including 38 (37%) who became spasm free for at least 6 months (38). As a result of this growing evidence for intractable infantile spasms, our center has used the KD in children for new- onset infantile spasms (if the family brings the child in within 2 weeks after seizure onset) (10). To date, 10 out of 24 (42%) infants became spasm free within 2 weeks of treatment. Additional information about the use of the KD for new-onset infantile spasms is available through the Carson Harris Foundation.

New indications continue to be studied. One exciting development has been the recent attention to the use of the KD for refractory status epilepticus (39). The epilepsy condition entitled FIRES (febrile infection–related epilepsy syndrome), often difficult to control with poor outcomes, appears to be very susceptible to the KD (40). Providing the KD as a formula through a nasogastric tube to a patient in an intensive care unit with status epilepticus is a very feasible option, with successful results typically described within 7 to 10 days (39). Prospective multicenter studies for refractory status epilepticus are under way. Other conditions recently reported as responding to dietary therapy

in recent years include absence epilepsy, juvenile myoclonic epilepsy, Sturge–Weber syndrome, and hypothalamic hamartoma.

Contraindications to the diet do exist and are primarily metabolic in nature. Children with malnourishment, primary carnitine deficiency, carnitine translocase deficiency, porphyria, pancreatitis, fatty acid oxidation defects, and cardiomyopathy should not be started on the KD (4). In addition, families with poor oral intake, vegan food preferences, dyslipidemia, parent noncompliance, and epilepsy surgery candidates [for whom surgery is more likely to lead to seizure freedom (41)] should receive detailed counseling on the KD prior to its implementation. One study suggested that those receiving phenobarbital at KD onset were less likely to respond as well (18).

ADULTS

Although described in the 1930s, KD treatment in adults with intractable epilepsy has more recently rarely been utilized and infrequently studied (8). Largely as a result of the emergence of the MAD as a less restrictive alternative, there has been a large amount of interest in this population and emergence of adult epilepsy diet centers (including in Baltimore and London) in the last few years. Evidence would suggest that when effective, the MAD will lead to seizure reduction within several weeks, thus the potential restrictiveness (if ineffective) need only be short-lived (15). Dietary therapy has been studied for adults with juvenile myoclonic epilepsy and refractory status epilepticus (39,42). The benefits of weight loss for obese patients with epilepsy may also be an additional valuable outcome. A prospective, randomized trial evaluating the MAD in combination with KetoCal [in a manner similar to a study in children (6)] is enrolling patients at our institution.

SIDE EFFECTS

Side effects do occur with dietary therapies as these treatments are neither alternative nor designed to be healthy (Table 70.4). They include constipation (improved with fiber supplements), acidosis (increased with illness), gastrointestinal upset and reflux, and lack of significant weight gain (occasionally weight loss) (13). Children who do not receive adequate vitamin and calcium supplementation will become deficient, and this must be avoided. At this time, the only mandatory supplements suggested in the Consensus Statement include an oral multivitamin, calcium, and vitamin D (4).

Table 70.4 Reported Side Effects of the KETOGENIC DIET

Common:
- Lack of significant weight gain
- Constipation
- Hypoglycemia (mostly with fasting)

Occasional:
- Gastrointestinal upset or gastroesophageal reflux
- Dehydration or acidosis (more frequent with illness)
- Dyslipidemia
- Growth slowing (especially in infants)
- Skeletal fractures (more common with long-term use)

Rare (case reports):
- Kidney stones (with use of oral citrates, otherwise occasional)
- Pancreatitis
- Cardiomyopathy
- Bruising
- Prolonged QT syndrome
- Basal ganglia changes
- Selenium and zinc deficiencies (if unsupplemented)
- Carnitine deficiency (symptomatic)

Less common, but potentially more serious side effects include dyslipidemia, kidney stones, bone fractures, and growth deficiency. Total and LDL cholesterol will often initially rise by 30% on the diet. However, lipid values stabilize after 6 months and return to normal values after several years on the KD (27,43). Kidney stones have been described historically in 6% of children placed on the KD but appear to be nearly completely prevented by empiric treatment with oral citrates (44). Decreased linear growth may occur, especially in young infants, and may be related to the level of ketosis rather than protein content of the KD (5,45). Less common side effects such as selenium and zinc deficiency, cardiomyopathy, pancreatitis, vitamin D deficiency, bone density decrease, and basal ganglia changes have also been reported. Years after the KD has been discontinued, there do not appear to be any obvious long-term adverse effects (46).

DISCONTINUATION

If ineffective, the KD can likely be discontinued within 3 to 6 months, as data suggest that benefits will occur in that time period. The optimal duration if beneficial is less clear, with several adults receiving the KD for several decades and being transitioned from pediatric KD centers (47,48). After 2 years, regardless of outcome, the risks of dietary therapy for general health and issues regarding compliance may outweigh benefits, and consideration of a gradual discontinuation should be discussed. Children with structural lesions, abnormal EEG findings, 50% to 90% seizure reduction, and those with tuberous sclerosis complex are at highest risk for worsening of seizures with diet discontinuation (49). There is no upper limit for KD duration, however, and each patient and family needs to be considered on an individual basis and involved in the decision-making process. We have found that many adults who are seizure free and driving will refuse to consider MAD discontinuation after 2 years when suggested.

Evidence indicates that once the decision has been made to wean the KD, the speed at which the diet is tapered and stopped is not relevant (50). Most children who are on the KD for long periods are weaned more slowly, in a manner similar to anticonvulsants. If ineffective, the KD can be stopped immediately without obvious ramifications (50). Our practice nowadays is to gradually reduce the ratio (or increase the daily carbohydrate limit for the MAD) every 2 weeks over a 2-month period. Abrupt discontinuations are more typically employed in monitored settings, such as a video–EEG

monitoring unit.

SUMMARY

The remarkable increase in interest of dietary therapy for epilepsy has led to expanded use for adults, new indications such as status epilepticus and infantile spasms, and worldwide availability. Careful questioning of methods of implementation has led to safer and less restrictive ways to start the classic KD in addition to the creation in the past decade of three "alternative" diets. Side effects are not only being clarified but also prevented with supplementation. As the mechanisms of action continue to be clarified, modifications to the KD will hopefully allow it to be more efficacious as well.

CHAPTER 71 VAGUS NERVE STIMULATION THERAPY

JAMES W. WHELESS

Epilepsy and seizures affect nearly 3 million individuals in the United States, with approximately 200,000 new cases diagnosed each year. Although antiepileptic drugs (AEDs) are the primary form of treatment, outcome surveys continue to reveal only mixed success even with the new AEDs, some with unique mechanisms of action, that have become available over the past 20 years (1,2). Approximately one-third of patients have seizures that are unresponsive to pharmacologic therapy (3–5). In addition, safety and tolerability issues associated with both the acute and chronic side effects and toxicity complications further diminish the effectiveness of AEDs (6–12). Nonadherence to AEDs, which is highly prevalent in the epilepsy population, also diminishes treatment effectiveness and further increases mortality as well as significantly increases health care utilization (13). Other treatment options are available for select subgroups of patients, including the ketogenic diet, which provides benefit to some children (14,15), and epilepsy surgery, which may manage or lessen poorly controlled seizures in 10% to 25% of patients (16). However, children and adults with uncontrolled seizures continue to carry a sad burden of higher mortality rates, higher rates of accidents and injuries, greater incidence of cognitive and psychiatric impairment, poor self-esteem, higher levels of anxiety and depression, and social stigmatization or isolation compared with the general population (17,18). The shortcomings of AEDs, dietary therapy, and epilepsy surgery in improving overall outcome highlight the need for other treatments, one of which is vagus nerve stimulation (VNS) therapy.

HISTORY

The effect of VNS on central nervous system (CNS) activity has been documented, with early attempts in the 1880s linking electrical vagus nerve and cervical sympathetic stimulation and carotid artery compression to the treatment of seizures (19). In the mid-1980s, Jacob Zabara, a biophysicist at Temple University, again suggested that electrical stimulation of the vagus nerve might prevent seizures. VNS therapy resulted from a hypothesis, formulated during his wife's Lamaze class, that the Lamaze method activated stretch receptors in the lungs, which in turn activated the vagus nerve (20). Vagus stimulation in the neck could quiet the abdominal muscle contractions that produce vomiting; Dr. Zabara likened these contractions to convulsions. Zabara believed that if VNS could alleviate vomiting and affect electroencephalographic (EEG) findings, it might ameliorate epilepsy. This theory was proved in his first canine studies (21), and a company—Cyberonics, Inc. (Houston, TX)—was founded in 1987 to develop VNS therapy, which would be delivered by a patented method using a generator device modeled after a cardiac pacemaker.

In 1988, the first patient to have a VNS therapy device implanted became seizure free (Table 71.1) (22). Five acute-phase clinical studies analyzing the safety and effectiveness of VNS therapy

followed (Table 71.2). The first two single-blind trials showed improved control in adults with intractable partial seizures who were not candidates for epilepsy surgery (22–24). The subsequent two randomized, blinded, active-control trials (E03, E05) led to approval of VNS therapy by the U.S. Food and Drug Administration (FDA) in July 1997 for the adjunctive treatment of refractory partial-onset seizures among patients 12 years of age or older. VNS therapy is also approved for the treatment of epilepsy without age or seizure type restrictions (in most countries) and treatment-resistant depression in more than 70 countries around the world, including member nations of the European Union, Japan, Canada, Australia, and China. As of October 2013, more than 70,000 patients have received VNS therapy worldwide.

The VNS therapy system is made up of a pulse generator, a bipolar VNS lead, a programming wand with accompanying software for a handheld computer, a tunneling tool, and handheld magnets (Fig. 71.1) (24,25). The generator transmits electrical signals to the vagus nerve through the lead. The software allows placement of the programming wand over the generator for reading and altering stimulation parameters (Fig. 71.2; Table 71.3). Each stimulation period is preceded by 2 seconds of ramp-up time and followed by 2 seconds of ramp-down time.

Three models of the VNS therapy generators are currently available: the Pulse Model 102 (single pin) and Pulse Duo Model 102R (dual pin), the Demipulse Model 103 (single pin) and Demipulse Duo Model 104 (dual pin), and the newer AspireHC Model 105 (available in single pin only) (Fig. 71.3). The Demipulse generators, which are smaller and lighter than the Pulse generators, and the AspireHC generators have improved diagnostics and faster communication with the programming system. The Demipulse generators may have shorter battery life at higher duty cycles than the Pulse generators. Currently, two leads are available in the United States: the Perennia Model 303 and PerenniaFLEX Model 304. All current lead models are single pin and come in two sizes: 2.0 or 3.0 mm (inner diameters of the helical coil) to account for various sizes of the vagus nerve. Dual-pin leads are no longer available. Therefore, the dual-pin generators (Model 102R and Model 104) are for replacement procedures only in patients with the previous dual-pin lead models. The Demipulse and AspireHC generators and Perennia model leads are not yet available in all countries (see the Addendum for sources of information on the VNS therapy system).

EFFICACY

The two pivotal studies—E03 and E05—were designed to demonstrate that high (therapeutic) and low (nontherapeutic) stimulation of the vagus nerve had different effects on the frequency of partial seizures (26,27). The effects of VNS therapy during the 12-week randomized phases of the studies,

which began 2 weeks after implantation, were gauged against 12- to 16-week baseline periods. E03 acute-study patients (27) (N = 114 implanted) had epilepsy for an average of 22 years. Seizure frequency was reduced by at least half in 31% of patients in the high-stimulation group, compared with 14% in the low-stimulation group. No patients became seizure free during the acute phase, but some reported reduced seizure severity and improved postictal recovery periods. Patients in the high-stimulation group either aborted or decreased 59.8% of seizures with the magnet. No factors were identified that predicted response.

The similarly designed E05 study was the largest prospective, controlled trial of a device for epilepsy treatment ever conducted (26). Patients (N = 199) had a median of 0.51 to 0.58 seizures per day during baseline. One patient receiving high stimulation became seizure free, and 23.4% of patients had a 50% or more reduction in seizure frequency after 3 months of treatment. The presence or absence of aura did not predict efficacy. Of the implanted patients, 99% completed the study.

Long-Term Clinical Studies

All patients exiting study E03 were offered indefinite open-label treatment at high (effective) stimulation; 100 (88%) of the 114 patients completed an additional 12 months of VNS therapy at therapeutic stimulation levels (14 patients discontinued because of lack of efficacy but were included in the analysis as intent to treat) (28). A median 20% reduction in seizure frequency occurred in the first 3 months of the extension study and improved over the ensuing months. In two-thirds of patients, a minimum 50% reduction during the initial 3 months continued during months 10 through 12. Results among the 195 patients in the continuing long-term E05 study showed a 50% or more reduction in seizure frequency in 35% of patients and a 75% or more reduction in 20% of patients after an additional 12 months of VNS therapy at therapeutic stimulation levels (29). The median reduction in seizure frequency was 45%, with seizure frequency reductions sustained over time and only mild-to-moderate side effects reported.

Postapproval Long-Term Outcomes

In addition to the clinical trial data, postapproval outcome studies show that VNS therapy is an effective treatment with increasing or sustained response rates over time. Response rates from the literature for studies reporting on at least 100 patients with a minimum of 12 months to more than 5 years of follow-up range from 50% to 64% (30–34). A retrospective review of a prospectively created database of 436 consecutive patients, both adults and children, at a single center showed a significant reduction in mean seizure frequency (mean reduction of 55.8%; $P < 0.0001$) at a mean follow-up of 4.94 years (34). The overall response rate in this group was 64%. A subset of this group that had at least 10 years of follow-up (n = 65) showed continued improvement over time, with a mean reduction in seizure frequency of 75% at 10 years (last observation carried forward, 76%) (35). At each recorded interval at 6 months and at years 1, 2, 4, 6, 8, and 10, seizure frequency was significantly reduced from baseline ($P < 0.001$) (35). The overall responder rate at last follow-up was 91%, with 10 patients seizure free for at least 2 years before their last follow-up visit. Another retrospective study with at least 12 months of follow-up (mean of 44 months; range of 12 to 120 months) across multiple centers showed a 51% reduction in mean monthly seizure frequency (32). The overall responder rate was 59%, with an additional 13% of patients having a seizure frequency decrease between 30% and 50%. The seizure-free rate in this study was 9%. A prospective, open

evaluation of 64 patients reported results for up to 5 years of follow-up (36). No change in AED dosages occurred during the first 6 months of VNS therapy, which lasted for an average of 20 months. In this population with refractory seizures, 44% experienced a substantial reduction in severity and frequency over a long period. A report on long-term outcomes of 30 patients receiving VNS therapy (37) showed continued improvements over time, with 54% of patients at 1 year and 61% at 2 years exhibiting seizure frequency reductions of 50% or more compared with baseline. In a study of 269 patients on unchanged AEDs over 1 year, seizure frequency rates decreased over time from a median decrease of 45% at 3 months to a median of 58% at 12 months, indicating that response to VNS therapy over the long term is sustained and independent of AED changes (31). Small, prospective studies report similar results as well as additional benefits beyond seizure reduction such as reduced postictal periods and seizure duration (38,39). The mechanisms underlying the gradual improvements in response to VNS therapy seen over time in these long-term studies have yet to be elucidated. However, these findings continue to support the fact that VNS therapy has important long-term efficacy in the refractory epilepsy population.

Pediatric, Elderly, and Special Populations

Studies indicate that response to VNS therapy is independent of age, seizure type, or epilepsy syndrome. In a large consecutive series of 141 children 18 years of age and younger with treatment-resistant epilepsy and at least 1 year of follow-up, seizure frequency significantly improved with VNS therapy (mean reduction 58.9%, $P < 0.0001$) (40). The mean age at initiation of VNS therapy was 11.1 years (range, 1 to 18); 86 (61%) were under age 12 years when they received VNS therapy. The mean duration of VNS therapy was 5.2 years (range, 25 days to 11.4 years). The overall responder rate for this population was 65%, with 41% experiencing 75% or greater reduction in seizure frequency. Comparisons between those older than 12 years of age and those younger than 12 years of age showed no differences in efficacy or safety between the groups. Additional pediatric studies show similar findings in addition to showed increasing response rates over time similar to those seen in the real-world outcome data for adults with VNS (41–46). A retrospective study of 46 children implanted under the age of 18 (median age of 12.1 years) showed median seizure frequency reductions in the range of 60% over 3 years with VNS therapy, with response rates more favorable among patients <12 years of age (42). Particularly favorable results, including reduced seizure frequency and severity and improved quality of life (QoL), have been reported among patients in open-label studies of Lennox–Gastaut syndrome and other refractory childhood epilepsies, such as hypothalamic hamartomas, epileptic encephalopathies, Rett syndrome, Dravet syndrome, and tuberous sclerosis complex (41,47–66). Verbal performance, alertness, motor and cognitive functions, and general behavior improved, sometimes dramatically (49,51,60,67,68). A retrospective study (68) showed that improved QoL (particularly in the area of alertness) was associated with VNS therapy in patients with autism (N = 59) or Landau–Kleffner syndrome (LKS; N = 6), with more than half of the patients in each group also experiencing a 50% or more reduction in seizure frequency at follow-up (12 months of follow-up for autism and 6 months for LKS patients). Studies have also shown both seizure frequency reductions and improved QoL among both institutionalized and noninstitutionalized patients with mental impairment/developmental delay (69,70). VNS therapy also successfully stopped a case of refractory generalized convulsive status epilepticus in a patient 13 years of age (71). Another report among three children admitted to the intensive care unit (ICU) after developing status epilepticus showed that VNS therapy allowed early cessation of status and discharge from the ICU

(61). In a study of VNS therapy among geriatric patients, 50 years of age or more, 21 of 31 patients experienced a 50% or greater decrease in seizure frequency at 1 year, accompanied by significant improvements in QoL from baseline over time (72).

Open studies indicate that VNS is a favorable treatment option for a wide range of patients regardless of age or seizure type (40,73–79). A recent meta-analysis of VNS therapy efficacy showed that children and those patients with generalized epilepsy benefited significantly from VNS therapy (79). A study of stimulation parameters among patients of different ages (80) recommended age-related stimulation adjustments based on age-related changes seen in vagus nerve characteristics. Early studies indicated that children might respond more rapidly than adults, with reductions in the interval between stimulations resulting in improved control (Table 71.3) (51,62,67). Additional pediatric studies reported that higher output currents might be required, particularly when lower pulse durations are used (81–83). Optimal stimulus parameter settings for patients of various ages or with specific seizure types or syndromes, however, have not yet been defined.

MECHANISM OF ACTION

The mechanisms by which VNS reduces seizure activity in humans were not known at the time VNS therapy was approved by the FDA. However, considerable progress in mechanistic VNS research has been made over the last 15 years. Electrical stimulation of the peripheral vagus nerve requires polysynaptic transmission to mediate the antiseizure effect. The anatomical distribution of vagal projections underlies the therapeutic actions of VNS therapy. Vagal visceral afferents have a diffuse CNS projection, with activation of these pathways broadly affecting neuronal excitability (25,84,85). Another review (84) examined the vagus nerve projections and CNS connections, as well as the current animal and human imaging studies, which indicate that VNS exerts both acute and long-term antiepileptic effects.

EXPERIMENTAL STUDIES

The first studies of the anticonvulsant effects of VNS were conducted in 1937 (85). Subsequent experiments in cats showed that vagal stimulation produced EEG desynchronization (86) or synchronization, depending on the parameters used (87,88). Stimulation of the slow-conducting fibers most effectively resulted in EEG desynchronization. Hypersynchronized cortical and thalamocortical neuronal interactions characterize seizures; therefore, it was postulated that desynchronizing these activities would lead to anticonvulsant effects of VNS.

Initial work in cats and recent studies of strychnine-induced seizures in the dog, maximal electroshock and pentylenetetrazol-induced seizures in the rat, and the alumina-gel monkey model (21,86,89–92) showed that cervical vagal stimulation decreased interictal epileptiform discharges (IEDs) and shortened or aborted seizures; the antiepileptic effects outlasted the stimulus (21,89,92,93) and depended on its frequency and cumulative duration (89–91,93). These effects are now known to be mediated by activation of myelinated A and B fibers (94–96). Most central projections of the vagus nerve terminate in the nucleus of the solitary tract, with extensions to brainstem nuclei, thalamus, amygdala, and hypothalamus. Increased release of gamma-aminobutyric acid (GABA) and glycine by brainstem and subcortical nuclei was proposed as the antiepileptic mechanism of VNS therapy (90,91). Brainstem nuclei are known to influence seizure susceptibility (97–101); based on animal studies, the nucleus of the tractus solitarius is likely the key brainstem

structure involved in transmitting and modulating VNS antiseizure effects.

Also unknown are the processes that mediate the sustained anticonvulsant effect of VNS therapy, but this effect, which outlasts the stimulation, suggests long-term changes in neural activity. Expression of fos immunoreactivity was induced by VNS in regions of the rat brain important in epileptogenesis (102) ; fos immunolabeling in the locus caeruleus suggested VNS modulation of norepinephrine release. Increased norepinephrine release by the locus caeruleus is antiepileptogenic. In rats with chronic or acute locus caeruleus lesions, VNS-induced seizure suppression was attenuated, supporting a noradrenergic mechanism (97). This first evidence of a structure mediating the anticonvulsant action of VNS may have pharmacologic implications for clinical practice. Drugs that activate the locus caeruleus or potentiate norepinephrine effects may enhance the efficacy of VNS. Pending the results of further animal testing, it is likely that the antiepileptic action of VNS is mediated through neuronal networks that project from brainstem to forebrain structures. Vagal projections to noradrenergic and serotonergic neuromodulatory systems of the brain may also explain the positive effects of VNS in improving mood disorders.

In summary, animal studies have established three distinct temporal patterns for the anticonvulsant effects of VNS: (i) acute abortive effects, in which an ongoing seizure is attenuated by VNS; (ii) acute prophylactic effects, in which seizure-inducing agents are less effective in provoking seizures when applied at the end of VNS; and (iii) chronic progressive prophylactic effects, in which total seizure counts are reduced more following chronic VNS stimulation. In addition, animal studies have shown that VNS can antagonize the development of epilepsy in the kindling model of epileptogenesis (103). Based on these studies, the mechanism of action of VNS therapy appears to be largely distinct from that of AED therapies (84).

CLINICAL STUDIES

Initial scalp recording performed in a small number of adults did not demonstrate a significant effect of VNS on EEG total power, median frequency, power in any of the conventional frequency bands (104), interictal epileptiform activity, or the waking or sleep background rhythms (22,104–106). At seizure onset, however, VNS has terminated both the clinical and the EEG seizure activity (106). Studies that are more recent have suggested that some patients may have a change in IEDs with VNS. Fifteen adults with refractory partial-onset seizure disorders showed a significant reduction in IEDs during stimulation and the interstimulation period immediately following stimulation, compared with baseline, with the reduction in interical epileptiform discharges greater among patients whose seizures decreased by more than 50% on VNS. Additionally, the patients who had a significant decrease in interical epileptiform discharges experienced the positive effect of magnetic activation, resulting in extra stimulation, abolishing seizures (107). A single adult patient undergoing presurgical evaluation with intrahippocampal depth electrodes showed alteration of interical epileptiform discharges by VNS (increased spikes at 5 Hz, decreased at 30 Hz) (108). Chronic VNS in children was recently reported to reduce IEDs (109). However, this population was quite different from that in the earlier adult series. Included were patients with generalized and partial-onset seizures, greater frequency of interical epileptiform discharges, and younger age. During 12 months of VNS therapy, both generalized and focal spikes were diminished; however, this did not correlate well with seizure reduction. Pattern reversal visual evoked potentials, brainstem auditory evoked potentials, and cognitive (P300) potentials were all unaffected by VNS (110).

Release of anticonvulsant neurotransmitters at the projection sites of vagus nerve afferent fibers

was hypothesized as a mechanism of action (110,111). Cerebrospinal fluid samples assayed for amino acid and neurotransmitter metabolites in 16 patients before and after 3 months of VNS therapy showed a treatment-induced increase in GABA (an inhibitory amino acid), a decrease in aspartate (an excitatory amino acid), and an increase in ethanolamine (a membrane lipid precursor) (111).

Positron emission tomography (PET) $H_2{}^{15}O$ cerebral blood flow (CBF) imaging identifies the neuroanatomical structures recruited by VNS in humans. A pilot study of three adults showed activation of the right thalamus, right posterotemporal cortex, left putamen, and left inferior cerebellum (112). Localization to the thalamus may explain the therapeutic benefit of VNS and is consistent with the role of that structure as a generator and modulator of cerebral activity. Moreover, anatomic and physiologic evidence from both animal and human data further support the role of the thalamus in epilepsy (113), with stimulation of either the anterior thalamic nucleus or centromedian thalamic nucleus in animals being associated with anticonvulsant effects (114). In a study of high and low stimulation (115), PET demonstrated CBF alterations at sites that receive vagal afferents and projections, including dorsal medulla, right postcentral gyrus, thalamus, cerebellum bilaterally, and limbic structures (bilateral hippocampus and amygdala). The high-stimulation group had more activation and deactivation sites, although the anatomical patterns during VNS were similar in both groups. Finally, acute CBF alterations were correlated with long-term therapeutic response, in an attempt to exclude those regions that show changes in VNS-induced synaptic activity, but may not participate in VNS-related anticonvulsant actions (116). Decreased seizure frequency was associated with increased CBF only in the right and left thalami. Studies of chronic VNS therapy have shown the same anatomical distribution of CBF (112,117). Demonstration of these acute regional alterations does not clarify the mechanism of action of long-term, intermittent VNS, which may involve neurotransmitters or neurochemicals at those sites that outlast the stimulation.

Functional magnetic resonance imaging (fMRI) evaluating the time course of regional CBF alterations during VNS therapy can be performed safely in patients implanted with a vagal nerve stimulator (118). Preliminary fMRI studies have agreed with the PET studies, with the most robust activation observed in the thalami and insular cortices, with some activation also seen in ipsilateral basal ganglia, anterior parietal cortex, and other cortical areas (118,119).

SELECTION OF CANDIDATES

In the United States, VNS therapy is indicated as an adjunctive treatment for adults and adolescents 12 years of age or older with refractory partial-onset seizures (24). In the European Union, VNS therapy is indicated as an adjunctive treatment for patients with partial- or generalized-onset seizures without an age limitation. However, indications for VNS therapy were derived from the clinical trial experience, not from an understanding of its physiologic action. Age, sex, seizure type or syndrome, etiology, frequency of seizures, or IEDs do not predict response to VNS therapy. The type or number of coadministered AEDs also does not predict response (73,120). However, many studies show favorable outcomes in many of these populations, although complete seizure freedom is rarely achieved (79). A recent study also indicates that VNS therapy should be considered in patients with posttraumatic epilepsy, which is often resistant to AED therapy and not often amenable to epilepsy surgery (121).

In October 2013, the American Academy of Neurology updated the evidence-based VNS therapy guidelines for the treatment of epilepsy (122). The updated guidelines provide an update on data regarding the efficacy and safety of VNS therapy for epilepsy since publication of the original

guidelines in 1999. Previous guidelines did not provide guidance on many of the epilepsy patient populations in which VNS therapy is actively being used. The literature review found 1274 manuscripts for VNS therapy since the last review. Of these, 216 articles were reviewed to answer 8 clinical questions, summarized in Table 71.4. The clinical evidence supports the use of VNS therapy across a range of refractory epilepsy populations, and the impact of the reviewed studies (with specific focus on the intensity and magnitude of the responses) continues to be quite supportive.

Table 71.4 Summary of AAN Updated Evidence-Based Guidelines for VNS Therapy

Clinical question	Recommendation/clinical context
Is VNS therapy beneficial in children with epilepsy?	VNS therapy may be considered as adjunctive treatment for children with partial or generalized epilepsy (C)
Is VNS therapy beneficial in patients with LGS?	VNS therapy may be considered in patients with LGS (C)
Is VNS therapy associated with mood improvement in patients with epilepsy?	In adult patients receiving VNS therapy for epilepsy, improvement in mood may be an additional benefit (C)
Is VNS therapy associated with reduced seizure frequency over time?	VNS therapy may be considered progressively effective in patients over multiple years of exposure (C)
Does rapid cycling[a] improve seizure frequency more often than do standard stimulation settings?	Optimal VNS therapy settings are still unknown. The evidence is insufficient to support a recommendation for the use of standard stimulation vs. rapid stimulation.
Does using additional magnet-activated stimulation trains for auras or at seizure onset interrupt seizures?	VNS therapy magnet activation may be associated with seizure abortion when used at the time of seizure auras (C). Seizure abortion with the magnet use may be associated with overall response to VNS treatment (C)
Have new safety concerns emerged since the last VNS therapy assessment?	No new safety concerns were identified The rates of Sudden Unexpected Death in Epilepsy (SUDEP) dropped in the first 2 years of VNS therapy
Do adverse effects differ among children and adults?	Children may have greater risk for wound infection than adults due to behaviors more common in children. Extra vigilance in monitoring for occurrence of site infection in children should be undertaken.

[a]Rapid cycling is shorter On times and Off times, typically 7 s On and 30 s Off compared with standard settings, typically 30 s On and 5 min Off.

C, based on data from class III studies; U, unproven, data inadequate or conflicting.

Although optimal use parameters continue to be defined, candidates should meet the following criteria: (i) medically refractory seizures, (ii) adequate trials of at least two AEDs, (iii) exclusion of nonepileptic events, and (iv) ineligibility for epilepsy surgery (Fig. 71.4). Focal resective surgery (temporal lobectomy or lesional neocortical epilepsy) is preferred in appropriate patients because of its superior seizure-freedom rate (123–125). Recent open studies suggest that VNS therapy may be used among patients considered for corpus callosotomy, producing lower rates of morbidity (116–129), and among those who have previously undergone epilepsy surgery (41,130–132). A study of 376 patients (110 who had at least 1 failed craniotomy before VNS and 266 with no history of intracranial epilepsy surgery [IES] before VNS) showed no significant difference in the mean percentage seizure reduction between patients with and without a history of IES (59% vs. 57%; P = 0.42) (132). Earlier use (within 2 years of seizure onset or after failure of two or three AEDs) of VNS therapy may also produce a higher response rate and reduce the negative side effects associated with long-term epilepsy and AED therapy, which hinder development (30,40,133,134). Patients with a history of nonadherence to their AED regimens, particularly those on polypharmacy, may also be good candidates for VNS therapy because of the assured compliance and lack of further drug–drug interactions with VNS therapy (135,136).

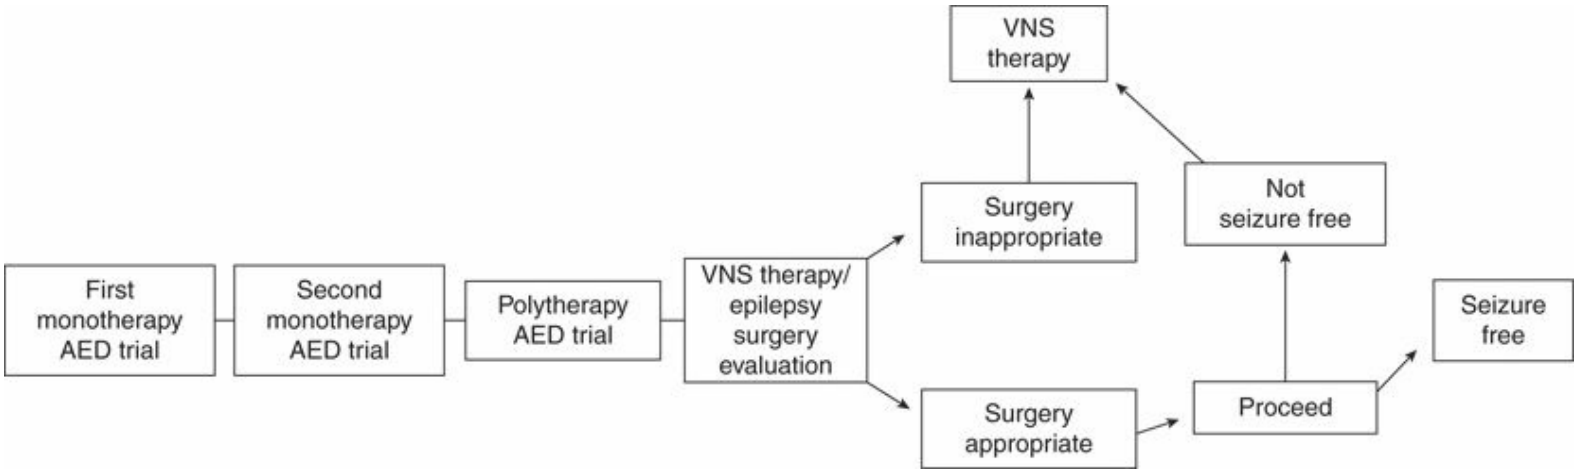

Figure 71.4. Treatment selection flow chart. AED, antiepileptic drug; VNS, vagus nerve stimulation therapy.

Use of VNS therapy is contraindicated in patients with prior bilateral or left cervical vagotomy, and safety and efficacy have not been established for stimulation of the right vagus nerve. Patients with existing pulmonary or cardiac disease should be evaluated carefully before implantation; chronic obstructive pulmonary disease may increase the risk for dyspnea. Patients with cardiac conduction disorders were not studied in the controlled trials. A cardiologist's evaluation should precede implantation, with postprocedural Holter monitoring performed if clinically indicated. Patients with a history of obstructive sleep apnea should be treated with care, as an increase in apneic events during stimulation is possible (137,138). Lowering stimulation frequency (i.e., pulse width and signal frequency to 250 μs and 20 Hz, respectively) may prevent exacerbation of this condition (137). However, most studies showing a decrease in airflow during sleep with VNS therapy reported this condition to be clinically insignificant (138). Moreover, beneficial effects on sleep and increases in slow-wave sleep also have been reported with VNS therapy, which may play a role in the antiepileptic mechanisms of VNS (139,140).

INITIATION AND MAINTENANCE

Hospitalization for implantation of the device is preceded by evaluations by a neurologist and by a surgeon with experience in the carotid sheath. With the patient typically under general anesthesia (although local or regional anesthesia has been used successfully as well) (141), the lead wires are placed on the left cervical vagus nerve and the generator is placed in a subcutaneous pocket in the left upper chest (142,143). Intraoperative electrical impedance testing ensures integrity of the system. Rare cases of bradycardia, asystole, or both mandate initial lead testing in the operating room (24,144,145); the anesthesiologist should be notified immediately before this test. Stimulation following intraoperative bradycardia has been shown to be safe, with no change in cardiac rhythm upon initiation of postoperative VNS, which was started under ECG monitoring (146). Reimplantation of a second VNS therapy generator upon battery depletion in two patients also showed no occurrence of bradycardia (146). Correct placement of the lead electrodes around the vagus nerve is critical. If there is concern about the lead placement, two methods have been utilized to help confirm correct placement of the electrodes intraoperatively (147), depending on the type of anesthesia used for the procedure. For patients receiving general anesthesia, the larynx and vocal cords can be monitored by fiberoptic endoscopy for contraction of the left lateral larynx wall and vocal cord tightening. For patients being implanted under local and regional anesthesia, stimulation

intensities can be increased until a voice alteration is noticed. The procedure neither is harmful to the patient nor greatly extends the length of the surgery.

Prophylactic antibiotics may be administered both in the operating room and postoperatively. The patient can be discharged after the procedure, which usually lasts for <1 hour, or can be observed overnight. Discharge education should include care of the incisions and use of the magnet. In clinical studies, the generator's output current was kept at 0 mA for the first 2 weeks; however, programmed stimulation is now being initiated at 0.25 mA in many operating rooms (41). Dosages of AEDs are generally kept stable for the first 3 to 6 months of stimulation unless an early response is noted.

A few weeks after implantation, the patient is examined to confirm wound healing and proper generator operation either to begin or to continue programming. Output current is increased in 0.25 mA increments as long as stimulation is comfortable (Table 71.1). The subsequent stimulation schedule is determined by patient response. Standard parameter settings range from 20 to 30 Hz at a pulse width of 250 to 500 μs for 30 seconds "on" time and 5 minutes "off" time (83). For an adult, to generate an action potential in the nerve (a therapeutic effect), research shows that optimal output current settings may range from 0.75 to 1.75 mA (148). At each visit, the generator and the battery are assessed for end of service; the battery's life expectancy of 7 to 10 years depends on the programmed stimulation parameters. If VNS therapy is to be continued, the generator can be replaced at the appropriate time in <20 minutes.

VNS may be continued indefinitely and without damage to the vagus nerve as long as the stimulation is <50 Hz and the on time remains less than the off time (24,149,150). Two safety features that protect patients from continuous stimulation or uncomfortable side effects are the magnet and the watchdog timer. The magnet can act as an "off" switch when held or taped over the generator. The watchdog timer is an internal monitor that limits the number of pulses to be delivered without an "off" time to prevent excess stimulation.

COMPLICATIONS AND ADVERSE EFFECTS

Surgical complications and difficulties are rare. Fracture of the electrode, related to fatigue at the junction between contact and the lead wire, was a common problem with early devices (23,151–154). Substitution of a quadrifilar wire and, later, a trifilar lead body coil improved electrode tolerance that had been compromised by repetitive neck motion. The two newest lead models (Perennia Model 303 and PerenniaFLEX Model 304) are designed to be even more resistant to fractures than previous models. The PerenniaFLEX is similar in design to the Model 302 but has a lead body designed with three high fatigue silicone tubes; the bifurcation is still caudal to the anchor tether but designed with a smoother transition to facilitate strain relief bend. The Perennia is constructed with a trifilar lead body coil and a continuous bilumen lead body silicone tube with the bifurcation cephalad to the anchor tether; this design makes the handling characteristics of the Perennia lead feel stiffer during the implantation procedure compared with the Model 302 and 304 leads. The Perennia model leads are approved by the FDA but are not currently available in all countries.

Incisional infections are unusual and generally respond to antibiotic therapy. Fluid accumulation at the generator site with or without infection occurs in 1% to 2% of implantations and resolves with aspiration and antibiotics; the rare cases of refractory infection require removal of the generator. However, one case of deep wound infection associated with implantation of the generator was reported to be managed successfully with open wound treatment without removal of the device, an

alternative option if removal of the device appears hazardous (155). Unilateral vocal cord paralysis, which accompanies approximately 1% of implants, may be caused by excess manipulation of the vagus nerve, and subsequent damage to the vagal artery and its reinforcing arterioles (156); in most cases, it remits completely over several weeks.

Common side effects, which occur primarily when the stimulator is actually delivering a pulse (Table 71.5), are dose dependent and usually mild or absent when VNS parameters are appropriately programmed (26,27,157); many patients become accustomed to them with time. Most patients experience hoarseness or a change in vocal quality and tingling over the left cervical region on delivery of the electrical pulse. Subjective dyspnea or a sensation of muscle tightening in the neck may occur, without changes on pulmonary function testing (26). Cough or throat pain during stimulus delivery sometimes necessitates a reduction in current or pulse width (158).

Despite the widespread visceral efferent projections of the vagus nerve, systemic effects are rare. Pulmonary function does not change significantly in patients without concomitant lung disease (26,159) but may deteriorate in the face of intense stimulation and obstructive lung disease (159). Inhalation of ipratropium bromide or lowering of the stimulus frequency or current is recommended. No substantial effects on cardiac function were reported during clinical studies (24,26,27,157,160). An analysis of total mortality and sudden death in epileptic patients (to August 1996) revealed the expected rate in individuals with severe, intractable epilepsy (161,162). The clinical studies demonstrated no clinically relevant effects on the gastrointestinal system, serum chemistries, AED concentrations, vital signs, or weight.

Rare reported side effects associated with VNS therapy include diarrhea (163), sternocleidomastoid muscle spasm (164), phrenic nerve stimulation (165), tonsillar pain (166), emergent psychiatric disorders (167,168), and prominent drooling and vomiting (169). Of seven patients treated with VNS therapy who developed a major psychiatric disorder (167), all had a history of a dysphoric disorder and most had daily seizures before treatment with VNS. The severe dysphoric or psychotic conditions emerged once seizure frequency was reduced by 75% or more but remitted or improved satisfactorily with psychotropic medication, with two patients also requiring a decrease or interruption of VNS therapy. Children with a history of dysphagia may experience swallowing difficulties during VNS therapy (169–171); adjusting the device settings or using a magnet to turn off the stimulator during mealtime may help. The majority of side effects, including many of the rare incidents reported, are amenable to stimulus modifications, which could include

changes in output current and/or pulse width.

ADVANTAGES AND DISADVANTAGES

Many patients maintained on VNS therapy can decrease their total AED burden, which typically results in a more alert patient who, while still receiving polytherapy, is without the cognitive or systemic side effects typically associated with multiple therapies. Therefore, use of AED monotherapy with VNS therapy may produce a better risk to benefit ratio than treatment with two AEDs. Even when AEDs cannot be substantially decreased or withdrawn, however, VNS therapy may allow amelioration of seizures with no risk of toxic organ reactions, drug interactions or failures, allergies, rashes, and other systemic adverse effects or cognitive side effects (172,173); in some patients, memory, alertness, mood, and communication have been shown to improve (105,174–178). Improvements in QoL independent of treatment effect on seizure frequency, as well as increased daytime vigilance, have also been reported (179–181). In addition, because the beneficial results are maintained without active patient participation, VNS therapy may be an ideal treatment for the partially compliant (135,136). Teratogenesis is not expected with VNS therapy. Although no controlled studies of VNS therapy in pregnancy have been conducted, an animal study showed no harm to fertility or to the fetus (182). Cases also have been reported in the literature of patients who became pregnant while on VNS therapy and gave birth to healthy babies (36,183). Finally, VNS therapy can both prevent and abort seizures. The ability to trigger the device externally (with the magnet) and to interrupt the seizure or improve the postictal phase empowers the patient and provides a sense of control over epilepsy.

On the other hand, VNS is an empiric therapy, with no way to predict response except by trial. The initial cost (often between $15,000 and $25,000) can be prohibitive without coverage by a third-party payer. Over the life of the system, however, this cost approximates that of many of the new AEDs (184). Moreover, although weeks to months may elapse before seizure frequency decreases, cost-effectiveness studies indicate that VNS therapy provides a substantial cost-savings benefit to hospitals over the long-term course of treatment (185,186). These cost benefits are sustained over time and are sufficient to cover or exceed the cost of the device. Further savings can be seen in significant reductions in health care utilization and time spent on epilepsy-related matters with VNS therapy over time. One study looked at health care utilization of 138 patients with refractory epilepsy comparing 1 year of baseline data followed by 4 years of quarterly follow-up data with VNS therapy and showed significant reductions in the numbers of emergency department visits (99% decrease), hospitalizations (70% decrease), and hospital lengths of stay (67% decrease) beginning with the first quarter after VNS implantation and therapy ($P < 0.05$ for all postimplantation quarters) (187). A 91% decrease was also seen in outpatient visits post-VNS therapy, and significant decreases were seen for average number of days on which patients could not work because of health-related concerns ($P = 0.002$) and average time spent caring for health problems ($P < 0.001$), which further reflect positive changes in the QoL of both patients and their caregivers as a result of VNS therapy in addition to health care utilization savings. In a US study evaluating the long-term medical and economic benefits of VNS therapy using Medicaid data from 5 states ($n = 1655$), VNS therapy was associated with lower average health care costs and epilepsy-related clinical events (135). Hospitalizations, emergency room visits, and outpatient visits all were significantly reduced during the post-VNS period compared with the pre-VNS period ($P < 0.0001$). Serious events such as grand mal status, fractures, and traumatic head injuries also were reduced in the post-VNS period. Despite the initial

expense of VNS therapy, the reductions in health care utilization and epilepsy events resulted in a net cost savings for VNS therapy after 1.5 years of treatment.

According to the manufacturer of the device, a transmit-and-receive head coil MRI should be used for head and extremity scans rather than a full-body MRI, with the generator programmed to 0 mA for the procedure and returned to the original settings thereafter (24). MRI scans following these procedures are safe in 1.5 and 3 T scanners (24). However, successful head coil MRIs have been performed among patients both with and without the device turned off (188). If the device does remain on during the MRI, the device should be interrogated postprocedure to ensure that the magnetic field did not deactivate the device or change the pre-MRI settings. Although not recommended by the manufacturer, successful body coil MRIs with the use of an ice pack over the area of the device leads have been reported among three patients (189). Diathermy, which could heat the system above safe levels and thereby cause either temporary or permanent tissue or nerve damage, should be avoided in patients receiving VNS therapy.

FUTURE DEVELOPMENTS

VNS therapy has raised interest in the role of neurostimulation as a treatment for refractory epilepsy. Since the first device implantation more than 20 years ago, the number of AEDs has increased; yet, uncontrolled seizures continue. The codification of refractory epilepsy by the ILAE in 2010 (190) increased visibility around the need for nonpharmacologic treatment options earlier in the course of the disease rather than waiting until multiple medications have failed and surgery is not an option. Other research questions, if answered, have the potential to dramatically improve the overall treatment of all patients with epilepsy. Are there unique stimulation parameters for certain seizure types (e.g., partial vs. generalized), syndromes (e.g., Lennox–Gastaut), or age groups? What are the psychosocial effects of VNS therapy on the families of individuals with epilepsy? Answers to such questions and improvements in technology will expand the role of VNS therapy for uncontrolled epilepsy.

Additional options for nerve stimulation in the treatment of refractory epilepsy currently under investigation include trigeminal nerve stimulation (TNS), transcutaneous vagus nerve stimulation, and transcutaneous auricular vagus nerve stimulation. TNS is proposed to activate similar pathways as VNS but less invasively and with the ability to provide bilateral stimulation (191). Although subjects in the treatment group of the initial randomized controlled trial for TNS in epilepsy were more likely to respond than patients in the control group, the study did not demonstrate efficacy of TNS in refractory epilepsy (192). Pilot studies of transcutaneous VNS in small groups of patients with refractory epilepsy are underway. Studies to determine whether any of these noninvasive options could potentially be used as a screening tool for VNS therapy may be warranted.

INTRODUCTION

Patients with drug-resistant epilepsy have a very low likelihood of achieving sustained seizure freedom with further trials of antiepileptic drugs (AEDs), and the treating clinician should consider early on whether these patients might be candidates for epilepsy surgery. Yet, the diagnosis of medically intractable epilepsy can be sobering. It communicates the chronicity of the condition and the futility of further AED trials. Therefore, arriving at this diagnosis requires careful and comprehensive consideration of the individual patient's diagnosis and management, which is best done in a systematic manner. Clinicians should first review the diagnosis of epilepsy, the type of epilepsy and seizures, and their frequency. They should then assess the treatments prescribed, how they have been administered, and whether extraneous factors may contribute to the lack of seizure control. Finally, they should establish which AEDs have failed and why. If reasons other than drug resistance or intolerance exist, they should be addressed before arriving at the diagnosis of medical intractability. This systematic approach is particularly important when surgery is being considered as the next therapeutic option, but also should be undertaken every time seizures recur or fail to respond to AEDs.

THE MISDIAGNOSIS OF EPILEPSY?

The misdiagnosis of epilepsy is a common cause of pseudoresistance, defined as ongoing seizures (or spells) due to misdiagnosis or inappropriate treatment (1). Epilepsy misdiagnosis has been reported to occur in 5% to 30% of cases in a variety of settings (2,3). These estimates include not only missing an epilepsy diagnosis but also undertreatment or incorrect treatment of epilepsy. Unfortunately, diagnosing epilepsy can be challenging due to the lack of standardized criteria or laboratory tests to guide clinicians.

There are a wide variety of symptoms and conditions that can mimic seizures and epilepsy, respectively (3). These include cardiovascular disorders (e.g., syncope, transient ischemic attaches, transient global amnesia, arrhythmia), movement disorders (e.g., tics, paroxysmal dystonia), sleep disorders (e.g., night terrors in children in particular, narcolepsy and cataplexy), and mental health conditions (e.g., psychogenic nonepileptic seizures). Syncope and psychogenic nonepileptic seizures represent the two most common causes of epilepsy misdiagnosis (3).

Impact of Misdiagnosis

Misdiagnosing epilepsy can have serious consequences. For example, a patient may be inappropriately exposed to AEDs and their side effects including neurotoxic effects and hypersensitivity reactions. A woman of childbearing potential misdiagnosed as having epilepsy and started on AEDs could potentially expose her fetus to the potential teratogenic and neurodevelopmental effects of this AED (4). A patient may also experience, as a result of being misdiagnosed with epilepsy, unnecessary negative psychosocial outcomes such as the loss of driving privileges and/or employment and stigmatization (3,5,6). Patients with psychogenic nonepileptic seizures are vulnerable and may end up in a critical care unit due to AED toxicity and sedation (7) as a result of overtreatment due to "pseudoresistance." We advocate early prompt diagnosis of psychogenic nonepileptic seizures, which has been associated with better outcomes (8). Finally, misdiagnosis could even result in death if the symptoms are due to a cardiac cause such as a life-threatening arrhythmia that is not treated promptly.

COMMON ERRORS IN THE DIAGNOSIS OF EPILEPSY AND SEIZURES

Epilepsy drug resistance may also occur due to incorrect classification of the epilepsy syndrome or seizure types. A detailed history (including a witness history) and diagnostic investigations will increase the likelihood of accurately diagnosing a patient with the correct type of seizures and epilepsy syndrome (9).

Accurate epilepsy and seizure classification is necessary for many reasons but most importantly to guide treatment. For example, some AEDs can worsen certain types of seizures and result in pseudoresistance, while others are suboptimal for specific seizure types. Once it has been determined that a patient has epileptic seizures, the following questions should be explored to ensure that the correct therapy is used (2,10):

1. What type of seizure(s) is the patient having?
2. Does the patient have focal or generalized epilepsy?
3. If the epilepsy is focal, is it temporal or extratemporal?
4. What is the cause of the epilepsy, that is, structural, metabolic, of presumed genetic origin, or of unknown etiology?

Three common errors in the diagnosis of seizures and epilepsy may result in incorrect treatment and AED pseudoresistance, that is, incorrect distinction between focal and generalized epilepsy, confusion between myoclonic or tonic seizures and focal motor seizures, and inability to distinguish between absence and focal dyscognitive seizures.

Generalized Versus Focal Seizures

Failure to recognize generalized epilepsy is of particular concern because AEDs such as carbamazepine and phenytoin can control bilateral convulsive seizures (formerly known as generalized tonic–clonic seizures) but have been shown to worsen absence and myoclonic seizures (7). The distinction may be challenging because seemingly focal symptomatology may accompany

generalized seizures. In one study (11), focal EEG abnormalities were identified in 45% of patients with various types of generalized epilepsies of presumed genetic origin. Another study examined clinical features of 58 patients with EEG-confirmed generalized epilepsy of presumed genetic origin (12). Many of these patients had focal EEG or clinical features (e.g., head turning to one side). Most importantly, 71% of these patients were on inappropriate treatment, of which 55% were pseudoresistant to AEDs. Optimizing treatment with AEDs indicated for the relevant syndromes resulted in 78% of the pseudoresistant patients becoming drug responsive (12). Misdiagnosing generalized epilepsy can occur in part because of the incorrect assumption that generalized epilepsy or presumed genetic origin is rare beyond childhood. It is important to recognize that a sizeable proportion of generalized epilepsies of presumed genetic origin begin after ages 18 (35%) and 20 (28%) (13).

Myoclonic or Tonic Versus Focal Motor Seizures

The myoclonic seizures of juvenile myoclonic epilepsy (JME) are frequently misdiagnosed as focal seizures with motor features, and as such may be inappropriately treated with agents indicated for focal epilepsies (5). This can result in an exacerbation of myoclonic seizures. Tonic seizures (often noted in those with generalized epilepsies of structural or metabolic causes) are often similarly misdiagnosed as focal seizures of supplementary motor area origin and as a result can be inadequately treated (14).

Absence Versus Focal Dyscognitive Seizures

Absence seizures, particularly if they are atypical, can be misdiagnosed as focal dyscognitive seizures (i.e., complex partial seizures). Both are longer in duration than typical absence seizures and can be associated with automatisms and postictal confusion. The EEG provides important diagnostic information, but the correct diagnosis requires a comprehensive and detailed history, physical examination, and investigations (especially EEG and brain MRI). Misdiagnosing atypical absence seizures as focal dyscognitive could be detrimental to patients because each seizure type requires different AEDs. Using AEDs indicated for focal epilepsies can be associated with worsening atypical absence seizures, and treating focal seizures with a drug such as ethosuximide will not be beneficial.

CAUSES OF POOR SEIZURE CONTROL

Establishing the diagnosis of epilepsy, and determining the type of epilepsy and seizures, provides an important roadmap for choosing the correct AED for an individual patient. However, even with a correctly chosen AED, other factors can contribute to poor seizure control and AED pseudoresistance. These include using a wrong dose, interactions with other medications, poor adherence to a correctly chosen AED, and lifestyle issues.

Incorrect Treatment

Incorrect medical treatment of patients with epilepsy has been long recognized as an important contributor to pseudoresistance (2). It occurs more often in general practice than in specialists' clinics and is seen both in adults (15) and children (16). In one study, incorrect or suboptimal AED

therapy in patients with uncontrolled seizures occurred in 56% of those with newly diagnosed epilepsy and 41% of those with chronic epilepsy (17). In this study, seizures remained uncontrolled due to a treatment trial of only a single AED (39%), inadequate use of AEDs (44%), and development of side effects at low AED doses (29%). These are all important aspects that should be explored in patients with uncontrolled seizures, before deeming them medically intractable.

Incorrect AED

Studies of patients with chronic, uncontrolled seizures show that about 60% of these cases are due to drug resistance (17–19), whereas 40% have pseudoresistant epilepsy. Most commonly, pseudoresistance in these patients is due to receiving the wrong medication for their epilepsy syndrome, which in some studies is reported in 30% of adults (19) and 37% of children (20). Common among these errors is the use of carbamazepine for absence seizures, ethosuximide for complex partial seizures, phenytoin for epileptic spasms, or vigabatrin for myoclonic seizures. Patients with primary generalized epilepsy are particularly vulnerable to receiving incorrect AEDs. In one study, failure to obtain or interpret a history of myoclonic jerks resulted in incorrect diagnosis and inappropriate treatment of two-thirds of patients with JME (21).

Incorrect Dosage

Incorrect AED dosage is important as a cause of pseudoresistance. The AED dosage at which most patients achieve seizure control is usually modest to moderate, for example, 600 mg of carbamazepine, 1000 mg of valproate, and 200 mg of lamotrigine, and correspond to about two-thirds of the WHO defined daily dose (DDD) for these medications (http://www.whocc.no/atc_ddd_index/) (22). Only 15% to 20% of patients require higher dosages to achieve seizure freedom (23). Patients who fail a first AED at low dosages (presumably because of side effects) are significantly more likely to be controlled with additional trials of AEDs (24). For example, those who fail the first AED at doses lower than 50% of the DDD are 60% more likely to achieve sustained seizure freedom with further AED trials. This has two implications for planning referrals for presurgical evaluation. First, failure of a dose equivalent to 50% to 75% of the DDD might be considered as drug failure and count toward the definition of drug resistance, without having to escalate to the full DDD. Second, in patients who fail an AED at a higher dosage (>75% of the DDD), clinicians should be ready to discuss referral for presurgical evaluation early on, because these patients have a lower likelihood of future seizure control.

Drug Interactions

The pharmacokinetics of many of the older-generation AEDs (i.e., phenytoin, phenobarbital, carbamazepine, primidone, valproate) and to a lesser degree some of the newer AEDs (e.g., lamotrigine, topiramate, zonisamide, felbamate) involve hepatic metabolism through pathways such as the cytochrome P450 isoenzyme system and uridine glucoronyl transferases, which can be activated by a number of drugs, resulting in lower steady-state serum concentration of AEDs and ultimately loss of seizure control. Of particular importance are interactions among various AEDs, which may be overlooked in busy clinical practice. For example, the plasma concentration of valproic acid can be reduced by 49% to 76% in patients who are also treated with phenobarbital, phenytoin, and carbamazepine (25). Notable examples of interactions resulting in decreased steady

state of various AEDs are listed in Table 72.1 (25,26). Poor seizure control should prompt a thorough assessment and correction of coadministered medications before establishing the diagnosis of pharmacoresistant epilepsy.

Table 72.1 Drug Interactions That may Cause Lower AED Concentrations and Poor Seizure Control

Drug added	AED effect decreased
Oral contraceptives	Lamotrigine
Rifampicin	Older-generation AEDs
Carbapenem	Valproic acid
Antivirals nevirapine and efavirenz	Older-generation AEDs
Carmustine, vinblastine, methotrexate, and bleomycin	Phenytoin (decreased absorption)
Cisplatin	Carbamazepine, valproic acid
Methotrexate	Valproic acid
Antacids	Phenytoin, phenobarbital, carbamazepine, gabapentin
St. John's wort, alcohol	Older-generation AEDs
Enzyme-inducing AEDs (phenytoin, carbamazepine, phenobarbital, primidone)	Benzodiazepines, lamotrigine, zonisamide, felbamate, tiagabine, topiramate, older-generation AEDs

Older-generation AEDs = phenobarbital, primidone, phenytoin, carbamazepine, valproate.

Nonadherence

Nonadherence, generally defined as medication-taking behavior that does not coincide with medical advice or instruction, is common in epilepsy and can result in loss of seizures control. Nonadherence in epilepsy has been assessed using a variety of methods, has a prevalence 30% to 70%, and results in increased costs, hospitalizations, emergency room visits, seizures, and mortality (27–31). In patients with apparent pharmacoresistance, clinicians should explore the possibility of poor adherence to AEDs through careful elicitation of AED usage, serum levels, pill counts, or even hospital admissions to assess adherence and serum levels serially. Common factors associated with AED nonadherence include unacceptable side effects, poor communication or understanding regarding AED use, unaffordability, inconvenient dosing, and lower socioeconomic status (27–31).

Lifestyle and Psychosocial Factors

Common and imminently correctable lifestyle factors associated with an increase of breakthrough seizures and pseudoresistance to AEDs include poor sleep habits, alcohol and substance abuse, and exposure to specific triggers. The relation between sleep and epilepsy has been known since antiquity, and the admonition to maintain good sleep hygiene to prevent seizures can be traced to hippocratic writings (32). Laboratory and human observations support the epileptogenic effect of

sleep deprivation, particularly for generalized seizures and epilepsies (32). The role of alcohol and substance abuse in triggering seizures is well recognized; can be due to direct toxicity, withdrawal, enzyme induction, or drug interactions; and should be explored as a cause of uncontrolled seizures (33). Finally, among psychosocial factors, stressful life events (34), depression, and anxiety are often identified as causes of seizure exacerbation or loss of seizure control, and patients associate emotional well-being with better seizure control (35). The association of depression and seizures is bidirectional and mediated through a number of direct (e.g., neurotransmitters) and indirect (e.g., nonadherence) mechanisms (36).

DRUG-RESISTANT EPILEPSY

Definition

Once pseudoresistance to AEDs has been ruled out, clinicians face management of drug-resistant epilepsy. Based on broad consensus and using a pragmatic approach aimed at creating an operational definition that could be applied in clinical practice, in 2010, the International League Against Epilepsy established the current definition of drug-resistant epilepsy as "failure to achieve sustained seizure freedom with adequate trials of at least two appropriately chosen and used AED regimens (whether administered as monotherapies or in combination)" (37). Although simple at first glance, its implementation requires several key elements clinicians need to consider (38). First, inappropriately or inadequately used AEDs do not count toward establishing drug resistance, and if the former cannot be assessed, the outcome of that particular AED is considered as "undetermined" for the individual patient. Second, AED side effects are of crucial importance in clinical practice but were not included as a defining factor of drug resistance because the focus was on lack of response, rather than poor tolerability (38). Third, seizure freedom refers to seizure freedom from all seizure types, big and small, as recognized by patients, caregivers, and the clinical team. Finally, sustained seizure freedom has to last at least 1 year or three times the previous longest seizure-free period, whichever is longer. This time period has a practical rationale (e.g., employment, driving, decision to start or change AED) and was derived from the statistical "rule of 3," in which the 95% probability of seizures not occurring is roughly equivalent to three times the longest seizure-free period previously experienced by the patient (38). This definition has clear implications for considering surgical evaluation and candidacy earlier, rather than later.

Predictors and Trajectories of Drug Resistance

Several factors can help predict AED resistance in epilepsy, thereby helping identify early in the process patients who may benefit from presurgical evaluation (3). The epilepsy syndrome is among the most consistent predictors of drug resistance. Patients with presumed genetic epilepsies and frequently self-limited epilepsy syndromes (e.g., childhood absence epilepsy or benign rolandic epilepsy with centrotemporal spikes) are more likely to achieve remission than those with epilepsies of structural or metabolic causes (3). Other factors that can foreshadow drug resistance include age of onset (<1 year or >12 years), neonatal seizures, focal seizures or multiple seizure types, high initial seizure frequency, MRI showing hippocampal atrophy (<10% achieve remission), cortical dysplasia (<25% achieve remission) or dual pathology, neurologic deficits (3), and failing the first two AEDs at moderate or high doses (24). Attentive clinicians who identify these factors early on can advise

patients promptly regarding the possibility of surgery.

Once patients fail two initial AEDs, they have a very low chance of future sustained seizure freedom (3). About two-thirds of patients achieve remission with the initial AED, and the probability of achieving remission decreases by 50% with the failure of each subsequent two AEDs (18,39,40). However, drug resistance is a dynamic process, patients move in and out of drug resistance over time in a complex but increasingly understood pattern of relapses and remissions. Four main outcome patterns have been identified in cohort studies of medically treated patients with epilepsy: (a) 40% of patients enter permanent early remission, usually with the first or second AED; (b) 20% enter a delayed but permanent remission with additional AED trials; (c) 15% exhibit a relapsing–remitting disease course; and (d) 25% to 30% never achieve remission despite AED treatment (3,41). Importantly, patients may enter a period of seizure remission after being deemed drug resistant. However, studies consistently show that the majority of these patients relapse (3,42), further emphasizing the importance of timely referral for presurgical evaluation rather than waiting for eventual, unsustained periods of seizure control.

The Role of Surgery

There is extensive evidence about the highly favorable risk–benefit and cost-effectiveness ratio of epilepsy surgery in carefully selected patients, as well as of its durability and favorable impact on psychosocial aspects, quality of life, and prevention of early death (3). Yet, surgery remains underutilized. Wait times for surgical referral seem unchanged over the last two decades and therefore impervious to the evidence (43). Efforts to improve appropriate referral of patients for presurgical evaluation include creation of user-friendly, rigorously developed tools that can assist front-line clinicians (and patients) assess whether presurgical evaluation may be appropriate (44). However, clinicians and educators need to understand the factors underpinning referral. The message about the benefits and safety of epilepsy surgery has been issued repeatedly but perhaps not effectively. Clinicians and patients need to be aware that the likelihood of achieving sustained seizure remission is very low after meeting the definition of drug resistance and that other therapeutic avenues, including surgery, should be explored earlier than later.

CONCLUSIONS

Pseudoresistance to AEDs is highly prevalent and should be systematically addressed in patients with poor response to AEDs. In patients meeting the definition of drug-resistant epilepsy, clinicians need to formulate a rational treatment plan based on the likelihood of achieving seizure remission with further AEDs. This includes consideration of evaluation for epilepsy surgery. Although the diagnosis of medical intractability is certainly an indication for considering epilepsy surgery, patients may not have to be intractable before being evaluated for possible epilepsy surgery. Consider, for example, a patient who has entered a second remission of seizures after having relapsed and whose MRI shows a well-defined epileptogenic lesion known to have a low probability of sustained seizure remission, such as hippocampal sclerosis or focal cortical dysplasia. In these patients, evaluation for epilepsy surgery should be entertained early on in the course of the disease, with appropriate consideration of risks and benefits.

CHAPTER 73 MAGNETIC RESONANCE IMAGING IN EVALUATION FOR EPILEPSY SURGERY

AHSAN N.V. MOOSA AND PAUL M. RUGGIERI

Prior to the advent of modern neuroimaging, candidates for epilepsy surgery were selected based on seizure semiology, neurologic examination, and EEG features. Direct cortical EEG, intraoperatively or with implanted electrodes, was often critical to identify the epileptogenic zone. The epileptogenic lesions per se were identified only after histopathologic analysis of resected brain tissue. CT and later MRI provided powerful tools for the identification of the epileptogenic lesions preoperatively, thereby changing the approach of presurgical evaluation in patients with lesions. Invasive neurophysiologic techniques became unnecessary in many cases, and the pool of surgical candidates widened with improved postsurgical outcome (1–3).

Brain MRI is currently the best available tool for identification of epileptogenic lesions. It provides two critical details of a lesion—the presumptive pathology and the precise anatomic location. The strong soft tissue contrast of MRI makes it particularly well suited to identify even the most subtle structural abnormalities such as cortical dysplasias that are often associated with refractory epilepsy. The multiplanar capabilities of MRI allow study of the precise anatomic location of these lesions in relation to eloquent cortices, which is a critical point for surgical planning. Newer MRI techniques, including 3-T magnets, functional MRI (fMRI), and diffusion tensor imaging (DTI), have further improved the detection of subtle abnormalities and provided information about brain function and network connectivity.

The intent of this chapter is to provide the reader with a working knowledge of major anatomical landmarks on brain MRI relevant to the eloquent cortex location, a general understanding of various MRI pulse sequences, and how these images are applied in the evaluation of patients with epilepsy. A mini-atlas of common epileptogenic lesions is displayed at the end of the chapter. Other related topics including fMRI, voxel-based morphometry, and DTI are addressed in Chapters 77, 78, and 79, respectively.

MAJOR ANATOMICAL LANDMARKS OF THE BRAIN ON MRI

Epileptogenic lesions resulting in medically refractory epilepsy commonly include mesial temporal sclerosis (MTS), malformations of cortical development (MCD), encephalomalacia, slow-growing benign tumors, hamartomas, and vascular malformations. In most cases, the anatomic location and extent of these otherwise benign lesions are more critical than the pathology itself. Anatomic location of the lesion is the chief determinant of the type of epilepsy syndrome. The extent of the lesion and its

spatial relationship to eloquent areas of the brain has major implications for the surgical strategy. Hence, a three-dimensional working knowledge of MRI neuroanatomy is critical for optimal interpretation of the lesions. Extensive review of neuroanatomy is beyond the scope of this chapter. The main focus of this section is to review the anatomy relevant for the location of the eloquent cortex and temporal lobe anatomy, as temporal lobe epilepsy remains the most common surgically remediable epilepsy syndrome in most epilepsy centers.

Eloquent cortex refers to areas of cerebral cortex that are indispensable for defined cortical function and whose damage leads to predictable pattern of neurologic deficits. The key eloquent areas relevant to epilepsy surgery are the primary motor cortex, Broca area, Wernicke area, and visual cortex. Although routine MRI provides information about the expected location of these regions, fMRI provides additional functional information, particularly important when the lesions occur in early life or the anatomy is distorted by lesions.

Broca and Wernicke Areas

In most right-handed subjects and a significant number of left-handed subjects, the language areas reside in the left hemisphere. Broca area refers to the expressive language area, and Wernicke area refers to the receptive language comprehension center. The location of Broca area in the dominant inferior frontal gyrus is relatively consistent. On the contrary, the location of Wernicke area is variable. Identification of the presumptive location of Broca and Wernicke areas begins with the knowledge of anatomy of the sylvian fissure.

The sylvian fissure has three major components: an anterior ascending and anterior horizontal rami, a central stem with its minor rami, and a posterior terminal ascending ramus. Broca area is located in relation to the anterior end of sylvian fissure, and the Wernicke area is located in relation to the posterior end of the sylvian fissure in the dominant hemisphere. The central stem of the sylvian fissure is in relation to the inferior regions of the motor and sensory cortex.

Sagittal sections of MRI provide excellent view of the sylvian fissure and the various gyri in relation to it (Fig. 73.1A and B). In far lateral sagittal sections, the V- or Y-shaped anterior horizontal (anterior arm of V or Y) and anterior ascending rami (posterior arm of V or Y) of the sylvian fissure can be identified (see Fig. 73.1A and B). The sulcus that is superior and perpendicular to these anterior rami is the inferior frontal sulcus, and the sulcus posterior and parallel to the anterior ascending rami of the sylvian fissure denotes the inferior precentral sulcus. The “M”-shaped region around the banks of the V- or Y-shaped anterior rami of sylvian fissure forms the inferior frontal gyrus, which is limited superiorly by the inferior frontal sulcus (4,5). The inferior frontal gyrus consists of three regions, namely, pars opercularis, pars triangularis, and pars orbitalis (Fig. 73.1B). In most normal subjects, pars opercularis, which lies between anterior ascending rami and the inferior precentral sulcus, and/or the region around the anterior ascending rami in pars triangularis, harbor the Broca area in the dominant hemisphere (4). On coronal sections, precise identification of location of Broca area is difficult but may be accomplished by tracing the inferior frontal sulcus posteriorly.

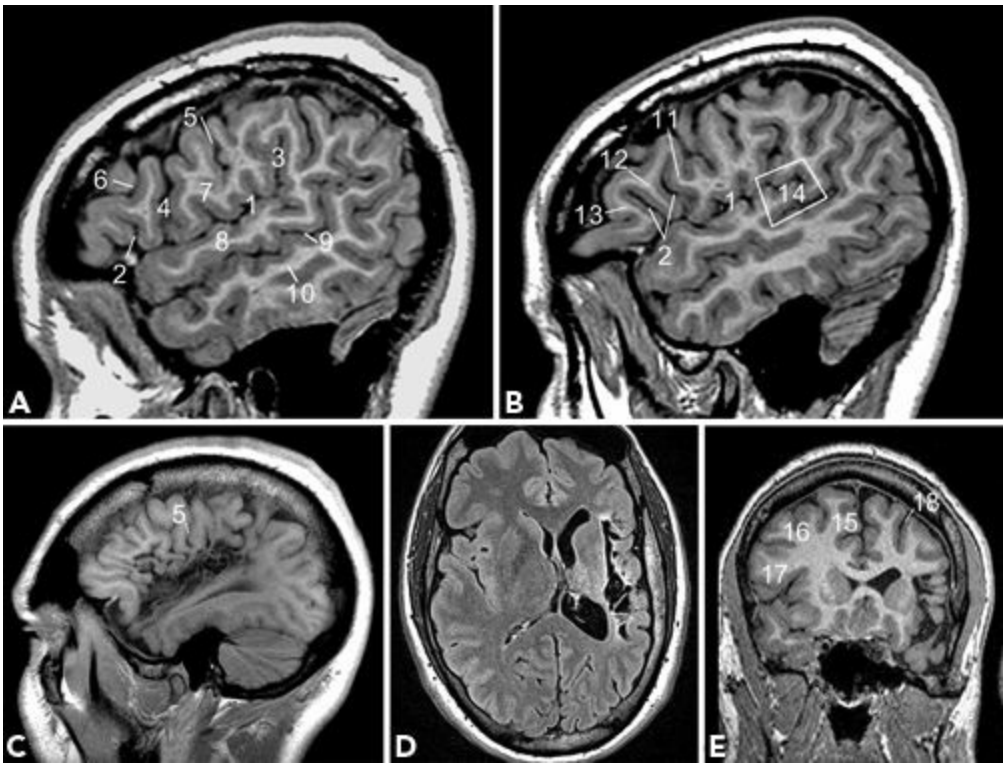

Figure 73.1. Broca and Wernicke area: **A, B:** Major landmarks on sagittal images to identify Broca and Wernicke area. **C–E:** Left perisylvian encephalomalacia due to perinatally acquired ischemic injury displayed in sagittal, axial, and coronal planes. The lesion involves the region of potential Broca and Wernicke areas (fMRI in this subject confirmed language representation in the right hemisphere, likely a result of plasticity due to early brain injury). (1, sylvian fissure; 2, "V"-shaped anterior rami of sylvian fissure; 3, posterior ramus of sylvian fissure; 4, precentral sulcus—inferior part; 5, central sulcus; 6, inferior frontal sulcus; 7, precentral gyrus—inferior part; 8, superior temporal gyrus; 9, superior temporal sulcus; 10, middle temporal gyrus; 11, pars opercularis; 12, pars triangularis; 13, pars orbitalis; 14, usual location of Wernicke area over the dominant hemisphere; 15, superior frontal gyrus; 16, middle frontal gyrus; 17, inferior frontal gyrus; 18, superior frontal sulcus.)

Wernicke area is located in relation to the posterior end of sylvian fissure, which terminates in the temporoparietal region as the ascending posterior rami. Wernicke area lies in the posterior part of the superior temporal gyrus (4.5 cm posterior to the tip of the temporal pole) extending around the banks of the posterior terminal ascending ramus of the sylvian fissure or around the superior temporal sulcus in the language-dominant hemisphere (Fig. 73.1B). In a minority, the middle or inferior temporal gyrus harbors Wernicke area. Rarely, Wernicke area may lie within the anterior part of the superior temporal gyrus (6–8). On coronal sections, tracing the sylvian fissure and superior temporal sulcus posteriorly may assist in the identification of Wernicke area. Atypical locations of language area tend to occur when congenital or early-acquired brain lesions are located in the vicinity of the presumptive language areas (Fig. 73.1C–E). These lesions may result in shift of the language areas to the perilesional regions or, in extreme cases, to the contralateral homologous region of the brain. This can be confirmed by a Wada test or fMRI studies.

Primary Motor Area: The Precentral Gyrus

Surgery for epileptogenic lesions around the central sulcus poses special challenges due to the risk of motor deficits. A thorough knowledge of the anatomy of the central sulcus and precentral gyrus—the primary motor area—is crucial to localize the lesions around this region. The central sulcus and the precentral gyrus are best identified on the axial and sagittal images (Figs. 73.2 and 73.3). The precentral gyrus is outlined anteriorly by the precentral sulcus and posteriorly by the central sulcus.

On axial MR images (Fig. 73.2A and B), five features help to localize the central sulcus and precentral gyrus (9–11):

1. The central sulcus begins near the interhemispheric fissure and descends in a slight forward angle toward the sylvian fissure. The central sulcus is longer than other adjacent sulci and is least intersected by other sulci. The precentral sulcus is frequently discontinuous and intersected by superior and inferior frontal sulci on its course toward the sylvian fissure.
2. The sagittally oriented superior frontal sulcus at its posterior end meets the coronally oriented precentral sulcus; the adjacent gyrus posterior to the precentral sulcus is the precentral gyrus.
3. The right and left marginal sulci (the ascending terminal portion of the cingulate sulcus on the medial surface of hemisphere) on either side of the interhemispheric fissure produce an easily recognizable mustache-like image (Fig. 73.2A). The central sulcus is usually the first sulcus anterior to this marginal sulcus in most individuals.
4. The precentral gyrus is often 1.5- to 2-fold bigger (sagittal thickness) than the adjacent postcentral gyrus.
5. The hand motor area on the precentral gyrus has an easily recognizable morphologic pattern in most individuals and can further aid in identification of the precentral gyrus. The most common morphologic pattern described on axial image is the “inverted omega” or “knob”- or “knuckle”- like appearance, with its rounded knob abutting the central sulcus. Other morphologic patterns such as “horizontal epsilon” and “asymmetric horizontal epsilons” have been recognized (10,11).

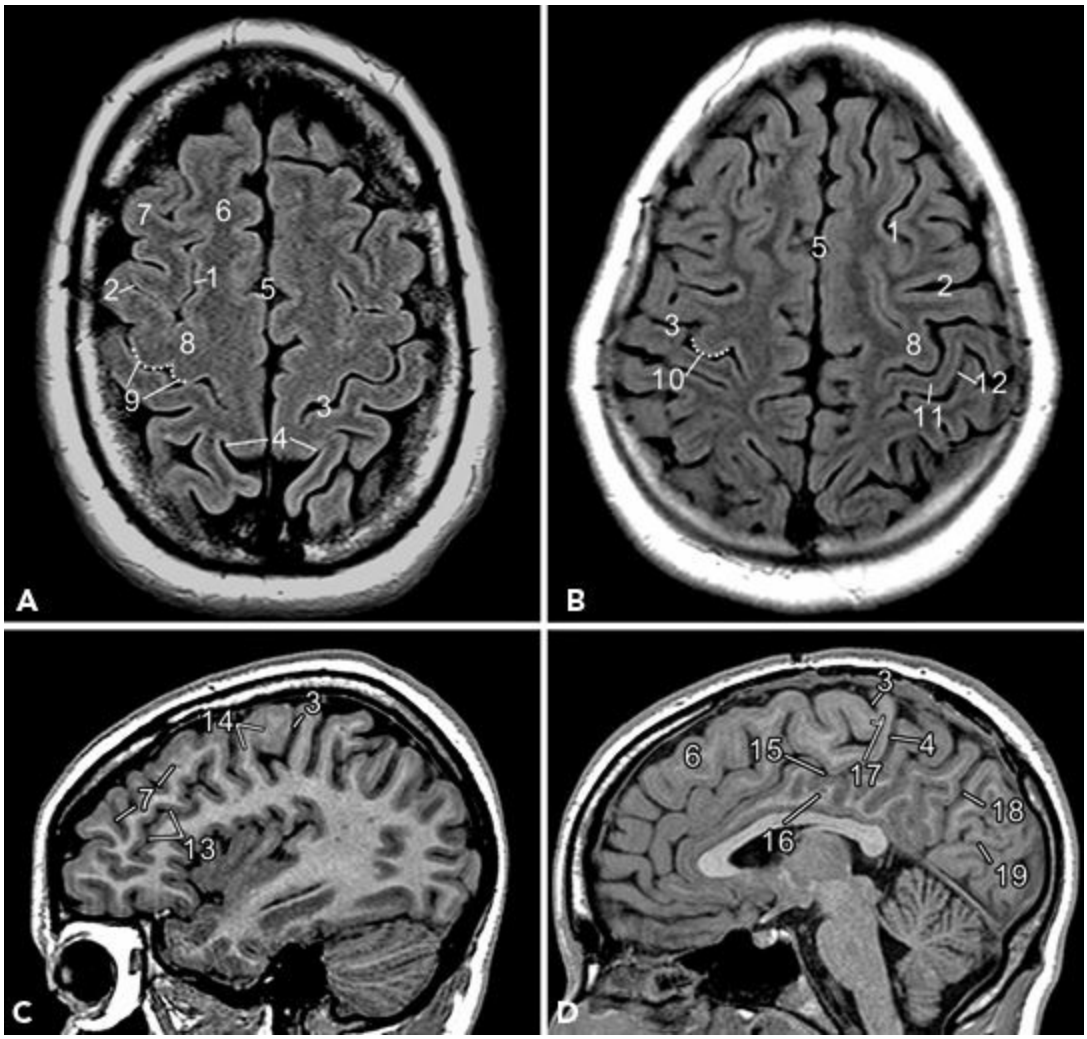

Figure 73.2. Primary motor area: Major landmarks on axial **(A** and **B)** and sagittal images **(C** and **D)** to identify the central sulcus and primary motor area (precentral gyrus). (1, superior frontal sulcus; 2, precentral sulcus; 3, central sulcus; 4, marginal sulcus (note mustache-like appearance); 5, interhemispheric fissure; 6, superior frontal gyrus; 7, middle frontal gyrus (note "zigzag appearance" in sagittal image); 8, precentral gyrus; 9, "horizontal epsilon"–shaped hand motor area; 10, "knob"-shaped hand motor area in a different subject; 11, postcentral gyrus; 12, postcentral sulcus; 13, inferior frontal sulcus; 14, posteriorly directed "hook"-shaped hand motor area on sagittal plane; 15, cingulate sulcus; 16, cingulate gyrus; 17, paracentral lobule; 18, parietooccipital sulcus; 19, calcarine fissure.)

On sagittal MR images, the central sulcus and precentral gyrus can be identified at three different levels—the far lateral surface, along the hand motor region, and over the medial surface (Figs. 73.1A and 73.2C and D).

1. As described in the earlier section of Broca area, in far lateral sagittal images, at the anterior end of sylvian fissure, the anterior ascending rami of sylvian fissure can be identified (Fig. 73.1A). The sulcus posterior and parallel to the anterior ascending rami denotes the inferior precentral sulcus, which descends inferiorly and often meets the sylvian fissure. The central sulcus lies posterior and parallel to the precentral sulcus, and it usually does not unite with the sylvian fissure unlike the precentral sulcus. Thus, the opercular (lower) part ends of the precentral gyrus and postcentral gyrus (primary sensory cortex) together form the subcentral gyrus (4,5).
2. Further medially, in the mid parasagittal sections (Fig. 73.2C), the hand motor area may be recognized as a posteriorly directed "hook"-shaped appearance (the sagittal view of the "knob" described on axial plane) and usually better visualized if thin sagittal sections are obtained.
3. Further medially (Fig. 73.2D), in the medial surface of the cerebral hemisphere,

identification of the cingulate sulcus and its ascending segment—the marginal sulcus—assist in delineation of the central sulcus. The central sulcus makes a small dip in the medial surface and is often the first sulcus anterior to marginal sulcus. The region on either side of the central sulcus on the medial side forms the paracentral lobule, which carries motor and sensory representation for contralateral lower extremity.

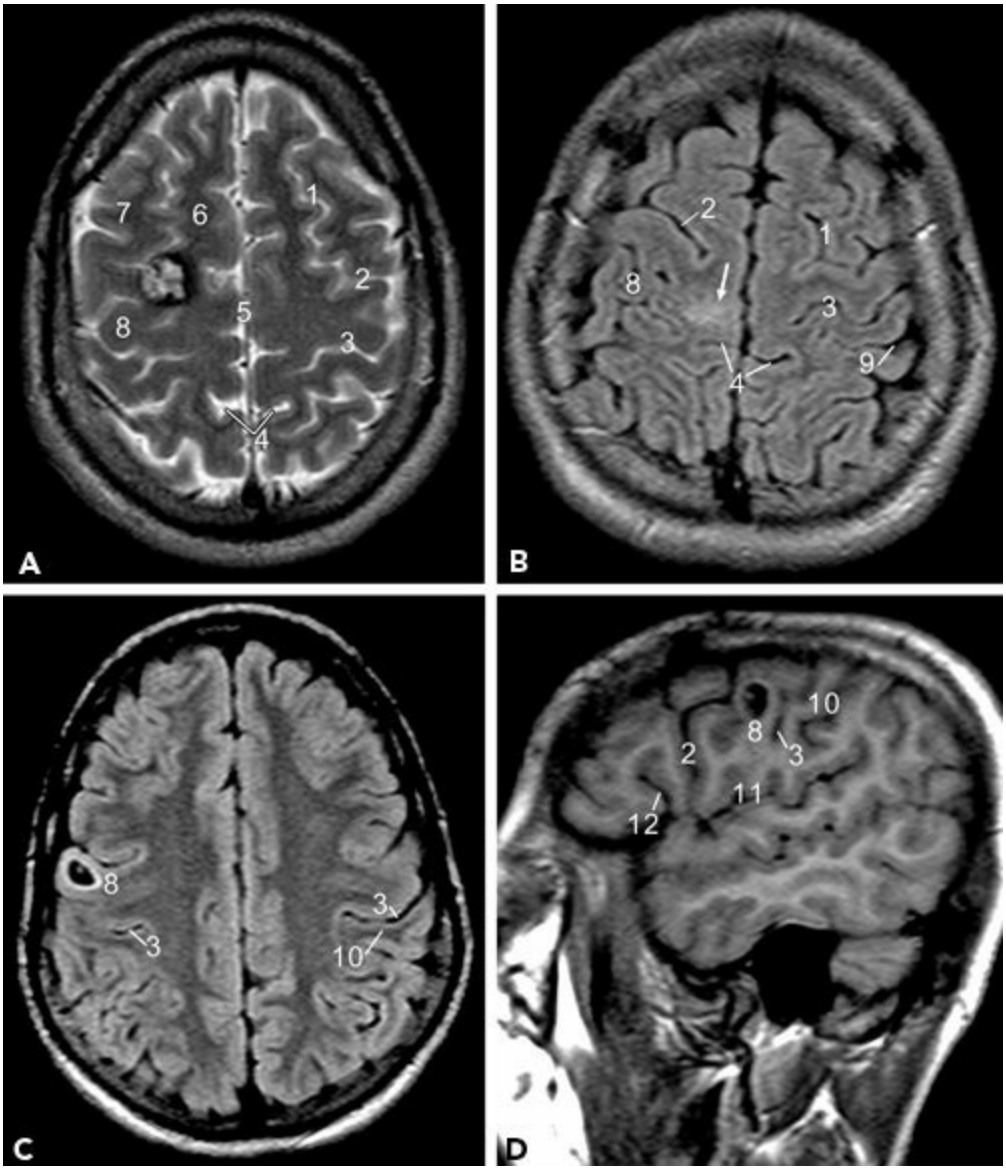

Figure 73.3. Lesions around the region of the central sulcus and precentral gyrus. **A:** T2-weighted image shows a cavernoma at the junction of the right superior frontal gyrus and precentral gyrus. **B:** FLAIR image shows an area of hyperintensity over the paramedian precentral and postcentral gyrus. **C, D:** A cystic lesion in the precentral gyrus over the lateral convexity displayed in axial and sagittal planes. (1, Superior frontal sulcus; 2, precentral sulcus; 3, central sulcus; 4, marginal sulcus; 5, interhemispheric fissure; 6, superior frontal gyrus; 7, middle frontal gyrus; 8, precentral gyrus; 9, postcentral sulcus; 10, postcentral gyrus; 11, sylvian fissure; 12, anterior rami of sylvian fissure.)

On coronal MR images, precise identification of the central sulcus and precentral gyrus is difficult using the coronal slices alone. On volume acquisition images, the inferior precentral gyrus may be identified by tracing the inferior frontal sulcus posteriorly.

Visual Area: The Calcarine Cortex

Calcarine cortex, the primary visual area, is located in the inferior and superior lips of the calcarine

fissure in the occipital lobes. Calcarine fissure can be readily identified on the sagittal and coronal images (Figs. 73.4 and 73.5) (12). On sagittal images close to midline (Fig. 73.4A), in the medial surface of the occipital lobe, calcarine fissure extends from a point below the splenium of corpus callosum to the occipital pole. The parietooccipital sulcus extends from the anterior part of calcarine fissure and extends upward in an oblique direction toward the dorsal surface of the brain. Between the parietooccipital sulcus and the calcarine fissure lie the cuneus—a wedge-shaped region in the medial occipital lobe. Precuneus lies anterior to this, between the parietooccipital sulcus and the marginal sulcus. On axial images, the parietooccipital sulcus is more readily visualized on multiple slices because of the oblique orientation of the parietooccipital sulcus (Fig. 73.4B).

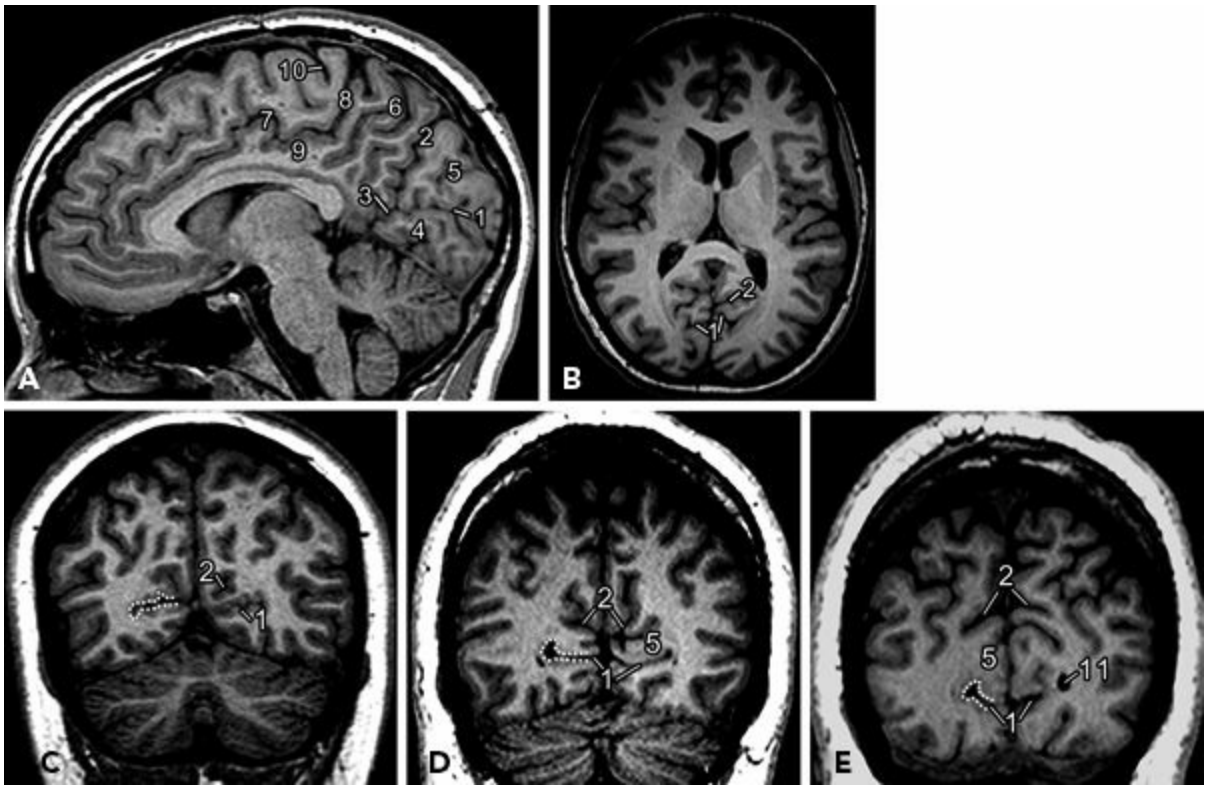

Figure 73.4. Visual cortex: Major landmarks on sagittal **(A)**, axial **(B)**, and coronal **(C–E)** planes to display calcarine fissure and parietooccipital sulcus. (1, calcarine fissure; 2, parietooccipital sulcus; 3, anterior calcarine sulcus; 4, lingual gyrus; 5, cuneus; 6, precuneus; 7, cingulate sulcus; 8, marginal sulcus; 9, cingulate gyrus; 10, central sulcus; 11, occipital horn of lateral ventricle.) Dotted lines on coronal images indicate region of visual cortex on the right side.

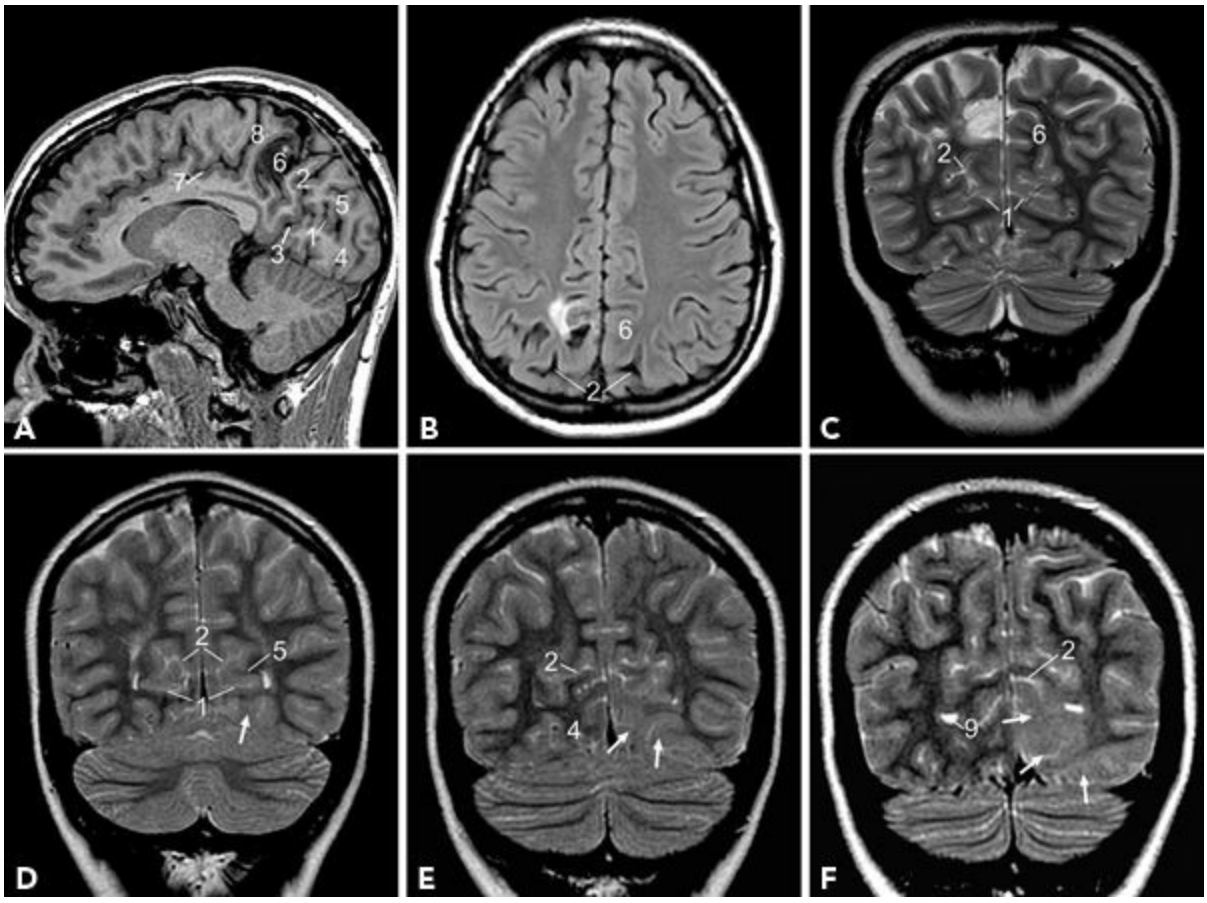

Figure 73.5. Lesions around the calcarine fissure and parietooccipital sulcus. **A–C:** Residual tumor with postoperative changes noted in the right precuneus region displayed in sagittal, axial, and coronal planes. Note that the lesion is anterior to the parietooccipital sulcus and posterior to the marginal sulcus. **D–F:** T2-weighted image shows hyperintensity (arrows) of the cortex and subcortical white matter in the left occipital lobe; lesion is inferior to calcarine fissure in anterior images **(D)** but involves calcarine fissure, cuneus, and lateral occipital gyrus in posterior sections **(F)**. (1, calcarine fissure; 2, parietooccipital sulcus; 3, anterior calcarine sulcus; 4, lingual gyrus; 5, cuneus; 6, precuneus; 7, cingulate sulcus; 8, marginal sulcus; 9, occipital horn of lateral ventricle.)

On coronal MR images, both calcarine fissure and the parietooccipital sulcus are readily identified as the two major fissures in medial occipital lobes that diverge as they course posteriorly (Fig. 73.4C–E). Calcarine fissure becomes shallow as it courses posteriorly and does not quite extend to the occipital pole. The parietooccipital sulcus is generally deeper and reaches dorsal surface and can normally be somewhat asymmetric in depth and configuration (12).

Temporal Lobe

Broadly, temporal lobe epilepsy is categorized as mesial temporal epilepsy and lateral temporal epilepsy syndromes based on presumed anatomic origin of epileptogenicity. Temporal lobe on its outer surface is limited superiorly from the frontal lobe by sylvian fissure. The posterior limits of temporal lobe are poorly defined by an imaginary line from the preoccipital notch of the basal aspect of temporal lobe to the superior aspect of the parietooccipital sulcus. Lateral temporal region consists of three major gyri, namely, the superior, middle, and inferior temporal gyri divided by the superior and inferior temporal sulci. There are two gyri on the basal aspect—the laterally located fusiform or occipitotemporal gyrus and the medially located parahippocampal gyrus (PHG). The fusiform gyrus is limited laterally from the inferior temporal gyrus by the lateral occipitotemporal sulcus and separated medially from the PHG by the collateral sulcus. Temporal structures medial to the collateral sulcus are referred to as mesial temporal structures (13–17).

Mesial temporal structures are best visualized on volumetric high-resolution coronal MR images (Fig. 73.6). Hippocampal formation, amygdala, and PHG are usually considered together as part of the mesial temporal epilepsy network. The term hippocampal formation is often used to denote the hippocampus proper along with the dentate gyrus. Hippocampus derives its name from its morphologic resemblance to a "sea horse," best appreciated on sagittal images (Fig. 73.6A). It has three parts, namely, head, body, and tail of hippocampus, from anterior to posterior. The head and body of hippocampus extend posteriorly along the inferomedial border of temporal horns of lateral ventricles (Fig. 73.6A and B). Head of hippocampus is the most voluminous part and occupies the anterior end of hippocampus (Fig. 73.6D). Head of the hippocampus is further recognized by its typical undulating superior margin produced by the digitations on the ventricular surface of the structure, better visualized on coronal T2-weighted or inversion recovery images. Many landmarks have been used to identify body and tail of hippocampus, but the most useful would be internal landmarks such as fimbriae and crus fornix—the output tracts of hippocampus. On the coronal MR images, posterior to the head of hippocampus, the appearance of fimbriae signals the junction of head and body of hippocampus (Fig. 73.6E). Further posteriorly, the clear appearance of crus fornix signals the beginning of the tail of hippocampus (Fig. 73.6F). The tail of the hippocampus and fornix course superiorly and medially along the medial margins of atria of lateral ventricles. The dentate gyrus is often indistinguishable from the hippocampus proper and forms a single unit on MR images. The dentate gyrus runs parallel to the hippocampus with its cuplike superior surface covering the CA4 region, forming the hilus of hippocampus. The dentate gyrus continues anteriorly as the band of Giacomini, also referred as tail of dentate gyrus, and posteriorly curves around the callosum as indusium griseum. The amygdala, located on the roof of the temporal horn of the lateral ventricle, is anterior and superior to the head of hippocampus (Fig. 73.6C). The amygdala fuses with the globus pallidus superiorly (13–18).

ventricle; 2, amygdala; 3, head of hippocampus; 4, body of hippocampus; 5, tail of hippocampus; 6, collateral sulcus; 7, hippocampus; 8, sylvian fissure; 9, superior temporal gyrus; 10, ambient cistern; 11, middle temporal gyrus; 12, inferior temporal gyrus; 13, occipitotemporal (fusiform) gyrus; 14, parahippocampal gyrus; 15, fimbriae—hyperintense structure within the box; 16, crus of fornix.)

The PHG is located inferolateral to the hippocampal formation and extends posteriorly along the margin of the tentorium cerebelli in contact with the ambient cistern medially. The hippocampal sulcus separates the PHG from hippocampal formation superiorly, and collateral sulcus separates it from the fusiform gyrus laterally on the basal aspect (Fig. 73.6C and D). Anterior end of the PHG is hooked backward and medially, to form the uncus. The PHG has two components, namely, the subiculum and the entorhinal area. Subiculum, the superomedial part of PHG, is continuous with the CA1 of hippocampus and forms the bed of hippocampal formation. Entorhinal area is a poorly demarcated area located in the uncus and the anterior extension of PHG. In the posterior part, the anterior end of calcarine fissure divides the PHG into a superior and an inferior part. The superior part called isthmus curves up and continues with the cingulate gyrus, and the inferior part continues posteriorly with the lingual gyrus of occipital lobe (13–16).

MRI: TECHNICAL CONSIDERATIONS

Most centers use a 1.5 T MRI for routine imaging to evaluate for medically refractory partial epilepsy. 3 T MRI scanners are now widely available and increasingly used for epilepsy protocol imaging. 3 T MRI is likely to replace the 1.5 T MRI for imaging of potential epilepsy surgical candidates. Most MRI studies for evaluation of epilepsy incorporate a sagittal T1-weighted spin-echo acquisition as a scout image to position the slices of the subsequent pulse sequences. The other sequences and the imaging planes are tailored according to the referral information about presumptive epileptogenic zone. Broadly, two kinds of protocols are used in epilepsy imaging—temporal lobe protocol and extratemporal protocol. Different centers use different sets of sequences in these protocols. In general, high soft tissue contrast, thin sections, and imaging in all three planes are critical to epilepsy protocols. A cost- and time-effective protocol, frequently employed at Cleveland Clinic, is shown in Table 73.1.

In general, T1-weighted (short repetition time [TR], short echo time [TE]) images serve largely to define the anatomy, and T2-weighted (long TR and long TE) images are well suited for detecting most brain pathology. Fast spin-echo (FSE) or hybrid rapid acquisition relaxation enhancement sequences have replaced the earlier double-echo T2-weighted imaging because of inherent advantages in signal-to-noise ratio, acquisition time, and reduction in motion artifacts (19,20). The heavily T2-weighted images provide strong contrast between CSF and brain parenchyma and tissues with long T2 relaxation times. On the other hand, strong contrast produced by very long TRs and long echo trains can be detrimental and may obscure some parenchymal lesions and gray–white junction (19). The series of 180-degree pulses used in FSE T2 images reduces artifacts in plane with CSF motion as well as susceptibility artifacts at bone–CSF interfaces or adjacent to metallic foreign

bodies. However, the same effect makes the visualization of some blood products less evident than on conventional spin-echo imaging. The absence of 180-degree rephasing pulse in the gradient-echo sequences accentuates the local susceptibility artifact related to blood by-products and compensates for this shortcoming of FSE sequences. Consequently, a gradient-echo sequence should be used in any patients in whom vascular malformations or prior trauma is the apparent etiology (Fig. 73.7).

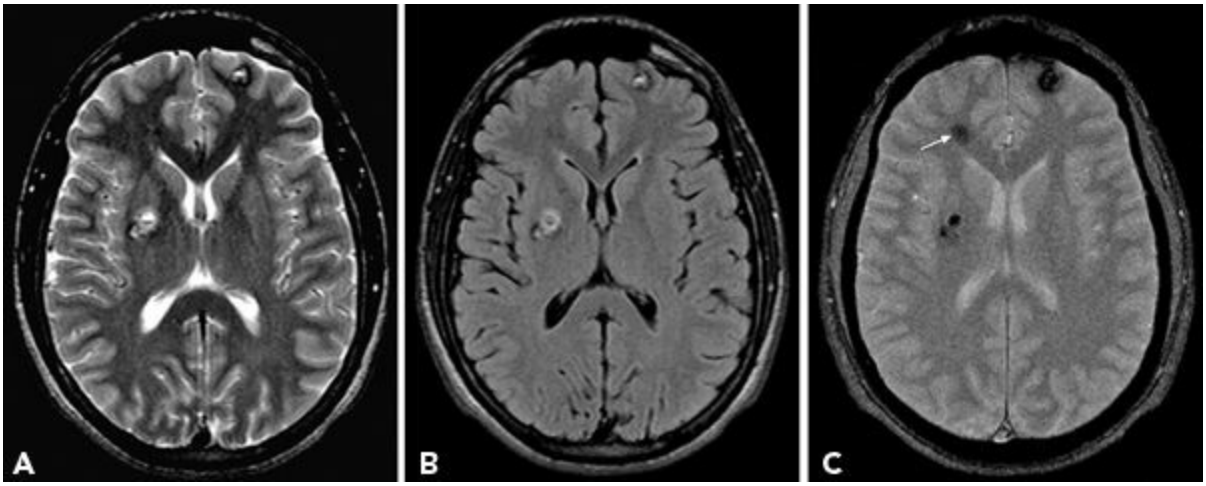

Figure 73.7. Axial T2-weighted **(A)**, FLAIR **(B)**, and gradient-echo images **(C)** show multiple cavernomas. Gradient-echo sequence reveals additional lesion in right frontal region (arrow) that is inconspicuous on T2 and FLAIR images.

FLAIR images improve the detection of lesions by suppressing the CSF signal and accentuating the signal of lesions with relatively short T1 and long T2 relaxation times (21). Fast FLAIR incorporates a preparatory 180-degree pulse and inversion time before the long TR/long TE FSE sequence to nullify the signal intensity of CSF. Hence, it has a specific advantage over T2 for lesions in the brain–CSF interface, namely, periventricular and subpial cortex location, as the CSF signal appears dark. In MTS, the hyperintense signals in the hippocampus may be obscured by the hyperintense CSF in the temporal horns on T2 sequences (21–23). FLAIR, by suppressing the CSF signal, accentuates the abnormality in the hippocampal region. Although FLAIR is often thought to be as "a heavily T2-weighted image with dark CSF," the nature of FLAIR sequence causes anything with relatively short T1 and long T2 relaxation times to be hyperintense on the FLAIR images. Some of these lesions may be overlooked on the T2-weighted study alone (Fig. 73.8). Direct comparison of T2 and FLAIR makes it clear that the lesions that are evident on both sets of images are often more obvious on the fast FLAIR. Lesions that are better visualized by fast FLAIR include subtle hyperintensity blurring the gray–white junction of MCD, subcortical foci of gliotic hyperintensity in areas of encephalomalacia, and the extent of infiltration of low-grade neoplasms.

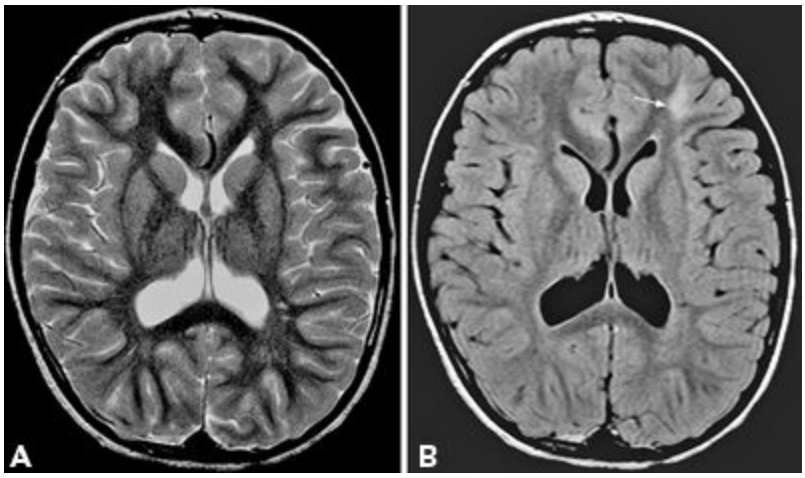

Figure 73.8. MR images to demonstrate superior visualization of subcortical hyperintensity associated with focal cortical dysplasia on FLAIR sequence. The dysplastic region in the left frontal region, nearly invisible on the T2-weighted image **(A)**, is conspicuous (arrow) on the FLAIR image **(B)**.

FLAIR has its own limitations. (i) Motion artifacts due to CSF pulsations, often more striking in the basilar cisterns, can blur the medial temporal regions. Fast T2 sequences are less susceptible to this, and hence, correlation with T2 makes this a relatively minor issue. (ii) Suppression of contrast between gray and white matter may obscure visualization of small foci of heterotopic gray matter without correlative pulse sequences. (iii) Detection of prior hemorrhages is limited with both fast FLAIR and fast T2 images because of the common sequence structure. (iv) Lastly, the contrast on fast FLAIR seems to be most limiting in young children (<2 years) with immature white matter. Normal children in this age group demonstrate patchy foci of hyperintensity in the subcortical and sometimes periventricular white matter that may be misinterpreted as abnormal. Conventional spin density images tend to be more helpful in this age group.

Volumetric High-Resolution Imaging

Conventional spin-echo imaging is generally sufficient to characterize a lesion when it is relatively large. In the case of smaller lesions, it may be difficult to interpret the nature of lesion or even identify the abnormality at all without high-resolution volumetric imaging. The best example of this would be the case of focal area of the dysplastic cortex, which constitutes the major substrate in many patients with refractory extratemporal epilepsy. Diagnosis of these subtle malformations requires critical evaluation of the thickness and morphology of cortical mantle, delineation of the interface between gray and white matter, and detection of minor signal intensity changes in the subcortical white matter. The 4- to 5-mm-thick slice of the routine T2 and FLAIR images frequently fails to detect such subtle abnormalities. Consequently, three-dimensional high-resolution volumetric imaging with T1-weighted gradient- echo protocols has become an integral and critical part of imaging for epileptogenic lesions.

Sequences such as fast spoiled gradient-recalled echo (SPGR), magnetization-prepared rapid acquisition gradient echo (MP-RAGE), and fast spoiled gradient-recalled acquisition in a steady state (GRASS) can be performed rapidly with very short TRs and TEs that provide strong T1-like contrast between gray and white matter (24,25). The hypointensity of the gray matter is quite comparable to the adjacent CSF, and hence, signal abnormalities in the gray matter are generally quite subtle. Conversely, many lesions in the white matter are obvious, but the signal intensity characteristics are frequently nonspecific. Lesions such as gliosis, heterotopia, and neoplasm may have the same degree

of hypointensity and may be indistinguishable based on volumetric sequence alone. Lesion morphology, correlation with other pulse sequences, and the clinical setting are necessary to distinguish the lesions. Images acquired through the volumetric study protocols do not have the true T1 contrast as they are gradient-echo sequences and not spin-echo sequences as in conventional T1 image. Hence, lesions that are typically hyperintense on T1 images such as blood products, dystrophic calcification, and proteinaceous fluids may not be apparent on this high-resolution volumetric imaging using gradient-echo sequences.

These three-dimensional sequences are designed to cover the entire head with very thin 1-mm contiguous slices. These thin slices are especially sensitive to detection of subtle dysmorphism of the cortical mantle and can also highlight minimal mass effect by depicting effacement of the adjacent sulcus in case of small tumors. Detection of subtle variations in configuration and volume of hippocampus is greatly improved by high-resolution volumetric imaging and has markedly reduced the need for invasive monitoring in patients with suspected MTS (26). Similarly, detection of concomitant malformation of cortical development in patients with MTS is critical in presurgical evaluation. Routine 4- to 5-mm FLAIR and T2 images are susceptible to volume averaging artifacts and thus misleading when one tries to assess the morphology of hippocampus. Even minimal tilt of the head in the scanner may accentuate this problem. The thin, contiguous three-dimensional slices minimize the volume averaging errors and improve detection of selective atrophy, developmental dysplasia, and subtle masses such as gliomas in the hippocampal formation by visual inspections alone. Volume averaging errors are further minimized if the slices are taken perpendicular to the long axis of the hippocampal formation. Quantitative volumetric analysis of the hippocampal formation and T2 relaxometry—a technique to quantify the signal intensity—may potentially improve recognition of subtle variations in volume and signal abnormality, respectively, as compared to visual inspection alone. However, these techniques are time consuming with minimal additional advantage if any and are not routinely used in clinical practice (27,28).

Other MRI Techniques and Their Utility in Epilepsy

In the last decade, newer MR imaging techniques have tremendously improved our understanding of the disorders of the brain. Careful selection of these sequences may provide useful information in selected causes of epilepsy such as cavernomas, posttraumatic epilepsy, epidermoid cyst, tuberous sclerosis, and acute symptomatic seizures. Some of the newer techniques provide information about the function and connections of the brain further assisting in surgical strategy.

Diffusion-weighted imaging (DWI) has revolutionized the neuroimaging of acute stroke but has limited role in epilepsy. In DWI, diffusion weighting is achieved by two strong diffusion-sensitizing gradients applied symmetrically around the 180-degree radiofrequency pulse of a spin-echo sequence. This leads to dephasing followed by rephasing of protons. Protons that have moved during and after the dephasing gradient move randomly, which leads to incomplete rephasing and signal attenuation. Areas with restricted diffusion of water molecules retain the signal and appear bright on DWI. The degree of diffusion restriction can be quantified by apparent diffusion coefficient (ADC) value. Areas with restricted diffusion appear bright on DWI with low signal intensity (correspondingly low ADC values) on ADC maps (29,30). In focal epilepsies, peri-ictal changes with foci of hyperintensity on DWI with decreased ADC values presumably due to cytotoxic edema have been reported (31,32). Isolated low ADC values without overt hyperintensity on DWI are more common in the peri-ictal studies (33). Conversely, interictal DWI has revealed increased ADC

values, which may reflect neuronal loss and increased extracellular space. Other disorders related to epilepsy that may show DWI abnormalities include the following: cortical and subcortical abnormalities in status epilepticus, tumors such as epidermoid cyst (Fig. 73.9), and transient lesions of splenium of corpus callosum related to seizures and antiepileptic drugs (34–36). A significant increase in ADC has been reported in epileptogenic tuber compared to other tubers in patients with tuberous sclerosis and may be helpful in surgical decisions (37).

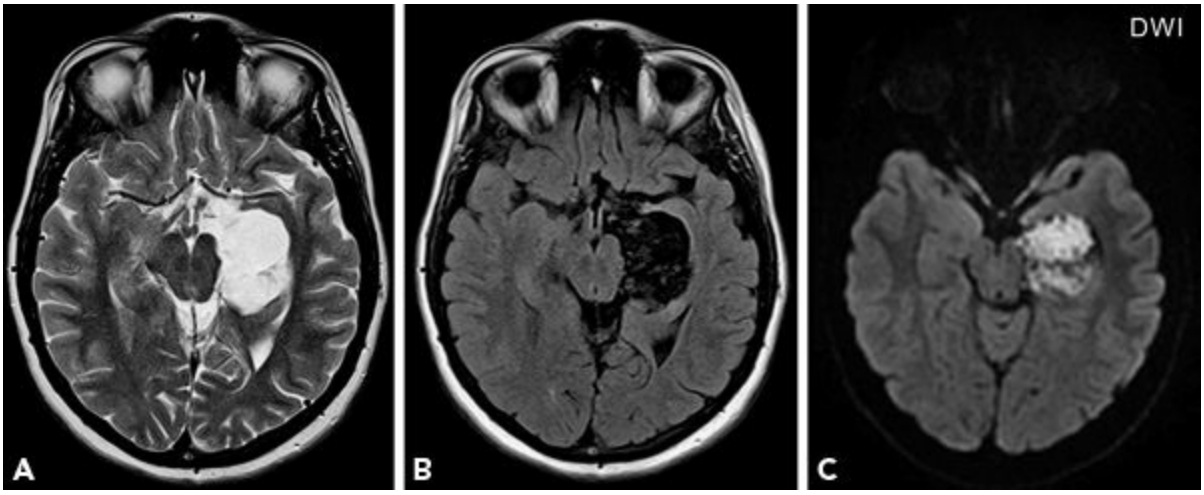

Figure 73.9. A cystic lesion in the left medial temporal region, with signal characteristics similar to CSF, hyperintense on T2-weighted image **(A)** and hypointense on FLAIR **(B)**, shows diffusion restriction on DWI **(C)** consistent with epidermoid cyst. Histopathology confirmed the diagnosis.

DTI demonstrates the connections of different regions of the brain. Unlike conventional DWI, the diffusion-sensitizing gradients are applied in six different directions in DTI. As a result, the directionality of water diffusion is studied in addition to magnitude of diffusion. In general, the diffusivity is greater parallel (i.e., along the long axis of the tracts) to than perpendicular to the fiber tracts, and this can be quantified by DTI (38,39). DTI and its role in epilepsy evaluation are presented in greater detail in Chapter 78.

Susceptibility-weighted imaging (SWI) techniques that exploit differences in magnetic susceptibility of tissue components may provide additional information in epileptogenic lesions containing blood products such as cavernomas, certain posttraumatic epilepsies, and Sturge–Weber syndrome. T2* gradient echo (GRE) is the most commonly used sequence for detecting remote blood products. However, SWI—now widely available commercially—is superior to T2* GRE in detection of remote hemorrhages. SWI is a high-resolution three-dimensional gradient-echo technique, which exploits the small differences in magnetic susceptibility among different components of the tissue such as deoxygenated blood, iron, and calcium compared to the surrounding brain tissue. This also illustrates the smallest of veins (because veins contain higher deoxygenated blood) in the submillimeter caliber in great detail. Lesions such as cavernomas tend to be multiple, and some lesions not apparent on T2* GREs may be recognized with SWI (40). In Sturge–Weber syndrome, SWI improves detection of transmedullary and periventricular veins and cortical gyral abnormalities compared to contrast-enhanced T1 images (Fig. 73.10). The cortical gyral abnormalities on SWI seem to represent venous stasis–related hypoxia and correspond to the hypometabolic areas detected on FDG-PET. Thus, SWI has the potential to show functional information in addition to anatomical details in Sturge–Weber syndrome (41,42).

STRATEGIES TO IMPROVE LESION DETECTION

Conventional epilepsy protocol imaging as outlined, using a 1.5 T MRI, is sufficient for most cases of chronic epilepsy. However, the scenario of a patient with medically refractory epilepsy with no lesions detected on MRI is fairly common in epilepsy centers. Failure to diagnose a structural abnormality reduces the likelihood of consideration for epilepsy surgery. Invasive monitoring with subdural grids and depth electrodes may be required in some of these patients. The success rates for epilepsy surgeries done in such patients with "unremarkable MRI" are substantially lower (43–45). The single most common epileptogenic substrate that evades detection in such situation is MCD. Appropriate utilization of newer techniques in MRI may improve the detection of MCD and other subtle lesions missed by the routine epilepsy protocol. Reviewing the initial MRI with a more experienced reader familiar with characteristics of the subtle MCD is probably the first step to improve the detection. Localization data acquired from seizure semiology, EEG, MEG, and other imaging modalities such as PET and SPECT may also help localize the area of interest, and a more focused review of the images can be helpful in some cases. Some of the imaging strategies that may be employed to improve lesion detection are discussed in the following section.

3 T MRI AND 7 T MRI

Increase in the magnetic field strength in 3 T MRI improves the signal-to-noise ratio and contrast-to-noise ratio, thereby improving the detection of subtle lesions (46). The gray–white contrast is superior on the volumetric high-resolution imaging with 3 T MRI, despite the difference in T1 relaxation times of brain tissue at 3 T (Fig. 73.11). Subtle blurring at the gray–white junction without hyperintensity on T2 or FLAIR, a common and sometimes the only MRI finding of MCD, is better visualized on these images. 3 T MRI is not without its disadvantages. One potential disadvantage with 3 T MRI is decreased gray–white contrast with T1 spin-echo imaging compared to 1.5 T MRI. Inversion recovery sequences can alleviate this effect but cannot be used when one attempts to compare these images with a contrast-enhanced T1 image, as inversion recovery pulse interferes with visualization of contrast. Reducing the excitation flip angle improves gray–white contrast despite

reduction in signal-to-noise ratio. Higher magnetic field strength also accentuates the susceptibility effects, and this can cause artifacts. Conversely, studies that exploit the susceptibility effects, namely, SWI and fMRI techniques such as BOLD (blood oxygenation level dependent), are benefited by 3 T MRI. Other minor limitations of 3 T study include increased acoustic noise and increased device incompatibility (46–48).

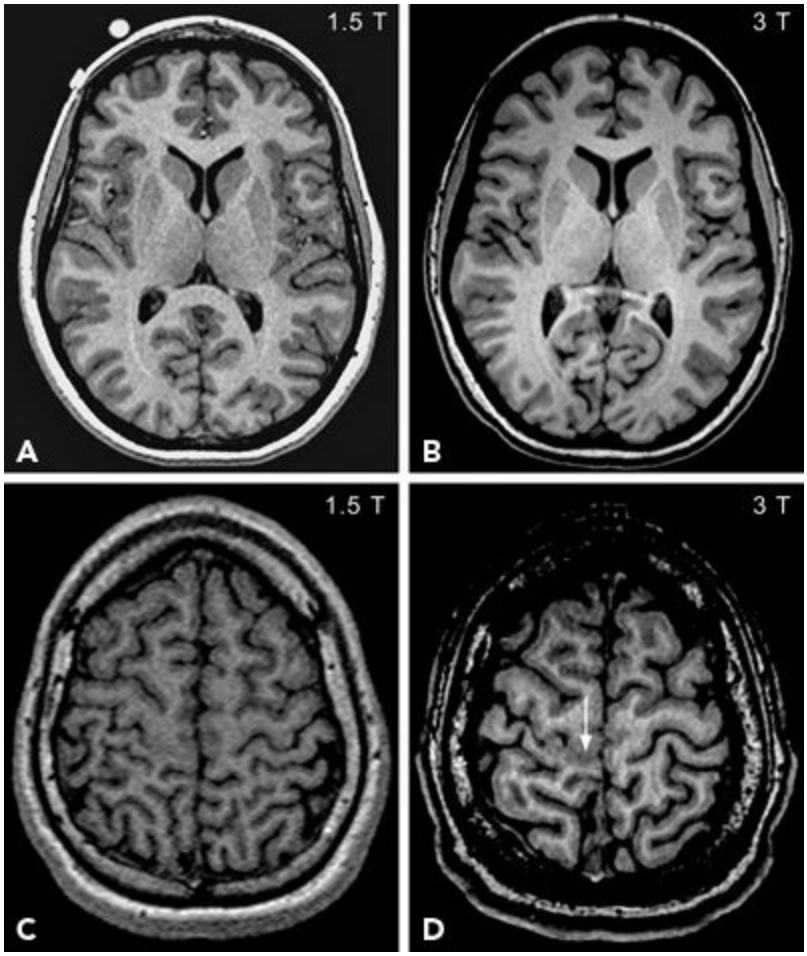

Figure 73.11. Comparison between 1.5 T and 3 T MRI (same patient). **A, B:** Axial MP-RAGE images with 1.5 T **(A)** and 3 T **(B)** MRIs show improved signal-to-noise ratio resulting in better gray–white contrast, on 3 T MRI. **C, D:** Subtle blurring of gray–white region on the banks of central sulcus (arrow), barely visible on the 1.5 T MRI **(C)**, is better visualized on 3 T MRI **(D).**

Clinical experience with 3 T MRI in epilepsy suggests improved detection of lesions compared to 1.5 T imaging. A 20% to 48% increase in detection of new or additional information by 3 T study compared to 1 to 1.5 T MRI (46,49–51) has been reported in some studies. Two of these three studies also used phased array coils, and it is unclear whether the improved lesion detection rate was solely due to higher magnetic field strength. Higher detection rate of MCD is the main reason for improved yield of 3 T MRI in these studies. Anecdotal experience suggests that these lesions are often visible on 1.5 T studies but are diagnosed with more certainty by 3 T study. 7 T MRI is currently available for use in few centers. In a group of patients with mesial temporal lobe epilepsy, 7 T MRI showed differences in patterns of atrophy in mesial structures (52). The clinical impact of these findings in management of patients remains to be studied.

Surface Coils and the Multichannel Phased Array Coils

Surface coils instead of the routine head coils have been used in an attempt to improve imaging of

selected regions of the brain and help to confirm or exclude suspicious abnormalities over the presumed epileptogenic zone. Surface coils improve the signal-to-noise ratio thereby improving the spatial resolution of the structures close to the surface coils (Fig. 73.12). The structures away from the "view" of the surface coils are poorly visualized. As a result, poor imaging quality for deeper structures makes surface coils less desirable for evaluation of mesial temporal structures. In the past, limited coverage of brain by surface coils required careful planning with preimaging working hypothesis about the possible epileptogenic zone to guide the placement of surface coils. Localizing information from seizure semiology, EEG, video-EEG, prior MRI (in case of subtle questionable abnormalities), and other studies such as SPECT and PET should guide the placement of the coils (53). Limited coverage of cortex (and the resultant "tunnel vision"), overall increase in scan time, need for preimaging hypothesis, and decreased signal-to-noise ratio for the deeper structures were major limitations precluding routine use of surface coils.

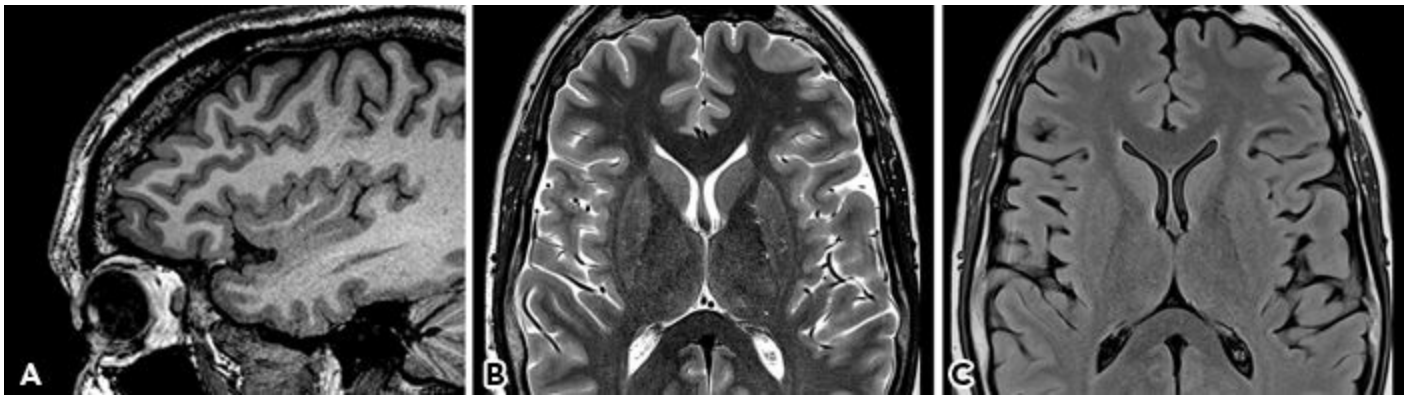

Figure 73.12. MRI with surface coils placed over the frontal regions yield high-resolution images of the frontal lobe. Deeper structures farther from the coil (temporal structures on sagittal image and basal ganglia on axial images) are poorly visualized due to decreased signal-to-noise ratio.

Increased anatomical coverage by increase in the number of elements in the phased array coils has minimized the limitations of traditional surface coils. Using 3 T MRI with eight-channel flexible phased array coils in 40 patients with focal epilepsy, a 65% increase in yield was reported in a subgroup of patients with previous unremarkable 1.5 T MRI (50). Though the differences appear robust, this study did not distinguish the effect of the higher field strength from the effect of surface coils. In another recent study of 25 patients with extratemporal epilepsy, 3 T MRI with two flexible surface coils was compared with 1 to 1.5 T MRI. Though additional abnormalities were seen in 20% of cases on 3 T MRI, authors concluded that there was no added benefit with the use of surface coils (49).

Three-Dimensional Reconstructions

Each of the pixels that constitute a two-dimensional MR image actually has a third dimension in anatomic imaging—the dimension of the thickness. As three-dimensional MRI produces slices without an interslice gap, it avoids the problem of lost data found with conventional two-dimensional imaging. If the imaging voxels in the three-dimensional acquisitions are designed to achieve an equivalent length in all three imaging planes (isotropic data), the images can be reconstructed in any alternate plane without compromising the spatial resolution or fidelity when compared to the original images. On the other hand, if the voxels were too anisotropic, the reconstructed images will be

noticeably degraded compared with the original data. In practice, data can only be "nearly" isotropic as patients will not routinely tolerate the length of time required to acquire truly isotropic data.

With standard imaging planes, the complex interposition of gyrus and sulcus of the normal brain's convolutional pattern potentially leads to errors in interpretation of thickness in gray matter. Slices that cut through the in-plane cortex (along the gray matter) lead to apparent thickened cortex and potential misdiagnosis as malformed cortex. Conversely, cautious avoidance of such "overcalls" can potentially lead to underdiagnosis of truly thickened areas of malformed cortex as well. Subtle MCDs may be suspected on the original images but are difficult to confirm in the original plane, until after the images are reconstructed in other planes. Alternatively, the lesion may be clearly apparent on the original acquisition; yet, there may be difficulty in delineating the spatial relationships of the lesion relative to the adjacent eloquent cortex. Volumetric high-resolution images obtained in epilepsy protocols can be reconstructed in various planes. Reformatting the images in multiple planes may enable to view the images in a plane perpendicular to the gyri thereby reducing the spurious thickening of the cortex seen in images in plane with the gyri.

Image reconstruction in a curvilinear plane—a plane parallel to the cortical surface and perpendicular in relation to the gyri—is being performed at some centers. The resultant images show progressively deeper surfaces of the brain like "peeling an onion." In this technique, a surface is obtained initially by manually outlining the cortical surface in the coronal plane at selected intervals. This surface serves as a matrix to generate progressively deeper slices using a software. These curved slices will result in more uniform distribution of gray matter on both hemispheres assisting in comparison of homologous regions of the cortex (54–56). Apart from improving the detection of subtle MCDs, such surface reconstructions have the potential to assess the location of subdural grids and depth electrodes more precisely. However, the clinical utility of these techniques in large patient population has not been studied.

Several centers now use other postprocessing techniques in multiple ways. Voxel-based morphometry is a promising automated technique to detect subtle dysplastic lesions by accentuating the abnormalities in the gray–white junction (57). Voxel-based morphometry and its role in epilepsy evaluation are presented in Chapter 77.

Serial MRI in Infants and Young Children

Signal characteristics of immature myelin in infants and young children can pose significant challenges in interpretation of studies obtained in infancy. Lesions such as MCDs and cortical tubers have varying signal characteristics based on the developmental stage of the myelin of the lesions and the surrounding brain. For example, in infants, the dysplastic cortex and adjacent subcortical regions may appear hypointense on T2-weighted images and hyperintense on T1 sequences, contrary to the reverse pattern seen in older children and adults (58–60). The lesion characteristics change to the more typical adult pattern over time with progressive myelination. In some patients, with progressive myelination, these lesions tend to become less obvious or rarely "vanish" on follow-up imaging (61). Reviewing only the most recent images may fail to detect the lesions. Conversely, a "new lesion" of MCD may be detected on follow-up imaging in a child with previously "normal MRI" in early infancy. The poor visualization of the lesions on earlier MRI may be explained by the poor background contrast of the bright immature myelin on the T2 images (62). Follow-up MRI during 2nd year of life or later allowing normal myelination to take place may unmask areas of MCD with decreased or absent subcortical myelin. Similarly, cortical tubers of tuberous sclerosis may be more

evident on follow-up imaging (Fig. 73.13). Apart from changes in myelination, increased growth of tubers and dystrophic calcification may contribute to their better visibility on follow-up imaging. Serial MRIs are also helpful in other epileptic disorders such as Rasmussen encephalitis and Sturge–Weber syndrome to demonstrate progressive regional or hemispheric cortical atrophy.

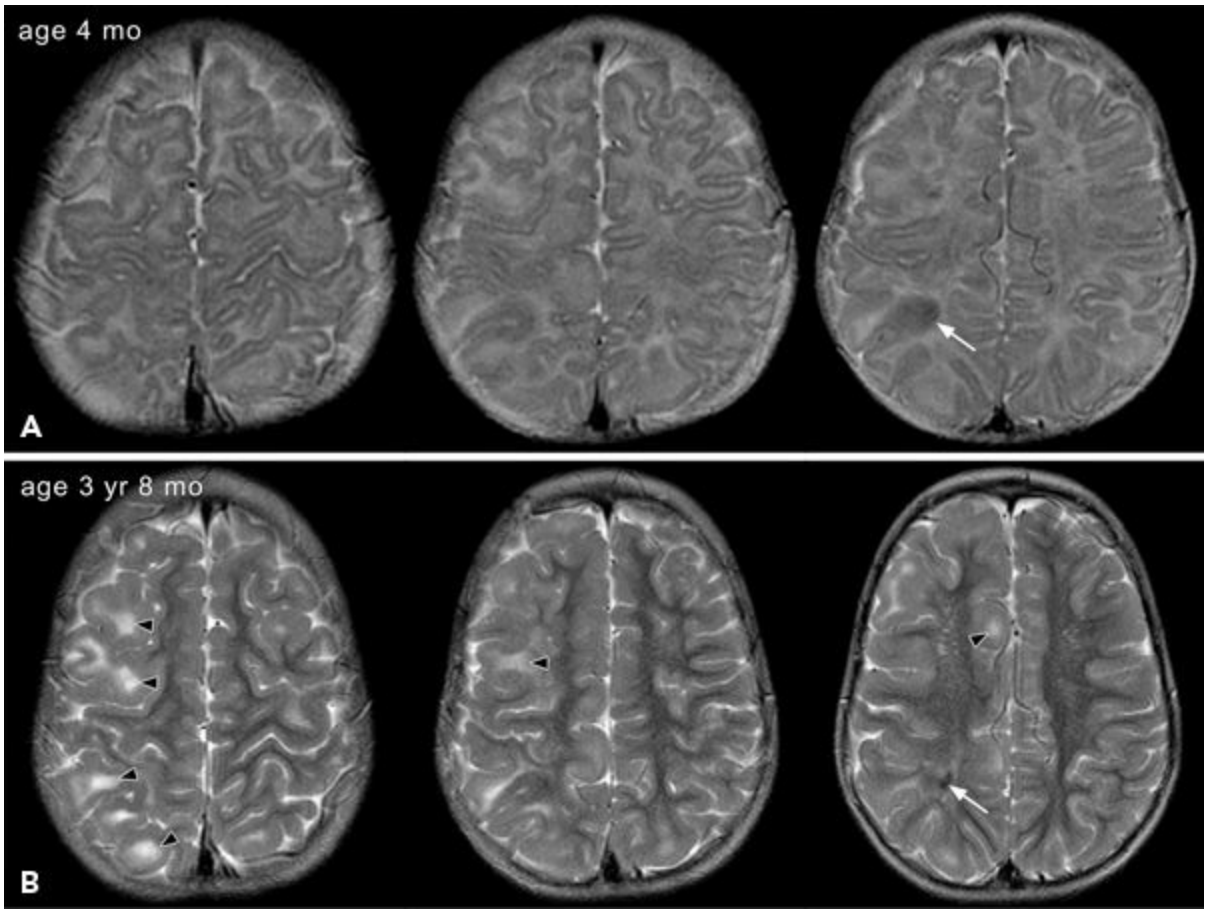

Figure 73.13. MRI in a child with tuberous sclerosis performed at 4 months of age **(A)** and at 3 years and 8 months of age **(B)**. Cortical and subcortical tubers (arrowheads) were more evident on follow-up imaging because of myelination of white matter, improving the "background contrast." Increase in size of lesions with brain growth, calcification (arrow), and abnormal myelination around the lesions may also contribute to better visibility on follow-up MRI. MAGNETIC RESONANCE SPECTROSCOPY

Magnetic resonance spectroscopy (MRS) offers the potential to noninvasively analyze the biochemical composition of a specific brain area. Certain patterns of focal alterations in the biochemical structure may reflect altered neuronal or glial function providing localizing information.

MRS can be acquired in any conventional high-field MRI system with appropriate software (63). Proton spectroscopy is the most widely accepted MRS technique in clinical settings, as it demands no additional hardware and has superior spatial resolution than alternative nuclei such as phosphorus. MRS generates a proton spectrum for a voxel or group of voxels that can be as small as 1 cm^3. Only limited areas of the brain can be studied in a time fashion that is acceptable for clinical practice. It is therefore necessary to have a preimaging hypothesis about the location of epileptogenic focus to decide on the placement of spectroscopy voxels. The position of the voxel is chosen based on localizing information available from conventional MRI or other localizing information when MRI is normal. Restricted anatomic coverage with single-voxel techniques is a major limiting factor when the lesions are large or indistinct or absent on the MRI. Multivoxel technique provides the capability of greater anatomic coverage and is particularly appealing if the location of epileptogenic focus is uncertain.

The primary choice in parameters with conventional MRS is between short and long TEs. Long TE acquisition produces spectra that include N-acetylaspartate (NAA), choline, creatine/phosphocreatine, and possibly lactate. Short TE acquisitions include the same metabolites as well as myo-inositol, glutamate and glutamine, gamma-aminobutyric acid (GABA), alanine, glucose, scyllo-inositol/taurine, and protein/lipids (64–66). Changes in relative quantities of these metabolites, in comparison with corresponding tissue on the presumably normal contralateral hemisphere or controls, are used to characterize the tissue metabolically. NAA signal is the best studied and most sought after signal on MRS; NAA signal though signifies neuronal loss or dysfunction, a linear correlation between the two has not been found. Mitochondrial dysfunction without actual neuronal loss has also been postulated as the mechanism for low NAA signal. Decreased regional NAA concentration in the epileptogenic zone is the most characteristic interictal abnormality described in intractable partial epilepsy. Abnormal lactate peaks in the epileptogenic zone may be identified when MRS study is performed within 6 hours of seizures.

Use of MRS in localization of epilepsy has been studied in both temporal and extratemporal epilepsies. In patients with bilateral mesial temporal abnormalities, the epilepsy may arise predominantly from one side. In such cases, studies using single-voxel technique comparing the two temporal lobes have provided additional concordant lateralizing information enabling surgical decisions (63,67,68). In a meta-analysis of MRS in temporal lobe epilepsy, presence of ipsilateral MRS abnormality and absence of bilateral abnormalities were associated with seizure good outcome. However, bilateral MRS abnormalities may be seen in as many as 35% of temporal lobe epilepsy patients with good outcome (69). In a study of nonlesional extratemporal epilepsy, widespread spectroscopic abnormality—greatest in the presumed epileptogenic zone—has been reported (70,71). The true impact of MRS on surgical decision making for complex patients with poor localization information is unclear and has not been studied critically to provide meaningful integration of MRS in the presurgical epilepsy workup.

Ability to study tissue levels of glutamine and GABA by MRS offers lot of scope to study various epileptic disorders, as elevation of the excitatory glutamate and reduction of inhibitory GABA can result in seizures. Elevation of “glutamine plus glutamate” in frontal lobes has been reported in idiopathic generalized epilepsies as well (72,73). Despite the attractive concept of noninvasive biochemical sampling of the brain, MRS has not impacted epilepsy practice to earn a definitive role in routine presurgical workup. With the advent and wide availability of other tools such as PET and SPECT, the role of MRS has further diminished.

CONCLUSION

Anatomic visualization of substrates of epilepsy by MRI has tremendously advanced the field of epilepsy surgery. Various MRI techniques providing information on function and connections of the various areas of the brain have further helped the surgical strategy. Still, a significant number of patients with refractory partial epilepsy do not have an identifiable lesion on MRI. Epilepsy surgery in such cases, when performed, often requires invasive intracranial monitoring with subdural grids and depth electrodes, despite which the outcome remains poor. Malformation of cortical development is the most common lesion that evades detection in these cases. Further improvements in MRI techniques and its integration with other modalities such as SPECT, PET, and MEG may help to improve the detection of these lesions and minimize the need for invasive monitoring. Development of newer MR techniques in the future may also have the potential to improve the understanding of the cytoarchitectural and molecular abnormalities of the brain with a greater impact in the field of epilepsy.

CHAPTER 74 VIDEO–EEG MONITORING IN THE PRESURGICAL EVALUATION

JEFFREY WILLIAM BRITTON

Surgery remains an important option in the treatment of intractable partial epilepsy. Thirty to forty percent of patients with epilepsy will not respond to first- or second-line medications (1). Such patients remain subject to the consequences and risks associated with intractable seizures. Surgery has been shown to be effective and safe for select patients with medically intractable focal epilepsy (2). Successful surgery requires the identification of patients in which the epileptogenic zone is localizable. Video–electroencephalogram (EEG) monitoring plays a crucial role in epileptogenic zone estimation and in the selection of surgical candidates. Localization requires the integration of clinical, imaging, and video–EEG monitoring data before final plans are determined. Video–EEG monitoring may provide the only localizing information in some patients, particularly in those without an underlying neuroimaging abnormality. It also helps in confirming the epileptogenic significance of structural lesions that may be encountered in the evaluation of intractable epilepsy patients and may help clarify the most relevant lesion in patients with more than one lesion. In addition, video–EEG monitoring may also help verify whether a single or more than one seizure focus is present in a potential surgical patient. Finally, the video recordings obtained can be shown to witnesses of the patient's habitual seizures in order to confirm that the patient's typical seizure type was recorded in the evaluation process prior to making final surgical decisions.

This chapter discusses the clinical personnel, equipment, and safety issues to consider in establishing an epilepsy monitoring unit. The importance of ictal semiology and specific localizing signs are reviewed. Finally, the principles and limitations of ictal EEG are addressed, highlighting the findings most likely to be encountered in patients with surgically remediable focal epilepsy.

EQUIPMENT AND PERSONNEL

Guidelines for the technical and clinical aspects of video–EEG monitoring have been published (3) (see also http://www.acns.org/pdf/guidelines/Guideline-12.pdf). Important considerations regarding video–EEG monitoring safety are discussed below and summarized in Table 74.1.

Table 74.1 Summary of Important Quality and Safety Attributes of a Video–EEG Monitoring Facility

Video–EEG monitoring: equipment, safety, facilities, and personnel

Video–EEG acquisition equipment
- Digital video–EEG acquisition systems with remote viewing capability, 20 channels minimum
- Redundant data storage in case of server and local hard drive failure
- Amplifiers with temporary local data storage capability
- Cameras (ceiling mounted) with remote control, autofocus, low-light capabilities

Safety monitoring and intervention preparedness
- Continuous observation of patient by nurse or EEG technician
- Continuous monitoring of EEG by technologist preferred
- EKG monitoring
- Pulse oximetry
- IV access and maintenance
- Supplemental oxygen and airway availability
- Hand-off process for night coverage
- Standardized protocol and orders for acute seizure emergencies
- Standardized dismissal process

Facilities
- Inpatient preferred
- Safe bathroom features
- Unobstructed path to patient
- Close proximity of EEG technicians and nursing staff to patient

Personnel
- EEG technician—24-h coverage optimal
- Nursing—24-h availability necessary
- Physician (primary and on-call)—24-h availability necessary
- Rapid response team and intensive care availability

Video–EEG Equipment

Most epilepsy centers use digital video–EEG acquisition systems for video–EEG monitoring. Digital video allows viewing of recorded events remote from the video–EEG monitoring area, provided the hardware and network infrastructure available is adequate to meet the high-volume data stream demands. The video camera selected should have low-light recording capabilities in order to allow the capture of nocturnal events. Cameras selected should also have autofocus functionality and remote control capabilities for camera angle and zoom so as to enable technical staff to acquire optimum video during an event.

The advantages of digital EEG data over analog are significant. Digital EEG data lends itself to postacquisition processing, which is not possible with analog EEG. Spike and seizure detection algorithms can also be run during digital EEG acquisition, which may help in the detection of abnormalities. Selection of amplifiers that allow local data storage with flash memory during disconnections from the primary network offers additional advantages, particularly in active patients such as young children, and those few patients who may require transport away from the central EEG

recording area during evaluation.

Personnel

The presence of appropriately trained and experienced EEG technologists is crucial in order to ensure quality recordings. Twenty-four–hour technician coverage is optimal, as equipment issues can arise at any time potentially affecting several hours of data if not promptly addressed. Continuous observation is also critical in patient safety. Nursing staff familiar with seizure identification and management is also important. Patients undergoing epilepsy monitoring are at risk for falls, seizure-related injuries, aspiration, and cardiorespiratory complications, all of which can be mitigated by prompt nursing intervention (4). Nursing and EEG technology personnel are also crucial to provide clinical testing during seizures for semiologic analysis purposes. Physician coverage must be available to manage prolonged seizure activity or seizure-related cardiorespiratory complications. Twenty-four–hour EEG interpretation should also be available in the event questions arise regarding the EEG or clinical status during off hours. Remote access to ongoing video–EEG monitoring data is very helpful for this purpose.

SEIZURE PROVOCATION, PATIENT MANAGEMENT, AND SAFETY CONSIDERATIONS

The goal of presurgical video–EEG monitoring is to record a complete sample of a patient's seizures in order to clarify the region or regions of seizure onset. Sleep deprivation, photic stimulation, hyperventilation, exercise, and supervised medication withdrawal are commonly used to increase the yield of recorded seizures. Drug withdrawal should only be performed in a setting in which real-time seizure detection and medical intervention are available.

Supervised Medication Withdrawal

Medication withdrawal should be individualized for each patient, balancing the need to record a sufficient number of seizures and the risks based on the patient's individual seizure history. Starting medication withdrawal prior to admission is not generally advisable given the risks. A common approach is to reduce the dose of one medication by 33% to 50% on the first monitoring day and then to continue reducing the dosages of one or more drugs at a similar rate on successive days until a sufficient number of seizures have been recorded. Individual patient attributes should be kept in mind when strategizing medication withdrawal for epilepsy monitoring purposes. For example, withdrawal may not be necessary at all in patients with a high seizure frequency on full medication therapy. Conversely, some patients with long seizure-free intervals may require a more abrupt withdrawal schedule in order to achieve the monitoring goals. Also, psychiatric difficulties may arise when withdrawing certain antiepileptic drugs with mood stabilizing properties such as valproate, topiramate, carbamazepine, and lamotrigine. Once a tapering plan is decided, it is important to clearly communicate the schedule and goals to the team so that medications are resumed as soon as the objectives have been met, even if this occurs after hours.

Patient Care, Monitoring, and Planning

A standardized rescue plan should be established in the monitoring unit in order to minimize treatment delay in acute seizure emergencies. This rescue plan should include objective criteria for treatment initiation, such as a number of seizures over a defined time period, or for seizures lasting beyond a defined maximal seizure duration. Other criteria for intervention may include the occurrence of a generalized seizure in a patient without a prior history or the emergence of agitation in a patient. While protocols are useful, customization to meet the unique needs of individual patients are often necessary. Creation of an admission order set for the epilepsy monitoring unit containing the standard protocol is advised to ensure that rescue plan orders are put in place at admission. All health care team members need to be educated as to the unit's standard rescue plan. Immediate access to the patient's records is required, and regular updates as to the goals of admission need to be documented clearly and communicated to the team and handed off to cross-covering personnel so that once the goals of monitoring have been achieved, antiepileptic medication can be resumed.

Rescue plans typically entail use of intravenous (IV) medications as a component. It is important that IV access be secured in all patients undergoing medication withdrawal upon admission and that processes be in place to monitor IV viability so that it can be relied on in the event of an emergency. It is critical to inquire specifically about drug allergies and significant nonallergic idiosyncratic reactions to potential rescue medications at admission so that needs for deviation from the standard rescue plan can be identified early. IV lorazepam or diazepam at subanesthetic levels are typically used in epilepsy monitoring rescue plans. IV fosphenytoin can also be considered, but requires EKG and blood pressure monitoring and should only be used in a setting where cardiac arrhythmia and hypotension can be acutely managed if detected.

Given the risk of cardiac arrhythmia during seizures (5), continuous EKG monitoring should be performed during video–EEG monitoring. Continuous pulse oximetry should also be used as apnea can complicate seizures. Twenty-four–hour physician availability is necessary to handle any acute situations that may arise during hospitalization. ICU and supportive services such as a rapid response team should be available in the event of the need for acute airway management and resuscitation.

Uniform policies for ambulation and activity should be established and made clear to patients upon admission due to the risk of seizure-related falls and injury. Sharp corners in the seizure-monitoring environment should be minimized. An unobstructed path to the patient bed needs to be ensured so that staff can attend to the patient in a timely manner. Bathroom fixtures pose safety risks, and accommodations need to be considered to minimize the potential for injury in the event a seizure occurs there. Side rails with pads are reasonable to help prevent patients from falling out of bed during a seizure; however, they can pose an unintended risk in some cases, particularly those with hypermotor semiology.

Risks of Video–EEG Monitoring

Medication withdrawal can result in first-time generalized tonic–clonic seizures and other new-onset seizure types in patients without a history of similar seizures, and this can be traumatic for the patient and family. Tongue bite wounds are not infrequent but rarely require treatment beyond conservative measures. Other injuries that can occur in association with video–EEG monitoring include vertebral compression fractures and shoulder dislocations. Caution is required when reducing antiepileptic medications in patients with a previous history of shoulder dislocation and in patients with an established diagnosis of osteopenia. Seizure-related falls can lead to subdural hematoma and skull fractures. Exercise modalities that do not require an upright posture should also be considered. If

treadmills and exercise bicycles are used, a nurse or aide need to be present to help prevent seizure-related falls.

Postictal psychosis can arise in the EEG monitoring setting (6). Patients with a prior history of postictal psychosis are at higher risk, but psychosis can occur for the first time in the EEG monitoring setting. Clinical presentation may include aggressiveness and combative behavior, posing a risk to the staff. An action plan needs to be anticipated in patients deemed at risk based on prior history and availability, and close collaboration with psychiatric services is crucial in these cases.

Dismissal from the Video–EEG Monitoring Unit

Patient stability needs to be assured prior to dismissal. Patients undergoing EEG monitoring often have been subjected to significant changes in antiepileptic medication therapy over a short period of time, which may predispose them to further seizures following discharge. Typically, the patient's usual medication regimen should be resumed 24 hours prior to dismissal. In some cases, it may be prudent to reload patients with parenteral or oral loading doses of their maintenance therapy in anticipation of dismissal. In particularly unstable patients, one should consider obtaining serum levels in order to ensure achievement of therapeutic drug concentrations prior to discharge. It is also advisable to ensure appropriate supervision for the next 1 to 2 days following dismissal by family or other appropriate caretakers.

VIDEO–EEG AND LOCALIZATION OF THE EPILEPTOGENIC ZONE

Clinical Localization: Ictal Semiology

Analysis of ictal semiology can provide valuable localizing information complementary to the ictal EEG (7). Concordance between the ictal semiology and other localizing data helps strengthen hypotheses regarding localization, while discordance should raise concerns. Similarly, the presence of multiple semiologies suggests the possibility of multiple seizure foci, which may influence the prospects for surgical success. Lateralizing and lobar localizing signs are not present in all seizures in all patients, but are specific when present. In one study, lateralizing signs were present in 46% of recorded seizures and 78% of patients (8). Lateralization by ictal semiology was correct in 78% of a population with excellent surgery outcome in two studies (8,9). In terms of lobar localization, temporal versus frontal lobar localization could be correctly determined in 76% of patients by semiologic analysis of a cohort of patients with Engel class I outcome (10). Lateralizing and localizing signs of significance in epilepsy surgery patients are summarized in Tables 74.2 and Table 74.3 and discussed further below.

Table 74.3 Ictal Semiology: Lobar Localizing Signs

Temporal lobe localization
- Aura characteristics
  - Epigastric rising; olfactory, dysgeusic, auditory hallucinations
  - Experiential—déjà/jamais-vu; dissociative symptoms
- Oral and/or manual automatisms
- Dystonic hand posturing
- Ictal spitting, postictal nose wiping
- Postictal confusion lasting several minutes
- Postictal aphasia present (if dominant hemisphere involved)

Frontal lobe localization
- Explosive onset
- Hypermotor activity
- Lower extremity automatisms (bicycling, kicking)
- Nocturnal seizure clustering of several per night
- Brief or absent postictal confusion
- Postictal aphasia infrequent unless primary language cortex involved

Occipital lobe localization
- Unilateral simple visual hallucinations (shapes and colors)
- Eye deviation
- Nausea/vomiting, migraine in children

Peri-Rolandic localization
- Unilateral clonic activity as earliest seizure manifestation
- Unilateral sensory disturbance as earliest seizure manifestation
- Todd paralysis

A number of principles need to be kept in mind when analyzing ictal semiology. First, clinical seizure manifestations are influenced by the propagation of seizure activity from one cortical region to another, which can lead to false localization. For example, aphasia may occur in patients with seizures of nondominant temporal origin following spread to the dominant hemisphere. Second, while the specificity of some of the semiologic signs approach 90%, the sensitivity is lower, and localizing clinical signs may be absent in some patients (8,10). Third, seizures arising in functionally silent regions may not show clinical manifestations until spread to eloquent cortex has occurred, which might falsely suggest seizure origin in the region of propagation. Finally, some regions of the brain lead primarily to subjective perceptual changes that are not appreciable on review of video data due to the absence of a motor or behavioral correlate.

Lateralizing Signs

Some clinical signs are primarily of lateralizing value. These are summarized in Table 74.2 and are discussed in more detail in the following section. Select lateralizing signs are illustrated in Figures 74.1 through 74.3.

Ictal Speech Preservation and Aphasia.

Ictal speech preservation is highly suggestive of nondominant lateralization in temporal lobe seizures, while ictal aphasia suggests involvement of the dominant hemisphere, frequently of the dominant temporal lobe (11). Ictal aphasia may also occur in nondominant temporal lobe seizures following

contralateral propagation. Measuring the time to speech recovery can help in such cases. In one prospective study, recovery of speech within 1 minute of seizure onset was associated with nondominant lateralization (12). Ictal aphasia is less common in dominant hemisphere extratemporal seizures, except for those seizures arising in close proximity to the operculum. When assessing speech during seizure activity, it is important to make sure that any detected speech alteration is not primarily due to orolingual motor impairment, for example, secondary to tonic, clonic, or atonic involvement of the tongue or larynx, as the localizing implications are different.

Unilateral Dystonic Hand Posturing.

Unilateral dystonic hand posturing is associated with contralateral seizure onset (13). This sign is common in temporal lobe seizures and thought to be due to seizure propagation to neighboring basal ganglia. Figure 74.1A shows a patient with unilateral dystonic hand posturing.

Ipsilateral Unilateral Manual Automatisms.

Unilateral manual automatisms are of lateralizing significance primarily when seen in association with unilateral dystonic posturing affecting the contralateral hand (13). When present, unilateral automatisms usually involve the ipsilateral hand. Unilateral automatisms can be mistaken for unilateral upper extremity clonic activity. Distinguishing unilateral automatisms from clonus is important as the lateralizing implications are opposite.

Unilateral Forced Head Turning (Version) at Secondary Generalization.

Forced head turning during transformation from a partial to a secondary generalized seizure typically occurs in the direction contralateral to the hemisphere of seizure onset (14). Head-turning movements are considered versive if they are unquestionably forced and involuntary, resulting in sustained or unnatural posturing (15). Figure 74.1B shows an example of forced head turning. Conversely, early nonforced head turning usually occurs ipsilateral to the seizure focus, but this is less reliable than late forced head turning. Figure 74.1A shows ipsilateral nonforced head turning in addition to contralateral dystonic hand posturing.

Unilateral Forced Head Turning (Version) at the End of Secondary Generalization.

Forced head turning at the end of a secondary generalized tonic–clonic seizure is frequently ipsilateral to the side of seizure onset. Spread of the seizure to the contralateral hemisphere during the course of the seizure is responsible for late ipsiversion (16). Therefore, late version, unlike initial version, is frequently ipsilateral and cannot be assumed to indicate seizure onset in the contralateral hemisphere.

Unilateral Facial or Limb Clonic Seizures.

Unilateral clonus lateralizes to the contralateral hemisphere. Unilateral facial clonic seizures can sometimes present on the scalp EEG in the form of asymmetric rhythmic muscle artifact involving the derivations overlying the affected facial and scalp muscles. Figure 74.1C shows unilateral left facial contraction contralateral to a right frontocentral seizure focus secondary to a right precentral focal cortical dysplasia.

Ictal Vomiting.

Ictal vomiting is an uncommon seizure manifestation that correlates with nondominant lateralization when present in temporal lobe seizures (17), although exceptions with dominant onset exist (18). Ictal vomiting may also present in occipital seizures, in which case it is of less lateralizing significance.

Postictal Nose Wiping.

Nose wiping with one hand following temporal lobe seizures typically involves the ipsilateral hand (19). Postictal nose wiping is more characteristic of temporal as opposed to extratemporal seizures (20). Unilateral nose wiping is illustrated in a patient following a right temporal lobe seizure in Figure 74.1D.

Ictal Spitting.

Ictal spitting is usually associated with nondominant temporal lobe seizures (21). It is thought to be due to hypersalivation secondary to stimulation of the central autonomic network.

Unilateral Piloerection.

This typically occurs ipsilateral to the seizure focus and is usually seen in temporal lobe seizures (22).

M2E, Fencing, and Figure of 4 Posturing.

"M2E" posturing refers to a posture consisting of contralateral shoulder abduction, elbow flexion, and head deviation toward the elevated arm. This is depicted in Figure 74.1E in a patient with right frontal seizures. The "fencing" posture refers to a position assumed during secondary generalization where the contralateral upper extremity is extended, the ipsilateral arm flexed and abducted at the shoulder, and head rotated contralateral to the seizure focus. The hips may be abducted as well. An example is shown in Figure 74.1F. "Figure of 4" posturing refers to a position where the contralateral upper extremity is extended and the ipsilateral upper extremity flexed at the elbow so that it crosses the extended arm giving rise to the shape of the number "4" (23). An example is shown in Figure 74.1G.

Todd's Paresis and Ictal Paresis.

While relatively uncommon, unilateral postictal Todd paralysis correlates with seizure lateralization to the contralateral hemisphere. Todd paralysis is more common in seizures arising from the peri-Rolandic region, but can be seen in the context of temporal lobe epilepsy. "Ictal paresis" is a rare semiologic manifestation typically occurring contralateral to the seizure focus in patients with extratemporal seizures (24). Ictal paresis can be mistaken for transient ischemic attacks. An example is shown in Figure 74.1H.

Lobar Localization

Semiology can help with lobar localization, particularly in differentiating temporal and extratemporal seizures.

Temporal Localization.

An aura of experiential phenomena such as an out-of-body experience, epigastric rising sensation, and olfactory and dysgeusic hallucinosis suggests temporal localization. Manual and oral automatisms present frequently during temporal lobe seizures, and verbal and nonverbal vocalizations may be present. Cessation of activity at seizure onset is common. Dystonic hand posturing may occur. Figure 74.2A and B show unilateral dystonic hand posturing and oral automatisms in a patient during a right temporal lobe seizure. Temporal lobe seizures typically last 1 to 3 minutes in duration. A postictal confusional period lasting a few to several minutes followed by a desire to sleep is also typical in temporal lobe seizures. However nondominant temporal lobe seizures and those with limited bitemporal involvement may not be associated with a significant postictal period.

Frontal Lobe Seizures.

The clinical presentations of extratemporal frontal lobe seizures are protean. A number of semiologic differences have been identified (10). In contrast to temporal lobe seizures, frontal lobe seizure auras, if present, are usually less descript, at times consisting of vague light-headedness. Frontal seizures are often brief, lasting 1 minute or less, and are sometimes characterized by an explosive onset, with prominent hypermotor activity and complex lower extremity automatisms such as bicycling movements and kicking (Fig. 74.3A and B). Vocalizations, such as the utterance of profanities and screaming, may also occur. In some patients, extratemporal seizures, in particular frontal lobe seizures, occur more frequently out of sleep (25). While nocturnal predominance may be seen in temporal lobe seizures as well, a seizure pattern of multiple brief clusters of seizures occurring exclusively during sleep is more characteristic of frontal lobe seizures. Nongeneralized seizures of frontal origin are often followed by a brief postictal period relative to that of temporal lobe seizures. However, not all frontal lobe seizures behave in the same manner. Some frontal lobe seizures may evolve over prolonged periods of time, and postictal confusion may sometimes be seen. Semiology is particularly important in the process of diagnosing frontal lobe seizures, as the ictal EEG is often nondiagnostic in these patients, particularly in those with seizures of supplementary motor or orbital frontal onset (26).

EEG Localization in Video–EEG Monitoring

Interictal and ictal EEG analysis are essential in the presurgical evaluation. An understanding of the localizing patterns seen in partial epilepsy and limitations of ictal EEG localization are essential.

A minimum of 20 scalp EEG channels should be used when performing prolonged video–EEG monitoring. Midline, right, and left parasagittal and right and left temporal head electrodes should be utilized. Additional inferior temporal electrodes should be considered in patients where a temporal lobe focus is suspected. Nasopharyngeal, foramen ovale, and transsphenoidal electrodes have been advocated by some to improve the sensitivity and specificity of ictal EEG localization, particularly in patients with mesial temporal seizures.

Interictal Epileptiform Abnormalities

Although the ictal EEG receives the most scrutiny in video–EEG monitoring, the interictal recording is also of localizing value. The interictal background may contain focal slowing or suppression over the epileptogenic region, which can help localize areas of brain dysfunction relevant to the patient's

seizures. Also, the presence of interictal epileptiform abnormalities beyond the boundaries of the epileptogenic zone or contralateral to the suspected focus may influence surgical prognostication (27). Generalized interictal epileptiform activity may be seen in addition to focal abnormalities in some patients with focal epilepsy, suggesting a mixed seizure disorder. Finally, in some cases, the interictal EEG may be of greater localizing value than the ictal EEG, particularly in extratemporal focal epilepsy. Figure 74.4A–D shows focal interictal epileptiform abnormalities in four patients undergoing epilepsy surgery evaluation. In the extratemporal cases shown (see Fig. 74.4B–D), the interictal activity had clearer localizing attributes than the ictal EEG.

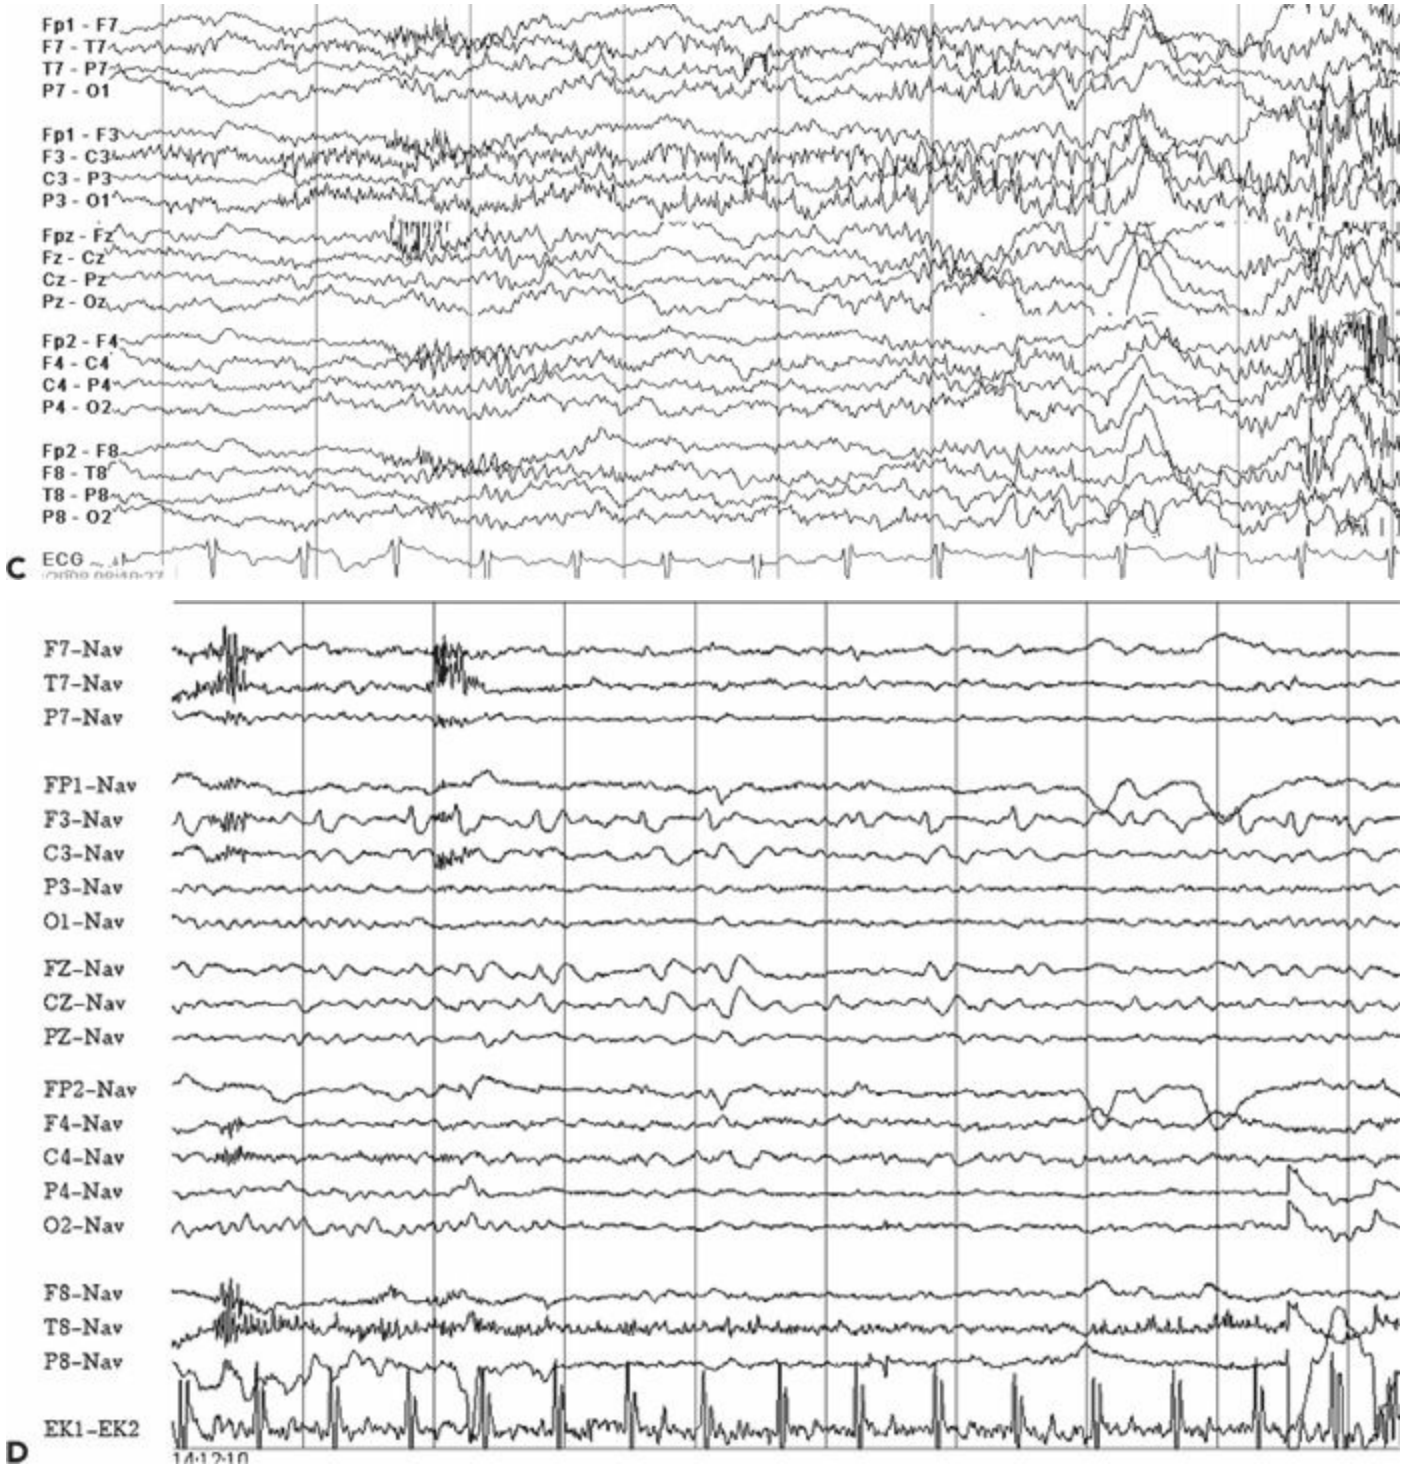

Figure 74.4. Localizing interictal abnormalities in epilepsy surgery patients with partial epilepsy. **A:** Right temporal sharp waves and temporal intermittent rhythmic delta activity (TIRDA) in a patient with right temporal lobe epilepsy secondary to mesial temporal sclerosis. **B:** Left occipitoposterior temporal spikes in a patient with a left medial occipital cortical dysplasia. **C:** Left centroparietotemporal spikes in a patient with a cortical dysplasia localized to the left inferolateral postcentral gyrus region. **D:** Repetitive left frontal spikes in a patient with nonlesional frontal lobe epilepsy localized with intracranial monitoring to the left dorsolateral frontal region.

The interictal EEG may be of prognostic value in epilepsy surgery patients. Anatomic concordance of interictal abnormalities and other localizing data in a given patient confers a favorable prognosis in temporal lobe epilepsy surgery (27). In addition, the quantity of interictal activity may be of prognostic value in certain epilepsy syndromes. In one temporal lobe epilepsy surgical series, 29% with frequent spikes (>60 spikes per hour) experienced an excellent surgical outcome compared to 81% with infrequent spikes (<60 spikes per hour) (28). One explanation proposed for this observation was that frequent interictal discharges may be an indicator of a

neocortical temporal seizure focus as opposed to mesial temporal.

The Ictal EEG

While analysis of the ictal EEG plays an essential role in epilepsy surgical planning, there are some limitations. In a retrospective study of patients with Engel class 1 surgical outcomes, ictal EEG localization was possible in 57% of recorded seizures and 72% of patients, and false localization occurred in 6% (29). In light of these and similar findings, it is clear that the ictal EEG cannot be relied on in isolation. Proper selection and counseling of patients for epilepsy surgery requires correlation of the ictal EEG, interictal EEG, neuroimaging, and semiology in addition to other localizing tests if needed.

Limitations of Ictal EEG.

Acquisition of an interpretable ictal scalp EEG often poses technical challenges. In frontal lobe seizures, artifact secondary to hypermotor behavior may obscure the EEG. Oral automatisms during temporal lobe seizures may give rise to myogenic artifact in the temporal derivations, which may obscure the ictal EEG.

Other factors are important to consider when evaluating the ictal EEG. High-frequency discharges >100 Hz are now recognized as important features of the epileptogenic zone on intracranial recordings (30). However, such activity may not be appreciable on scalp EEG given their low amplitude and frequency limits of most routine EEG amplifiers. Acquisition of the ictal EEG is also limited by the unfavorable location of many cortical regions with respect to scalp EEG electrode localization, and the topographical discrepancies between the complexities of the cortical surface versus scalp. Due to these factors, fewer than 10% of spikes involving a cortical surface area of <10 cm^2 on subdural recordings are usually detectable on the scalp EEG (31). As a result, certain regions of the brain, such as the insula, interhemispheric regions, and inferior cortical regions, do not lend themselves to scalp EEG analysis. Given this, there are significant limitations as to the resolution of ictal EEG localization. For example, it may be possible to determine that a seizure arises from the temporal region, but it may not be possible to determine whether it is of medial or neocortical temporal onset. Finally, seizures arising from some cortical regions may show their earliest expression on the ictal EEG in a brain region of propagation. For example, orbital frontal foci are often indistinguishable from temporal lobe foci based on EEG given the proximity of the orbital frontal cortex to the temporal head region. Occipital seizures are also known to propagate early to the temporal lobes, which may give rise to false-positive EEG localization.

Another limitation of EEG localization is encountered in infants, children, and adolescents with refractory epilepsy due to congenital or early-acquired focal or hemispheric epileptogenic lesions. Such patients may have hypsarrhythmia, generalized slow spike-and-wave complexes, or other generalized patterns on ictal and interictal EEG, with few or even no focal features. Selected children with early developmental lesions may be favorable candidates for epilepsy surgery, despite generalized manifestations on EEG (32). The mechanism for the diffuse EEG expression in such children is unknown, but a factor may be the earlier interaction between the focal lesion and the developing brain.

Features of Ictal EEG Recordings.

The seizure pattern recorded in an individual patient with a single epileptogenic zone typically remains consistent from seizure to seizure. Significant variability of the ictal EEG in a single patient should raise the possibility of a relatively large epileptogenic zone or multiple seizure foci. Conversely, seizures from the same brain region in different patients may show interindividual variability due to individual differences in anatomy and physiology.

A variety of ictal EEG discharge patterns have been described in association with focal seizures. These include (i) rhythmic theta, delta, or alpha activity; (ii) paroxysmal fast activity (rhythmic activity in the beta frequency range or higher); (iii) suppression (focal, asymmetric, or diffuse); (iv) repetitive epileptiform abnormalities; and (v) arrhythmic mixed frequency activity (33,34).

The distribution of the EEG discharge is important. While focal, regional, or lateralized discharges are more typical in the focal epilepsy population, the presence of bisynchronous or diffuse activity at onset does not necessarily exclude the possibility of a surgical focus. For example, bisynchronous and diffuse ictal EEG onset may be present in surgical candidates with supplementary motor area seizures. In such cases, intracranial monitoring is often necessary to resolve localization. Mesial temporal and lateral frontal seizure foci are most amenable to localization with ictal scalp EEG. Conversely, localization of mesial frontal, orbital frontal, parietal, and occipital seizure foci is difficult with ictal EEG.

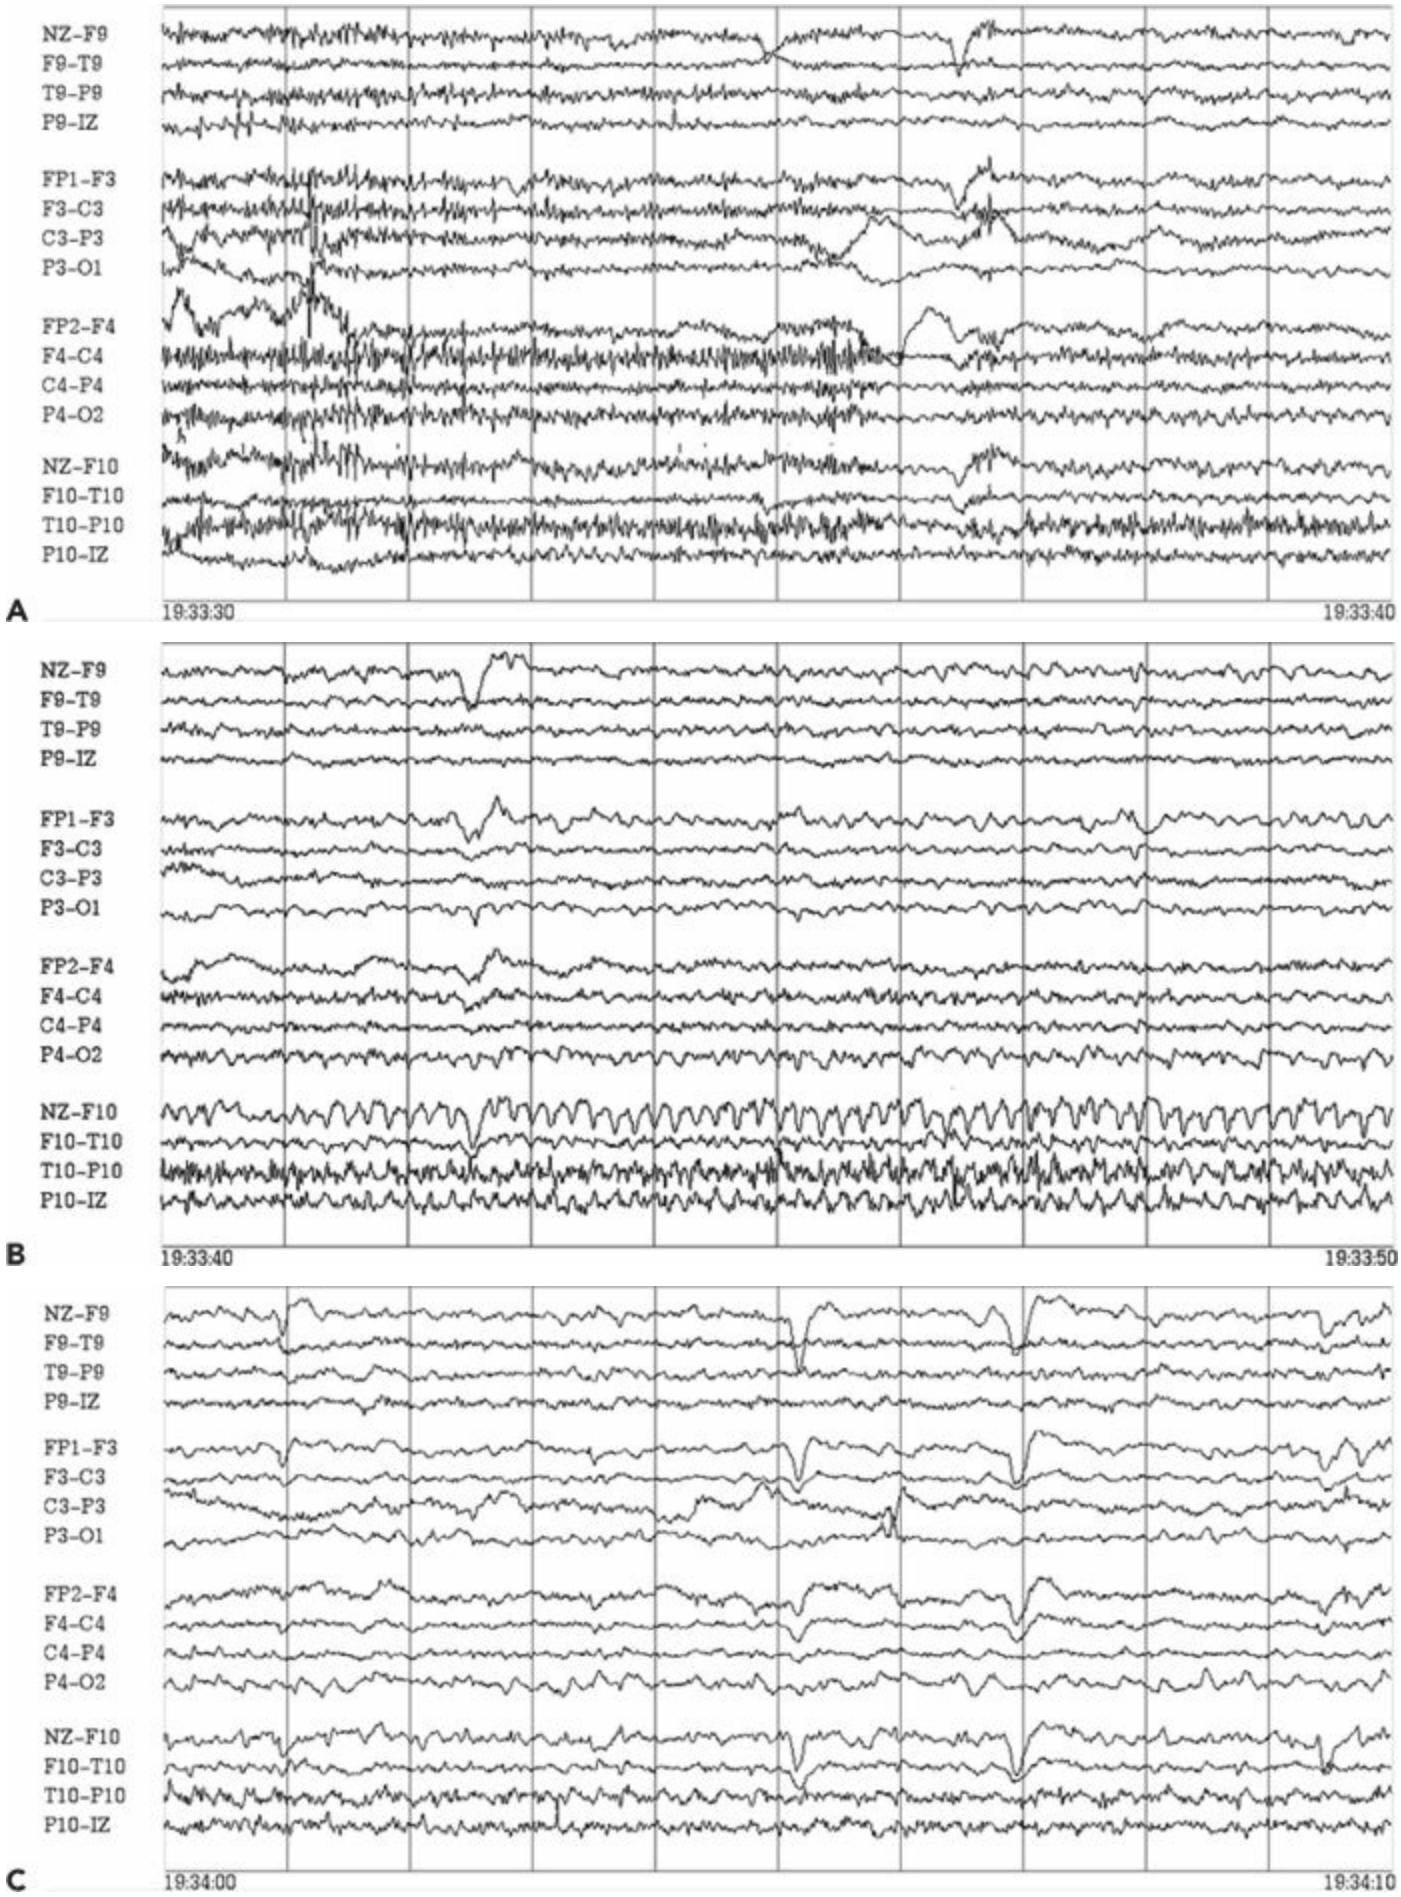
Determining the Ictal EEG Onset.

The video and EEG should be reviewed in concert in order to determine whether the timing of the ictal EEG onset correlates with clinical onset. In general, an EEG onset that precedes the clinical onset provides a better estimate of the epileptogenic zone, and the first 30 to 40 seconds of a seizure provide the most useful localizing information. Due to seizure propagation, later portions of the seizure discharge are of less value. The postictal record however can be useful, particularly in temporal lobe epilepsy where localized slowing can sometimes be seen in the ipsilateral temporal region.

Temporal Lobe Seizures: Mesial Versus Neocortical Temporal Onset.

Mesial temporal seizures typically manifest as an evolving rhythmic theta discharge arising over the ipsilateral temporal derivations. A typical right mesial temporal seizure is shown in Figure 74.5A–D. The discharge morphology is often sinusoidal at onset, the individual waveforms showing a rounded contour rather than sharp in the early portion of the seizure (see Fig. 74.5A). Sometimes a transient suppression of the EEG background may precede temporal lobe seizures. This may be lateralized or diffuse and is more apparent in seizures arising out of sleep (35). Temporal lobe seizures may also begin with semirhythmic repetitive epileptiform discharges at onset rather than a sinusoidal morphology. While temporal seizures are typically focal or lateralized at onset, they may be bilateral or diffuse, evolving into a more lateralized discharge over the ipsilateral temporal region after the first several seconds of the seizure. As the seizure continues, the waveforms often become sharper in appearance and the frequency increases slightly (see Fig. 74.5B). Rhythmic activity then begins to appear in the parasagittal and midline regions, presumably secondary to propagation to the cingulum or due to formation of a vertical dipole in the mesial temporal region with the positive component oriented superiorly (36). Contralateral temporal spread often develops in the middle to latter portions of the seizure. At seizure termination, the discharge frequency typically decreases to the delta

frequency range (see Fig. 74.5C), and ipsilateral semirhythmic 1- to 2-Hz delta activity may be present in the postictal period (see Fig. 74.5D).



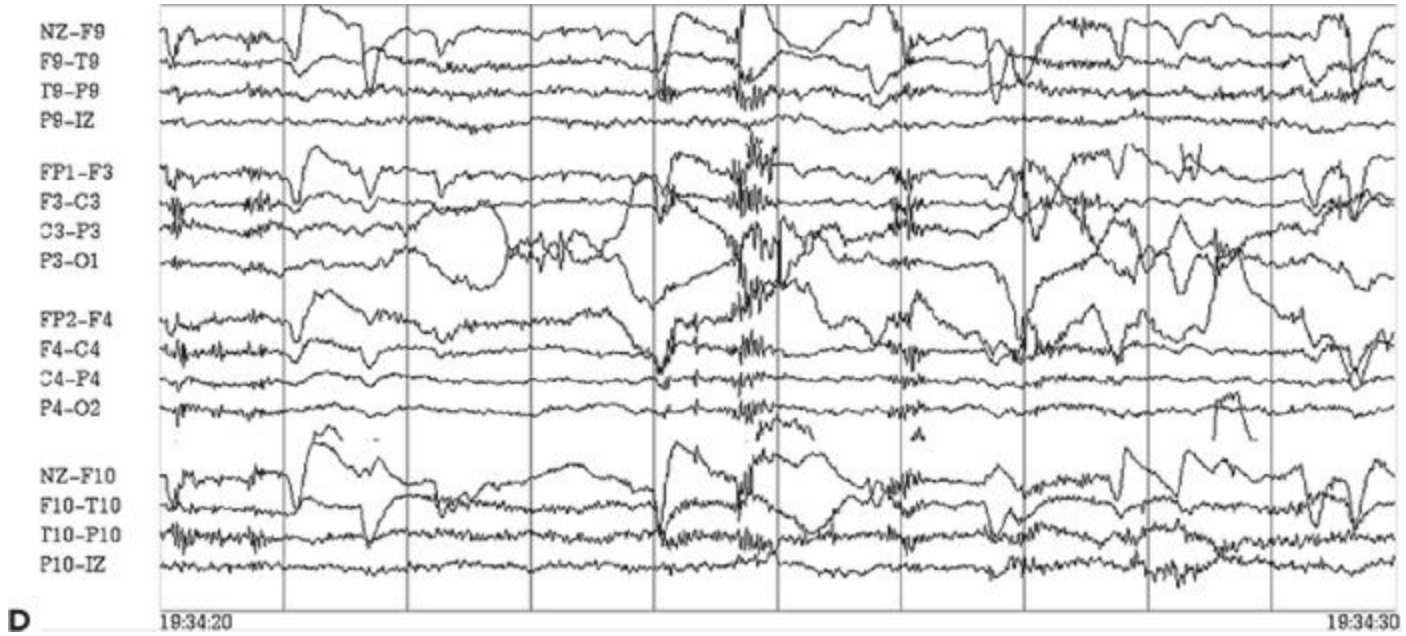


Figure 74.5. Ictal EEG evolution during a right temporal seizure in a patient with mesial temporal sclerosis. **A:** Ictal EEG onset consists of sinusoidal rhythmic theta over the right temporal derivations. **B:** The discharge evolves to form rhythmic sharply contoured theta activity with phase reversal over the right anterior temporal derivations. **C:** The right temporal discharge frequency decreases toward the end of the seizure to the delta frequency range. **D:** Subtle lateralized postictal delta slowing and attenuation of the background is present over the right hemispheric derivations following seizure termination.

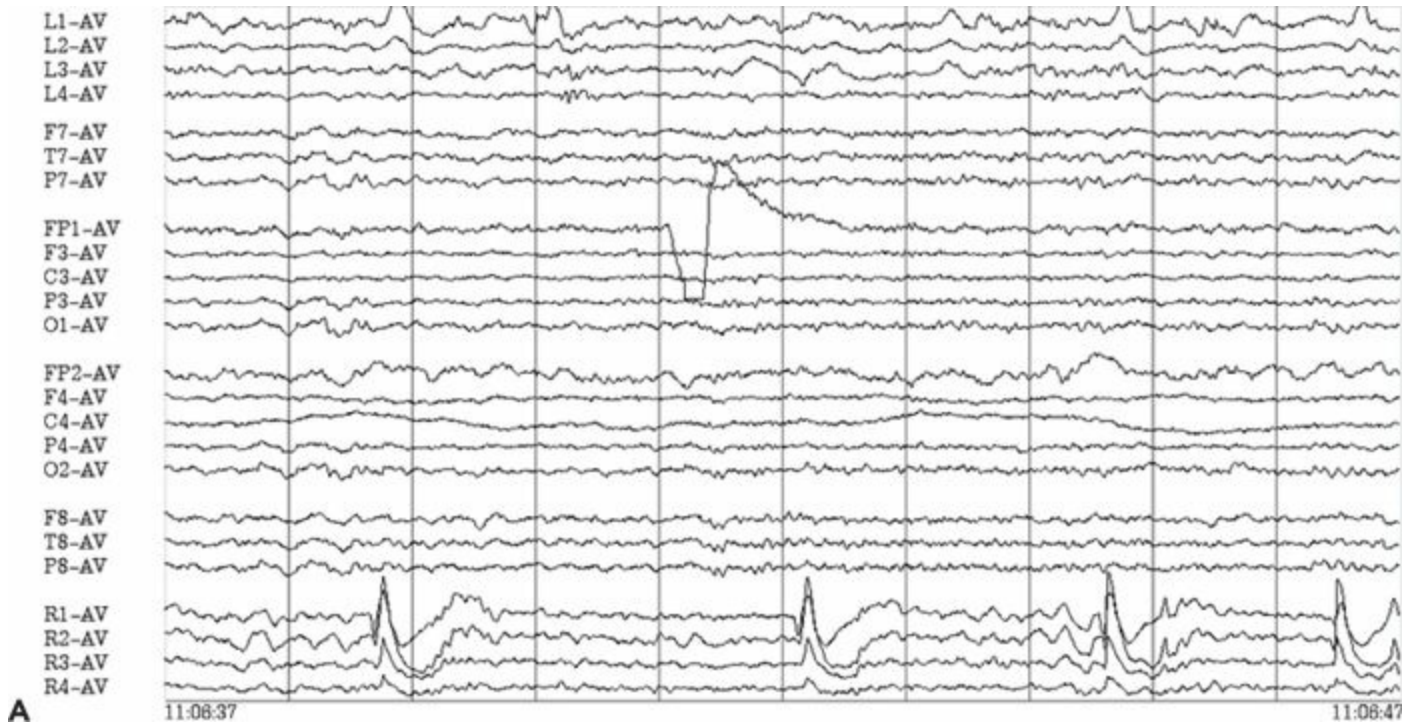
False ictal EEG lateralization is uncommon in temporal lobe epilepsy but can occur, that is, in seizures that spread from one hippocampus to the other prior to propagation to the ipsilateral temporal neocortex. It can also occur when the seizure onset is such that the ictal EEG field is oriented parallel to the scalp electrode surfaces. Sometimes the EEG seizure onset presents with bitemporal discharges, and in this scenario, ictal EEG lateralization may not be possible. Mesial temporal depth electrode recordings may be necessary to resolve seizure lateralization in such cases. Figure 74.6A and B shows a recording in a patient undergoing simultaneous scalp and bitemporal depth electrode recordings demonstrating a relatively belated bitemporal scalp EEG discharge 48 seconds after right mesial temporal depth onset.



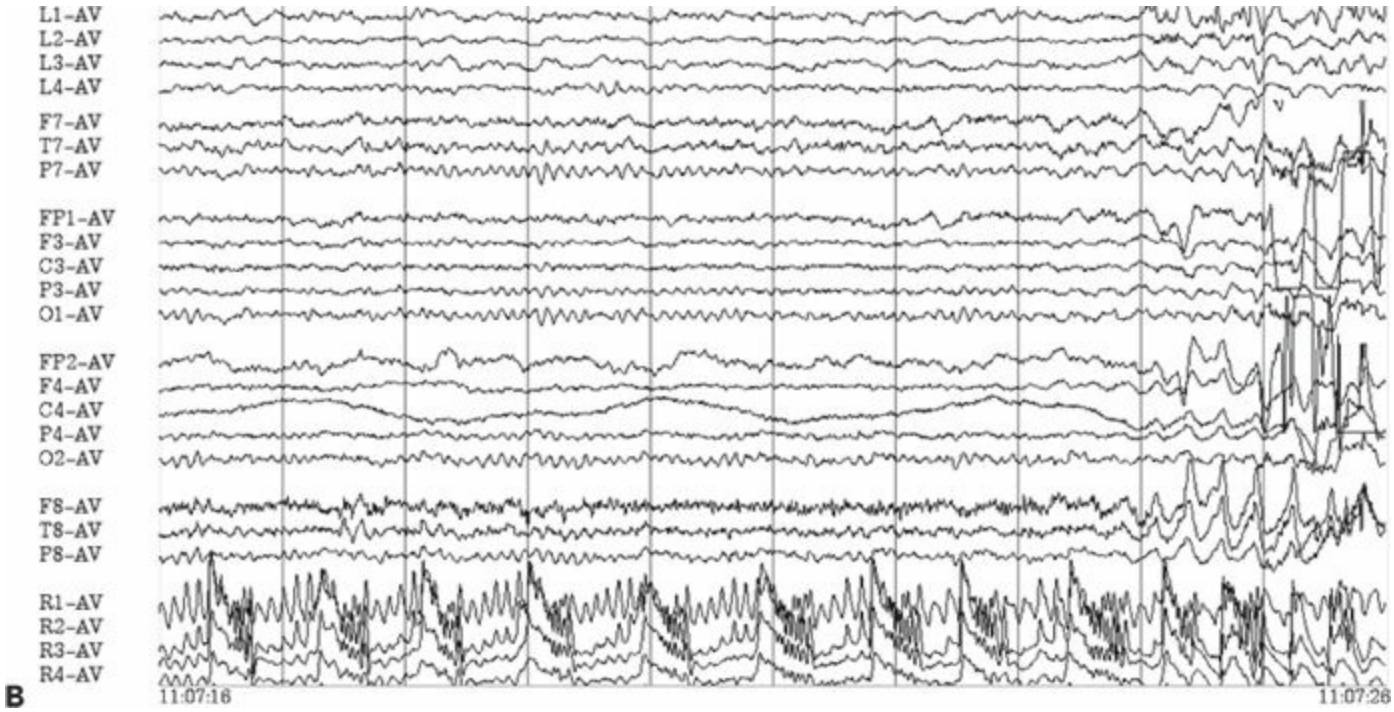


Figure 74.6. Simultaneous bitemporal depth and scalp EEG recording in a patient with temporal lobe epilepsy. **A:** Seizure onset in the right temporal depth (labeled R1-4-AV) without associated changes in the right temporal scalp derivations (labeled F8, T8, P8–AV). **B:** Right temporal scalp activation begins 48 seconds after right medial temporal depth onset, consisting of high-amplitude rhythmic sharp activity involving F8, T8, P8—AV in the last 2 seconds of the figure.

Neocortical temporal seizures cannot be reliably distinguished from medial temporal seizures on scalp EEG alone; however, some features suggest neocortical localization. In one study, the mean discharge frequency at seizure onset in neocortical temporal seizures was 1 Hz less than mesial temporal seizures (37). In another study, mesial temporal seizures presented with an initial regular 5- to 9-Hz inferotemporal rhythm and occasionally by a vertex/parasagittal positive rhythm of the same frequency and neocortical temporal seizures showed an irregular polymorphic 2- to 5-Hz discharge or repetitive semiperiodic sharp waves at onset (38). Seizures without a clear lateralized EEG discharge were most commonly neocortical in this study. In another series, mesial temporal seizures were more likely to show fast rhythmic sharp waves (>4 Hz) at seizure onset than neocortical temporal seizures (mean 81% vs. 60%, $P = 0.05$), neocortical seizures were more often bilateral at onset (mean 55% vs. 26%, $P < 0.05$), and bilateral propagation occurred more rapidly (mean 23 vs. 74 second, $P < 0.005$) in neocortical than mesial temporal seizures (39). Sphenoidal electrodes can help delineate mesial and neocortical temporal seizures; however, intracranial monitoring is usually necessary to resolve sublobar localization in surgical cases.

Seizures from cortical regions other than the temporal lobes may show the earliest EEG activity over the temporal derivations due to extensive corticocortical connections between the temporal and extratemporal cortical regions and hence lead to false EEG localization. In one study of 33 nonlesional patients with temporal lobe seizure activity on ictal scalp EEG, 11 had an extratemporal seizure focus on intracranial monitoring with propagation to the temporal region (40). There is no EEG feature that can reliably distinguish a propagated temporal discharge from a temporal origin rhythm. In addition to propagation from other cortical regions, certain deep structures connected to the limbic system such as the hypothalamus in the setting of hypothalamic hamartomas may show the earliest EEG discharge over the temporal regions potentially leading to false localization. The use of dense array EEG acquisition may help resolve sublobar and lobar localization challenges posed by nonlesional epilepsy cases. However, the complexity of the cortical surface anatomy and

discrepancies between the cortex and scalp surfaces pose barriers to the ability to resolve source localization with scalp ictal EEG.

Frontal Lobe Seizures.

The EEG is of less localizing value in frontal lobe seizures. There are several reasons for this including artifact secondary to hypermotor behavior that often accompanies frontal seizures and the complex anatomy of the frontal lobe, much of which is located at a distance with respect to scalp electrodes. While some ictal EEG features are relatively characteristic for frontal lobe seizures, ictal EEG localization was not found to be a significant prognostic factor in one series of successful frontal lobe epilepsy surgery cases (41).

The ictal EEG in mesial frontal seizures often does not show a scalp EEG discharge at clinical seizure onset due to the disadvantageous localization of the seizure-onset zone with respect to the recording electrode surface. As the seizure progresses in mesial frontal seizures, rhythmic theta or delta activity may appear late over the midline and bilateral parasagittal regions. The EEG often remains obscured by artifact throughout seizures of mesial frontal origin, particularly in those with hypermotor semiology. Several other ictal patterns have been described in association with mesial frontal seizures including generalized spike and wave, a diffuse electrodecremental pattern, and rhythmic vertex alpha activity. It is often difficult to lateralize mesial frontal seizures on EEG. In the absence of a structural or functional imaging abnormality in such cases, intracranial monitoring is usually necessary.

Focal ictal EEG abnormalities are more likely to be present in patients with dorsolateral frontal seizures due to the closer proximity of the area of seizure onset to the recording electrodes. The ictal onset in dorsolateral frontal seizures may manifest as a focal low-amplitude high-frequency discharge, an example of which is depicted in Figure 74.7. Such a discharge at onset may be prognostically favorable in epilepsy surgery candidates. Recording multiple seizures may help increase the yield of the ictal scalp EEG in these patients.

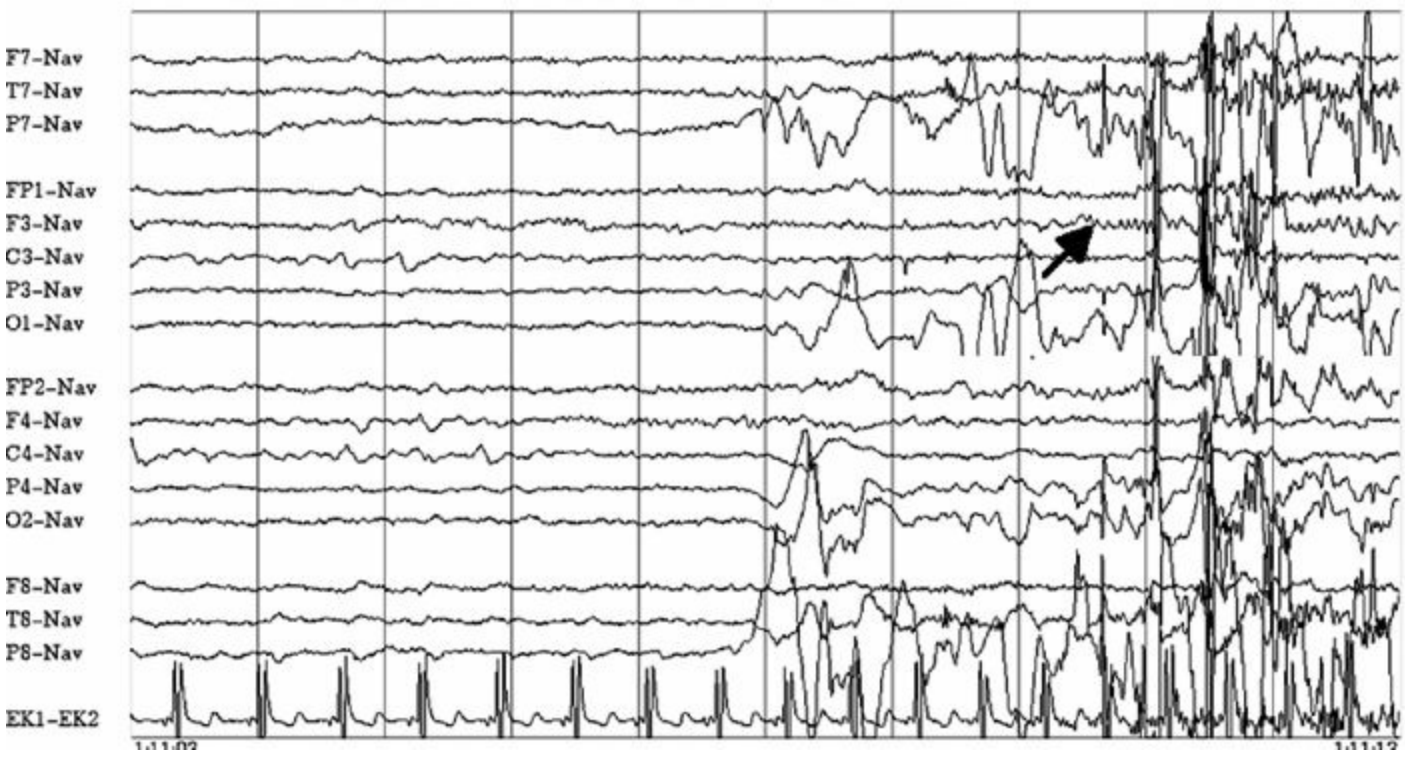

Figure 74.7. Ictal EEG during an extratemporal seizure of left lateral frontal onset. This patient's interictal EEG is shown in Figure 74.1D. At clinical onset, there is attenuation of the EEG background and a high-frequency discharge ("beta buzz") present over the left frontal region (arrow).

Orbital frontal seizures often propagate to the ipsilateral temporal region, which can cause erroneous localization to the temporal lobe. Orbital frontal seizures can also spread to other regions of the frontal lobe.

Occipital Lobe Seizures.

Occipital seizures are difficult to localize on ictal EEG even in lesional patients. Seizures arising from the calcarine cortex may give rise to bilateral or contralateral discharges due to the anatomic orientation of the medial occipital cortical surface relative to the scalp electrode recording surface. Confounding matters further from an EEG standpoint is the fact that occipital seizures often spread to the temporal and frontal regions, which can result in false localization to these areas if other localizing data are lacking.

Parietal Lobe Seizures.

The parietal lobe is the least common area of seizure onset in focal epilepsy, and the ictal EEG is often not localizing. Like seizures from other extratemporal sites, parietal seizures often propagate to neighboring regions, leading to challenges in clinical and ictal EEG localization in the absence of a structural lesion on magnetic resonance imaging (MRI). In one large surgical series, the sensitivity of ictal EEG in a seizure-free parietal lobe epilepsy cohort was 35.7%, compared to 64.3% for MRI, 50% for PET, and 45.5% for ictal SPECT (42).

CONCLUSION

Video–EEG monitoring is essential in the presurgical evaluation of patients with medically refractory focal epilepsy. There are some risks to video–EEG monitoring. Therefore, it is important to put in place appropriate policies and safety measures to minimize the potential for harm in these patients. Twenty-four–hour patient observation by nursing or technical staff is essential to ensure prompt identification of seizure activity and associated complications in monitored patients. All data acquired during video–EEG monitoring, including the ictal semiology, the interictal EEG, and the ictal EEG, should be analyzed in the process of seizure localization. Conclusions based on analysis of the video–EEG session then need to be correlated with neuroimaging and other localizing data prior to final surgical planning.

CHAPTER 75 NUCLEAR IMAGING (PET, SPECT)

WILLIAM DAVIS GAILLARD

Functional imaging studies using radiotracers, such as positron emission tomography (PET) and single photon emission computed tomography (SPECT), are performed primarily to identify or confirm the ictal focus in preparation for surgery and to investigate the pathophysiology of partial and generalized seizure disorders. Less commonly, PET is performed to identify eloquent cortical regions to be spared during epilepsy surgery.

PRINCIPLES: PET AND SPECT

Radiotracer studies using PET or SPECT allow for the in vivo assessment of physiologic function in humans. Such studies include glucose consumption ([^{18}F]fluoro-2-deoxyglucose; [^{18}F]FDG), cerebral blood flow ([^{15}O]water), and neurotransmitter synthesis (dopamine and serotonin) or receptor–ligand binding (agonists or antagonists to benzodiazepine, opiate, serotonin, and N-methyl-D-aspartate [NMDA] receptors). A physiologic probe designed to assess a targeted function is labeled with a radioactive tag. The decay of the radioactive tag is associated with the emission of high-energy particles, or gamma rays, that are subsequently detected by the scanner, and their origin is then computed. PET has a practical resolution of 2 to 3 mm, which is superior to that of SPECT. Furthermore, unlike SPECT, PET studies can be quantitated. Use and application of PET ligands are determined by compound half-lives: ^{18}F-tagged compounds have a 110-minute half-life, ^{11}C a 20-minute half-life, and ^{15}O a 2-minute half-life. As a consequence of its longer half-life, [^{18}F]FDG cannot be used to assess short-lived physiologic phenomena such as ictal states, whereas the very short half-life of [^{15}O]water renders it suitable for capturing the brief activity of cognitive processes. Given the relatively short half-life of PET ligands, data acquisition must occur shortly or immediately after injection.

In contrast, SPECT ligands have a longer half-life. ^{99m}Tc-Hexamethyl-propyleneamine oxime (^{99m}Tc-HMPAO) or ^{99m}Tc-ethyl cysteinate dimer (^{99m}Tc-ECD) for cerebral perfusion has replaced ^{123}I-based ligands such as [^{123}I]iodoamphetamine and [^{123}I]trimethyl-hydroxymethyl-iodobenzylpropane diamine, so that data can be collected hours after injection. SPECT is less expensive and more readily available than PET, but the basic premises are similar. SPECT ligands used in epilepsy are primarily markers of perfusion, though some receptor ligands are also available, such as [^{123}I]iomazenil ([^{123}I]IMZ), for benzodiazepine receptor studies. The compounds that mark blood flow, HMPAO and ECD, have a distribution in the brain that is proportional to cerebral blood flow. Both ligands are lipophilic; they generally cross the blood–brain barrier on their first pass through brain tissue, become trapped, and exhibit little subsequent redistribution. A potential limitation is that neither ligand has linear uptake at high cerebral blood flow rates, and thus cerebral

blood flow is underestimated under certain circumstances (1). Although there are some individual differences in tracer distribution (1), the efficacy of HMPAO and ECD in epilepsy studies is comparable.

PET IN THE EVALUATION OF EPILEPSY

[^{18}F]FDG-PET and Temporal Lobe Epilepsy

The most clinical experience for evaluating patients with partial epilepsy is with [^{18}F]FDG-PET. Several studies demonstrate interictal regional decreases in glucose consumption that are invariably ipsilateral to the seizure focus—typically, but not always, most pronounced in the temporal lobe (Figs. 75.1 and 75.2) (2,3).

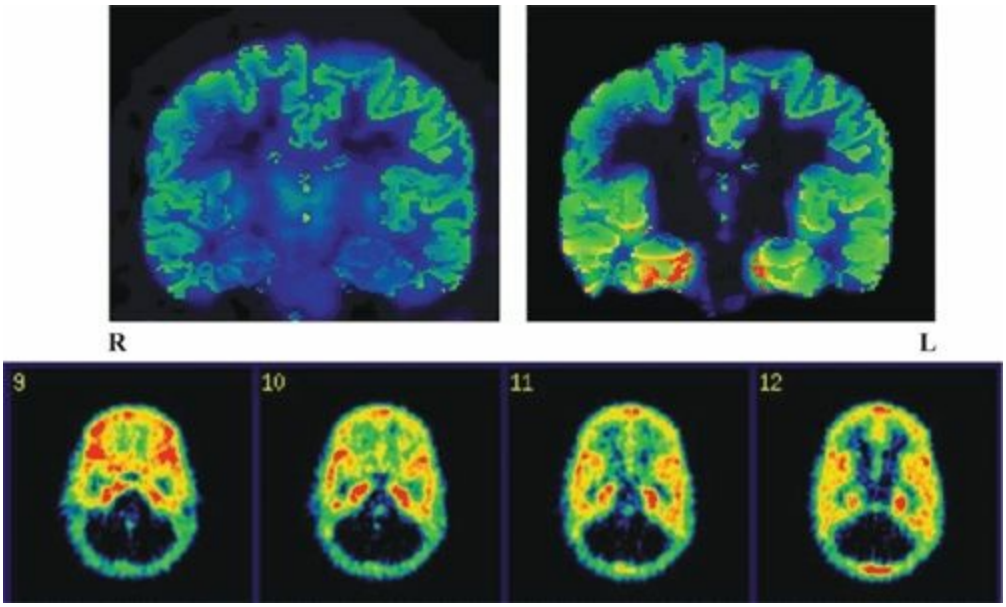

Figure 75.1. [^{18}F]FDG-PET (**upper row left**) showing normal glucose uptake. [^{18}F]FCWAY-PET (**top row right**) shows decreased binding in the left temporal lobe, most pronounced in the amygdala and hippocampus. Lower row are axial views of [^{18}F]FCWAY PET in a normal volunteer. There is no ligand binding in the cerebellum, reflecting absence of 5HT 1A receptors in cerebellar tissue. Raphe nucleus ligand binding can be seen. Left image is the right brain. (Courtesy of Dr. William H. Theodore. National Institutes of Health, Bethesda, Maryland.)

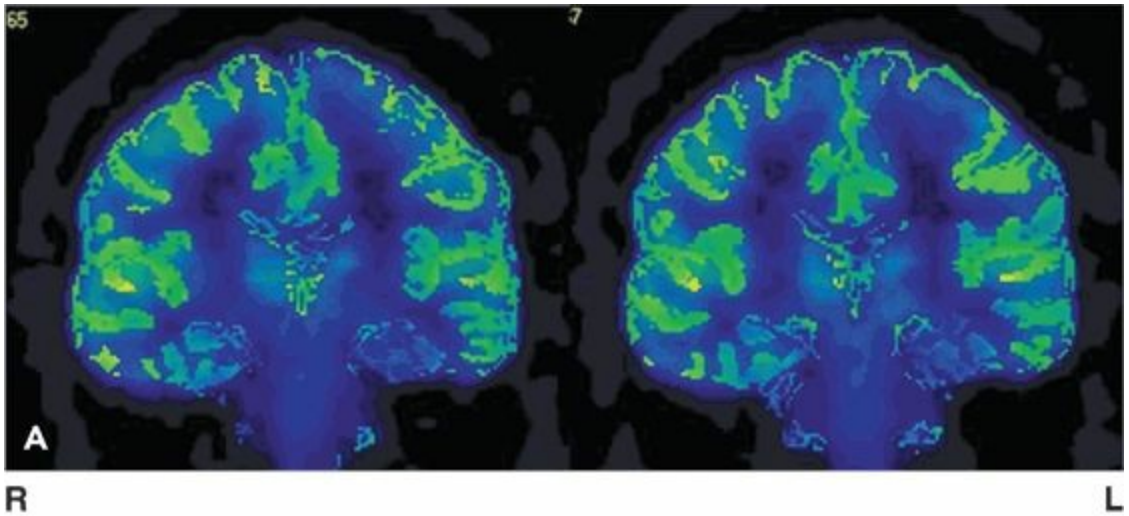

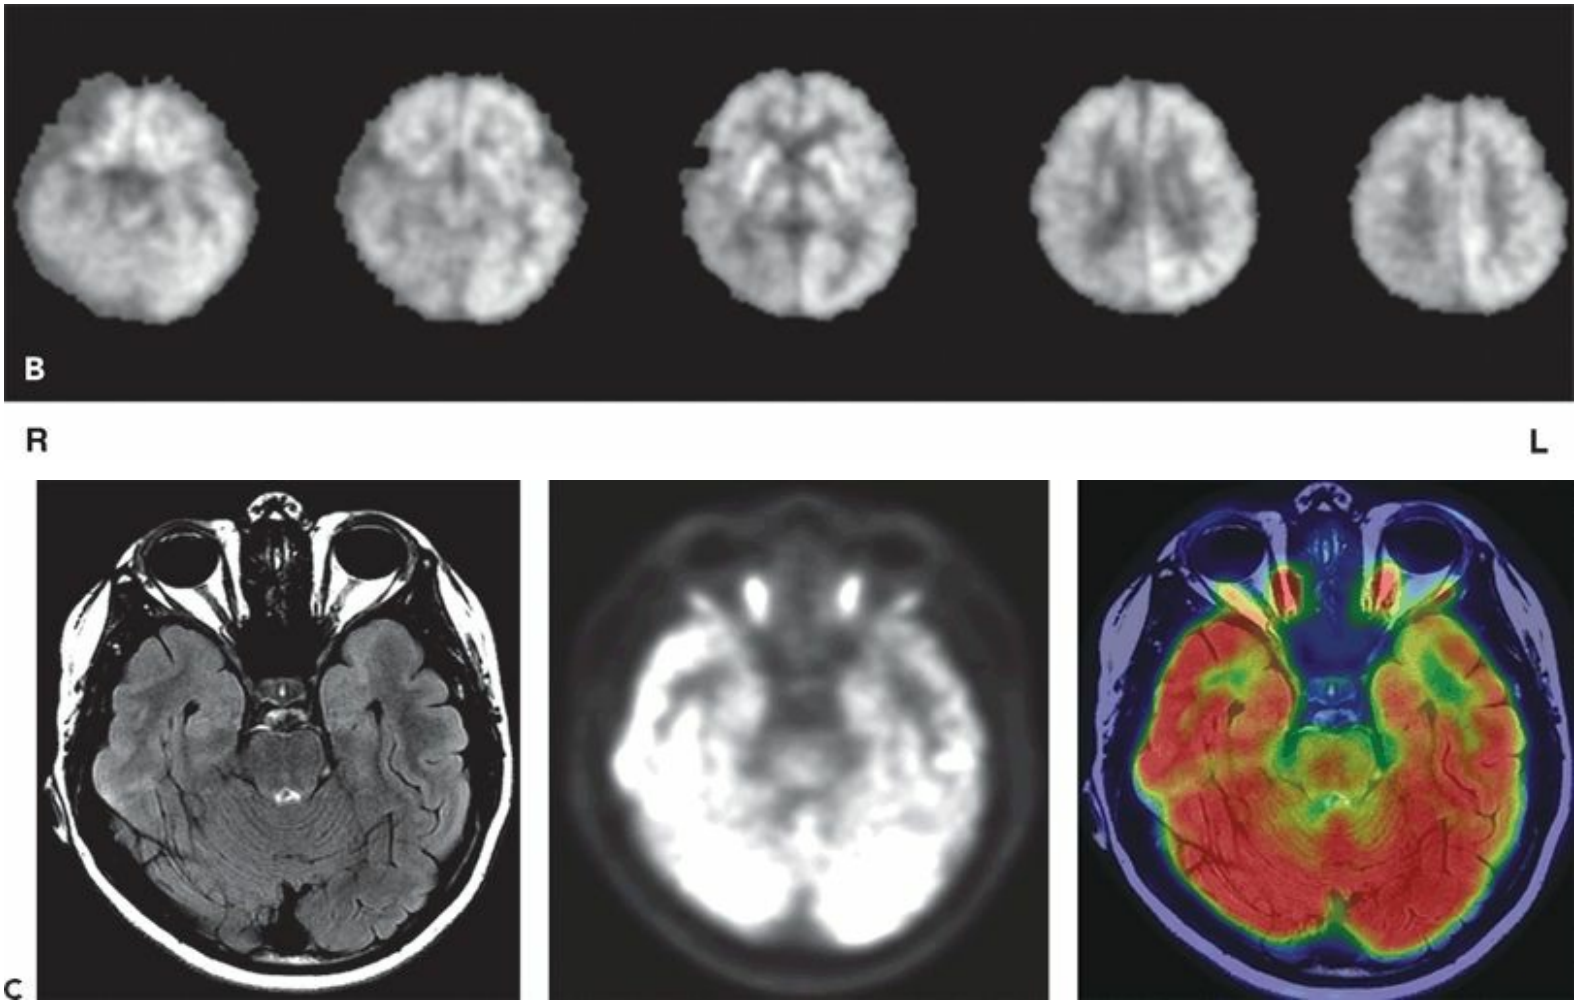

Figure 75.2. A: [^{18}F]FDG-PET in an adult with left TLE showing decreased glucose uptake in mesial temporal regions following partial volume correction. (Courtesy of Dr. William H. Theodore. National Institutes of Health, Bethesda, Maryland.) **B :** [^{18}F]FDG-PET scan in a 14-month-old child with focal seizures (right posterior quadrant focus), secondary generalization, and normal MRI. Figure shows right posterior quadrant hypometabolism. **C:** [^{18}F]FDG-PET scan of a 15-year-old female, with focal epilepsy with altered consciousness, who has subtle left anterior mesial tip temporal focal cortical dysplasia (MRI) and widespread decrease in hypometabolism (PET). MRI, PET, and coregistered PET/MRI are shown. Left image is the right brain. (National Institutes of Health, Bethesda, Maryland.)

Sixty-five percent to 90% of patients with temporal lobe epilepsy (TLE) demonstrate regional hypometabolism; this figure is closer to 90% on recent generation scanners and approximately 60% for patients with normal MRI (4–6). The area of decreased glucose utilization is often more extensive than the epileptogenic zone and may extend into the adjacent inferior frontal or parietal lobe neocortex (3) and occasionally into the ipsilateral thalamus (7) and contralateral cerebellum (3). The regional abnormalities are invariably unilateral to the ictal focus. However, lobar localization is somewhat less reliable, about 80% to 90%. False lateralization as demonstrated after surgery (2) occurred in few patients, specifically when interpretation relied upon nonquantitative analysis, or occurred during subclinical seizures (2,8). Focal interictal regional hypometabolism also predicts a good surgical outcome (5,9–11). Different investigators using different methods and regional analyses have found several different regional hypometabolism patterns predictive of good outcome: inferior lateral temporal, anterior lateral, and uncus (5,9,11). Additionally, extent of resection of PET abnormalities correlates with postoperative outcome (12). Bilateral temporal hypometabolism is associated with a less optimistic surgical outcome and in half of patients reflects bilateral foci (13). Patients with focal temporal abnormalities have a 93% likelihood of good surgical outcome, and those without, 63% likelihood of good outcome (10,11). The ability to confirm the focus and predict

surgical outcome is better when quantitative means are used, typically when asymmetry indexes [AI; e.g., AI = 2(left − right)/(left + right)] are greater than two standard deviations from normative data or about 10% to 15%. However, region of interest measures may be less useful for small, well-demarcated neocortical abnormalities that reflect limited focal cortical dysplasia. Lesser degrees of asymmetry, though visually apparent, may result in misleading information and erroneous conclusions (4,10,11). Voxel-based statistical methods performed in a standard anatomic atlas that allows comparison of individual patient images to normal control group data have been advocated as an alternative means of reliable analysis (14). Given that [^{18}F]FDG-PET is often performed to confirm the focus, focal abnormalities may reduce the need for, or extent of, invasive monitoring when laterality of the focus is in doubt (2,10,11). Issues of frontal versus temporal focus may not always reliably be resolved by interictal [^{18}F]FDG-PET studies, and invasive studies or other PET ligand studies may be needed. Conflicting localizing or lateralization data nearly always merit invasive monitoring.

Ictal [^{18}F]FDG-PET studies are uncommon because of technical constraints such as ligand availability and unpredictability of seizures. They may show profound focal increases in glucose consumption, but results may also be normal or show decreased consumption. The results depend on the delivery of ligand, time and duration of the seizure, and degree of offsetting postictal hypometabolism. Although of interest, they are of limited clinical use, except during focal status epilepticus (15).

The reasons for regional hypometabolism are incompletely understood. Glucose consumption occurs primarily at the synapse. Regional hypometabolism appears to reflect a decrease in glucose influx from reduced glucose transport across the blood–brain barrier, which correlates with subsequent reduced phosphorylation. Cell loss with ensuing synaptic loss and altered remote projections, or degree of hippocampal atrophy in mesial temporal sclerosis, may account for a portion, but not all, of regional hypometabolism in TLE (16,17). Hypometabolism does not correlate with lifetime generalized tonic–clonic seizure or complex partial seizure (CPS) frequency (18). Dysplastic tissue with aberrant synaptic connectivity can have either decreased or normal glucose consumption (19). The abnormalities in some circumstances appear to be functional, as some patients have profound decreases in glucose uptake and no discernible pathology; regional decreased glucose uptake may vary with relation to previous ictal events and clinical manifestations of the previous seizure. In patients with mesial temporal sclerosis, the predominant regions that may manifest decreased glucose consumption are the lateral neocortex and, to a lesser extent, the frontal cortex. This may reflect the distant projection of functional loss in mesial structures. Frontal hypometabolism and contralateral hypometabolism appear to be reversible with successful temporal lobectomy (20).

Studies differ in the extent to which patients with mesial temporal seizures show pronounced lateral hypometabolism: mesial greater than lateral, lateral greater than mesial, and equal mesial and lateral temporal reductions in glucose uptake have been reported (3,4,21). Patients with neocortical temporal epilepsy may have greater lateral than mesial metabolic abnormalities (21). Patterns of hypometabolism may reflect seizure characteristics and seizure propagation. However, there is sufficient variability among patients that individual predictions of seizure focus within the temporal lobe based on [^{18}F]FDG-PET cannot be made.

[^{18}F]FDG-PET will be abnormal when MRI shows significant abnormalities, for example, in mesial temporal sclerosis, tumor, vascular malformation, infarct, and most instances of cortical dysplasia. In this setting, [^{18}F]FDG-PET provides little additional information beyond MRI.

[^{18}F]FDG-PET may be more sensitive than MRI in TLE under some circumstances. Current PET techniques are helpful in 85% to 90% of patients, volumetric MRI in 60% to 70%, and magnetic resonance spectroscopy (MRS) in 55%. Higher-resolution scanning techniques, including high-resolution fast spin echo, fluid-attenuated inversion recovery, T2 relaxometry, magnetization transfer, and high-resolution thin-cut spoiled gradient recall anatomic sequences, and use of higher magnetic field strength (3T and now 7T) have reduced the utility of [^{18}F]FDG-PET (22). Comparison studies report varying efficacy results with different imaging modalities, which frequently reflect the particular research strengths of the investigators rather than the intrinsic advantages of the techniques studied.

Although glucose consumption in the temporal cortex is decreased, perfusion is often maintained, especially in the lateral neocortex (4,23). Interictal studies of cerebral blood flow using [^{15}O]water find a decrease in perfusion in only 50% of patients, but one-fifth of these provide falsely localizing information (4). This experience is similar to that in interictal SPECT studies and quantitative perfusion ascertained by arterial spin-labeled fMRI (5,24). These data suggest that vascular tone may be impaired in TLE and that the relationship between metabolism and perfusion is altered. For these reasons, interictal blood flow studies are unreliable markers of the epileptogenic zone and do not predict surgical outcome (4).

FDG-PET in Newly Diagnosed and Nonrefractory Localization–Related Epilepsy

Metabolic abnormalities are less common in patients with recent-onset, nonrefractory, or well-controlled partial epilepsy. Thirty percent of adults with nonlesional epilepsy within <3 years of seizure onset have focal [^{18}F]FDG-PET (25). Forty to 50 percent of adults without refractory seizures of limited duration (<5 years) have focal abnormalities (25,26). Presence of focal abnormalities does not predict 2-year outcome. Other studies report 20% of adults with well-controlled partial seizures had regional metabolic abnormalities. In these adult populations, localization of seizures is less certain than in patients with refractory epilepsy—an important consideration because patients with extratemporal lobe epilepsy are less likely to have abnormal [^{18}F]FDG-PET studies.

Chronic partial epilepsy typically begins during childhood. Twenty percent of children with new-onset focal epilepsy and normal MRI demonstrate regional hypometabolism. All (ipsilateral) abnormalities occurred among the children with a suspected temporal lobe focus. (27). Follow-up studies did not show any change in extent or magnitude of regional hypometabolism; a combination of MRI and PET findings predicted outcome—those with persistent abnormalities fared less well (28). In another study, regional hypometabolism changed in relation to seizure frequency in children with worsening seizures (29). Similar to adults, 70% of children with chronic partial epilepsy (duration 10 years) have focal metabolic abnormalities. There is evidence that adult patients with a greater duration of epilepsy are more likely to have focal [^{18}F]FDG-PET abnormalities (3,23,27). Partial seizures of greater duration are also associated with a greater dissociation between metabolism and blood flow (4,23). These [^{18}F]FDG and cerebral blood flow studies, along with cross-sectional studies using volumetric MRI, may be taken as evidence that TLE in some patients is associated with chronic and continued neuronal injury (23,30).

Other PET Ligands in Temporal Lobe Epilepsy

In addition to widespread reduction of glucose utilization in cortical projection areas, with relatively preserved perfusion, ligand-binding studies reveal additional functional abnormalities in patients with TLE (Table 75.1). These findings reflect hippocampal atrophy, loss of neuron populations, or a neuronal response to epilepsy.

Table 75.1 PET Ligands in Temporal and Neocortical (Nonlesional) Epilepsy

Ligand	Tracer	Action	Temporal lobe epilepsy	Neocortical
FDG	^{18}F	Glucose uptake and consumption	Decreased mesial, lateral	Decreased
FMZ	^{11}C	GABA-A receptor benzodiazepine site antagonist	Decreased HF, amygdala	Mixed
FCWAY	^{18}F	5HT1A receptor antagonist	Decreased HF, amygdala, insula	
MPPF	^{18}F	5HT1A receptor antagonist	Decreased mesial temporal lobe	
AMT	^{11}C	Precursor, 5HT/kynurenine synthesis	Increased in normal HF	Increased dysplasia; epileptogenic tubers
Carfentanil	^{11}C	Opiate mu receptor agonist	Increased TL neocortex, decreased amygdala	
Cyclofoxy	^{18}F	Opiate mu, kappa receptor antagonist	Increased ipsilateral TL	
Diprenorphine	^{11}C	Opiate mu, kappa, delta receptor agonist	No change	
Methyl ketamine	^{11}C	NMDA receptor antagonist	Decreased	
Fallypride	^{18}F	D2/D3-receptor	Decreased, ipsilateral temporal pole, lateral cortex	
SCH23390	^{11}C	D1 receptor		ADNFLE, reduced in striatum
Fluoro-L-DOPA	^{18}F	Dopamine precursor	Decreased, bilateral caudate, putamen, and substantia nigra	
Doxepin	^{11}C	H1 receptor agonist	Decreased	
Deprenyl	^{11}C	MAO B inhibitor (glial)	Increased	
PBR28	^{11}C	Translocator protein (activated microglia and astrocytes)	Increased (especially in MTS)	
GR205171	^{11}C	Neurokinin-1 receptor	Increased	

ADNFLE, autosomal dominant nocturnal frontal lobe epilepsy; AMT, alpha-^{11}C-methyl-L-tryptophan; FCWAY, ^{18}F-trans-4-fluoro-*N*-2-[4-(2-methoxyphenyl) piperazin-1-yl]ethyl-*N*-(2-pyridyl)cyclohexane carboxamide; FDG, ^{18}F-deoxy glucose; FMZ, ^{11}C-flumazenil; HF, hippocampal formation; MAO, monoaminooxidase; MPPF, 2′-methoxyphenyl-(*N*-2′-pyridinyl)-p-^{18}F-fluoro-benzamidoethylpiperazine; NMDA, *N*-methyl-D-aspartate; TL, temporal lobe; MTS, medial temporal sclerosis.

GABA-A Receptor Studies

Unlike [^{18}F]FDG-PET, which typically demonstrates hypometabolism that is more widespread than the epileptogenic zone, PET with [^{11}C]flumazenil ([^{11}C]FMZ), a benzodiazepine antagonist of the gamma-aminobutyric acid (GABA)-A receptor, shows focal abnormalities confined to the hippocampal formation (6,31). Autoradiography of pathologic tissue indicates that most decreased [^{11}C]FMZ binding is proportional to cell loss (6). In contrast, some [^{11}C]FMZ-binding studies performed in patients with mesial temporal sclerosis argue for an absence or downregulation of GABA receptors beyond that expected by atrophy alone. After accounting for partial volume effect, a 38% reduction in [^{11}C]FMZ binding is found in sclerotic hippocampus beyond reduction in hippocampal formation volume (31). In partial epilepsy, a greater degree and extent of decreased [^{11}C]FMZ binding are seen in patients with more frequent seizures, and decreased binding may extend to projection areas of the epileptogenic region (32). In mesial temporal sclerosis, there is decreased

[^{11}C]FMZ binding in one-third of patients in the contralateral hippocampal formation but to a lesser extent than in the epileptogenic hippocampus. This finding is similar to those in MRS studies. However, in patients with a temporal focus and normal MRI, [^{11}C]FMZ-PET is less useful (6). SPECT with [^{123}I]IMZ, a benzodiazepine ligand (33), shows results similar to those of the PET ligand and more useful than cerebral blood flow–based SPECT (34).

Serotonin Receptor and Synthesis Studies

Serotonin (5HT) IA receptor binding is reduced, to a greater degree than reduced glucose uptake, in epileptogenic mesial temporal lobe and adjacent insula as deduced by the selective antagonists including those with normal MRI [^{18}F]trans-4-fluoro-N-2-[4-(2-methoxyphenyl)piperazin-1-yl]ethyl]-N-(2-pyridyl)cyclohexanecarboxamide ([^{18}F]FCWAY) and [^{18}F]2′-methoxyphenyl-(N-2′-pyridinyl)-p-18F-fluoro-benzamidoethylpiperazine [^{18}F]MPPF (see Fig. 75.1) (35–37). Regional [^{18}F]FCWAY binding contributes to likelihood of achieving seizure freedom following temporal lobe resection (10). Alpha-[^{11}C]methyl-L-tryptophan ([^{11}C]AMT) is increased in the hippocampus ipsilateral to mesial TLE in patients with normal hippocampal formation volumes, but not MTS (38). [^{11}C]AMT, designed as a serotonin precursor, may also be a marker for quinolinic or kynurenic acid, compounds implicated in excitatory neurotransmission (38,39). Decreased receptor binding in mesial temporal structures is more pronounced than reductions in cerebral metabolism. Decreased binding also correlates with severity of depression in epilepsy patients (40) comparable to patients with primary depression.

Other Ligands

Table 75.1 lists findings from several studies of investigational ligands in limited populations using probes for opiate, histamine, and NMDA receptors as well as glial markers. Studies using [^{11}C] PBR28, a probe of the translocator protein that is increased in activated microglia and astrocytes, hence a marker of inflammation, find increased binding in the hippocampus, amygdala, and fusiform gyrus in the epileptogenic temporal lobe; the asymmetry was highest in patients with mesial temporal sclerosis (Fig. 75.3) (41).

Increased in vivo expression of an inflammatory marker in TLE. J Nucl Med. 2012;53(2):234–240.)

PET in Extratemporal Lobe and Neocortical Epilepsy

[^{18}F]FDG-PET is less efficacious in identifying the epileptogenic zone in extratemporal lobe epilepsy than in TLE (42). Most extratemporal lobe epilepsy series include patients with structural lesions that, not surprisingly, show concordant hypometabolism. When patients with abnormal MRI findings are excluded, 11% to 50% of the relatively small patient populations remaining show regional decreases in glucose consumption (6,43). Some investigators have found a good correlation between regional hypometabolism and the epileptogenic zone; others have found a reasonable correlation with side, but not site, of ictal origin. FDG-PET abnormalities remote from the lesion lessen prospects of surgical outcomes. Coregistration of FDG-PET and high-resolution MRI may increase yield of identifying malformations of cortical development, the most common presumed cause of "nonlesional" epilepsy in children and adults (see Fig. 75.2C) (44,45).

[^{11}C]FMZ-PET studies yield mixed and inconsistent results (6,46). [^{11}C]FMZ binding may be reduced and is more restricted in cortical extent than [^{18}F]FDG-PET abnormalities, when present. It appears to correlate with the site of ictal activity and, if resected, is associated with improved outcome (47). Patients with acquired lesions may have regional focal reductions in [^{11}C]FMZ binding concordant with the lesion, but most marked at the margins (46). In other studies, two-thirds of patients with neocortical epilepsy and normal MRI had [^{11}C]FMZ abnormalities, either increased or decreased, which were bilateral in half of the subjects (46,48). Techniques that correct for gray

matter volume averaging may be helpful in identifying abnormal [^{11}C]FMZ binding in cortical dysplasia (48). Given these mixed findings, the role of [^{11}C]FMZ in nonlesional epilepsy remains unclear. In patients with extratemporal lobe partial epilepsy, ictal SPECT may be a better identifier of the epileptogenic cortex, which is discussed below.

PET in Generalized Epilepsy

PET has been used to explore generalized epilepsies, predominantly of the absence type. Glucose consumption and perfusion are globally increased (49). [^{15}O]Water studies performed during electroencephalographic (EEG) bursts of spike and wave demonstrate not only an increase in global perfusion but also a preferential increase in the thalamic regions, supporting the notion of the thalamus as the facilitator of absence events (50). There are no differences in [^{11}C]FMZ or [^{11}C]diprenorphine binding in absence epilepsy. In juvenile myoclonic epilepsy, [(11)C]PE2I, a marker of dopamine transporter activity, is reduced in the midbrain and the high-affinity dopamine (D2/D3) receptor ligand [^{18}F]fallypride ([(18) F]FP) is reduced in the putamen (51).

PET in Children with Epilepsy

[^{18}F]FDG-PET studies of normal development show increased glucose utilization in all brain areas, peaking around 5 to 8 years of age, that parallels synaptic (52). Mature patterns of glucose uptake are established in the primary motor and sensory cortex before they are consolidated in the association cortex. [^{18}F]FDG-PET studies of children with partial epilepsy show regional abnormalities similar to those seen in adults with temporal or extratemporal lobe epilepsy and are discussed above (see Fig. 75.2). Although primary generalized epilepsies are typically viewed as pediatric disorders, imaging studies in these populations have only been performed in adults (see PET in Generalized Epilepsy). Pediatric epilepsy syndromes that have been studied include infantile spasms, Lennox–Gastaut syndrome, Landau–Kleffner syndrome, Rasmussen encephalitis, and several of the cortical dysplasias, including tuberous sclerosis.

Children with infantile spasms may show extensive hypometabolism, usually in posterior brain regions (19). These abnormalities often correspond to MRI abnormalities and may identify areas of dysgenesis not readily apparent with older MRI techniques. However, some children with a generalized EEG and normal MRI exhibit regional metabolic abnormalities (53). PET has been used in these cases to remove the epileptogenic zone in children with catastrophic epilepsy. In some children, however, the metabolic abnormalities seen at onset of infantile spasms may resolve with time and thus may represent a functional state that is potentially reversible with successful medical therapy (54). In children with Rasmussen encephalitis and hemimegalencephaly, widespread hemispheric hypometabolism is typically seen. PET has been advocated in some circumstances to assess the integrity of the good hemisphere before extensive cortical resection (19,55).

In tuberous sclerosis, tubers are often hypometabolic, whereas there is some evidence that the more epileptogenic tubers have increased serotonin or kynurenic acid synthesis, reflected by increased [^{11}C]AMT uptake (56). [^{11}C]AMT uptake is also increased in focal cortical dysplasia; MRI (especially in children <2 years) and [^{18}F]FDG-PET may be normal (Fig. 75.4) (39,56).

(Courtesy of Dr. Harry Chugani, Detroit Children's Hospital.)

PET studies in Lennox–Gastaut and Landau–Kleffner syndrome have yielded mixed results. Children with Lennox–Gastaut syndrome may have focal or multifocal abnormalities, diffuse cortical hypometabolism, or normal studies (57,58). Children with generalized EEG, nonfocal examinations, longer- duration seizures, and normal MRI have normal or diffusely hypometabolic studies. A minority of children exhibit regional metabolic abnormalities, either hypometabolic or hypermetabolic, but many of these children have focal neurologic examinations or partial seizures (57,58). In Landau–Kleffner syndrome and electrical status epilepticus of sleep, inconsistent results have been seen with [^{18}F]FDG-PET, mostly involving temporal hypometabolism. However, other areas may be hypometabolic or hypermetabolic (59).

PET and Antiepileptic Drugs

Several studies have examined the effect of antiepileptic drugs on glucose consumption and to a lesser extent on cerebral perfusion. The GABA-ergic receptor agonists phenobarbital and benzodiazepine reduce glucose consumption by 20% to 30%. In contrast, vigabatrin, an inhibitor of GABA degradation that increases cerebrospinal fluid GABA, reduces glucose uptake by only 8.1% (60). The sodium channel blockers carbamazepine and phenytoin reduce glucose uptake by 9.5% and 11.5%, respectively. Valproate, when used in conjunction with carbamazepine in patients with epilepsy, results in a 22% reduction. However, with monotherapy in normal volunteers, the reduction is only 9.5% with a decrease in perfusion of 14.9%. Although the effects of antiepileptic drugs appear to be global, there is some evidence with valproate of greater decreases in cerebral blood flow in the thalamus, which may reflect an effect of valproate in controlling generalized epilepsies.

CEREBRAL BLOOD FLOW STUDIES USING SPECT

SPECT and Seizure Focus Identification

Interictal SPECT studies demonstrate regional hypoperfusion in 40% to 50% of patients with partial epilepsy of temporal lobe origin that is ipsilateral to a proven epileptogenic area. However, approximately 5% to 10% of studies are falsely lateralizing (4–6,61). These findings are similar to those of interictal perfusion studies performed with [^{15}O]water PET, discussed above. SPECT is more suitable for ictal studies than either [^{15}O]water or [^{18}F]FDG-PET and has provided both useful and reliable information. This is possible because both ^{99m}Tc-HMPAO and ^{99m}Tc-ECD have a rapid first-pass uptake but long half-life. The long half-life permits bedside injection at ictus as well as time to arrange for data acquisition scanning within 4 to 6 hours after injection. Ictal SPECT, when compared with an interictal study, demonstrates regional hyperperfusion in 67% to 90% of patients (Fig. 75.5). In a majority of patients, this correlates with the ictal focus and has been validated with simultaneous invasive video-EEG. These findings hold true for temporal as well as extratemporal lobe epilepsy in both children and adults (5,62–64). The usefulness of ictal studies approaches that of [^{18}F]FDG-PET in patients with TLE, and ictal studies are probably superior for extratemporal focus localization (65–67). Partial seizures often show more reliable results than secondarily generalized seizures (68). False localization is reported in 3% to 4% of studies, presumably because of seizure propagation, and is more likely to occur with later injection times (5). Subtraction techniques with MRI coregistration provide enhanced comparison and semiquantitation of perfusion changes between the interictal and ictal states compared with visual comparison alone (32% to 39% vs. 83% to 85%) (see Fig. 75.5) (69). Focal ictal SPECT also predicts whether surgical outcome will be good (67,70). Many SPECT studies have included patients with clear structural abnormalities such as tumor, mesial temporal sclerosis, and vascular malformations. As with [^{18}F]FDG-PET, in this setting, it is unclear whether SPECT contributes to the patient evaluation (71). It is most useful in evaluating patients with nonlesional partial epilepsy, especially extratemporal partial epilepsy. Ictal subtraction SPECT may also be useful in evaluating patients who have failed initial surgery.

Chronic invasive recording and surgery subsequently confirmed the ictal focus identified by subtraction SPECT techniques. (Courtesy of Dr. Gregory Cascino, Mayo Clinic, Rochester, Minnesota.)

Ictal SPECT findings are related to the timing of injection and the clinical manifestations of seizure propagation (72). For an ictal SPECT study to be useful, injection of the ligand must occur during the ictus and no later than 30 seconds after cessation of the seizure. The earlier the injection (<20 seconds from seizure onset), the more reliable are the study results, and the better the surgical outcome (73). During the ictus, there is focal increase in cerebral blood flow to the involved cortex, often with decreased perfusion in adjacent areas. After the seizure, there is postictal hypoperfusion, which may return to an interictal state rapidly (64). Postictal hypoperfusion abnormalities are more reliable than interictal hypoperfusion (60% to 70% vs. 40% to 50%, respectively). After ligand injection, lorazepam is sometimes administered to diminish the likelihood of subsequent seizures. The data from the scan can be acquired up to 6 hours after the injection. Furthermore, it is important to recall that if a patient has multiple seizure types, each type must be captured. Automated systems may be helpful to improve timing and reliability of ligand delivery; video-EEG monitoring is critical for interpretation of SPECT studies (74). Newer SPECT ligands (^{99m}Tc-HMPAO and ^{99m}Tc-ECD) have greater stability and offer a longer window of injectability (from 30 minutes to 4 hours after composition).

[^{15}O]WATER PET AND BRAIN MAPPING OF CORTICAL FUNCTION

Although interictal [^{15}O]water PET has not been useful in identifying the epileptogenic zone and the

short half-life of [^{15}O]water makes ictal studies impracticable, [^{15}O]water PET have proved useful in identifying eloquent cortex to be spared during surgery. fMRI has supplanted most brain mapping with [^{15}O]water PET (see Chapters 79 and 80 for more extensive discussion of brain mapping). The principles underlying brain evaluation with [^{15}O]water PET and fMRI are similar. Both techniques rely on the observation that increased neuronal activity, primarily at the synapse, is associated with regional increases in cerebral blood flow (75,76). Detecting the location of changes in blood flow that occur during cognitive tasks (e.g., involving language) allows the mapping of neural networks involved in these tasks. PET is a direct measure of cerebral blood flow, has the advantage of measuring capillary rather than venous blood flow, and is less sensitive to motion—thus allowing spoken and overt responses—and may be more suitable for patients who are less cooperative or who are cognitively impaired. PET can also be used to image patients with contraindications to MRI (e.g., implanted metallic devices).

Although [^{15}O]water PET studies of language and cognition are typically analyzed and presented as group rather than individual data sets, advances in PET technology allow for repeated injections of [^{15}O]water in individuals, resulting in less radiation exposure and making feasible reliable individual perfusion maps of cognitive processes (77). Such methods are reliable for lateralization and, unlike the intracarotid amobarbital procedure, localization of language function. Most of these studies rely on verbal fluency or naming tasks, similar to fMRI studies reviewed below, which readily identify anterior language areas.

Bookheimer et al. (78), using an auditory comprehension and naming task, compared individual activation patterns with PET and subdural grid stimulation and found excellent correlation between the disruption elicited by cortical stimulation and the cerebral blood flow activation elicited by task performance. Their study is the first to confirm the assumed reciprocal relationship between activation as defined by local increase in blood flow and the disruption of function elicited by cortical stimulation. Like other functional studies, these studies are valid only for specific aspects of language assessed by the experimental paradigm. Not all activated areas may be critical to language function. Furthermore, what is crucial may not exceed statistical threshold and may not be apparent. Other studies using PET to identify the motor sensory cortex find good correlation (<5 mm) with corticography (79).

CLINICAL RECOMMENDATIONS FOR USE OF METABOLIC AND FUNCTIONAL IMAGING IN EVALUATION OF PATIENTS WITH PARTIAL EPILEPSY

MRI, MRS, PET, and SPECT provide complementary information. When a structural lesion is present, for example, with a tumor or mesial temporal sclerosis, then further imaging, though of interest, usually does not provide information relevant to clinical care. MRS and PET may add information in patients with TLE when routine MRI is normal. [^{18}F]FDG-PET provides excellent lateralization of seizure focus but less reliable localization and a lower yield in patients with extratemporal epilepsy. Ictal SPECT is most useful in extratemporal lobe epilepsy, where other modalities are less helpful or unavailable; without EEG confirmation, invasive studies are usually

indicated in these settings. The contribution of new PET ligands is not well established, but [^{11}C]FMZ, [^{18}F]FCWAY, and [^{11}C]AMT may provide additional localizing information. [^{15}O]water PET is a reliable technique for lateralization and localization of language and location of motor function.

CHAPTER 76
MAGNETOENCEPHALOGRAPHY

RICHARD C. BURGESS AND JOHN C. MOSHER

The past two decades have seen an explosion of techniques for more refined functional assessment of brain status, in both health and disease, along with incredible progress in anatomic imaging that has brought us resolution undreamed of 15 or 20 years ago. Foremost among these in the clinical realm are fMRI and magnetoencephalography (MEG), techniques that complement each other by their differing resolution in time and space and by the very different nature of the signals that they record (1). The unique features and essential differences of the methods that can be used to assess functional coupling between different brain areas—or its disruption—can be exploited to great advantage in the evaluation of epilepsy patients when multiple complementary imaging modalities are combined.

The goal at epilepsy surgery centers during intensive presurgical evaluation of patients is to ascertain whether the patient has epilepsy, to identify the type of epilepsy, and—if focal—to find the location of the epileptogenic zone or network, with a view toward possible surgical resection. This goal is achieved by employing a variety of diagnostic and localization techniques in a slightly different fashion depending on the medical center. However, almost all centers rely on the most noninvasive methods first. For patients whose epileptogenic focus is undetermined after video-EEG (VEEG) monitoring, additional noninvasive testing is required. MEG is a technique that records the results of the identical phenomenon, that is, neural currents, but which is complementary to EEG.

MEG measures the minute magnetic fields that are generated within the brain and that can be recorded from outside the head, unimpeded by tissue boundaries, such as meninges, skull, and scalp. Synchronous activation of about 10^7 synapses produces a detectable field outside the head, and the skull and other extracerebral tissues are essentially transparent to the magnetic fields emanating from these neuronal networks. The magnetic fields generated by the brain and recorded by MEG are very small, approximately 50 to 250 fT or about a billion times smaller than the earth's magnetic field. MEG measurements are entirely noninvasive; patients are not exposed to any radiation, harmful agents, or strong magnetic fields.

While other modalities infer brain function indirectly by measuring changes in blood flow, metabolism, oxygenation, etc., MEG, as well as EEG, measures neuronal and synaptic function directly, and, like EEG, MEG enjoys submillisecond temporal resolution. The brain sources generate magnetic fields that can be recorded by external sensors. These magnetic signals are not distorted by anatomy, because magnetic susceptibility is the same for all tissues—including the skull. Hence, MEG allows for a more accurate measurement and localization of brain activities than does EEG. Because one of its primary strengths is the ability to precisely localize electromagnetic activity within brain areas, MEG results are always coregistered to the patient's MRI. When combined in this way with structural imaging, it has been called magnetic source imaging (MSI), but MEG is best understood as a clinical neurophysiologic diagnostic test.

A current dipole generated in the cerebral cortex produces not only electric potentials but also

magnetic fields (2–4). MEG is a noninvasive tool that provides precise localization of the epileptic activity generating these fields—both interictal and sometimes ictal (as shown in one of the patient examples below)—as well as mapping of functional cortex. Clinical whole-head systems currently have 200 to 300 magnetic sensors, thereby offering very high resolution. The measurement of magnetic fields provides information not only about the amplitude of the current but also its orientation (5).

The origin of the electrical currents in the brain must be inferred from the extracranial electric potentials (EEG) or magnetic field (MEG), based on a projection of extracranial field data onto the surface or into the volume of the brain. This task is easier and more accurately accomplished with MEG because, unlike EEG, the magnetic field is not distorted by the inhomogeneous and poorly defined conductivities of the layers that separate the currents in the brain from the electrode sensors on the surface of the scalp. Especially important in epilepsy, MEG also has a higher signal-to-noise ratio than EEG (6), and a higher detection sensitivity for interictal discharges. An area of discharging cortex of at least 6 to 10 cm^2 is required for an epileptic spike to be seen on EEG (7), and to be easily recognizable requires 20 to 30 cm^2 (8), whereas MEG needs only 4 to 6 cm^2 (9–11).

Dipole sources in sulci or fissures generate tangential currents and are the likely major contributors to the activity recorded by MEG, resulting in several favorable brain areas for MEG source localization. Theoretically, the roof of the temporal lobe, opercular area, mesial frontoparietal cortex, and deep sulci, such as the central sulcus, are optimal areas for MEG source generators because these regions include large volumes of cortical area that are perpendicular to the surface of the head, thereby generating mostly tangential currents. Epileptic sources in these regions not uncommonly produce discharges that are clearly visible on MEG, but not detectable on simultaneously recorded EEG (12). Another reason that regions outside the temporal lobe are most probably more accessible to MEG than temporal sources is because the magnetic field originating from the lowest part of the brain, for example, basal temporal cortex, may not always be adequately recorded (13), and therefore, MEG's recording and localization abilities are better in extratemporal lobe epilepsy (ETLE) than in TLE (11,14). A recently published small series comparing intracranial recordings to MEG found that MEG detected and localized 95% of the neocortical spikes, but only 25% to 60% of mesial spikes (15). Thirdly, the spherical head model, typically employed for calculation of epileptic spike location, is a better approximation in the extratemporal regions (16).

The two primary clinical indications for MEG are well established (and confirmed specifically by the applicable CPT codes issued in 2003)—namely, epilepsy localization and mapping prior to neurosurgical lesion resection. In the evaluation of patients with epilepsy, the role of MEG can be further defined:

- Identification of epileptogenic areas that are difficult or impossible to identify on scalp EEG
- Confirmation of the ictal-onset zone established by other tests
- Demonstration of widespread or multifocal discharges suggesting an unfavorable prognosis for epilepsy surgery
- Identification of eloquent areas of cortex and their proximity to planned areas of resection

The recent (2009) MEG policy by the American Academy of Neurology specifically highlights the value of MEG "when discordance or continuing questions arise from amongst other techniques designed to localize the focus." In nonlesional cases, or in patients where the EEG is nonlocalizing, MEG can be particularly helpful. Even when it picks up no new areas of epileptic activity, MEG

provides more precise localization than scalp EEG (17). A substantial minority of epilepsy patients, especially nonlesional cases, will still require invasive recording prior to resective surgery, and MEG has been shown to be of crucial assistance in determining the placement of the intracranial electrodes. In MRI-positive cases, MEG is especially helpful in pinpointing the source of epileptic activity when lesions are extensive or multiple.

BACKGROUND

The first human MEG recordings were made by Cohen in 1968 (18), but the field awaited the development of ultrasensitive magnetic field measurement sensors, superconducting quantum interference devices (SQUIDs), in order to achieve the adequate sensitivity needed clinically. The early single-channel, then 7-channel, then 37-channel devices evolved to become commercially produced whole-head systems in the mid-1990s (19,20). Present MEG systems contain hundreds of magnetic sensors surrounding the head, and are able to record in either a seated or supine position.

The advantages of MEG for recording brain signals have a strong theoretical basis and are well known in practice:

- No exposure to radiation, magnetic field, or other active device.
- Inherently higher source resolution.
- Reference free, that is, no contamination by signal from the reference.
- Easy to obtain multichannel, whole-head, high–spatial-density recordings.
- No direct connection to patient required.
- Signals not attenuated or distorted by bone and scalp, or other inhomogeneities that exist between brain and surface.
- Head modeling during source analysis is significantly simpler, less prone to error, and hence more accurate due to lack of signal distortion.

MEG has been found to be valuable in preoperative evaluation of patients being considered for epilepsy surgery (21,22), and MEG's use in these patients has been the subject of several other reviews (23,24). Nevertheless, few studies exist that compare MEG localization with direct intracranial electrode recording (ICEEG), and the patient numbers have been small (10,11,15,25).

One of a handful of studies that has demonstrated true clinical value for MEG in a prospective, blinded crossover-controlled, single treatment case series of 69 sequential patients was published by Sutherling in 2008 (26). Although the effect on outcome was not studied, they looked at the decisions made at patient management conference before and after presentation of MEG results. They found that MEG provided entirely new information in 33%, altered the ICEEG examination (phase 2) in 23%, and changed the surgical decision in 20%. All of the patients in this study were extratemporal, and the postoperative outcome results demonstrated clear benefit from MEG in 21% of the patients who went to resection (9% of the patients in the study).

In an important 2006 publication, Knowlton et al. (27) studied the effect of MEG on the subsequent placement of ICEEG electrodes in a prospective study of 115 patients, 43% of whom were ETLE. By the design of the study, MEG could only prompt the addition of supplemental electrodes after an initial decision was made without considering MEG. Forty-nine patients proceeded to intracranial evaluation, where this study investigated the concordance between ICEEG and MEG localization to the sublobar level, with a view toward the practicality of eventually

substituting MEG for ICEEG in some patients. MEG and ICEEG had about the same success in localizing the epileptic source, 65% and 69%, respectively. Agreement at a sublobar level between tests was good; 55% were localized and concordant for site. There were 7 cases (14%) who were localized by ICEEG but not by MEG and 3 cases (6%) localized by MEG but not by ICEEG. MEG's positive predictive value for seizure localization was 82% to 90%, depending on whether computed against ICEEG alone or in combination with surgical outcome. A notable conclusion from this study is that the absence of ictal recordings (usually the situation in MEG) did not affect the results.

In another 2006 paper, Knowlton (28) demonstrated in a blinded prospective study that, beyond the basic evaluations using scalp VEEG monitoring and MRI, MEG was more valuable than were the other noninvasive techniques, consistently demonstrating higher sensitivity and specificity values than FDG-PET and ictal SPECT in the evaluation of 72 patients subsequently evaluated with intracranial recordings. Furthermore, localization concordance with the ICEEG on a sublobar level was greatest with MEG.

In a study comparing a short-duration MEG with multiday scalp VEEG monitoring, Pataraia et al. (29) found MEG to be superior to long-term VEEG, with MEG localization in the resected area in 70%, but EEG concordant in only 40%. MEG evaluation has even been advocated as the screening tool of choice for frontal lobe epilepsy by a group in the Netherlands (30). Simultaneous MEG and EEG were recorded in 24 patients; in 18 patients, at least 6 spikes per hour were recorded. Not only were spikes much more frequent on MEG than EEG, but localization via MEG was successful in twice as many patients as EEG (14 vs. 7 patients).

MODELING OF THE SOURCE AND THE HEAD

The fundamental task of the MEG procedure and the accompanying analysis by the magnetoencephalographer is to solve the "inverse problem," that is, determination of the electrical source currents, which must have produced the magnetic field external to the head during the MEG recording. This is an "ill-posed" problem that depends on suitable models of the source and the head.

Both EEG and MEG measure exactly the same phenomena, namely, summated electrical currents produced by excitatory and inhibitory postsynaptic potentials (PSPs), primarily from the pyramidal cells in the upper layers of the cortex. Simplifying assumptions suggest that a single pyramidal cell can generate a 20 fA-m current (31); more recent computational models and experimental evidence suggest that a single cell may generate as much as 200 fA-m (32). As a rough approximation, 1 million PSPs are summed up; therefore, the modeling approach is to lump together these intracellular "impressed" currents flowing within the cell bodies and their corresponding potentials along their cellular walls into one overall "primary source" (33) called the "equivalent current dipole" (ECD). Thus, 1 million PSPs can theoretically generate a 20 nA-m to 200 nA-m ECD, or equivalently, 10 to 100 microamperes of current flowing along 2 mm of the cortical column.

This primary current model, comprising impressed currents within the cell bodies and their corresponding microcellular boundary potentials, is in contrast to the "macrocellular" model that emphasizes the location of the ECD in the brain with respect to the other "macro" boundaries, namely, the inner skull, outer skull, and scalp surfaces. The ECD creates a potential field pattern at all of these surfaces, which EEG records at the scalp. This same ECD and its corresponding potential pattern also create a current flow throughout the brain, in turn generating a magnetic field recorded as the MEG. The ECD is considered the "primary source," the potentials on the boundaries are the "secondary sources," and the currents generated by the ECD are the "secondary" or "volume"

currents. Thus, MEG measures the magnetic field due to the combined primary and secondary current flow, whereas EEG measures the potentials of the secondary sources at the scalp as generated by the ECD (31,33). Each modality therefore measures a different component of the same underlying neuronal activity, and the two combined are quite complementary.

As introduced, the ECD must be considered in relationship to the macro boundaries, where the conductivity changes markedly, which effectively creates secondary sources and alters the volume current pattern. This "head modeling" is a computational challenge in its own right, separable from issues of source modeling. The boundary with the greatest impact on source modeling is the skull, with a resistivity on order of 100 times greater than the scalp or CSF on either side. As reviewed elsewhere (34), many models and computational methods have been introduced on how to best model the impact of the skull on the EEG and MEG model. The oldest and simplest model considers the head to be a single perfect sphere, or a series of concentric spheres, that models the skull surfaces and scalp. Recent years, with the routine adoption of MRIs, have seen the use of more sophisticated models that tessellate these same surfaces with tiny triangular elements, yielding "boundary element modeling" (BEM).

Obtaining a correct solution for the EEG is difficult, involving substantial complexity of the head model. However, MEG is in fact mostly insensitive to any boundary other than the shape of the inner skull (34,35). Thus, MEG head modeling is generally far more robust than EEG to the inevitable head modeling approximations, and indeed, the sphere or series of overlapping spheres are often adequate for MEG head modeling (16). Clinical software packages generally offer either the sphere model or BEM solutions to the head modeling problem.

The ECD emphasizes a focal location on the cortex. By electromagnetic superposition, we can model more complex distributions of multiple or distributed sources by simply adding together the individual ECDs. A "multiple dipole model" assumes several distinct ECDs are (nearly) simultaneously active, whereas a "distributed" source model considers an extended contiguous region of cortex, such that a single ECD no longer suffices to explain the complexity of this broad region. The most widely used model in patients with epilepsy is the single equivalent current dipole (SECD) (21,36,37). This decision is partly based on extensive experience and validation, as well as the simplicity and speed of computation using this model. The other factor that makes the SECD so well suited in epilepsy is our clinical concept of curable focal epilepsy as arising from a small and restricted source, exactly the circumstance best modeled by the SECD.

If, as stated above, both MEG and the more familiar EEG record the same phenomenon, why is "source localization" so tightly associated with MEG? Because MEG modeling is more robust and the forward model so straightforward and computationally efficient, conventional MEG practice is to analyze the location of waveforms of interest using these computerized modeling techniques (e.g., the SECD). For assessment of the location of the electrical activity from EEG, computerized modeling methods are often problematic, and the electrical field distributions are easier to interpret visually without resorting to computational methods, as detailed in Chapter 7.

RECORDING TECHNIQUE

Whole-head MEG systems have a cylinder-shaped Dewar (container vessel) with a helmet-shaped concavity on one end, into which the subject's head is placed for measurement (5,31). Typically, 100 to 300 channels of magnetic sensors coupled to SQUIDs are arrayed over the inner surface of the concavity, immersed in the liquid helium within the Dewar, and maintained at a temperature of 4.2 K.

The equipment containing the Dewar with the MEG sensors (Fig. 76.1) is housed in a magnetically shielded room (MSR) in order to block magnetic interference coming from the environment. Active noise cancellation, that is, real-time feedback compensation, helps to counteract any residual interference, which penetrates into the MSR. Implanted devices such as vagal nerve stimulators, pacemakers, and responsive neural stimulators do not preclude MEG recording (38–40), but postprocessing to eliminate extracranial interference is required (e.g., spatiotemporal signal space separation [tSSS] (41).

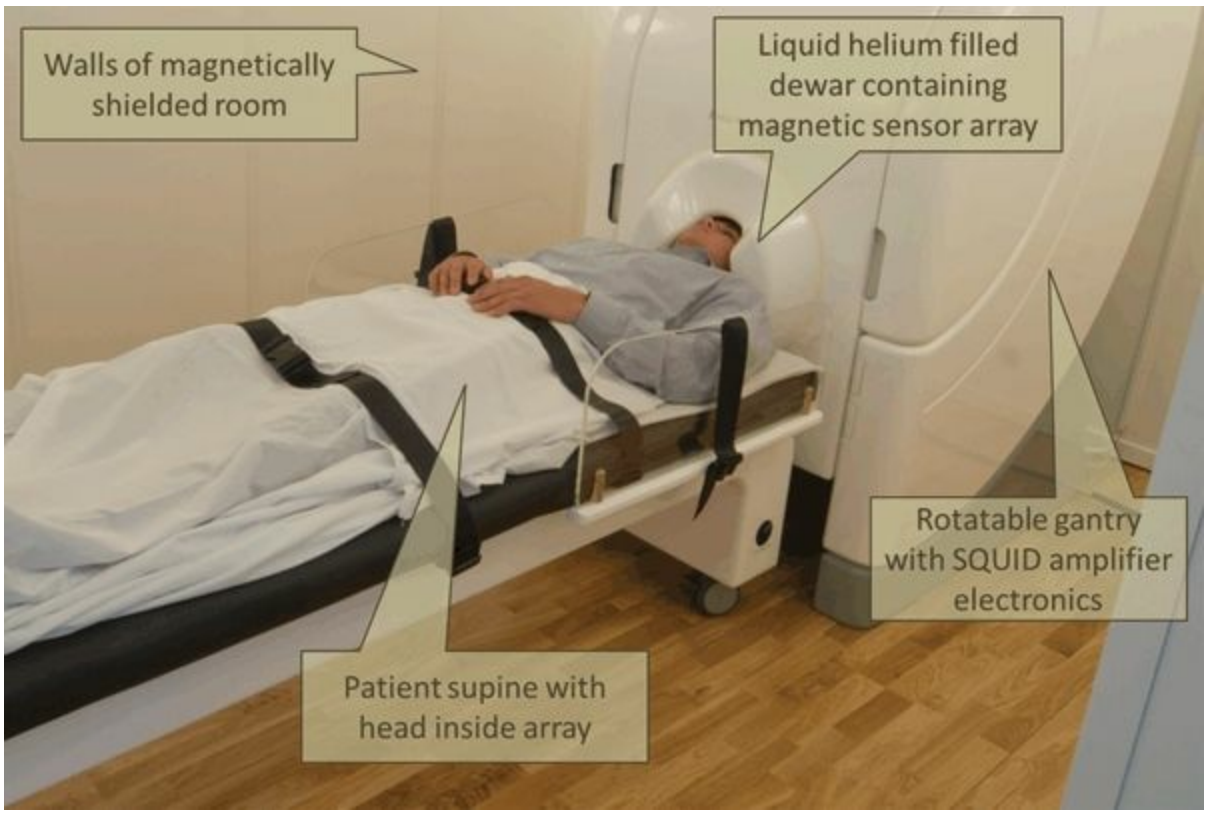

Figure 76.1. MEG can be recorded in either the supine or seated position. Patients are placed in a seated position when it is necessary to view a screen or to carry out a task requiring hand–eye coordination. In epilepsy patients, the supine position is used most often in order to promote sleep as an activation procedure for epileptiform activity. The MSR is large enough to accommodate a screen for presentation of visual stimuli or to allow a parent or caregiver to accompany an anxious patient during the MEG study.

In contrast to electroencephalography, where the electrodes are in fixed positions on the scalp, the MEG sensors bear only a vague relationship to brain regions. In addition, the location of the head within the Dewar varies from patient to patient, and it changes even during a recording session on an individual patient. The spatial relationships of the sensor locations to the brain are obtained indirectly based on three-dimensional digitization of several anatomical landmarks, for example, nasion and preauricular points, and by "head position–indicating" (HPI) coils that are affixed to the head with collodion. The locations of the HPI coils, as well as the locations of the anatomical fiducials, are carefully digitized so that their positions can be coregistered with the same landmarks ascertained from the patient's MRI.

Because the patient must remain relatively still during MEG recording, duration is limited and generally confined to the interictal state (24). Typical MEG monitoring times for epilepsy patients range from 40 minutes to a few hours. Continuous head-position monitoring and correction obviates the need for general anesthesia. Systems that can continuously monitor and correct for head movement have been developed (42,43) and clinically validated (44). Incorporation of these movement

compensation methods into commercial MEG systems has dramatically increased their practical clinical utility, especially in children who are unable to stay still. MEG is now extensively employed in children (45–51). While it is well known from EEG that epileptic spikes, which indicate the "irritative zone," are not always coincident with the ictal onset zone, localization by MEG is generally a robust indication of the epileptogenic zone (52,53).

ANALYSIS AND INTERPRETATION

It is important to review the raw MEG waveforms and to realize that these "brain waves" are analogous to the familiar EEG waveforms (Fig. 76.2). Experience as an electroencephalographer can be applied to MEG, and the fundamental concepts of field determination and source localization, previously established for EEG, are also similarly applied to MEG interpretation (54). Review of the recorded data, typically about 1 hour per patient, is accomplished by paging through 10-second pages in a process quite similar to the traditional electroencephalographic review of high-density EEG, employing several "montages" of MEG sensors. In contrast to EEG, MEG is inherently reference free (55).

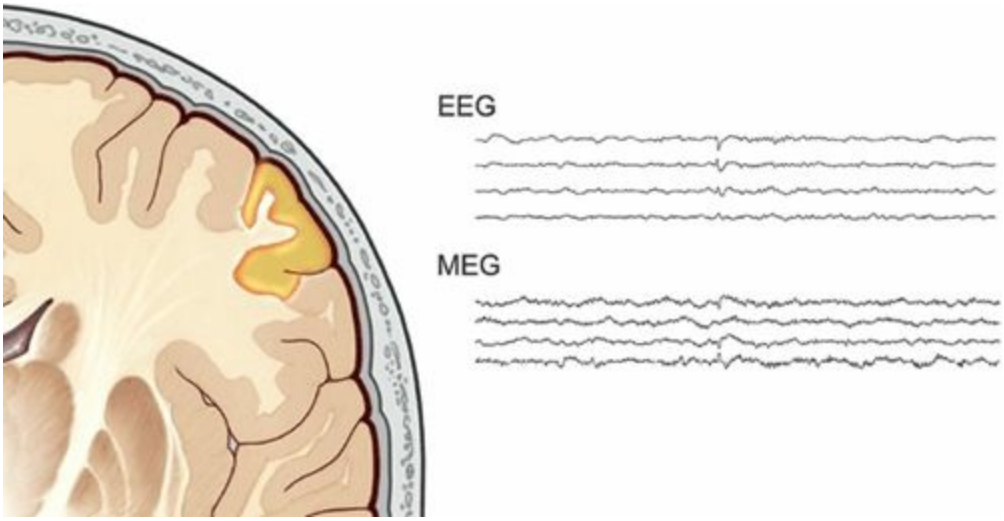

Figure 76.2. Epileptic activity is embodied as an electrical signal. The electrical current also generates a magnetic signal at the same time. Although the morphology and apparent polarity can be different, they record the same phenomenon. EEG is better at detecting radially oriented activity, while MEG sees tangential activity better. It is rare for MEG to be blind to a source, however, as some tangentially oriented cortex is almost always involved, as illustrated by the spike in this figure.

Although there are some differences between normal variants seen in MEG and EEG, identification of MEG spikes essentially follows traditional EEG criteria: Sharp contour, standing out from the surrounding background, following a physiologic distribution, and often presenting with an aftergoing slow wave. The EEG can be viewed separately (blindly if desired) or simultaneously (Fig. 76.3), but in the majority of patients, spikes and sharp waves are more copious on the MEG channels than on EEG (30,54). Since EEG and MEG record the same phenomenon, epileptic spiking for example, reports should include the results of MEG localization along with interpretation of the simultaneous EEG.

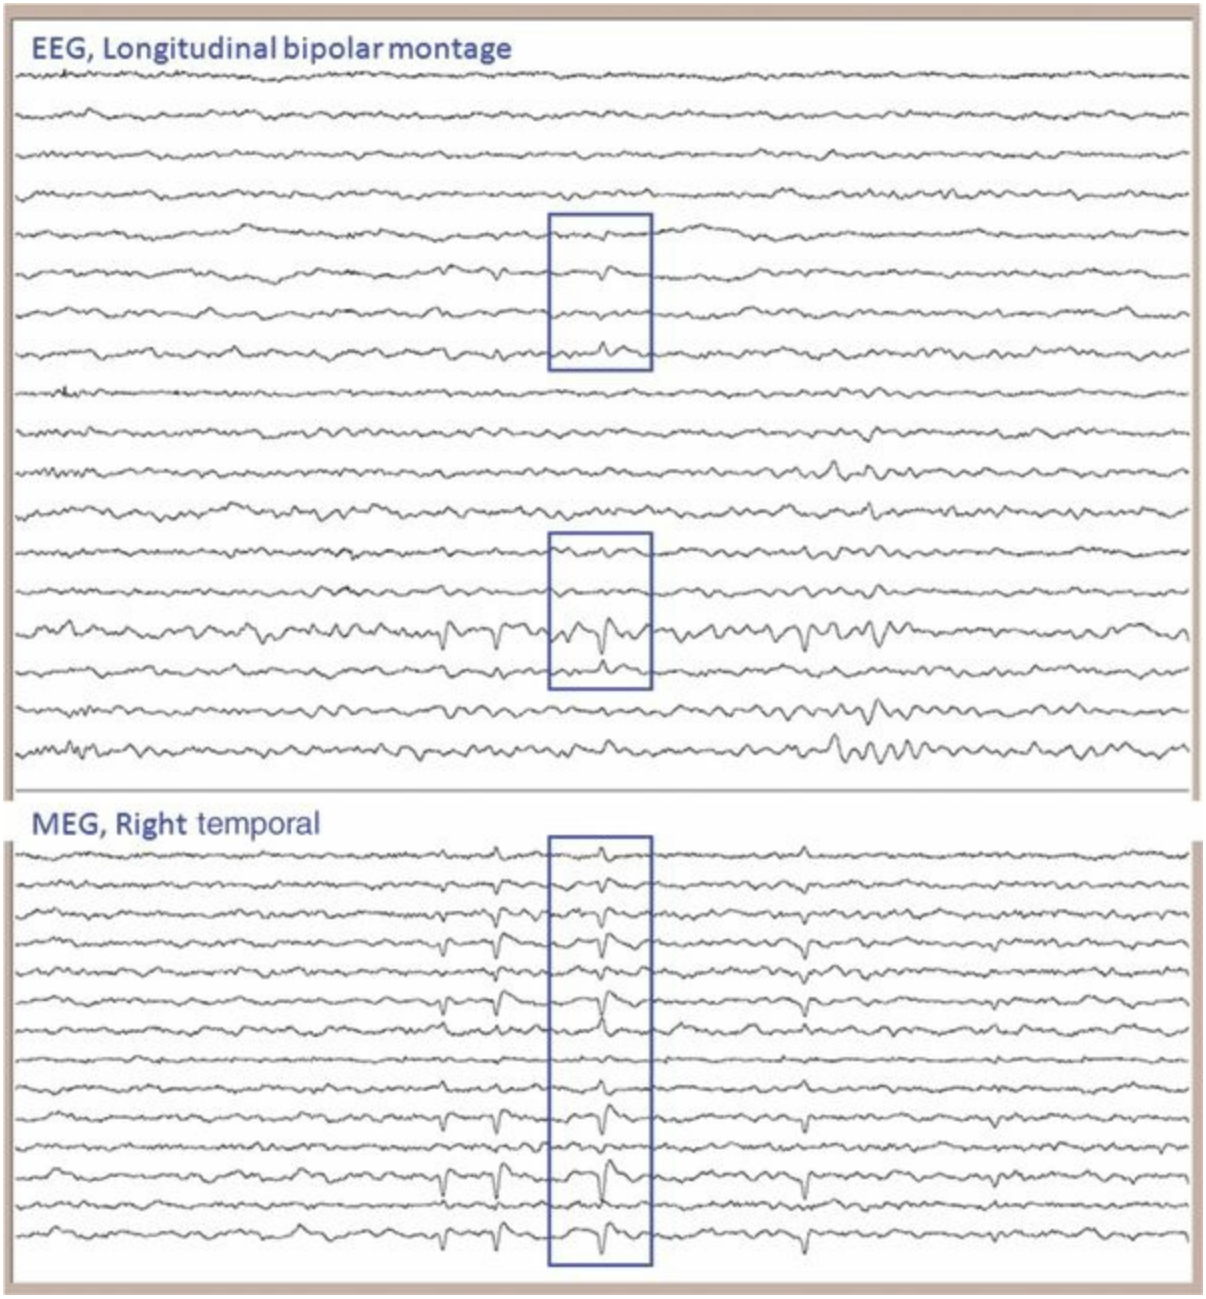

Figure 76.3. It is critical to review both the MEG channels and the simultaneously recorded EEG. They can be displayed and reviewed separately or, as shown here, together. The time window shown is 10 seconds (in this and all subsequent figures). It is important to ensure that the MEG can localize spikes habitually seen on the patient's previous EEG. Looking at only the MEG spikes which are coincident with EEG, however, would waste a wealth of information that the abnormalities seen only or more prominently on MEG provides.

After identifying and marking candidate spikes in the raw waveforms, the next step is to ascertain what part of the brain is generating these epileptiform discharges. Magnetic field distribution is usually displayed as an iso-field contour map with the aid of computerized calculation. The field distribution produced by a single current dipole is observed as a pair of influx and outflux field maxima distributed on each side of the dipole location (5). Assuming a single dipolar generator for a typical "dipolar" field distribution, an ECD is localized below the middle point of both influx and outflux field maxima. As introduced above in source modeling, this localization is carried out by synthesizing a putative dipole location in a plausible (typically spherical) head model, computing the theoretical field pattern associated with this location, comparing it to the actual measured field pattern, and then iteratively adjusting the location until theory and measurement achieve the "best fit."

The reason that the term "single equivalent current dipole" (or SECD) is encountered frequently

in MEG is often misunderstood. We look for a "dipolar field" distribution for reassurance that employment of the SECD model is appropriate. Modeling the source of cerebral currents as an SECD offers a convenient and rapid method for finding the location of that source. Dipole models are well established for known regional sources, such as somatosensory evoked responses. However, for sources of unknown origin like epileptic spikes, the interpreter must make sure that the SECD is reasonable, as the solution can be significantly biased by the interpreter's assumptions. Several automated approaches have been proposed to avoid such biases (56–58), but there has been scant utilization of such techniques in clinical work.

Computerized source estimation is more feasible in MEG than in EEG, because of the relatively simpler source and volume conductor models. Employing the vendor's (Elekta Neuromag, Helsinki, Finland) or third-party (such as CURRY [Compumedics, Charlotte, NC], BESA [MEGIS, Gräfelfing, Germany], etc.) software, epileptic spikes can be localized using an equivalent current source dipole model, on an interactive basis as each spike is encountered, in order to continuously build and test a hypothesis. Alternatively, spike identification can be carried out in a first pass, then source localization as a second pass. Our process is to carry out localization of individual spikes, and never to average spikes, because of the well-known pitfalls of spike averaging (59). Whether the localization of each spike is considered acceptable is based on:

- Presence of a dipolar appearing magnetic field pattern
- No simultaneously occurring artifact
- Stability of the localization with time (i.e., within a window of approximately 5 to 50 ms)
- Acceptable goodness of fit/confidence volume (usually a function of SNR)

Figure 76.4 illustrates the selection of a time point to localize, the magnetic field potential at the scalp surface, and SECD-modeled source of the sharp wave in the right parietal operculum.

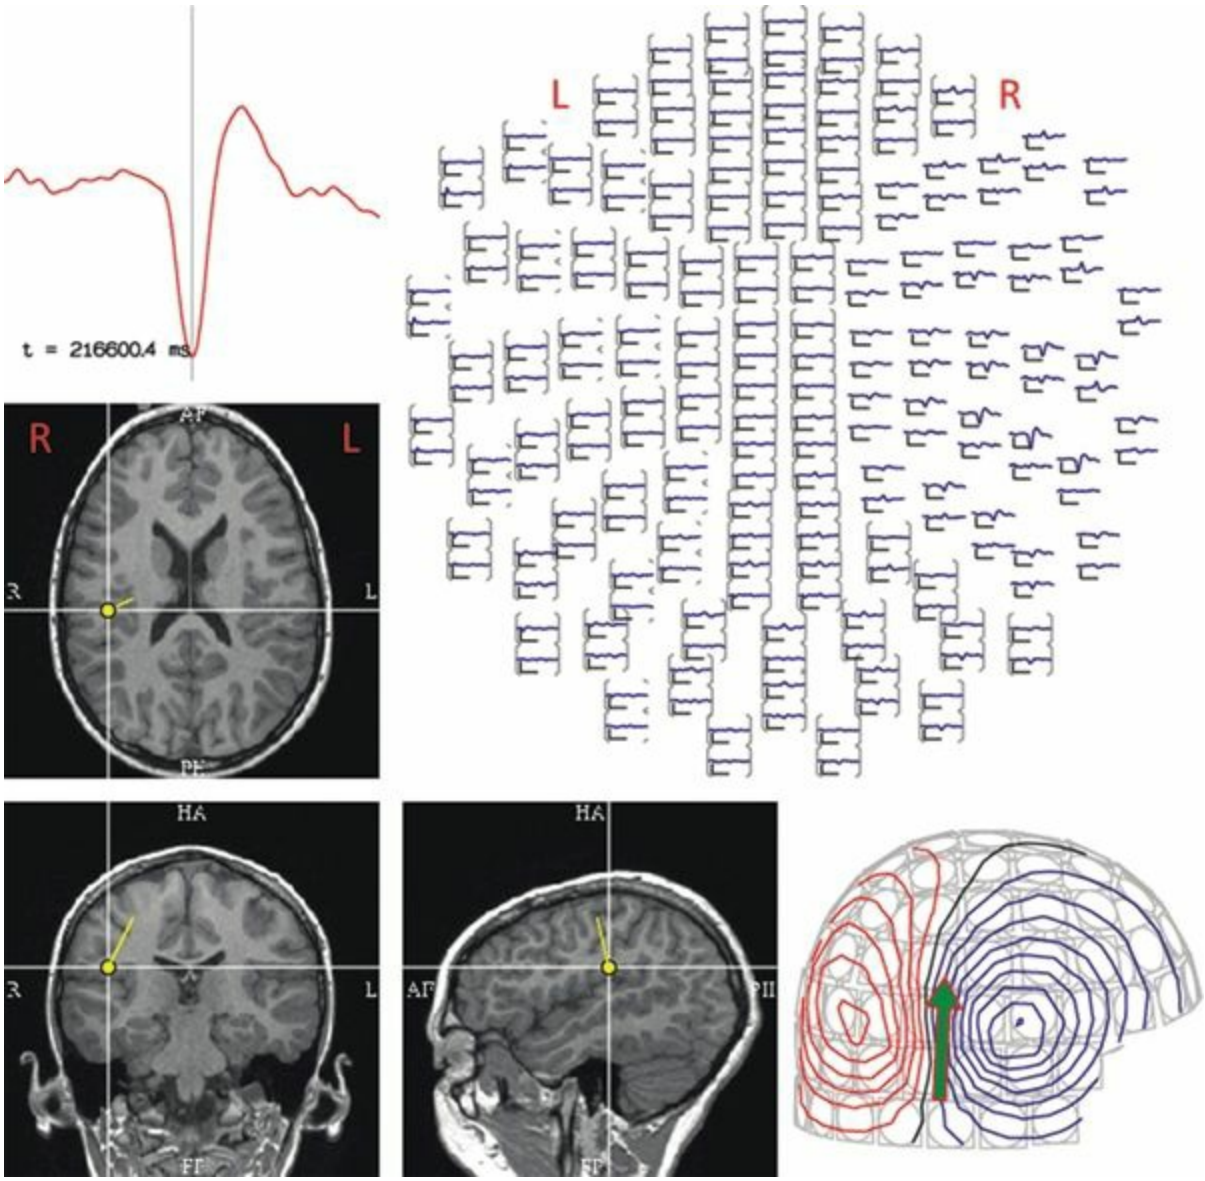

Figure 76.4. This figure depicts the analysis steps that are part of the SECD localization, for the sharp wave that is displayed in Figure 76.3. A representative signal from one of the MEG sensors is shown in the time-expanded graph in the upper left. In the top view of 204 (out of a possible 306) sensors (shown at the upper right), the magnetic activity of this same epoch can be seen maximally in the right temporal sensors. The magnetic field distribution over the head, shown in the lower right, with red indicating magnetic efflux (i.e., exiting the head) and blue showing influx (i.e., entering the head) illustrates a typical "dipolar field." The results of SECD analysis are instantly coregistered to the patient's MRI, implicating a source in the right parietal operculum. (R = right, L = left.)

Sources deemed to be acceptable are coregistered to the patient's own MRI, primarily based on three spatial fiducials, the nasion, and both preauricular points. Using these digitized landmarks and continuous monitoring of the position of the HPI coils during the recording, the location and orientation of the ECD solution can be coregistered with the anatomy and displayed graphically. Typically for epileptiform discharges, dipole locations of several representative spikes are shown (13,36,51,60–62). Some magnetoencephalographers try to superimpose as many as 100 dipoles on one image, in an effort to convey the extent or variability of spike distribution (63).

In electroencephalography, source localization has not yet been broadly accepted as a clinical tool (64). Visual, manual inference of the localization, aided by judicious montage selection (see Chapter 7), has served the electroencephalography community well. Part of the poor penetrance of source localization into the EEG community is due to the requirement for modeling the conductivity of all of the layers of the head and the inherent inaccuracy that this suboptimal modeling produces. In addition, the application of a large number of EEG sensors (sometimes called "high-density EEG") in

order to have sufficient data points for improved source localization has historically been a practical limitation. MEG suffers from neither of these limitations (65,66). Computerized source localization methods are always included as part of the analysis of MEG signals. Not only are the 300 or more time series difficult to analyze visually, but the underlying physics of MEG source modeling make it considerably simpler and more accurate than for EEG. Simple, single-layer, spherical head models have proven adequate for MEG source localization (16,67). In a study from Utrecht (68), spikes localized with MEG were closer to the presumed epileptogenic lesion (tubers) than those localized from EEG recorded at a separate time. In addition, agreement on identification of spikes was higher (as measured by kappa scores) on MEG (151 channels) than on EEG (mostly 85 channels).

Whether the localizations of all detected spikes are diagnostically significant is determined from:

- Number of acceptable dipoles
- Tightness of the dipole cluster
- Orientation of the dipoles
- Plausibility of the location

Studies of the localization accuracy of MEG have shown variable results, primarily dependent on the phenomenon under study (e.g., epileptic spikes vs. SEF), the location of the activity (e.g., dorsal, inferior, mesial), signal-to-noise ratio (which is dependent on room shielding, noise cancellation methods, etc.), localization technique (ECD vs. linear methods), and types of subjects (highly motivated volunteers vs. clinical patients). In studies employing phantoms, typical MEG accuracy for dipole localization is 2 to 4 mm, while EEG achieves only 7 to 8 mm (69,70). The higher spatial resolution is a function of not only the typically greater number of sensors used in MEG relative to EEG but, more importantly, an inherently more accurate forward model (70,71).

In either modality, however, it is important to distinguish the resolution of a single dipole versus a pair (or more) of dipoles, simultaneously fit to the same time slice. If the SECD is unsuitable due to high modeling error, one approach is to employ two synchronous dipoles. As theoretically examined previously (72), while the modeling error is naturally reduced (due to more modeling parameters), the stability of the location of two dipoles is dramatically diminished. The resolving ability of a pair of synchronous dipoles may be as poor as several cm (72). In practice, the vendor or commercial software may not provide automatic fitting procedures and error control of the multiple synchronous models, further complicating routine clinical application, in contrast to the single ECD. An alternative to multiple dipole modeling is to attempt modeling the non-SECD source as a “patch” constrained to cortex (73,74), but this approach also requires a much greater degree of sophistication in reliably and routinely extracting cortical surfaces from a patient’s MRI and then designing the parameters of the patch (e.g., the extent and pattern of assumed activation across the patch). Thus, for routine clinical modeling, the SECD remains the viable approach.

The temporal resolution of MEG is limited only by the sampling rate of the recording system, meaning that it is possible to record wide-band MEG signals all the way to the upper frequency limits of any brain process. This is particularly important in epilepsy where the high spatial and temporal resolution of MEG makes it possible to analyze propagation of epileptic activity and to evaluate the relationship of multiple areas of epileptogenicity, as the case in Figure 76.5 illustrates.

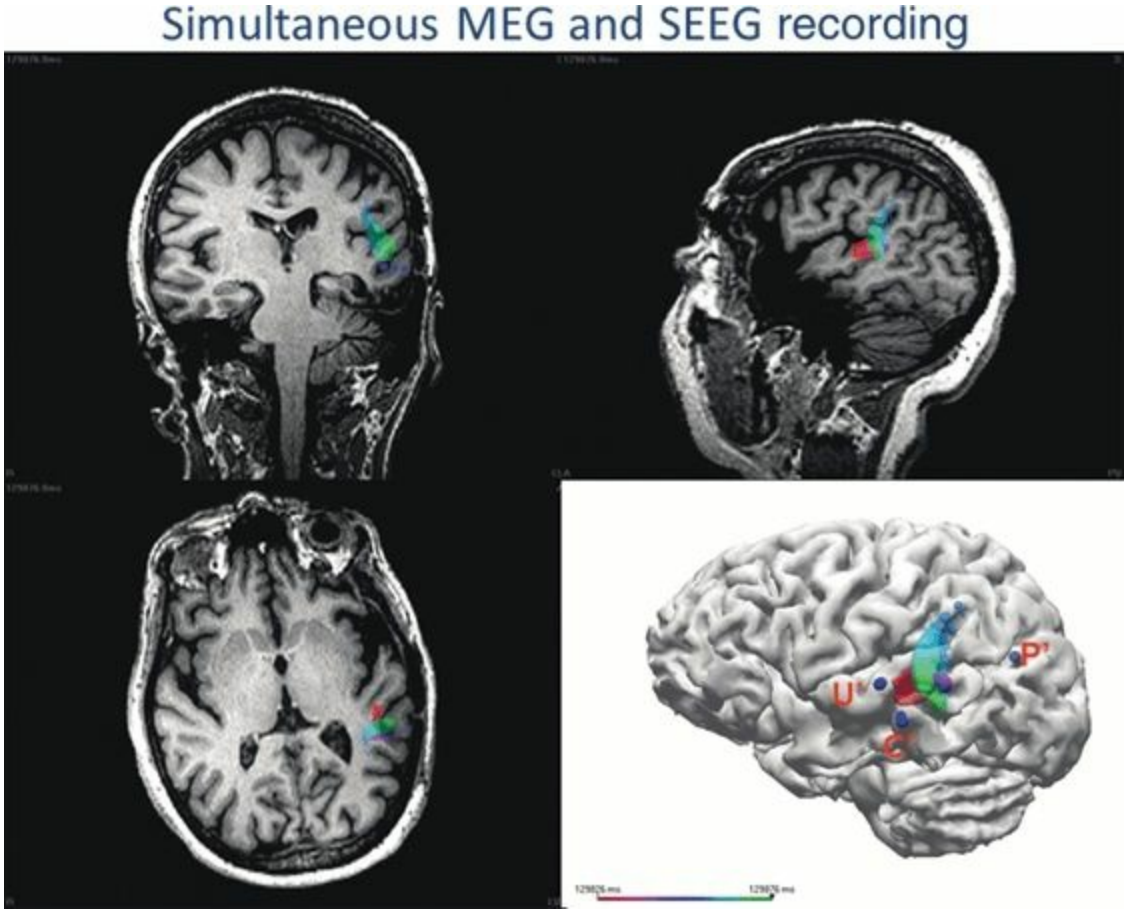

Figure 76.5. This 55-year-old patient had undergone a previous left temporal lobe resection, but automotor seizures with left temporoparietal seizure activity on scalp EEG activity recurred within 2 months. During her intracranial evaluation with SEEG electrodes, spike activity was seen at the C' and U' electrodes, but the main area of concern was at the P' electrode where the onset of seizures was noted. Because of the proximity of Wernicke area, the C' area was not a candidate for surgical removal, but U' could be removed. The patient was sent to the MEG laboratory for simultaneous MEG and SEEG recording with the following questions posed: Is C' entirely separate? Or is there some connection from P' to C' and U'? A sequential dipole fit was performed on spikes detected maximally at C' on the SEEG, evaluating the rising slope of the spike, and the trajectory of the entire 50 ms time course is shown by the multiple dipoles moving from red to green. The epileptic activity moves from the posterior bank of the resection to the posterotemporal gyrus (pink epoch), then back to the posterior bank of the resection, and onward to the posterior superior temporal gyrus (purple epoch), and finally, there is posterior propagation toward the occipital area (green epoch).

INDICATIONS AND BENEFITS IN EPILEPSY

MEG provides another localization data point in the workup of patients being considered for epilepsy surgery. Concordance or discordance of multiple-modality information helps to guide the therapeutic strategy, and it is helpful prognostically as well. In a study of 22 children with normal or minimal MRI findings, good outcome correlated with inclusion of MEG dipole clusters within the resected area, and none of the patients with scattered dipoles or with clusters not resected became seizure free (49). This study confirmed that the best outcomes following epilepsy surgery occur when VEEG and MEG localization results are concordant. Similarly for patients who underwent invasive recordings at our institution, 87.5% were seizure free when ICEEG and MEG were concordant and resected, but only 30% of discordant cases achieved seizure freedom (75).

In patients with tuberous sclerosis, MEG has been used to identify the “hot tuber,” that is, the most epileptogenic of the lesions, whose removal will likely result in the best surgical outcome, using either source analysis (76,77) or other techniques such as “synthetic aperture magnetometry” (78,79).

Especially in those patients with skull defects, as a result of either previous neurosurgery or

traumatic injury, EEG localization may be misleading. In these difficult patients, MEG's immunity to the effects of variations in conductivity offers reliable localization (50,80,81). MEG can also prompt a focused rereview of MRI, converting a nonlesional case into an MRI-positive case (82,83).

APPLICATION AND UTILITY IN COMPLICATED EPILEPSY PATIENTS

Because of the complexity of their evaluation and the difficulties encountered while trying to develop a treatment plan, the majority of the referrals to the MEG lab include patients with intractable epilepsy who are being considered for epilepsy surgery. The typical scenarios where MEG can be of particular benefit are when:

- Other noninvasive tests do not adequately localize the epileptogenic zone or produce conflicting results.
- The MRI is normal.
- More refined definition of the focus in relation to structural lesions is needed.
- Multiple or extensive lesions are present, and it is unclear which part of the lesion or adjacent cortex is epileptogenic.
- Preexisting cranial defects from previous neurosurgery or other alterations of the anatomy distort the localization provided by EEG.
- Contemplated surgical resection is adjacent to essential functional areas of the brain.
- Guidance for placement of intracranial electrodes is required.

The following three cases typify the challenges and results obtained in the evaluation of epilepsy patients with MEG.

Nonlocalizable on Scalp EEG

This 55-year-old, right-handed male, with the onset of seizures at age 25, has mostly nocturnal seizures consisting of asymmetrical tonic posturing. Previous EEGs were negative, MRI was negative, and the ictal SPECT showed bilateral frontal activation. During scalp VEEG monitoring, the findings included only extremely rare bifrontal spikes and nonlocalizable seizures. The sharp waves on MEG shown in Figure 76.6, however, were easily detected, and they were robustly localized in a tight cluster, which was subsequently confirmed by intracranial recording.

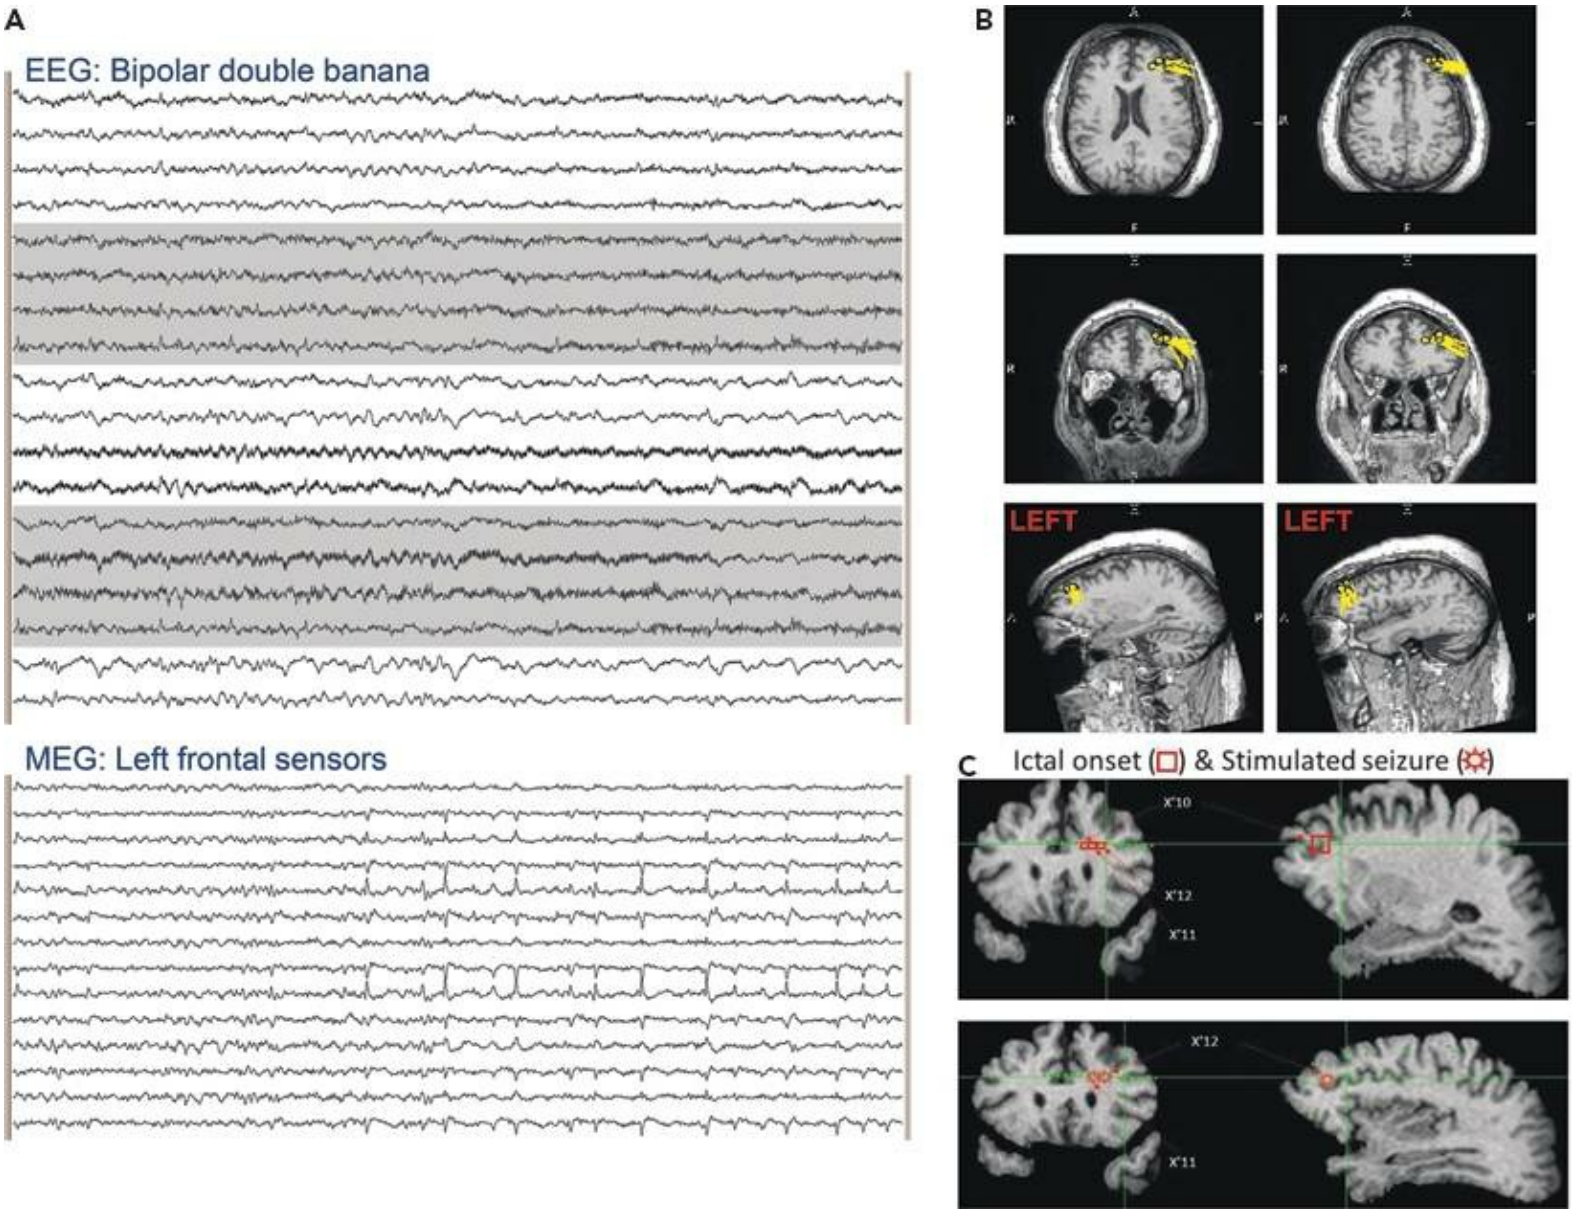

Figure 76.6. The EEG in (**A**) (standard longitudinal bipolar montage) shows no detectable epileptiform activity. The selected MEG channels from the same time epoch at the bottom of (**A**) show frequent sharp waves, which are localized to the left middle frontal gyrus and superior frontal sulcus in (**B**). The subsequent intracranial EEG investigation summarized in (**C**) demonstrates that the patient's seizures were coming from the same location. Eleven spontaneous seizures were captured with onset at SEEG electrode contacts X'10,11,12, and the seizures evoked by electrical stimulation were at the same location.

Multiple, Widespread Areas on EEG

In this 32-year-old patient, the EEGs displayed a multifocal picture that appeared to implicate several areas. The patient's seizure onset was at age 6, and his seizures consisted of abdominal aura, followed by dialeptic seizures, progressing to generalized tonic–clonic seizures. The MRI showed right hippocampal sclerosis, but the PET showed hypometabolism of the both medial temporal lobes, as well as the posterior aspect of the right temporal lobe. The results in Figure 76.7 illustrate how MEG was able to clarify the propagation of the epileptic activity, because of its high temporal and spatial resolution.

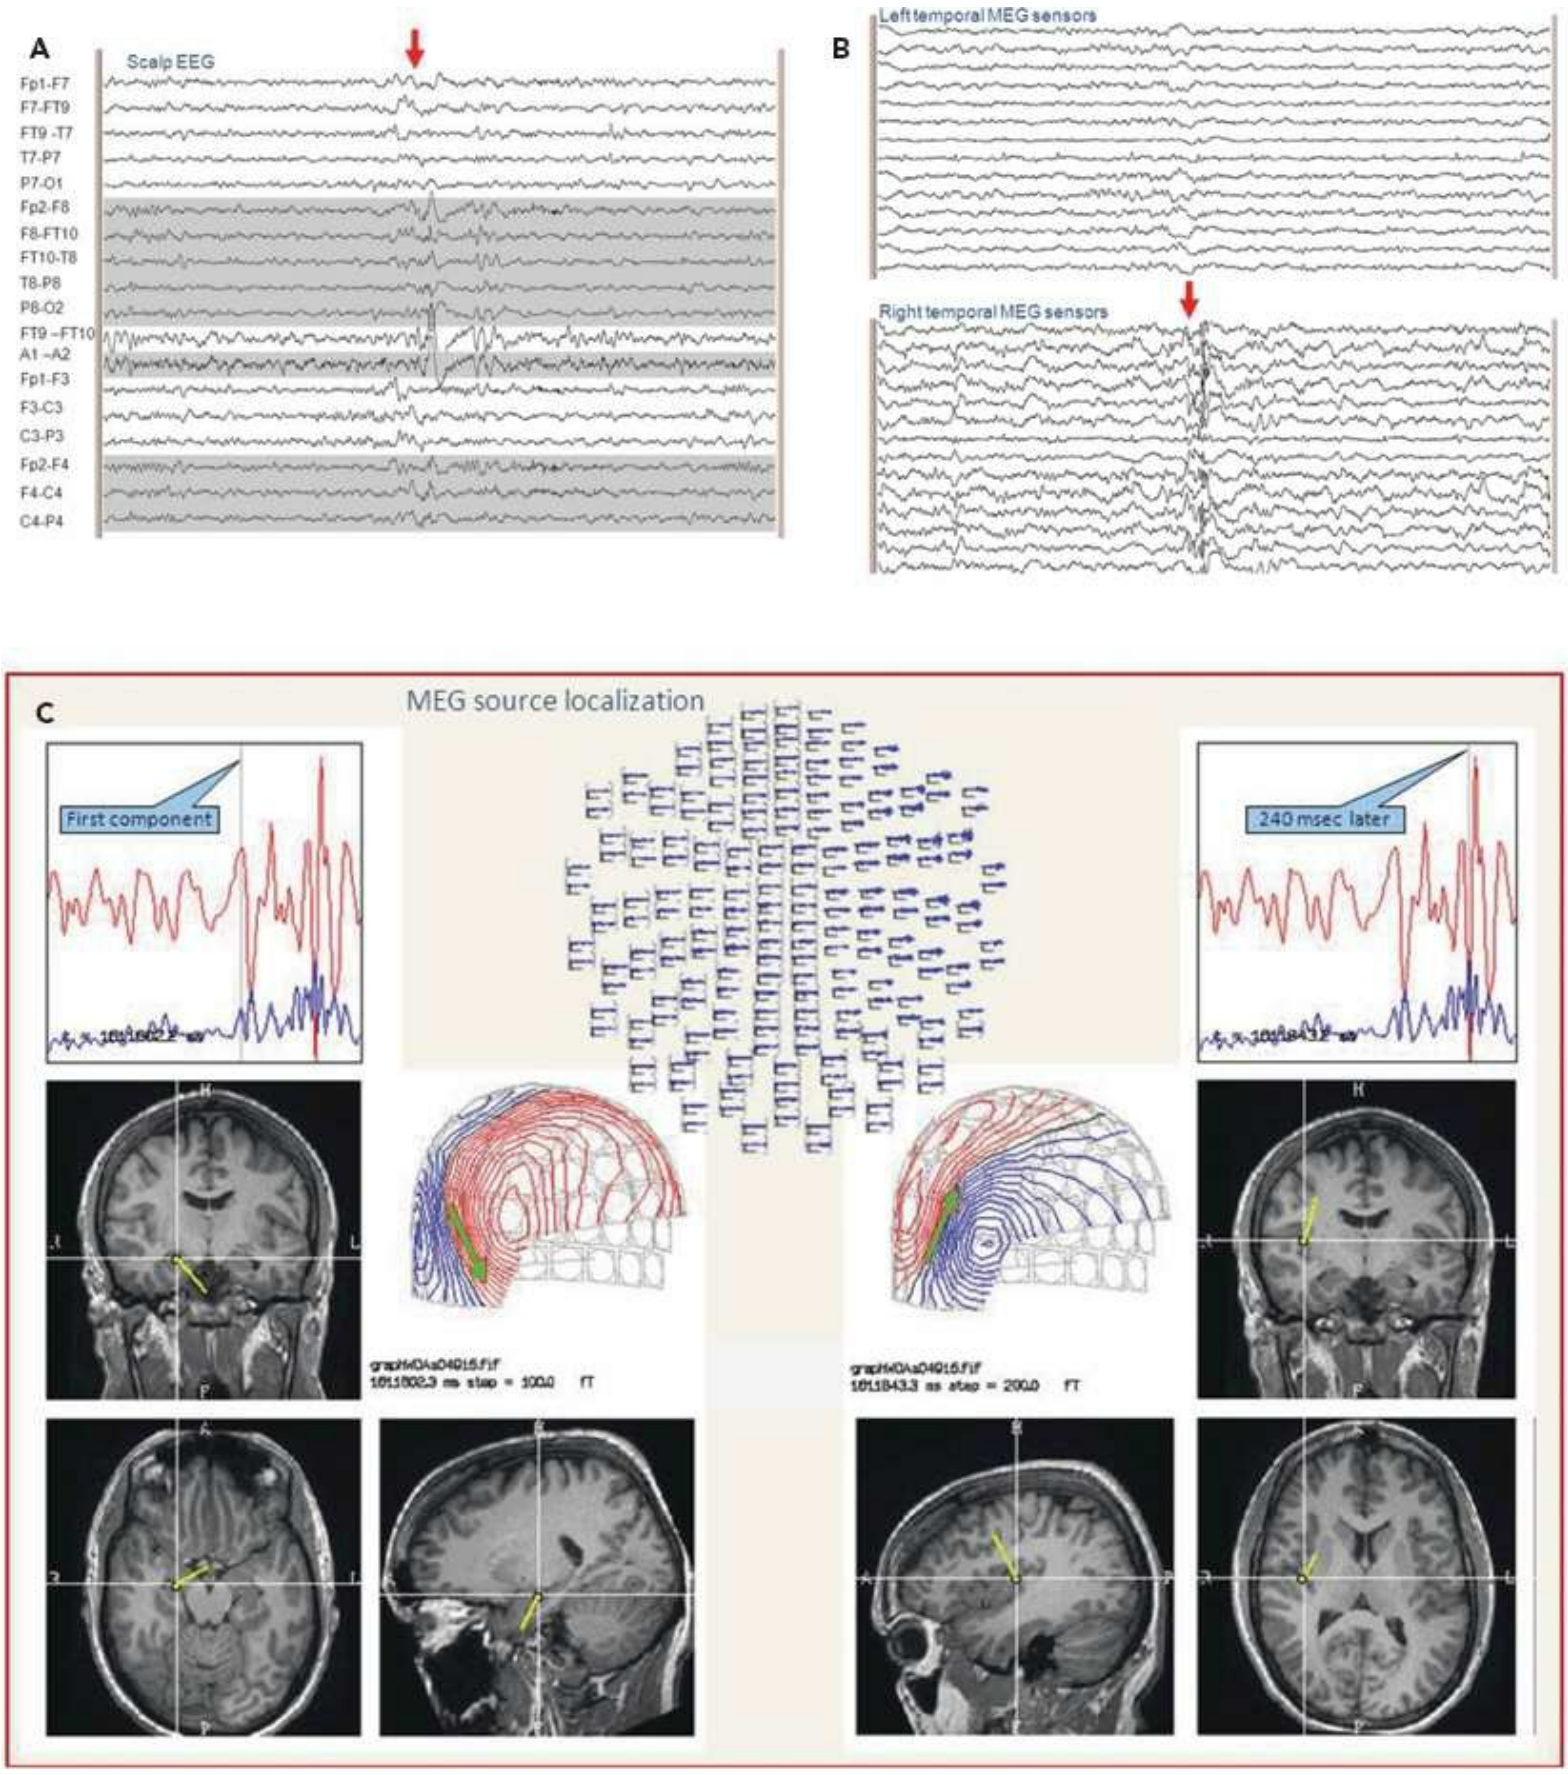

Figure 76.7. The EEG, in (**A**), shows polyspikes with a complicated distribution in the right frontotemporal region. The selected MEG sensors seen in (**B**) during the same time epoch show clear definition of the multiple components of the polyspikes. The localization of the sequence of these components shown in (**C**) clarifies the spread from the right hippocampus to the insula.

Ictal MEG Recording

Although seizures in the MEG are relatively uncommon, they can be serendipitously captured. At the Cleveland Clinic, this occurs in approximately 10% of the patients referred to the MEG laboratory, and when they occur, these recordings of ictal onset by MEG can yield precise localization of the epileptogenic zone. The patient illustrated in Figure 76.8 had six seizures during MEG recording, one of which was a clinical seizure, manifest as a left somatosensory aura, and the rest showed no clinical signs. The MEG demonstrated a clear difference, with the seizures accompanied by clinical manifestations propagating from the posterior middle frontal gyrus to the postcentral gyrus. This propagation pattern was confirmed when the patient underwent intracranial monitoring with subdural grid electrodes.

Figure 76.8. An ictal MEG recording captured six seizures in this patient. Five, with no clinical signs, ranged in duration from 10 to 50 seconds, one of which is shown in (**A**). The seizure without clinical signs showed spike-and-wave complexes, maximally in the right parietal sensors. The clinical seizure on MEG, shown in (**B**), was marked by background attenuation, the development of an increasing beta discharge, followed by polyspikes in the right parietal sensors. Localization of the portions of the clinical seizure indicated by the arrows was performed and is illustrated by the red dipole locations in (**C**). From each of the seizures without clinical signs, two time points each were localized, indicated on the figure by the yellow dipoles. Location of the central sulcus is marked by "CS." The propagation, which is shown by the red dipoles, explains the reason for the clinical manifestations (**B**).

When the noninvasive data are not entirely concordant, or when the surgical strategy requires further localization, implantation of intracranial electrodes may be contemplated (see Chapter 81 in this volume). MEG's role in providing guidance for the implantation is extremely important in order to assure adequate sampling of the epileptogenic areas.

SENSITIVITY AND YIELD

MEG has a different spatial sensitivity than EEG and generally does show more spikes than scalp EEG (30,54,84). The sensitivity of MEG is higher for tangentially oriented current flow (55,85–88). However, Hillebrand and Barnes (89) found that <5% of the cortical surface is within 15 degrees of the radial orientation, and at that point, the strength is 25% of that of the tangential dipole. In a more recent study (90), potential sources were distributed over all possible cortical areas. A cortical patch was defined as radial if the orientation angle was within ±10 degrees from the scalp surface normal, and it was defined as tangential if the orientation angle was within ±10 degrees of a line parallel to the scalp surface. The ratio between the number of tangential and radial sources was approximately 3:1. Therefore, for realistic sources in heads, which are never exactly spherical, MEG is very rarely blind to a source due to orientation.

Comparison of the sensitivity of MEG versus EEG to epileptic spikes has been investigated by many authors (24,71,91–93), some concentrating on the temporal lobe (94), over an extended period of MEG's history. Recent studies looking blindly at EEG and MEG, which were recorded simultaneously, have consistently shown a higher sensitivity for MEG (54,95–97). An example of the oft-reported "MEG-unique" spikes is illustrated in Figure 76.6.

It is important to understand that not all epileptic discharges produced in the cortex are detectable externally by either EEG or MEG. Certainly, there are prominent spikes, which are recorded easily by intracranial electrodes, but which are invisible on MEG. The combination of signal amplitude, volume of discharging tissue, and distance to the sensors determines the degree to which the MEG sensors can see neural activity (10) as illustrated in Figure 76.9 (98). The strength of the magnetic field decreases in proportion to the square of the distance from the current dipole, according to the Biot–Savart law. Therefore, the sensitivity of MEG to deep sources is similar to scalp EEG (87). In addition, there are some unusual situations where almost none of the sources are tangentially oriented, such as in polymicrogyria, where MEG's sensitivity will be poor (88).

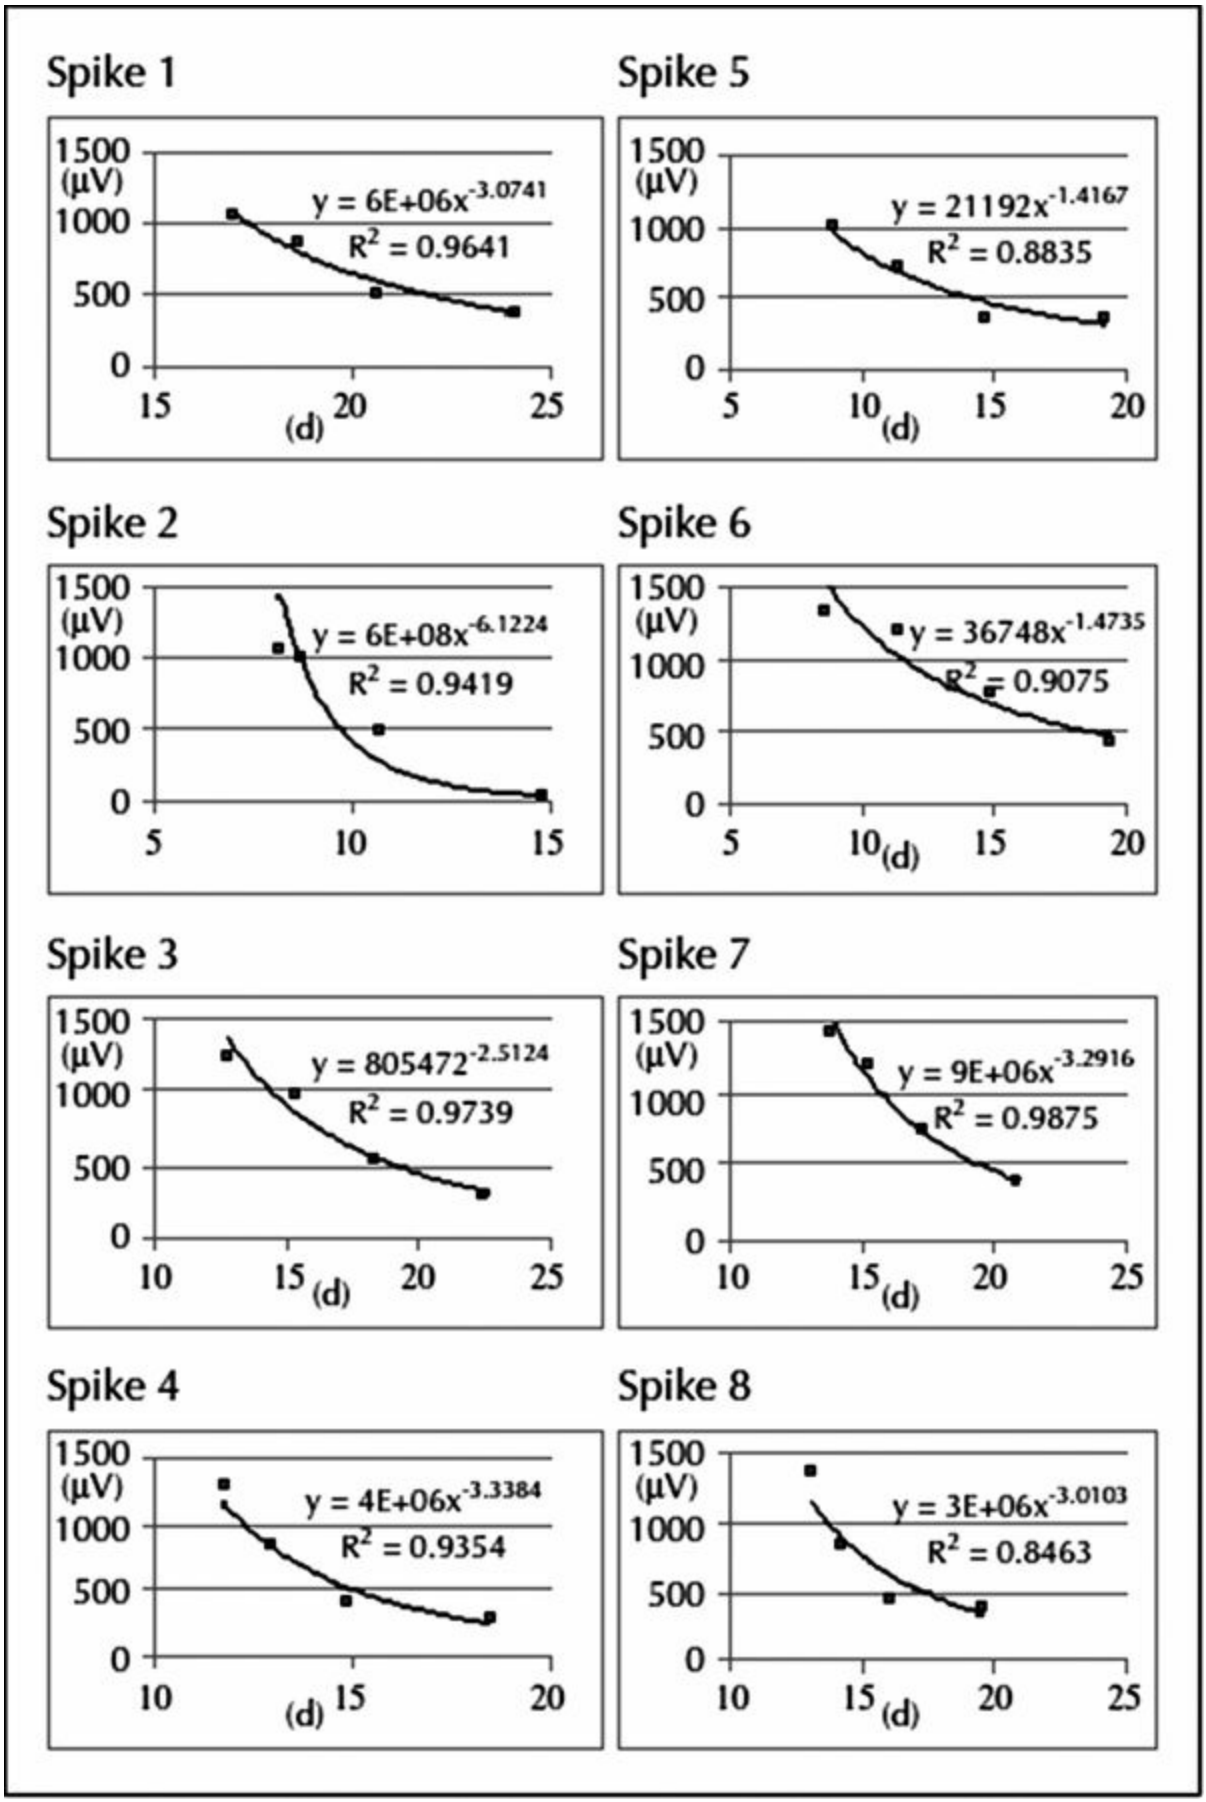

Figure 76.9. Results of the analysis of eight spikes from different locations recorded simultaneously with MEG and SEEG, showing the relationship between the electrical amplitude (μV; y-axis) on each SEEG contact and the distance (d; mm; x-axis) from each spike dipole to the SEEG contacts. The falloff as a function of distance was well approximated by a quadratic function with a high R^2 value (>0.80) for all of the simultaneously recorded spikes. The MEG dipole locations reflect the center of the discharge, and the SEEG contacts detect this activity via volume conduction. (130)

Although generally the focus of magnetoencephalography in epilepsy is on localizing interictal spikes, other forms of analysis can be very helpful. Pathologic slow waves can be localized, especially in patients with structural lesions, as an indication of the epileptic substrate (99–101). Techniques based on an assumption of abnormal connectivity can localize epileptogenic areas even in the absence of any frank spikes (102,103).

MAPPING OF ELOQUENT CORTEX

Since another very important task during preoperative evaluation of epilepsy patients is the identification of eloquent cortical areas nearby the proposed surgical resection, MEG fulfills this second purpose through its functional mapping capability. Functional MRI localization of eloquent areas based on hemodynamic activation (see Chapter 73) has high resolution, but may be difficult in children where the MRI can produce claustrophobia, and parents cannot easily accompany and comfort the child (104,105). Because sensory and motor functions are close to the central sulcus, because the orientation of the current flow is in the tangential direction that MEG is best at recording, and because the areas activated by typical evoked field paradigms are small regions easily modeled by SECD, MEG is especially good at localization of somatosensory and motor cortex.

Evoked magnetic fields (MEFs) are generated using stimuli very similar to those used in the familiar evoked electrical potentials. Magnetoencephalography shares with EEG high temporal resolution, but its chief advantage for mapping is in its high spatial resolution. MEFs are therefore done for localization; unlike electrical EPs, MEF latencies and latency asymmetries are not typically employed to screen for abnormalities. The precision and validity of MEFs in the primary modalities of somatosensory evoked fields (106–108), auditory evoked fields (109,110), and visual evoked fields (111–113) have been well established. The potential evoked by voluntary movement of a single finger, widely used in MEG to map the motor cortex (114,115), produces a complex neuromagnetic response: first, a decrease of beta and a simultaneous movement-related increase in gamma are seen followed by a rebound in beta above baseline, amenable to coherence analysis (116). Higher cortical functions such as language are also amenable to MEG source localization (117–123).

FUTURE OPPORTUNITIES FOR MAGNETOENCEPHALOGRAPHY

MEG is primarily an advanced tool, with availability limited to multidisciplinary epilepsy centers, used in selected patients as described above. The number of centers with MEG capability is increasing, however, and greater reliance on MEG as a screening method has been advocated (30). Furthermore, more compact MEG systems are in preparation making more widespread use of MEG more feasible in the future. Recently, MEG has been heavily utilized as a tool for investigating connectivity (124). In epilepsy, the hypothesis, which drives this approach, is that epileptogenic regions are hyperconnected. Investigation may employ simple measures of coupling of power in various frequencies (125) or coherence (102,126). Research utilizing more advanced methods such as imaginary coherence (127,128) or phase coupling (129) is also being evaluated for their clinical utility.

Although MEG has not yet been prospectively demonstrated to replace invasive recording, MEG

has the potential to change the way that we interpret depth/SEEG recordings in the multidisciplinary environment. In a study examining several cases of simultaneous depth and MEG recordings, Kakisaka et al. (130) showed that intracranial electrical source activity falls off in a logarithmic manner, and MEG can help to clarify confusing ICEEG results (Fig. 76.10) and may help to prevent inaccurate ICEEG interpretations that lead to surgical failure.

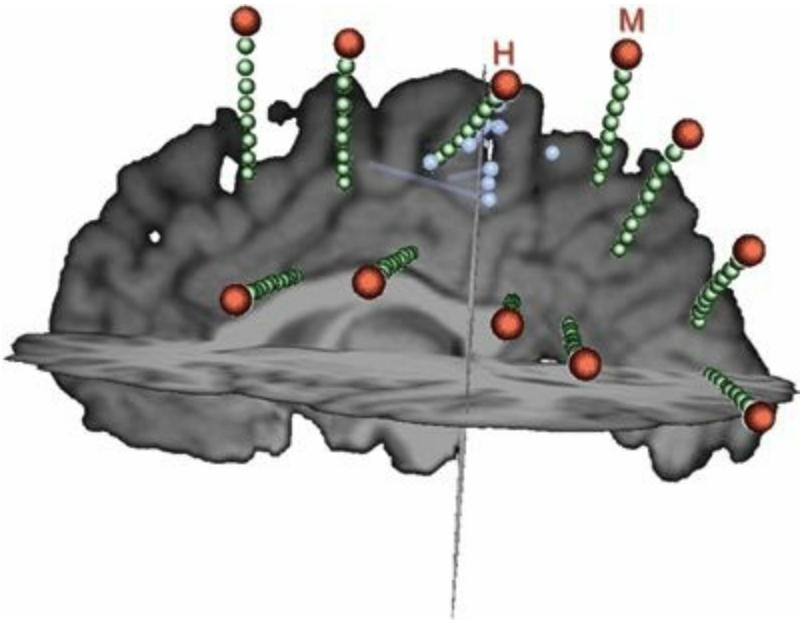

Figure 76.10. During intracranial EEG evaluation in this patient, interictal and ictal discharges were seen over a wide area of SEEG contacts (green), most prominently on several contacts of the H and M electrodes. As demonstrated quantitatively in Figure 76.9, the activity recorded by SEEG drops off rapidly with distance from the source. As seen in this figure, the spacing between SEEG electrodes is substantial. MEG can help to "fill in the gaps" produced by the sparse intracranial electrode coverage. In this case, the MEG localization (dipoles shown as blue spheres and their orientation indicated by blue rods) suggests that the abnormal activity is coming from between the H and M electrodes.

CONCLUSION

MEG is particularly valuable during the evaluation of epilepsy patients when other noninvasive measures (intensive inpatient VEEG monitoring, MRI, and PET) are not concordant or have not yielded a consistent hypothesis. MEG has distinct advantages over EEG for the purposes of precise localization (17), especially in patients with skull defects or when a focal abnormality is suspected, but the EEG appears to show bilateral synchrony. MEG has a higher sensitivity for the detection of epileptic spikes (30,38,44,62,98,130–133), and MEG's ability to precisely localize the epileptogenic zone is superior to scalp EEG (17,30). In some studies (60,61,134,135), MEG has been shown to reduce the need for invasive monitoring. Although MEG cannot completely replace invasive EEG recordings, its use may guide the placement and tailor the design of intracranial investigations, and in some patients obviate unnecessary invasive evaluations.

CHAPTER 77 MRI POSTPROCESSING TECHNIQUES AND CLINICAL APPLICATIONS

Z. IRENE WANG, STEPHEN E. JONES, AND ANDREA BERNASCONI

INTRODUCTION

In the presurgical evaluation of drug-refractory epilepsies, the importance of accurately detecting and delineating an MRI lesion cannot be overstated. Discovering a previously undetected lesion can drastically change the presurgical planning and surgical outcome. The lack of a lesion on MRI has consistently been shown as a predictor for surgical failure (1,2). In contrast, MRI-positive surgical candidates are two times more likely to become seizure free after epilepsy surgery than MRI-negative patients (3).

Although visual inspection of high-resolution MRI can detect a fair number of epileptogenic lesions, such as hippocampal sclerosis (HS) and focal cortical dysplasia (FCD), conventional visual analysis can be quite limited in its ability to recognize the existence and extent of subtle lesions. However, with the advent of advanced MRI acquisition and postprocessing techniques, novel quantitative image analyses can increase the yield of visualized structural lesions relevant to the underlying epilepsies in a sensitive, replicable, and rater-independent fashion, and thus significantly complement conventional MRI visual analysis. In this chapter, we aim to summarize the state-of-the-art image postprocessing methodologies in the context of presurgical evaluation and epilepsy research.

OVERVIEW OF IMAGE PROCESSING

A typical MRI epilepsy protocol usually includes a 3D T1-weighted volumetric acquisition, coronal thin-section T2-weighted and fluid-attenuation inversion recovery (FLAIR) acquisitions, in addition to other sequences. Of these, the volumetric sequences provide exquisite anatomical detail from contiguous thin slices that can be reformatted to any plane; as such, these sequences are usually the most useful for postprocessing. A first step for most image processing methods is correction of MR field inhomogeneity, which causes undesired variation in signal intensity across the image. The next step is alignment of a given image volume to a 3D stereotactic space, which enables comparison of brain structures among different individuals. Large population control averages are generally used as the common reference (4). Importantly, references for adults should not be used to study pediatric cohorts. Subsequently, each voxel is differentiated and classified into tissue classes, primarily gray matter (GM), white matter (WM), and cerebrospinal fluid. Tissue classification and segmentation provide the basis for further analyses such as voxel-based morphometry (VBM), shape analysis, and texture analysis.

VBM has been one of the most popular postprocessing algorithms to date. This fully automated technique extracts GM and WM maps from individuals to make statistical comparisons with respect to a normal database (5). Contrary to methods restricted to a selected brain area at a time, VBM detects structural differences throughout the brain without a priori assumptions (6). An important step in VBM analysis is smoothing of the segmented GM and WM maps with an isotropic Gaussian kernel. Image smoothing reduces variability of individual anatomy and inaccuracies from spatial normalization, therefore increasing the signal-to-noise ratio. In the smoothed images, each voxel represents a weighted average of the neighboring voxels (i.e., GM and WM "concentration"). Importantly, the size of the Gaussian kernel should correspond to the mean size of the abnormality to be detected. Statistical inference is performed using the general linear model allowing for testing of GM/WM changes related to a specific variable. VBM was originally developed to perform group analysis, but it can be optimized to assess structural abnormalities on an individual level.

MRI POSTPROCESSING IN TEMPORAL LOBE EPILEPSIES

HS is the most frequent cause of refractory temporal lobe epilepsies (TLE) and the most frequent pathologic substrate in patients with TLE (7). The primary features of HS on the MRI are loss of volume, loss of internal architecture, and signal hyperintensity on FLAIR and T2-weighted sequences (8–10). Experienced raters generally identify visually obvious HS; however, quantitative postprocessing analysis can reliably detect subtle and bilateral hippocampal abnormalities, as well as cortical abnormalities accompanying HS.

Volumetry

Before calculating hippocampal volume, segmentation of the hippocampus needs to be performed. Manual segmentation of the hippocampus is accurate, reproducible, and able to detect volume loss with a high degree of sensitivity (11,12), which typically involves the hippocampal head and body, as well as the entorhinal cortex in patients with TLE (11). Manual segmentation is, however, time consuming and rater dependent. An increased demand to study large cohorts of healthy and pathologic brains has motivated the development of automated segmentation procedures. Most methods employ deformable (13,14), appearance-based (15), or atlas-based approaches (16). Although automated segmentation algorithms in healthy controls have generally performed satisfactorily, in TLE patients, the agreement between manual labeling and automated segmentation has been relatively low. The reduced accuracy may result from the observation that about 40% of TLE patients show hippocampal "malrotations" (17), that is, atypical shape and positioning of the hippocampus that are mainly characterized by a rounder appearance and atypical orientation of the hippocampus, and an abnormally deep and verticalized collateral sulcus (18–20). A recently developed surface-based multitemplate automated algorithm (21), however, achieved a level of accuracy in TLE patients virtually identical to healthy controls, with submillimeter precision.

Shape Analysis

Visualization of hippocampal shape may extend evaluation to details not evident by measurements of the hippocampal volume. Using a large-deformation high-dimensional mapping method (HDM-LD),

Hogan et al. studied 30 TLE patients with histopathologically confirmed HS and their age-matched controls. The asymmetry in the shape of the hippocampus was studied by forming an asymmetry vector field based on flipping the right-side hippocampal surface to the left side in each patient. The HDM-LD technique showed significant inward deviation in the Sommer sector of the sclerotic hippocampi. Another established method to quantify fine-scale local position and curvature in the hippocampus is through a medial axis model (22,23). This methodology was applied to 88 patients with TLE, 78 patients with malformation of cortical development, and 46 age- and sex-matched healthy controls (24). The analysis of curvature revealed medial bending of the posterior hippocampus in patients with TLE, compared with a superomedial shift of the hippocampal body observed in patients with malformation of cortical development (24).

An extension of shape analysis to adjacent convexities often shows a pathologic relationship. For example, hippocampal malrotation in TLE is associated with increased complexity of the temporolimbic cortices, encompassing parahippocampal, temporopolar, insular, and frontoopercular regions, implying that neurodevelopmental factors may play a role in the epileptogenic process of TLE (20).

Voxel-Based Analyses

VBM has consistently revealed GM reduction extending beyond the atrophic hippocampus, not only the adjacent parahippocampal and anterior temporal regions but also the frontal lobe, suggesting a disruption of frontolimbic pathways. The widespread abnormalities have been shown to be associated with seizure frequency (25), epilepsy duration (26,27), precipitating factors (28), and cognitive dysfunction (29–32). Patients with persistent seizures after removal of the hippocampus may present a more widespread neocortical GM volume loss (33,34).

The sensitivity of voxel-based analysis can also be increased by directly mapping T2 relaxation times, that is, analyzing absolute T2 value rather than the T2-weighted signal. In the vast majority of TLE patients with hippocampal atrophy, T2 relaxation times within the hippocampal GM ipsilateral to the focus have increased by at least 10 ms when compared to controls (35–37). Using a dual-echo sequence (38,39), Bernasconi et al. studied the hippocampal T2 relaxation times of 11 patients with unilateral TLE and no evidence of atrophy on the volumetric MRI (40). More than 80% of these patients exhibited abnormally high T2 relaxation times in the hippocampus ipsilateral to the epileptic focus, suggesting that T2 mapping can provide additional lateralizing information in TLE patients with normal MRI (40).

Pell et al. proposed a voxel-based relaxometry approach that provides an unbiased general search of the whole brain volume and does not require manually drawn regions of interest at the hippocampus. Their approach was tested in 19 TLE patients with unilateral HS and in 38 healthy controls and showed comparable performance to conventional region-of-interest analysis (41).

Cortical Thickness

Bernhardt et al. assessed the reproducibility of neocortical thinning and its clinical significance with respect to surgical outcome in TLE (42). They evaluated 58 TLE patients with hippocampal atrophy on volumetry and 47 TLE patients who had normal hippocampal volumes. In both groups, similar topology and rates of neocortical thinning were found predominantly in frontocentral, temporal, and cingulate regions, demonstrating that static and dynamic effects of epilepsy similarly impact the

neocortex of patients with or without hippocampal atrophy (42). This study also examined temporal changes in cortical thickness in TLE patients with multiple scans, showing progressive cortical thinning in the frontal lobes. The cortical thinning was found to be significantly larger in patients with ongoing seizures than in patients with controlled seizures, providing compelling evidence that TLE is a progressive disorder (42).

MRI POSTPROCESSING IN EXTRATEMPORAL LOBE EPILEPSY

In extratemporal lobe epilepsy (ETLE), FCD is the most common pathologic substrate underlying patients undergoing epilepsy surgical evaluation (43). FCD is also the most common underlying pathology in epilepsies with apparently normal MRI (44). Typical MRI findings of FCD include indistinction of gray–white junction, T2/FLAIR cortical signal abnormality, T1 cortical signal abnormality, abnormally thickened cortex, and subcortical T2/FLAIR abnormality. FCD lesions are generally much more difficult to detect compared with other types of lesions, as they can be quite subtle with small sizes, appearing buried in the complex convexities of the neocortex. Given the practical constraints of time, MRI readers may miss lesions that are only discerned with increased scrutiny. This is especially problematic when noninvasive clinical data, such as scalp EEG and semiology, do not point to a specific area. Thus, MRI readers lack a testable anatomic hypothesis, and subsequently the study may be read as negative. Under these circumstances, a whole-brain MRI postprocessing technique directing the reader's attention to potentially dysplastic abnormalities may prove to be essential. Another advantage of MRI postprocessing for the neocortex is that it operates in 3D. This allows the simultaneous consideration of information from consecutive slices, whereas conventional visual analysis examines the brain volume one slice at a time, and therefore requires a high level of expertise to synthesize information from consecutive slices.

Voxel-Based Analyses

Several studies have applied VBM on T1-weighted volumetric MRI to detect FCD in individual patients. In patients with MRI-visible FCD, increase in GM concentration colocalized with the lesion in 63% to 86% of cases (45–50). Increased sensitivity tends to be associated with an increase in false-positive results. Practically, balance between sensitivity and specificity may be achieved on a case-by-case basis. When there is an a priori hypothesis based on clinical and EEG data to confine the analysis to a certain brain region, one may opt for maximal sensitivity; whereas when EEG or other functional imaging data do not point to a region of interest, it is essential to eliminate false positives and opt for maximal specificity. In addition to colocalizing the lesions, VBM studies consistently reported GM abnormalities extending beyond the visible FCD, sometimes distant from the epileptogenic area (47–49,51,52). In the absence of false positives in normal controls, these changes could be due to occult dysplastic regions undetectable by visual analysis or represent an abnormal gyration (48). It is also conceivable that these changes may potentially become active at a later stage and cause seizure recurrence after surgery (53). It would be thus advisable to interpret the significance of structural abnormalities beyond the primary structural lesion in relation to electroclinical data and functional imaging modalities.

Quantitative MRI contrasts such as T2 relaxometry, double inversion recovery, and magnetization transfer ratio imaging have yielded 87% to 100% sensitivity in patients with MRI-visible FCD;

however in patients with a negative MRI, the sensitivity was reported to be <30% (51,54–56). Consistent with the VBM studies, signal changes outside the putative epileptogenic zone were found in 6% to 42% of patients (51).

Computational Models of FCD

Computer-based models, first introduced by Bernasconi et al. (57), can be generated to search for the distinctive morphologic characteristics of FCD on MRI. Enhancement of the GW junction blurring has been used to detect subtle cortical malformations (58–60) and can provide helpful information in patients with MRI interpreted as negative using conventional visual analysis (58,61,62), as illustrated in Figure 77.1.

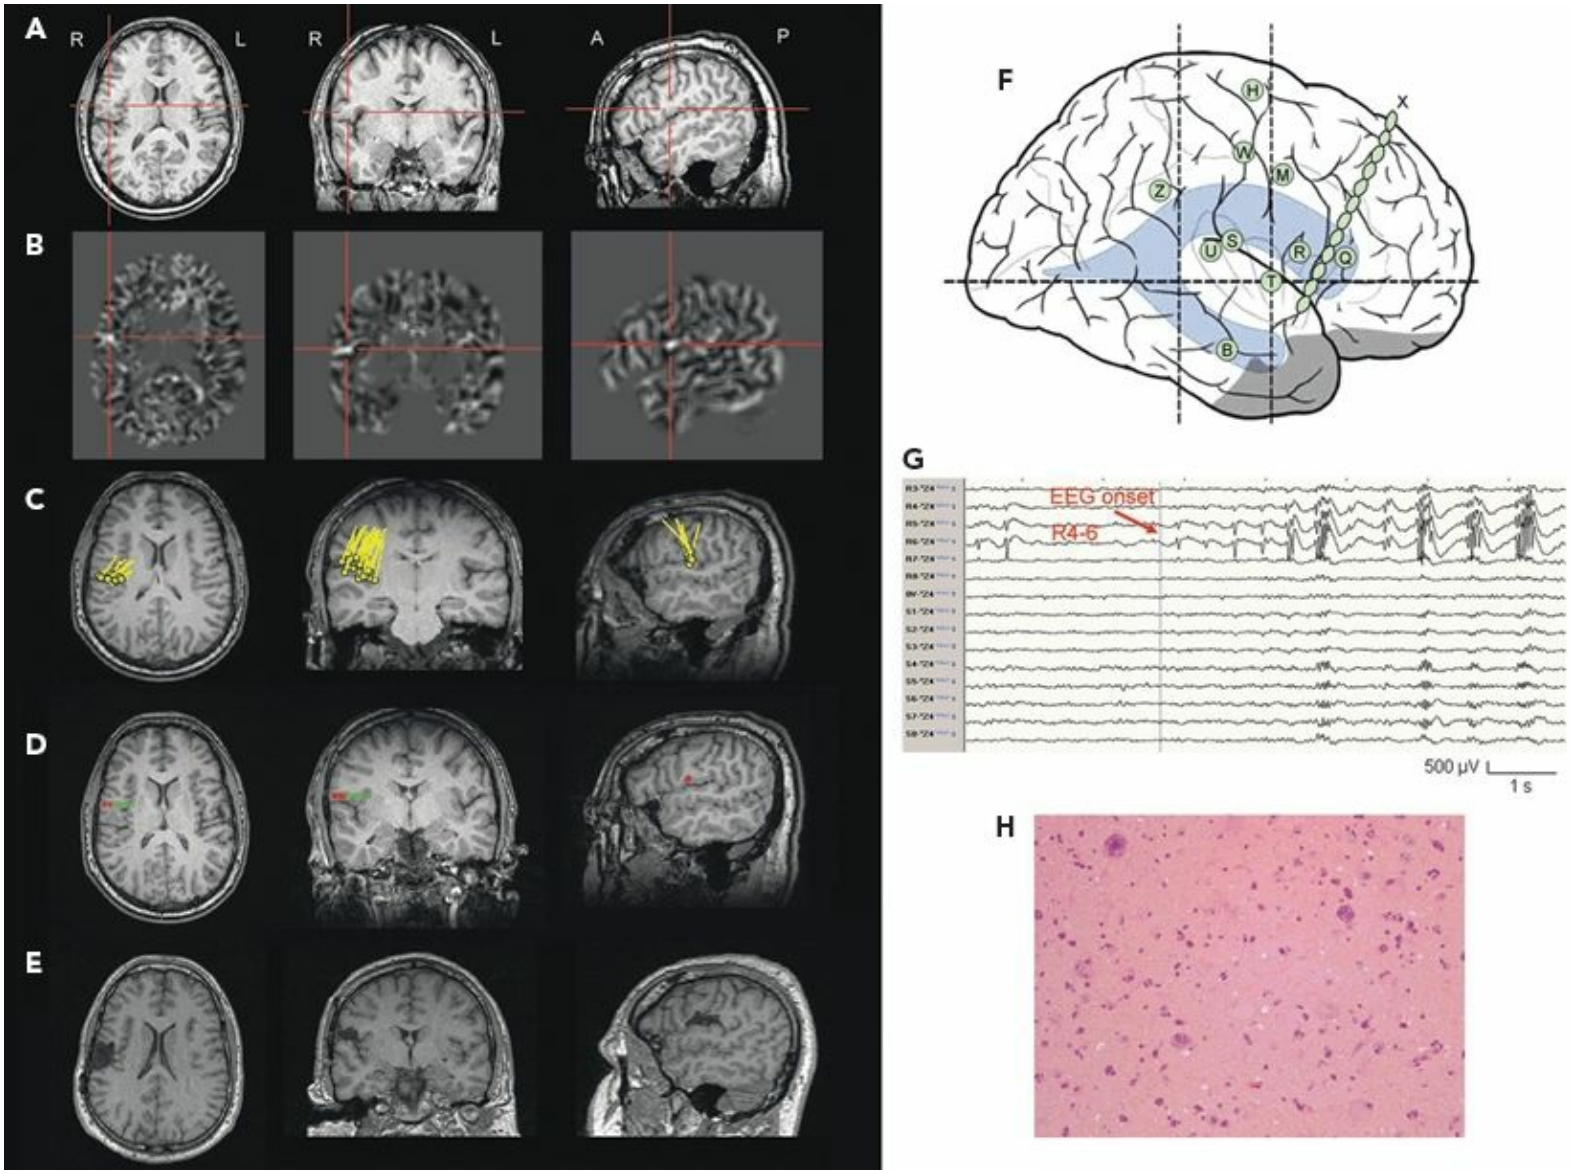

Figure 77.1. A 30-year-old male presented with pharmacoresistant seizures preceded by an aura of a tingling sensation deep in his throat, spreading to his left face, and then followed by left face clonus with occasional left arm posturing. Scalp EEG monitoring did not reveal any ictal anomaly. Previous high-resolution 3-tesla MRI was reported as normal. An FDG-PET study showed subtle hypometabolism involving the right frontal and temporal operculum. Ictal SPECT was nonlocalizing. MRI postprocessing of the GW junction was performed on 3D T1-weighted volumetric sequence. Review of the GW junction feature map led to the identification of a structural abnormality at the right frontal operculum ($z > 4$), as shown in **(B)**, coregistered with the patient's MRI in **(A)**. This abnormality is concordant with magnetic source imaging interictal dipole localization **(C)** and seizure onset on stereo-EEG **(D)**. Limited resection (**E**) included the abnormality and rendered the patient seizure free. **F:** Stereo-EEG (SEEG) implantation schema. **G:** Ictal onset on SEEG. R4-6 corresponds to red contacts in **(D)**. Stimulation of R4-6 induced the habitual seizure of the patient, with the same

ictal EEG pattern as shown in **(G)**. **H:** Histopathology showing features of FCD ILAE type IIb with balloon cells (HE; original magnification = 200×). To date, the patient has been seizure free for more than 4 years.

Quantifying cortical thickening and signal hyperintensity, in addition to evaluating gray–white matter transition, provides a more comprehensive analysis of the complex and variable morphologic anomalies related to the various forms of FCD (63). Bernasconi et al. proposed morphologic and first-order texture models creating 3D maps of cortical thickness, gradient (transition between GM and WM), and a relative intensity operator designed to emphasize T1 signal hyperintensity. The first-order texture models were then combined into a single composite map to optimize visibility. In a group of 16 patients with histologically proven FCD, visual analysis of the composite map increased sensitivity by 30% when compared to conventional MRI visual analysis, while maintaining a high specificity (57). Figure 77.2 illustrates the application of first-order texture models to a patient with frontal lobe epilepsy.

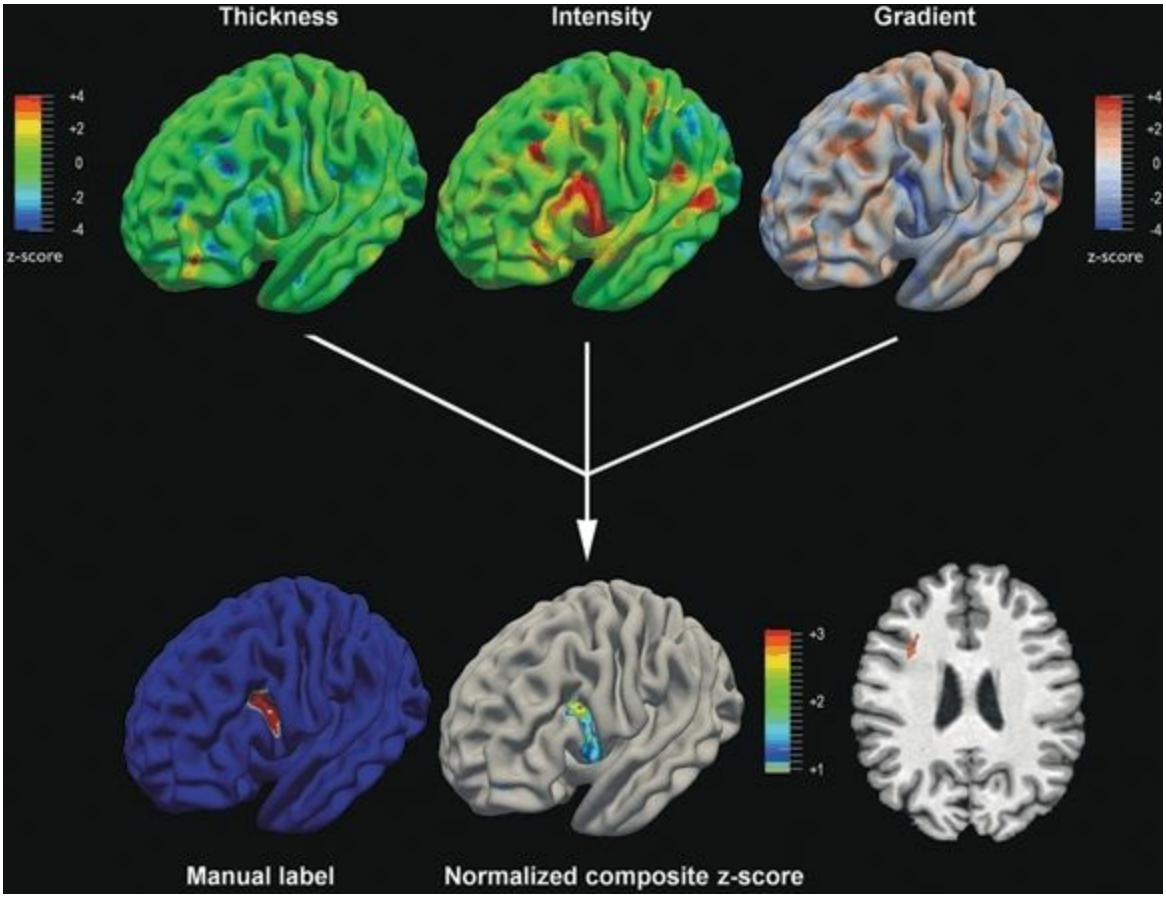

Figure 77.2. In this patient with frontal lobe epilepsy, high-resolution 3-tesla MRI was reported as normal, likely because of the subtle nature of the dysplasia, as demonstrated by the coronal T1-weighted MRI section (**right lower corner**, red arrow). The upper panels display the T1-weighted derived computational models normalized with respect to controls (z-score maps). The cortical thickness map is unremarkable. Conversely, the gray matter intensity map and the gradient map (modeling gray–white matter blurring) show significant anomalies. The normalized composite map identifies the lesional area as the only anomaly compared to controls and shows almost identical overlap with the lesion label obtained trough manual segmentation. Histopathology of the surgical specimen confirmed the diagnosis of FCD ILAE type IIb.

In a subsequent study of 23 patients with histologically proven FCD by Colliot et al., FCD lesions were characterized by simultaneous GM thickening, hyperintense signal, and blurring of the GM–WM transition in 78% of the patients. In all patients, the FCD lesion had at least two of these three characteristics. These MRI postprocessing features occurred regardless of the lesion volume, and they characterized not only large FCD lesions but also subtle ones that had been overlooked by visual

inspection (64).

Antel et al. reported further development of this approach consisting of second-order texture analysis to quantify tissue organization through quantification of spatial relationships of gray-level intensity pairs that is less apparent to the human eye (65). Second-order features, including angular second momentum, contrast, and difference entropy, were used to develop automated pattern recognition using a novel two-stage Bayesian classifier to perform FCD lesion detection. This fully automated technique was applied to a group of 18 patients with histologically confirmed FCD, and correctly detected the FCD in 83% of them. In contrast, conventional visual MRI analysis was able to detect the FCD in only 61% of patients (65).

Notably, consistent with findings from voxel-based methods, computer-based models have revealed structural abnormalities that did not colocalize with any EEG abnormalities (62,65,66). Inspection of the feature maps revealed that these abnormalities exhibited patterns similar to FCD; however, visual analysis of these regions on the original structural MRI did not show any FCD. Given the absence of false-positive findings in normal controls, combined with report of diffuse or nonfocal cortical involvement in FCD (66–69), these clusters may indicate dysplastic abnormalities much more widespread across the hemispheres than the changes visible on the MRI and may explain, at least in part, why in some cases complete resection of MRI lesion does not always lead to seizure freedom.

MRI-visible FCD is sometimes considered the "tip of the iceberg" as the extent of the underlying structural pathology often goes beyond it. The exact delineation of the spatial extent of an FCD lesion carries significant clinical relevance as it can guide surgical resection. Colliot et al. proposed an automated method to segment FCD lesions on T1-weighted MRI using a combination of deformable models (70). In this approach, a feature-based level set driven by known MRI characteristics of FCD first separates lesions from nonlesional tissue. A second deformable model, designed to expand the previous result toward the cortical boundaries while preventing lateral intracortical motion into healthy tissues, finalizes the lesion segmentation. The quantitative evaluation in 18 FCD patients demonstrated strong agreement with expert manual labels (70).

Sulcal Morphometry

Sulcal and gyral abnormalities in ETLE patients are characterized by a spectrum of changes ranging from clefts of various depth to broad gyri (71), shallow or deep sulci, or gyral simplification (72,73). In the absence of visually discernible cortical thickening and GM blurring, these sulcal morphologic signs may be the only marker for cortical dysgenesis (71). Besson et al. reported that 85% of small FCD lesions that elude visual inspection were found at the bottom of an abnormally deep sulcus (74). Local weakness within the developing cortical mantle, co-occurrence of incomplete maturation, decreased neuronal density, and disrupted connectivity in the areas surrounding the FCD may play a role in the mechanism underlying this presentation (43,75). Regis et al. utilized a sulcal root/meridian parallel model for automated extraction, identification, and statistical analysis of cortical sulci (76). This approach was tested in a small series of MRI-negative patients with frontal lobe epilepsy, in whom subtle abnormal gyration patterns were found in the epileptogenic zone. Interestingly, small FCD not detected with MRI was found on histopathology, particularly in the depth of the posterior superior and intermediate frontal sulci (76).

CHALLENGES AND FUTURE DIRECTIONS

The detection of cortical abnormalities in patients with nonlesional epilepsy represents a considerable challenge for the future. The sensitivity to detect lesions that are undetectable by conventional MRI has been shown to increase proportionally to the number of techniques employed, suggesting that each contrast interrogates specific aspects of tissue structure. As subtle FCD lesions may only differ slightly from the normal cortex, a multivariate framework may be necessary to assess the combined sensitivity of various contrasts (43).

In the context of presurgical evaluation, results of MRI postprocessing will need to be confirmed with modalities that can characterize the pathophysiologic features of suspicious imaging findings, such as EEG, magnetic source imaging, PET, or SPECT. This is particularly important in the presence of multiple abnormalities detected by postprocessing, as illustrated in Figure 77.3. Understanding of postprocessing-positive structural changes outside the putative epileptogenic zone will require further correlative studies with electrophysiology, pathology, and long-term surgical follow-up.

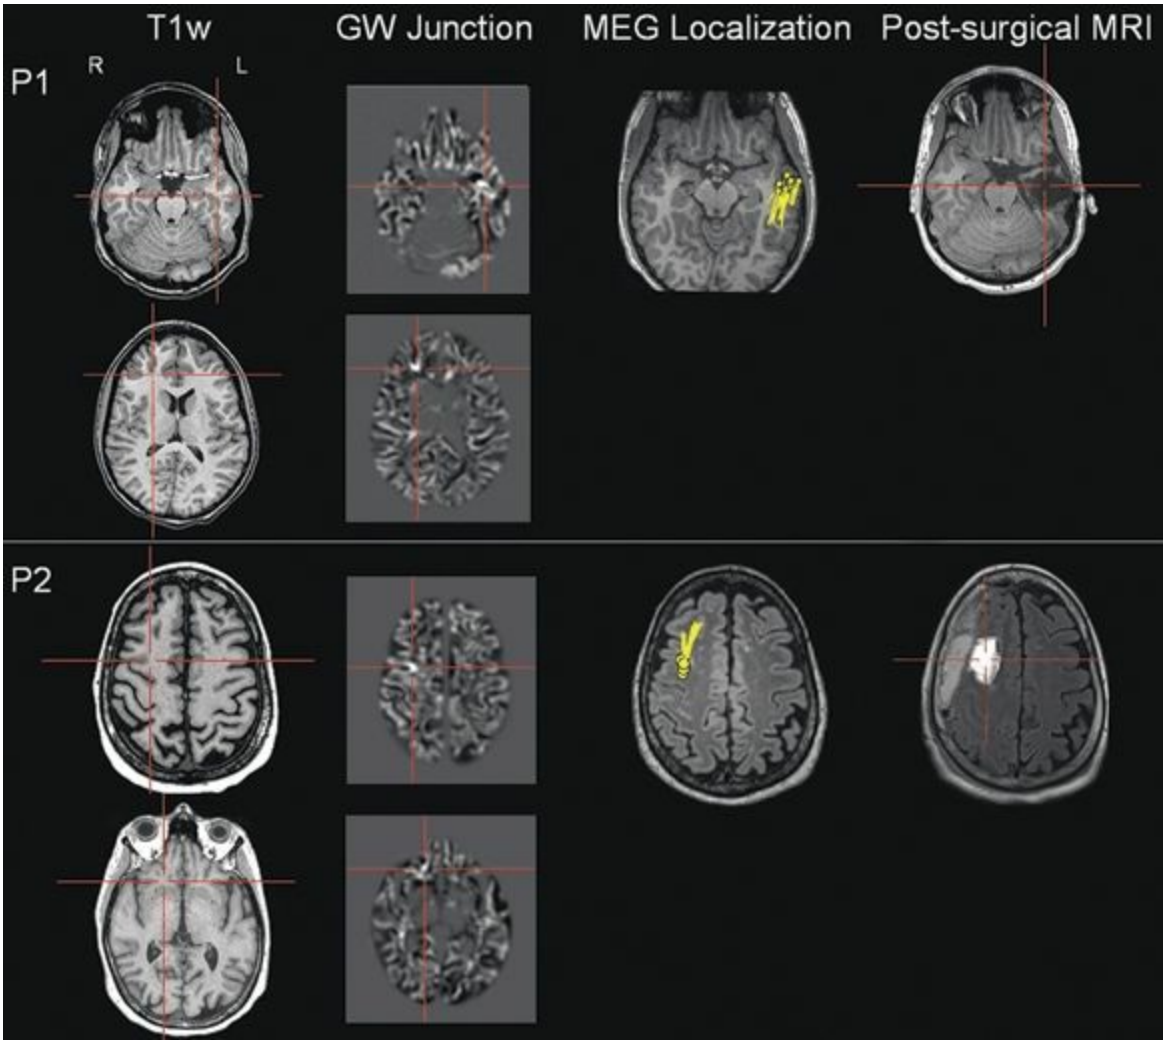

Figure 77.3. These two patients (P1 and P2) illustrate the importance of correlating MRI postprocessing findings with an electrophysiologic measure. For both patients, high-resolution 3-tesla MRI was reported as normal. In P1, scalp EEG evaluation showed left temporal interictal spikes, and ictal onset was in the left temporal and right centroparietal regions. In P2, scalp EEG evaluation showed right frontocentral interictal spikes, and ictal onset was in the right frontocentral and right temporoparietal regions. Within each panel, the conventional T1-weighted images are in the first column; the MRI postprocessing results of the GW junction are in the second column; the magnetic source imaging (MSI) localization is shown in the third column; the postsurgical MRI is shown in the last column. Each patient had two $z > 4$ abnormalities indicated by the GW junction feature map from postprocessing, but only one

MSI focus. The abnormality concordant with the MSI focus was resected and led to seizure freedom in both patients (follow-up >12 months).

Improved spatial resolution and tissue contrast provided by ultra–high-field (7T) MRI is going to continue to expand the power of image processing. This will allow refining further the in vivo patterns of brain pathology within anatomically and functionally distinct areas and may provide the basis for more accurate histopathologic correlative studies (77). Future studies are needed to evaluate whether 7T MRI can provide additional diagnostic information in patients with a subtle, overlooked dysplastic lesion at lower field strengths.

CONCLUSION

Improving noninvasive localization is paramount in the surgical treatment of refractory epilepsies. As a noninvasive and cost-effective approach, MRI postprocessing is promising because unlike visual assessment, it provides quantitative, reliable, and reproducible data. For patients with lesions too subtle to be detected by conventional MRI visual analysis, MRI postprocessing techniques, integrated by a multimodality approach with other functional measures, allow for more accurate identification of epileptogenic abnormalities. Thus, MRI postprocessing techniques have the potential to increase the diagnostic yield of MRI in any epilepsy center utilizing a standardized epilepsy protocol on a 1.5-T or 3-T scanner. Moreover, these techniques have the potential to reveal the extent of cortical abnormalities invisible to the eye, which could further improve surgical outcomes. It is our hope that MRI postprocessing techniques will be used as an important complement to the test battery of existing presurgical evaluation in an increasing number of epilepsy centers.

CHAPTER 78 DIFFUSION TENSOR IMAGING (DTI) AND EEG-CORRELATED FMRI

BEATE DIEHL AND LOUIS LEMIEUX

Magnetic resonance imaging (MRI) techniques have greatly improved our ability to investigate the structure and function of the epileptic brain (1). Detecting possible underlying structural abnormalities or causes of epilepsy is one important aspect of such advances, and currently pathologic lesions are identified in about 80% of all refractory focal epilepsies (2). In addition, novel imaging results are being explored to inform about cortical function or dysfunction in patients with epilepsy, as well as correlates of the ictal-onset zone and irritative zone (3).

The objective of epilepsy surgery in pharmacoresistant focal epilepsies is the complete resection or at least disconnection of the epileptogenic zone while preserving eloquent cortex (2,4). This chapter focuses on the contribution of two novel imaging technologies to optimize surgical results. Diffusion tensor imaging (DTI) is a novel MRI technology that allows measurement of water diffusion in the brain tissue, providing information of microstructural changes. In addition, white matter architecture and tract morphology can be interrogated allowing for the first time to reconstruct major tracts in vivo.

The simultaneous recording of electroencephalographic (EEG) and functional MRI (fMRI) was first demonstrated in patients with epilepsy in the early 1990s and has since become an important research tool in epilepsy and beyond (5). Simultaneous EEG–fMRI (or simply "EEG–fMRI") is uniquely capable of providing data to address the question: What patterns of hemodynamic change take place throughout the brain (5) in relation to epileptiform discharges seen on scalp EEG? For interictal pathologic activity, simultaneous EEG is indispensable while ictal hemodynamic changes can be studied meaningfully without reference to concurrent EEG in some patients. Although EEG–fMRI has been primarily used as a localization technique, it can be combined with ever more advanced modeling methodologies to study the dynamics of networks. Together, both technologies may allow for novel insights in understanding the ictal-onset zone, irritative zone, and functional deficit zone.

DIFFUSION MR IMAGING

Principles of Diffusion Imaging

The MRI signal results from the radio frequency excitation of water protons in tissue. In a medium without any boundaries, the random translational motion or brownian motion of water molecules results from the thermal energy carried by these molecules. In the brain, however, such diffusion is

restricted by intra- and extracellular boundaries. Various animal models have been used to assess the most important boundaries affecting diffusion in the brain, revealing that myelin is the main barrier to water diffusion (6–9).

The principles of diffusion MRI were first developed in vivo in the mid-1980s (10,11). In diffusion-weighted imaging (DWI), images are sensitized to diffusion by using pulsed magnetic field gradients incorporated into a standard spin echo sequence (10,12). Taking measurements in at least three directions allows for characterization of the mean diffusion properties within a voxel in the image.

By applying diffusion gradients in six or more directions, the diffusion tensor, a mathematical construct, can be calculated. This allows assessing not only the amplitude of diffusional motion but also the directionality (13–15). The fact that diffusion is not the same in the three main spatial directions, but is asymmetric in the brain and restricted in certain directions, gave rise to the concept of "anisotropy" (13,16). DTI has been developed to explore this directional information and to gain greater insights in the structural changes, possibly on a microscopic level. Fractional anisotropy (FA) is a scalar (unitless) index most commonly used to assess the overall degree of directionality; it ranges from 0 (full isotropy) to 1 (complete anisotropic diffusion). Diffusion in different directions, such as parallel (main direction of diffusion) and perpendicular to the main fiber tract orientation, can be studied. Together, these quantitative measures help to characterize the integrity of the underlying white matter and may allow the understanding of the pathophysiologic mechanisms consistent with such diffusion abnormalities.

Exploring white matter changes in epilepsy, how they relate to epileptogenicity, and whether they may be a surrogate marker for cognitive difficulties is a matter of ongoing research. Furthermore, DTI in combination with tractography has become a powerful opportunity to subdivide compartments of white matter representing different tracts and study their diffusion properties selectively.

Experimental Insights into Tissue Structure Using DTI

Several animal models of tissue injury and degeneration have been used to measure serially diffusion changes and correlate them carefully with histology. Using an in vitro model of wallerian degeneration in frog sciatic nerve, axonal and myelin degeneration causes a decrease in diffusion anisotropy due to reduced parallel and increased perpendicular diffusivity (9). Myelin has been shown to modulate perpendicular diffusivity (7,8), although it is not the only factor involved (17). In humans, reductions in the principal direction and increases in radial diffusivities have been shown in chronically degenerated white matter tracts (18). Serial DTI measurements in three patients who underwent corpus callosotomy to treat medically refractory seizures and drop attacks revealed interesting insights into the diffusion changes in the corpus callosum after the surgery (19). An initial decrease in parallel diffusivities evidencing the breakdown of the axons (19,20) is followed in the chronic stage (2 to 4 months later) by an increase of the radial diffusivities as myelin sheath degeneration is noted. Water molecules become more mobile perpendicular to the axons, resulting in an increase in radial diffusivities.

Tractography

Lastly, anisotropy information forms the basis of reconstructing tracts. Anisotropy in white matter results from the organization of tissue as bundles of axons and myelin sheaths run in parallel, and the

diffusion of water is freer and quicker in the long axis of the fibers than in the perpendicular direction (17). By assuming that the largest principal axis of the diffusion tensor aligns with the predominant fiber orientation in an MRI voxel, we can obtain vector fields that represent the fiber orientation at each voxel. The three-dimensional reconstruction of tract trajectories, or tractography, is an extension of such vector fields (21). However, tractography only came into use in the late 1990s, due to the complexities to develop reliable computer algorithms to reconstruct the tracts. Some of the limitations and technical difficulties of tractography include the spatial resolution of DTI, which is in the order of several millimeters, as well as noise. Various acquisitions and postprocessing analysis techniques have been proposed (21), and methods continue to evolve. Voxel sizes are much larger than the resolution needed to image single axons. Hence, in vivo DTI studies can, at present, only display an approximation of the main tract direction and do not have a resolution even close to a cellular level. White matter tractography is generally done in two different ways, either with a method known as "deterministic" tractography or with a "probabilistic" method. Using deterministic methods, seed points are placed, and the tract grows in both directions along the dominant diffusion direction. This requires a preset threshold for angles and FA, and track is terminated when it reaches a voxel with subthreshold FA, or when the turning angle exceeds this threshold. As the main direction of water diffusion is used for tract reconstruction, crossing fibers will not be represented, and only the main tracts and its main direction will be displayed. The probabilistic methods probe fiber orientation distributions at each voxel and are computationally more intensive, but can more reliably reconstruct crossing fibers.

To date, atlases have been published of anatomical correlation of the DTI-based FA maps and tractography results (22–24), which are largely based on comparison to anatomical drawings and dissection maps.

There is no doubt that validation is of central importance for the development of tractography; how to validate and against what gold standard is a matter of debate.

Peri-Ictal DWI and DTI Changes in Humans

DWI has initially been introduced in clinical practice for the early detection of stroke. It has proven to be very sensitive to areas affected by ischemia (10). Subsequently, peri-ictal and postictal changes in diffusivity have been observed in animal models of status epilepticus and in patients both after status epilepticus and after single short seizures. Systematic investigations of diffusion changes in rats following bicuculline-, kainic acid–, and pilocarpine-induced status epilepticus have highlighted changes closely correlated with the presumed area of seizure onset and with the resulting histopathologic changes. Furthermore, such changes are dynamic, leading initially to restricted diffusion due to cytotoxic edema and, after several days, to normalization or facilitated diffusion (25–28). Diffusion imaging may, therefore, provide an opportunity to directly image the areas involved in seizure generation and possibly spread.

The first report of diffusion changes in a patient with focal status epilepticus was published in 1997 (29). Status consisted of clonic jerking of the right leg, which continued for 22 days and was followed by transient paresis. DWI during status showed decreased diffusion in the motor cortex of the right leg (Fig. 78.1) and an area of facilitated diffusion in the underlying white matter. This was explained by a shift of water into cortical neurons at the site of the seizure focus, that is, cytotoxic edema that is associated with restricted diffusion and vasogenic edema with a shift of water in the extracellular space in the underlying white matter (30).

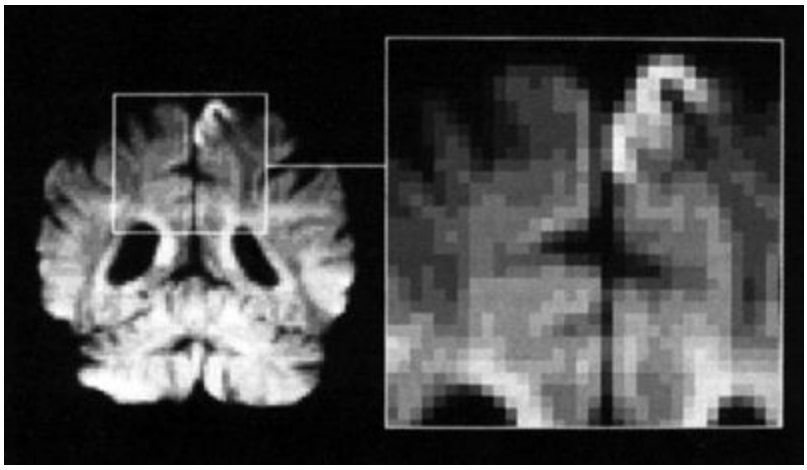

Figure 78.1. Area of restricted diffusion in the left superior frontal gyrus shown in a patient with right leg clonic status epilepticus. (From Wieshmann UC, Symms MR, Shorvon SD. Diffusion changes in status epilepticus. Lancet. 1997;350(9076):493–494, with permission.)

Following this case report, multiple systematic investigations have explored peri-ictal DWI in an attempt to assess the usefulness of this novel technology to delineate the ictal-onset zone. Overall, the presence of dynamic diffusion changes has been documented in the majority of cases, but the correlation between the presumed epileptogenic zone and the diffusion changes is quite variable (31–35). Correlations seem closer in patients with longer seizures (or status) and short duration between seizure end and scan (31,33). A single case report in man confirms that restricted diffusion is a marker of the ictal-onset zone: An area of restricted diffusion adjacent to the lesion in the right frontal lobe in a patient with repetitive prolonged focal motor seizures corresponded to the region of focal electrocorticographic seizures that was mapped intraoperatively (36).

Studies using DTI to study peri-ictal changes allowed for comparison of the sensitivity of diffusivity changes versus anisotropy changes and to assess whether DTI provides higher sensitivity to seizure-induced changes. The results remain rather disappointing, and it has become apparent that dynamic changes affected the diffusivity to a much higher degree than the directionality (32). Peri-ictal mean diffusivity reductions are seen in about half of the patients investigated, but only a relatively small proportion (20%) colocalized with the presumed ictal-onset zone, even when patients were scanned within 45 minutes after the seizure (35). In addition, whole-brain analysis using statistical parametric mapping (SPM) revealed distant areas of diffusivity change, possibly highlighting the network involved in ictal spread.

In order to minimize delays between seizure and scanning, flumazenil was used to induce seizures in patients assessed for epilepsy surgery (37). Despite almost immediate MRI scanning, diffusivity decreases were seen in the hippocampus on the seizure-onset side and in both parahippocampal gyri.

Therefore, it seems possible that diffusion changes after single seizures appear more transient and require immediate access to scanning. If in the future such an environment can be provided, in combination with higher-resolution scanning and possibly also higher field strengths of MR scanners, postictal studies may be of higher yield.

Interictal DTI and DWI Changes

Temporal Lobe Epilepsy

Patients with mesial temporal lobe epilepsy (TLE) due to hippocampal sclerosis reveal increased diffusivity in the ipsilateral hippocampus, indicative of structural disorganization and expansion of extracellular space, reflecting neuronal loss and other microstructural changes (38–43). These changes parallel the abnormalities noted on conventional MRI scans with atrophy and T2 signal increase. When assessing DWI compared to conventional MRI using volumetric T1 acquisitions and FLAIR, it was not more sensitive in detecting hippocampal sclerosis (40). In addition, in patients without lateralizing differences between the hippocampal formations, both hippocampi often showed increased apparent diffusion coefficient compared to a control population, indicating bilaterality of the disease. Such bilateral abnormalities are present throughout the limbic system, including fornix and cingulum in both adults (44,45) and children (46).

When patients with TLE were evaluated using a region-of-interest approach, diffusion abnormalities extend into the ipsilateral hemisphere and even into the contralateral hemisphere (44,45,47–50), as has recently been summarized in a meta-analysis of 13 studies comparing white matter tracts ipsilateral and contralateral to the epileptogenic temporal lobe to controls (51). Such more widespread changes have been confirmed using voxel-based approaches, which compare one individual to a group of normal controls and thus do not have selection bias to a particular region of interest (50). These changes are not reversible after successful temporal lobectomy, which may suggest structural abnormalities as opposed to functional changes due to seizures (52).

DTI can also identify abnormal areas in temporal and extratemporal focal epilepsy with normal conventional MRI. Out of 30 patients, increases in diffusivity were found in 8 patients (26%), and 6 of the 8 diffusivity alterations were in the presumed epileptogenic zone (53). In addition, group analysis of nonlesional left TLE patients revealed increased diffusivity and reduced anisotropy within the ipsilateral temporal lobe; the right TLE group displayed a trend in the same direction (53). Although such a group effect is not helpful in an individual patient, it suggests that given greater sensitivity and increased signal-to-noise ratios, an effect in individual patients may be demonstrated. Overall, such occult lesions are most likely caused by disruption of white matter architecture due to dysgenesis or by seizure- related damage leading to atrophy, gliosis, and expansion of the extracellular space, resulting in increased diffusivity and potentially also decreased anisotropy.

Extratemporal Lobe Epilepsy

Case numbers of extratemporal epilepsies in the presurgical epilepsy workup are rising, and these cases are often challenging as precise localization of the epileptogenic zone in relation to cortical function is mandatory. Diffusion changes are seen in a variety of lesions associated with focal epilepsy and often localize outside the temporal lobe, such as cortical dysplasia.

Reductions in anisotropy and increase in diffusivity within the MRI visible lesion and also outside of it have been reported in a variety of cortical dysplasias (54,55). Reductions in FA in most patients in normal-appearing white matter surrounding dysplastic lesions are likely due to gliosis, axonal loss, poor myelination, or increased cell bodies (e.g., ectopic or abnormal neurons, balloon cells). In addition, distant anisotropic changes can also be observed, possibly due to wallerian degeneration of tracts or gliosis resulting from chronic seizures. Investigations on the impact of cortical dysplasia on connectivity and adjacent tracts showed decreased tract size and displacement of tracts in larger dysplasias, as well as rarefaction of subcortical connections surrounding cortical dysplasia (56). Figure 78.2 shows altered connectivity in a patient with right temporooccipital epilepsy, with polymicrogyria and heterotopic gray matter in the same region.

Probing Diffusion Changes: What Can It Tell Us in Human Epilepsy

Analyzing the pattern of diffusion changes with respect to diffusivities parallel and perpendicular (radial) to the main axonal direction provides in vivo insights into the underlying cause of diffusivity increase and decreased FA. Several studies revealed that the most commonly seen pattern of DTI changes associated with focal epilepsy was unchanged parallel diffusivity and increased perpendicular diffusivity (45,47,48,57,58). As detailed above, such a pattern of FA changes seen in most studies evaluating DTI in TLE is most consistent with chronic wallerian degeneration, possibly due to cell loss in the temporal lobe secondary to seizure-induced cell death.

In order to evaluate potential mechanisms for such more widespread diffusion changes in TLE, it was investigated if different underlying pathologies as determined by preoperative MRI cause differential diffusion changes (45). Patients with TLE and hippocampal sclerosis were compared to nonlesional TLE: While some white matter bundles are affected equally in both forms of TLE, abnormalities of the bundles directly related to the mesial temporal structures (i.e., the fornix and cingulum) appear to be unique to TLE with hippocampal sclerosis.

It has been demonstrated that DTI can be used to delineate the neurocognitive correlates of localized white matter damage in TLE, such as working memory (59), visual and verbal memory, and language dysfunction (57,60), and research into such structure function relationships is ongoing.

Interictal DTI and DWI Changes: Conclusion

Interictal DTI highlights areas of abnormal diffusion measures in temporal and extratemporal lobe epilepsies, both lesional and nonlesional. Specifically, mean diffusivity appears more sensitive to changes seen in patients with chronic refractory epilepsy compared to FA. The only exception may be cortical dysplasias. DTI abnormalities are seen in all areas, indicating pathology on conventional MRI. In addition, DTI changes may often be found outside the lesions, both contiguous and less frequently also noncontiguous to the lesion. Abnormalities mostly with increased diffusivity and reduced FA have also been found in patients with cryptogenic focal epilepsy. Analysis of water diffusivity changes reveals a pattern of increase in perpendicular diffusivity and not of parallel diffusivity. This may indicate wallerian degeneration as one of the main mechanisms accounting for the structural changes underlying the DTI abnormalities remote from focus and lesion.

Such abnormal areas in patients with intractable epilepsy, therefore, probably represent structural disruption, possibly reflecting either an underlying pathology or gliosis due to secondary damage. This requires further study with MRI–histology correlation in more patients.

Interictal DTI and Irritative and Ictal-Onset Zone

Close correlations between the interictal abnormalities highlighted using DTI, pathology, and epileptogenicity are rare. Intracranial recordings in a patient with cryptogenic focal epilepsy showed seizure onset in the right orbitofrontal region, colocalizing with an area of abnormal diffusivity (61), and postresection pathology revealed gliosis. Of note, however, is that this patient is not completely seizure free.

Few papers have evaluated in detail the concordance between diffusion abnormalities and irritative zone and ictal-onset zone as evaluated using invasive recordings. Two studies have used voxel-based statistical approaches to highlight areas of abnormal diffusion in a small number of patients undergoing stereo-EEG evaluations (62,63). In one study (63), 13 of the 16 patients were found to have DTI abnormalities. DTI abnormalities consisted mainly of increases in mean diffusivity and were concordant with the epileptogenic zone in seven. FA abnormalities added little in localization. The specificity of DTI abnormalities was better in extratemporal lobe epilepsy: 20% of TLE had congruent findings, whereas four of five extratemporal epilepsies concurred.

Another study investigated 14 patients with frontal lobe epilepsy (9 nonlesional), and almost all patients showed areas of increased diffusivity (62). In this study, the sensitivity of diffusion imaging in defining regions that were the site of electrical abnormalities was about 57% for the area of seizure onset and 65% for the irritative zone, and the specificity was low. It is of note, however, that areas of diffusion abnormalities may not have been sampled, as coverage is necessarily limited with stereo-EEG. An interesting aspect in this study is that lesional epilepsies had very high sensitivity, as the lesion led to diffusion abnormalities, but very low specificity. In nonlesional epilepsies, cases in which epileptologists may particularly turn to novel imaging for additional support of a hypothesis for invasive recordings, three out of the nine patients had diffusion changes in the seizure-onset zone.

Overall, the limited data available suggest that diffusion changes correlate better with areas of interictal spiking than the ictal onset. Furthermore, the presence of DTI abnormalities certainly does not mean that the seizures are arising in the vicinity. However, DTI changes may provide some additional information to guide placement of invasive electrodes. Interestingly, a recent study using a surface-based laminar analysis of gray and white matter showed differential findings regarding diffusivity in the seizure-onset zone (64), compared to healthy controls. In 18 children with nonlesion extratemporal lobe epilepsy, such analysis revealed increased diffusivity in the cortical gray matter,

most pronounced in the outer fraction of the gray matter, also involving the white matter underlying the epileptic cortex. The electrographically normal cortex, in contrast, showed decreased diffusivity in inner and middle cortical fractions compared to controls. The authors speculated whether this may be indicative of surround inhibition.

In conclusion, data remain sparse and correlating electroclinical abnormalities using invasive recordings with diffusion changes may allow for better insights in the future.

Tractography and Epilepsy Surgery

DTI is the first imaging modality that allows direct noninvasive visualization of white matter tracts. Several investigations have focused on retrospectively correlating DTI-based tractography with postoperative deficits, to assess if this technology could provide predictive information for a deficit and could maybe even aid in preservation of function if such information were integrated in neuronavigation systems. Anterior temporal lobectomies can cause a contralateral superior quadrantanopsia in up to 10% of patients by disrupting Meyer loop. The anterior extent of Meyer loop has large interindividual variability and cannot be visualized using conventional imaging (65). Tractography has been used to demonstrate the optic radiation in normal subjects (66), and its use was subsequently explored for temporal lobectomies (67,68) and the anteroposterior extent of the damage to Meyer loop as determined postoperatively correlated well with the degree of visual field loss (68). Pre- and intraoperative DTI-based fiber tracking (69) showed significant correlation between the fiber tracking estimation and the outcome of visual field deficits after surgery.

These data provide evidence that tractography has the potential to inform about risks of epilepsy surgery procedures. Once successfully implemented into neuronavigation systems, this information may also be used intraoperatively to tailor resections (70). Aside from the technical issues of performing tractography in health and disease, the intraoperative brain shift after craniotomy is another significant impediment. The availability of intraoperative MRI may represent one method to correct for this movement and may improve the accuracy of the data to aid surgical planning.

Extratemporal surgeries will also benefit from visualizing crucial connections and tracts such as the pyramidal tract. Implementation of DTI-based tractography has already been shown to benefit patients undergoing brain tumor surgeries and resections of vascular malformations (70–74) and will certainly be increasingly used in epilepsy surgery.

EEG–fMRI

Up to now, the localization of the generators of interictal epileptiform discharges (IEDs) has been mainly addressed through EEG and magnetoencephalography (MEG), techniques with exquisite temporal resolution. fMRI offers good spatial resolution and localization of events that are accompanied by a blood oxygen level–dependent (BOLD) response (5). A question that must be addressed first when considering fMRI as an epilepsy localization tool is whether epileptiform paroxysmal events (interictal and ictal) are associated with detectable BOLD signal changes. In this regard, evidence from multiple sources including visual observation of the cortex during surgery, PET, SPECT, and near-infrared spectroscopy (NIRS) is conclusive: Seizures are commonly accompanied by regional hemodynamic changes. In the case of interictal discharges, the above techniques are unsuitable, some due to their fundamentally limited temporal resolution (PET, SPECT) and others due to limited spatial sensitivity profiles, such as NIRS. fMRI with its temporal resolution

of the order of a few seconds and excellent whole-brain mapping capability may offer a way to map out hemodynamic changes throughout the brain linked to short events from individual IEDs, to runs of spikes, and sharp waves to seizures. Importantly, fMRI's localization capability is independent of the extent or complexity of the involved brain region or regions, in contrast to EEG/MEG source analysis, and therefore may be more capable of revealing their full extent. The EEG is used as an indicator of events of interest, such as spikes or ictal discharges, from which a model of the fMRI signal is derived a posteriori and used for analysis of the fMRI time series data. The adjunct of simultaneous video can provide important information for the fMRI modeling (75).

fMRI of Spontaneous Brain Activity: Data Acquisition, Analysis, and Interpretation

In the following paragraph, we discuss some of the main technical aspects, applications, and findings of fMRI used to map spontaneous hemodynamic changes in patients with epilepsy. In most studies, the patient is asked to lie in the scanner with eyes closed and whole-brain scanning is performed in the expectation of capturing events of interest, usually interictal discharges, although drugs have been used in a small number of studies to modulate epileptiform activity specifically for the purpose of fMRI (76,77). Because of the random nature and temporal characteristics of epileptic activity, the fMRI data thus acquired are commonly analyzed within the framework of event-related designs, in contrast to the more conventional block designs used in many cognitive studies. This is done using the EEG (and video, when available) as a basis for modeling the variations in the BOLD signal related to epileptic activity. For this purpose, short epileptiform discharges such as single spikes have been likened to, and represented mathematically as, brief stimuli. As described in Chapter 79, the BOLD response to brief stimuli develops and resolves over a period of roughly 25 seconds, generally peaking between 5 and 7 seconds, and then undershoots the baseline slightly, roughly 15 seconds poststimulus, before returning to baseline, and is therefore essentially biphasic (i.e., it has positive and negative phases); this is the hemodynamic response function (HRF) (78). We note that a substantial amount of intersubject and interregional variability of the HRF in healthy subjects has been documented (79). The possibility of deviation of the shape of the HRF in patients with epilepsy due to the effects of pathology or other factors has implications for the technique's sensitivity and potential clinical usefulness. Furthermore, the choice of an accurate representation of the HRF is greater for the detection of regions of BOLD change in event-related designs than for block designs. Importantly, event-related designs are generally less efficient than block designs for the detection of BOLD changes.

Before embarking on a review of the application of EEG–fMRI in focal epilepsy, we discuss a small number of fMRI studies of seizures for which concurrent EEG was not used.

fMRI of Seizures (Without Concurrent EEG)

fMRI data acquired in the resting state have been used to map BOLD signal changes linked to ictal or peri-ictal events. The lack of concurrent EEG means that the analysis and interpretation of the fMRI is heavily reliant on clinical changes observed during the events and the use of this information for the labeling of scans as being ictal or interictal. Apparent BOLD changes were revealed by subtraction of scans acquired at baseline from scans acquired during motor seizures in a child (80). In one study (81), the authors identified patterns of signal change in the absence of any overt ictal activity, and

these changes were consistent with invasive localization. In another case report, ictal signs identified in relation to scan acquisition times were used to plot T2* signal changes relative to a baseline value voxel by voxel, revealing regions of signal increase and decrease preceding and during the motor seizure (82). Federico et al. (83) studied preictal fMRI changes based on visual observation without concurrent EEG in two cases. Regions of signal change were identified by comparing blocks of scans immediately preceding the seizures to blocks acquired 3 to 5 minutes before ictal onset. Inspection of the signal time course in those regions and "control" regions revealed patterns suggestive of specific preictal BOLD increases and decreases to a lesser extent taking place around 10 minutes before seizure onset in one case, similar to a case in which EEG was recorded during fMRI. Although interesting, this type of analysis of fMRI data is suboptimal in many respects such as potential subjectivity of the identification of the event onset (and the resulting model of the BOLD signal) and possible bias associated with physiologic and scanner-related artifacts (5).

EEG-Correlated fMRI: The Technique

While the clinical manifestations may be used as event markers for seizures, this is not the case for subclinical events such as IEDs. Therefore, the study of the hemodynamic changes associated with IED necessitates the recording of EEG during fMRI. Concurrent EEG, and video, may help in the interpretation of ictal events for the purpose of fMRI modeling. The technique that consists in the simultaneous acquisition of EEG and fMRI data is commonly referred to as EEG-correlated fMRI, or EEG–fMRI. Due to the various interactions between the two technologies, data quality and patient safety are serious concerns and have been the subject of a large amount of work since the first ever EEG recording took place inside an MR scanner (84). The main problems are pulse-related and image acquisition artifacts on EEG, image artifacts due to passive components (EEG leads and electrodes) and active components (EEG amplifier/digitizer) (85).

While many developments have led to the commercialization of EEG recording systems capable of providing the investigator with basic tools capable of producing good quality data for some applications, such as EEG–fMRI of visually identifiable IED, EEG and image data quality continue to preoccupy many users partly because some problems may never be completely solved (e.g., pulse-related artifact on EEG) and partly because the application boundaries continue to be pushed (increasing scanner field strength, study of ever more subtle EEG features, etc.). Therefore, EEG–fMRI data acquisition continues to be a field of development and investigators undertaking EEG–fMRI investigations in epilepsy are advised to obtain continuous technical support.

EEG–fMRI of Seizures

Although potentially most relevant for presurgical localization, the study of the hemodynamic changes during ictal patterns is problematic due to safety concerns, and the rarity and unpredictability of seizures in most patients mean that ictal EEG–fMRI studies are generally fortuitous. Once such data have been acquired, their analysis is made difficult due to the effects of head motion, the long duration of the events (same time scale as some fMRI artifacts), and the uncertain relationship between clinical and EEG manifestations on one hand and the pathologic neurophysiologic activity on the other. Nonetheless, based on simple fMRI modeling assumptions, ictal EEG–fMRI has shown BOLD increases often of larger amplitude and extent than interictal patterns and associated higher yield* than interictal EEG–fMRI. For example, using a flexible modeling strategy adapted to long

events, a large, electroclinically concordant BOLD increase was revealed in relation to a single subclinical seizure (86). In a patient with multiple seizures, a similarly concordant pattern of BOLD increase was revealed with large contralateral areas of simultaneous BOLD decreases (87). In a series of eight selected cases with malformations of cortical development (MCD) in whom seizures were studied using EEG–fMRI, the relationship between ictal and interictal BOLD patterns and MR-visible lesions seemed to reflect the specific pathology; for example, in cases with nodular heterotopia, there was a tendency for the ictal BOLD changes to involve the overlying cortex (88). In a recent series of patients recruited specifically for the purpose of studying preictal and ictal hemodynamics, typical seizures were captured in 20/55 cases (89). Across the group, there was a tendency for widespread preictal fMRI changes, followed by more localized, often in the vicinity of the confirmed or presumed seizure-onset zone, hemodynamic changes at onset and subsequent spread during seizure evolution.

*…Yield: proportion of cases in which significant event-related BOLD changes are revealed.

†…The actual delay may have varied due to the manual nature of the process, but an uncertainty of the order of ±1 second would be of little consequence given the time scale of BOLD changes.

EEG–fMRI of Interictal Epileptiform Discharges

The overwhelming majority of cases studied using EEG–fMRI have focused on revealing BOLD changes linked to IED. The primary aim of early studies in patients with focal epilepsy has been the demonstration of IED-related changes to localize the generators of the discharges, with the focus gradually shifting to the study of the details of the BOLD map localization in relation to other tests (MRI, EEG, etc.) and other aspects of these patterns such as the sign of BOLD change.

Two variants of the technique have been used for this purpose: IED-triggered fMRI and the more flexible and now widely used continuous EEG–fMRI. In IED-triggered fMRI, the MR acquisition, usually of a single image volume, was started following the identification of a spike or sharp wave; a fixed delay of a few seconds between spike and scan was employed, calculated based on the assumption that IED-related BOLD change will follow the course of the normal HRF.† A set of images acquired following IED were compared to images acquired following periods of background EEG. Such studies revealed significant BOLD increases in a large proportion of cases mostly concordant with the presumed or suspected generator localization (76,77,90–94). We note that these studies largely ignored the possibility of IED-related BOLD decreases. The finding of BOLD increases in expected locations in the majority of cases in which IED were captured confers a degree of validity to the assumption that IED-related changes are roughly in line with the HRF derived from physiologic stimuli in healthy subjects, peaking at around 6 seconds postspike.

Due to the appeal of having access to the entire EEG record during scanning, IED-triggered fMRI has now been superseded by continuous EEG–fMRI that was made possible by EEG scanning-related artifact correction algorithms (95,96). In continuous EEG–fMRI, scans are acquired without interruption resulting in a continuous time series of scan data. Importantly, the analysis of continuous EEG–fMRI data to reveal regions of increase or decrease BOLD signal related to events of interest (e.g., pathologic EEG discharges) is based on building models (general linear model [GLM]) of the BOLD signal over the entire scanning session, which can be challenging due to spontaneous changes in brain state at rest (97,98).

The analysis of EEG–fMRI is commonly based on conventional, visual EEG interpretation by expert observers and therefore suffers from the same limitations, although the impact of this

subjectivity has not been thoroughly investigated (see (5) for a review of the technique's principles and limitations; see (99) for a rare study on the impact of EEG interpretation on the fMRI results). Using this approach in selected case series in focal epilepsy, and assuming that the IED-related HRF does not deviate substantially from the norm, regions of statistically significant BOLD signal changes were revealed in around 70% of the cases in whom IEDs were captured during scanning sessions with durations of the order of 40 to 60 minutes (90,100). Overall, the pattern of BOLD increases and decreases is often complex, although the localization of the BOLD increases tends to match the presumed or confirmed IED generator localization. BOLD decreases tend to be more remote and less representative of the IED field distribution (100,101). In TLE, a similar mix of BOLD increases and decreases involving the ipsilateral and contralateral (homologous) cortex was observed (100–102), with a consistent pattern of BOLD decrease in the precuneus (103), reminiscent of the so-called default-mode network (Fig. 78.3) (104).

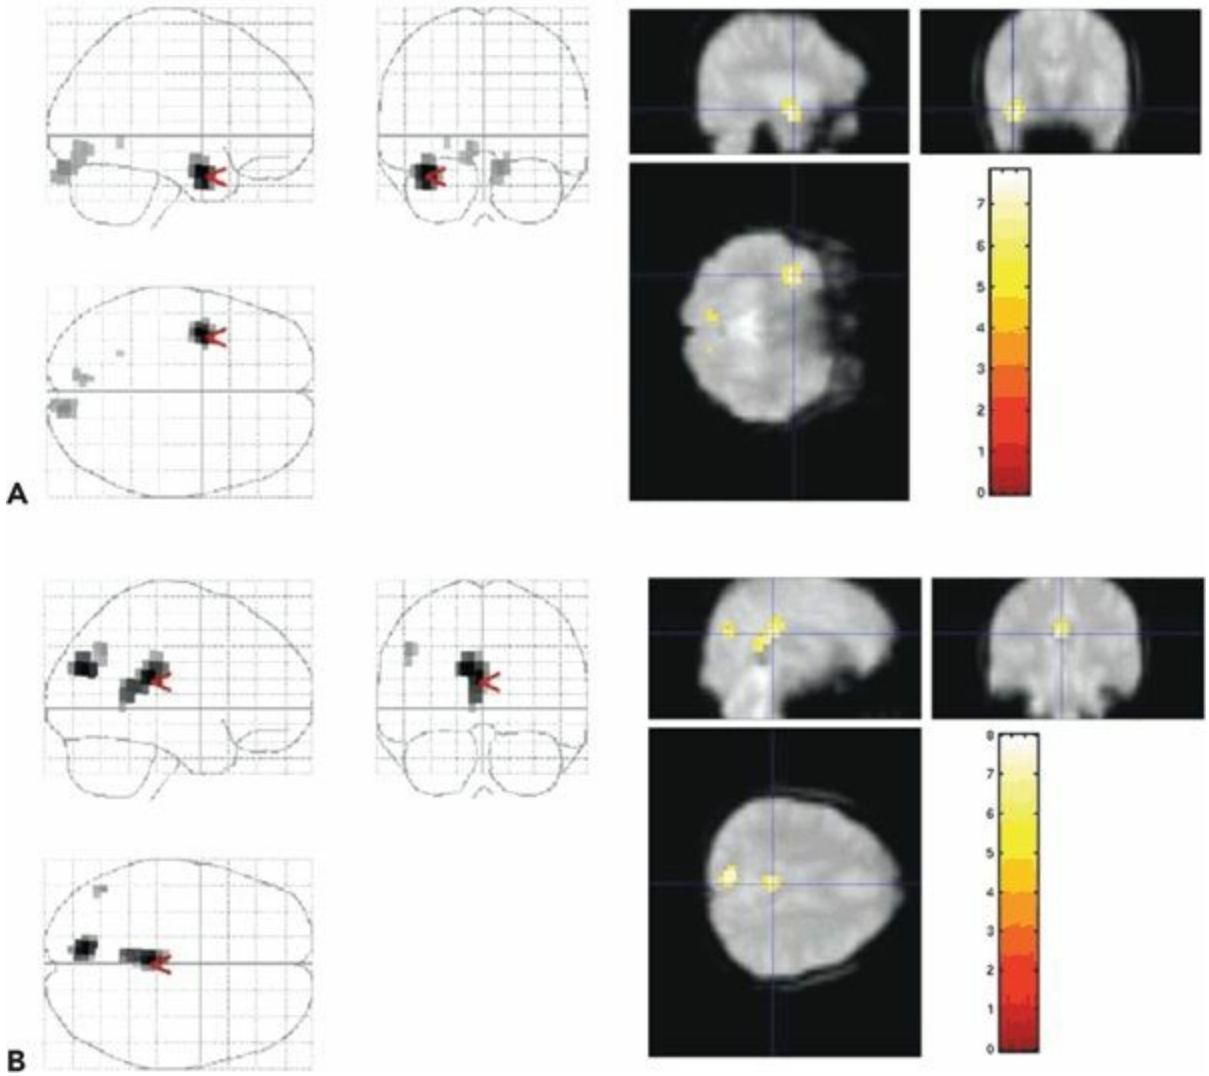

Figure 78.3. IED-related BOLD changes. Patient with left hippocampal sclerosis and left temporal IEDs who underwent EEG–fMRI. **A:** BOLD increase in the left temporal lobe with smaller clusters in the occipital region. The red arrow and cross hair represent the location of the most significant BOLD change. The left of the figure shows all statistically significant BOLD changes superimposed onto the SPM "glass brain." The right of the figure shows parasagittal, coronal, and axial sections through the EPI data at the location of the statistical maximum. **B:** Retrosplenial BOLD decrease associated with the same IED. This effect, which is thought not to represent activity of the source of the spike seen on EEG, is commonly observed in relation to interictal activity in the temporal lobe. (From Salek-Haddadi A, Diehl B, Hamandi K, et al. Hemodynamic correlates of epileptiform discharges: an EEG-fMRI study of 63 patients with focal epilepsy. One of the advantages of continuous EEG–fMRI over spike-triggered fMRI is that it allows one to estimate the shape of the IED-related HRF, which is important if deviations from the norm are suspected with potential impact for analysis sensitivity. This can be done by using different sets of functions instead of the canonical HRF such as Fourier expansions or series of gamma functions (105–107). The results of this type of study are somewhat conflicting and differences of opinion persist on the best approach for modeling IED-related BOLD changes in terms of sensitivity. For example, a study has revealed BOLD signal changes seemingly preceding IEDs mostly generalized in nature; these have been labeled "noncausal" (107). However, the specificity of such deviations is uncertain. On the other hand, it has been shown that rare statistically significant deviations from the normal HRF, such as time course with a peak earlier than the normal 6 seconds postevent, are mostly remote from the presumed generators and suggestive of data-fitting artifacts (108) and, perhaps most importantly, that no notable increase in yield results from the inclusion of causal noncanonical HRF in the GLM (100). Deviations from the causal relationship: EEG abnormality → time-locked BOLD change may be particularly relevant in studies of seizures (83) where it is known that scalp EEG often does not reflect the earliest electrophysiologic changes. No such evidence, from simultaneous scalp and intracerebral measurements, for example, exists for interictal discharges to our knowledge.

Comparisons of the localization of IED-related BOLD changes with spike source analysis based on high-density EEG have been performed as a form of cross-validation. Comparisons of fitted point dipoles or more sophisticated distributed source model with IED-related BOLD clusters from spike-triggered fMRI data showed a relatively coherent pattern of spatial concordance and the complementary and valuable nature of the information derived from the two techniques, although the agreement criteria and fMRI modeling and source imaging procedures vary greatly between studies (109–113). When considered, the sign of IED-related BOLD change‡ did not significantly affect the degree of concordance with the presumed or confirmed generators (111,113).

‡…Taken in this context to be the sign of the first or dominant peak (or through) of the average IED-related BOLD time course relative to baseline.

Comparisons of IED-correlated fMRI maps and intracranial EEG findings have also been performed in the spirit of cross-validation. An early study in a small group of patients showed that in cases where one electrode was located near BOLD clusters, at least one of the electrode contacts showed epileptiform activity (109). In a series of 25 patients with drug-resistant epilepsy from 3 epilepsy centers, the localization of interictal scalp EEG–fMRI was compared to intracranial EEG (13 cases) and/or localization of resected tissue and surgical outcome (21 cases) (114). Using a novel technique designed to tackle the problem posed by the relatively frequent occurrence of the absence of IEDs on the EEG recorded during fMRI (usually limited to around 30 minutes), the authors proposed to map the hemodynamic correlates of EEG patterns derived from IEDs recorded outside the scanner. Using EEG topographic maps derived from clinical long-term EEG recordings, and by calculating their spatial correlation with topographic maps calculated from the intra-MRI EEG as a function of scan time, Gouiller et al. showed a quasi-doubling of sensitivity and good anatomical concordance with the "gold standard" localization particularly for lateral temporal and extratemporal epilepsy.

EEG–fMRI has been used to study the characteristics of the IED-related BOLD changes in specific pathologies (115–117). In relation to gray matter heterotopia and MCD, variability in the BOLD patterns was in line with previous findings, with a tendency for BOLD increases within the pathologically abnormal regions and decreases generally but not exclusively more remote from the abnormality (116,117). The neurobiology of the observed patterns remains to be fully elucidated, but

IED-related BOLD decreases in MCD have been attributed to either a loss of neuronal inhibition in the presence of normal neurovascular coupling in the regions surrounding the abnormality or abnormality of neurovascular coupling. Similar patterns of IED-related BOLD signal changes were revealed, involving the lesion and remote regions in patients with cavernomas (118) and tuberous sclerosis (in children) (119).

While the promising results of studies comparing localization based on EEG–fMRI to other forms of localization, the technique's role in presurgical evaluation remains unknown. To our knowledge, no prospective randomized, controlled trial has been performed to assess the efficacy of imaging techniques for the purpose of presurgical evaluation to date, and this also applies to EEG–fMRI (120). In a group of 29 patients in whom surgery could not be offered based on the results of routine investigations, clusters of significant IED-correlated BOLD signal change concordant with presumed seizure focus were revealed in eight cases (121). In four patients, the BOLD maps consisted of multiple clusters, in line with the results of other tests. In the other four cases, the BOLD maps consisted of a single cluster, two of which were concordant with intracranial EEG, allowing surgery to be considered. Based on this evaluation as a second-line technique, the authors suggested that EEG–fMRI can play a significant role in presurgical evaluation.

In a series of 23 patients with FCD, sensitivity was 95% of the 12 cases in whom IEDs were recorded during fMRI (122). The authors found that widespread, discordant regions of IED-related hemodynamic change reflected widespread seizure-onset zone and were associated with poor surgical outcome. Further evaluation of the role of EEG–fMRI as part of the panoply of presurgical localization tests is required.

CONCLUSION

DTI and EEG–fMRI offer novel and complementary information to localize the epileptogenic zone. EEG–fMRI's unique characteristics among functional imaging techniques make it likely to make a strong contribution to the definition of the irritative zone and of the ictal-onset zone in a smaller proportion of cases. However, its role in focus localization and contribution to the presurgical evaluation remains to be determined.

DTI may increase the sensitivity of MRI to lesions and improve our understanding of the local and remote impacts of the epileptogenic lesion on pathways and networks. In addition, it may help us better understand the often progressive cognitive changes seen in uncontrolled focal epilepsy and the functional deficit zone. Whether this information will be useful in predicting deficits following epilepsy surgery is unknown. MRI tractography will be increasingly used for neuronavigation during epilepsy surgery and may help limit surgical morbidity. Lastly, combining tractography and EEG–fMRI may provide novel insights in propagation of epileptic activity and for identifying effective and functional connectivity between cerebral areas involved in the epileptic network and the structural basis of this. With its greater ability to capture widespread, multifocal epileptic generators than EEG/MEG, EEG–fMRI may have a specific role as a predictor of more complex surgical cases. However, continued active research is required to translate these impressive advances in neuroimaging to improved outcomes.

CHAPTER 79 LANGUAGE AND MEMORY MAPPING

JEFFREY R. BINDER AND CHAD CARLSON

INTRODUCTION

The effectiveness of surgery for the treatment of drug-resistant epilepsy is well established, and side effects of surgery are usually minor. The most common cognitive side effects are relative loss of naming ability and relative decline in verbal episodic memory ability, each of which occurs in roughly 50% of patients who undergo left temporal lobe resection. Because not all patients show these declines, and most epilepsy surgeries are elective, it is appropriate to offer patients an individual assessment of risk whenever possible. Risk of naming and memory deficits is inversely correlated with the severity of temporal lobe pathology, which is related in turn to such factors as age at onset and duration of epilepsy, baseline preoperative naming and memory performance, and structural imaging (MRI, PET, SPECT) biomarkers. In addition, the risk of naming and verbal memory decline is correlated with hemispheric lateralization of these functions; thus, functional mapping of language and memory has an important role to play in the preoperative assessment of risk. Language mapping may also have a role to play in guiding the placement of resection boundaries to spare critical functional zones.

Over the past two decades, functional magnetic resonance imaging (fMRI) has become widely used for both lateralization and localization of language, largely supplanting the intracarotid anesthesia (Wada) test. Compared to the Wada, fMRI is noninvasive and therefore safer, provides more precise localization, and is considerably less expensive. The bulk of this chapter will review current evidence supporting the validity of using fMRI for preoperative risk assessment. There may remain, however, important indications for the Wada test in selected cases, and an algorithm is proposed for identifying such cases. The chapter concludes with an overview of other techniques used for language mapping, including magnetoencephalography (MEG), cortical stimulation mapping (CSM), and electrocorticography (ECoG).

FMRI LANGUAGE MAPPING

fMRI is based on neurovascular coupling, wherein focal increases in neural activity produce focal increases in cerebral blood flow. Increased blood flow results in a net decrease of deoxygenated hemoglobin in the affected capillary and venous beds, which causes the ambient magnetic field in these regions to become more homogeneous (deoxyhemoglobin is paramagnetic; i.e., it produces a microscopic perturbation of the magnetic field). This local “smoothing” of the magnetic field leads to a focal increase in the MRI signal measured with acquisition sequences that are sensitive to field inhomogeneity, or T2*. This link between neural activity and MRI signal, called the blood oxygen level–dependent (BOLD) effect, is the basis for nearly all fMRI. Because it depends on changes in

blood flow that develop over several seconds, BOLD fMRI is a hemodynamic imaging method and lacks the temporal resolution of EEG or MEG.

An important fact to emphasize is that fMRI measures relative changes in BOLD signal; thus, fMRI activation maps represent a difference between conditions, not absolute levels of activity in a single condition. An fMRI result can only be defined by specifying at least two conditions (often referred to as the activation condition and the baseline) under which the BOLD signal was measured. A frequent error is to mistake the quiet, "resting" state as a true baseline with little or no neural activity. In reality, the conscious resting state involves a large amount of neural activity, much of it reflecting internal use of language and conceptual knowledge (1). For example, people often plan or imagine future or past activities when they are at "rest," and these planning and imagining processes require retrieval of concepts (and words) for things, people, and events. Consequently, fMRI protocols that try to identify language zones by comparing a speaking or speech listening task with a resting baseline are likely to identify mainly motor and auditory cortices rather than language zones (2).

Another important point to stress is that fMRI language protocols vary substantially; there is no single standard task contrast for mapping language areas with fMRI. This reality reflects, in part, the fact that language is not a single process, but rather a set of distinct processes supported by somewhat separable (though highly interacting) brain networks. Some of these processes and their neural substrates are discussed briefly below.

Phoneme Perception

Speech is composed of complex and rapidly changing auditory signals that are perceived as consonant and vowel sounds, known as phonemes. The identification of phonemes is a distinct stage in speech comprehension separate from word identification, as illustrated by the fact that nonsense phoneme strings like "brillig" can be uttered by a speaker and perceived by a listener without conveying any meaning. The rare syndrome called pure word deafness is an isolated deficit of phoneme perception, in which patients cannot distinguish between heard phonemes but show perfectly normal written word comprehension and speech production, indicating intact word and concept knowledge.

Functional imaging studies have conclusively localized phoneme perception to the superior temporal gyrus (STG) and superior temporal sulcus (STS) in both hemispheres (3,4). These regions are activated whenever subjects listen to speech sounds (whether words or meaningless pseudowords) compared to less complex sounds such as noise or tones. These observations are consistent with localization data from patients with pure word deafness, who typically have bilateral lesions restricted to the STG and STS (5). This modern conceptualization of the STG as a region supporting phoneme perception is notably different from the traditional conceptualization of this region as "Wernicke area." As typically defined, Wernicke area is responsible for word comprehension, whereas the imaging and lesion data clearly implicate the STG in a prelexical auditory perceptual process.

The clinical importance of this distinction cannot be overstated. It is an unfortunate fact that many clinical fMRI language mapping protocols use passive listening to spoken words, contrasted with scanner noise or another nonspeech sound, to ostensibly identify language comprehension networks. The resulting activation, invariably involving the STG bilaterally, is usually labeled "Wernicke area" and taken to represent areas critical for word comprehension. There are, however, several

misconceptions in this approach. The activation represents an auditory perceptual process, not a word comprehension process (3); thus, damage to these regions will not cause a word comprehension deficit. Because the process is bilaterally represented, a unilateral lesion is unlikely to produce even a deficit of phoneme perception (6). Finally, because words and concepts are constantly being activated when subjects are "resting" in the scanner (even when passively listening to noise), the contrast between words and noise fails to evoke any change in neural activity in the brain regions that support word and concept processing.

Phonologic Access

Language production requires mental retrieval of words, a process referred to as phonologic access. Phonologic access occurs after a concept has been retrieved and can be thought of as retrieving a label or name for the concept (7). Inability to access phonologic representations results in anomia and phonemic paraphasia during speech production tasks. The brain regions implicated in phonologic access are in the left posterior perisylvian area, particularly the posterior STG, posterior STS, and supramarginal gyrus (SMG). Contrasts between visual stimuli that can and cannot be named (e.g., pictures vs. nonsense shapes; pronounceable vs. unpronounceable letter strings) reliably produce activation in these regions (8,9) as do silent word generation tasks (10,11). These regions overlap partly with those implicated in speech perception, though the phonologic access system is more posteriorly located. These systems cannot be entirely overlapping, since lesions in the posterior perisylvian cortex produce phonemic paraphasia but not speech perception deficits (i.e., conduction aphasia). As noted above, the speech perception system is also bilaterally represented, which may explain why it is more resistant to left STG damage than is the phonologic access system, which is more strongly left lateralized.

Semantic Memory

Semantic memory refers to knowledge about concepts, objects, people, actions, events, properties, relationships, etc. Much of this knowledge is represented symbolically in language and underlies our understanding of word meanings. Aspects of this knowledge are retrieved whenever we speak spontaneously, name objects, or comprehend language.

The neural basis of semantic processing has been addressed in a large number of functional neuroimaging studies, and the results of these studies are remarkably consistent, showing a broadly distributed network of brain regions underlying semantic memory storage and retrieval. Five major brain regions are implicated: (i) the ventral temporal lobes, including middle and inferior temporal, fusiform, and anterior parahippocampal gyri; (ii) the angular gyrus; (iii) anterior parts (pars orbitalis and pars triangularis) of the inferior frontal gyrus (IFG); (iv) dorsomedial prefrontal cortex, including the superior frontal and portions of the middle frontal gyrus; and (v) the posterior cingulate gyrus (12). These are multimodal and supramodal regions, distant from primary sensory and motor areas, and likely involved in integrating highly abstract information. Activation in these regions tends to be left lateralized, though most studies show at least some activation in homologous regions of the right hemisphere. As noted above, people continuously activate these semantic networks when they are spontaneous thinking, planning, or imagining; therefore, language mapping protocols that seek to identify these regions require an active baseline task that prevents spontaneous thinking and does not engage concept retrieval, such as an attentionally demanding perceptual task (2).

The functional imaging results are consistent with pathologic data from patients with semantic disorders. For example, lesion localization studies in patients with transcortical sensory aphasia, a syndrome characterized by multimodal semantic impairment with intact phonologic processing, implicate widely distributed regions of the left ventral temporal lobe and angular gyrus (13). Semantic dementia, a degenerative disorder characterized by gradual loss of semantic knowledge, is associated with progressive neuronal loss in the anterior and ventral temporal lobes bilaterally (14). Whereas these temporal and parietal lesions damage the semantic memory store itself, dorsal left prefrontal lesions impair the ability to retrieve information from the semantic store. These latter lesions produce transcortical motor aphasia, a syndrome characterized by inability to initiate spontaneous speech (13).

Retrieval, Selection, and Maintenance

Using language depends on a variety of executive "control" processes, including the ability to voluntarily activate phonologic or semantic information as needed for a given task, the ability to select the correct name or concept when a number of competing alternatives are activated, and the ability to maintain the selected item(s) in short-term memory while the task is completed. For example, if the task is to answer a question, such as "What farm animal gives milk?", it is necessary to use the content words in the question (i.e., farm, animal, give, milk) to activate a field of associated concepts, select from among several activated alternatives (e.g., cow, goat, sheep), use the selected concept to retrieve an associated name, and maintain the concept and name in an activated state during production of the response. These control processes depend mainly on the left prefrontal cortex (15,16).

This modern view of the left prefrontal cortex contrasts with the traditional concept of "Broca area" as a region involved only in speech production. In fact, the same retrieval, selection, and maintenance operations are required for many tasks in which no speech production occurs, such as silently naming a picture, or comprehending a sentence. Damage to the prefrontal cortex produces obvious impairments on a range of language production tasks, but usually not because speech articulation or motor sequencing is impaired. Rather, frontal lesions impair the ability to voluntarily retrieve concepts and verbal labels and to maintain these in short-term memory. The contribution of these regions increases as the need for these control processes increases, for example, as sentences become more complex or ambiguous, or items to be retrieved become less familiar.

Summary

Our understanding of human brain language networks has improved dramatically as a result of functional imaging research. The classical aphasia model linking "comprehension" with the posterior STG and "production" with the IFG is a vast oversimplification and incorrect in many important respects. A clear understanding of component language processes and their relationship to specific activation and baseline tasks is critical for the design and interpretation of clinically useful language mapping procedures. The selection of language activation tasks for fMRI is reviewed in more detail elsewhere (17).

FMRI LANGUAGE MAPPING IN EPILEPSY

SURGERY

Language lateralization by fMRI has been compared to Wada language testing in numerous studies (18), usually by assigning patients to categories such as "left dominant," "right dominant," or "mixed" on each test and calculating rates of concordance between the tests. The proportion of concordant cases depends on how these arbitrary categories are defined, as well as other factors such as the fMRI tasks and the numerical methods for calculating asymmetry. A sample size–weighted average across 23 such studies showed an overall concordance rate of 85%, a value that agrees closely with the rate observed in the largest study, which showed concordance of 86% in a sample of 229 patients (19). Thus, concordance between fMRI and Wada language lateralization tests is good but not perfect.

The longstanding use of language dominance categories (i.e., left, right, and mixed) is gradually giving way to the realization that language lateralization is a continuously graded rather than an all-or-none phenomenon, with relative degrees of dominance rather than distinct categories (20–22). Thus, while most patients who undergo left hemisphere surgery for epilepsy are left dominant for language, there is variation within this group in terms of the degree of left dominance. This variability raises the question whether graded degrees of language dominance are reflected in graded levels of risk.

A standard approach for expressing lateralization in fMRI studies is to calculate a laterality index (LI) expressing the asymmetry of activation in numerical form. The first such LI was based on a simple count of the voxels that survived statistical thresholding in each hemisphere (20). The formula (L - R)/(L + R), where L and R refer to the voxel counts in each hemisphere, yields a number that varies from +1 when all activated voxels are on the left side to −1 when all activated voxels are on the right. LI values obtained with this method vary somewhat as a function of the threshold used for defining activated voxels; thus, several authors have explored alternative asymmetry measures that do not require thresholding (21–24). No consensus regarding the optimal method for calculating activation asymmetry has yet emerged from these studies.

Predicting Naming Outcome

The primary cause of discordance between fMRI and Wada language testing is that fMRI tends to detect more right hemisphere involvement in language processes than the Wada (19). Many authors have assumed that this indicates a degree of inaccuracy on the part of fMRI (25), but the real "gold standard" in this case is not the Wada test but rather prediction of language outcomes. Which test is more accurate in predicting risk? To answer this question, one study (26) analyzed language fMRI in 24 left temporal lobe epilepsy (TLE) patients. The fMRI paradigm used a contrast between an auditory word comprehension task ("semantic decision") and a nonlinguistic tone discrimination task ("tone decision"). An analysis of this contrast is shown in Table 79.1, illustrating the use of controls for nonlinguistic aspects of the word comprehension task and the selective activation of phoneme perception and semantic processes (27). Asymmetry of activation for this task contrast is correlated with language lateralization on the Wada test (20). All patients also underwent Wada testing preoperatively and assessment of object naming using the Boston Naming Test (BNT) before and 6 months after anterior temporal lobe (ATL) surgery.

Thirteen patients (54%) showed variable degrees of decline relative to a control group of 32 right ATL patients. The fMRI LI was the strongest predictor of naming outcome ($R = -0.64$, $P < 0.001$), indicating that stronger language lateralization toward the left (surgical) hemisphere was associated with poorer naming outcome. This fMRI measure showed 100% sensitivity, 73% specificity, and a positive predictive value (PPV) of 81% in predicting significant decline. By comparison, a Wada language lateralization index showed a somewhat weaker correlation with outcome ($R = -0.50$, $P < 0.05$), 92% sensitivity, 43% specificity, and a PPV of 67%. The authors also created multivariate models to determine the contribution of fMRI relative to other noninvasive predictors. Both age at epilepsy onset and preoperative performance showed strong trends toward a correlation with outcome, and together, these variables predicted approximately 27% of the variance in outcome. Adding the fMRI LI to this model accounted for an additional 23% of the variance ($P < 0.01$). Addition of the Wada language asymmetry score did not further improve the model (R^2 change = 0.01).

Another study on this topic examined naming outcome in 10 left ATL patients who had discordant fMRI and Wada language results preoperatively (28). Such patients are relatively rare because the baseline rate of discordance is only approximately 15%, less than half of these discordant cases are likely to have left ATL surgery, and not all surgery patients are available for postoperative testing. Using optimized multivariate prediction models derived from 55 left ATL patients with concordant fMRI and Wada language lateralization, predicted change scores were computed using either the fMRI LI or the Wada language asymmetry index. Of the 10 cases, naming outcomes were more accurately predicted by the fMRI model in 7, more accurately by the Wada model in 2, and equally well by both tests in the remaining case.

Though based on relatively small samples, these results show how preoperative fMRI language lateralization can be used to predict risk for language decline in the setting of left ATL resection, allowing patients and physicians to more accurately weigh the risks and benefits of the surgery. It is crucial to note, however, that these results hold true only for the particular methods used in these studies (both of which were conducted at the same center) and may not be generalizable to other fMRI protocols, analysis methods, patient populations, or surgical procedures. Future studies should confirm these results using larger patient samples and test whether other fMRI protocols in current widespread use have similar predictive capability.

Tailoring Resections

Although many centers use fMRI language activation maps to plan resection boundaries, the evidence

supporting this approach is largely anecdotal, and several known limitations of fMRI suggest caution in using this approach. The largest obstacle is variability in the sensitivity of fMRI. As mentioned above, task contrasts used for fMRI language mapping vary considerably and produce markedly different activation patterns (2). Poor detection of semantic memory networks in the anterior and ventral temporal lobe is a particular problem (29). Regions declared inactive using one task contrast often show activation using a different contrast. Individual factors such as degree of head movement and variation in attention can markedly alter the magnitude of noise relative to the task-related signal of interest, resulting in large individual variation in sensitivity even for the same task contrast.

A second source of uncertainty in language fMRI is the potential for activation to be "nonessential." Language tasks typically engage attention and other nonspecific cognitive processes. These processes can produce activation on fMRI language maps, and resection of these nonspecific activation zones would not necessarily produce language deficits. More generally, language and other complex cognitive functions are supported by broad networks with a wide distribution across the brain. The effects of damaging a small region within such a large network are largely unknown. The clinical consequences of these problems with sensitivity and specificity are substantial. A brain region believed to be "safe" to resect because it fails to show activation may in fact provide an essential process that is not detected because of an insensitive task contrast or subject-specific noise. On the other hand, a brain region believed to be essential simply because it is activated may in fact be performing a nonessential function.

Although several published reports describe good outcomes using fMRI language maps to tailor resections (e.g., (30)), none of these studies incorporated quantitative measures of language ability, nor did they include control patients who did not undergo tailored resections. As discussed below, CSM remains the clinical standard for detecting essential language zones. Unlike fMRI and other activation methods, CSM produces a temporary functional lesion and therefore more directly indicates the potential effects of resection. Correlation between fMRI and CSM language maps has been highly variable across studies, likely reflecting variation in the tasks used and other methodologic factors, but appears to be moderate at best (31). Some centers use fMRI maps to identify brain regions to be examined with CSM, thereby increasing the efficiency of CSM and the number of stimulation trials that can be conducted at each electrode (32). This application assumes a high degree of sensitivity for fMRI, which, as noted above, is currently a problematic assumption.

LATERALIZATION OF EPISODIC MEMORY FUNCTIONS: FMRI AND WADA

Functional imaging of memory systems can assist with two clinical tasks: (i) lateralization of seizure foci in TLE, and (ii) assessment of risk to memory function from ATL surgery. For seizure focus lateralization, the memory portion of the Wada test may detect asymmetric dysfunction of the mesial temporal lobe (MTL), which can be used as an adjunct test for seizure focus lateralization (33,34). When functional asymmetry consistent with the side of seizure focus is demonstrated on Wada testing, seizure control is better than when no asymmetry or reversed asymmetry is observed (35–37). Although several studies suggest that MTL activation asymmetry on fMRI may also be correlated with side of seizure focus and seizure outcome in TLE (38–41), sample sizes in these studies have been small, and no studies have yet examined whether fMRI contributes additional predictive value beyond ictal EEG, ictal semiology, PET, structural MRI, and other markers of seizure focus lateralization.

The other goal of memory lateralization is to assess risk to memory function from ATL surgery. Verbal episodic memory decline after left ATL resection is observed in 30% to 60% of such patients (42–52). One main focus of the preoperative evaluation in ATL surgery candidates is, therefore, to estimate risk of verbal memory decline in patients undergoing left ATL resection. Nonverbal memory decline after right ATL resection is much less consistently observed in both groups and individuals (47,48,51,52).

The Wada memory test was originally developed for the purpose of predicting global amnesia after ATL resection (53), though its reliability for this purpose has often been questioned (54,55). Studies of its ability to predict relative verbal memory decline have been inconsistent, with several suggesting good predictive value (43,46,56) and others showing little or none, particularly when used in combination with noninvasive tests (48,51,52,57–59). Noninvasive tests that are modestly predictive of memory outcome include structural MRI of the hippocampus, interictal PET, preoperative memory function, and age at onset of epilepsy (42,44,48–52,60–63).

An often neglected key point in the discussion of memory lateralization is that the goals of seizure focus lateralization and memory outcome prediction call for fundamentally different methodologic approaches. In the case of seizure focus lateralization, the ideal functional test activates the MTL symmetrically in healthy people, thus allowing optimal detection of deviation from normal symmetry in either direction. In contrast, prediction of verbal memory outcome requires a procedure that specifically identifies verbal memory processes, which typically show strong lateralization. Pictures and objects are encoded into memory in both verbal and nonverbal forms, producing bilateral MTL activation in healthy people (64), and thus are ideal for detecting seizure focus lateralization. In contrast, bilateral activation responses to pictures may predict little or nothing regarding verbal memory outcome, because they represent a mix of verbal and nonverbal processes.

Predicting Verbal Memory Outcome with fMRI

Several studies examined the use of preoperative fMRI to predict verbal memory change from ATL surgery (for a detailed review, see (65)). Several studies (40,41,66) used pictorial scene-encoding tasks that activate the MTL bilaterally on fMRI, a pattern that suggests activation of both verbal and nonverbal memory systems. Prediction of verbal memory outcome using these paradigms was weak at best. In contrast, Bonelli et al. (67) examined activation during a word-encoding task and observed a strong relationship between hippocampal activation asymmetry and verbal memory change in 29 patients undergoing left ATL surgery. The method used an “asymmetry image” created in each individual by contrasting activation levels in mirror-symmetric voxels in the left and right temporal lobe. A small sphere around the hippocampal voxel with the highest asymmetry value was used as a region of interest (ROI) in each patient. The authors observed a strong correlation ($R^2 = 0.23$, $P = 0.008$) between activation asymmetry in this ROI during word encoding and change in verbal memory scores after left ATL surgery, indicating that greater asymmetry toward the left was associated with greater decline in verbal memory. This fMRI measure showed 100% sensitivity, 41% specificity, and 35% PPV for predicting a significant verbal memory decline.

An alternative approach uses language lateralization to predict verbal memory change (52), based on the assumption that material specificity of episodic memory encoding reflects the type of information the MTL receives from the ipsilateral neocortex. If so, then language lateralization should be a reliable indicator of verbal memory lateralization. Binder et al. studied 60 left ATL patients preoperatively with the semantic decision–tone decision fMRI contrast discussed above (Table

79.1), as well as a battery of verbal and nonverbal memory measures before and 6 months after surgery. All patients also underwent preoperative Wada language and memory testing. The strongest predictor of verbal memory change was preoperative memory performance ($R^2 = 0.44$, $P < 0.0001$). The next strongest predictor was fMRI language LI ($R^2 = 0.19$, $P < 0.001$). Wada memory asymmetry was only marginally predictive ($R^2 = 0.11$, $P < 0.05$) and in fact was a weaker predictor than Wada language asymmetry ($R^2 = 0.16$, $P < 0.01$). Age at epilepsy onset was also modestly predictive ($R^2 = 0.12$, $P < 0.01$). The noninvasive measures (preoperative performance, age at onset, fMRI LI) were combined in a multivariate model that explained 59% of the variance in verbal memory change. This model showed 90% sensitivity, 80% specificity, and 69% PPV for predicting significant decline. Addition of the Wada language and memory data did not significantly improve the model.

It is noteworthy that language lateralization, whether measured by fMRI or the Wada test, turns out to be a better predictor of verbal memory outcome than Wada memory asymmetry. The explanation for this apparent paradox rests on two hypotheses. First, verbal memory encoding processes tend to colateralize with language processes. Second, visual stimuli such as pictures and objects can be dually encoded as both names and visual objects. Wada memory procedures that use such stimuli (including the Wada test used by Binder et al.) therefore do not provide a measure of verbal memory lateralization, but rather a measure of overall memory lateralization that includes both verbal and nonverbal encoding processes. Thus, verbal memory lateralization is more tightly linked with language lateralization than with Wada memory asymmetry. Of greatest concern are patients who show marked declines in verbal memory postoperatively despite preoperative Wada results indicating lateralization of memory to the right side (52). In such cases, overall memory as measured by the Wada was lateralized to the right, but verbal memory remained on the left, a situation that cannot be determined using dually- encoded visual stimuli.

Summary

fMRI can be used to help predict the risk of verbal memory decline from left ATL surgery, using either asymmetry of hippocampal activation during a verbal encoding task or overall language lateralization. Prediction models can be further improved by combining fMRI data with indices of preoperative memory ability and age at seizure onset. In one large study, Wada testing did not improve prediction accuracy compared to a model combining fMRI and other noninvasive measures (52).

These results call into question the routine use of the Wada test for predicting material-specific verbal memory outcome, particularly if a validated fMRI test is available. Some centers use the Wada to assess risk for global amnesia, which can occur after bilateral MTL damage (53,68,69). According to this theory, anesthetization of the targeted MTL is necessary to discover whether the contralateral hemisphere is healthy enough to support memory on its own. Empirical observations, however, provide little support for such an approach. Global amnesia following unilateral temporal lobe resection appears to be rare in the extreme (70–72) and was usually associated with preoperative structural deficits of the contralateral hippocampus. Evidence suggests that contralateral hemisphere "memory failure" on the Wada test suffers from poor test–retest reliability and does not reliably predict amnesia (54,55,71,73–78). Wada testing is the only option for patients with contraindications to MRI or inability to comply with activation tasks. For other patients, we propose that use of the Wada test be reserved only for those at greatest risk for global amnesia, that is, patients undergoing unilateral ATL resection who have structural or functional evidence of damage to the

contralateral MTL. Figure 79.1 illustrates this decision algorithm.

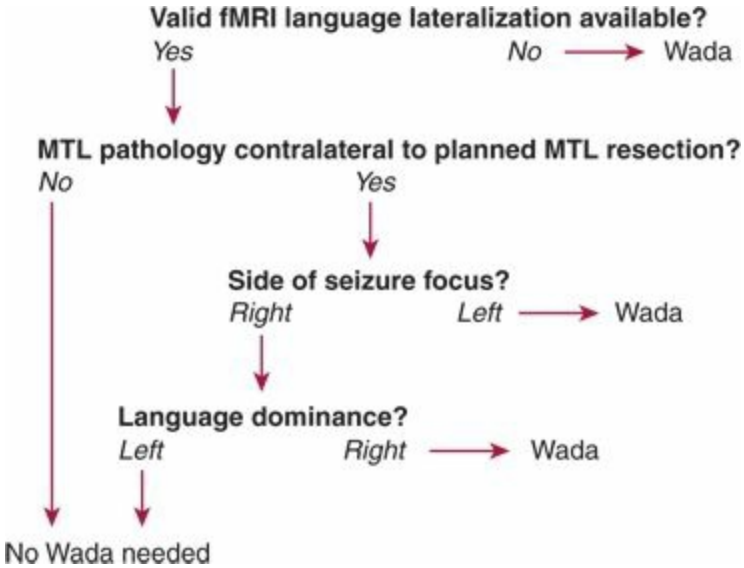

Figure 79.1. A suggested algorithm for use of the Wada test in patients undergoing surgery on the medial temporal lobe (MTL). Wada language and memory testing is generally recommended when a validated fMRI language lateralization protocol is unavailable or cannot be performed. Wada testing may also be helpful in patients with clear evidence of MTL pathology contralateral to the planned side of surgery, as these patients may be at risk for global amnesia. This risk is negligible, however, when surgery is conducted in the non–language-dominant hemisphere. Thus, if surgery is planned in the right hemisphere and the left hemisphere is language dominant by fMRI, Wada memory testing is likely of little predictive value.

MAGNETOENCEPHALOGRAPHY LANGUAGE MAPPING

MEG measures the magnetic fields that result from intracellular currents generated by excitatory and inhibitory postsynaptic potentials. In contrast to fMRI, this is a direct measurement of neural activity. In contrast to EEG, the sensors used in MEG are primarily sensitive to tangential sources (i.e., sources in the sulci oriented parallel to the surface of the head). Typical MEG systems provide hundreds of sensors spread across both hemispheres. The large number of channels and the more limited propagation of the magnetic fields allow for improved spatial resolution compared to typical scalp EEG recordings while retaining the excellent temporal resolution of EEG.

Activity measured with MEG must be modeled mathematically to deduce the source(s) responsible for the observed sensor signals, a process referred to as solving the inverse problem. Numerous methods have been used, ranging from modeling with a single equivalent current dipole (73–75) to modeling with thousands of potential sources distributed throughout the cortex (76–79). These models allow images to be generated depicting localized activity on the subject's MRI, referred to as magnetic source imaging. As with EEG, the signals can be characterized either by averaging phase-locked responses (evoked response) or by averaging changes in power within a specific frequency band (induced response).

As with fMRI, the choice of testing paradigm plays a significant role in the activations observed with MEG, and many different language paradigms have been used. Direct comparisons between these studies are complicated by differences in source localization method and other factors. Relatively few have compared MEG results with Wada language testing. In the most extensively studied protocol (73–75), patients performed an auditory word recognition memory task using

previously studied target words intermixed with distractor words. Evoked responses, averaged over target and distractor words relative to a resting baseline, were modeled using single equivalent current dipoles at 4-ms intervals, and LIs were computed by counting the number of late (>200 ms) dipole solutions in the superior temporal region of each hemisphere. In the largest of these studies (74), the MEG LIs agreed with Wada language testing in 74/85 patients (87%). A study performed at a different center using the same MEG protocol, however, showed complete agreement between MEG and Wada language testing in only 24/35 patients (69%) (75). Using more lenient criteria, the authors reported "complete or partial agreement" in 86% of the patients.

Bowyer et al. (76) used a silent verb generation task (think of an action associated with a presented noun; e.g., airplane—fly) and a silent picture naming task for MEG language lateralization and compared the results with Wada testing in 27 patients. A current density model called MR-FOCUSS was used for localization of the averaged evoked response relative to a resting baseline. LIs were computed for three different latency intervals: 150 to 550 ms, 208 to 270 ms (called "receptive language processing" by the authors), and 396 to 476 ms ("expressive language processing"). For the verb generation task, concordance with the Wada was 81% for the longest interval, 56% for the "receptive" interval, and 63% for the "expressive" interval. For the picture naming task, concordance was 78% for the longest interval, 48% for the "receptive" interval, and 89% for the "expressive" interval.

Hirata et al. (78) used a MEG paradigm in which patients silently read Japanese words. Sources of induced beta/ low-gamma (13 to 50 Hz) desynchronization were localized using a distributed model called synthetic aperture magnetometry (80). A language LI, calculated using the difference between left and right peak responses in a frontal ROI, was concordant with Wada language testing in 51/60 patients (85%). A similar smaller study examined induced beta desynchronization using a verb generation task. Lateralization by MEG was concordant with Wada language lateralization in 13/14 patients (93%) (79).

MEG shows promise as a noninvasive method for language lateralization, with a few studies showing concordance rates of roughly 80% to 85% with Wada language testing. These results should be validated in larger samples. Methods used in these studies have varied widely, and an optimal approach is not yet clear. No studies have tested the ability of MEG to predict language or verbal memory outcomes after surgery.

CORTICAL STIMULATION MAPPING

Direct electrical stimulation of the brain was initially used to identify the motor and sensory cortex (81). Stimulation of these areas typically yields positive phenomena, such as a movement or focal body sensation. In contrast, stimulation of language zones typically disrupts function; thus, language mapping requires the use of active tasks. Both the choice of task and the nature of the error with stimulation are important for understanding the potential impact of resection at or near the stimulation site (82). Three regions are typically targeted during CSM language mapping: the lateral frontal lobe, lateral temporal and inferior parietal lobes, and the basal temporal lobe.

Frontal regions associated with language processing include the inferior frontal and middle frontal gyri, and stimulation of this region has been associated with both language production deficits (e.g., writing or speech arrest) and comprehension deficits (83–85). Lateral temporal and parietal regions associated with language processes include the superior and middle temporal gyri, the angular gyrus, and the SMG. As with frontal lobe CSM, deficits in both language production and

comprehension have been reported with CSM in these posterior regions (84,86). Basal temporal language sites, typically located in the fusiform gyrus, have also been associated with both language production and comprehension deficits during stimulation (87).

It is important to recognize that disruption of language tasks during CSM may occur from a variety of distinct causes. Stimulation of the language cortex typically results in speech arrest, paraphasic errors, or comprehension errors; however, stimulation of other regions may produce similar responses, and differentiating between these findings is critical to avoid false localization. Stimulation over primary motor and premotor areas controlling the lips and tongue may result in difficulty speaking or even overt speech arrest. Stimulation over motor planning regions, such as the supplementary motor area, can produce negative motor deficits that disrupt speech. Careful attention to lip and tongue movements along with the use of repeated simple phonemes (e.g., "ba-ba-ba") can help identify motor phenomena that are interfering with testing. Stimulating at a lower intensity may also help clarify the nature of the deficit in cases of speech arrest, as the lower intensity will often produce a less complete impairment, allowing observation of dysarthric or apraxic deficits or changes in speech volume or pitch associated with these motor areas. Experiential phenomena elicited by stimulation (e.g., hallucinations and déjà vu) may distract patients enough to cause arrest of speech or failure to attend to the task. Reminding the patient to report any such sensations, and regular questioning to assess what the patient felt with any observed response, will help identify potential distracting phenomena. Another type of response that can limit testing is the presence of ipsilateral facial or head pain resulting from dural spread of the current. Focal seizures can also be triggered by stimulation, leading to disruption of speech as an ictal phenomenon. Simultaneous EEG monitoring during stimulation will alert the clinical team to afterdischarges or seizures that may be interfering with participation.

Given the differences in language deficits that can occur following injuries to these anatomically distinct regions (88), a targeted approach to mapping the different regions with different task paradigms appears reasonable. However, studies have demonstrated a broader range of stimulation-induced deficits than would be predicted based on lesion localization data. One such study involved 45 patients with subdural grid electrodes implanted over the left hemisphere (84). Language tasks included assessment of automatic speech production (recitation of the alphabet, counting), spontaneous speech production (repeating single words or short phrases, reciting their zip code), auditory comprehension (following one-, two-, or three-step commands and answering simple questions), and written comprehension (reading silently a question or command and answering/following). The lateral frontal lobe was examined in 43 patients. Language production deficits were identified in 25 (58%), and language comprehension deficits were identified in 11 (26%); 30 (70%) had at least one detected language site. Among 43 patients with lateral temporal electrode coverage, 38 (88%) had at least one detected language site. Deficits in language production occurred in 29 patients (67%), and deficits in language comprehension were observed in 26 (60%). The basal temporal lobe was examined in 29 patients, and 13 (45%) had at least one language site identified; detailed analyses of the elicited dysfunction were not obtained in all patients. There was no difference in the frequency of comprehension disruptions between the anterior and posterior language regions, whereas language production was more likely to be disrupted in the anterior language area.

In an attempt to improve correlation with functional imaging studies, Ojemann et al. (89) used a verb generation task (generate a verb associated with a visually presented noun) during CSM. These results were also compared with an object naming task. A total of 14 patients were studied, 10 of

these during an awake craniotomy. Verb generation sites were identified in 13 patients, with 5 demonstrating frontal disruption sites and 11 showing lateral temporal lobe sites; three patients had both frontal and temporal sites. Spatial overlap between verb generation and object naming sites was incomplete. Ten patients had sites where stimulation disrupted verb generation but not object naming, and seven patients had sites where stimulation disrupted object naming but not verb generation. These data further highlight the limitations of a strictly anatomically driven approach to stimulation paradigms. Of note, the resections in this series did not involve the verb generation language areas, so their clinical importance for resection planning could not be assessed.

These data underscore the importance of a comprehensive approach to language assessment during CSM in any potential language regions. Task paradigms used for mapping at a given center are often specific to the center, often with strong influences from the primary training sites of the physicians at that center.

Despite the widespread use of CSM as a "gold standard" for localization of language in the operative setting, data supporting its usefulness for preserving language function are limited. The 14 patients described by Ojemann and Dodrill (90) underwent CSM during picture naming, sentence reading, and a short-term verbal memory task. Postoperative language deficits were more likely when the resection fell within 2 cm of a site showing stimulation-evoked naming impairment. Similar results were seen for sites with stimulation-evoked short-term verbal memory impairment, but this was less reliable than picture naming.

These data together with the previous picture naming work of Penfield and Roberts (91) led to the establishment of picture naming as one of the standard tasks for CSM language mapping, and the resection of visual naming sites was avoided. While CSM was most often applied to areas on the lateral convexity, stimulation in the basal temporal regions was also found to disrupt language functions (92). This finding is of clinical significance, because, unlike posterior lateral temporal regions where positive naming sites are often observed, the basal temporal cortex is often within the ictal-onset zone and thus the planned area of resection. In a series of patients mapped with multiple language tasks (92), 13 whose resections included basal temporal language-positive sites showed a 9% mean decrease on the BNT postoperatively, compared with a 4% decrease in 12 patients with no language-positive sites resected ($P = 0.03$).

The validity of CSM for preventing postoperative naming deficits was investigated in a multicenter retrospective study capitalizing on variation in the utilization of CSM and surgical approaches between centers (93). A total of 217 patients who underwent left ATL surgery were categorized into four groups: those who underwent tailored temporal resection with CSM either intraoperatively ($n = 23$) or extraoperatively ($n = 27$) and those who underwent temporal lobectomies without CSM either with a standard temporal lobectomy ($n = 118$) or with a modified temporal lobectomy sparing the STG ($n = 49$). All four groups had a statistically significant decline in mean postoperative naming (BNT) performance. There was no difference in BNT change score between the two groups who had cortical mapping and the two groups who did not ($P > 0.35$). Among those who had mapping, there was no difference in outcome between those undergoing intraoperative versus extraoperative mapping ($P > 0.4$). Among those who did not have mapping, there was no difference between standard and modified temporal resection ($P > 0.43$).

As this study and others illustrate, some patients experience postoperative naming decline despite CSM with picture naming, raising doubts about the sensitivity of this task. Hamberger et al. (94) studied an alternative task in which subjects produce a name in response to an auditory verbal description (e.g., "What does a king wear on his head?"). CSM using this task detected more language

sites in the ATL than did a picture naming task. In a subsequent study (95), 19 patients underwent tailored resections designed to stay at least one centimeter away from picture naming sites, without regard to the description naming results. Declines in postoperative naming function were seen in 3/12 patients (25%) with preservation of both visual and auditory naming sites and in 6/7 patients (86%) in whom visual naming sites were preserved but at least one description naming site was resected (P = 0.02). Interestingly, resections in both groups mainly caused declines in picture naming. This dissociation between the modality tested versus the modality impacted postoperatively challenges the assumption that cortical stimulation necessarily mimics the postoperative state.

Although distinct anatomic regions responsible for language and associated with language responses during CSM have been identified, a broad assessment of language functions including both language production and comprehension is recommended. Despite this recommendation and the continued use of CSM as a clinical gold standard, the evidence that tailoring resections based on CSM (regardless of the language paradigm utilized or the region being resected) actually leads to sparing of language functions is relatively limited. Optimization and validation of CSM remains a work in progress.

ELECTROCORTICOGRAPHY

Direct cortical stimulation not only requires an invasive procedure to gain access to the cortex for stimulation, it also delivers small amounts of current that may produce afterdischarges or seizures, which may limit or even preclude reliable testing at one or more sites. Testing is done on one site at a time, which can result in a lengthy procedure. The use of implanted intracranial electrodes for stimulus-induced mapping (electrocorticography, or ECoG) allows simultaneous testing of all the recording electrodes without the application of current. This offers the possibility of a shorter procedure that can map a broader area of cortex without the risk of induced seizures.

Evidence concerning the validity of ECoG for language mapping is currently limited to a few small studies comparing ECoG with CSM language mapping. The majority of these focused on induced changes in the gamma or high gamma frequency bands, though desynchronizations in lower (alpha and beta) frequency bands have also been explored. In one of the larger examples, involving 13 patients, the sensitivity of ECoG for identifying naming or mouth-related motor function areas was 43% and the specificity was 84% (96). Another study with 13 patients reported a sensitivity of 91% and specificity of 62% using an auditory description naming task (97). A similar study with 12 patients reported a sensitivity of 63% and specificity of 57% (98). In all of these studies, ECoG tended to show more language sites than CSM. No studies have yet examined the effects of resecting or sparing ECoG activation sites on language outcome.

PRAGMATIC ISSUES

Not all functional mapping techniques are available at all centers, and not all patients are candidates for all types of studies. Expertise with fMRI varies considerably from center to center, and regrettably some centers still conduct language and memory mapping studies without input from cognitive scientists, often resulting in data of dubious value. MEG and ECoG are not universally available at all surgical centers, and expertise and methodologic approaches with these techniques also vary substantially. Patients may be unsuitable for fMRI because of claustrophobia, implanted devices, or inability to perform activation tasks. Restrictions on MRI in patients with implanted

devices have lessened in recent years, and even many patients with vagal nerve stimulators and cardiac pacemakers can be scanned under certain conditions (99–101). Correlation between fMRI and Wada language testing has so far been demonstrated only using active tasks that induce changes in the level of language or memory encoding in which a patient is engaged. As discussed above, the use of "passive" tasks is unlikely to accomplish this modulation of higher cognitive activity reliably. Although language lateralization measures obtained using active tasks are robust to variation in the level of task performance (19,102), patients should at a minimum perform above chance levels to ensure that there is some degree of engagement in the tasks. When a validated fMRI protocol is unavailable, or a patient cannot undergo fMRI, Wada testing for language and episodic memory lateralization is the current preferred alternative.

CHAPTER 80 MAPPING MOTOR FUNCTION

MARTIN STAUDT, JUAN CARLOS BULACIO, AND DILEEP R. NAIR

INTRODUCTION

The motor region of the brain occupies the caudal aspects of the frontal lobe. Brodmann divided this region into two main areas: area 4 (or BA4) called the primary motor (or M1) region and area 6 (or BA6) called the premotor region. This correlates with the functional cognitive–motor gradient of the frontal lobe distributed along a rostrocaudal axis. The cognitive aspects of motoric function are more rostrally distributed within the premotor region, whereas the caudal aspects involved in the execution of movement are within the primary motor cortex (1).

Investigations of patients with focal epilepsy arising in the frontal lobe require some comprehension of the spatial relationship to these motor regions in making sense of seizure semiology as well as in planning epilepsy surgery. The evaluation for epilepsy surgery attempts to identify epileptic regions of the brain and its relationship to any adjacent eloquent cortex (2). The identification of cortical and subcortical structures harboring sensorimotor functions is a crucial step in the planning and execution of surgical procedures, which potentially involve or neighbor these structures. Of the many primary and nonprimary sensorimotor areas in the human brain, the identification of primary motor cortex (M1) and of primary somatosensory cortex (S1) is most critical, since lesions in these areas always bear the risk of permanent deficit. Nonprimary motor areas (like the supplementary motor area [SMA], premotor regions, or the secondary somatosensory cortex [SII]) are less critical in this respect. Resection of the SMA region could lead to temporary contralateral weakness and even mutism, but these deficits usually resolve over a period of one to several weeks (3). This chapter therefore focuses on the mapping of M1 and S1, and its relevance for epilepsy surgery.

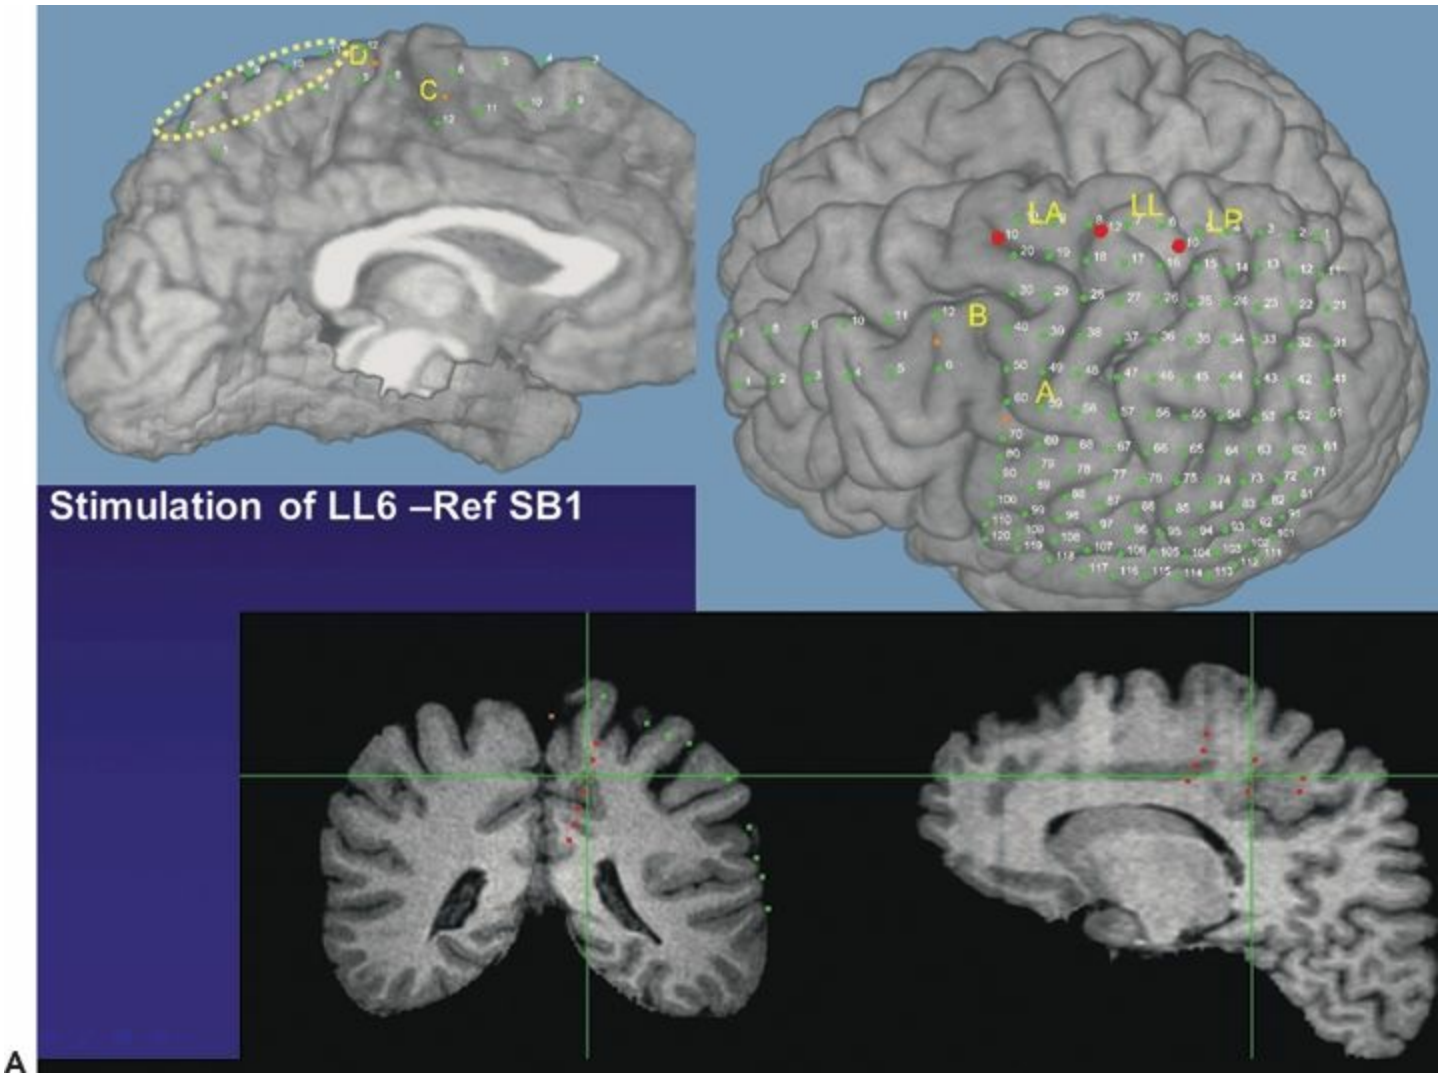
INVASIVE MAPPING

Extraoperative Direct Electrical Cortical Stimulation

Direct electrical stimulation of the cerebral cortex has been used for over 50 years in the localization of eloquent cortex (4). This method of mapping can be performed during surgery or with the use of chronically implanted subdural or depth electrodes. This section mostly discusses eloquent function mapping with cortical stimulation in extraoperative setting using subdural electrodes. Identification of eloquent cortex located in or near the epileptogenic zone is often one of the primary indications for using invasive recordings (5).

Cortical stimulation via subdural electrodes may produce two observable effects in the motor cortex: (a) a positive phenomenon, that is, activation of some function, such as clonic or tonic

movements, or (b) a negative phenomenon, that is, interference with a function, such as cessation of motor activity or loss of muscle tone. Cortical stimulation also has the potential to induce seizures, and therefore, continuous electrocorticographic monitoring is essential to monitor for afterdischarges. Afterdischarges are epileptiform discharges that may be elicited by electrical stimulation. Monitoring for afterdischarges can inform adjustment of stimulation parameters to prevent clinical seizures. It is also important not to ascribe function to a region of cortex that was associated with afterdischarges as the resultant clinical manifestation may have occurred based on the propagation to a site distant from the region that was stimulated (Fig. 80.1).



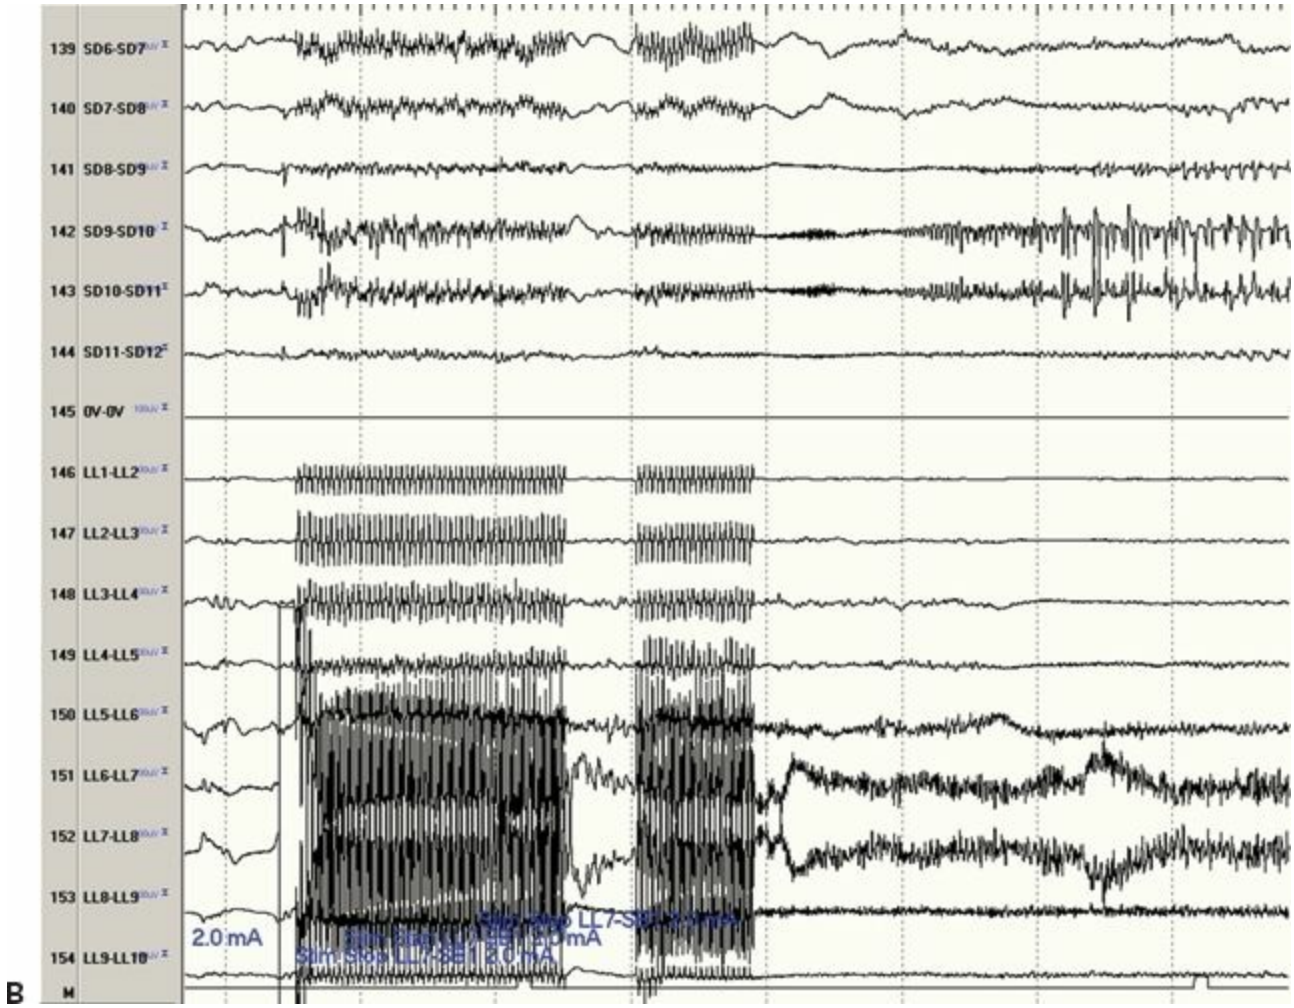


Figure 80.1. Figure A is an MRI coregistration of four subdural arrays (plates) and three depth electrodes. The subdural arrays include a high-density 10 × 12-electrode array (labeled "A" plate) and three 2 × 6-electrode subdural arrays (labeled "B" plate covering the left dorsolateral frontal cortex, "C" plate covering the mesial left frontal cortex, and "D" plate covering the mesial parietal cortex). The three depth electrodes each have eight electrode contacts and are placed in the caudal portion of the superior frontal gyrus (LA depth), in the precentral sulcus (LL depth), and close to the central sulcus (LP depth). Figure B shows the electrocorticography during electrical stimulation of the LL depth electrode. The channels are displayed in a bipolar recording of the "D" plate and LL depth. Stimulation of depth electrode LL6 referenced to subdural electrode B1 elicited an afterdischarge noted most prominently at subdural electrode D10 greater than at subdural electrodes D7, D8, D9, and D11.

Although patients are often weaned from their anticonvulsants during their stay in the epilepsy monitoring unit in order to better assure that seizures are captured, they are often restarted on anticonvulsants prior to the beginning of stimulation testing, typically by acutely loading them the day before. Reinstitution of anticonvulsant medication acutely without titration, however, may complicate cortical stimulation testing, as patients may become fatigued or toxic, making interpretation of clinical symptoms related to cortical stimulation more difficult. Stimulation mapping may be less reliable in the setting of general anesthesia. Some functions, such as language, can only be tested in the awake state. Mapping language in cooperative patients can be performed either during an awake craniotomy or in the invasive EEG–video monitoring unit (2).

Stimulation and Testing Procedure

Cortical stimulation is carried out in a systematic fashion in order to adequately map the accessible functions. Completion can sometimes take several days. The stimulation parameters used at the Cleveland Clinic are as follows: 25 Hz, biphasic, constant current stimuli, of duration 0.3 ms, with intensity ranging from 1 to 15 mA. The stimulus is applied to an "active" electrode, while a distant

"reference electrode" in a noneloquent region serves as a nonactive current sink. The active electrode is varied electrode by electrode throughout the entire grid, thereby testing the function of the cortical region underlying each electrode in turn. When the stimulus is applied to two adjacent electrodes, the typical close bipolar configuration, ascertaining which of the two electrodes elicited the given functional effect can be difficult. Therefore, many neurophysiologists initially stimulate all involved electrodes covering adjacent electrodes of the area of interest and subsequently confirming electrodes with suspected function during stimulation against a "silent," usually more distant, electrode. The stimulus intensity is increased in steps of 1 to 2 mA while carefully watching for functional changes as well as for the occurrence of afterdischarges.

When stimulation testing has been completed, a map outlining the various eloquent functions can be compared with the maps of ictal and interictal activity to help guide surgery resection margins. In the ideal situation, areas found to be responsible for eloquent functions are separated from the epileptogenic zone.

In general, surgical resection of eloquent cortical areas identified by cortical stimulation will lead to neurologic deficits. There are exceptions, however, and surgical removal of some "eloquent" cortical areas (such as primary motor face area) leads only to temporary neurologic deficits, with complete or almost complete neurologic recovery.

Neurophysiologic Effects of Cortical Stimulation

There are three general types of neuronal structures that can be affected by electrical stimulation: local neurons, afferent inputs, and fibers of passage. The current density, membrane depolarization, or hyperpolarization can affect the voltage distribution seen in the tissue medium generated by stimulation (6). The stimulation-induced membrane polarization in turn affects voltage-gated ion channels to induce action potentials, which in turn results in the clinically observed behavioral response (2). However, a neuron can either be activated or suppressed in response to extracellular stimulation depending on its position in relation to the electrode and the stimulation parameters being used. The sum of the effect from stimulation to neuronal output is made up of the direct effect on local neurons and the indirect effect of induced transsynaptic excitation and/or inhibition (2). Electrical stimulation of the human cortex is one experimental model that could reproduce the effect of activation of the cortex by an epileptiform discharge (7). Depolarization and hyperpolarization of cell membranes produces action potentials, which results as positive or negative clinical effect. Positive or negative clinical effects are dependent on stimulus intensity and stimulated area (8–10).

Mapping Primary Motor and Primary Sensory Areas

Direct cortical stimulation of the premotor and motor areas has been widely used to localize human motor function. The main objective is to identify the primary motor cortex so that surgical damage can hopefully be avoided in cases where the anatomical landmarks may have been distorted due to the presence of a lesion or in nonlesional cases where the resection needs to be maximized (11). Penfield's and Jasper's description of the somatotopic distribution of human motor function in the primary motor cortex has stood the test of time with only a few variables patterns observed in individual patients (4). Using gradual increments in the square wave biphasic stimuli, the patient is observed for motor responses involving contralateral muscle contraction. For the most part, the central sulcus is a reliable demarcation separating motor and somatosensory cortex, and there is a

consistent relationship among tongue, face, thumb, and finger in the dorsoventral axis (Fig. 80.2). Somatosensory function can be elicited from the human brain by electrical stimulation, from three areas—the primary sensory cortex (SI) in the postcentral gyrus, the SII in the frontal and parietal operculum, and the supplementary sensorimotor area in the mesial surface of the frontal and parietal cortex. The SI can be defined as the postcentral or anterior parietal region. The clear somatotopy of SI corresponds to that of the motor strip with the exception of the representation of the genitals that is found only in the postcentral cortex (12).

Special Considerations in Children

Cortical mapping in children poses additional unique challenges. The changes inherent to a developing nervous system and absence of firm guidelines for electrical safety necessitate that the energy and charge requirements be kept to a minimum. In addition, the cooperation from pediatric patients is commensurate with the age and level of development and as such may be limited. This makes it challenging to obtain a reproducible objective study of cortical stimulation in selected patients with mental handicaps and in the very young (13).

The stimulation paradigm in infants and young children could be different from used in adults. The longer chronaxies characteristic of immature cortex and poorly myelinated nervous system require increments of both stimulus intensity and pulse duration in order to approach the chronaxie while minimizing the energy required eliciting a response. Stimulation is begun at a low intensity (1.0 mA) and gradually increased in increments of 0.5 to 1.0 mA, keeping an eye on afterdischarges and/or clinical response. Pulse durations are increased from a starting level of 0.3 ms up to a maximum of 1.0 ms. Jayakar et al. (14) were also able to demonstrate that most clinical responses in children were obtained at or above the afterdischarge threshold. This was felt to be a result of maturational factors giving rise to variations in the coupling of functional responses to afterdischarges. Faced with

an absence of clinical response in the presence of afterdischarge therefore does not exclude the presence of eloquent cortex under that electrode. Motor tasks administered must be tailored to the patient's age and neurocognitive status.

Response Characteristics

Motor responses can be obtained at all age groups with some ontogenic trends. In children younger than 2 years of age, tongue movements are difficult to elicit, and they may demonstrate bilateral rather than unilateral responses from the lower face when the lower rolandic region is stimulated. Individual finger movements are usually first manifest at or after 3 years of age. Clonic finger movements appear after tonic finger movements. These observations are likely to be a result of the maturing systems in Brodmann area 4.

Cortical Somatosensory Evoked Potentials

The mapping of the evoked cortical response to peripheral nerve stimulation can give clues to the localization of central sulcus as well as somatotopic organization of the sensorimotor cortex of hand, face, and leg regions. The responses are cortically generated contralateral to the side of peripheral nerve stimulation over the primary somatosensory cortex. In this regard, the responses from cortical evoked potential mapping can be used to cross-check the functional mapping of other modalities such as cortical stimulation. This may be particularly important in children in whom it may be difficult to reliably interpret responses from cortical stimulation (15), or in patients with malformations around the sensorimotor cortex (16).

The standard methodology for somatosensory evoked potentials applies when performing cortical somatosensory evoked potentials (SEP) mapping. An electrical transcutaneous monophasic stimulation (current durations of 100 to 300 μsec) is applied over a peripheral nerve. Median nerve at the wrist, posterior tibial nerve at the ankle, and mandibular branch of the trigeminal nerve are common sites of stimulation for cortical SEP mapping of the hand, foot, and face regions, respectively. Due to the stimulation artifact encountered while performing trigeminal nerve stimulation, the polarity of the stimulation is alternated in order to diminish the stimulus artifact. The intensity of the stimulation is set either at motor threshold or slightly above motor threshold. Stimulus rates of 1 to 10 per second are commonly used, and averaging of 500 sweeps usually results in good signal-to-noise recordings from scalp somatosensory evoked potentials (17). Cortical SEPs usually can be recorded with less number of sweeps as the signal-to-noise ratio is five to eight times higher than with scalp recordings. Band pass should be set from 3 Hz to 2000 Hz.

Cortical SEP mapping is obtained using subdural electrodes placed over the mesial and lateral convexity of the frontoparietal cortex. These responses can be recorded acutely during surgery or in the extraoperative setting. Cortical SEP responses to median nerve stimulation show initial peak latencies around 20 ms in adults. Responses consist of an initial negativity in the hand postcentral gyrus area (called N1 or N20) and a smaller positive polarity in the precentral region (called P1 or P20) (18,19). These two opposite polarity potentials make a phase reversal between the post- and precentral gyrus across the central sulcus in a referential derivation (Fig. 80.3.) (20). Following these initial N1/P1 responses, a second prominent positive peak (P2 or P25) response can be seen that appears over the postcentral gyrus. These occurrences of these waveforms can be explained by a two-dipole model over the postcentral gyrus (18,19). The generator of the initial N1/N20 response is

thought to be in the posterior wall of the central sulcus (Brodmann area 3b). The horizontal dipole in area 3b thus produces a widely distributed polarity inversion across the central sulcus. The source of the P2 or P25 response is thought to be due to a radially oriented generator at the crown of the postcentral gyrus (Brodmann areas 1 and 2), which is more narrowly distributed with no polarity inversion.

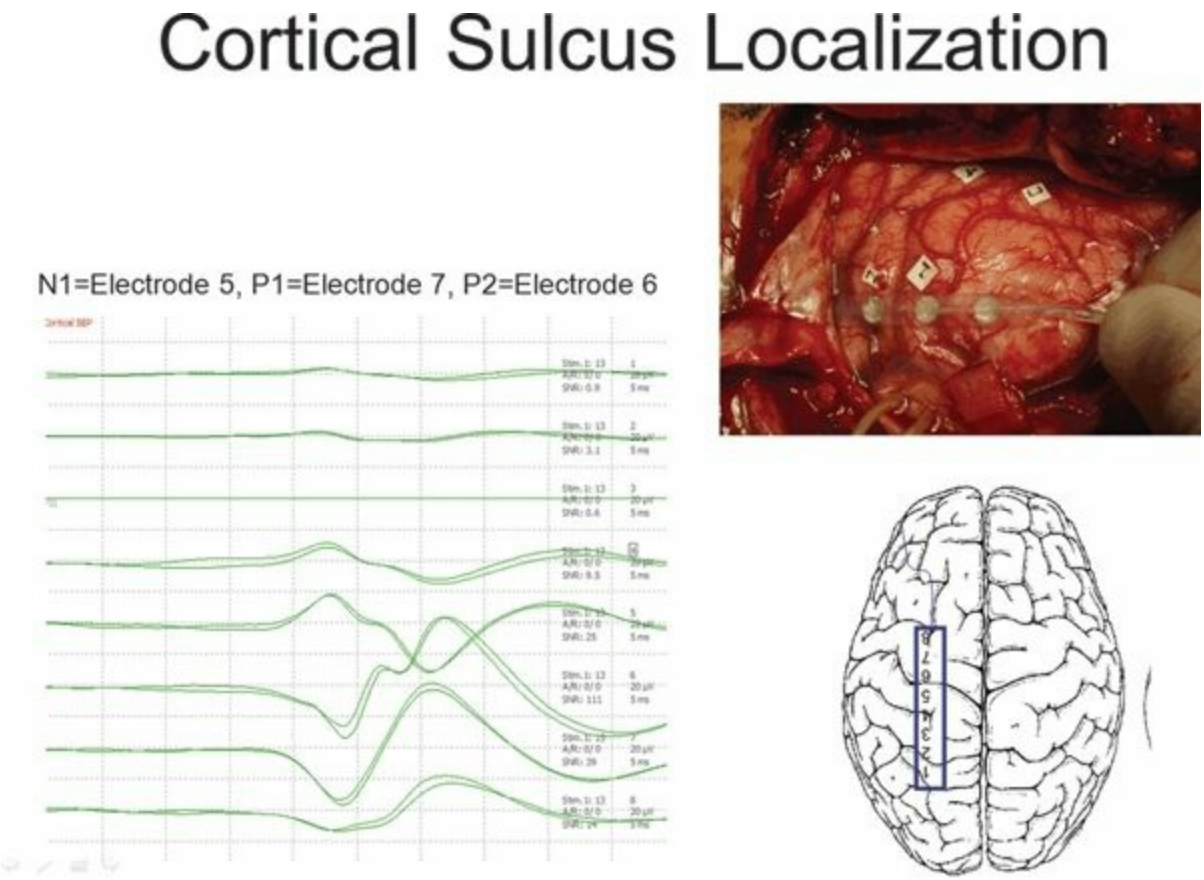

Figure 80.3. Cortical somatosensory evoked potentials (SEP) mapping performed intraoperatively on a 1×8 subdural strip placed over the left frontoparietal lateral convexity. The recordings are referenced to a needle electrode placed in the surgical scalp incision. The N1 or N20 response is seen maximally at electrode 5, the P1 or P20 response is seen at electrode 7, and the P2 or P25 response is seen at electrode 6.

Trigeminal nerve stimulation produces a cortical SEP response around 15 ms, with similar polarity inversion across the central sulcus with a N15 response over the face postcentral gyrus and P15 over the face precentral gyrus. The P15 response is not always seen even when a N15 is obtained (21). Posterior tibial cortical SEP response shows an initial positive peak around 37 ms (called the P37) seen over the medial surface of the mesial parietal lobe in the region of the leg postcentral gyrus. This component has a quite steep fall off and usually makes no polarity inversion (22).

NONINVASIVE MAPPING

Transcranial Magnetic Stimulation

Transcranial magnetic stimulation (TMS) is a noninvasive procedure that can be used to search for cortical areas sending out corticospinal motor projections. During a TMS examination, short but strong magnetic pulses are applied via handheld coils to the surface of the head, which induce an

electric current in the underlying brain tissue. When the coil is positioned over the primary motor cortex, this electric current is transmitted transsynaptically to pyramidal cells. In these cells, a volley of action potentials is generated that travels down the corticospinal tract, depolarizes the alpha motor neurons in the anterior horn of the spinal gray matter, and thus produces a short muscular contraction. This muscular contraction can be recorded via surface electromyography electrodes, the so-called motor evoked potential (MEP). With the use of focal "figure-of-eight" coils, the stimulation is highly specific, so that rather detailed somatotopic information can be obtained for the stimulated motor cortex. TMS is easy to perform, inexpensive, and not painful nor harmful; the method has, however, several disadvantages:

- Contraindications have to be taken into account (similar to MRI).
- There might be a—very low—risk to induce a seizure in epileptic patients.
- Infants, toddlers, and preschool children often have high stimulation thresholds, which makes it sometimes impossible to obtain useful results in this age group.
- Many antiepileptic drugs further increase the stimulation threshold.
- A basic level of patient compliance is required.

Although being quite specific, the spatial information that can be obtained from "standard" TMS is rather crude, since only stimulation points on the scalp can be determined for certain target muscles. This disadvantage can be overcome with the additional use of neuronavigation together with TMS, which allows a 3-D co-registration of the stimulation points with a 3-D MRI data set, so that the stimulated cortical structures can be identified. Nowadays, several manufacturers offer such "neuronavigated TMS systems," which are increasingly used as a noninvasive alternative or in preparation of more invasive mapping procedures prior to epilepsy surgery.

Due to its noninvasiveness, TMS also allows an investigation of brain structures remote from the site of the operation. Most importantly, it allows the investigation of the contralesional hemisphere, searching for the phenomenon of "interhemispheric reorganization of primary motor representations"—which can be of utmost importance in the planning of resections including the central (rolandic) region of one hemisphere, for example, for hemispherectomies.

When cortical malformations or early brain lesions involve the primary motor cortex or the corticospinal tract of one hemisphere, the contralesional hemisphere can maintain its (normally transient) ipsilateral corticospinal projections (23,24). Thus, the contralesional hemisphere can "take over" motor control of the (paretic) extremities. This phenomenon can easily be studied using simple focal TMS: In these patients, TMS of the contralesional hemisphere will elicit MEPs in target muscles of both the contralateral (nonparetic) side and of the ipsilateral (paretic) side of the body, with a similar latency (difference typically not more than 1 ms) (25). There is growing evidence that this finding (short-latency MEPs in the paretic hand after TMS of the contralesional, but not of the lesioned hemisphere) predicts preserved hand function after resections of the rolandic areas or hemispherectomies of the lesioned hemisphere (26).

Functional Magnetic Resonance Imaging

Functional magnetic resonance imaging (fMRI) is a second noninvasive procedure that permits mapping of the sensorimotor system. In contrast to TMS, fMRI is not specific for the primary motor cortex, but typically shows several components of the sensorimotor system, including M1S1, but also

areas like the SMA, premotor cortex, or the cerebellum.

fMRI also allows for an investigation of somatotopy. In the clinical setting, most centers have a set of task for the visualization of upper and lower extremity as well as for the face. At the pediatric epilepsy center in Vogtareuth, we use active or passive fist clenching, active or passive flexion/extension of the toes, and "kissing movements" of the lips. In sufficiently cooperative subjects, this method allows reliable identification of the somatotopic aspects of the pre- and postcentral gyrus (M1S1). This can be helpful when lesions or malformations have distorted the anatomical landmarks that are normally used for the identification of M1S1 or when growing tumors have shifted these representations. In the absence of interhemispheric motor reorganization (see above), active and passive movement will produce similar results, so that in less cooperative subjects, one can rely on passive movements alone.

In patients with interhemispheric reorganization of M1, however, the interpretation of active and passive hand movements becomes rather complex:

Interhemispheric reorganization (as described above for corticospinal motor projections) is apparently not available for primary somatosensory projections. For these projections, however, a different mechanism of "developmental plasticity" is available: Due to the late maturation of thalamocortical projections, they can "bypass" even large white matter lesions and still reach the postcentral gyrus to form the primary somatosensory cortex (27). Therefore, many patients with ipsilateral corticospinal motor projections show a "hemispheric dissociation" between an (ipsilaterally reorganized) M1 representation of the paretic hand, while its S1 representation is still organized contralaterally, that is, in the lesioned hemisphere (28). And since fMRI of active movements with the paretic hand activates both M1 and S1, these patients show activation of both rolandic areas—ipsilateral (contralesional) M1 and contralateral (ipsilesional) S1. In contrast, passive hand movements will, in this situation, only activate the contralateral (ipsilesional) S1. But even when this typical constellation is identified, TMS must still be recommended to test both rolandic activations for the presence or absence of corticospinal motor projections (Fig. 80.4).

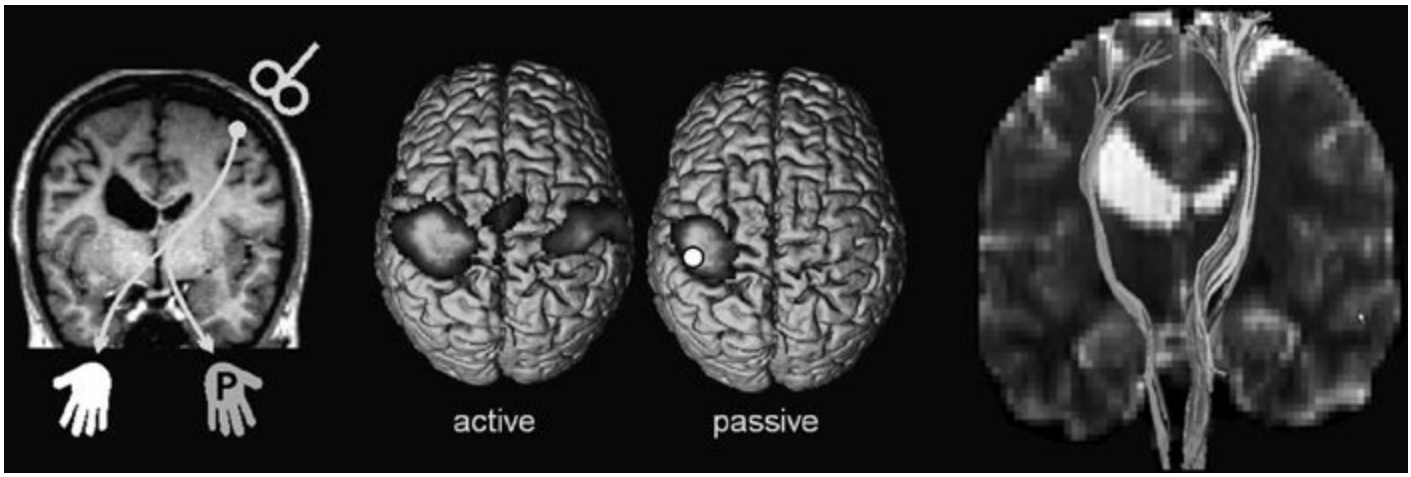

Figure 80.4. An example of a patient with a large unilateral periventricular brain lesion and ipsilateral corticospinal projections from the contralesional hemisphere to the paretic hand (left). fMRI during active movements of the paretic hand (P) reveals bilateral activation of the rolandic (pericentral) cortices; during passive movement of the paretic hand, only the contralateral rolandic area in the affected hemisphere is activated, indicating a contralaterally preserved primary somatosensory (S1) representation of the paretic hand in the affected hemisphere. Accordingly, the white dot represents the topography of the magnetoencephalographically determined S1 representation of the paretic hand. Finally, diffusion tensor tractography (right) visualized trajectories of somatosensory afferent fibers that bypass the lesion on their way to the rolandic cortex of the affected hemisphere. (From Staudt M, Braun C, Gerloff C, et al. Developing somatosensory projections bypass periventricular brain lesions. Neurology. 2006;67:522–525.)

The phenomenon of M1–S1 dissociation is not confined to patients with early white matter lesions, but can also occur in patients with early cortico-subcortical infarcts and in patients with unilateral brain malformations, for example, hemispheric polymicrogyrias. The importance of these investigations again is provided by first observations that hemispherectomies in such patients with presumed M1–S1 dissociation did not abolish an active grasping ability of the paretic hand—although these operations probably disconnected the paretic hand from its S1 representation (26). In this context, it is important to note, however, that not all patients with rolandic or hemispheric polymicrogyrias show this phenomenon of M1–S1 dissociation: In some of these patients, the M1 representation of the paretic hand is still located within the polymicrogyric cortex (Fig. 80.5) (29,30).

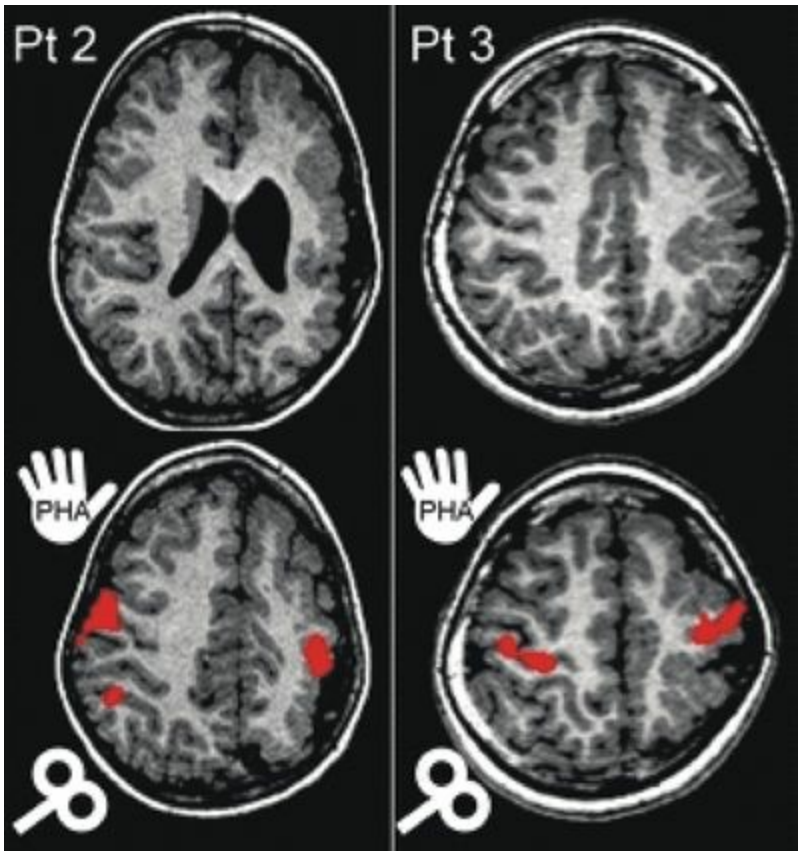

Figure 80.5. Two patients with hemispheric polymicrogyrias and congenital hemiparesis. TMS (indicated by the white figure-of-eight coil) elicited MEPs in the paretic hand (PHA) only by stimulation of the contralesional hemisphere, while TMS of the polymicrogyric hemisphere did not elicit any responses. fMRI during active movements with the paretic hand, however, elicited activation both in the rolandic region of the ipsilateral (contralesional) hemisphere and in the polymicrogyric hemisphere. This combination is highly suggestive for the phenomenon of a hemispheric M1–S1 dissociation. Both patients were still able to grasp actively with their paretic hands after hemispherectomy. (From Zsoter A, Pieper T, Kudernatsch M, Staudt M. Predicting hand function after hemispherotomy: TMS versus fMRI in hemispheric polymicrogyria. Epilepsia. 2012;53: e98–e101.)

CONCLUSIONS

The main goal of cortical stimulation is to ensure precise mapping results allowing maximal resection of epileptogenic tissue in areas adjacent to functionally significant cortex. Long-term results following subdural electrode implantation are much better when implantations are for functional mapping than for localization of the epileptogenic zone (31). Noninvasive mapping techniques like fMRI or TMS can provide information that has a major impact on surgical decisions. This is particularly important in the detection of reorganizational processes in patients with early brain lesions.

CHAPTER 81 STRATEGIES AND INDICATIONS FOR EVALUATION WITH INVASIVE ELECTRODES

JORGE ALVARO GONZÁLEZ-MARTÍNEZ, WILLIAM E. BINGAMAN, PATRICK CHAUVEL, AND IMAD M. NAJM

INTRODUCTION

The main goal of epilepsy surgery is the complete resection (or disconnection) of the cortical areas or networks responsible for the generation of seizures (epileptogenic zone, EZ), with the main clinical purpose of complete seizure control in patients who have otherwise failed multiple antiepileptic medications. The EZ may at times overlap with functional (eloquent) cortex. For these reasons, accurate and comprehensive mapping of the anatomoelectroclinical (AEC) network defining the epileptic condition is most important during the presurgical evaluation. Equally important is mapping of the extent of the EZ and its possible overlap with clinically testable functional regions. In order to presurgically define the anatomical location of the EZ and its proximity to possible cortical and subcortical eloquent areas, an array of noninvasive tools are available: recorded seizure semiology, scalp electroencephalographic (EEG) recordings (ictal and interictal epileptic patterns), magnetic resonance imaging (MRI), positron emission tomography (PET), ictal single photon emission computed tomography (SPECT), neuropsychological testing, and/or magnetoencephalography (MEG) (1–3).

In this chapter, we discuss the main goals of presurgical evaluation of patients with medically intractable epilepsy and the indications and the surgical strategies for the placement of subdural or stereoelectroencephalography (SEEG) depth electrodes. The rationale behind the choice of each one of the two intracranial EEG recording techniques is also discussed.

GOALS AND TECHNIQUES OF PRESURGICAL EVALUATION

Following the establishment of the diagnosis of pharmacoresistant epilepsy (usually defined as a failure to respond to two or more adequately chosen and used antiepileptic medications) (4), a presurgical evaluation is indicated with two main goals: (i) mapping of the AEC network leading to the identification of the EZ and its extent and (ii) assessment of the functional status of the epileptic region(s). Achievement of both goals will lead to optimization of postresective seizure and functional outcomes following epilepsy surgery.

Multiple techniques may be used in order to achieve the above-stated goals: scalp EEG and video–EEG monitoring is needed to confirm the diagnosis of epilepsy (interictal and ictal EEG

recordings) and to identify the network structures that may be involved in seizure generation and progression (through analysis of the recorded seizure semiology) leading to the formulation of a clear AEC hypothesis. Further validation of the anatomic hypothesis is achieved through imaging (the identification of lesion on MRI), with or without metabolic imaging (including FDG-PET hypometabolism that may point to focal regions of cortical dysfunction). Other studies that may include ictal (and interictal) SPECT, MEG, EEG-fMRI, among others, further point to areas of dysfunction within a network or identify the three-dimensional localization of interictal epileptic regions, respectively.

These noninvasive studies identify the epileptogenic area and its possible anatomical cause usually in more than half of patients undergoing presurgical workup (around 70% of the patients who are operated on at Cleveland Clinic in 2012) (Unpublished data). But a formulation of a clear AEC hypothesis may not be possible in some patients, or an AEC is generated, but the exact location of the epileptogenic area within the network, its extent, and/or its overlap with functional (eloquent) cortex remain unclear. These patients may be candidates for an invasive evaluation using either subdural grids (SDGs) or SEEG depth electrodes.

RATIONALE FOR THE USE OF INVASIVE EVALUATION TECHNIQUES IN EPILEPSY SURGERY

Three major presurgical resection details are needed in the process of defining the EZ: (i) accurate localization, (ii) mapping of EZ extent, and (iii) assessment of functional status of the EZ.

As an electroclinical concept, the localization of the EZ is done in the majority of cases through scalp EEG recordings. It is usually complemented by functional semiologic details of the ictal events (seizures). Additional anatomic, metabolic, and/or functional techniques help to anatomically identify and localize the possible epilepsy-producing lesion. The gold standard techniques for the localization of the epileptogenic zone (scalp EEG and video recordings of the seizure semiology) are sufficient to approximate the location of the epileptogenic zone (3,5–7) and to generate an AEC network hypothesis. Nevertheless, scalp EEG does only approximate the boundaries of the epileptic region. This is mainly due to the fact that scalp EEG detects only epileptiform activity that results from EEG synchronization of relatively large areas of cortex, estimated in some studies to be between 6 and 10 cm^2, and EEG recordings are affected by the smearing effect of bone and other high-resistance structures (e.g., meninges and scalp) between the cortical generators and the recording electrodes (1,8,9).

A thorough analysis of the seizure semiology and the sequence of ictal clinical manifestations adds functional and clinical depth to the EEG data and therefore contributes to the generation of the AEC hypothesis. An AEC hypothesis is pursued in cases with focal lesions on the MRI that are overlapping with the electroclinical network. Additional information may be provided by PET, MEG, and other anatomic/functional/metabolic techniques.

The localization of functional areas in the brain and mapping of their extent and their potential spatial overlap with the EZ are an essential part in the process of developing an adequate and individualized resective surgical strategy (1,6,10). As focal cortical dysplasias (FCDs) are the most common pathologic substrates for focal epilepsies and are differentially located in the frontal lobe

(therefore in potentially eloquent cortex), an understanding of the functional status of the involved region(s) and its anatomical and pathologic correlations are essential (1,6,11,12). Some FCD lesions are characterized by significant FLAIR signal increase on MRI and located in anatomically functional areas (e.g., primary motor, Broca area). The center of these lesions (in particular type IIB lesions) may not be functional (upon direct electrical stimulation) and may show no evidence of intrinsic epileptogenicity as assessed through direct mapping of the ictal onset zones (12). On the other hand, FCD lesions with mild or no FLAIR signal increase may be functional and intrinsically epileptogenic (13,14). Similar electrocorticography (ECoG) patterns were reported in patients with low-grade glial tumors (e.g., dysembryoplastic neuroepithelial tumor and ganglioglioma), whereas pathologically dysplastic and intrinsically epileptic areas are found immediately surrounding these lesions (15). Functional cortex may be displaced within the same hemisphere, and therefore, the exact location of function may have direct implications on the options for epilepsy surgery.

Therefore, the precise anatomical localization and mapping of eloquent cortex and its relationships with a well-defined epileptic area are the two most important components of any presurgical evaluation. Delineation of these aspects will facilitate the surgical planning and optimize the chances for a safe resection of the epileptic region (thus maximizing the chances for seizure freedom and minimizing the risks of neurologic deficits). For these reasons, there is a need for direct cortical recording and electrical stimulation mapping of selected areas of the brain based on clear hypothesis generated by a detailed presurgical evaluation.

INDICATIONS OF INVASIVE EVALUATION IN EPILEPSY SURGERY

The main indications for an invasive evaluation in focal pharmacoresistant epilepsy (with the main purpose of direct cortical recording) are to address the main challenges and limitations of various noninvasive techniques. Based on the limitations outlined above of the various noninvasive techniques, an invasive evaluation should be considered in any one of the following cases whereas:

1 . MRI-negative cases: The MRI does not show a cortical lesion in a location that is concordant with the electroclinical/functional hypothesis generated by the video–EEG recordings.
2. Electroclinical and MRI data discordance: The anatomical location of the MRI-identified lesion (and at times the location of a clearly hypometabolic focal area on PET) is not concordant with the electroclinical hypothesis. These include cases of deeply seated brain lesions such periventricular nodular heterotopia or deep sulcal lesions. In addition, scalp EEG recordings in 85% to 100% of patients with FCD show interictal spikes that range in their distribution from lobar to lateralized and from difficult to localize to diffuse (including generalized spike-and-wave patterns in some cases of subependymal heterotopia) (16,17). The spatial distribution of interictal spikes is usually more extensive than is the structural abnormality as assessed by intraoperative inspection or MRI visual analysis (16,18).
3 . Multiple, in part discordant lesions: There are two or more anatomical lesions with the location of at least one of them being discordant with the electroclinical hypothesis, or both lesions are located within the same functional network, and it is unclear if one (or

both) of them is (are) epileptic.

4 . Overlap with eloquent cortex: The generated AEC hypothesis (MRI-negative or MRI-identifiable lesion) involves potentially highly eloquent cortex. The identification of the EZ, mapping of its extent, and its relationship with potentially eloquent cortex are not typically resolved in these cases. These include patients with suspected focal cortical dysplasia as the possible pathologic substrate for epilepsy (13,19–21).

In these instances, an invasive evaluation usually leads to the formulation of a clear resective surgical strategy. The recommendation for invasive monitoring and its type is made during a multidisciplinary patient management meeting that includes neurologists, neurosurgeons, neuroradiologists, and neuropsychologists. Areas and networks of coverage/sampling are determined based on a well-formulated AEC hypothesis including results of the noninvasive studies. We use two extraoperative invasive methods to accomplish these goals: SDG electrodes and stereotactic placement of depth electrodes (stereoelectroencephalography, SEEG).

THE SUBDURAL GRID METHOD

Prolonged intracranial recordings were initially reported in 1939 when Penfield et al. used epidural single contact electrodes in a patient with an old left temporoparietal fracture and whose pneumoencephalography disclosed diffuse cerebral atrophy (22). Decades later (1980s), the use of SDG arrays became more popular in North America following multiple publications that demonstrated their safety and efficacy (1,23,24). Prior to that, most invasive techniques used in North America involved extraoperative recordings from epidural electrodes or intraoperatively placed neocortical surface electrode recordings.

SUBDURAL GRID IMPLANTATION TECHNIQUE

Subdural electrodes consist of discs (stainless steel or platinum) that are embedded in strips or sheets of polyurethane or other synthetic materials. These are implanted over the cortical surface corresponding to the AEC hypothesis. Variability in shape and size of the electrodes permits some flexibility in tailoring the extent and shape of the coverage area. Custom-designed arrays of subdural electrodes have been configured for placement in specific anatomical locations. For example, to record from interhemispheric brain regions, rows of electrodes arranged in curvilinear fashion are designed to follow the curvature of the corpus callosum. SDGs are inserted through either open craniotomy incisions or burr holes and registered stereotactically for extraoperative mapping. The cortical coverage may extend beyond the visualized cortical area(s), as grids may be slid over the edges of the craniotomy to cover adjacent areas for better ECoG recordings or functional sampling. Besides the ECoG recordings and direct electrical stimulation studies, grids can be used to record somatosensory evoked potentials after stimulation of the trigeminal (lip) or median nerves. Somato-sensory evoked potentials (SSEP) with cortical recordings provides a highly accurate neurophysiologic mean for central sulcus localization.

Incision and craniotomy should allow for placement of electrodes in addition to the anticipated area of resection. Positioning of the patient should allow for stereotactic guidance in the event that depth electrodes are to be placed during the same operation. As part of the Cleveland Clinic Epilepsy Center surgical protocol, perioperative antibiotics, dexamethasone, and mannitol (0.25 g/kg) are

given. The incision should be large enough to allow for a sizable craniotomy. Usually a T-shaped or large question mark incision is used. If basal temporal coverage is needed, the incision should extend down to the zygoma. Orbitofrontal coverage can be easily achieved as long as the incision allows for visualizing the key hole and turning a flap just above this level. Interhemispheric coverage necessitates an incision that extends to the midline. In order to facilitate placement of electrodes, the basal and mesial surfaces should be carefully inspected for cortical draining veins that might impede grid placement. Using bayoneted forceps, and under a constant stream of irrigation, the grid electrodes can be slid into place. Any resistance would likely indicate the presence of a draining vein, and therefore, the trajectory of the grid should be adjusted.

If indicated, depth electrodes may be inserted using semistereotactic guidance prior to inserting lateral cortical coverage. The entry point should be in the middle of a gyrus, avoiding sulci, with a trajectory that is as perpendicular to the cortical surface as possible. The parenchyma serves to anchor the electrode in place. Using the wand to find the trajectory from the entry point, the pial surface is incised and the electrode is inserted. Once the depth electrodes are in place, the grids for lateral coverage can be placed. Again using bayoneted forceps, the larger grid electrodes are laid over the cortical surface, tucking the edges under the borders of the dural flap. Once in place, each electrode wire is secured to the nearest dural edge with a stitch. The remaining closure is performed using standard neurosurgical technique (Fig. 81.1).

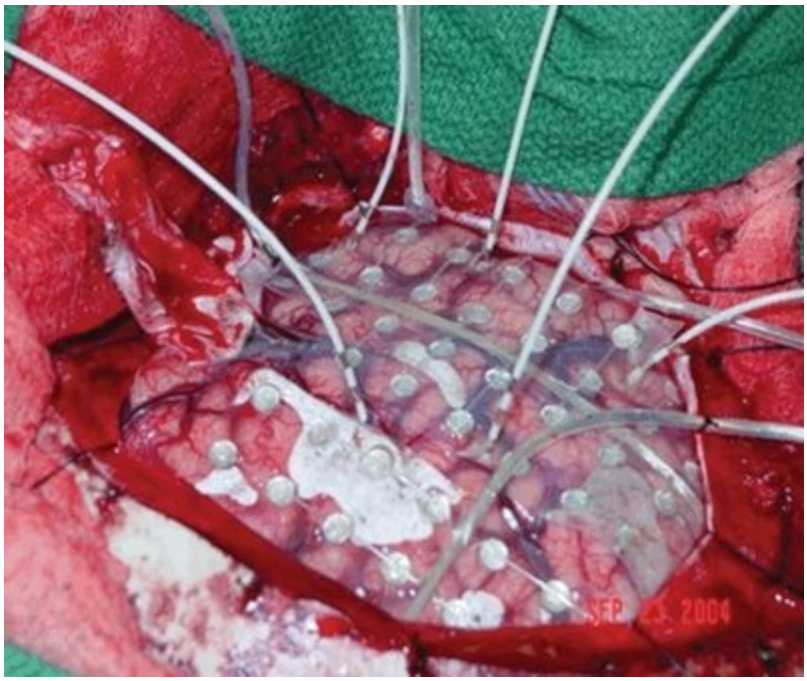

Figure 81.1. Intraoperative aspect of SDG/depth electrode implantation in a patient with extratemporal epilepsy and nonlesional MRI. The picture shows a large right-sided temporofrontal craniotomy with placement of SDGs at the dorsolateral convexity of the temporal area. Depth electrodes were implanted in the mesial structures of the temporal lobe (amygdala and hippocampus) and frontal opercular areas.

PRINCIPLES AND INDICATIONS OF SUBDURAL ELECTRODE PLACEMENT

Extraoperative mapping with the subdural method (which includes SDGs and strips) has the main advantage of allowing optimal coverage of the subdural space adjacent cortex with adequate and

continuous superficial functional mapping capabilities (13,25–27). A major strength of subdural electrodes consists in the comprehensive anatomical coverage of cortical surfaces, therefore allowing accurate anatomical–electrical and functional mapping of the areas of coverage. Limitations of SDG electrodes include the inadequate/partial/incomplete intrasulcal, deep brain, and interhemispheric coverage and the relative difficulty in multilobar, three-dimensional, and large functional network sampling (28). These characteristics are highlighted in the published results on the successes and failures following SDG implantation (29). The best resective surgical outcomes following SDG implantation are achieved in patients with clear cortical lesions (in particular tumors) and those patients in whom the SDG implantations were placed with the main purpose of functional mapping (12,29). On the other hand, the worst outcomes were seen in patients with no clear lesions on the MRI, nonspecific histopathology, and those who underwent either a sublobar resection or multilobar resections.

These characteristics suggest that the best candidates for extraoperative invasive evaluation with SDG are those patients with clear cortical surface lesion(s) (excluding the interhemispheric, cingulate gyrus, deep sulcal, and mesial frontal/temporal regions), specifically patients undergoing invasive evaluation for electrofunctional/eloquent cortex mapping in the setting of a superficial cortical lesion. Intraoperative ECoG, as compared to chronically implanted SDGs, is a limited option because it usually only provides information restricted to interictal activity. When used in patients under general anesthesia, anesthetic agents may influence EEG activity by altering the thresholds of afterdischarges and motor responses creating a misleading EEG picture (19). Additionally, intraoperative functional mapping often requires a cooperative patient that can tolerate being awake during surgery under local anesthesia. This is particularly difficult in the pediatric population.

LIMITATIONS AND COMPLICATIONS OF SUBDURAL GRID IMPLANTATIONS

The main limitations of SDG include surgical morbidity risks and the spatial/cortical sampling limitations as detailed above. SDG electrodes are foreign bodies that are surgically inserted in the cranial vault, and risks of the procedure include wound infection, flap osteomyelitis, acute meningitis, cerebral edema, and hemorrhage (30–32). Concerns about increased intracranial pressure may reduce the maximal number of electrodes that can be inserted and therefore may lead to incomplete or limited spatial coverage. Other limitations may include the technical challenges that are associated with SDG implantations following a first resective surgery failure (so called “re-do” surgeries). Technical challenges mainly occur due to cortical adhesions in this setting. As stated above, one of the main weaknesses of the subdural methodology is the inability to record from deep cortical areas, as in the depth of sulci, interhemispheric regions (in particular the cingulate gyrus), mesial temporal or frontal structures, and insula/opercular regions (28). Depth electrodes implanted using a non- or semistereotactic technique can partially compensate for the rather incomplete deep/mesial structure coverage with SDG, but as these electrodes are not fully stereotactically implanted, their placement may not be very accurate (29).

THE STEREOELECTROENCEPHALOGRAPHY METHOD

The SEEG method was developed in France by Jean Talairach and Jean Bancaud during the 1950s and has been mostly used in France and Italy as the method of choice for invasive mapping in refractory focal epilepsy (17,33,34). The principle of SEEG is based on AEC correlations with the main aim to conceptualize the 3-dimensional spatiotemporal organization of the epileptic discharge within the brain based mainly on seizure semiology. The implantation strategy is individualized, with electrode placement based on a preimplantation hypothesis that takes into consideration the primary organization of the epileptiform activity and the hypothetical functional epileptic network that may be involved in the propagation of seizures. For these reasons, the preimplantation AEC hypothesis is the most important element in the process of planning for SEEG electrodes placement. If the preimplantation hypothesis is incorrect, the placement of the depth electrodes will be inadequate and the interpretation of the SEEG recordings misleading. The most important characteristic of SEEG methodology is that it enables precise recordings from deep cortical and subcortical structures, multiple noncontiguous lobes, as well as bilateral explorations while avoiding the need for large craniotomies (21,28,35–38).

The SEEG technique was originally described as a multiphase and complex method, using the Talairach stereotactic frame and the double grid system in association with teleangiography (6,39). Despite its long reported successful record, with almost 60 years of clinical use, the technical complexity regarding the placement of SEEG depth electrodes may have contributed to its limited use in centers outside Europe. Taking advantage of new imaging and computational innovations, more modern and less cumbersome methods of stereotactic implantation of depth electrodes can be applied on a routine basis.

PRINCIPLES AND TECHNIQUE OF SEEG IMPLANTATION

The development of an SEEG implantation plan requires the clear formulation of a specific anatomoelectrofunctional hypothesis to be tested. This hypothesis is typically generated during the patient management conference based on the results of various noninvasive tests. At Cleveland Clinic, a final tailored implantation strategy is generated during a separate presurgical implantation meeting. Depth electrodes sample the anatomic lesion (if identified), the more likely structure(s) of ictal onset, the clinically active regions, and the possible electrical pathway(s) of seizure-onset propagation (functional networks). The EZ may correspond to the first clinical sign or may reflect a spread area from a “clinically silent” ictal onset zone within a functional network. For these reasons, a three-dimensional “conceptualization” of the network nodes upstream and downstream from the hypothesized clinical onset region is an essential component of the presurgical implantation strategy. The desired targets are reached using commercially available depth electrodes in various lengths and variable number of contacts, depending on the specific brain region to be explored. The electrodes are implanted using conventional stereotactic technique through 2.5-mm diameter drill holes. Depth electrodes are inserted using orthogonal or oblique orientation, allowing intracranial recording from lateral, intermediate, or deep cortical and subcortical structures in a three-dimensional arrangement, thus accounting for the dynamic, multidirectional spatiotemporal organization of the epileptic pathways.

As part of our routine practice, the patient is admitted to the hospital on the day of surgery. The day before surgery, a stereo contrasted volumetric T1 sequence MRI is performed. Images are then

transferred to our stereotactic neuronavigation software (iPlan Cranial 2.6, Brainlab AG, Feldkirchen, Germany) where trajectories are calculated the following day. The day of surgery, while the patient is under general anesthesia, the Leksell stereotactic frame (Elekta, Stockholm, Sweden) is applied using standard technique. Once the patient is attached to the angiography table with the frame, a stereo DynaCT and a three-dimensional digital subtracted angiogram are performed. The preoperative MR images, the stereo DynaCT, and angiographic images are then digitally processed using a dedicated fusion software (syngo XWP, Siemens Healthcare, Forchheim, Germany). These fused images are used during the implantation procedure to confirm the accuracy of the final position of each electrode and to insure the absence of vascular structures along the electrode pathway, which may not be noted on MRI with contrast. Following the planning phase using the stereotactic software, trajectories' coordinates are recorded and transmitted to the operating room. Trajectories are in general planned in orthogonal orientation in relation to the skull's sagittal plane in order to facilitate implantation and later on interpretation of the electrode positions. Using the Leksell stereotactic system, coordinates for each trajectory are then adjusted in the frame and a lateral view fluoroscopic image is performed in each new position. Care is taken to assure that the central beam of radiation during fluoroscopy is centered in the middle of the implantation probe in order to avoid parallax errors. If the trajectory is aligned correctly, corresponding to the planned trajectory and passing along an avascular space, the implantation is then continued, with skull perforation, dura opening, placement of the guiding bolt (AdTech, Racine, WI; Integra, Plainsboro, NJ), and final insertion of the electrode under fluoroscopic guidance. If a vessel is recognized along the pathway during fluoroscopy, the guiding tube is manually moved a few millimeters until the next avascular space is recognized and implantation is then continued. The electrode insertion progress is observed under live fluoroscopic control in a frontal view to confirm the straight trajectory of each electrode. For additional guidance, a coronal MRI slice corresponding to the level of each electrode implantation is overlaid onto the fluoroscopic image.

A postimplantation DynaCT scan is performed while the patient is still anesthetized and positioned in the operating table. The reconstructed images are then fused with the MRI dataset using the previously described fusion software. The resulting merged datasets are displayed and reviewed in axial, sagittal, and coronal planes allowing verification of the correct placement of the electrodes (21).

Following the surgical electrode implantation, patients are transferred to the epilepsy monitoring unit (EMU). The duration of admission at the EMU varies from patient to patient and depends on several factors including number and quality of recorded ictal and interictal patterns. In the last 4 years, patients undergoing SEEG implantation at Cleveland Clinic stayed on average 7 days (range from 3 to 28 days). After obtaining the necessary information, electrodes are removed in the operating room, in a procedure performed under local anesthesia and sedation. The results of the SEEG evaluation are discussed during another patient management conference, and recommendations for surgical resection are made. Patients are discharged the next morning, and resective surgery is scheduled 2 to 3 months following SEEG electrode removal (Fig. 81.2).

INDICATIONS OF SEEG ELECTRODE PLACEMENT

In addition to the general indications for invasive monitoring, specific indications can be considered to choose SEEG in detriment to other methods of invasive monitoring. These criteria include:

1. The possibility of a deep-seated or difficult-to-cover location of the EZ in areas such as the mesial structures of the temporal lobe, opercular areas, cingulate gyrus, interhemispheric regions, posterior orbitofrontal areas, insula, and depths of sulci
2. A failure of a previous subdural invasive study to clearly outline the exact location of the seizure-onset zone. The failure to identify the EZ in these patients may be due to multiple reasons that include the lack of adequate sampling from a deep focus or a clinically silent focus upstream from the EZ
3. The need for extensive bihemispheric explorations (in particular in focal epilepsies arising from the interhemispheric or deep insular regions)
4. Presurgical evaluation suggestive of functional network involvement (e.g., limbic system) in the setting of normal MRI (Table 81.1)

Table 81.1 Selection Criteria for Different Methods of Invasive Monitoring in Medically Refractory Focal Epilepsy

Clinical scenario	Method of choice	Second option
▪ Lesional MRI: Potential epileptogenic lesion is superficially located near or in the proximity of eloquent cortex.	SBG	SEEG
▪ Nonlesional MRI: Hypothetical EZ located in the proximity of eloquent cortex.		
▪ Lesional MRI: Potential epileptogenic lesion is located in deep cortical and subcortical areas.	SEEG	SBG with depths
▪ Nonlesional MRI: hypothetical EZ is deeply located or located in noneloquent areas.		
▪ Need for bilateral explorations and/or reoperations	SEEG	SBG with depths
▪ After SDGs failure	SEEG	SBG with depths
▪ When the AEC hypothesis suggest the involvement of a more extensive, multilobar epileptic network	SEEG	SBG with depths
▪ Suspected frontal lobe epilepsy in nonlesional MRI scenario	SEEG	SEEG

In these scenarios, the SEEG methodology may be considered as a more appropriate and safer option. As mentioned above, the SEEG methodology has the advantages of allowing extensive and precise deep brain recordings and stimulations with minimal associated morbidity. A majority of patients undergoing reoperations may have failed epilepsy surgery during preceding subdural evaluations because of difficulties in accurately localizing the EZ. These patients pose a significant dilemma for further management, having relatively few options available. Further open SDG evaluations may carry the risks associated with encountering scar formations and still having limitations related to deep cortical structure recordings. A subsequent evaluation using the SEEG method may overcome these limitations, offering an additional opportunity for seizure localization and sustained seizure freedom (28) . The main disadvantage of the SEEG method is the more restricted capability for performing functional mapping. Due to limited number of contacts located in the superficial cortex, a contiguous mapping of eloquent brain areas cannot be obtained as in the subdural method mapping. In order to overcome this relative disadvantage, the functional mapping information extracted from the SEEG method is frequently complemented with other methods of mapping, such as diffusion tensor imaging (DTI) images or awake craniotomies (21).

INVASIVE MONITORING MORBIDITY

In the Cleveland Clinic SEEG series, the total complication rate was 3%. Other groups reported similar results. Cossu et al. reported a morbidity rate of 5.6%, with severe permanent deficits from intracerebral hemorrhage in 1% (36). In our series, all three complications were hemorrhagic, which has been reported in several studies to be the most common complication in the setting of depth electrode placement (21,36). Other published series reporting complications across invasive monitoring procedures (SDGs and depth electrodes) documented rates ranging from 0% to 26% (32,40,41). SDG electrode implantation has historically been shown to have low permanent morbidity (0% to 3%) compared with depth electrodes (3% to 6%) since there is no intraparenchymal passage. Although it is difficult to compare morbidity rates between SDGs and SEEG due to the variability in patient selection, different institutions, and variable number of implanted electrodes, our early experience suggests that the SEEG method provides at least a similar degree of safety when compared with SDGs or strips. This impression is also shared by others (34,36,42,43).

CONCLUSIONS

The goals of invasive monitoring in pharmacoresistant focal epilepsy may include (i) the need for better anatomical localization and spatial delineation of the extent of the EZ and (ii) the need for the definition of cortical and subcortical functional brain areas. Extraoperative mapping with the subdural method (which includes SDGs and strips) has the advantage of allowing an optimal anatomical and contiguous coverage and sampling of adjacent cortex leading to accurate functional mapping. In addition, from a surgical perspective, subdural implantations are open procedures, with better management of possible intracranial hemorrhagic complications. The disadvantages of the subdural method are related to the inability to record and stimulate deep structures such as the insula, posterior orbitofrontal, cingulate gyrus, depths of sulci, etc. In these scenarios, the SEEG methodology may be considered as a more adequate and safer option. SEEG has the advantages of allowing extensive and precise deep brain recordings and stimulations with minimal associated

morbidity.

CHAPTER 82 SURGERY FOR MEDICALLY REFRACTORY TEMPORAL LOBE EPILEPSY

SUMEET VADERA, WILLIAM E. BINGAMAN, AND IMAD M. NAJM

INTRODUCTION

Temporal lobectomy is commonly utilized for patients with medically intractable epilepsy and mesial temporal sclerosis (MTS), but this procedure can also be utilized for a variety of other epileptogenic lesions including malformations of cortical development (MCD) as well as neoplastic and vascular lesions of the temporal lobe (1). Although the term "standard temporal lobectomy" is used in the medical literature to describe removal of the lateral and mesial temporal lobe structures, there are significant variations in the technique based upon institutional practices and surgeon preference. The authors will discuss indications for this procedure and then describe techniques involved with resection.

INDICATIONS FOR TEMPORAL LOBECTOMY

As with all resective epilepsy surgery, prior to consideration for temporal lobectomy, patients must demonstrate (i) concordance of noninvasive data implicating the temporal lobe and (ii) medically intractable epilepsy after an adequate trial of anticonvulsants (2). It is important to keep in mind that as patients fail anticonvulsant medications, the likelihood of seizure freedom on medication alone falls precipitously with each additional medication trial. A study by Kwan and Brodie (3) showed that in patients with newly diagnosed epilepsy, only 47% became seizure free with administration of the first AED and only 14% with the second AED. Several studies have shown that temporal lobectomy is safe and superior to medical treatment, so the authors advocate for early surgical consideration in all patients with focal temporal lobe epilepsy who fail two anticonvulsant medications (4–6).

PRESURGICAL EVALUATION

There are several steps involved in the presurgical evaluation of patients prior to consideration for temporal lobectomy. Figure 82.1 shows a typical presurgical evaluation algorithm. Once the history, examination, video electroencephalography (vEEG), and magnetic resonance imaging (MRI) are obtained, the remainder of the workup is tailored entirely to the patient's clinical presentation (2,7–9). Therefore, not all studies are performed on all patients.

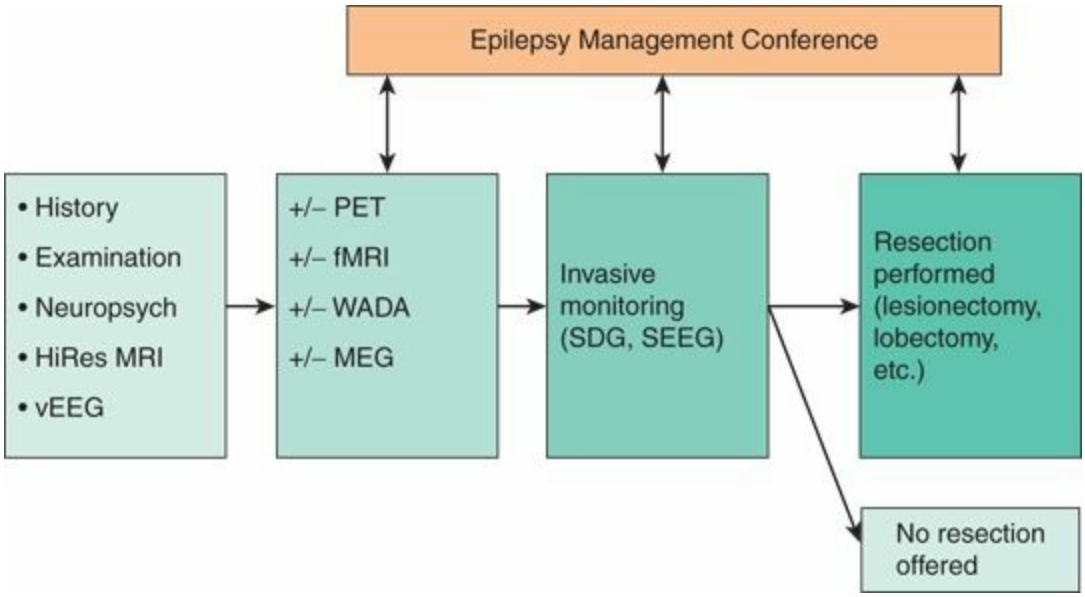

Figure 82.1. Typical presurgical evaluation algorithm for patients being considered for temporal lobectomy.

History and Neurologic Examination

The first step in evaluating any patient for temporal lobectomy is a thorough history and physical examination by a trained and experienced epileptologist. The history can assist with localizing the epileptogenic region and the possible underlying etiology. The history should specifically include any perinatal complications, history of childhood febrile convulsions, descriptions of auras, speech abilities during seizures, and whether the patient has any memory/naming difficulties. Physical examination is important to document any preoperative motor deficits and can be helpful if extratemporal (i.e., frontal lobe) epilepsy is suspected.

vEEG Monitoring—Semiology and EEG Patterns

Patients should undergo prolonged vEEG in a dedicated epilepsy monitoring unit to confirm the diagnosis and type of epilepsy (2,7). vEEG allows for a noninvasive method to evaluate the approximate localization and lateralization of the epileptogenic region. The ictal and interictal discharges help localize the region of interest, while the video recordings allow for a better understanding of seizure semiology and may assist with lateralization and localization.

Mesial Temporal Lobe Epilepsy

In adults with temporal lobe epilepsy undergoing temporal lobectomy, MTS is one of the most common pathologies and has been shown to be as high as 75% in some studies (10). Classically, patients describe an aura of a rising abdominal sensation, which often progresses to hand and mouth automatisms such as "picking" at their clothing or surroundings. They may also demonstrate contralateral dystonic hand movements during ictal onset. EEG recordings in patients with MTS typically show ipsilateral interictal anterior temporal lobe sharp waves and slowing. Sharp waves in the contralateral anterior temporal lobe have been described in patients with MTS but not in patients with other mesial temporal lobe lesions. Presence or absence of language function during a seizure can also be very helpful when attempting to lateralize language function and cerebral dominance (11).

Neocortical Temporal Lobe Epilepsy

Patients with neocortical temporal lobe epilepsy often present with different semiologies and EEG patterns than those with MTS. Motor phenomena may be more pronounced and are commonly seen earlier than in patients with MTS. EEG typically shows lateral and posterior distribution of ictal and interictal patterns (T7/8, P7/8) (1,12). Dual pathology can also be present, and there are several studies in the literature that describe lesions in the lateral temporal lobe (i.e., MCD and cavernomas) with associated MTS (13). To adequately assess the involvement of the mesial temporal lobe in these patients with "dual pathology," invasive electrode recordings may be considered prior to resective surgery.

Imaging Studies

High-resolution (1.5 or 3.0 T) MRI of the brain is the most important study to evaluate structural lesions in patients with temporal lobe epilepsy. At our institution, a dedicated epilepsy protocol MRI study is obtained on all patients evaluated for temporal lobe epilepsy. This includes thin-slice coronal T1-weighted magnetization prepared rapid gradient echo imaging, fluid attenuated inversion recovery (FLAIR) coronal sequences, and T2-weighted coronal sequences (Table 82.1). Contrast may be administered if a neoplasm is suspected. If available, 3.0 T MRI allows for better signal-to-noise ratio and should be utilized whenever possible to visualize subtle lesions such as MCD.

Table 82.1 Sequences for Epilepsy Protocol MRI

MRI epilepsy protocol (+/– gadolinium)
Volumetric coronal T1
Volumetric coronal and axial FLAIR
Coronal and axial T2

The epilepsy protocol utilizes several coronal sequences because these studies are best able to compare the size and shape of the hippocampi when evaluating for MTS. Hippocampal sclerosis also commonly exhibits increased signal intensity on FLAIR and T2 imaging. When MTS is noted, it is important to look for other temporal lobe lesions (i.e., MCD) as they may coexist with MTS and have been shown in up to 30% of these cases (2,14). This dual pathology may manifest itself as irregularities within the cortical ribbon or blurring of the gray–white junction. As mentioned previously, 3.0 T MRIs allow for increased resolution to detect structural lesions and should be considered in patients with no findings on 1.5 T MRI studies (15).

When evaluating language location in patients with temporal lobe epilepsy, the authors believe that functional MRI (fMRI) studies offer advantages over intracarotid sodium amobarbital testing (Wada tests) and now frequently use fMRI as the study of choice. One major advantage is that fMRI is noninvasive and does not put the patient at risk of periprocedural intracranial emboli that Wada testing may cause. Recent studies also suggest that fMRI is able to predict postoperative memory deficits with good accuracy (16,17).

Other studies such as fluorodeoxyglucose photon emission computed tomography, subtraction (ictal minus interictal) radionuclide blood flow studies, and magnetoencephalography are important

to utilize in the noninvasive presurgical evaluation and will be discussed elsewhere.

Neuropsychological Preoperative Evaluations

Neuropsychological testing and psychosocial and psychiatric evaluations are important during the presurgical evaluation period as the temporal lobe is involved in emotion, language, and memory. Oftentimes, patients will complain of difficulty remembering grocery lists or names of acquaintances, and this may prompt the patient to seek out a surgical evaluation. Although these complaints can be confounded by medication side effects, they are still very helpful in evaluating for baseline memory function and can help explain to the patient what to expect with regard to their memory after surgery. Formalized neuropsychological testing is also important to gain a baseline measure of overall intellectual functioning as well as verbal and visuospatial memory scores. The patient undergoes a litany of standardized neuropsychological tests, which are repeated 6 months after surgery. Postoperative memory outcomes are related to preoperative function and temporal lobe dominance. It is very important to discuss likelihood of postoperative memory decline in patients at risk. Invasive monitoring can also be utilized in patients who are high functioning with dominant temporal lobe epilepsy to attempt to preserve mesial structures and memory function.

When the presurgical evaluation has been completed, a multidisciplinary Epilepsy Management Conference should meet to evaluate all the data and decide upon the appropriate course of action. Ideally, this conference should consist of epileptologist(s), neurosurgeon(s), neuropsychologists, psychiatrists, neuroradiologist(s), nurses and midlevel providers, EEG technicians, and social workers. This conference is very important because a multidisciplinary approach to epilepsy surgery allows for the best care of patients with medically intractable epilepsy by creating a hypothesis of the location of the epileptogenic zone as well as an appropriate surgical strategy (see Fig. 82.1) (8,18,19).

ANATOMY OF THE TEMPORAL LOBE

An excellent understanding of the structural and functional anatomy of the temporal lobe is crucial when performing temporal lobectomy. The anterior, lateral, mesial, and basal surfaces are all well defined, while the posterior border is continuous with the parietal and occipital lobe. Mesial structures include the amygdala, hippocampus, parahippocampal gyrus, and the uncus. There are five gyri and four associated sulci in the temporal lobe (Table 82.2).

Table 82.2 Temporal Lobe Gyri and Sulci in Descending Order

Gyrus (superior to inferior)	Sulcus (superior to inferior)
Superior temporal gyrus	Superior temporal sulcus
Middle temporal gyrus	Inferior temporal sulcus
Inferior temporal gyrus	Occipitotemporal sulcus
Fusiform/occipitotemporal gyrus	Collateral sulcus
Parahippocampal gyrus	

Within the temporal horn, important anatomic structures include the inferior choroidal point

(anterior choroidal artery enters the choroid plexus here), the hippocampus occupying the mesiobasal portion of the ventricle, the fornix, the choroid plexus, the choroidal fissure, and the amygdala in the anterosuperomedial portion of the ventricle. Other important surgical landmarks during temporal lobectomy include the sylvian fissure, the vein of Labbé, the brainstem, posterior cerebral artery, basal vein of Rosenthal, and the third and fourth cranial nerves (20).

Aside from anatomic landmarks, there are also several important functional regions in the temporal lobe that must be considered. These include visual field fibers (Meyer loop), which cause contralateral upper quadrantic visual field deficits when removed ("Pie in the Sky" deficits), as well as important memory and language centers when operating on the dominant hemisphere. The exact location of language cortex in the dominant temporal lobe can vary significantly, and if necessary, intra- and extraoperative studies may be required to specifically localize language if a generous temporal lobectomy is planned. This includes awake craniotomy and direct cortical stimulation to test for language intraoperatively or invasive electrodes and functional stimulation to test for language extraoperatively. Some studies have shown that a small percentage of patients have language areas in the superior temporal gyrus (STG) as well as the basal temporal lobe, and as such, some centers will not remove the STG during temporal lobectomy, although no study has shown performing STG resection leads to long-term language deficits (12,21).

Meyer loop is located in the temporal lobe as the visual fibers extend from the lateral geniculate body before looping posteriorly to the calcarine cortex. These fibers are located in the roof of the temporal horn, and standard temporal lobe resections injure these fibers in as many as 50% of cases causing "Pie in the Sky" visual field deficits (22). When counseling patients, one can emphasize that this should not affect driving or other activities of daily living and that patients generally learn to ignore the deficit over time.

TEMPORAL LOBECTOMY PROCEDURE

In performing a temporal lobectomy, it is important to keep in mind whether the dominant or nondominant temporal lobe is being resected as this impacts the extent of posterior resection that can be performed. In dominant temporal lobe surgery, the posterior cut along the STG should be no more than 4.5 cm as measured from the temporal pole to avoid language deficits. In nondominant temporal lobe surgery, it is safe to extend this farther than 5.5 cm. It is important to visualize the vein of Labbé as this can limit posterior resection, especially when performing nondominant resections. Overly aggressive posterior resections can injure the geniculocalcarine tract leading to complete homonymous hemianopsia. If the surgical plan includes a generous temporal lobectomy, it is important to counsel the patient about this risk (23).

Standard preoperative measures are utilized including antibiotics, general anesthesia, arterial lines, IV access, and sterile preparation of the operative field. Hyperventilation and mannitol may be used for brain relaxation. A shoulder roll is used to limit neck rotation, and the head is placed in pins and turned 30 degrees from the midline so the operative site is accessible. The neck is gently extended to allow for the sylvian fissure to become perpendicular to the surgical approach, and finally, the vertex is rotated downward so that the temporal lobe falls away from the floor of the middle fossa to assist with the surgical approach. The ideal position will allow for the mesial structures to be readily visible and easily accessible to the surgeon once lateral temporal lobectomy is performed. Stereotactic navigation is optional and is not routinely used at our institution.

A small amount of hair is clipped along the surgical region, and a "reverse question mark"

incision is made 1 cm anterior to the tragus at the level of the zygoma, extending to the posterior part of the pinna and then curving anteriorly just above the insertion of the temporalis muscle. The temporalis is then sharply cut in a "T" manner ensuring that a cuff of muscle is left to suture the muscle back to. The anterior end of the "T" should go toward the anatomic "keyhole," and the inferior end of the "T" should go to the root of the zygoma. The muscle is then elevated from the bone and retracted from the surgical field.

Burr holes should be placed at the root of the zygoma and at the anatomic "keyhole" to give adequate exposure to middle fossa floor and superior aspect of the temporal lobe, respectively. Frontal lobe exposure is not necessary and should be minimized. Extending the craniotomy as anterior as possible and removing some of the sphenoid wing assist with the temporal lobectomy and are recommended. If air cells are noted at the bone edges, bone wax may be used to seal them off and prevent postoperative cerebrospinal fluid (CSF) leakage.

There are often several large arteries on the dura, including the middle meningeal branch, that may cause significant bleeding. These should be coagulated as proximal as possible to avoid shrinkage of the dura. The dural flap is reflected anteriorly and the temporal lobe visualized. An appropriately sized craniotomy should include the sylvian fissure along the superior limit of the bony edge, and the floor of the middle fossa should be visualized with minimal retraction of the inferior temporal gyrus. The sylvian fissure and floor of the middle fossa should be readily visible without brain retraction, and the temporal pole should be within 1 to 2 cm of the anterior bony edge of the craniotomy. Excess brain swelling may be treated with head elevation, mannitol, and/or hyperventilation.

The posterior limit of resection along the STG is now measured with a Penfield #1 dissector placed so the curve of the instrument follows the curve of the temporal pole and the instrument follows the STG. The appropriate length is decided based upon the laterality as well as any associated vessels. Vessels supplying the posterotemporal lobe should be preserved to avoid strokes along the edge of the resection cavity. On the other hand, vessels supplying the anterior temporal lobe are usually safe to ligate because the tissue they supply will eventually be removed.

Once the posterior line of resection is marked, dissection begins along the STG a few millimeters inferior to the sylvian fissure. This is done with bipolar coagulation and sharply dividing the pia followed by subpial aspiration of the cortical tissue. This allows exposure of the temporal pia of the sylvian fissure and the underlying insula and middle cerebral arteries. Large MCA branches should be visible through the temporal pia of the insula, which can help distinguish the correct plane. Dysplastic tissue often can be lifted off the pia very easily and requires minimal coagulation. The pia will end at the inferior circular sulcus of the insula, and this is also where the temporal stem begins. Avoid going deep to the plane of the pia past the inferior circular sulcus as this can cause inadvertent injury to vital structures including the basal ganglia and brainstem. Extend the resection anteriorly until the dura anterior to the temporal pole is reached. The posterior cut continues inferiorly at the premeasured point previously determined (3 to 4.5 cm left, 5.5 cm right). The posterior line of resection extends from just below the sylvian fissure at the STG angling posteriorly along the middle and inferior temporal gyrus so that slightly more inferior temporal gyrus is removed than STG. To avoid excessive bleeding, all pial edges should be coagulated and divided sharply during this portion of the procedure. The cortical tissue is aspirated down to the depth determined by exposure of the inferior circular sulcus. The basal temporal lobe is divided in line with the posterior cut as the fusiform gyrus is aspirated to expose the collateral sulcus. This dissection should be continued as long as the floor of the middle fossa is visible. As you perform this procedure, continue to look for

the edge of the tentorium as this will provide an important anatomic landmark later on in the case. If the edge of the tentorium is encountered, it is likely that the collateral sulcus has already been divided. The collateral sulcus is an important landmark as it facilitates controlled entry into the inferior horn of the lateral ventricle. As the inferior resection is continued, the ventricle should be encountered by gently aspirating the white matter near the end of the collateral sulcus. In patients with severe hippocampal sclerosis, sometimes the hippocampus can go unnoticed during the lateral temporal lobe dissection. To avoid complications in these cases, it is important that you utilize the tentorium as an anatomic boundary and use the above techniques to find the ventricle and the hippocampus. Once the ventricle is encountered, a cotton patty can be placed within the ventricular space to serve as a landmark and assist with the completion of the lateral temporal lobectomy. The ventricle can be opened further with gentle aspiration and coagulation directly over the patty. The hippocampus and amygdala will be readily visible once this is opened in entirety. The final cut involves connecting the anterior and posterior cuts by following the lateral ventricular sulcus. When this is complete, the lateral temporal lobe can be removed in entirety. Prior to removal, ensure that all draining veins are coagulated as this can cause excess bleeding. Also, note that bradycardia is sometimes encountered when coagulating along the floor of the middle fossa, and if this is noted, immediately stop coagulating and wait until this resolves. Finally, avoid excessive coagulation along the middle fossa floor as the heat may disseminate and cause injury to the fourth nerve, which runs immediately under the dura.

The resection of the mesial structures can be performed with loupe magnification or operating microscope. The operating microscope allows for improved magnification and illumination. The anatomy in this region is complex, and it is recommended that the operating microscope be utilized until a level of comfort is reached at which point loupes may be considered. Careful removal of the parahippocampus, hippocampus, and amygdala requires a thorough understanding of the relationships existing between these structures in the perimesencephalic cistern, the hippocampal sulcus, and the choroidal fissure and point. Failure to respect important landmarks at this point can lead to serious complications and patient harm. The next two steps may be performed in series or in parallel. The first step is removal of the amygdala and the uncus, and the second step is removal of the hippocampus and parahippocampus. It is important to respect the pial planes as they will protect the underlying structures from injury, especially along the perimesencephalic cistern. This can be done using subpial aspiration and minimal bipolar coagulation.

To remove the amygdala, begin by identifying the choroidal point as this serves as the uppermost border of the resection. This point is where the anterior choroidal artery enters the temporal horn and supplies the choroidal plexus. It is very important that this artery is not injured and that choroidal plexus coagulation is limited as this can lead to anterior choroidal artery territory strokes, which can be devastating. To find a safe plane to resect the amygdala, place a cottonoid patty such that it connects the choroidal point to the MCA branches that are visualized through the anterior sylvian pia. One may also utilize the roof of the ventricle as the uppermost border for resection. Continue to deepen this cut straight downward until mesial pia is reached. It is very important that this cut is not extended superiorly as the upper amygdala merges with the globus pallidus and can cause injury to the patient. As mentioned before, it is also important that the anterior choroidal artery is not coagulated as this can lead to hemianopsia and hemiplegia secondary to an anterior choroidal territory stroke. This cut is continued until the pial plane is reached, which overlies the brainstem, third nerve, and PCA. The remainder of the amygdala/uncus complex can be removed by gently separating the tissue from the pia. Finally, the posterior cut is made at the amygdalohippocampal

sulcus, and this should allow for removal of the amygdala/uncus complex. If the anterior edge of the tentorium, third nerve, and anterior PCA are not visualized, the amygdala complex has not been removed entirely.

The next step is to perform the hippocampal resection, and this is done first by gently aspirating any residual parahippocampal tissue, which is visible mesial and deep to the collateral sulcus. When this is removed, the hippocampus can be retracted toward the floor of the middle fossa with minimal retraction on the roof of the ventricle. The ventricle is opened up further until the tail of the hippocampus is visible as it extends around the brainstem. Care must be taken to avoid retraction upward along the roof of the ventricle or posteriorly along the edge of the remaining dominant temporal lobe as this can lead to hemiparesis and language deficits, respectively.

Once the parahippocampus is removed, the choroidal fissure is exposed by gently retracting the choroid plexus superiorly with the use of a cottonoid patty. Aspiration of the fornix of the hippocampus and dentate gyrus allows for the exposure of the underlying hippocampal sulcus. Tiny vessels in the hippocampal sulcus will be visualized and should be coagulated and cut sharply while leaving an arterial tail that is easily accessible. If this is not performed correctly, the stump can sometimes retract into the perimesencephalic cistern and cause a large subarachnoid hemorrhage, which is difficult to control and leads to a suboptimal result. Once the hippocampal sulcus is divided, the hippocampus and any remaining parahippocampus can be gently peeled off the underlying pia, and finally, the tail of the hippocampus can be amputated as it extends around the brainstem. The hippocampus can now be removed and sent to pathology for study. The mesial resection is then assessed and any remaining accessible posterior hippocampus removed. The posterior cut across the tail of the hippocampus should ideally allow for 3 to 4 cm of hippocampus to be removed.

At this point, hemostasis should be obtained with a combination of irrigation, hemostatic agents, and time. Coagulation should be used sparingly especially on the pial surfaces as this can cause heat spread and injury to underlying structures. The cavity is then filled with saline and the dura closed in watertight fashion. The craniotomy flap is attached with titanium fixation and the muscle sewn together and re-approximated to the residual cuff. The skin is then closed in anatomic layers over a subgaleal drain to reduce postoperative swelling.

OUTCOMES AND COMPLICATIONS

The best method to evaluate whether surgery is successful is by allowing the passage of time to dictate whether seizure freedom was achieved. Temporal lobectomy for medically intractable focal epilepsy, especially in patients with MTS, has been shown to have the best long-term seizure-free outcomes of any epilepsy surgery. The literature quotes seizure-free rates between 60% and 80%, although there is a decline over time, which is related to late-onset seizure recurrence (24–27). There is some controversy over whether normal MRI findings suggest worse seizure-free outcomes (24). One interesting finding noted during the postoperative period has been described as the “running-down” phenomena. This has been noted in up to 33% of patients and involves rare postoperative seizures after surgery, which essentially stops after approximately 6 months. It is hypothesized that this is related to a small residual focus of epileptogenic zone that has been debulked but not entirely removed. In this case, either this area loses the ability to create seizures or anticonvulsant medications are able to control the region (26).

Although hippocampal sclerosis is most common in adults, one study showed similar good outcomes relating to pediatric patients with hippocampal sclerosis, with an overall Engel grade 1 or

2 score of 84% (28).

Temporal lobectomy has the benefit of a high seizure-free rate as well as a very low rate of complication. Risks related to the procedure are very low and include infection (wound, craniotomy, meningitis, urine), hemorrhage (wound, epidural, subdural, intracerebral), red blood cell transfusion related to acute blood loss anemia, deep venous thrombosis, and anesthetic complications. Death after temporal lobectomy is exceedingly rare (26,28).

Aside from the complications that have already been discussed (visual field deficits, language and naming problems related to the dominant temporal lobe, cranial nerve palsies, and paresis and plegia), there are other common conditions that should be discussed with the patient that are not considered complications of the surgery. These include headaches, depression, swelling of the eye and face, jaw pain and difficulty eating (related to temporalis manipulation), and cosmetic deformity. Patients should be counseled that these conditions improve with time, although headaches and depression can make the patients feel very uncomfortable and anxious. Patients with a history of headaches, depression, and anxiety can sometimes find these are exacerbated after surgery.

Postoperative aphasia can be noted after dominant temporal lobe resection, although this is fortunately fairly uncommon. Patients may perseverate, have naming difficulty, or wake up with global or mixed aphasias. This can be very distressing for the patient and family members, and they should be counseled that language will likely return to baseline after an MRI is performed, which shows no stroke in the posterior dominant temporal lobe. Language function usually returns or improves within 24 to 48 hours. Steroids and speech therapy may be started during this period to assist with recovery. To minimize this complication, it is very important to avoid retraction on the posterotemporal lobe in the dominant hemisphere and preserving all vasculature that supplies the residual temporal lobe.

NEUROPSYCHOLOGICAL OUTCOMES

Patients often complain about cognitive dysfunction during the preoperative and postoperative period. Preoperatively, this can be related to medication effects on normal tissue as well as damage to the mesial structures with repeated seizure activity. Neuropsychological testing is important in the preoperative period to assist with counseling the patient on what to expect postoperatively. As mentioned earlier, patients at high risk for memory decline after dominant temporal lobectomy may benefit from invasive monitoring to assess the involvement of mesial structures. As one might expect, postoperative memory decline has been shown to be related to dominant temporal lobectomy, normal hippocampal size, normal baseline neuropsychological testing, and late onset of epilepsy. Although discussion has mainly focused on risks associated with dominant temporal lobectomy, surgery on the nondominant temporal lobe is associated with decline in visuospatial memory on repeat neuropsychological testing, but this is rarely clinically significant.

CONCLUSION

This chapter describes several variations on the “standard temporal lobectomy” across institutions and based upon surgeon preference, but interestingly, reported outcomes are universally quite good. The surgical treatment of medically intractable temporal lobe epilepsy is safe and effective and should not be delayed in patients that fail appropriate medical treatment. The preoperative workup should be completed at an epilepsy center that utilizes a multidisciplinary approach and is

comfortable with the surgical treatment of epilepsy.

CHAPTER 83 SURGERY FOR FOCAL CORTICAL DYSPLASIAS

IMAD M. NAJM, ANDRE PALMINI, AND WILLIAM E. BINGAMAN

INTRODUCTION

The term "focal cortical dysplasia" was first used to describe a specific malformation of the brain that consisted of disorganized cortex with enlarged irregular/disoriented neurons (1) and enlarged ballooned cells (2). Since then, FCD has been increasingly recognized as a cause of pharmacoresistant epilepsy that carries a less favorable prognosis for a seizure-free outcome following surgical resection (3–7). The increased incidence of FCDs reported in surgical series has been attributed to better preoperative identification of the lesions through improved magnetic resonance imaging (MRI) resolution, a better understanding of the electroclinical characteristics of various FCD subtypes, and reports of more favorable postoperative seizure outcomes.

This chapter reviews the pathologic subtypes of FCDs in light of the recently reported clinical, electrical, imaging, and functional observations since the last International League Against Epilepsy (ILAE) revision (8). We also discuss the presurgical evaluation and surgical management of FCDs in the setting of pharmacoresistent epilepsy.

HISTOPATHOLOGY OF FCDS

It is useful to think about the cerebral cortex along architectural and cellular axes. Normal cortex has a laminar distribution (architecture) of granular and pyramidal neurons (cells) along six layers. The hallmark of FCDs is an abnormal cortical microarchitecture, with loss of the laminar neuronal distribution. Furthermore, some types of FCD also have abnormal cell types, specific for this disorder. These have increased volume, are haphazardly distributed over the dyslaminated cortex, and are of two main types: dysplastic neurons and ballooned cells. Thus, a focal dysplastic lesion may feature abnormalities only in the architectural axis or in both, the architectural and the cellular axes. This understanding is crucial to correctly interpret the histopathologic classifications of FCDs.

The original histopathologic classification of FCDs that was introduced in 2004 addressed many practical aspects for the everyday presurgical evaluation and surgical management of patients with pharmacoresistant epilepsy due to FCDs (Fig. 83.1) (9). The original classification was recently revised by an ad hoc task force of the ILAE (8), which kept the core features of the original classification (10) and added a third FCD type. Thus, currently, FCDs are divided into three pathologic FCD subtypes: FCD ILAE type 1 is histopathologically characterized by architectural disorganization (i.e., dyslamination) at the columnar (type 1a), laminar (type 1b), or both (type 1c) levels. Focal cortical dysplasia ILAE type 2a is characterized by dysmorphic neurons in the setting of architectural disorganization, while type 2b included the changes seen in type 2a in addition to balloon cells. A third type of FCD was introduced (type 3) that dealt with other (principal)

pathologies associated to FCD, particularly FCD type 1. Five subtypes were included under FCD type 3: 3a, hippocampal sclerosis; 3b, tumor pathology; 3c, vascular malformations; 3d, occurring in the setting of any other brain lesions acquired during early life, that is, trauma, ischemic injury, or encephalitis; and type 3NOS (Not Otherwise Specified) in which an associated pathology is suspected based on imaging data but surgical material for pathologic examination and verification of diagnosis is not available. There is much to be learned on the independent epileptogenic potential of the dyslamination (i.e., FCD) associated with these principal pathologies and whether such associations should be considered as a single or dual pathology (11).

IMAGING CHARACTERISTICS OF FOCAL CORTICAL DYSPLASIAS

MRI techniques have provided a noninvasive window for the identification, localization, and some definition of the extent of some forms of FCDs.

FCD type 1: Nonspecific MRI changes were described for type 1. These include white matter volume reduction and subtle increased signals on fluid attenuated inversion recovery (FLAIR) and T2-weighted images. However, MRI is normal in the majority of patients with type 1 FCD (12,13). Nevertheless, it is important to seek very carefully for asymmetries in the cortical–white matter interdigitations, or in the white matter volume, because subtle changes may prove relevant and aid decision making (Fig. 83.2).

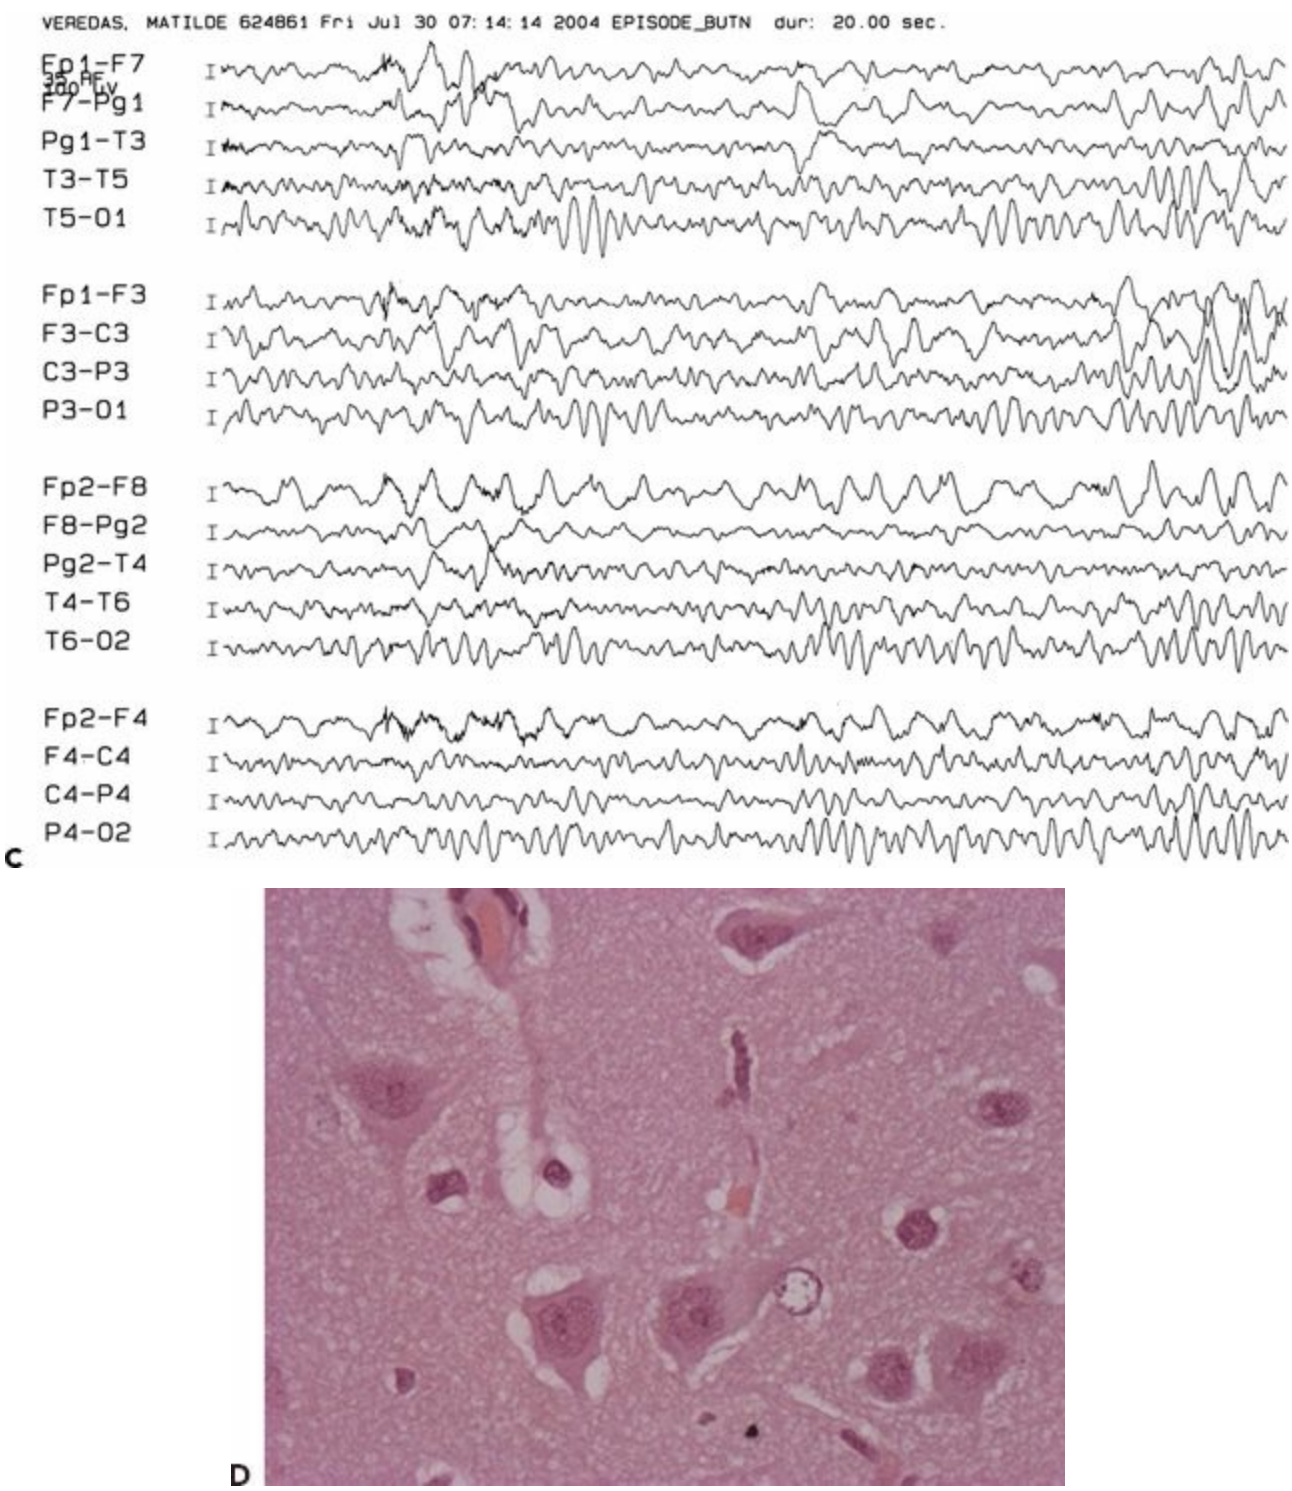

Figure 83.2. Two-year-old girl with frequent partial seizures, secondary generalization, and severe developmental delay. Sagittal **(A)** and axial **(B)** MRI sections showing a grossly dysplastic lesion in the right frontocentral region. Ictal EEG **(C)** suggested right frontal seizure onset. Following extensive frontocentral resection, the patient was seizure free for 30 months, when attacks recurred in the form of frequent startle-induced seizures with drop attacks. There was dramatic psychosocial regression. In **(B)**, note asymmetry of the white matter in the posterior quadrant, suggesting that the lesion was more considerably extensive than previously thought. Histopathology was FCD type 1 **(D)**.

FCD type 2: The most commonly reported abnormalities in FCD type 2 consist of focal changes in the cortical thickness, signal increase (mainly on FLAIR and T2-weighted sequences), and gray–white matter blurring, and in type 2b, the additional presence of a "transmantle" sign (a linear track of increased signal, extending from the periventricular region to the cortical mantle) (12–16). Recent observations show that type 2b dysplasia may show two distinct imaging patterns: (i) Mild to moderate FLAIR signal increase associated with increased thickness of the gray matter. These lesions tend to occur in the depth of sulci, in particular the precentral sulcus, superior frontal sulcus, and the

anterior extent of the sylvian fissure (frontal operculum) (17). (ii) A second group of balloon cell–containing FCD lesions is characterized by a "tuber-like" or "tumor-like" dense FLAIR signal increase in the center of the pathologic lesion surrounded by areas of variable FLAIR signal intensities (18), thickening of the cortical mantle, and gray–white matter blurring in association with transmantle signal increase pointing to the periventricular region (14,19,20). Less commonly described abnormalities such as cortical dimple, and hemispheric atrophy have been described in type 1 FCDs (21).

FCD type 3 lesions share the typical features of the associated lesions (HS, tumors, vascular malformations, scars) (22).

EPILEPTOGENICITY OF FCDS

The intrinsic in situ epileptogenicity of FCDs was previously reported by (4) using intraoperative electrocorticography (ECoG). Ictal or continuous epileptogenic discharges were mostly recorded from electrodes overlying dysplastic gyri. Direct cortical recordings demonstrated in situ epileptogenicity in FCD types 1, 2a, and some type 2b lesions (23,24) and showed various types of interictal epileptic activities (ranging from isolated spikes, polyspikes, repetitive spiking, to paroxysmal fast activities) and multiple ictal epileptic patterns (24). Some reports seem to suggest possible specific epileptic patterns in FCDs type 2, particularly repetitive, virtually continuous spikes (4,25,26). More recent data further suggested the in situ epileptogenicity of FCD through the recording of high-frequency oscillations (27).

The specificity of some interictal patterns as possible predictors of the area of ictal seizure onset has been reported, and focal continuous rhythmic discharges, repetitive spiking, and paroxysmal fast activities have been suggested as possible predictors of the ictal onset zone and early postoperative seizure outcome after resection of the area of focal electrical abnormalities (28).

We previously showed a differential distribution of the epileptic activities in balloon cell–containing lesions (type 2B) that display "tuber-like" or "tumor-like" high FLAIR signal intensities. The subregion within the balloon cell–rich FCD (mainly at the center of the MRI tuber-like abnormality) shows the least epileptogenicity, while the surrounding dysplastic cortical area containing few or no balloon cells (FCD type 1 or more often 2A) shows evidence of significant in situ epileptogenicity (24). On the other hand, deep sulcus balloon cell–containing lesions display intrinsic epileptogenicity (within the MRI-identified abnormality).

FUNCTIONAL STATUS OF FCDS

As a significant number of focal dysplastic lesions (FCDs) preferentially involve the frontal and temporal lobes, the issue of functional mapping and its potential overlap with epileptogenic cortex is the main challenge in the process of presurgical management of these patients (28). Dysplastic cortex has been shown to retain motor, sensory, or even language-related functions (29). Various electrical stimulation studies have shown that the dysplastic neocortex may conserve temporal and frontal language sites (30), but may display atypical motor homunculi (31,32). These studies demonstrate that function in dysplastic cortex could be preserved but may be reorganized and differences in functional expression may be dependent on the histopathologic subtype and spatial extent of the FCD. Some evidence is also provided by surgical intervention in high-functioning areas, in which a complete lesionectomy did not lead to motor deficit (33). What can be said, however, is that in FCD 2b, the

areas with the brightest signal changes most likely do not contain functions (and are less epileptogenic!) (33). These data lead to this rather provocative (and to a large extent hypothetical) question: Could incomplete resections of balloon cell-containing regions be an option considering their lack of epileptic potential and their possible protective effect against the seizures?

PREOPERATIVE EVALUATION AND SURGICAL MANAGEMENT OF PATIENTS WITH FCD: DIFFERENT SCENARIOS, VARIABLE APPROACHES

The precise anatomical localization and mapping of eloquent cortex and its relationships with a well-defined epileptogenic area are the most important components of any presurgical evaluation. They will facilitate the surgical planning and optimize the chances for a safe resection of the epileptogenic region (thus maximizing the chances for seizure freedom and minimizing the risks of neurologic deficits). Based on our current knowledge regarding FCDs, we suggest the following processes of presurgical evaluation and surgical management in patients with pharmacoresistant epilepsy.

The Preoperative Identification and Localization of FCD Lesion

MRI remains the gold standard and the most sensitive noninvasive window to the brain anatomy in the process of investigating the cause of epilepsy. As discussed above and elsewhere in this book, the identification of a lesion significantly enhances surgical candidacy, simplifies presurgical workup, and often improves seizure outcome. Furthermore, high-resolution MRI may help in the formulation of a hypothesis on the pathologic subtype of FCD (34). Interestingly, despite all advances in MRI, there remains a significant number of patients with FCDs (in particular FCD type 1) whose MRIs remain normal. A recent study found that more than 40% of patients with MRI-negative epilepsy harbor pathologic-confirmed FCD, the majority FCD 1 (35). However, apparently normal MRIs of children with severe epilepsies and mental retardation, with focal or multifocal discharges associated with secondary bilateral synchrony, should be examined with utmost care, seeking for asymmetries in the cortical–white matter interdigitations or in the white matter volume. Subtle changes may be a clue to a specific type of FCD type 1 that deserves aggressive surgical management (34,36,37).

Additional postprocessing techniques such as voxel-based MRI postprocessing using a morphometric analysis program (MAP) may help in the identification of some of these lesions: MAP abnormalities were found in 48% of the MRI-negative epilepsy patients (38).

Localization of the Epileptogenicity, Definition of Its Extent and Functional Mapping

Video electroencephalography (VEEG) would help in the identification of the network structures that may be involved in seizure generation and progression (through analysis of the recorded seizure semiology), therefore leading to the formulation of a clear anatomoelectroclinical hypothesis. Further validation of the anatomic hypothesis is achieved through imaging (the identification of lesion on MRI), with or without metabolic imaging (including FDG-PET hypometabolism that may point to

focal regions of cortical dysfunction). Other studies that may include ictal SPECT (SISCOM), MEG, and EEG-fMRI would further point to areas of dysfunction within a network or identify the three-dimensional localization of interictal epileptogenic regions, respectively.

Noninvasive studies achieve the goal of identification of the epileptogenic area and its possible anatomical cause in a sizable number of surgical patients (39–42). In many, however, formulation of a clear anatomoelectroclinical (AEC) hypothesis may not be possible, or an AEC hypothesis is generated but the exact location of the epileptogenic area within the network, its extent, and/or its overlap with functional (eloquent) cortex remain unclear (43–46).

The localization of functional areas in the brain, mapping of their extent, and their potential spatial overlap with the epileptogenic zone (EZ) are essential parts in the process of developing an adequate and individualized resective surgical strategy (39,47,48). As focal cortical dysplastic lesions (FCDs) are differentially located in the frontal and temporal lobes (therefore in potentially eloquent cortex), an understanding of the functional status of the involved region(s) and its anatomical and pathologic correlations are essential (39,49).

The pathologic differences and variable imaging characteristics in addition to the lack of known in situ biomarker(s) for the localization and mapping of the intrinsically epileptogenic dysplastic cortex constitute major challenges in the presurgical evaluation and surgical treatment of patients with FCDs (50,51). The main indications for an invasive evaluation in focal pharmacoresistant epilepsy due to suspected FCD (with the main purpose of direct cortical recording) are to address the main challenges and limitations of various noninvasive techniques. We recently recommended that an invasive evaluation should be considered in any one of the following cases (18):

1. The MRI does not show a cortical lesion in a location that is concordant with the electroclinical/functional hypothesis generated by the VEEG recordings (so-called MRI-negative cases).
2. The anatomical location of the MRI-identified lesion (and at times the location of a clearly hypometabolic focal area on PET) is not concordant with the electroclinical hypothesis. These include selected cases of deeply seated brain lesions such as deep sulcal lesions.
3. There are two of more anatomical lesions with the location of at least one of them being discordant with the electroclinical hypothesis, or both lesions are located within the same functional network, and it is unclear if one (or both) of them is (are) epileptic.
4. The generated anatomoelectroclinical hypothesis (MRI-negative or MRI-identifiable lesion) involves a potentially highly eloquent cortex (52–54).

In these instances, an invasive evaluation would lead to the formulation of a resective surgical strategy. The recommendation for an invasive monitoring and its type should be made during a multidisciplinary patient management meeting that includes neurologists, neurosurgeons, neuroradiologists, and neuropsychologists. Areas and networks of coverage/sampling should be determined based on a well-formulated AEC hypothesis (based on the results of all available noninvasive studies).

For this purpose, one intraoperative recording technique (ECoG) and two extraoperative invasive methods with chronic recordings—subdural grid electrodes (SDG) and stereotactically placed intracerebral electrodes (SEEG)—have been used to accomplish these goals.

Intraoperative recording is a limited option as it only provides information restricted to interictal activity. However, this type of recording may prove very useful when continuous repetitive

discharges are seen from involved cortex, as these have been shown to significantly correlate with the ictal onset zone (4,49,55). Furthermore, acute ECoG with carbon-ball electrodes may be performed in sequential stages during the resection, allowing electrical activity from depths of gyri and adjacent cortical regions to be repetitively probed (55). The influence of anesthetic agents on EEG activity may alter thresholds of afterdischarges and motor responses (52), although this has not been a universal observation and is often not relevant for the localization purposes of the study. Additionally, intraoperative language mapping often requires a cooperative patient who can tolerate being awake during surgery under local anesthesia. This is particularly difficult in the pediatric population.

Extraoperative mapping with subdural grid electrodes (SDG) has the main advantage of allowing an optimal coverage of the subdural space adjacent cortex with adequate and continuous superficial functional mapping capabilities (32,56–58). A major strength of subdural electrodes consists in the comprehensive anatomical coverage of cortical surfaces therefore allowing accurate anatomical electrical and functional mapping of the areas of coverage. Limitations of SDGs include the inadequate/partial/incomplete intrasulcal and interhemispheric coverage (59) and the need for craniotomy in order to implant. These characteristics are highlighted in the published results on the successes and failures following SDG implantation (60). Previous outcome studies showed that the best results following SDG implantation are achieved in patients with clear cortical lesions (in particular tumors), those who underwent lobar resections, and those patients in whom functional mapping was the main purpose of SDG implantation (49,60). These observations suggest that the best candidates for extraoperative invasive evaluation with SDG are those patients with clear FCD surface lesion(s) (excluding the interhemispheric, cingulate gyrus, deep sulcal, and mesial frontotemporal regions). A modified implantation approach of SDG and manually implanted depth electrodes has been used for the last 10 years at some epilepsy surgery programs. This modified approach has the main advantage of combining the two recording methods and thus allowing for excellent cortical coverage and some sampling of deeper lesions. But this modified approach does not allow extensive network coverage of functional networks and lacks the accuracy of the SEEG methodology.

Extraoperative recording with (SEEG) is indicated in patients with deep-seated lesions or in areas that are difficult to cover with SDG such as the interhemispheric regions (frontal, parietal, and occipital, in particular the paracentral lobule), opercular areas, cingulate gyrus, posterior orbitofrontal areas, insula, and depths of sulci. SEEG takes advantage of the more accurate anatomical presurgical workup and the possibility to stimulate into the depth of the sulcus and the subcortical pathways. There is at times a need for a complementation of the electrical localization with other methods of functional mapping such as diffusion tensor imaging, functional MRI, and intraoperative functional mapping (54). Limitations in SEEG include the need for more expensive testing preoperatively and specialized equipment in the operating room. The major risk of SEEG implantation is the higher risk of intracranial hemorrhage (3%) with associated permanent neurologic morbidity when compared to SDG implantation.

RESECTIVE STRATEGY IN FCD

The main principle that governs epilepsy surgery and in particular resection of FCDs is the “complete” resection of the EZ while preserving normal brain and function. This should be based on a clear definition of the anatomical, epileptic, and functional boundaries of the lesion and an accurate

hypothesis regarding the extent of the EZ. Every effort should be made to resect the lesion and the areas of ictal onset (from which ictal epileptic patterns were recorded). This is particularly important in patients with tuber-like FCD type 2b lesions, where an incomplete resection of areas adjacent to the visible lesion may exacerbate the epilepsy and results in acute postoperative refractory status epilepticus (61). What remains a subject of debate is the issue of recorded interictal patterns that are at times spatially distinct from the areas of ictal onset. As previous studies showed that some interictal patterns are highly predictive of ictal onset (such as continuous rhythmic discharges and paroxysmal fast activities) (4,28), we do recommend an extension of the margin of the resection to these areas. The significance of single spikes in the planning of the resection remains unknown, and although every effort should be made to resect these regions, their frequent location in regions that are noncontiguous with the lesion and the ictal onset zone precludes their complete resection.

Surgical strategy involves resection of involved cortical tissue while preserving blood supply. This is best accomplished by using a subpial resection technique to spare cortical vessels that may be passing through to irrigate noninvolved cortex. The involved cortex has often a more firm consistency, which allows surgical resection by following the plane between the softer normal cortical tissue and the firmer dysplastic tissue. In many of the type 2 FCD cases, the dysplastic cortex can be followed down into the white matter as one might follow the root of a plant into the Earth. It remains unknown whether resecting this deeper firm "tail" or "root" is clinically significant. When functional cortex is involved, the surgical approach must take into account the anticipated effect of operating in or near the functional cortex. Risks should be carefully detailed preoperatively so that postoperative expectations are clear. Intraoperative surgical techniques to identify and preserve function are the same as applies in other fields of neurosurgery and include cortical stimulation and surgery under awake conditions. Resection of some functional areas is well tolerated and should be undertaken when necessary and after proper informed consent to effect a cure from seizures. In general, surgery for FCD involves larger resections and outcomes improve when larger pieces of cortex are removed.

A final word is needed on the surgical strategies for children with severe epilepsies and mental retardation, in whom the association of (i) subtle asymmetries of gray–white matter volume (see Fig. 83.2) and (ii) focal or multifocal EEGs with frequent secondary bilateral synchrony (often wrongly suggesting symptomatic generalized epilepsies, yet due to unilateral pathology) indicates a specific kind of FCD type 1 causing epileptic encephalopathy (34,36). These are usually extensive lesions, involving either a quadrant or a whole hemisphere and should be completely resected as soon as possible. Resections are usually extensive and hemispherectomy may be needed, either as the initial or a second stage (36). When motor function is preserved, the central area and its connections may be spared by a technique known as "everything but motor" resection (62).

OUTCOMES OF EPILEPSY SURGERY IN PATIENTS WITH FCDS

Longitudinal outcome studies have shown that surgical treatment of pharmacoresistant epilepsy due to FCD yields less favorable results as compared to other well-recognized epileptic pathologies (63). Unfortunately, even if different subtypes of FCDs harbor clearly dissimilar anatomoelectroclinical features (especially types 1 and 2), surgical results, procedures, and outcomes are globally considered, not reflecting the enormous range in seizure freedom varying from 43% in type 1 to 75%

in type 2 (23).

A favorable long-term outcome with seizure freedom can be achieved in 47% to 79% of patients (13,23,64–70). Even in the more difficult cases that require invasive evaluation, epilepsy surgery in patients with medically intractable epilepsy due to FCD achieves favorable seizure outcome in a sizable number of patients. A recent long-term outcome study on patients who underwent invasive evaluation with subdural grids showed that complete seizure freedom was 61% at 1 postoperative year, 47% at 3 years, 42% at 5 years, and 33% at 10 years (60).

A recent study from the Cleveland Clinic reported on the longitudinal seizure outcome in a large series of patients with medically intractable epilepsy due to different types of FCD who underwent surgical resection following the implantation of intracranial electrodes (SDG, depth electrodes, and/or SEEG). This study identifies two patterns of epilepsy surgery failures that are likely due to two distinct causes: Most seizure recurrences (63%) were observed in the first 6 months after surgery. These early failures are due to an incomplete resection of the identified ictal onset zone, and late failures are dependent on the FCD pathologic subtype.

A favorable seizure-free outcome was achieved in half of the patients. Another previous study from the same institution on a smaller series of patients (n = 48) with FCD who underwent subdural electrode recordings between 1990 and 2004 showed a seizure-free outcome of 45% (28).

Long-term seizure control mainly depends on the pathologic subtype; whereas patients with type 2 FCDs show the best outcome, patients with type 1 FCD showed the least favorable outcome (60,71).

Isolated FCD 1 was observed in 31% of the patients, characterized by frequent seizures, negative MRI, and frequent frontal or multilobar involvement. In comparison to patients with FCD 1 associated with hippocampal sclerosis, other types of FCD, or tumors, the patients with isolated FCD 1 had a worse postsurgical outcome (46% in class 1) (64). This is also the case in children with epileptic encephalopathy associated with extensive unilateral FCD type 1 (36,37).Type 2 FCDs seem more prone to achieve long-term seizure freedom by the surgical treatment; moreover, FCD type 2b has an even better outcome reaching 88% of patients in class Ia (13,26).

RESULTS OF SURGICAL INTERVENTION IN PATIENTS WITH FCDS IN ELOQUENT CORTEX

Seizure freedom can be achieved in a significant number of patients with FCDs involving the eloquent cortex following a meticulous presurgical evaluation. Pondal-Sordo et al. (72) described an Engel I to III outcome in 73% of the 52 patients studied. However, only six patients had FCD. Surgical successes were also reported by Sandok and Cascino (73) in 14 patients with perirolandic lesion epilepsy where 78% were seizure free and only one patient suffered from a monoparesis: FCD was noted in only one patient in this cohort. Lehman et al. (74) reported 20 patients with lesions in the face area, with FCD pathology in only one patient. Seizure improvement was achieved in 90%, but six patients needed a reoperation.

Seizure-free outcome may be achieved in a significant number of patients with FCDs involving functional cortical areas (61,75). Devaux et al. (75) showed that seizure outcome was significantly associated with etiology in patients with epilepsy arising from functional areas (sensorimotor and supplementary motor areas, parietooccipital, insula, and language areas): 93% of Taylor-type FCD, whereas only 40% of cryptogenic epilepsies were in class I (75). Postoperative deficits were observed in 61% of patients but resolved completely in more than half of them (53%).

Another outcome study in patients with FCDs reported a successful seizure outcome and reduced seizure frequency in 88% of the patients (including an Engel class I in 59% of patients) with an incomplete resection and postoperative abnormalities on EEG representing the main recurrence risk factors for the type 2b FCD subgroup (61). However, deficits were noted in 59% of the patients. An intriguing finding in patients with type 2b FCD is the reported occurrence of focal status epilepticus in the immediate postoperative period (in 3 out of 8 patients). However, once a more aggressive surgical resection was performed, seizure freedom was achieved in all 3 patients.

These results show that a favorable seizure outcome can be achieved in a sizable number of patients with pharmacoresistant focal epilepsy due to FCD and arising from eloquent/functional cortex. The seizure outcome predictors in these patients depend on the type of the FCD lesion and its overlap with functional cortex. Patients with type 2 FCD have better surgical outcome and less functional deficit than those patients with type 1 FCDs. An overlap between function and in situ epileptogenicity is a predictor of a worse seizure outcome if the epileptogenic region is not completely resected.

CHAPTER 84 HEMISPHERECTOMY: INDICATIONS, PROCEDURES, AND OUTCOME

AHSAN N.V. MOOSA, JORGE ALVARO GONZÁLEZ-MARTÍNEZ, AJAY GUPTA, AND WILLIAM E. BINGAMAN

Hemispheric resections or disconnections are performed successfully to treat medically intractable hemispheric epilepsy in children and sometimes in adults, often resulting in remarkable improvement in seizure outcome and quality of life. New techniques are being constantly added to the surgical armamentarium of hemispheric disconnections, with the aim to minimize complications and improve outcome. In this chapter, we review the various aspects of hemispheric resections and disconnections, including a historical perspective, selection criteria, surgical methods, and outcome.

HISTORICAL PERSPECTIVE

Walter Dandy, in 1928, was the first to perform hemispherectomy for a patient with glioblastoma (1). Ten years later, McKenzie attempted to perform hemispherectomy in a patient with intractable epilepsy (2). In the 1940s, Krynauw systematically performed hemispherectomies in patients with intractable seizures and infantile hemiplegia (3). Only then, the technique gained acceptance in the management of handicapped patients with intractable epilepsy. Oppenheimer and Griffith, in 1966, reported delayed complications after anatomic hemispherectomy such as superficial hemosiderosis of the brain and obstructive hydrocephalus (4). Recurrent hemorrhage inside the operative cavity was considered the chief mechanism of these complications.

Further modifications of hemispherectomy were developed in order to prevent the late complications. Complete removal of the hemisphere was thought to increase the risk of repeated hemorrhages, and the idea of leaving some brain tissue in the cavity to "splint the brain" emerged. Subtotal hemispherectomies were attempted with poor results on seizure control. In 1983, Rasmussen described the so-called functional hemispherectomy—which involves resection of central and temporal lobes and disconnection of the anterior frontal and parietooccipital lobe; the residual disconnected tissue was left in place, to avoid late complications (5–7). Other techniques included the Oxford variation (or Adam modification, 1983), which included an anatomical hemispherectomy along with tacking the dura to the falx and tentorium to collapse the subdural space at the expense of a large epidural space (8), and hemidecortication aimed at removal of cortex leaving most of the subcortical structures including a rim of white matter around the ventricles (9).

The term "hemispherotomy" was first coined by Delalande in 1992 to describe a modified functional hemispherectomy, in which cortical resection was further minimized using a vertical parasagittal approach (10). Other modified techniques include the peri-insular hemispherotomy of Villemure and Mascott (11) and the transsylvian functional "keyhole approach" hemispherotomy of

Schramm et al. (12). All these variants of functional hemispherectomy represent attempts to perform a complete disconnection of the epileptogenic hemisphere with minimal tissue removal. In this chapter, the term hemispherectomy denotes to all forms of hemispheric disconnection unless otherwise specified.

SELECTION CRITERIA

Typical hemispherectomy candidates satisfy the following criteria: (i) medically refractory focal epilepsy; (ii) electroclinical evidence consistent with epilepsy from the affected hemisphere; (iii) large unilateral hemispheric lesions (e.g., encephalomalacia due to remote infarct, Rasmussen encephalitis, hemimegalencephaly (HME), multilobar dysplasia, Sturge–Weber syndrome); (iv) preexisting deficits ascribed to the diseased hemisphere, most commonly hemiplegia (loss of hand function in particular), cognitive delays, and sometimes visual field defect; and (v) minimal to no risk for new deficits after surgery deemed unacceptable to the patient, physician, or both. Most of these can be easily confirmed by a careful history and neurologic examination, video–EEG monitoring, and brain MRI. Values of additional tests such as PET and ictal SPECT are limited in catastrophic epilepsy due to large hemispheric lesions (5–16).

The majority of patients undergoing hemispherectomy satisfy the above-mentioned criteria, but a few exceptions may occur as outlined here. Firstly, abundant generalized EEG abnormalities may be noted in nearly a quarter of patients with congenital or early brain lesions. Sometimes, EEG abnormalities patients with large hemispheric encephalomalacia may appear higher over the healthy hemisphere. Successful hemispherectomy with good outcome despite generalized or contralesional maximum ictal and interictal EEG patterns has been reported (16). Second, we have also noted that structural abnormalities on the contralateral hemisphere are common in patients undergoing hemispherectomy (17). Hence, presence of bilateral MRI abnormalities or generalized EEG abnormalities should not be used as exclusion criteria for surgery. Lastly, although hemispherectomy is usually undertaken in patients with no useful preoperative hand function, high seizure burden and extremely poor quality of life may sometimes force families and patients to choose hemispherectomy even though it will result in a new or significantly worsened postoperative hemiparesis.

TIMING OF SURGERY

Many well-established epilepsy centers recommend early intervention to stop seizures and maximize chances for neurodevelopment (18–26). If the selection criteria (as outlined earlier) for hemispherectomy are met, surgery should be done as soon as possible.

In hemispherectomy for young infants, risk of perioperative morbidity and mortality should be carefully weighed against the risks of ongoing seizures by delay in surgery. In general, for noncatastrophic epilepsy, we consider a body weight of 10 kg or above acceptable. For catastrophic hemispheric epilepsy, surgery may be performed earlier with appropriate informed consent on the risks of excessive blood loss and mortality (14). Hemispherectomy has been safely performed at our center (Cleveland Clinic) for infants weighing as low as 5 kg at 2 months of age.

Surgery at younger age potentially offers maximum chances of neural plasticity to aid recovery of some key functions. In most right-handed subjects and a large proportion of left-handed subjects, the left hemisphere is dominant for language function. In patients with left hemispheric epilepsy due to early brain injury, hemispheric dominance may be atypical with the opposite hemisphere harboring

language abilities. Hemispherectomy is unlikely to have any impact on such patients especially when the preexisting damage is extensive. Surgery performed at a younger age (typically before 6 years) may lead to clinically significant functional recovery, even if the affected hemisphere harbored some language function (13). The intracarotid sodium amytal test may not be feasible and are not routinely performed at our center in such young patients with early brain injury. In older patients with later-onset brain injury, the need for language lateralization should be carefully reviewed before surgery.

ANATOMICAL REMARKS AND SURGICAL TECHNIQUES

Several techniques of hemispherectomy, hemispherotomy, and other hemispheric disconnections have been described. All these procedures have four common principles: (i) disruption of the descending and ascending fibers through the corona radiata and internal capsule, (ii) removal of the mesial temporal structures, (iii) complete callosotomy, and (iv) disruption of the frontal horizontal fibers, including the occipitofrontalis fasciculus and uncinate fascicle (27,28), The main difference among the various techniques lies in how the lateral ventricle is accessed—whether access starts from the temporal horn or from the body of the lateral ventricle—and the extent of brain resection necessary to gain access to the ventricular system. Other differences include the removal or preservation of the insula and the preservation or ligation of branches of the middle cerebral artery. In the following paragraphs, we simplistically describe the differences in the several techniques.

Anatomical Hemispherectomy

Anatomical hemispherectomy refers to complete removal of frontal, temporal, parietal, and occipital lobes preserving the thalamus and basal ganglia. Patient positioning is optimized to allow access to the lateral surface of the affected cerebral hemisphere and to minimize neck torsion. The head may be positioned in rigid point fixation or resting on a head support, depending on the patient's age. The head is turned 90 degrees with ipsilateral shoulder support and the vertex slightly down to allow access to the mesial temporal lobe structures and interhemispheric fissure (Fig. 84.1).

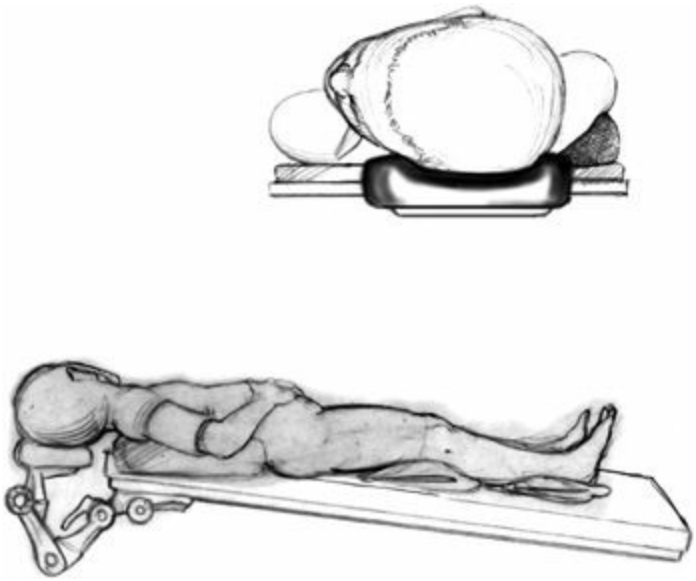

Figure 84.1. Patient's position for anatomical hemispherectomy.

The head is then shaved and a "T"-shaped incision planned to allow access from the floor of the middle fossa to the midline of the head. Superficial landmarks useful for incisional planning include anatomic midline from nasion to inion, the lateral edge of the anterior fontanelle, the transverse sinus location, the greater wing of the sphenoid bone, and the zygomatic arch (Fig. 84.2).

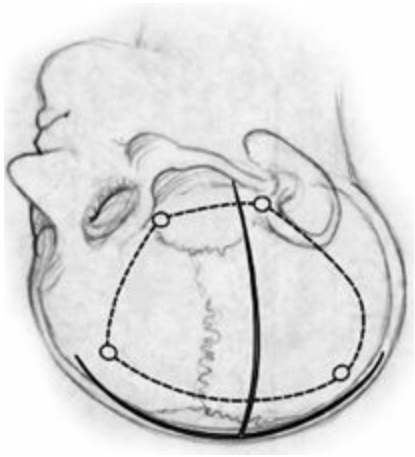

Figure 84.2. Important superficial landmarks, "T" incision and planned.

The T incision is designed by a line at least 0.5 cm from midline and a perpendicular line from the zygomatic root just anterior to the tragus. The midline incision extends from the hairline to a point 4 to 5 cm above the inion. The incision is made with caution in the younger patient with an open anterior fontanelle to avoid inadvertent sagittal sinus injury. The skin edges are then reflected and periosteum and temporalis muscle fascia visualized. The muscle is mobilized off the underlying bone with a "T" incision, reflecting each muscle cuff inferiorly. Burr holes are done at the keyhole, the floor of the middle fossa just above the zygomatic arch, and lastly along the parasagittal areas just off the midline to avoid sagittal sinus injury (if anterior fontanelle is closed). The optimal craniotomy flap allows exposure to the midline, orbitofrontal base, floor of the middle fossa, and total length of the sylvian fissure. The craniotomy flap is carefully removed with a high-speed air-drill craniotome.

After the dura mater is opened in an H fashion, the sylvian fissure is identified and venous drainage patterns inspected. The distance from the superior craniotomy edge to the interhemispheric fissure is verified. The locations of major draining veins to the sagittal sinus are noted and carefully protected until later in the procedure to avoid early and often devastating blood loss. The orbitofrontal region is inspected and the position of the olfactory tract visualized as an anatomic guide to the gyrus rectus and midline structures (Fig. 84.3).

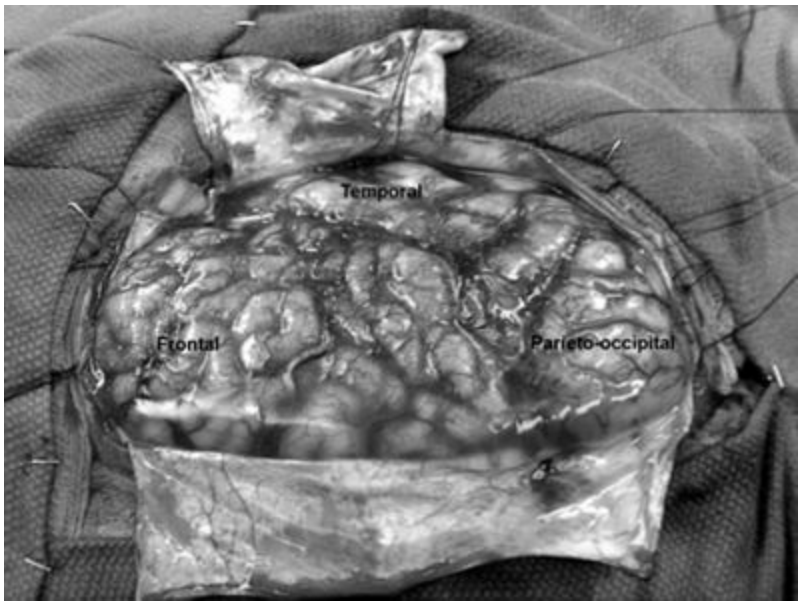

Figure 84.3. "H" dural opening and hemimegalencephalic brain.

The dissection of the sylvian fissure begins with early exposure and control of the middle cerebral artery trunk in the sylvian fissure just distal to the lenticulostriate branches. The sylvian fissure is split along its entire length using bipolar electrocautery, suction, and sharp microdissection (loupe magnification is preferred for this portion of the procedure). This should be done carefully to minimize bleeding, but cortex can be aspirated as necessary to aid in exposure. Once opened, the insular cortex including the inferior and superior circular sulci should be visualized along the length of the sylvian fissure.

The middle cerebral artery is then ligated with bipolar cautery and surgical hemostatic clips (Fig. 84.4). The inferior circular sulcus is identified and the white matter of the temporal stem is localized just deep to the sulcus. Using suction aspiration, the white matter is removed along the temporal stem, and the temporal horn of the lateral ventricle is entered. A cottonoid patty is placed here to protect the choroid plexus and prevent blood from entering the ventricular system. The pial dissection along the anterior (temporal) aspect of the sylvian fissure is carried below the main sylvian vein to the floor of the anterior aspect of the middle fossa. The anterior temporal pole is then aspirated to expose the edge of the tentorium. The white matter dissection of the temporal stem is then continued posteriorly to achieve exposure of the temporal horn from the anterior aspect to the trigonal region (Fig. 84.5). A long, thin cottonoid is then placed posteriorly into the ventricle passing from the trigone up into the lateral ventricle.

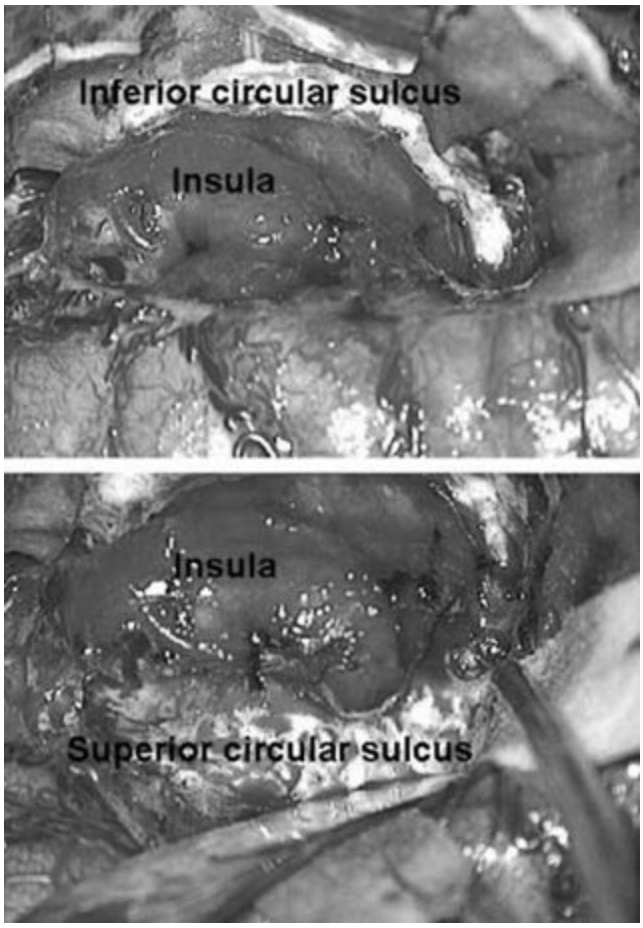

Figure 84.4. Exposure of superior and inferior circular sulcus surrounding insula.

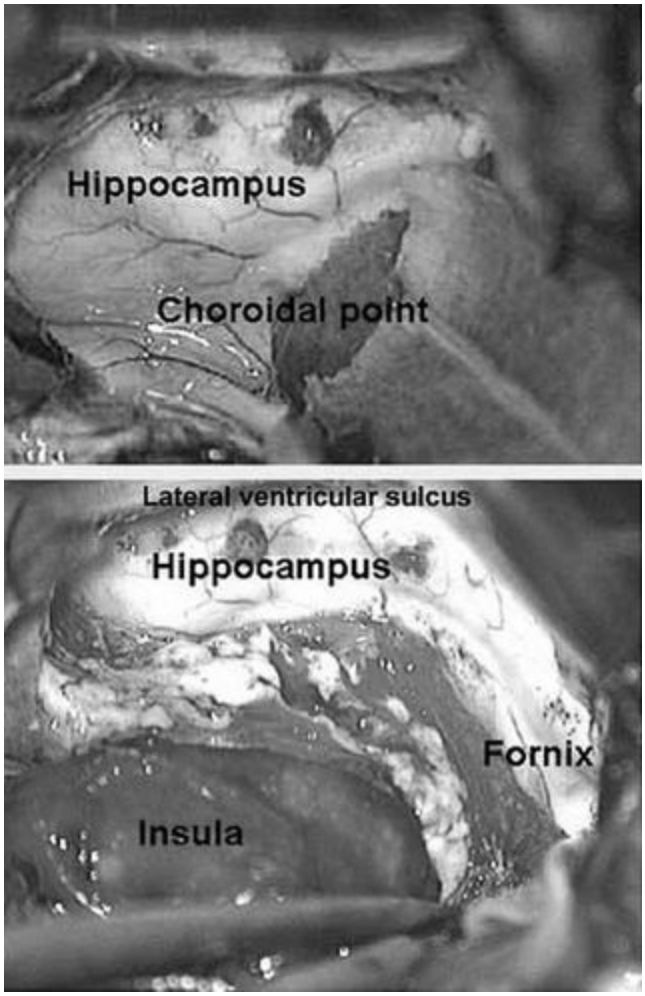

Figure 84.5. Temporal horn access through inferior circular sulcus and identification of important landmarks for mesial structures dissection.

The posterior trigonal area is then plugged with a large cotton ball to prevent blood from entering the lateral ventricle. Exposure of the tentorial edge and basomesial temporal pia is then achieved by dissection of the lateral ventricular sulcus (collateral eminence) from within the temporal horn, just lateral to the hippocampus. This can be done with bipolar coagulation and suction or ultrasonic aspiration. In either case, the amygdala, hippocampus, and choroid plexus are protected from injury with cottonoid patties. Once the mesiobasal pia is identified just lateral to the parahippocampal gyrus, the dissection can be extended anteriorly to meet the prior pial dissection at the floor of the anterior middle fossa. The parahippocampus is then aspirated to identify the tentorial edge. The tentorial edge is then followed from anterior to posterior, curving back behind the mesencephalon. At this point, the posterior cerebral artery branches can be ligated as they pass from the perimesencephalic cistern over the tentorial edge to the temporooccipital cortex. At the conclusion of this phase of the operation, the temporal lobe lateral to the parahippocampal gyrus has been disconnected and the posterior cerebral artery branches divided. The amygdala, hippocampus, and a remnant of the parahippocampal gyrus remain in place.

Suprasylvian dissection through the superior limiting (circular) sulcus of the insula takes place to divide the coronal radiata and expose the lateral ventricle along its length. This can be done by careful dissection from above the insula or by following the previous trigonal ventricular opening around the posterior aspect of the insula to the lateral ventricle (Fig. 84.6). Dissection is facilitated by dividing the posterior branches of the MCA at the end of the sylvian fissure. Once the corona radiata is divided, the entire length of the lateral ventricle is opened and the foramen of Monro plugged with a small cotton ball to prevent blood from entering the dependent ventricular system. Care should be taken to protect the choroid plexus to avoid unnecessary bleeding. Similarly, basal ganglia disruption can be prone to bleed and is best controlled by the application of hemostatic agents to the exposed surfaces.

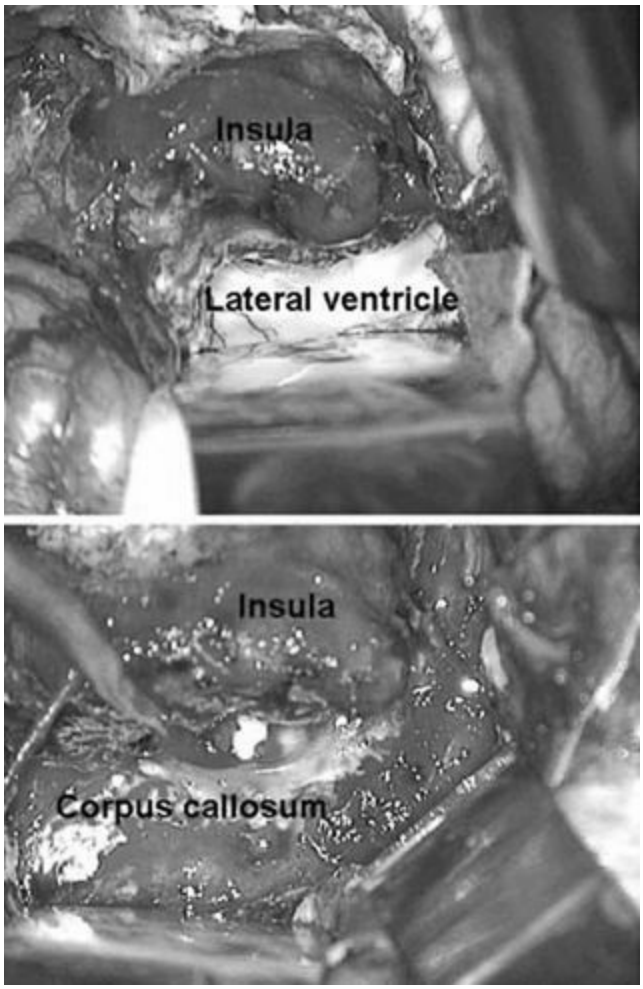

Figure 84.6. Opening of lateral ventricular system and corpus callosotomy. (Tip of the shunt from the opposite hemisphere is also seen.)

The corpus callosum is identified from within the ventricle at the junction of the septum pellucidum and the roof of the lateral ventricle. Aspiration of the roof of the lateral ventricle just above this area leads to the gray matter of the ipsilateral cingulate gyrus and falx cerebri. This is meticulously aspirated to prevent injury to the contralateral cingulum. Once this area is exposed, identification of the pericallosal arteries and corpus callosum proper is easily achieved. The corpus callosum and ipsilateral cingulate gyrus are then aspirated from the genu to the splenium. Complete sectioning is important to achieve and can be accomplished by following the pericallosal artery as it closely follows the characteristic course of the callosum. Special attention should be given to the genu and splenium to assure complete disruption of the horizontal fibers. Additional assistance is achieved by removal of the cingulate gyrus and identification of the inferior edge of the interhemispheric falx. Finally, the ipsilateral fornix is disrupted by aspiration at a point just anterior to the splenium. Next, the mesial dissection should continue anteriorly coagulating and dividing the pia of the ipsilateral mesial frontal lobe including the arterial branches from the anterior circulation. This mesial frontoparietal disconnection is followed anteriorly to the base of the frontal lobe just above the olfactory nerve (frontal pole). Posteriorly, the edge of the falx is followed as it transitions to the tentorium. This mesial parietooccipital resection should connect with the basal temporal disconnection below the sylvian fissure, which was performed earlier. At this point, the callosum is disconnected and the pia along the mesial aspect of the entire hemisphere is coagulated and divided. The only remaining portion of the hemisphere in place is the basal–frontal lobe below the genu and the draining veins to the venous sinuses.

The last remaining pia to be divided extends from the anterior aspect of the sylvian fissure down along the posterior–basal–frontal lobe. This pia is coagulated and divided along with the MCA branches to the frontal cortex. The posterior–basal–frontal lobe is aspirated, maintaining a plane just anterior to the anterosuperior insula (Fig. 84.7).

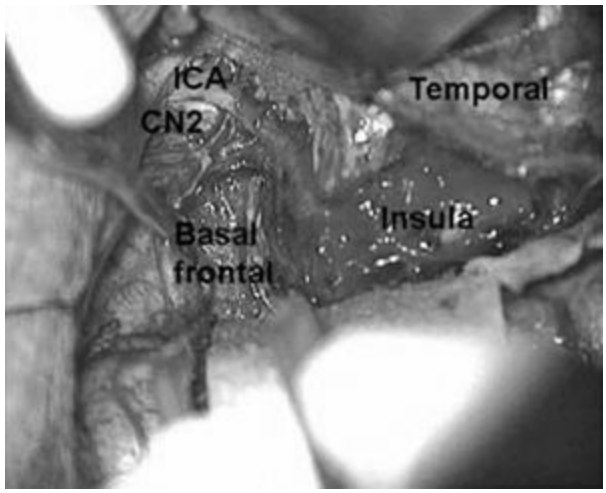

Figure 84.7. Important surgical landmarks of right frontobasal disconnection.

The orbitofrontal pia is then coagulated and divided down to the olfactory nerve, and the pia overlying the gyrus rectus is identified and divided. The gyrus rectus is then aspirated to expose the contralateral gyrus rectus and a cottonoid patty placed to mark the midline. The pial dissection along the olfactory nerve is then carried anteriorly to avoid disruption of the nerve. The remaining gyrus rectus is then aspirated with the posterior removal limited by the internal carotid artery. The deep white matter and mesial frontal gyri are removed in subpial fashion by a dissection plane marked by the anterior aspect of the frontal horn starting below the prior dissection of the genu of the corpus callosum. This dissection is carried out through the caudate nucleus along the course of the anterior cerebral artery to where it joins the internal carotid artery. Special care should be taken after the hemisphere is removed to ensure complete removal of the basal–posterior–frontal lobe. Once all the pial surfaces and white matter tracts have been cut, the draining veins to the sinuses are circumferentially coagulated and divided and any bleeding points packed with hemostatic agent. At this point, the entire hemisphere can be removed in one anatomic piece and sent for pathologic study. The remaining amygdala–hippocampus bloc is then removed as the last portion of the procedure.

The insular cortex can be removed if so desired by subpial aspiration using the ultrasonic aspirator or suction coagulation. As the middle cerebral artery has already been controlled, arterial injury is of less concern than in the functional hemispherectomy operation. Care must be taken to limit resection to the insular gyri to avoid injury to deeper subcortical structures. Perhaps stereotactic imaging would be useful at this stage, although a practical approach is to stop the dissection when underlying white matter is reached.

Adams Modification of Anatomic Hemispherectomy

Adams modification was an attempt to avoid the complications of hemosiderosis and hydrocephalus. The classic anatomic hemispherectomy is supplemented by a muscle plug in the foramen of Monro on the resection side and by folding down the stripped dura of the convexity bone onto the falx, central

block (composed by basal ganglia and thalamus and middle fossa cavity). The subdural space is occluded and outflow of cerebrospinal fluid from the opposite side is prevented. Using this technique, there seems to be a higher rate of infection, but the rate of hydrocephalus seems to be reduced, compared to the classic anatomic resection (8).

Functional Hemispherectomy and Other Disconnection Techniques

Classic Functional Hemispherectomy

Rasmussen et al. proposed "functional hemispherectomy," minimizing tissue resection (5–7). The overall goal of the functional hemispherectomy is to disconnect the frontal lobe (through an incision placed just anterior to the genu of the corpus callosum) and to disconnect the parietal and occipital lobe (through a posterior incision) and remove the temporal lobe and central part of the frontal and parietal lobe. The fiber tracts projecting from the remaining parts of the frontal, parietal, and occipital lobes to the brainstem and spinal cord are then transected. The blood supply to the disconnected cortical regions is kept intact.

In the functional hemispherectomy procedure, T-shaped scalp incision (similar to one described under anatomic hemispherectomy) is performed. The craniotomy is smaller than in the anatomical hemispherectomy, especially in the anterior–posterior orientation, and is mainly centered in the topographic location of the insula. The dura is opened in the same manner as it has been described for the anatomical hemispherectomy.

The first cortical incision is made along the upper margin of the sylvian fissure, by coagulating and incising the pia and its blood vessels, dissecting down into the frontal and parietal operculum, down to the plane of the insular cortex. From the anterior and posterior ends of this dissection, a central resection is performed, exposing the entire sulcus limitans of the insula and, consequently, the insula cortex. The incisions are extended to the medial surface to the level of the cingulate gyrus, which is preserved at this stage to protect the pericallosal artery, but removed later. By deepening the dissections in the superior sulcus limitans of the insula, the body of the lateral ventricle is entered and the central bloc of tissue removed.

The temporal lobe is removed by coagulating and dividing the pia and its vessels along the superior temporal gyrus, back to the posterior limb of the upper resection, and anteriorly around the temporal pole, down to the uncus. The roof of the temporal horn is entered and then the lateral portion of the temporal lobe is removed through the collateral sulcus. The hippocampus is dissected and removed through the coagulation of the hippocampus sulcus. The hippocampus is dissected free, and the amygdaloid nucleus is removed.

The deep white matter of the medial and inferior aspects of the frontal lobe is divided in the coronal plane, from the central resection area to the most basal and posterior area of the frontal lobe, just rostral to the anterior perforated substance and medial and lateral olfactory striae. The anterior portion of the corpus callosum is also divided, from its body to the knee and rostrum portions, stopping at the level of lamina terminalis. In the same way, the white matter of the parietal lobe is divided posterior to the splenium from the ventricular ependyma, from the body and atrium of the lateral ventricle to the pia overlying the falx and the floor of the middle fossa. Following subpial dissection, the cingulate gyrus is removed. In the same way as the anterior callosotomy, the posterior corpus callosum is also divided, from the topography of the central resection to the splenium. Just anterior to the splenium, the fimbriae and fornices from both hippocampus formations join, forming

the hippocampus commissure, which will need to be completely disconnected. After irrigation, the craniotomy is closed as previously described for anatomical hemispherectomy.

Hemidecortication

It is based on the principle that only the epileptogenic cortex needs to be removed in order to achieve seizure freedom. The concept was first delineated by Ignelzi and Bucy in 1968 (9). The integrity of the lateral ventricle is largely preserved, except at the temporal lobe, where removal of the hippocampus requires opening of the temporal horn. Although the main aim is to avoid opening the ventricular system, removal of the hippocampus makes opening of the temporal horn a necessary step. In this procedure, a large wound surface is created, and, in cases of HME, where dysplastic ectopic gray matter is located in the white matter, orientation can be difficult.

Transsylvian, Transventricular Functional Hemispherectomy

This approach was developed and refined by Schramm and colleagues (12). The key features of this approach are (i) small craniotomy and transsylvian exposure of the insular cortex; (ii) anterior mesial temporal lobe resection, including amygdala and hippocampus; (iii) transcortical access to the ventricular system through the limitans sulcus of the insula, from the tip of the temporal horn to the tip of the frontal horn; (iv) frontal–basal disconnection anterior to the anterior cerebral artery; (v) mesial disconnection following the anterior cerebral artery through the anterior portions of the corpus callosum to the splenium; and (vi) posteromedial disconnection in the ventricular trigone following the outline of the falcotentorial border to the temporomesial resection cavity. This procedure is especially suited for cases with enlarged ventricles, porencephalic cysts, and marked atrophy of the insula–basal ganglia block or for cases with larger ventricle and cisterns.

The size of the craniotomy is chosen guided by the length of the corpus callosum, the anteroposterior diameter of the basal ganglia thalamus–insula block (limen insulae to pulvinar), and the degree of ventricular enlargement. The sylvian fissure is then opened, and the circular sulcus is exposed, taking advantage of the fact that the temporal operculum is overlying the inferior limb of the limitans sulcus only about 0.5 to 1 cm, whereas the frontal operculum can overlie the frontal limb of the circular sulcus up to 3 cm. Access to the temporal horn is gained through the inferior circular sulcus approach. The uncus and the lateral parts of the amygdala are removed, and the hippocampus also is taken out either by suction or en bloc. Sparing the major branches of the middle cerebral artery, the ventricular system is then opened all around the insular cortex. From inside the anterior horn of the lateral ventricle, a dissection line is now created by suction and bipolar coagulation from the frontal horn floor, just anterior from the foramen of Monro, down to the basal arachnoid, just anterior to the middle and anterior cerebral arteries. The mesial disconnection can now be continued around the corpus callosum following the anterior cerebral artery. Callosotomy is then performed within the ventricle, back to the area of the splenium. The fornix and the hippocampus tail are disconnected and resected, until the mesial temporal lobe resection cavity is reached.

According to Schramm and colleagues (12), the transsylvian–transventricular hemispherectomy with only a minimal mesial temporal lobe resection should not be used for HME cases, even if ventricles are enlarged, for two reasons: the insular cistern may be atypically configurated and the transsylvian approach can be more difficult even with enlarged hemisphere. In HME, the transsylvian–transventricular hemispherectomy should be combined with resection of the entire temporal lobe or with resection of the frontal operculum to the level of the insular cortex. This

resection facilitates the transcortical access from the limitans sulcus of the insula to the lateral ventricle and creates room for postoperative swelling.

According to Bonn series, possible disadvantages of this procedure include problems identifying anatomical landmarks due to the limited exposure. Hydrocephalus, possibly induced by the large wound surface and the transventricular approach, was not seen in the transsylvian "keyhole" hemispherectomies for all causes so far. No case of incomplete disconnection toward the midline was detected, but too anteriorly placed disconnections were seen.

Peri-Insular Hemispherotomy

Peri-insular hemispherotomy was initially developed by Villemure and Mascott (11). The main features of this approach are (i) medium-sized craniotomy exposing the frontal, parietal, and temporal operculum in the whole length of the sylvian fissure; (ii) resection of the frontal and parietal operculum and underlying white matter, opening the whole lateral ventricle through the anterior and superior limitans sulcus of the insula and disconnection of the frontobasal area through the intraventricular approach; (iii) resection of the temporal operculum (T1 gyrus and underlying white matter) and exposure of the temporal horn through the inferior limitans sulcus of the insula; (iv) mesial disconnection through the corpus callosum, from the rostrum and knee to the splenium; and (v) temporomesial disconnection with only anterior resection of the amygdala, anterior aspect of the hippocampus and uncus.

Peri-insular hemispherotomy is best indicated in patients with enlarged ventricle and certain degree of atrophy, and because of the more extensive resection of the operculum and underlying white matter, it can be also applied for HME cases. Kestle et al. used this technique in 11 of their 16 cases. Estimated blood loss was 462 mL, compared to 1.3 L for decortication, 73% of their patients needed a transfusion, and there was no need for shunts (29).

Vertical Parasagittal Hemispherotomy

This approach was first described by Delalande et al. in 1992 (10). It includes initially a small parasagittal craniotomy, followed by complete callosotomy with opening of the roof of the lateral ventricle. Once the entire lateral ventricle is unroofed, posterior disconnection of the hippocampus is achieved by cutting the columns of the fornix at the level of the ventricular trigone. The vertical incision is performed lateral to the thalamus, choroid plexus, and choroidal fissure of the temporal horn, then following the temporal horn from the trigone to the most anterior part of the ventricle, keeping the incision in the white matter. The callosotomy is then completed by resecting the genu and the rostrum of the corpus callosum to the anterior commissure. The next step is the resection of the posterior part of the gyrus rectus, which will allow the visualization of the anterior cerebral artery and optic nerve and provide enough space for the last disconnection step, which is a straight incision anterolaterally through the caudate nucleus from the rectus gyrus to the anterior temporal horn.

ANATOMICAL HEMISPHERECTOMY VERSUS FUNCTIONAL HEMISPHERECTOMY AND OTHER DISCONNECTION TECHNIQUES

The discussion about what would be the appropriate surgical technique for treatment of intractable hemispheric epilepsy is controversial. The literature is full of personal series, specifically reporting seizure outcome and complications related to one specific technique. In addition, most of the studies are retrospective in nature, reporting results in populations that differ in age, severity of seizure, and pathologic substrate. There are no studies that directly compare functional versus anatomical hemispherectomy. In the largest series of patients treated with anatomical hemispherectomy, the surgical outcome is similar to that for functional disconnection (25,29–34). The group at Johns Hopkins reviewed their experience with anatomical hemispherectomy in infants and children (18,22). Of 21 patients with cortical dysplasia, 8 (38%) were seizure free and an additional six (29%) had mild seizures after surgery. In contrast, surgical series after functional hemispherectomy for CD report 50% to 67% of seizure-free rate with an additional 11% to 33% having only rare seizures. Although number are small in all these studies and the radiologic involvement of CD is not well outlined in some of these reports, these results suggest that functional hemispherectomy is at least as effective as anatomical hemispherectomy. The frequency of complications may also be lower after functional hemispherectomy. In one series, of five patients with HME who continue to have seizures after functional hemispherectomy, three had seizures that arose from the operated hemisphere and two had seizures arising from the contralateral hemisphere. These results suggest that anatomic hemispherectomy may be more effective in patients with HME and that functional hemispherectomy may be better suited for patients with more restricted hemispheric cortical dysplasia. At the Cleveland Clinic, we believe that anatomical hemispherectomy provides a better seizure outcome in patients with cortical dysplasia and HME. In a series of patients with catastrophic epilepsy in young ages, incomplete disconnection was the only variable statistically associated with persistent seizures after surgery (14). In a total of 18 patients, 6 patients had persistent seizures after surgery. Two patients had the diagnosis of HME and four had cortical dysplasia. From this group, four patients had incomplete disconnection, always located in the posterior basal–frontal areas. All four patients underwent reoperation, converting the procedure to anatomical hemispherectomy. All four patients achieved seizure freedom. In our studied group, we found that for patients with HME, anatomical hemispherectomy is a better option. In general, the lateral ventricle from patients with HME is characterized by an irregular shape, a relative hypoplasia of the temporal horn. Such anatomical peculiarities, together with irregular and abnormal thickness of the cerebral mantle, deep heterotopic gray matter, distorted trajectory of the anterior cerebral arteries, abnormal large veins at the level of the malformed sylvian fissure, and the possible interdigitation of the mesial aspect of the hemispheres, make the functional hemispherectomy a technically difficult procedure in this group of patients. In our surgical series, all patients with HME who underwent functional hemispherectomy resulted in uncontrolled seizures after surgery; the conversion to anatomical hemispherectomy resulted in seizure freedom in all patients (14).

Although several authors reported higher complications rates in anatomical hemispherectomy (5,35–37), particularly hemosiderosis and secondary hydrocephalus, we did not observe such findings in our patients. With specific regard to hemosiderosis associated with anatomic hemispherectomy, one could speculate whether late mortality from hemispherectomy was caused by the effects of chronic deposition of Fe^{2+} on the cerebral parenchyma, from repeated intracranial hemorrhages, or it was simply the outcome of hydrocephalus, which escaped detection before the introduction of computerized tomography (CT). It is worth noting that reports concerning hemosiderosis have been practically absent in the literature since the 1970s; nevertheless, hemosiderosis is still cited as a common reason for avoiding anatomic hemispherectomy.

OUTCOME AFTER HEMISPHERECTOMY

There are different perspectives in assessing outcome after hemispherectomy. Seizure outcome is the primary concern, but the long-term functional outcome is equally important in improving the quality of life. Additionally, morbidity associated with the different procedures has to be considered.

Seizure Outcome After Hemispherectomy

In various cross-sectional studies on outcome after hemispherectomy, the seizure-free rates range from 52% to 80% (38–43). We recently examined longitudinal outcome of 170 children who underwent hemispherectomy over a 10-year period at the Cleveland Clinic (38). At a mean follow-up of 5.4 years, 66% of children were seizure free (Engel 1a). Of 58 patients with seizure recurrence, 8 had late remission (seizure free for 1 year or more at last follow-up) and another 16 patients had >90% reduction in seizures (38). Overall, 80% of children were either seizure free or had major improvement after hemispherectomy. Similar seizure outcome has been reported after hemispherectomy in adults with refractory epilepsy due to large middle cerebral artery infarct or cortical malformation (44).

In the Cleveland Clinic hemispherectomy series, age at seizure onset, age at surgery, epilepsy duration, etiology, presence of generalized epileptiform abnormalities, bilateral abnormalities on brain MRI, and type or side of hemispherectomy had no effect on seizure outcome. Prior hemispheric surgery, nonlateralized ictal EEG, acute postoperative seizures, and bilateral abnormalities on PET were predictive of poor seizure outcome on univariate analysis. On multivariate analysis, only the latter two emerged as independent predictors of poor outcome. In one of the earlier reports, children with malformation tended to have poor seizure outcome; we did not find etiology as a predictor in our study. At our center, we favor more tissue resection, not infrequently anatomic hemispherectomy, in children with HME for reasons cited in the earlier section. Head-to-head comparison between different techniques of hemispherectomy is not feasible as most centers tend to do favor one particular technique. Overall, the reports from various centers do not suggest a major difference in seizure outcome with different techniques.

Seizure recurrence after hemispheric disconnection procedure indicates either continued seizures from operated side due to incomplete disconnection or independent epilepsy arising from the opposite hemisphere. Seizure semiology, interictal and ictal EEG findings, and MRI may assist in differentiating in some patients. However, in our experience, EEG findings after disconnective hemispherectomy are complicated and may be unhelpful. It is difficult to reliably confirm the completeness of resection by MRI as well. At our center, in many such cases with failed functional hemispherectomy, we proceed to perform removal of residual tissue on the operated side (thereby converting to anatomic hemispherectomy) to ensure effective hemispherectomy. This strategy has helped in achieving seizure freedom in a third of patients and major improvement with >90% seizure reduction in as high as two-thirds of patients (38,45).

Functional Outcome After Hemispherectomy

Several studies in the past addressed the functional outcome after hemispherectomy. Although most studies do not have a comparative group to study the effects of the surgery per se, most clinicians firmly believe that successful hemispherectomy improves functional outcome as well (46,47). From a practical standpoint, the alternative course of persistent daily seizures and continued worsening of

neurologic status is unacceptable to most families.

We recently reported the functional status of 115 children who underwent hemispherectomy at the Cleveland Clinic (47). In our cohort of 115 children, 92% were able to walk independently or with assistance (Fig. 84.8). Children with bilateral motor deficits (worse on the side concordant with surgery) or MRI abnormalities in the unoperated hemisphere or seizure recurrence were more likely to have poor motor outcome. Over two-thirds of children in this series had spoken language skills sufficient for regular conversation; nearly half of these children had age-appropriate language abilities as perceived by their families. Preoperative language delay, bilateral MRI abnormalities, and seizure recurrence were associated with poor language outcome. Age at seizure onset and left-sided surgery had no significant impact on the language outcome in this cohort. Reading abilities were poor in 59% of children and only 18% of children had age-appropriate reading ability. Per parental report, 73% of patients had minimal to no behavioral problems; the rest had significant problems in home and school environment. Children with postoperative seizure recurrence were more likely to have behavioral problems. Although visual field defect is expected to be present in every patient, families did not perceive it as a major handicap. Patients were accustomed to the defect and were able to take precautions to avoid major mishaps (47).

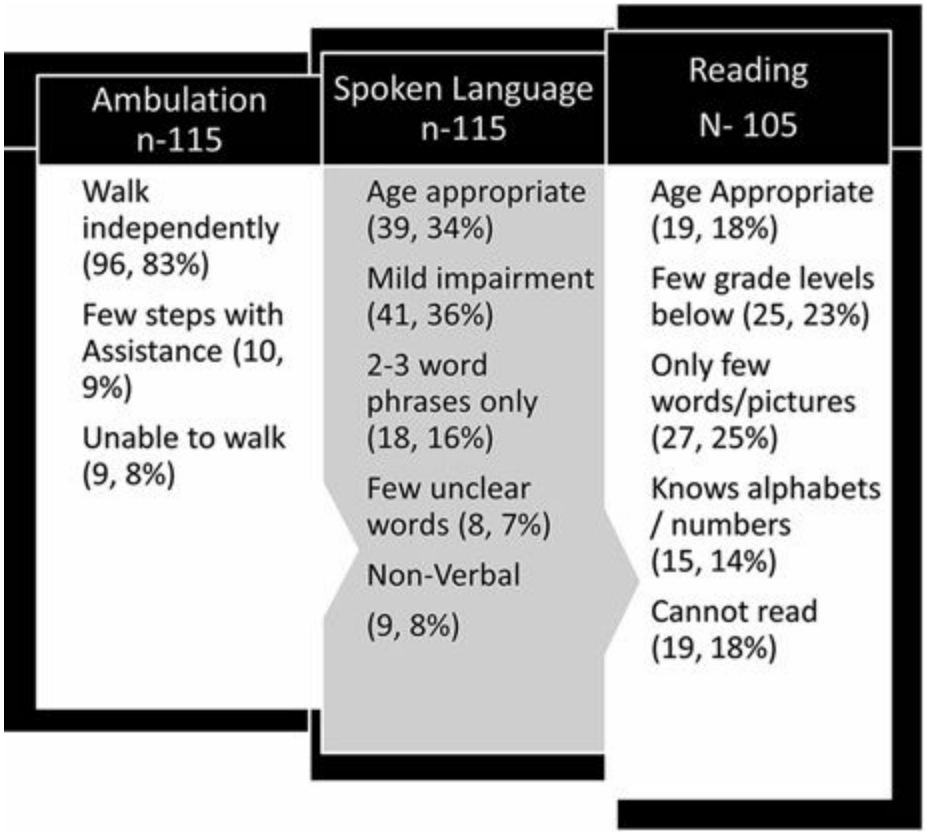

Figure 84.8. Functional outcome after hemispherectomy in 115 children. Mean age at follow-up was 12.7 (±6) years. Reading status was assessed in children older than 6 years (n = 105).

Seizure outcome emerged a single most important predictor of functional outcome. Seizure freedom improved the odds of good outcome in ambulation, behavior, spoken language, and reading skills (Fig. 84.9). This observation may suggest that hemispherectomy improves functional outcome by providing seizure freedom (47).

Complications: Acute and Delayed

Hydrocephalus in the early postoperative period is a common complication across all surgical series. In a recent large multicenter study of 690 patients undergoing hemispherectomy, 23% required treatment for hydrocephalus (48). Anatomic hemispherectomy and prior brain surgery were identified as risk factors for hydrocephalus. A quarter of the hydrocephalus may evolve 3 months postsurgery, highlighting the importance of continued surveillance. Mortality rate in various series has ranged from 0 to 3% (18,38–42,49). Postoperative fever is common, in as high as 82% of children after hemidecortication (50). Chemical meningitis is a common cause of postoperative fever but careful exclusion of infectious causes is warranted. Other complications such as subdural and epidural hematomas also may occur infrequently.

Superficial hemosiderosis of the brain after hemispherectomy appears to be very rare with no published reports in the past three decades. A fall in delayed worsening after hemispherectomy may be related to decreased incidence of superficial siderosis of brain secondary to modifications in the hemispherectomy techniques as well as improvement in treatment hydrocephalus in the post-CT era.

CONCLUSION

Hemispherectomy and other disconnection procedures for intractable epilepsy provide excellent and dramatic results with a satisfactory complication rate. Modifications in surgical techniques and better

perioperative care has improved the outcome in the last 60 years. Despite this, discrepancies related to complication rate and seizure outcome among different techniques are still unresolved. A large prospective multicenter study is necessary to indicate the better surgical technique for a specific pathology and population group. Nevertheless, early surgery in patients with catastrophic epilepsy seems to be associated with better seizure control and cognitive prognosis.

CHAPTER 85 SURGICAL APPROACH IN MULTILESIONAL OR MULTILOBAR EPILEPSIES

ELIA M. PESTANA KNIGHT, AJAY GUPTA, AND ELAINE WYLLIE

Multilesional epilepsy, by definition, involves more than one lesion that is distributed noncontiguously in one or both hemispheres. One or more lesions may be responsible for the generation of seizures. A typical example is seen in patients with tuberous sclerosis. While the presence of multiple brain lesions does not necessarily indicate multiple ictal onset zones or multifocal epilepsy, this poses additional challenges in presurgical evaluation.

Multilobar epilepsy, for purpose of this chapter, involves an epileptogenic zone that extends into multiple lobes of one hemisphere, with or without a lesion seen on MRI. The area is contiguous with homogenous or heterogeneous brain MRI findings in the regions/lobes of interest. This chapter focuses on lesional cases. The surgical approach to nonlesional cases in focal, multifocal, unilobar, or multilobar epilepsy will be covered in Chapter 86.

The topic of multilesional and multilobar epilepsy has been sparsely addressed in the epilepsy-related literature. Data regarding the evaluation, indications for surgery, and surgical outcomes in these patients are often buried in single-center descriptive studies. Multiple cohort data are combined with cases of extratemporal epilepsy or in series dedicated to pediatric or adult populations or to a specific epilepsy etiology (1–7), making it difficult to determine the real incidence and prevalence of multilesional and multifocal epilepsy.

Multilesional and multilobar resections range from 3% to 22% of the epilepsy surgeries reported in the medical literature in different centers (8–12). The number of multilobar resections is higher in the pediatric epilepsy population than in the adult population.

Patients with multilobar and multilesional epilepsies often have medically intractable epilepsy, or catastrophic epilepsies in the case of children. Multilobar resections account for 9% of the surgeries in children with infantile spasms (13) and 16% to 20% of the surgeries in infants with catastrophic epilepsy (14,15). Approximately 35% of the reoperations in patients with epilepsy result in multilobar resections (16).

This chapter will focus on:

- The selection of surgical candidates from patients with multilobar and multilesional epilepsy
- The selection of the surgical procedure
- Outcomes of multilobar and multilesional epilepsy

Figure 85.1 is a proposed algorithm for the evaluation of patients with multilobar and multilesional epilepsy to determine what type of procedure should be performed. We follow this algorithm for the discussion in this chapter. At the end of the chapter, the reader can find four cases illustrating the use

of algorithm for surgical decision making.

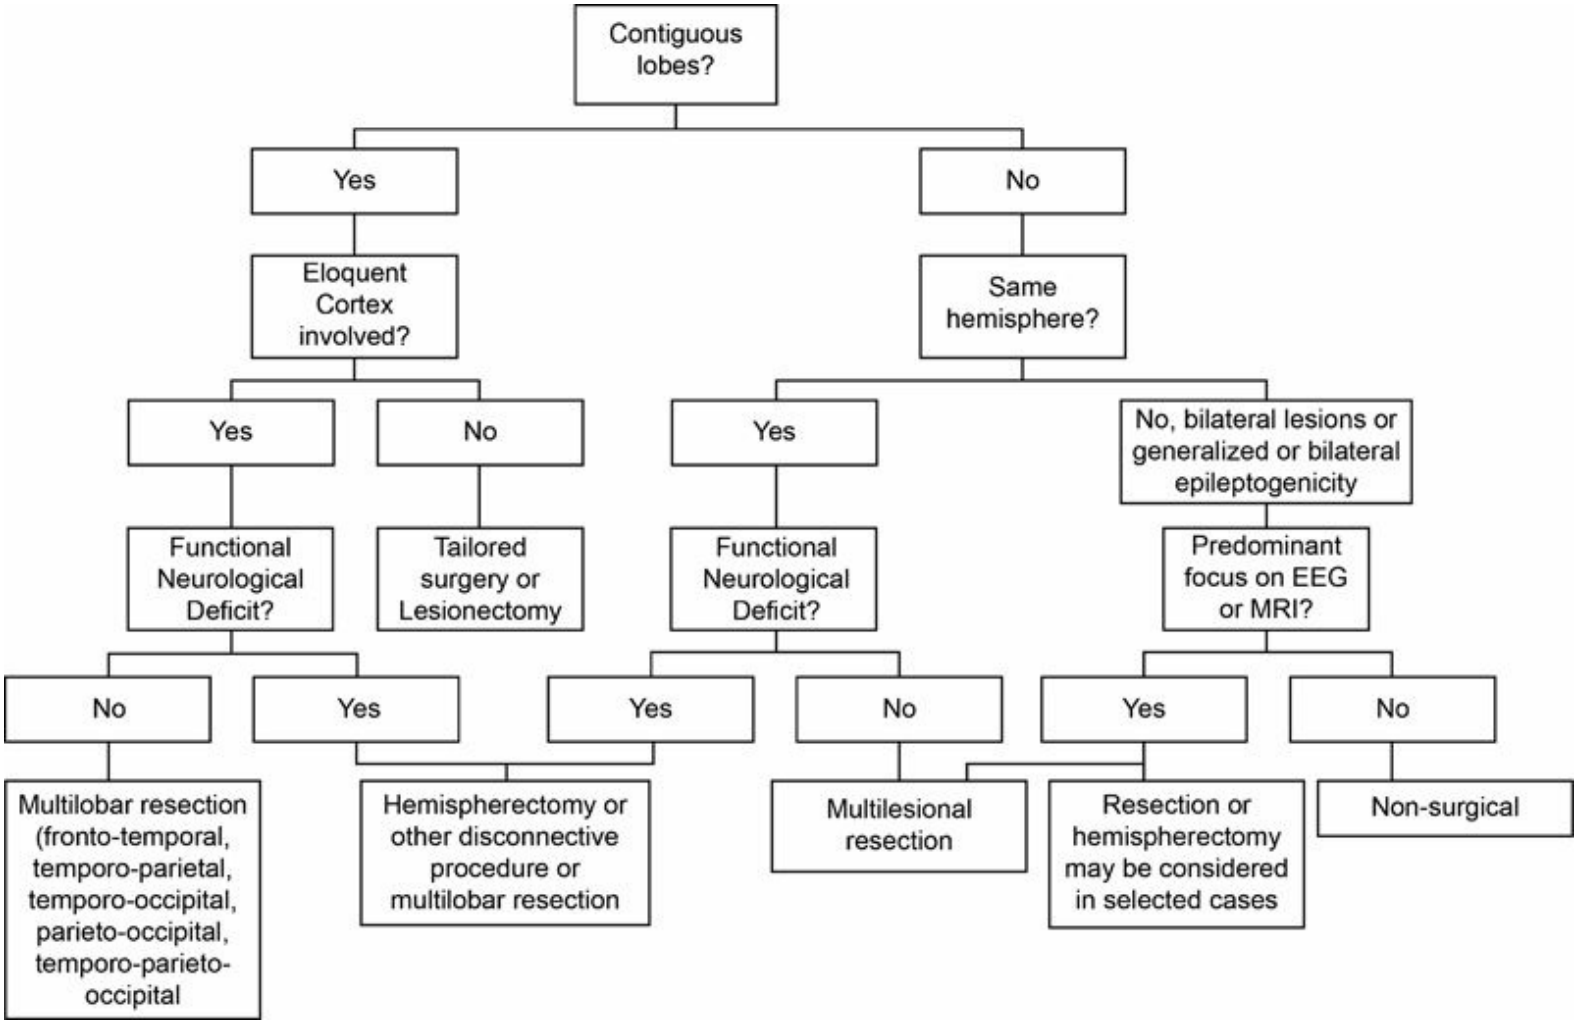

Figure 85.1. Proposed algorithm for the evaluation of patients with multilobar and multilesional epilepsy. The algorithm departs from the findings in the brain MRI. The first element to consider is whether lesions in contiguous lobes or not. Contiguous lesion algorithm continues on the left side of the scheme with next step focused in the relationship of the lesion with the eloquent cortex and the presence of functional neurologic deficit. Noncontiguous lesions follow the path of the right side of the scheme with the next step determining if the lesions are noncontiguous in the same hemisphere or bihemispheric and the presence or not of functional neurologic deficit or involvement of the eloquent cortex. Cases illustrating the use of the algorithm can be found at the end of the chapter.

SELECTION OF CASES WITH MULTILOBAR AND MULTILESIONAL EPILEPSY FOR SURGICAL CANDIDATES

The selection of surgical cases from patients with multilobal and multilesional epilepsy is based on several factors: brain MRI findings, VEEG, other neuroimaging techniques, and clinical data, including seizure semiology and findings of the clinical exam.

MRI FINDINGS

The role of the MRI in the identification of surgical candidates has been well established. The proposal from the Pediatric Epilepsy Surgery Subcomission (17) and the practice parameters of the Quality Standards Subcommittee of the American Academy of Neurology (18) mandate a brain MRI

using a specified epilepsy protocol as part of the minimal presurgical evaluation of children and adults for temporal lobe and neocortical epilepsies. Brain MRI is a diagnostic tool that is readily available in most epilepsy centers around the world, particularly those in developed countries (19).

The definitions of multilobar and multilesional epilepsies used in this chapter will be based on brain MRI findings. The results of the brain MRI are the first step at the beginning of the algorithm proposed in Figure 85.1. A brain MRI will identify the type, etiology, and location of a lesion. Although the etiology of the lesion is important in following the algorithm, for surgical planning purpose, the location of the lesion is equally important.

Etiology of the Lesion

The MRI findings in multilobar epilepsies include dysplasias, hemimegalencephalic syndromes, Sturge–Weber syndrome, Rasmussen encephalitis, polymicrogyria, periventricular encephalomalacia, or other encephalomalacias from trauma, stroke, tumors, etc.

MRI substrates in multilesional epilepsies include tuberous sclerosis complex, inflammatory and postinfection lesions, bilateral strokes or watershed infarcts, tumors, and vascular malformations.

All these etiologies are discussed in detail in Section B of this book. The frequency with which these lesions are seen in tertiary epilepsy centers has been extensively discussed in the medical literature. Cortical dysplasia remains the most common of all multilobar and multilesional epilepsies. Nevertheless, one community-based epidemiologic study of lesions identified by brain MRI in children with epilepsy found that 16% of the children (82 out of 518) had abnormalities in the brain that could be responsible for their epilepsy (20). 37% of the patients in this group had pre- and perinatal-acquired cerebral injuries, 27% had cortical dysplasia, 22% had other discrete lesions such as tumors, and 15% had lesions associated with genetic conditions.

Location and Extent of the Lesion

The brain MRI will help to determine whether the lesions are located within one hemisphere or are bilateral, and whether the lesion(s) is unilobar or multilobar. The brain MRI also determines whether the lesion is cortical, subcortical, or both and its relationship with the eloquent cortex. Cortical lesions located near the eloquent cortex, as well as lesions located near the major tracks (pyramidal tract, optic tract, arcuate fasciculus, etc.), put the patient at risk for neurologic deficit during surgical resection. Adding Diffusion Tensor Imaging (DTI) sequences could help with the surgical planning in such cases (21,22).

Forty-six percent of the cases in a community-based study involved bihemispheric brain lesions (20). We have learned in recent years that bilateral lesions do not preclude successful epilepsy surgery (23).

In addition to brain MRI, surgical decision in patients with multilobar and multilesional epilepsy includes data from other imaging modalities such as PET, SPECT, and DTI. In some patients MRI postprocessing are needed. The role of these techniques in the evaluation of epilepsy surgical candidates is covered in Chapters 75, 77, and 78.

Refractory Epilepsy

Since our surgical selection algorithm is based on brain MRI findings, this chapter minimally discusses the role of refractory epilepsy and incidental findings in patients with nonsurgical epileptic

syndromes or patients with epilepsy-related findings in brain MRI who never have had a seizure.

Refractory epilepsy is defined as the failure of two to three drugs that are used appropriately and adequately for the seizure type, although some variations on time of seizure freedom and time required from onset of seizures to time of evaluation have been used for research purposes (17,18,24,25). While brain MRI opened a new era in epilepsy surgery, its results must be interpreted with caution and in the appropriate clinical setting before referring the patient for epilepsy surgery. One study reported incidental brain abnormalities in 23% of normal children (26). A study of candidates for cochlear implants found incidental or unexpected brain abnormalities in 18% of the sample, including a few cases of periventricular nodular heterotopia (27). The incidental findings of brain lesions led to additional investigation and sometimes to surgeries—for example, in cases with brain tumors. A more complicated situation occurs when the patient has a history of epilepsy or seizures. Incidental brain abnormalities have been described in 3% of children with idiopathic epileptic syndrome and 10% of children with nonidiopathic epilepsy, normal neurologic exams, and nonpharmacoresistant epilepsy (20). Thus, the definition of refractory epilepsy is necessary but not indispensable for the referral for epilepsy surgery. A community study found that 6 of the 82 children with epilepsy as well as brain abnormalities and brain tumors (4 neoplasias and 2 DNETs) underwent surgeries even when their epilepsy was not pharmacoresistant (20).

Clinical Aspects: Semiology, Exam Findings, Weight, and Age

Semiology

The semiology of the seizures, specifically early in the course of seizures, is very important when considering epilepsy surgery. The presence of focal features can point to a specific brain region or location (15,28–32). Auras, lateralizing signs, and postictal symptoms are also very important in assigning both hemispheric and lobar localizations (28,30,33).

Semiology is even more critical in patients with multilobar or multilesional substrates. In multilobar cases, semiology may help predict early seizure spread in relationship to a large lesion. For example, in patients with posterior quadrant dysplasia, limb clonic or versive seizures at the onset may suggest anterior ictal spread. Hypomotor semiology may suggest a posterior spread. In multilesional patients, semiology may help narrow down the inventory of lesions that could possibly result in the semiology. More than one semiology during VEEG may suggest multiple ictal-spread patterns from one region or multiple independent seizure-onset zones. Hence, a critical review of history and VEEG with an appropriate sampling of seizure data is vital to building an effective surgical strategy.

Age-related syndromes in infants and children, such as epileptic spasms or Lennox–Gastaut-type seizures, could be the manifestation of focal epilepsy secondary to a focal, unilobar, multilobar, or hemispheric lesion (15,32,34,35). Seizures characterized by arrest of activity with very subtle limb movements and/or automatisms are also seen in this group, and some seizures with clear asymmetric features fail to point to a generalized or a focal epilepsy (15,36). Detailed evaluation of seizure semiology during VEEG becomes very important in these cases.

Clinical Exam

The clinical exam is equally important when determining the type of brain surgery to be performed. In

addition to the proximity of the lesion to the eloquent area, the presence of motor deficit, hemianopsia, neglect, etc., are important when deciding the extension of the surgery. The degree of motor deficit is equally important. The possibility of a new neurologic deficit is a deterrent to patients and relatives when considering epilepsy surgery, and worsening of an existing neurologic deficit is also not desired. Risk of neurologic deficit was the cause for refusing resection in seven of nine children with subdural grids who were studied at the Cleveland Clinic (37). In these cases, an early consent discussion that includes clearly defined risks and benefits could lead to alternative or palliative treatments. In some patients, assessment of hemiparesis may be difficult because it fluctuates with acute worsening and recovery over weeks to months. Such phenomenon is seen in Rasmussen's. This is also reported in Sturge–Weber syndrome where a component of ischemia makes a pattern of observation over time more important rather than one-time assessment. Occurrence of epilepsia partialis continua in patients of Rasmussen's, poststroke cases, and rarely in focal cortical dysplasia makes this even harder as the patient may not be able to cooperate or part of the deficit could be ascribed to Todd paralysis.

Weight and Age

These are important factors in scheduling surgery. Infants as young as 1 month and weighing 4 kilograms have undergone surgery for catastrophic epilepsy (14,15,38). Although operative risks are greater in very small infants or the elderly, there are no absolute age or weight limitations for epilepsy surgery if seizures are difficult to control. The expertise and comfort of the neurosurgeon and the hospital team are the ultimate determining factors.

THE SELECTION OF THE SURGICAL PROCEDURE

Multilobar Resection/Disconnection

Patients with multilobar and multilesional epilepsy involving contiguous lobes and located in or near eloquent cortex are candidates for multilobar resection or disconnection, assuming the absence of a significant preexisting neurologic deficit. These cases may require additional invasive evaluation if a more tailored surgery is possible or desired.

A variety of multilobar resections or disconnections can be performed, depending upon the location of the lesion and information provided from the presurgical and invasive evaluations. Types of multilobar resections or disconnections include occipital plus, frontotemporal (FT), temporoparietal (TP), and frontoparietal (12,39,40).

The most common type of multilobar resection or disconnection is the occipital plus or posterior quadrant surgery. The posterior quadrant resection/disconnection includes temporoparietal–occipital (TPO), parietooccipital (PO), and temporo-occipital surgeries. The most common of these procedures is the TPO, which accounts for 21% to 46% of the multilobar resections or disconnections (12,39,40). In adults, TPO is less commonly performed and only accounts for approximately 5% of the surgeries (12,41,42). The TPO is selected when data support the fact that the frontal lobe is free of lesions, is not epileptogenic, and can be preserved. It is also the procedures of choice when there is need to preserve the motor and sensory cortex.

The decision to perform a multilobar resection versus a disconnection depends on the experience and expertise of the center. Daniel et al. described a series of patients in which the selection of the

technique changed over the years. Earlier surgeries included anatomical posterior quadrantectomy or TPO resection; years later, the predominant procedure was the functional posterior quadrantectomy or extended temporal lobectomy with PO disconnection. Peri-insular posterior quadrantectomy has been described as the latest approach for posterior quadrant epilepsy (43). This technique includes disconnection of the temporal lobe followed by disconnection of the PO lobes during the same surgical procedure (39,42,43). Other approaches— rationale of this is not clear—such as a two-stage procedure with PO lobectomy followed by a temporal lobectomy in a separate surgery were used in some of the patients (43). Etiologies for occipital plus resections include malformation of cortical development, sequels of stroke or other vascular injuries, tumors, tuberous sclerosis, and Sturge–Weber syndrome. In general, occipital plus resection has a better long-term outcome than FT and TP resections.

Variations of focal resections with or without multiple subpial transections have been described in patients with perirolandic epilepsy (44). Nevertheless, seizure outcome with complete seizure freedom has been reported only in 31% of the cases with new neurologic deficits present in up to 23% of the cases. In other patients with multilobar lesions in which sparing of the motor cortex is desired, proposed surgery includes the premotor resection of the frontal lobe combined with a TPO resection (44,45). This technique provides seizure improvement but not freedom. Random cases with multifocal epilepsy can have improved quality of life when the resection is targeted toward the region producing more disabling or frequent seizures (46).

Hemispherectomy, Hemispherotomy, and Other Disconnective Procedures

Patients with epilepsy secondary to large multilobar brain lesions generally undergo hemispherectomy, although there are some exceptions, particularly when the surgical procedure is risking a new neurologic deficit.

Hemispherectomy or other disconnective procedures may be indicated for patients with multilobar and multilesional epilepsy involving contiguous lobes and located in or near the eloquent cortex who have a preexisting significant, complete or nearly complete neurologic deficit (47,48). In some patients with this scenario, the benefits from hemispherectomy may outweigh the risks of continuing seizures, hence favoring a more aggressive approach. In some patients with Rasmussen syndrome, hemispherectomy may be preemptively done due to anticipated deficits. Although quite controversial and not a widely accepted practice, there is a school of specialists who believe patients with Sturge–Weber syndrome should get early hemispherectomy rather than a focal resection. Etiologies for patients with epilepsy who require hemispherectomy include Rasmussen encephalitis, vascular or posttraumatic encephalomalacia, in particular perinatal infarction, cortical dysplasia, and hemimegalencephaly. Pathologic analysis of samples from 34% of patients with encephalomalacia found additional abnormalities consistent with cortical malformation (48). Functional or anatomical hemispherectomy is a procedure that is very well tolerated in infants and young children with catastrophic epilepsy (49). Compelling data indicate that the presence of mild or moderate MRI abnormalities in the hemisphere contralateral to the one with the main MRI abnormality is not a contraindication for epilepsy surgery. Surgery in these cases has a short-term positive outcome of 79%, compared to results in patients who did not have contralateral abnormalities (23). Similarly, patients with generalized epilepsy and generalized or contralateral EEG findings, who had congenital, perinatal, or early-acquired brain lesions on MRI, underwent successful epilepsy surgery

(35,50). Sixty-four percent of patients in the series reported by Wyllie et al. received a hemispherectomy, and 14% had a posterior quadrant or occipital plus resection. Seven out of the 10 patients with bilateral EEG abnormalities in the series reported by Gupta et al. underwent hemispherectomy; 5 out of the 7 patients were completely free of seizures at follow-up (50). Six out of 27 (22%) patients with Lennox–Gastaut syndrome underwent hemispherectomy, with Engel class I archived in 5 out of the 6 patients (51).

Multilesional/Multifocal Resections and Multistage Surgeries

Following a complete presurgical evaluation, multilesional and multifocal resections are performed in patients with multiple epileptogenic lesions or multiple ictal onset zones. The medical literature covering this topic is limited because patients with multilobar surgeries are often lumped together with those requiring multifocal /multilesional surgeries. The indications for evaluation and outcomes of the surgical procedures are, therefore, difficult to determine. Another limitation is that documentation of the success of multifocal epilepsy surgery is sometimes limited to case reports.

Tuberous sclerosis (TS) is the most common etiology for a multilesional resection. Other etiologies include cortical dysplasias, postinfectious encephalitis, posttraumatic epilepsy, vascular injuries, tumors (in particular, brain metastases), postradiation epilepsy, etc. Some patients have dual pathologies that include malformations of cortical development and mesial temporal sclerosis (52,53). Multiple pathologies are reported in up to 10% of the specimens from patients with medically refractory epilepsy studied in one anatomopathology laboratory (54).

In the past, patients with multifocal ictal onset zones were considered nonsurgical candidates. Multifocal ictal onset zones were the reason for not performing resections in four out of nine children studied with subdural electrodes and reported by Pestana Knight et al. (37). One study in adult patients with epilepsy documented that resections were not performed after invasive evaluation in 10 out of 22 patients because of diffuse or multifocal ictal onset zones (52). Another study reported poorly localized epilepsy in 9 out of 17 cases in which resections were not performed after invasive monitoring (55). Currently, patients with multifocal epilepsy who were deemed ineligible for surgery on the basis of evaluations with subdural grids alone, or subdural grids in combination with a few depth electrodes, are benefitting from stereo-electroencephalographic (SEEG) evaluation (56,57). Vadera et al. reported 14 patients who failed subdural grid evaluation and received a second evaluation with SEEG. Ten of these patients had resections after SEEG placement. At 11 months, 60% of the patients were seizure free (56). SEEG offers some advantages to patients with multifocal, unilateral, or bilateral epileptogenic foci or lesions. These include the possibility of studying epileptogenicity in deep gyri, sulci, and bilateral brain structures when noninvasive or invasive studies had failed to localize the epileptogenic zone (57,58).

Some patients with multifocal or multilesional epilepsy may also benefit from multistage procedures. Implantation of electrodes is followed by resection and reimplantation of electrodes with further evaluations and resections, depending upon the patients' characteristics (45,55,59). Multistage procedures have been performed in patients who require up to four admissions and two to three operations at each admission (55), with a relatively low complication rate (45,55,59). Staged and bilateral invasive evaluations have changed the outcomes for seizure control for patients with TS and those with lesions involving the motor cortex (60,61). Chapter 30 also discusses surgical strategy in patient with tuberous sclerosis complex.

Other Surgical Procedures

Multiple Subpial Transections

Some patients are candidates for limited brain resection as a palliative, more than a curative, treatment. Multiple subpial transection is another technique that has been used in cases with lesional or nonlesional epilepsy. The technique has been used alone or in combination with lesionectomies, lobectomies, or multilobar resections (61,62) and is discussed further in Chapter 88.

Limited Resection for Extensive Lesions

Catenoix et al. (63) studied seven patients with large multilobar lesions and seizure semiology consistent with mesiotemporal epilepsy who underwent temporal lobectomies. All patients became free of seizures after the surgery and remained so after a mean follow-up period of nearly 3 years. The researchers concluded that patients with ictal symptoms that are consistent with temporal lobe epilepsy have excellent seizure outcomes following temporal lobectomy, regardless of the size or extent of the brain lesions. This study analyzed only a limited number of patients with a very specific seizure semiology.

Seizure outcome of 75% at follow-up was also described in a series of four patients with infrasylvian multilobar polymicrogyria who underwent partial resection of the polymicrogyria (3/4 patients) combined with anterior mesial temporal resection. These patients had complex malformations that include polymicrogyria, squizencephaly, focal cortical dysplasia, and hippocampus malrotation (64).

Nonsurgical Candidates

Some patients do not receive epilepsy surgery because of the extent of the lesion, high risk for new postsurgical deficits, or the suspicion of multifocal epilepsy. Selwa et al. (65) followed patients for 4 years who were not surgical candidates. Twenty-one percent of the patients were seizure free at follow-up; others reported reduced seizure frequency. Roth et al. (55) reported on seven patients who became seizure free after invasive monitoring alone, without epilepsy surgery. Particular cycling of the epilepsy could possibly explain the findings that seizure freedom in these two different patient groups is possible in some refractory cases.

Some other cases considered not surgical candidates could benefit from palliative procedures such as corpus callosotomy or neurostimulation.

OUTCOME OF MULTILOBAR AND MULTIFOCAL EPILEPSY

There are data supporting the position that complete resection obtains the best seizure control after surgery and that incomplete resection of the lesion is a predictor of poor outcome. Seizure outcomes in patients with epilepsy due to large hemispheric or multifocal lesions who underwent small or limited resections are not well known.

Sarkis et al. (12) from the Cleveland Clinic reported 71% seizure freedom at 6 months in 63 patients who underwent multilobar epilepsy surgery. Seizure-free outcome was reduced to 52% at 5

years and 41% at 10 years after surgery. They did not study patients with extensive brain lesions who underwent limited resections. Bulacio et al. (66) (Fig. 85.2) reported a probability of a little above 0.1 of seizure freedom at 10-year follow-up for patients who underwent multilobar resection. This population included patients who had invasive evaluation only, which is not representative of current trends in pediatric epilepsy surgery in some tertiary care centers.

CONCLUSIONS

Patients with multilobar and multifocal epilepsy are a heterogeneous group with different etiologies and epilepsy locations. Refractory epilepsy is common in these cases and catastrophic epilepsy is commonly seen in younger children. Therefore, many of these patients represent a treatment challenge. Some of these cases need presurgical and invasive evaluations tailored to individual needs. Novel surgical strategies and improved perioperative care have improved seizure outcome and lowered surgical risk in these patients. Overall, they can expect improved quality of life for these surgeries. Although it is difficult to group these cases for outcome analysis, further understanding of the epilepsy outcomes is needed.

ANNEX

Figures 85.3 through 85.7 show cases illustrating the decision making of the algorithm for the evaluation of patients with multilobar and multilesional epilepsy, shown in Figure 85.1.

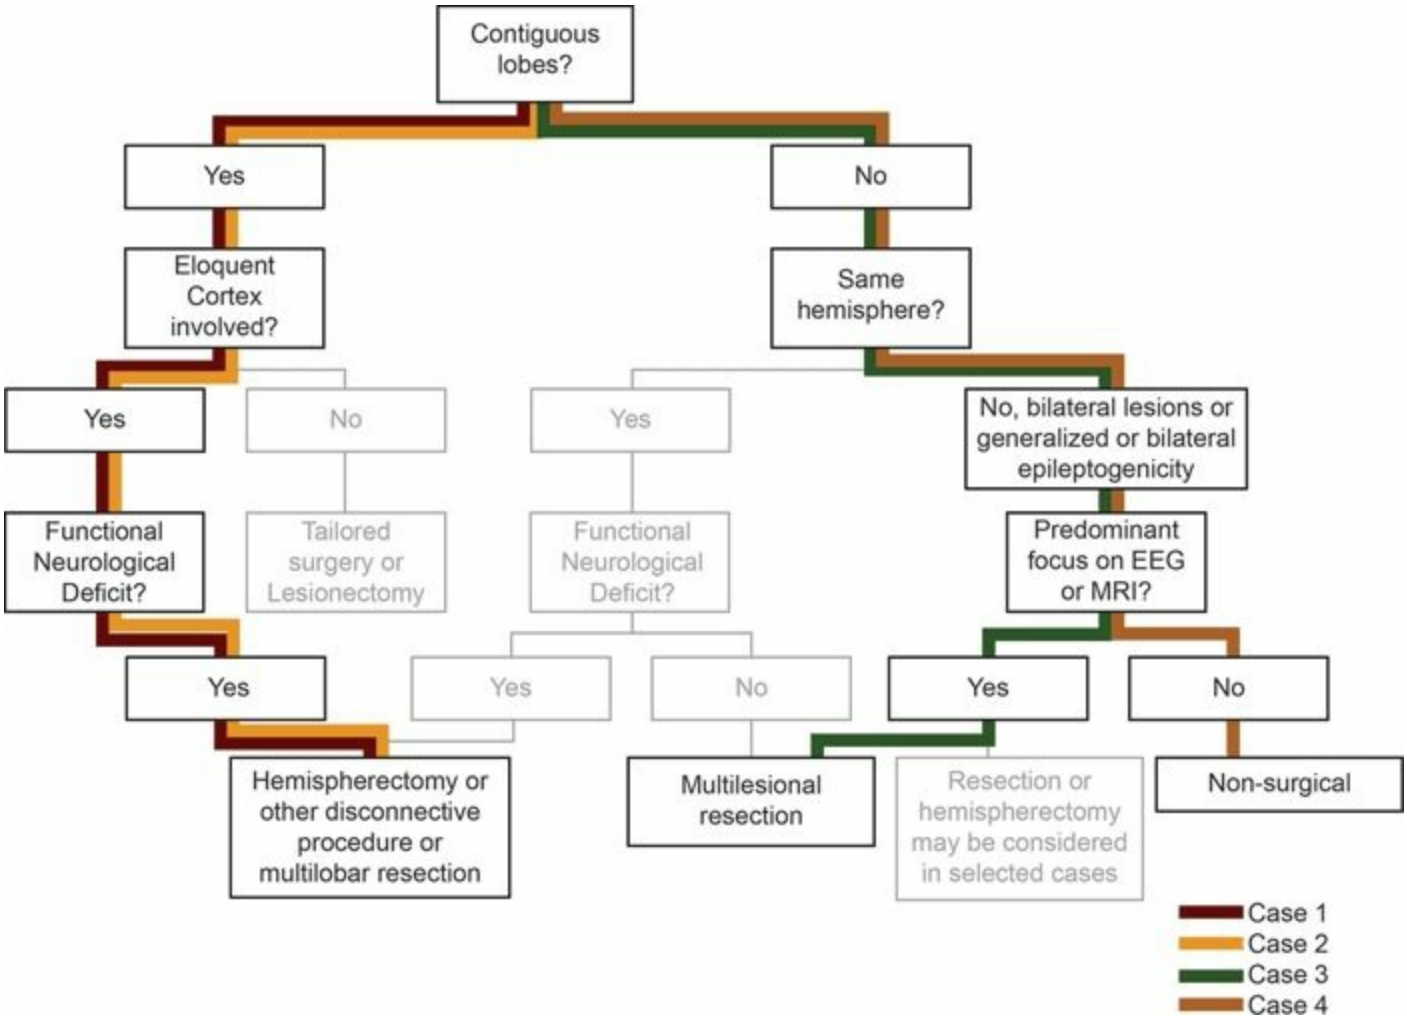

Figure 85.3. Progression in the proposed algorithm for the evaluation of patients with multilobar and multilesional epilepsy in four patients with different clinical scenarios. Each case is color coded in the figure key: Case 1 in red, Case 2 in yellow, Case 3 in green, and Case 4 in orange.

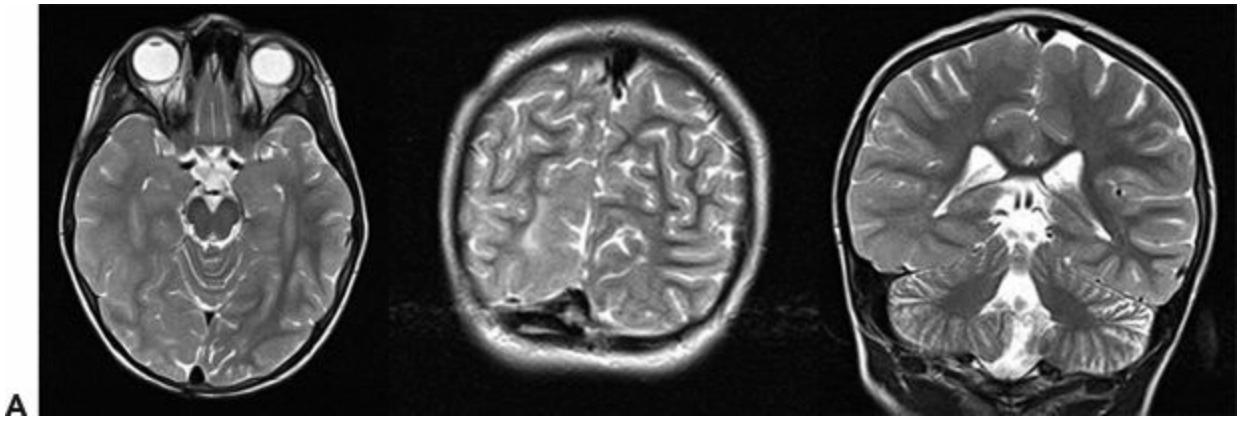
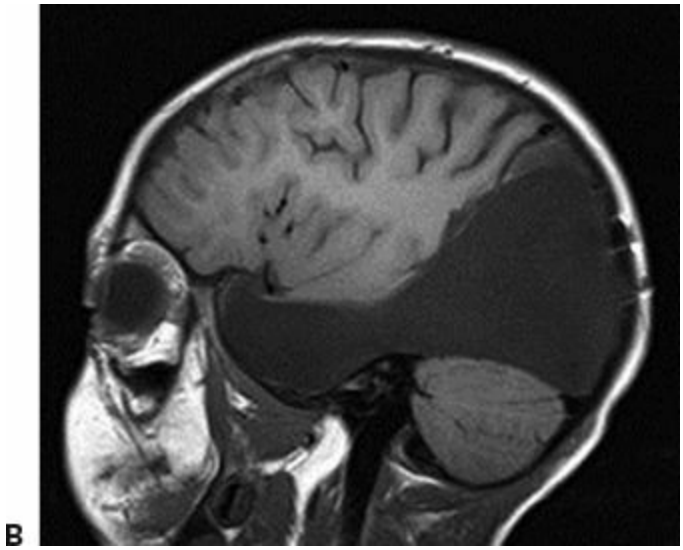
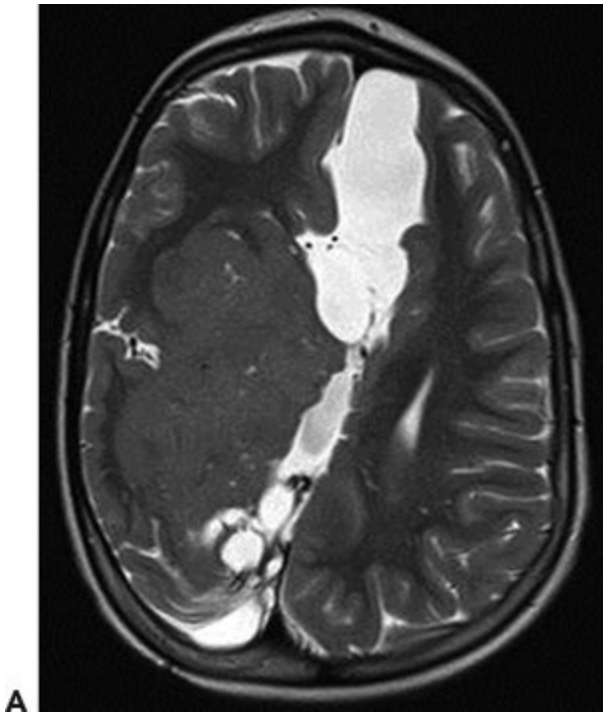
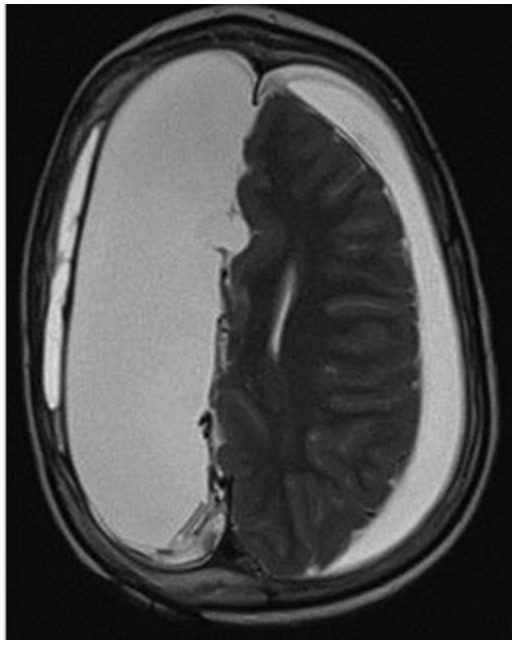


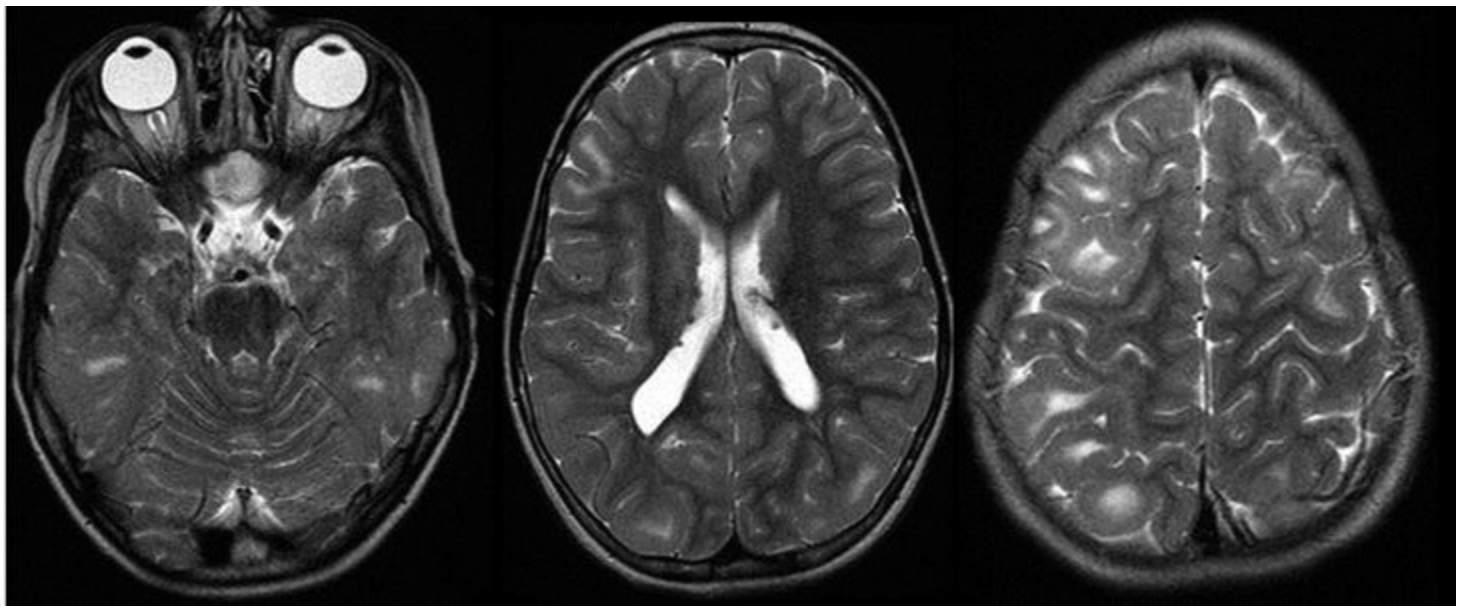


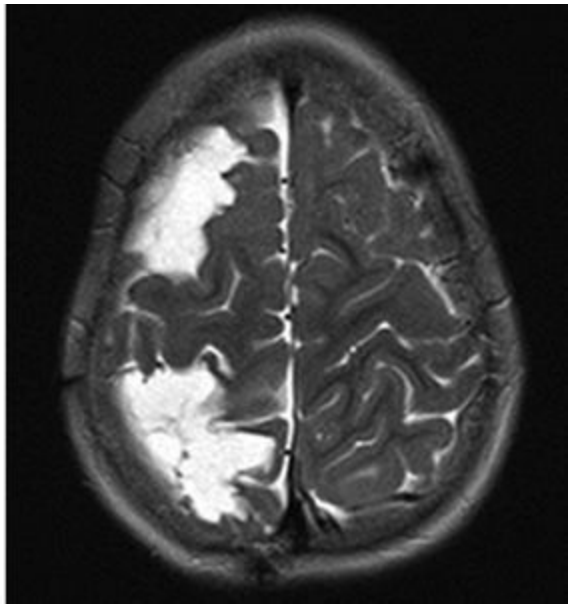
A:Brain MRI axial and coronal T2 images on Case 1. The figure documents the presence of extensive cortical dysplasia in the right TPO region with blurring of the gray–white matter junction. Case 1 is a 5-year-old right-handed male with seizure onset at age 2 months. Initial seizures were infantile spasms that responded to ACTH therapy initially. At the time of the presurgical evaluation, he was having multiple daily seizures described as behavioral arrest (hypomotor seizures) and bilateral asymmetric tonic seizure. On examination, there was evidence of delayed cognition for age, left hemineglect, mild left hemiparesis, and a possible left hemianopia. He was receiving treatment with felbamate, lacosamide, and rufinamide. Previous antiepileptic drugs included ACTH, clonazepam, levetiracetam, oxcarbazepine, and topiramate. He had a vagus nerve stimulator implanted. Interictal findings on video–EEG evaluation were right hemispheric sharp waves, right bioccipital sharp waves with maximum right and rare left occipital sharp waves. There were generalized polyspikes during sleep and continuous slow activity over the right hemisphere. Hypomotor seizures had an ictal onset in the right occipital region or right hemisphere. Figure 85.3 showed the decision making for this case in color red. **B:**Postoperative brain MRI sagittal FLAIR image of Case 1. The figure shows a multilobar resection that included right TPO lobe. Case 1 has been seizure free for 14 months after this surgery.





A:Brain MRI axial T2 image on Case 2. The figure documents the presence of severely dysmorphic brain with massive right hemisphere cortical dysplasia, callosal dysgenesis, and complex supraventricular midline cyst. Case 2 is a 7-year-old right-handed male with chromosomal abnormality 8p21.3 duplication and 4q13.3 deletion (unknown clinical significance) who had seizure onset at age 11 months. His initial and ongoing seizures were hypomotor seizures that often time were not identified by his relatives. He also had left arm clonic status epilepticus lasting several hours to a day and occurring around three times per year. On examination, he had a left hemiparesis with no fine motor movements in the left hand and left hemineglect. He was taking oxcarbazepine and topiramate. Rectal diazepam failed to control episodes of partial status epilepticus. Previously, he was taking levetiracetam. He had a ventriculoperitoneal shunt placed at birth due to complex midline cyst and hydrocephalus. Interictal activity on video–EEG was characterized by right centroparietal and right frontocentral sharp waves. There was continuous slow in the right hemisphere with asymmetric background. Several hypomotor seizures were recorded with onset in the right centroparietal region. Figure 85.3 shows the decision making for this case in color yellow. **B:**Postoperative brain MRI T2 axial image on Case 2. In this case, the complexity of the malformation did not allow for a functional hemispherectomy. Case 2 has been seizure free for 12 months after anatomic hemispherectomy.





A:Brain MRI Axial T2 images of Case 3. Case 3 is a 12-year-old right-handed female with TSC2 mutation. Her seizures began at age 2 weeks. Initial seizures were infantile spasms that improved but nor resolved with ACTH therapy. Before surgery, she had multiple seizures per day that were described as complex motor behavior evolving to hypomotor seizures (behavioral arrest) and then followed by epileptic spasm. She also has generalized tonic seizures. On examination, she has cutaneous tuberous sclerosis stigmata and clinical/behavioral features consistent with cognitive impairment and pervasive developmental disorder. She was nonverbal and had left hemineglect. Systemic evidence of TSC included left eye astrocytoma and bilateral renal angiomyolipomas. At the time of the presurgical evaluation, she was taking zonisamide, valproic acid, levetiracetam, and clonazepam. In the past, seizures were refractory to ACTH, pyridoxine, topiramate, oxcarbazepine, lamotrigine, and carbamazepine. Interictal abnormalities on video–EEG included continuous slow activity lateralized right hemisphere maximum right centroparietal region, multiregional sharp waves right more than left hemisphere, generalized polyspikes, and generalized spike and wave complexes. Typical clinical seizures and electrographic seizures were recorded with an ictal onset in the right centroparietal region. Hypomotor seizures had nonlocalizable onset. Figure 85.3 shows the decision making for this case in color green. **B:**Postoperative brain MRI Axial T2 images of Case 3. Case 3 had right-side multilesional resection with sparing of the motor cortex. Surgery was done with cortical stimulation studies and electrocorticography. At last outcome, 5 years after the surgery, Case 3 has had a seizure reduction of 80% compared to her presurgical baseline. She has occasional tonic seizures and isolated tonic spasms mainly when she is ill.

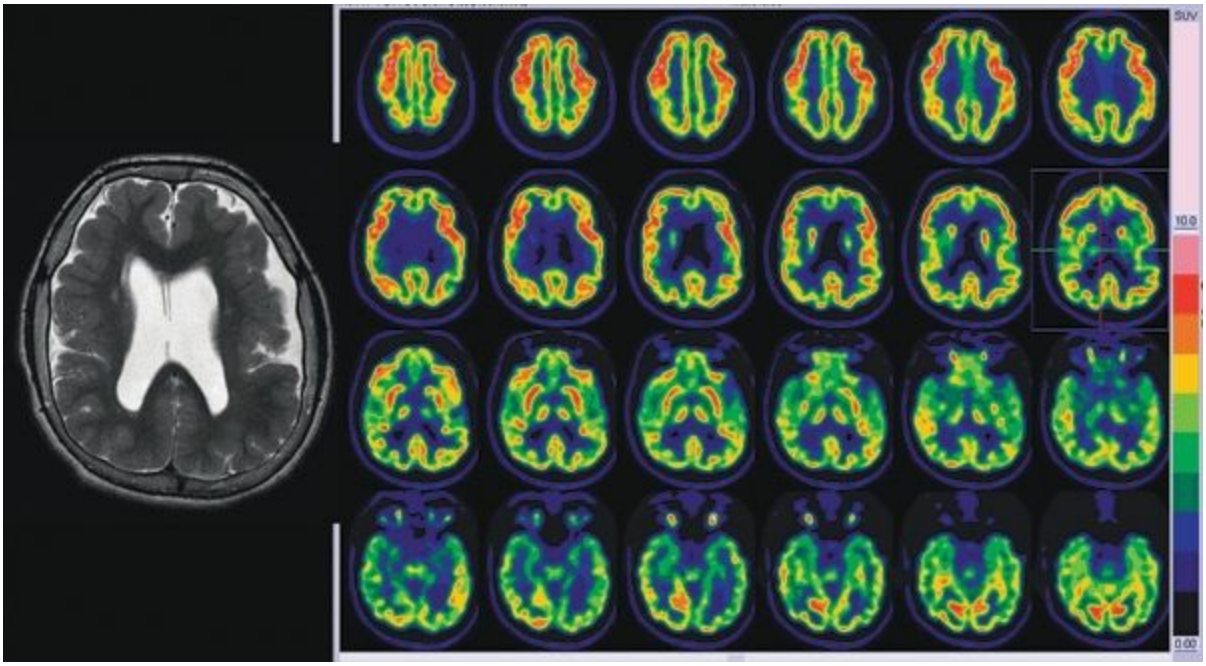


Figure 85.7. Brain MRI Axial T2 image and PET scan of Case 4. MRI shows bilateral polymicrogyria. PET scan shows bilateral extensive and multilobal hypometabolism. Case 4 is a 16-year-old right-handed male with seizure onset at age 7 months. His seizures are axial spasms, myoclonic seizures, and atypical absence seizures. He has multiple seizures daily. On examination, he has clinic features consistent with moderate cognitive impairment and spastic quadriparesis with lower extremity predominance. Current

medications are topiramate, vigabatrin, clobazam, clonazepam. Rescue medication is rectal diazepam. Previous medications included lacosamide, lamotrigine, levetiracetam, rufinamide, valproate, and ketogenic diet. He also had a vagus nerve stimulator implanted. On video–EEG, he has continuous slow generalized and axial spasms and myoclonic seizures both with generalized onset. This case is not a surgical candidate. Figure 85.3 shows the decision making for this case in color orange. In patients like Case 4, palliative procedures such as callosotomy could be considered to reduce the daily seizure burden.

CHAPTER 86 SURGICAL APPROACH IN NONLESIONAL CASES

DEEPAK LACHHWANI AND JORGE ALVARO GONZÁLEZ-MARTÍNEZ

INTRODUCTION

Nonlesional refractory focal epilepsy cases invariably lead to a challenging path toward curative epilepsy surgery. The identification of a pathologic substrate on magnetic resonance imaging (MRI) is useful for an appropriate surgical strategy and most predictive of long-term seizure outcome. Patients with nonlesional MRI on the other hand require a more rigorous pre surgical evaluation and often end up with a disappointing surgical outcome (1).

For example, a long-term study involving 85 patients with extratemporal epilepsy and normal MRI showed only 11% (9/85) were seizure free with 10 or more years of follow-up. These 9 patients belonged to the subgroup of 24 who had had received surgical resection (38% seizure free) (2). Therefore, while surgical treatment provided hope for 38% in this study, the alternative of medical management only was uniformly dismal with respect to seizure outcome. Interestingly, this study found the scalp EEG to be the most useful test to identify patients who were likely to have an excellent outcome, while the presence of a localized SISCOM did not predict surgical outcome. Nonlesional temporal lobe epilepsy patients have a slightly better outlook after surgery. Reports of excellent surgical outcome range from 41% to 65% (3–6).

Therefore, nonlesional refractory focal epilepsy is a challenge eagerly awaiting a solution. Despite years of advances in imaging modalities such as positron emission tomography (PET), single photon emission computed tomography (SPECT), magnetic resonance spectroscopy, magnetoencephalography (MEG), etc., none of these tests have shown independent predictive value in formulating surgical strategy in this cohort of patients. Presurgical management begins with a sound clinical hypothesis based on epilepsy history, seizure semiology, and a corroborating video–EEG evaluation involving scalp EEG. By definition, nonlesional epilepsy means that an MRI fails to reveal a plausible epileptogenic substrate. At this juncture, revisiting the initial hypothesis of seizure origin is critical before employing additional imaging techniques in the face of a normal MRI. For the epileptologist, each one of these imaging techniques holds the promise to better define the epileptogenic zone (EZ). Due to lack of convincing published data regarding predictive value of these tests, the answers yielded by these modalities may benefit if it supports a localizing hypothesis. Concordance of the initial clinical hypothesis and data from carefully chosen tests segues to an invasive evaluation directed toward a tailored resection. This chapter focuses on methods that share center stage in evaluating nonlesional epilepsy cases followed by available invasive evaluation techniques.

IS THE MRI TRULY NORMAL?

"The eye sees only what the mind is prepared to comprehend." Henri-Louis Bergson (1859–1941)

In nonlesional cases, it may be especially relevant to paraphrase Bergson in that the eye sees only what the mind is prepared to comprehend and what an MRI can reveal. Two critical steps can sometimes reveal an MRI answer hidden in plain sight: correct MRI technique and an expert review of the MRI. Before labeling an MRI as normal, it is essential to ensure that the proper technique was used to obtain the MRI and an expert reviewed the images within the clinical context. Standard MRIs may fail to detect 57% of focal epileptogenic lesions, while dedicated MRI protocols to evaluate epilepsy patients may show focal lesions in 85% of patients with "nonlesional" standard 1.5 T MRI (7). In the same study, authors found the sensitivity for detection of focal lesions of "nonexpert" reports of standard MRI was 39%, while that of "expert" reports of epilepsy specific MRI was 91%.

Advanced techniques utilizing 3-T or higher-strength magnets have provided additional insight in studying anatomic details crucial for surgical planning (8,9). Phased array surface coils performed at 3 Tesla (3 T PA-MRI) interpreted by experienced, unblinded radiologists yielded useful information in 48% of the studies previously performed with a 1.5-Tesla magnet (9). In 65% of the 1.5-Tesla studies reported as normal, 3-T PA-MRI was able to appreciate a new lesion. In 33% of the 1.5-Tesla identified lesions, 3-T PA-MRI provided better anatomic boundaries of the lesion (9). Overall, 3-T PA-MRI techniques influenced decision making in 38% of the patients in this group, mostly affecting the decision to perform surgery. Advances in MRI techniques have improved the signal-to-noise ratio, reduced scan time, and increased spatial resolution as well as contrast-to-noise ratio.

Moreover, in very young patients, the timing of MRI can have a significant influence on yield. Throughout infancy, as axons myelinate, their T2 signal shifts from being brighter than surrounding cortex to darker than surrounding cortex. Due to these maturational changes, focal lesions are best appreciated before 6 months of chronologic age. A normal MRI study obtained between 9 and 18 months of age should be repeated after 2 years to account for a lesion that may be present but not evident during transitional signal changes (10). Appropriate MRI techniques and protocols for patients suspected to have focal epilepsy are well described in the literature (10,11).

PET

[18F]FDG-PET is the most frequently used nuclear functional imaging technique in patients with focal epilepsy. The uptake of radiotracer during the interictal state provides dynamic information regarding regional and general metabolism of the brain. After injection of a radiotracer, the subject is monitored with simultaneous EEG recording. The characteristic finding is a regional hypometabolism in the interictal state of patients with focal epilepsy. A meta-analysis of studies from 1992 to 2006 found that ipsilateral PET hypometabolism shows high concordance and good predictive value for seizure-free outcome even in cases with normal MRI (12). Ictal activity can have a variable influence on glucose uptake. Therefore a PET study needs to be interpreted with caution if EEG monitoring during uptake of radiotracer demonstrates a seizure or frequent spiking on EEG.

[18F]FDG-PET correctly identifies the diseased temporal lobe in >86% of nonlesional TLE patients (5). It is not uncommon for PET hypometabolism to be more widespread when compared to hypometabolism seen in patients with HS on MRI (12). The degree of hypometabolism may vary and is more often subtle in patients with type I dysplasia (13), one of the presumed substrates in nonlesional MRIs. A subtle abnormality on PET coupled with the poor resolution of the PET images raises the risk of overlooking a milder yet telling FDG-PET abnormality. A useful technique is to

coregister the patient's FDG-PET images to the MRI. Coregistration of the FDG-PET to the patient's MRI may enhance the detection of subtle hypometabolic areas and guide subsequent surgical strategy (14). In a cohort of patients where FDG-PET/MRI coregistration was included as a standard component of presurgical evaluation, this technique was especially useful in guiding surgery in 33% of patients with normal MRI and mild type I dysplasia (13).

Statistical parametric method analysis can be used as a complementary analytic tool for FDG-PET imaging, although a paucity of normative data in young patients poses a limitation and a visual evaluation is the mainstay in most epilepsy centers (15,16).

Alternate PET ligands such as [11]C-alpha-methyl-L-tryptophan (AMT) have shown promise particularly in evaluating patients with tuberous sclerosis. Their role in nonlesional MRI is not clear. One study found seizure outcome was poor in patients with normal MRI, with normal histopathology but abnormal AMT-PET, while it was better in patients with normal MRI and normal AMT-PET (17). The patient numbers were small, and additional data are needed to assess usefulness of AMT-PET in nonlesional MRI. Another technique, flumazenil (FMZ)-PET, helps to assess benzodiazepine receptor distribution. A prospective study found its usefulness in patients with bitemporal epilepsy as well as in patients with nonlesional MRI and FDG-PET–negative temporal lobe epilepsy (18). Recent studies showing seizure-related short-term plasticity of benzodiazepine receptors may help point to a potential avenue of FMZ-PET usefulness if performed within a few days in patients with normal MRI patients (19).

SISCOM

Interictal SPECT scan when compared with the ictal SPECT scan provides a snapshot of regional increase in blood supply keeping pace with the increased metabolic needs of the seizure-onset zone in patients with focal epilepsy. The subjective visual comparison of interictal and ictal SPECT images has been supplanted by digital subtraction of the images, followed by coregistration of the subtracted image to the patient's MRI (SISCOM, subtraction ictal single photon emission computerized tomography coregistered to MRI). The threshold of change included in the subtracted image is conventionally set at two standard deviations from the mean.

SPECT radio ligand injection needs to be timed early in the course of a seizure to capture the first and relatively restricted change in perfusion before the ictal activity spreads beyond the seizure-onset zone. This poses practical challenges, and despite best efforts, a late injection or a postictal injection (especially in brief seizures) may be unavoidable. The dynamic perfusion changes may transition from a relative increase from baseline (ictal) all the way to a reduction from baseline (post ictal). Interpreting subtracted SPECT images within the context of scalp EEG–confirmed time of injection is valuable in identifying a potential epileptic focus (hypo- or hyperperfused relative to baseline) in 77% of patients (20). Surgical outcomes are favorable when SPECT-provided information is incorporated in preoperative planning particularly when intracranial EEG data is concordant with the SPECT data (21). Thus, the role of SPECT is best as an adjunctive tool in nonlesional patients, with a contribution toward invasive implantation strategy.

MEG

Magnetic source imaging utilizes the magnetic fields associated with electric current dipoles to provide regional topography of the interictal epileptiform abnormalities. Bone and tissue are

transparent for the magnetic field, and hence magnetic signals are not attenuated when compared to the electrical (EEG) signals, which undergo significant attenuation, and small-amplitude spikes may not be visible on surface EEG. MEG is more sensitive in detecting interictal epileptiform discharges when compared to EEG (22). Postprocessing of magnetic dipoles offers a clear three- dimensional view of the epileptic discharges emanating from the cortical generators. In MRI-negative patients, MEG may serve as an adjunctive tool, and if the findings are in agreement with the initial hypothesis, MEG may facilitate planning for invasive evaluation. In a series of adult patients, who underwent MEG, the concordance between MEG spike cluster and findings on invasive recordings was 70% to 100% in 9/13 patients with no visible MRI lesions (23). The presence of MEG dipole clusters bode well for seizure-free outcome, while patients with poorly localized MEG spikes were not seizure free. Of note, the study found that complete removal of a MEG source cluster was not necessary for achieving seizure-free outcome (23).

Another retrospective study involving mostly nonlesional (15/22) pediatric patients noted that the number and density of preoperative clustered spike sources within the postoperative MRI-delineated resection bed is not associated with seizure-free outcome (24). There was no statistical difference in seizure-free outcome between the groups with >70% or <70% of MEG spike cluster removed. The role of MEG is attractive as an adjunctive tool to find convergent data in nonlesional patients. Additional data are needed to assess whether MEG may prove to be a better tool over other functional imaging modalities in the subset of nonlesional patients.

RATIONALE FOR THE USE OF INVASIVE MONITORING IN NONLESIONAL CASES

As an electroclinical concept, the localization of the EZ is done in the majority of cases through scalp EEG recordings. It is usually complemented by functional semiologic details of the ictal events (seizures). Additional anatomic, metabolic, and/or functional techniques would help to anatomically identify and localize the possible “epilepsy-producing lesion.” The gold standard techniques for the localization of the EZ (scalp EEG and video recordings of the seizure semiology) are sufficient to approximate the location of the EZ (25–28) and to generate an anatomoelectroclinical (AEC) network hypothesis. Nevertheless, scalp EEG only approximates the boundaries of the epileptic anatomic area to be resected. This is mainly due to the fact that scalp EEG detects only epileptiform activity that results from EEG synchronization of relatively large areas of cortex, estimated in some studies to be between 6 and 10 cm^2, and EEG recordings are affected by the smearing effect of the bone and other high-resistance structures (e.g., meninges and scalp) between the cortical generators and the recording electrodes (29).

More specifically, in patients with refractory focal epilepsy in the settings of nonlesional MRI, a thorough analysis of the seizure semiology and the sequence of ictal clinical manifestations would add a functional and clinical depth to the EEG data and therefore contribute to the generation of the AEC hypothesis. As described above, additional information may be afforded by PET, MEG, and other anatomic/functional/metabolic techniques. Finally, the localization of functional areas in the brain and mapping their extent and their potential spatial overlap with the EZ are essential components in the process of developing an adequate and individualized resective surgical strategy in patients with nonlesional MRI (27,30).

As focal cortical dysplastic (FCD) lesions are the most common pathologic substrates for focal

epilepsies and are differentially located in the frontal lobe (therefore in potentially eloquent cortex), an understanding of the functional status of the involved region(s) and its anatomical and pathologic correlations are essential (27,31,32). Mild forms of cortical dysplasia (FCD type I) frequently present with subtle or no MRI changes and may be functional and intrinsically epileptogenic (33,34).

Therefore, the precise anatomical localization and mapping of eloquent cortex and its relationships with a well-defined epileptic area are the two most important components of any presurgical evaluation. They will facilitate the surgical planning and optimize the chances for a safe resection of the epileptic region (thus maximizing the chances for seizure freedom and minimizing the risks of neurologic deficits). This is particularly important in patients with difficult to localize seizures associated with nonlesional MRIs, since the absence of the "epileptic lesion" makes the clear localization and anatomical delineation of the EZ much more challenging by noninvasive methods of localization. For these reasons, in specific clinical scenarios associated with nonlesional MRI, an extraoperative monitoring phase is needed.

INDICATIONS OF INVASIVE EVALUATION IN PATIENTS WITH NONLESIONAL MRI

The main indications for an invasive evaluation in focal pharmacoresistant epilepsy are to address the major limitations of various noninvasive techniques. Based on the limitations outlined above of the various noninvasive techniques, an invasive evaluation should be considered in nonlesional patients in any one of the following cases:

1. The MRI does not show a cortical lesion in a location that is concordant with the electroclinical/functional hypothesis generated by the video–EEG recordings (so-called MRI-negative cases).
2. The anatomical location of the MRI-nonidentified lesion (and the location of a clearly hypometabolic focal area on PET) is not concordant with the electroclinical hypothesis. In addition, scalp EEG recordings in 85% to 100% of patients with FCD not visible on MRI show interictal spikes that range in their distribution from lobar to lateralized, from difficult to localize to diffuse (35,36).
3. The generated AEC hypothesis in MRI-negative cases involves a potentially highly eloquent cortex. The identification of the EZ, mapping of its extent, and/or its relationship with potentially eloquent cortex are not typically resolved in these cases. These include patients with suspected focal cortical dysplasia as the possible pathologic substrate for the epilepsy (33,37–39).

In these instances, an invasive evaluation would lead to the formulation of a clear resective surgical strategy. The recommendation for invasive monitoring is made during a multidisciplinary patient management session that include neurologists, neurosurgeons, neuroradiologists, and neuropsychologists. Areas and networks of coverage/sampling are determined based on a well-formulated AEC hypothesis based on the results of the noninvasive studies. Two extraoperative invasive methods have been used to accomplish these goals: subdural grid (SDG) electrodes and stereotactic placement of depth electrodes (stereoelectroencephalography, SEEG).

PRINCIPLES AND INDICATIONS OF SUBDURAL ELECTRODES PLACEMENT

Extraoperative mapping with the subdural electrodes (which includes SDGs and strips) has the main advantage of allowing an optimal coverage of the subdural adjacent cortex with adequate and continuous superficial functional mapping capabilities (33,40,41). A major advantage of subdural electrodes consists in the comprehensive anatomical coverage of cortical surfaces, therefore allowing accurate anatomical electrical and functional mapping of the areas of coverage. Limitations of SDG electrodes include an inadequate/partial/incomplete intrasulcal, deep brain and interhemispheric coverage, and the relative difficulty in multilobar, three-dimensional, and large functional network sampling (42). These characteristics are highlighted in the published results on the successes and failures following SDG implantation (43). The best resective surgical outcomes following SDG implantation are achieved in patients with clear cortical lesions especially tumors and those patients in whom the SDG implantations were placed with the main purpose of functional mapping (32,43). On the other hand, the worst outcomes are seen in patients with no clear lesions on the MRI and nonspecific histopathology and those who underwent either a sublobar or multilobar resections.

These characteristics suggest that the best candidates for extraoperative invasive evaluation with SDG are those patients with clear cortical surface lesion(s) (excluding the interhemispheric, cingulate gyrus, deep sulcal, and mesial frontal/temporal regions), in particular those patients where the main indication for the invasive evaluation is electrofunctional/eloquent cortex mapping in the setting of a superficial cortical lesion. In nonlesional patients, the indication of SDGs and strips is likely reserved in patients where the hypothetical EZ is located in clear proximity to eloquent cortical areas.

INDICATIONS OF SEEG ELECTRODES PLACEMENT

In addition to the general indications for invasive monitoring specified above, specific indications can be considered to choose SEEG in detriment to other methods of invasive monitoring. These criteria included the following:

1. The possibility of a deep-seated or difficult-to-cover location of the EZ in areas such as the mesial structures of the temporal lobe, opercular areas, cingulate gyrus, interhemispheric regions, posterior orbitofrontal areas, insula, and depths of sulci.
2. A failure of a previous subdural invasive study to clearly outline the exact location of the seizure-onset zone. The failure to identify the EZ in these patients may be due to multiple reasons that include the lack of adequate sampling from a deep focus or a clinically silent focus upstream from the EZ.
3. The need for extensive bihemispheric explorations (in particular in focal epilepsies arising from the interhemispheric or deep insular regions).
4. Presurgical evaluation suggestive of a functional network involvement (e.g., limbic system) in the setting of normal MRI.

In these scenarios, the SEEG methodology may be considered as a more appropriate and safer option.

As mentioned above, the SEEG methodology has the advantages of allowing extensive and precise deep brain recordings and stimulations with minimal associated morbidity. In reoperations, mainly in patients who underwent a previous subdural evaluation, the possibilities are that the majority of these patients failed epilepsy surgery because of difficulties in accurately localizing the EZ. These patients pose a significant dilemma for further management, having relatively few options available. Further open SDG evaluations may carry the risks associated with encountering scar formations and still having limitations related to deep cortical structure recordings. A subsequent evaluation using the SEEG method may overcome these limitations, offering an additional opportunity for seizure localization and sustained seizure freedom (44). The main disadvantage of the SEEG method is the more restricted capability for performing functional mapping. Due to limited number of contacts located in the superficial cortex, a contiguous mapping of eloquent brain areas cannot be obtained as in the subdural method mapping. In order to overcome this relative disadvantage, the functional mapping information extracted from the SEEG method is frequently complemented with other methods of mapping, as DTI images or awake craniotomies (39).

CONCLUSION

Due to recent advances in numerous diagnostic modalities, nonlesional cases of refractory focal epilepsy have a better chance to be considered for a surgical treatment strategy than any other previous time. This is due to refinement of existing imaging techniques as well as adoption of less commonly used invasive techniques such as SEEG. Without a clear hypothesis to support the focal onset of seizures, invasive investigations are likely to mislead and should be avoided. However, when a priori hypothesis of focal onset of seizures is reasonably sound, initiating an invasive workup is recommended. Under such circumstances, the limitations of noninvasive investigations can be overcome with a carefully chosen technique of invasive evaluation (SDGs or SEEG). Outcome data are encouraging and support clinical judgment and judicious use of tools to explore surgery for this challenging subset of nonlesional cases.

CASE

A 15-year-old right-handed boy, with seizure onset at 8 years of age, had dialeptic seizures with automotor features, sometimes evolving to left head version followed by secondary generalized tonic–clonic seizure. Despite adequate medication trials, he was having one seizure/month to one seizure every 2 to 3 months. 3-T brain MRI was normal; MEG and FDG-PET did not provide further localizing information. Surface interictal and ictal EEG was consistent with right hemisphere epilepsy (Figs. 86.1 through 86.4). After careful deliberation at surgical conference, it was decided to undertake an SEEG evaluation focusing on the right frontal and perirolandic areas as well as right insula (Figs. 86.5 through 86.9). A tailored resection was based on the SEEG findings (Fig. 86.10) resulting in seizure freedom since surgery (>5 years). Histopathology did not show evidence of malformation.

CHAPTER 87 HYPOTHALAMIC HAMARTOMA

JOHN F. KERRIGAN

Hypothalamic hamartomas (HHs) result in a rare but distinctive epilepsy syndrome. Clinical research over the past two decades has led to improved understanding of the diversity and complex natural history of this disorder, including the recognition that HHs are intrinsically epileptogenic. Multiple treatment options have emerged over the past 10 to 15 years, a revolutionary development for what was once considered an untreatable disease. The choice of a surgical treatment modality should be individualized to the patient's clinical course and lesion anatomy as shown by high-resolution magnetic resonance (MR) imaging. HH is the best human model for subcortical epileptogenesis and is an excellent clinical model for studying some of the fundamental questions associated with severe epilepsy in children, such as secondary epileptogenesis and epileptic encephalopathy. This chapter explores this unique form of epilepsy.

HISTORY

Pathologic laughter, most likely representative of gelastic (or laughing) seizures, was first described by Trousseau in 1877 (1). In 1950, Martin (2) drew attention to the floor of the third ventricle as a possible site of origin for gelastic seizures. List was the first to clearly identify the association between HH and epilepsy in 1958 (3). The neurologic features associated with HH, including treatment-resistant gelastic seizures beginning in infancy, and later development of additional seizure types, along with cognitive impairment and psychiatric symptoms, were delineated by Berkovic et al. in 1988 (4).

Since seizures usually arise from the cerebral cortex (including the hippocampus), it was initially assumed that the HH was a marker for epileptogenic abnormalities elsewhere in the brain. However, in 1994, using implanted intracranial electrodes for seizure monitoring, Kahane et al. (5) demonstrated that ictal discharges associated with gelastic seizures arise within the HH lesion itself. A host of subsequent reports have confirmed that the HH is intrinsically epileptogenic, and therefore a potential target for surgical treatment. Early efforts with subfrontal or subtemporal surgical resection were disappointing for most patients. The current era of HH treatment was initiated with the use of the transcallosal interforniceal approach for open surgical resection by Rosenfeld et al. in Melbourne in 2001 (6).

The last 10 years have seen a very rapidly moving landscape with the emergence of multiple surgical treatment options, including noninvasive techniques [gamma knife (GK) radiosurgery] and stereotactic ablation procedures. At this point, it is appropriate to say that no one treatment option is ideal for all patients with HH and epilepsy and that the choice of definitive therapy should be individualized to the patient's clinical course and pathologic anatomy. This chapter explores the clinical features that suggest the choice of one treatment option over another. However, an evidence-

based algorithm that guides the choice of treatment for individual patients is not yet possible.

CLINICOPATHOLOGIC SUBTYPES AND EPIDEMIOLOGY

HH lesions are associated with two distinct, though overlapping, clinicopathologic syndromes (7–11). Pedunculated HH lesions, also referred to as parahypothalamic HH, are associated with central precocious puberty (CPP). These patients usually do not have epilepsy or developmental and behavioral problems. The second subtype, known as sessile (or intrahypothalamic) HH, is associated with gelastic seizures, cognitive impairment, and psychiatric problems. Approximately 40% of these patients will also have CPP.

There are no recognized differences in the histopathology of resected HH tissue between these two subtypes. Rather, the differences are more likely related to the anatomy of lesion attachment to the hypothalamus. HH lesions associated with CPP have an attachment to the tuber cinereum, usually with a narrow stalk and base of attachment, while those associated with epilepsy have a more posterior, and broader, base of attachment in the region of the mammillary bodies (12,13). Patients with HH lesions that attach both to the tuber cinereum and the mammillary bodies (which correlates with large HH lesion size) are more likely to have both epilepsy and CPP. This chapter focuses on HH associated with epilepsy, unless otherwise stated.

HHs are relatively rare. The prevalence of HH with epilepsy is 1 in 200,000 children and adolescents in a Scandinavian population (14). There are no known racial or ethnic predilections for HH, although it may be slightly more common in males.

Most HHs are sporadic and are not associated with other congenital malformations or a positive family history. However, approximately 5% of all HH cases are associated with Pallister–Hall syndrome, which includes other malformations such as polydactyly, imperforate anus, and bifid epiglottis (15,16). Additional syndromes in which HHs can occur include Waardenburg syndrome (17), oral–facial–digital syndrome type IV (16,18), Bardet–Biedl syndrome (16), and, rarely, neurofibromatosis I (19).

NEUROPATHOLOGY

In comparison to other intrinsically epileptogenic tissues, such as mesial temporal sclerosis or focal cortical dysplasia of neocortex, HH has a relatively simple histopathology. As a hamartoma, the individual constituent cells appear normal, but cellular relationships and spatial organization are disordered. HH tissue consists of intermixed neurons and glia, although the relative proportion of these differs significantly from case to case (20). A universal feature of all epileptic HH lesions appears to be the tendency of neurons to cluster, although the abundance, size, and cellular density of these clusters vary significantly (21). The current mechanistic model for HH epileptogenicity hypothesizes that these clusters are the “functional unit” of HH tissue (22).

While the array of HH neuron phenotypes will undoubtedly become more diverse with further investigation, current studies have recognized two types, the small and the large HH neuron. Small HH neurons (generally <16 μm in diameter) have an interneuron-like phenotype, with expression of glutamic acid decarboxylase (GAD), the synthetic enzyme responsible for the presynaptic production of gamma-aminobutyric acid (GABA) (23). These cells are abundant (accounting for approximately

90% of all HH neurons) and have a relatively simple morphology with short, unbranched, aspiny dendrites (24). Functionally, these neurons also have intrinsic pacemaker-like firing activity with microelectrode recordings of perfused HH tissue slices or acutely dissociated single small HH neurons (23,25).

Large HH neurons (diameter >20 μm) are less abundant, have a pyramidal appearance more consistent with projection-type neurons, and do not show intrinsic pacemaker-like firing activity. However, they do have the interesting property of depolarizing and firing in response to pharmacologic exposure to $GABA_A$-receptor agonists, such as muscimol, in slice preparations obtained from freshly resected HH tissue (26,27). A working model for HH epileptogenesis is presented in Figure 87.1 (22).

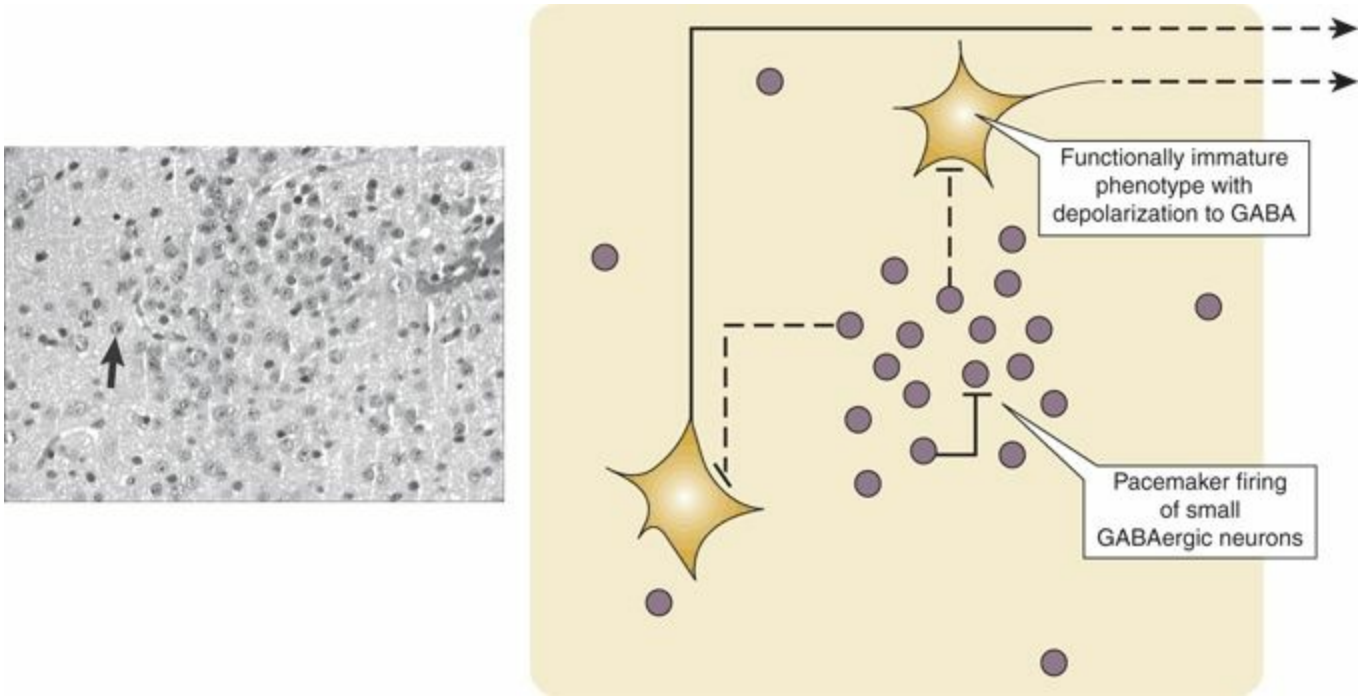

Figure 87.1. Preliminary cellular model for HH epileptogenesis based upon laboratory findings derived from surgically resected HH tissue [references (21–27); reviewed in (22)]. A photomicrograph of HH tissue is shown on the left side of the figure (hematoxylin and eosin stain). A small HH neuron (typically <16 μm in diameter) is indicated by the arrow, characterized by the well-defined nuclear membrane and densely staining nucleolus (21). A cluster of small neurons is seen immediately to the right of the arrow. The working model for epileptogenesis is shown on the right side of the figure. Small HH neurons tend to occur in clusters (21). They also express GAD and demonstrate intrinsic, spontaneous pacemaker-like firing activity in microelectrode recordings from freshly resected HH slice preparations (23). Their projections appear to be local, indicated by the solid line connecting two small HH neurons (24). Large HH neurons (typically >20 μm in diameter) have the morphology of projection neurons and may express excitatory neurotransmitters (24). These large neurons depolarize to GABA agonist administration (26,27). The evidence for structural and functional connections between small and large HH neurons is incomplete, indicated by the use of a dashed line. Small HH neurons within the cluster may be functionally connected by gap junctions (unpublished observation). The destination of the axonal projections of large HH neurons is unknown, also indicated by dashed lines. We hypothesize that clusters of small spontaneously firing HH neurons are linked in a functional network, resulting in the synchronized release of GABA, which has an excitatory effect on the larger projection neurons (22).

ETIOLOGY

Most HH cases are sporadic, and the underlying cause is unknown. However, HH is a cardinal feature of Pallister–Hall syndrome, known to result from haploinsufficiency of GLI3, a zinc finger transcription factor in the sonic hedgehog pathway. Somatic mutations (mutations present in the tumor only) in GLI3 are associated with HH in approximately 15% to 25% of sporadic cases, based upon

current genotyping technology (28,29).

While somatic mutations in GLI3 may be responsible for sporadic HH in some cases, other mutations are also likely to be discovered. At least two other susceptibility loci have been reported, specifically SOX2 and 6p25.1-25.3, a locus which includes FOXC1 (30,31). Like GLI3, SOX2 and FOXC1 are known to be transcription factors that are active during morphogenesis of the ventral forebrain. A project utilizing whole exome sequencing of DNA derived from HH compared to whole blood is currently under way (unpublished observation).

The specific molecular mechanisms controlling cellular proliferation that result in HH are unknown.

CLINICAL FEATURES

There is a great deal of diversity with respect to the age of onset, severity, and evolution of the neurologic symptoms in patients with HH and epilepsy (32). The tremendous clinical variability from case to case must be kept in mind when evaluating patients with a possible diagnosis of HH. These same clinical features, particularly the presence or absence of neurologic deterioration and the pace at which it is occurring, affect the decision-making process for deciding the type and timing of therapeutic intervention.

Epilepsy: Gelastic Seizures

Gelastic seizures are the most specific symptom associated with HH. They are usually brief, typically just a few seconds in duration, and usually last <30 seconds. They usually occur daily, with multiple seizures per hour in more severely affected patients. Gelastic seizures can be associated with little or no change in consciousness, particularly early in the clinical course, although making this determination in infants and young children can be challenging. Superficially resembling laughter, the patients generally do not experience mirth, and most family members can readily distinguish the gelastic seizure from true laughter. Not uncommonly, patients may have clinical events that more closely resemble crying rather than laughing (ictal crying or dacrystic seizures). Gelastic seizures can also be quite subtle. A purely subjective sensation, described as a pressure to laugh, can be described by communicative patients (33). They are commonly mistaken for other conditions, particularly during early infancy, including colic and gastroesophageal reflux disease (34).

Gelastic seizures associated with HH begin at an early age and are usually the first seizure type (35). In our experience, the clinical diagnosis is almost always delayed by months or even years. In retrospect, parents can identify the onset of peculiar laughing spells at a very early age. The mean age of onset for gelastic seizures in our series of HH patients with refractory epilepsy (N > 180) is 11 months, with onset before 1 month of age in 45% and before 1 year of age in 81%. However, in this series, seizures have presented as late as age 13 years, emphasizing the clinical diversity within the HH population. Gelastic seizures become less frequent during the first decade and may disappear entirely as other seizure types develop (36). Uncommonly, patients with HH may not develop gelastic seizures until early adulthood (37).

The EEG features associated with HH and gelastic seizures deserve emphasis, specifically because ictal recordings, obtained with the conventional placement of electrodes over the scalp, often show no change in the EEG from the ongoing background, which itself is often normal (38–40). Hence, clinicians need to be alert to this fact so as to not miss the correct diagnosis of epileptic

seizures. Alternatively, nonlocalizing ictal changes may be observed, such as relative flattening of the EEG background, generalized paroxysmal fast activity, or an absence of interictal spikes (4,32,41,42). There is limited utility to video–EEG seizure monitoring for most patients with HH and epilepsy (42).

Gelastic seizures do not usually respond to antiepilepsy drugs (AEDs). Consequently, the timing of surgical intervention (here, this term includes GK radiosurgery) is the major decision point facing the patient, family, and clinician. Brief, infrequent gelastic seizures are not disabling. If the child is making good developmental progress, a decision to withhold surgical intervention is appropriate. However, under these circumstances, the clinical course needs to be observed carefully for any adverse changes.

Epilepsy: Other Seizure Types

Seventy-five percent of patients with gelastic seizures and HH will develop other types of seizures (35,36). The age at which other seizure types will appear varies, but is most likely to occur between 4 and 10 years of age (4). Mullati et al. (36) have reported two to five seizure types for each patient with childhood onset of epilepsy due to HH, and virtually all seizure types have been reported, including infantile spasms accompanied by hypsarrhythmia (43). A review of the published reports regarding lifetime prevalence of seizure types in patients with HH suggests that complex partial seizures occur in 50% to 60% of patients, tonic–clonic seizures in 40% to 60%, atypical absence in 40% to 50%, tonic seizures in 15% to 35%, and "drop attacks" in 30% to 50% (32,35,36,44–46). Seizures associated with HH are usually refractory to management with AEDs (47).

When they occur, complex partial seizures often suggest temporal lobe localization (most frequently) or frontal lobe localization based upon seizure semiology and the results from conventional video–EEG seizure monitoring utilizing scalp electrodes. However, surgical outcomes following temporal lobe or frontal lobe resections in HH patients are universally poor (48).

Freeman et al. (49) have reported the presence of a symptomatic generalized epilepsy phenotype in 12 of 20 patients undergoing HH resection. Their cohort of patients demonstrated features of Lennox–Gastaut syndrome, including tonic seizures, and slow spike-wave and polyspike activities on interictal EEG. Seizure onset (gelastic seizures were the first seizure type in 92% of these patients) began between birth and 24 months of age (mean 0.3 years), while tonic seizures developed between 2 months and 9 years of age (mean 6 years).

The interictal EEG is frequently normal early in the natural history of epilepsy associated with HH, particularly when gelastic seizures may be the only seizure type (32,35,36,42). However, the appearance and subsequent evolution of abnormal EEG findings parallel the worsening of the epilepsy with the emergence of multiple seizure types (4,35,36,49). In the review of Tassinari et al. (35), EEG studies in HH patients with multiple seizure types showed normal results in only 2%, generalized spike or spike-wave findings in 47%, multifocal independent spikes in 18%, and focal spikes (most frequently over the temporal regions) in 33%. Localization of the epileptic process in HH is complex, as seizures (simple partial, complex partial, or secondarily generalized) can originate within the HH and spread to cortical regions. These seizures may or may not have a clinically apparent gelastic component at the onset.

However, the observed changes in seizure type and the evolution of EEG findings also suggest a process of secondary epileptogenesis, in which distant cortical structures begin to generate seizure events that are independent of the original seizure focus (in this case, the HH lesion) (50–53).

Initially, the new focus is dependent upon the presence of the original focus, such that removal of the HH will lead to a decrease in seizure frequency and eventually complete disappearance of seizures arising from the second focus (the "running-down phenomenon") (51). With time, however, usually over a period of years, the second focus becomes entirely independent of the original, inciting focus, such that its removal does not influence the independent epileptogenesis of the second focus. The original concept of secondary epileptogenesis was formulated in the context of temporal lobe epilepsy (54), but epilepsy associated with HH is also consistent with this model (46).

Video–EEG recordings with intracranial electrode implantation have demonstrated that seizure activity developing later in the course of the disease may not arise from the HH lesion (5,49,50,55). Approximately 10% of patients undergoing resective surgery for HH experience the running-down phenomenon, in which seizures of neocortical origin decrease in frequency and eventually stop over a period of weeks or months (56). The running-down phenomenon is observed in 21% to 40% of those HH patients who are ultimately seizure free following surgical resection (at least 1 year of postoperative follow-up) (56,57). Conversely, failure of surgical treatment in HH cases may be attributed to secondary epileptogenesis, as patients with 100% HH lesion resection may continue to have residual seizures in the absence of any other identifiable structural lesion (56).

Although the possibility that there are other cerebral abnormalities must be considered (58,59), most HH patients do not have observable structural abnormalities by high-resolution magnetic resonance imaging (MRI) (56,60–63). The cellular mechanisms for secondary epileptogenesis and the running-down phenomenon are unknown (53).

Cognition and Development

The clinical course of worsening epilepsy and increasingly abnormal EEG findings can also be accompanied by developmental regression and cognitive decline (4,32,64–67). There is a great deal of individual variability in this regard, but approximately 50% of HH patients with the onset of seizures during infancy will experience this deteriorating clinical course (47). Therefore, the degree of impairment demonstrated by any individual patient is a potentially moving target. There are no published series that document this natural history with longitudinal study of a large cohort of patients, but those detailed individual case reports that are available are compelling (64,68).

Cognitive impairment is common in HH patients, with or without the deterioration noted above, occurring in 80% or more of the patients with the intrahypothalamic subtype of HH (35,44,69). Cognitive problems correlate with the presence of epilepsy as a comorbid feature. Patients with parahypothalamic HH typically do not have epilepsy, and also have little or no cognitive impairment (70). The severity of cognitive impairment and developmental retardation correlates with an earlier age of seizure onset (47), and HH lesion size and subtype (69).

Behavior and Psychiatric Symptoms

Patients with epilepsy and intrahypothalamic HH lesions also have a high likelihood to develop clinically significant behavioral and psychiatric problems (4,44,71). These symptoms can present the most significant day-to-day problem for affected families and in some instances lead to placement outside the home. Mood lability and rage attacks are the most frequent symptoms. Patients can have poor frustration tolerance, with acting-out behavior and excessive reactivity to relatively minor stimuli, sometimes with destructive and aggressive features (72).

There is a strong positive association between the incidence of refractory epilepsy, cognitive impairment, and behavioral disturbance in HH patients (47). There is abundant descriptive literature that worsening seizures, cognitive decline, and behavioral deterioration occur simultaneously (4,64,65,73,74). HH is a clinical model for epileptic encephalopathy, although the basic mechanisms responsible for this are unknown.

TREATMENT

Rationale for the HH as the Therapeutic Target

There is now compelling evidence that gelastic seizures arise from HH tissue (66). This idea was slow to gain acceptance, since localization-related seizures were thought to arise exclusively from cortical structures (75,76). However, Kahane et al. (5,55) reported in 1994 that if ictal video–EEG recordings included intracranial monitoring with an electrode in the HH, then the ictal EEG pattern associated with gelastic seizures was initially seen in the HH lesion. This has subsequently been confirmed by multiple additional reports (50,71,77–79). Electrical stimulation of the electrode contacts within the HH can provoke the patient's habitual gelastic seizures (50,77,79). Functional imaging with single photon emission computed tomography (SPECT) has demonstrated increased perfusion in the HH with ictal SPECT imaging (77,80), and ictal imaging with flourodeoxyglucose positron emission tomography has also shown increased metabolism within the HH lesion (59,81). Perhaps, the most important evidences for the intrinsic epileptogenesis of HH lesions are the outcomes observed with surgical resection, in which gelastic seizures can be abolished with successful surgical removal or disconnection.

Absence of Controlled Treatment Trials

There are no controlled trials investigating treatment issues for HH and epilepsy. However, over the past decade, multiple uncontrolled treatment series have been published as HH cases became concentrated at multidisciplinary referral centers (56,57,61,63,82–89).

Antiepilepsy Drugs

There is broad consensus in the literature about the lack of efficacy of AEDs (47). It is likely that the number of medication-responsive patients is underestimated due to the ascertainment bias of epilepsy referral centers, and a small number of cases responsive to AEDs have been reported (8,33,81). However, probably <5% of patients with intrahypothalamic HH and epilepsy achieve complete and sustained seizure control with medications alone. AEDs are often reported to have little impact on the frequency of gelastic seizures but may be valuable by reducing the frequency of other seizure types (66). At this time, no AED has emerged as demonstrating superior efficacy for treating epilepsy associated with HH. As a consequence, AEDs are probably best chosen based upon other factors, including adverse event profile and ease of administration.

Presurgical Evaluation

Video–EEG seizure monitoring is a conventional component of the evaluation process for epilepsy

surgery. However, as the HH lesion is deep in the brain, the results of seizure monitoring with electrode placement over the scalp have limited utility, and these results should be used with caution when planning surgical interventions (42). In general, in HH cases, seizure monitoring is more likely to identify patterns of ictal spread, rather than localizing seizure onset. Even for those patients with secondary epileptogenesis, seizure activity arising from the second focus is dependent (for an undetermined time) upon the presence of the HH (see the discussion of the running-down phenomenon). Accordingly, for almost all patients with HH and epilepsy, the HH lesion is the most appropriate initial surgical target.

Invasive seizure monitoring, with electrodes implanted into the HH as well as multiple other brain regions, was necessary to prove seizure localization in HH cases. However, this type of implantation is technically challenging, has a low but definite risk of surgical complications, and rarely alters the decision-making process. Accordingly, we do not recommend intracranial monitoring for most HH patients.

The timing of surgical intervention is influenced by the emergence of multiple seizures types, often accompanied by cognitive and behavioral regression. Neuropsychological testing is recommended at yearly intervals, if possible, to monitor for changes that may not be immediately apparent in the classroom or in the home.

MRI is the most important modality for diagnosis and surgical planning. For HH patients, MRI should include a coronal T2 fast spin-echo (FSE) sequence with thin cuts and no imaging gaps through the hypothalamus. The presence or absence of structural abnormalities elsewhere in the brain must also be determined.

Surgical Resection/Disconnection

Patients with the parahypothalamic (or pedunculated) subtype of HH usually do not have epilepsy or cognitive disturbance and are medically treated with gonadotropin-releasing hormone agonists (such as leuprolide acetate). Accordingly, surgical resection is usually not indicated for this subgroup of HH patients (8,90).

However, some of the early case reports of resective surgery for patients with CPP secondary to HH happened to include children with gelastic seizures, and improvement in seizure control was noted (91,92). Subsequent reports with HH resection specifically for epilepsy indicated encouraging results for seizure control in some patients and suggested an improved outcome for cognitive and behavioral functioning (67,93,94).

The last decade has seen significant improvements in the operative techniques available for surgical resection and/or disconnection of HH lesions associated with epilepsy. The relative merits of one treatment approach over another are based upon the individual circumstances of each patient, including the surgical anatomy of the HH. The clinical course for each patient, particularly as it relates to any signs of regression or worsening, also influences the decision to use one treatment modality over another, as well as the timing of intervention.

HH Classification and Surgical Anatomy

When considering the surgical options, the classification of HH lesions must be refined beyond the binary model used thus far, specifically, intrahypothalamic and parahypothalamic HH subtypes. Several authors have proposed classification schemes for HH lesions, including Valdueza et al. (8),

Regis et al. (62), and Delalande and Fohlen (82,95). Regardless of the classification system that is used, our experience suggests that there is a relatively smooth continuum between these subtypes. However, while the advantages of one classification scheme over another are debatable, each of these schemes addresses an important issue: the surgical anatomy of the HH lesion. Currently, our preference is to utilize the Delalande classification system (82,95) (Fig. 87.2).

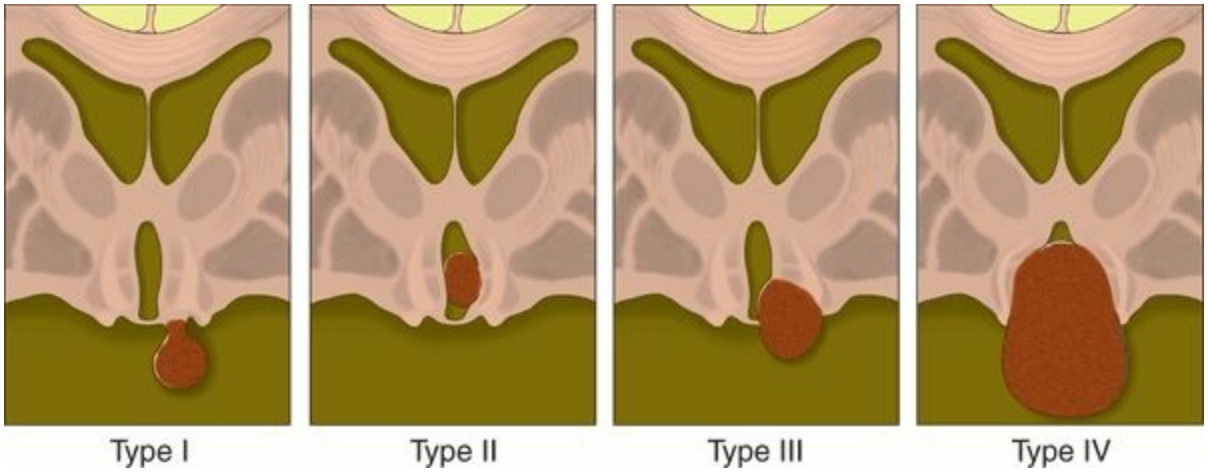

Figure 87.2. Classification system for HH, proposed by Delalande and Fohlen (95). Type I lesions have a horizontal base of attachment, below the normal position of the floor of the third ventricle. If attached by a narrow stalk to the tuber cinereum, they result in CPP, whereas more posterior attachment to the region of the mammillary bodies may result in epilepsy. Larger type I lesions can result in both CPP and epilepsy. Type II lesions have a vertical plane of attachment to the wall of the third ventricle, completely above the normal position of the floor of the third ventricle. Type III lesions may be unilateral or bilateral and have a plane of attachment that extends both above and below the floor of the third ventricle. Consequently, these lesions have both vertical and horizontal planes of attachment when viewed on a coronal sequence. Type IV lesions are termed "giant," though features clearly distinguishing them from type III lesions were not provided (95). (Copyright Barrow Neurological Institute, 2013.)

Selecting the optimal surgical approach must take into account the location and size of the HH lesion, and most importantly, the anatomy of its base of attachment to the hypothalamus (82,95–98). Type I lesions in the Delalande system are attached to the inferior (horizontal) surface of the hypothalamus. This type includes those HH lesions with a thin peduncle or stalk, often attached to the tuber cinereum, and associated with only with CPP, but can also include HH lesions with a broader or more posterior base of attachment that are associated with epilepsy. These lesions are best resected or disconnected by an inferior or pterional approach. Conversely, Delalande type II lesions have a vertical plane of attachment within the third ventricle and are best suited to a superior surgical approach to resection (transcallosal interforniceal or transventricular endoscopic [TE]), stereotactic thermal ablation, or GK radiosurgery. Delalande types III and IV have both vertical and horizontal planes of attachment (both above and below the normal position of the floor of the third ventricle). The superior approaches noted above may be adequate, but some of these cases may require a combined approach, with either simultaneous or staged resections.

Pterional Approach

Until 2001, resective surgery for HH was almost always performed with a surgical approach from below the lesion. As reported by Nishio et al. (94,99) and Machado et al. (67) in detailed case studies, resection of the HH via a pterional approach had the potential to control seizures and improve the patient's cognitive and behavioral level of functioning. Other surgical approaches for the HH lesion from below have also been reported, including orbitozygomatic (98), subfrontal (71), and

lamina terminalis approaches (71). In those instances where a complete resection via a pterional approach is possible, seizure outcomes are good (66% seizure free with complete resection of the lesion) (47,86). Pterional resection (in our hands usually an orbitozygomatic approach) is still the most appropriate means of resection for HH cases with epilepsy and type I lesions (86).

However, the pterional approach is not suited to the surgical anatomy of most HH cases, where a substantial component of the HH has a vertical plane of attachment within the third ventricle (Delalande types II to IV). Additionally, the complication rate, including stroke and cranial nerve injury, was substantial in earlier series (47,71). These approaches traverse territory with vascular structures, including the internal carotid artery, anterior and posterior communicating arteries, and their associated perforating branches. The optic tracts and chiasm and the third cranial nerve are also vulnerable (96).

Transcallosal Anterior Interforniceal (TAIF) Approach

Although utilized previously for other pathologies (100), Rosenfeld et al. (6,97) in Melbourne, Australia, were the first to utilize the TAIF approach to the third ventricle to resect HH lesions in patients with refractory epilepsy. This approach, utilizing microsurgical technique and intracranial guidance systems, allows for excellent direct visualization of the HH and its base of attachment within the third ventricle. Rosenfeld's modification of the transcallosal approach to the third ventricle, with a more anterior, transseptal trajectory, minimizes retraction of the columns of the fornix and also avoids injury to the internal cerebral veins, located more posteriorly (97).

The Melbourne group has published a series of 29 consecutive patients undergoing intrahypothalamic HH resection via the TAIF approach (57). Age at surgery ranged from 4 to 23 years (mean age 10 years). All patients had multiple seizure types, including gelastic seizures. Coexisting morbidities included a history of CPP in 13 (45%), intellectual disability in 21 (72%), and behavioral problems, most frequently rage and aggression, in 18 (62%).

At least 95% resection of HH lesion volume was achieved in 18 patients (62%). Postoperative follow-up for a minimum of 12 months showed 15 patients (52%) who were completely seizure free and 7 patients (24%) with at least a 90% improvement in seizure frequency. Surgical resection was generally well tolerated. Small, unilateral ischemic strokes of the thalamus and internal capsule occurred in two cases (7%), both with complete recovery, and transient third cranial nerve injury was reported in one patient. The majority of patients (55%) developed mild, asymptomatic hypernatremia postoperatively, but no patients had persistent disturbances in fluid or electrolyte homeostasis. Five patients (17%) required thyroid hormone replacement therapy following surgery. Increased appetite with weight gain was reported in 45% of patients but resolved in half of these with time.

Impairment of short-term memory was, however, a significant issue. The TAIF surgical approach, despite its more anterior trajectory, requires retraction of the columns of the fornix. Transient memory disturbance was noted in 14 patients (48%) during the immediate postoperative period, but residual difficulties were reported by only 4 (14%). Attention and behavior were noted to improve in many of the patients in this series, but further details were not available (57).

Very similar results were subsequently reported by Ng et al. (56) at the Barrow Neurological Institute in Phoenix. In this series of 26 consecutive patients undergoing TAIF, 54% were completely seizure free. The likelihood of complete seizure freedom (with at least 1 year of postoperative follow-up) had a positive correlation with the percentage of HH lesion volume that was successfully

resected ($P < 0.05$). The risk and type of surgical complications were also similar. Notably, transient short-term memory impairment was noted in 58% of the patients but persisted in only two patients (8%).

Transventricular Endoscopic Approach

Transcortical TE resection and/or disconnection is also a treatment option for HH patients with refractory epilepsy (61,71,82,85,95,101–104). Barrow has reported a series of 37 consecutive HH patients treated with endoscopic resection/disconnection for treatment-resistant seizures (61). All patients had at least 1 year of follow-up. The mean age at the time of surgery was 11.8 years (range 0.7 to 55 years). All patients had a history of gelastic seizures at some time point during their clinical course, and 29 (78%) had active gelastic seizures at the time of surgery. Twenty-eight patients (76%) had type II HH lesions by the Delalande classification, and the median lesion volume was 1.0 cm^3. (In comparison, in the Barrow series of transcallosal resections noted above, 42% had a type II lesion, and the median HH lesion volume was 2.4 cm^3, reflecting the different selection criteria for each approach (56).)

Median follow-up was at 21 months. Eighteen patients (49%) were completely seizure free, while seizure frequency was reduced at least 90% in an additional eight patients (22%). Twelve patients were determined to have 100% of their HH lesions resected. Of these, eight (67%) were 100% seizure free (61).

As observed with the TAIF approach, most patients tolerated endoscopic resection well. However, some differences from the TAIF approach were observed, with a significantly shorter total length of hospital stay in the endoscopic group (mean 4.1 days) versus the previously reported transcallosal group (mean 7.7 days, $P < 0.001$) (56,61). Only five patients (14%) experienced postoperative short-term memory loss, but this appeared to be a permanent residual problem (by history) in three (8%), which is comparable to the TAIF approach. No patients with endocrine disturbance, either transient or permanent, were observed. However, eleven patients (30%) showed small unilateral thalamic infarcts on diffusion-weighted MRI sequences. These were clinically asymptomatic in nine of eleven cases and the remaining two patients made a complete clinical recovery. These infarcts were attributed to disruption or injury to small thalamic perforators as a result of local brain movement with excursions of the endoscope.

Wethe et al. (105) at Barrow have recently reported the postoperative neuropsychological testing results for patients with HH and treatment-resistant epilepsy. Of the cohort of 32 patients, 63% underwent endoscopic resection. For the entire cohort, there was a statistically significant improvement in full-scale intelligence quotient (IQ), with a preoperative mean of 83.0 and postoperative mean of 91.3 ($P < 0.001$). For the entire cohort, there was no significant difference for preoperative and postoperative scores relating to learning and memory. Improvement in cognitive functioning was most likely to occur in patients who were younger at the time of surgery (and had a shorter lifetime duration of epilepsy) and in those with lower scores with preoperative testing (105).

For those HH patients who require surgical resection/disconnection from above, the factors that favor the endoscopic approach include smaller lesions, unilateral attachment, adequate space within the third ventricle to manipulate the endoscope, and adequate size of the lateral ventricle and foramina of Monro for safe instrumentation. Factors that are more favorable for the TAIF approach include a younger age at the time of surgery (the columns of the fornix and leaves of the septum tend to fuse with age), larger lesions, and bilateral attachment.

Gamma Knife Radiosurgery

GK radiosurgery is now established as an ablative therapy for patients with HH and treatment-resistant epilepsy (55,83,101,106–113). GK is noninvasive and can deliver a clinically effective dose of radiation to a small volume of tissue via a large number of independent trajectories, with little or no injury to surrounding brain.

Regis et al. (114) have described a series of 27 patients with intractable epilepsy and HH with at least 3 years of follow-up after GK therapy. GK delivers its maximal destructive energy to the interior of the targeted lesion, and the intensity of energy delivery falls off toward the periphery of the lesion. A dose of at least 17 Gy is ideally delivered to the entire lesion. The peripheral treatment margin (usually referred to as the 50% isodose margin) is matched to the outer edge of the HH lesion, but the dosimetry map may need to be modified in proximity to the optic tracts or other radiosensitive structures.

A maximal threshold of 10 Gy to the optic tracts and 8 Gy to the optic chiasm and optic nerve was utilized for treatment planning for this prospective treatment study (114). In this series, the median HH diameter was 0.95 cm (range 0.5 to 2.6 cm) and the median volume of the marginal isodose was 0.65 cm^3 (range 0.13 to 2.67 cm^3). The median radiosurgery dose to the 50% isodose margin was 17 Gy (range 13 to 26 Gy, mean 16.9 Gy). Of the 27 patients reported, 10 (37%) were completely seizure free and an additional 6 (22%) were substantially improved with only rare gelastic seizures.

Efficacy is delayed from the time of GK treatment. Initially after treatment, seizure frequency may be improved, or patients may continue to have seizures at their pretreatment baseline. Several months following therapy, an increase in seizure frequency, lasting for only a few days up to several weeks, may be observed. Subsequent to this, patients responding to treatment will experience progressively fewer seizures, with complete seizure control after a period of 6 to 24 months. Regis et al. recommend waiting 36 months from the time of treatment to assess final efficacy.

GK has an excellent adverse event profile. Most patients have no complications or side effects attributable to GK treatment. No patients among the 27 treated were reported to have a permanent complication (114). Three patients (11%) experienced transient poikilothermia. In contrast to side effects that may be seen with resective surgery, there were no patients in this series that experienced weight gain, endocrine disturbance, adverse changes in cognition, or short-term memory complaints. The disadvantage of GK is the delayed onset of action for controlling seizures and the more limited anatomical spectrum of HH lesions to which it is suited.

GK is an important treatment option for many patients with HH and epilepsy, and should be the preferred treatment modality for smaller lesions, particularly for patients who are clinically stable and capable of tolerating the delay in efficacy to obtain improved seizure control. It is a less desirable approach for those patients who are progressively worsening with their epilepsy or experiencing cognitive decline or behavioral deterioration with uncontrolled seizures. Additional study to define the optimal role of GK compared to other treatment modalities is required.

Stereotactic Thermal Ablation

Radiofrequency thermal ablation has been described in a relatively small number of patients (37,77,79,87,115–118). This technique involves stereotactic placement of a depth wire into the HH target and then causing a destructive thermal lesion by physically heating the probe tip. Most of these publications are single case reports.

Kameyama et al. (87) have reported a series of 25 HH patients undergoing stereotactic thermal ablation with a follow-up interval of at least 6 months. Mean age was 14.8 years (range 2 to 36 years) at time of treatment. All patients had at least daily gelastic seizures, and 22 (88%) had multiple seizure types. HH lesions were classified as intrahypothalamic in 10 (corresponding most closely to Delalande type II; 40% of treatment cohort), parahypothalamic in 6 (corresponding to Delalande type I; 24%), and mixed in 9 (corresponding to Delalande types III and IV; 36%).

The radiofrequency thermocoagulation probes were placed with MRI-guided stereotaxis and heated to 74°C for 60 seconds, resulting in a 5-mm spherical lesion. Targeting prioritized the HH lesion at the point of attachment, maximizing the potential for disconnection, along with the central region of larger lesions. Up to 4 lesions could be created by moving the probe within its track. Additional passes were required for most patients to ablate the intended target for each individual patient (mean lesions per patient 7.2 [range 1 to 18] and mean tracks per patient 3.8 [range 1 to 8]). Six patients (24%) required a second thermocoagulation procedure to obtain final results.

Complete freedom from seizures (Engel class I) is reported in 76%. Gelastic seizures disappeared in 92% of patients. Results were more favorable in the pediatric subgroup with complete seizure control in 16 of 18 patients (89% Engel I), whereas seizures were completely controlled in only 3 of 7 adults (43% Engel I). There were no permanent complications. Transient problems following thermocoagulation treatment included hyperthermia (n = 4 patients), hyperphagia (n = 2), hyponatremia (n = 4), Horner's syndrome (n = 3), and short-term memory disturbance (n = 2). There was a significant increase in IQ or developmental quotient postoperatively (preoperative mean 67.6 and postoperative mean 75.9; $P < 0.0001$).

Stereotactic thermal ablation is emerging as the preferred treatment modality for many HH lesions, but expertise is available in a small number of centers. Further research is required to define the boundaries within which stereotactic thermal ablation is the optimal surgical approach versus microsurgical or endoscopic resection.

A recent technical innovation on the use of stereotactic thermocoagulation utilizes laser energy to heat the tip of the stereotactic probe and has the added advantage of near real-time MRI thermography to follow the delivery of the treatment dose with predetermined safety parameters (119). Curry et al. (120) have reported two HH patients treated with this device, both of whom were completely free of seizures with brief follow-up (5 and 2 months, respectively) at the time of initial publication. This technique (MR-guided laser interstitial thermal therapy) appears promising, but thus far, a limited number of patients with HH have been treated worldwide. Additional peer-reviewed research reports with a larger cohort and long-term follow-up are anticipated (120).

Interstitial Radiosurgery

Interstitial radiosurgery with stereotactic implantation of ^{125}I radioactive seeds has also been proposed as an ablative therapy for HH associated with epilepsy (63,121). Schulze-Bonhage et al. (121) in Freiburg, Germany, have reported a series of 24 patients (mean age 21.9 years), all of whom had treatment-resistant gelastic seizures, in addition to other seizure types. Mean HH lesion volume was 1.2 cm^3.

The treatment plan was designed to deliver a dose of 60 Gy at the outer margin of the HH, followed by radioisotope seed removal. Thirteen of twenty-four patients (54%) required at least one reimplantation for a second course of therapy if the response to the initial course was unsatisfactory. With follow-up of at least 2 years, 12.5% were seizure free (Engel I outcome) while 41.7% had at

least a 90% improvement in seizure frequency (121). Treatment response is described as occurring within 8 weeks following treatment. No complications were noted, but follow-up MRI 3 months after treatment revealed local cerebral edema in five of twenty three patients (22%), in some instances associated with headache and fatigue. Neuropsychological testing prior to implantation and at least 1 year following treatment showed no significant changes with groupwise analysis of the treatment cohort.

Staged Procedures for Giant HH

For the purposes of this discussion, giant HH lesions are defined as exceeding a volume of 4 cm^3, as determined by measuring the diameter of the lesion in the three major axes and applying the formula for determining the volume of an ellipsoid [vol = π × height × length × width/6]. HH lesions of this size account for 12% of our surgical series (22 of 180 patients). These lesions are problematic as patients with giant HH are at higher risk for severe epilepsy (122), developmental impairment (69), and CPP (13,60).

They are also challenging lesions with respect to surgical therapy, relating more to the nature of their attachment to the hypothalamus rather than to their size alone. Most giant HH lesions have both vertical (above the normal position of the floor of the third ventricle) and horizontal (below the normal position of the floor of the third ventricle) planes of attachment, and consequently, no one approach, from either above or below, may enable the surgeon to safely visualize the plane of attachment and adjacent structures (Fig. 87.3).

Figure 87.3. Delalande type IV (giant) HH, as shown on coronal T2-weighted FSE sequence, illustrating the complexity of attachment for these large lesions. There is a largely vertical plane of attachment within the third ventricle (vertical black arrow) and a largely

horizontal plane of attachment below the hypothalamus (horizontal black arrow). Note the dark signal corresponding to the left descending column of the fornix (black arrowhead), which partially traverses the HH to lead to the mammillary body (located posterior to this slice). (Copyright Barrow Neurological Institute, 2013.)

Gore et al. (123) described a "combined" approach in which two teams operated simultaneously, one approaching from above and one from below. This had the advantage of allowing the surgeons to visually meet as the lesion was resected and disconnected, but the logistics and need for space with two different surgical fields proved daunting. We now advocate a "staged" approach, in which two operations are planned roughly a week apart. The surgical modality (open microsurgical resection/disconnection, endoscopic resection/disconnection, or stereotactic thermal ablation) need not be the same for each stage but rather should be chosen based upon the unique surgical anatomy of each case.

Reoperation After Subtotal Surgical Treatment

Patients undergoing epilepsy surgery with unsatisfactory outcome may be candidates for a second operation. There are multiple possible causes for surgical failure, but incomplete removal of the primary epileptic focus is common (124). With respect to the treatment of HH, the complication rate from injuring normal hypothalamus and adjacent structures is high. Consequently, even with MR-guided intracranial navigation systems, the prudent neurosurgical approach is to err on the side of a more conservative resection and minimize the risk of injury to normal hypothalamus. In one representative study in this regard, Ng et al. (56) reported that only 9 of 26 (35%) of patients undergoing the transcallosal interforniceal approach had 100% resection when evaluated with volumetry on postoperative MR imaging (of these, 89% were seizure free).

For large HH lesions, disconnection, rather than complete resection, is an appropriate surgical strategy. However, the same principle applies: 100% disconnection is the goal, but real-world results may fall short of this target. In the series just mentioned, for those with residual tissue, only 4 of 17 (24%) had 100% disconnection with high-resolution postoperative imaging (56).

Pati et al. (125) have recently reported their experience with reoperation for HH. In this retrospective study, 21 of 157 consecutive HH patients (13%) underwent a second surgical procedure with the intent of removing or completely disconnecting residual HH. Subsequent to the second surgery, all patients had at least 6 months of follow-up: 2 patients (10%) seizure free, 4 (19%) with >90% improvement in seizure frequency, 10 (48%) with 50% to 90% improvement in seizure frequency, and 4 (19%) no change.

Currently, we consider GK radiosurgery as an attractive option for those undergoing a second procedure for residual HH after microsurgical resection or stereotactic thermal ablation.

Alternative Therapies

A limited number of HH patients have been reported following treatment with alternative therapies such as the ketogenic diet (KD) (74,126), vagus nerve stimulation (VNS) (14,127), corpus callosotomy (48,68,128), and deep brain electrical stimulation (DBS) (50,68,129–131). With the possible exception of corpus callosotomy, which should be discouraged in this patient population based upon unsatisfactory published reports, the other alternative therapies should be regarded as unproven therapeutic options (KD and VNS) or investigational treatment (DBS).

CONCLUSION

There has been tremendous progress in our understanding of HH over the past 15 years. Although uncommon, the intrahypothalamic subtype of HH can present with catastrophic epilepsy of early childhood. Many of these patients will experience a deteriorating course with worsening of seizures, cognitive functioning, and behavior. We now know that the HH itself is intrinsically epileptogenic and surgically treatable. A number of different therapeutic options are now available. While comparative trials have not been performed, it seems increasingly clear that no one treatment modality is appropriate for all HH patients. Treatment selection is based upon the individual circumstances of each patient, and each option is discussed with the family. The most important factors for consideration include the stability of the patient (seizure severity and the presence or absence of clinical deterioration) and the surgical anatomy of the patient's HH lesion.

CHAPTER 88 CORPUS CALLOSOTOMY AND MULTIPLE SUBPIAL TRANSECTION

MICHAEL C. SMITH, RICHARD W. BYRNE, AND ANDRES M. KANNER

Multiple subpial transection (MST) and corpus callosotomy share some common traits. Both are palliative surgical disconnection procedures that are effective in the treatment of medically intractable epilepsy in select patient populations. They both work by disrupting neuronal synchrony of epileptic activity in a critical population of neurons to stop the expression of seizures. MST breaks up the epileptic neuronal synchrony among cortical columns disrupting the epileptic focus itself by the transection of the horizontal fiber system disrupting the critical neuronal synchrony necessary to produce an epileptic spike. Corpus callosotomy disrupts the hemispheric synchrony that is critical in the expression of some generalized seizures such as atonic, tonic, and generalized tonic–clonic seizures. Both procedures are occasionally curative but effectively treat epileptic seizures that cannot be helped by focal cortical resection.

CORPUS CALLOSOTOMY

Corpus callosotomy was first introduced as a surgical treatment for medically intractable epilepsy by Van Wagenen and Herren in 1939 (1). The ultimate goal of callosal section is to abolish the bilateral synchrony (or near-synchrony) of cortical epileptiform activity, which can result in seizures with bilateral motor manifestations, such as atonic, tonic, myoclonic, and tonic–clonic seizures. However, as cited by Blume (2), synchronous corticofugal epileptic discharges can also disrupt brainstem mechanisms affecting posture and tone of proximal limb and axial muscles, leading to atonic or akinetic seizures. Here, we briefly review some of the more relevant studies that have played an important role in the development and refinement of the techniques used in corpus callosotomy.

Neurophysiologic Basis

The corpus callosum is the most important interhemispheric commissural connection in the brain, with approximately 180 million axons in humans (3). These axons connect homotopic as well as heterotopic cortical regions (4) and exert both inhibitory and excitatory effects (5). This latter property of the corpus callosum has been suggested as an explanation for the clinical reports of increased partial seizures after callosotomy in humans (6,7) and in animals (8). Studies in rhesus monkeys have shown that section of the anterior two-thirds of the corpus callosum resulted in the development of partial seizures five times faster than in nonbisected animals (9). In the amygdala kindling model of the cat, Wada and Sato (10) reported that section of the corpus callosum accelerated the final stages of generalized convulsions.

The corpus callosum provides interhemispheric connection, unifying of certain motor functions and sensory perceptions of the axial or midline visual and somatosensory world. Axons connecting

the frontal lobes occupy a rostral position, whereas those connecting parietal, temporal, and occipital cortices are positioned more caudally, in that order.

The role of the corpus callosum in epileptogenesis is evident from various studies in animals. In the feline model of generalized epilepsy, Musgrave and Gloor (11) demonstrated the loss of bilateral synchrony of spike and slow-wave discharges following the total section of the corpus callosum and anterior commissure. Callosal section in the photosensitive baboon, Papio papio, resulted in a decrement in the synchronization of epileptiform discharges and of seizures triggered by photic stimulation (12,13). In a study carried out on four monkeys by Kopeloff et al. (8) in 1950, seizures generated by unilateral application of aluminum oxide cream had a bilateral motor expression. Following callosal section, their clinical manifestations were restricted to a distribution contralateral to the seizure focus.

It must be remembered that although the corpus callosum may be the most important anatomic structure for the interhemispheric spread of epileptic activity, it is not the only one. Anterior and posterior commissures, thalamus, and brainstem structures may all play a role in the spread of discharge from one hemisphere to the other. Suppression of synchronized epileptic activity is routinely and repeatedly seen in acute models of generalized seizures. However, in most models of chronic epilepsy after callosotomy, some synchronized epileptic activity returns over the ensuing months. This suggests that the epileptic activity utilizes alternate pathways over time. In patients who demonstrate lateralized epileptic activity postoperatively, there is a general tendency for these discharges to synchronize again over the first postoperative year.

Studies in Humans

The first series of 10 patients was published in 1940 by Van Wagenen and Herren (1). However, the real interest in this procedure developed almost 30 years later when Wilson et al. (14) reported on the Dartmouth series of callosotomies. In general, clinical patient series have replicated animal studies, demonstrating the efficacy of callosotomy in treating seizures requiring bilateral synchrony for their clinical expression. In 1985, Spencer et al. (15) reported the abolition of a bilaterally synchronous ictal onset in 5 of 5 patients who underwent a complete section of the corpus callosum, but in only 5 of 10 patients who underwent a two-thirds anterior section. In contrast, interictal bisynchronous discharges persisted even after a complete section, albeit with a significantly lower frequency. A significant reduction in bisynchronous discharges has been reported in several other patient series (14,16–19). However, as with animal studies, there are a number of reports of an increase in partial seizures (2,20–24), and in some cases, the seizures are described as being more severe (25). Other authors report a conversion of generalized to partial seizures following callosotomy.

Indications

In 1985, Williamson suggested the use of corpus callosotomy to treat the following disorders: (i) infantile hemiplegia and its forme fruste, (ii) Rasmussen syndrome, (iii) Lennox–Gastaut syndrome, and (iv) frontal lobe epilepsy. However, its primary use has been in the treatment of patients with Lennox–Gastaut syndrome.

Efficacy

In general, the purpose of corpus callosotomy is to palliate the patient's intractable seizure condition by decreasing or abolishing the most incapacitating of generalized seizures and improving the patient's quality of life. Overall, 50% to 77% of patients with Lennox–Gastaut syndrome have been reported to have a satisfactory outcome, defined as seizure reduction of 50% to 80% or more in various reports. The best response has been observed in patients with "drop attacks" presenting as tonic and/or atonic seizures. However, there is evidence that patients with atonic seizures derived a greater benefit from the procedure than did those with tonic seizures (18,19,22,26–28). In 1996, Phillips and Sakas (29) reported the results of anterior callosotomy in 20 patients. They divided outcome into freedom from seizures and significant reduction (70%) of seizures. Using these criteria, 16 of 20 patients (80%) had significant improvement of at least a 70% decrease in seizure frequency. Patients with atonic seizures (11–13) had the best outcome, and favorable results were found in 14 of 18 patients with generalized tonic–clonic seizures.

Nei et al. (30) reported a series of 53 patients who underwent an anterior or complete corpus callosotomy. For those with generalized tonic–clonic seizures, almost 80% had ≥50% decrease in generalized tonic–clonic seizures and 60% had >80% reduction. Complications were seen in 21% with 3.8% of these being permanent. Gates et al. (31) reported that tonic seizures associated with an ictal electroencephalographic pattern consisting of an electrodecremental response were associated with a very good outcome in 92% of patients aged 10 years or older. However, this association of seizure type was not predictive of outcome in younger patients (16,31).

Corpus callosotomy has yielded a significant reduction of generalized tonic–clonic seizures in 50% to 80% of patients treated with the procedure (6). Oguni et al. (28) and Spencer et al. (7) have suggested that patients with secondarily generalized tonic–clonic seizures in the presence of electroencephalographic evidence of secondary bilateral synchrony and clinical or neuroradiologic evidence of focality derive greater benefit than do those with generalized tonic–clonic seizures without these characteristics. This view has not been universally accepted. Phillips and Sakas did not find neuroimaging or electroencephalographic findings to be predictive of outcome (29).

Patients with complex partial seizures are less likely to respond to this procedure; approximately 40% achieve a significant seizure reduction. Moreover, simple partial seizures are rarely affected by callosotomy. Corpus callosotomy had been used in patients with frontal lobe seizures in whom the seizure focus could not be lateralized because of very rapid spread of epileptiform activity. Clarke et al. (32) in 2007 found that a planned palliative corpus callosotomy may help identify a resectable epileptic focus. However, Purves et al. (33) reported six such patients who underwent a two-thirds anterior callosotomy without favorable results.

Jenssen et al. (34) reported nine patients with presumed idiopathic generalized epilepsy who underwent corpus callosotomy. Four patients had an 80% decrease in generalized tonic–clonic seizures, and eight had a 50% decrease in generalized tonic–clonic seizures.

Corpus callosotomy may be performed as a partial resection involving the anterior two-thirds (in the majority of cases) or a complete section. The decision to use one technique rather than the other remains controversial. Studies by Cendes et al. (35), Harbaugh et al. (27), and Reutens et al. (36) showed no differences in seizure control between complete and partial sections. However, Spencer et al. (7) reported elimination of generalized tonic–clonic seizures in 77% of patients who underwent a complete section of the corpus callosum, compared with 35% of patients who underwent a two-thirds anterior callosotomy. Rahimi concurred that in patients with secondarily generalized intractable epilepsy, complete callosotomy was superior to partial callosotomy (37). Following a reanalysis of 50 callosotomy patients, Spencer et al. (28) concluded that a two-thirds anterior section

should be considered for patients with tonic, atonic, or myoclonic seizures, whereas a complete section should be reserved for patients with incomplete response to the two-thirds anterior section. Maehara and Shimizu advocate a complete callosotomy, especially in children and in adults with widespread epilepsy (38). Jalilian et al. (39) reported on 27 children and adults and found that complete callosotomy results in a superior (class I–III) outcome of 91% versus anterior 2/3 callosotomy of 75% (class I–III) outcome. In any event, when a complete section is considered, it should be carried out as a two-stage procedure to minimize complications.

Impact on Quality of Life

Rougier et al. (40) reviewed the literature on the efficacy of corpus callosotomy and its effect on quality of life. They found a favorable outcome, defined as a 50% reduction of seizures reported in 60% to 80% of all patients with atonic and/or tonic seizures resulting in falls. Favorable outcomes for tonic–clonic seizures vary from 40% to 80%. Complex and simple partial seizures were significantly improved less often. Improvements in quality-of-life indices did not always correlate with reduction in seizure frequency. The length of time for which patients had refractory epilepsy and its deleterious effect on cognitive and social function were important variables in predicting quality-of-life improvements. In a study conducted at the Cleveland Clinic, 9 of 17 patients experienced a >80% reduction in their targeted seizures, and 15 of 17 reported satisfaction with the surgical outcome. However, improvements in alertness and responsiveness, not necessarily reduction in seizure frequency, were most closely associated with satisfaction with surgical outcome (41). Papo et al. (41) reviewed 36 patients with intractable seizures of mixed seizure types. Twenty-seven had an anterior callosotomy; eight had a complete callosotomy in two stages, and one had a posterior callosotomy. Of the 36 patients, 30 had adequate follow-up to report meaningful results. Fourteen had excellent results (defined as more than 90% reduction in targeted seizure type), five had good results (more than 50% reduction), six had poor results (<50% reduction), and five showed no change. Similar to other reports, global measures of quality of life did not always coincide with improvement of seizure frequency. In some patients with excellent seizure results, there was no clear change in quality of life. The authors suggest that this might be related to the long duration of uncontrolled seizures and their effect on cognitive function (41). In the series reported in 2013, Park et al. (42) concurred that there was a disconnect between corpus callosotomy's effectiveness in reducing seizures and improvement in quality of life in adults. Gilliam et al. (43) have also noted that overall clinical improvement did not always correlate with seizure reduction.

Asadi-Pooya et al. (44) document that corpus callosotomy's effectiveness and low permanent morbidity are demonstrated by over six decades of experience with this procedure. They note that besides seizure reduction, quality of life often improves.

VAGUS NERVE STIMULATION VERSUS CORPUS CALLOSOTOMY

While vagus nerve stimulation (VNS) is increasingly used for treatment of various seizure types in the Lennox–Gastaut syndrome, there have been a number of recent studies comparing VNS with corpus callosotomy. You et al. compared 14 patients with total callosotomy versus 10 patients with VNS implantation and followed them for more than 1 year. All patients had multiple seizure types, primarily atonic seizures and tonic seizures. Efficacy in seizure reduction was similar in the two

groups. They reported that 64.3% in the callosotomy group versus 70% in the VNS group had a 50% reduction in targeted seizures (45). The authors concluded the efficacy and safety of VNS and corpus callosotomy were comparable. This differs somewhat from Nei's report that compared corpus callosotomy (n = 53) with VNS (n = 25) with refractory generalized seizures (generalized tonic–clonic, tonic, and atonic). 79.5% in the corpus callosotomy group had 50% or greater response versus 50% in the VNS group. However, morbidity in the corpus callosotomy group was higher (21% vs. 8%), although only 3.8% of the complications in the corpus callosotomy group were permanent. The authors concluded that both procedures were efficacious, yet corpus callosotomy had greater efficacy, though with transiently higher morbidity (30).

Surgical Technique

Under general anesthesia, the patient is placed in the supine position with pressure points padded. The head is placed in pin fixation in neutral position with the neck slightly flexed. The hair is clipped and the skin prepped. A lumbar drain may be placed to aid in retraction of the midline. A variety of skin incisions may be used for anterior callosal sectioning, all of which give access to the anterior midline. A coronally oriented skin incision 2 cm anterior to the coronal suture exposing both sides of midline will give the needed exposure. Usually, this incision should expose more right side than left because approach from the right allows retraction of the nondominant hemisphere. Hodaie et al. (46) propose the use of image guidance in part to analyze the parasagittal veins in order to decide the side of entry. A craniotomy is performed just anterior to the coronal suture, crossing midline to expose the sagittal sinus. The procedure can be done without exposing the sinus, but retraction of the sinus is then not possible and sinus bleeding is more difficult to control if encountered. The dural flap is based on the sinus, and retraction of the dura allows retraction of the sinus. Although the exposure is anterior to the coronal suture, all but the most insignificant bridging veins should be spared. Planning the approach and exposure may be aided by examining preoperative magnetic resonance imaging (MRI) or magnetic resonance angiography (MRA) scans (Figs. 88.1 through 88.3). If a bridging vein complex does not allow retraction because of a far lateral entry of the vein into the sagittal sinus, a dural incision may be made in the form of a triangle around the laterally entering vein to allow retraction of the dural flap without disturbing the vein.

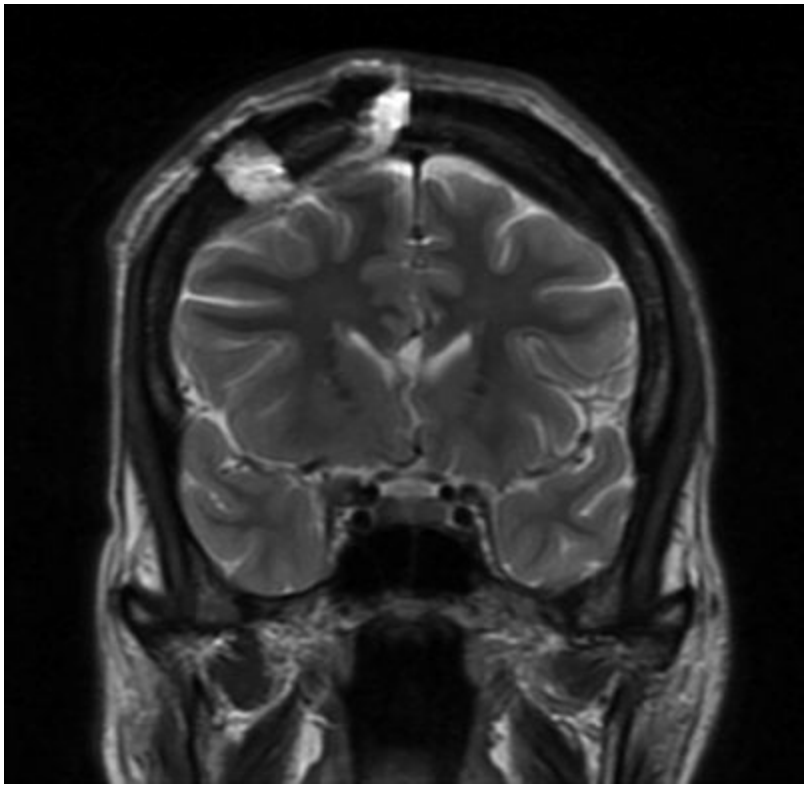

Figure 88.2. Coronal T2 magnetic resonance image showing the position of the craniotomy and the division of the genu into the midline cavum.

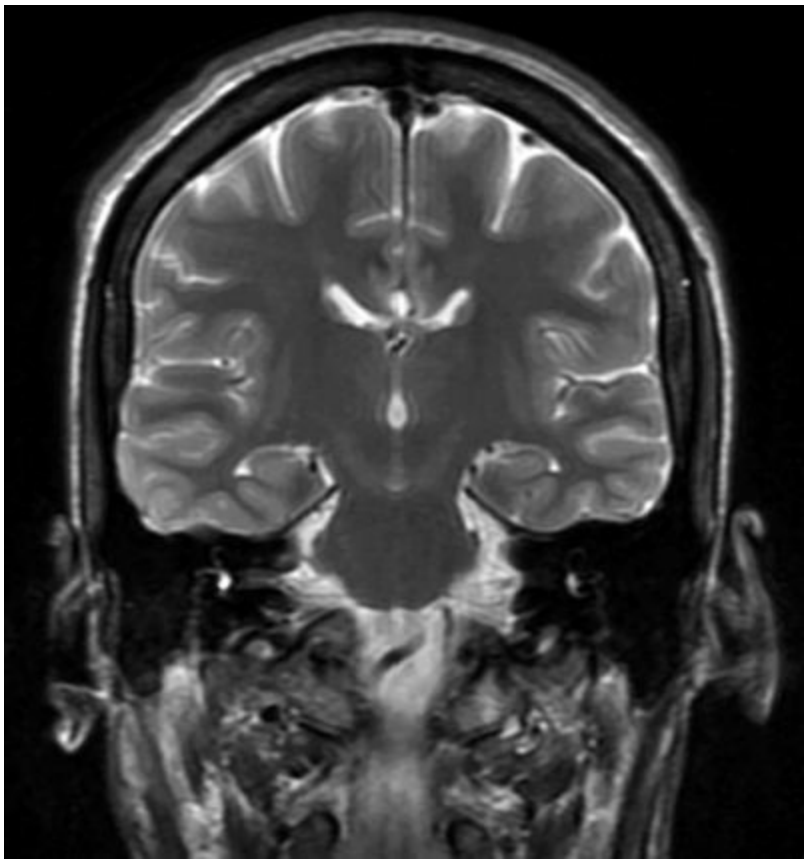

Figure 88.3. Coronal T2 magnetic resonance image showing division of the posterior body of the corpus callosum. Note the position of the fornices below the corpus callosum.

Once an unencumbered view of the intrahemispheric fissure is obtained, the medial aspect of the exposed frontal lobe is covered with moist cottonoids, and self-retaining retractors are gently advanced. The falx is followed down the midline until the cingulate gyri are encountered. An error that is sometimes made is to mistake this view of the adherent cingulate gyri for the corpus callosum. The cingulated gyri are separated under magnification in the midline, exposing the corpus callosum and the pericallosal arteries. Once this view is obtained and the retractors are set, a final check of the anterior exposure confirms the exposure of the anterior corpus callosum if the genu is visible.

The actual division of the anterior corpus callosum is done with a microdissection instrument and gentle suction. This should begin in the midline of the callosum just posterior to the genu. Great care is taken to separate, but not disturb, the pericallosal arteries. At this level, certain landmarks, such as the cavum of the septum pellucidum, are visible beneath the corpus callosum, even if it is only a potential space in the individual patient. This midline landmark is valuable, if found, because it confirms the complete transection of the callosal fibers and it allows one to stay out of the lateral ventricles. If the lateral ventricle is entered, intraoperative or postoperative bleeding may cause hydrocephalus. The transection is then carried forward into the genu and the rostrum of the corpus callosum. The disconnection is carried out downward following the A2 branches as they approach the anterior communicating artery complex. The extent of posterior callosal sectioning is decided preoperatively. Some surgeons advise a simple one-half callosal sectioning, which can be measured by comparing the intraoperative transection to the length of the callosum on the preoperative sagittal MRI. This and other techniques, such as intraoperative plain films and stereotaxy, have been described to confirm the length of callosotomy (47). Other authors advocate a three-quarter sectioning, as there is some indication that seizure control may be more complete. Jalilian et al. (39) reported that an upfront complete corpus callosotomy should be considered in children with lower

functional status. Bower et al. (48) reported that the majority of patients in their series that underwent an anterior two-thirds callosotomy derived significant benefit without requiring a completion of the callosotomy.

If a complete corpus callosotomy is to be performed, the sectioning may be done with a microdissector or suction aspiration to the splenium. A complete posterior sectioning is confirmed by viewing the arachnoid covered vein of Galen in the posterior midline. If only an anterior transection is planned, an MRI-compatible marker should be placed at the posterior border of the anterior transection in order to see it on imaging studies and to note on reoperation, if necessary, the extent of the first procedure. Hemostasis is obtained, and any entry into a lateral ventricle is covered with Gelfoam. A standard craniotomy closure is performed.

Over the past few years, there have been increasing reports in the use of radiosurgery or gamma knife to perform a corpus callosotomy (49–51). While the numbers in each series were small, efficacy was comparable to traditional surgical callosotomy (49–51). Moreno-Jimenez et al. (52) reported that DTI acquired after callosal radiosurgery showed progressive decrease in fractional anisotropy compared to controls. Falowski and Byrne (53) reported in 2012 CO_2 laser suction device versus bipolar electrocautery to improve midline dissection and decrease the likelihood of entering the ventricles.

Complications

Complications unique to corpus callosotomy as a surgical procedure are often neuropsychological in nature. Well-described acute and chronic neuropsychological sequelae are possible after callosotomy (54,55). Varying degrees of acute disconnection syndrome are commonly seen. This syndrome is characterized by a lethargic, apathetic mutism during the first few days after surgery. For most, this is always transient. The predictors of this transient state are related to the extent of callosal sectioning, baseline cognitive impairments, and the amount of traction necessary to gain access to the corpus callosum. Other early complications of the acute syndrome are incontinence, bilateral Babinski sign, and apraxia.

Chronic disconnection syndrome was initially not well recognized when callosotomy was first described (1). Detailed neuropsychological testing reveals deficits that are common after callosotomy but are not usually clinically significant. The majority of neuropsychological alterations, other than mutism, occur with posterior callosotomy. This is caused by disruption of communication between visual and tactile cortical sensory functions and verbal expression. Because of the disconnection between the hemispheres, an object placed only in the left visual field of a left hemisphere–dominant patient will be seen by the right hemisphere, but the information will not be transferred to the left hemisphere for speech production. Thus, the patient recognizes the object but cannot name it. Similarly, an object placed in the left hand, but not seen, may be recognized by its shape and size, but it will not be named. This is interesting but not clinically disabling to the patient because objects are normally seen by both hemispheres and can be felt with either hand. If a patient has bilateral speech representation, dysphasia may be a postoperative complication. This should be considered before complete callosotomy is performed on a patient with mixed speech dominance.

A disturbing complication known as alien hand syndrome has been reported (55). In this syndrome, poor cooperation or even antagonistic behavior between the left and right hand is noted. The verbal-dominant hemisphere may express displeasure with the actions of the ipsilateral extremities. This phenomenon is usually short lived and is usually seen only in the immediate

postoperative period; however, on rare occasions, it may persist. Performing only an anterior callosotomy can minimize the likelihood and the extent of these neuropsychological sequelae. If the anterior callosotomy is unsuccessful in controlling seizures, completion of the callosotomy may be performed at a later time.

Other observed complications are related to frontal lobe retraction: cingulate gyrus injury, injury to the pericallosal arteries, bridging veins or superior sagittal sinus, and hydrocephalus following entry into the lateral ventricle. Postoperative hydrocephalus secondary to entry into the ventricular system and a subsequent ventriculitis has been dramatically reduced by using an operative microscope and carefully respecting ventricle boundaries. Transient mutism may be reduced by minimizing the retraction of frontal cortex and retracting the nondominant frontal lobe, if possible. Despite this, mutism may occur transiently in up to 30% of patients.

Spencer et al. (7) reported a meta-analysis of long-term neurologic sequelae of both anterior and complete corpus callosotomy. They found that motor sequelae were reported in 56% of complete and 8% of anterior callosotomy patients; language impairments in 14% and 8%, respectively; and both cognitive impairment and behavioral impairment in 11% and 8%, respectively.

Some authors have suggested certain contraindications to corpus callosotomy. Spencer et al. (7,15) found that patients with severe mental retardation (IQ lower than 45) did not derive any benefit from the procedure. Other studies, however, have not found any relationship between IQ and outcome (32,33,56–58). A relative contraindication has been proposed concerning patients whose hemisphere of language dominance is not that of hand dominance (59). Speech difficulties, with sparing of writing, have been identified in patients who are right hemisphere dominant for speech and are right-handed, and dysgraphia with intact speech has been identified in left-handed patients with a dominant left hemisphere.

In conclusion, corpus callosotomy is an effective surgical technique for the treatment of selected pharmacoresistant epileptic syndromes, particularly certain types of seizure (i.e., atonic seizures). Over the past 10 years, its use has decreased as a result of the introduction of new antiepileptic drugs, especially lamotrigine and topiramate, and a rekindling of interest in the ketogenic diet. The vagus nerve stimulator has clear benefit for atonic/tonic seizures, and cortical stimulation may be beneficial for “drop” seizures, but no conclusive data are yet available. Certain epilepsy centers in the United States are routinely performing VNS before considering corpus callosotomy. In general, anterior corpus callosotomy is still an underutilized procedure, especially for patients with intractable atonic seizures associated with recurrent falls and subsequent head injury. Radiosurgery has been proposed as an alternative to surgical callosotomy by Pendl et al. (60). Although this is a promising approach, several questions about volume–dose analysis and long-term efficacy are yet to be fully answered (61,62).

MULTIPLE SUBPIAL TRANSECTION

Focal-onset medically intractable epilepsy has been surgically treated for 70 years by location of the seizure focus and resection of the involved cortex. A certain proportion of patients who undergo evaluation for possible surgical resection are found to have an epileptogenic zone originating in, or overlapping with, eloquent cortex. These patients traditionally have been denied surgery because resection of primary speech, motor, sensory, or visual cortex would result in unacceptable deficits. MST was developed specifically to address this problem. The purpose of this technique is to disrupt the intracortical horizontal fiber system while preserving the columnar organization of the cortex (i.e.,

its vertically oriented input and output systems and vascular supply) (63). The transection of horizontal fibers is aimed at preventing the propagation of epileptic discharges, thus averting the synchronous neuronal activation that ultimately results in the development of clinical seizures. The preservation of the columnar organization of the cortex prevents or minimizes the disruption of the functional state of the transected cortex.

The development of this technique was derived from three sets of experiments, each unrelated to the others or to the field of epilepsy surgery. The first set of experiments by Asanuma and Sakata (64), Hubel and Wiesel (65), and Mountcastle (66) demonstrated that the vertically oriented micro- and macrocolumns (with their vertically oriented input, output, and vascular supply) are the organizational unit of functional cortical architecture. The functional role of the intracortical horizontal fiber system is yet to be firmly established. However, this system is composed of fibers responsible for recurrent inhibition and excitation underlying neuronal plasticity. In the second set of experiments, Sperry (67) demonstrated that surgical disruption of the horizontal fiber system in the visual cortex of the cat, while sparing its columnar organization, does not affect its testable functional status. Tharp (68) postulated to the importance of the horizontal fiber system as a "critical component in cortical circuit necessary for generation and elaboration of paroxysmal discharges." Epileptic activity in the form of spikes or sharp waves requires a synchronous neuronal activation of a contiguous cortical surface of at least 12 to 25 mm^2 (68,69). Tharp found that epileptic foci would synchronize their activity if the distance between them was 5 mm or less, and disrupting the neuropil between the foci would desynchronize the epileptic activity.

With this information, Morrell et al. (63,70) hypothesized that sectioning of the intracortical horizontal fibers at 5-mm intervals, while preserving the columnar organization of the cortex, could abolish epileptic activity yet preserve the functional status of the transected cortex. Testing this hypothesis in the monkey, Morrell produced an epileptic focus with aluminum gel lesions in the left precentral motor cortex, which resulted in the development of focal motor seizures. Using a small wire, he disconnected the horizontal fibers at 5-mm intervals throughout the epileptogenic zone. This procedure, the first subpial transection for epilepsy, stopped the seizures, and the monkey suffered no motor deficits from the procedure. To confirm that what he had transected was motor cortex, 1 year later, Morrell surgically removed the transected area, resulting in the expected hemiparesis. With this experimental evidence, Morrell et al. moved forward into the treatment of intractable human neocortical epilepsy arising in or overlapping eloquent cortex.

Indications for Multiple Subpial Transection

MST is indicated in any patient in whom the epileptic zone arises from or overlaps with eloquent cortex. The procedure is performed after a detailed presurgical evaluation, which includes closed-circuit television/electroencephalographic recording of habitual seizures using scalp and intracranial electrodes, mainly subdural grids. In addition, detailed functional mapping to identify eloquent cortex by electrical cortical stimulation and evoked potentials is performed. Neuropsychological testing and intracarotid amobarbital tests, as well as functional neuroimaging studies, all assist in defining the baseline function and risks of the procedure. Magnetoencephalography studies have also been very useful in the evaluation of children with an acquired epileptic aphasia of childhood or Landau–Kleffner syndrome (LKS) (71). It allows more accurate identification of the source of the dipole, especially its depth within a sulcus.

MST can be performed as the sole procedure or in conjunction with resection of noneloquent

cortex, depending on the extent to which the epileptogenic zone involves eloquent cortex. Most cases of MST occur in conjunction with a cortical resection. Candidates are typically patients with dominant temporal neocortical epilepsy, dominant frontal lobe epilepsy, or primary sensory, motor, or visual cortex involvement. In patients undergoing resection/transection, resection of noneloquent cortex is performed to within 1.5 cm of the identified eloquent cortex. We recognize that this patient group is problematic for the evaluation of the clinical effectiveness of MST.

Cortical Surgical Anatomy

Human cortex is arranged in a gyral pattern, which is fairly constant between individuals. However, the microgyral patterns of individual gyri may considerably vary. These cortical variations must be taken into account in a procedure where transections are being made perpendicular to the long axis of a gyrus. Thus, careful inspection of each gyrus prior to the procedure is important. Gray matter is, on average, 5-mm thick over the crown of a gyrus. However, the depth of each sulcus differs by individual.

These points are critical in subpial transection procedures because the objective is to divide the neuropil into 5-mm intervals perpendicular to the long axis of the gyrus while preserving the overlying pia with its blood vessels and the underlying white matter tracts and U fibers.

Approximately a quarter of our patients have undergone MST as their primary procedure. These patients mainly had epilepsia partialis continua due to Rasmussen encephalitis or LKS. In the patients with Rasmussen syndrome, the epileptogenic zone arose from primary language and/or motor cortex, whereas in patients with LKS, it involved posterior language cortex.

Operative Procedure

Patients are given preoperative antibiotics and often steroids and are positioned so that the surgical site is at the highest point in the operative field. This makes intraoperative electrocorticography (ECoG), resection, and transection easier. The head is held in Mayfield head fixation, and all pressure points are padded. If the operation is done with the patient awake, the patient's comfort is especially important.

Anesthesia is accomplished with intravenous methohexital and a generous amount of local anesthesia. Although methohexital has been shown to activate interictal epileptiform activity, such activation does not extend beyond the epileptogenic zone (72). Furthermore, the degree of activation of epileptiform activity can be minimized by lowering the infusion rate of methohexital. At our center, we perform intraoperative ECoG in all cases, even when mapping with subdural grids has been done, to ensure that the initial transections result in the desired abolition of epileptic activity.

Transections

Before performing the transections, careful inspection of the gyri, microgyral pattern, sulci, and vascular supply is carried out. Transections are first performed in the more dependent areas to avoid the problem of subarachnoid blood obscuring the other areas. At the edge of the visible gyrus, in an avascular area, a 20-gauge needle is used to open a hole in the pia. The tip of the subpial transection hook is introduced into the gray matter layer and advanced to the next sulcus in a direction perpendicular to the long axis of the gyrus. The tip of the hook is held upward and is visible immediately beneath the pia. It is important that the pia be left undisturbed to minimize vascular injury

and scarring. The transection hook is designed with a handle, a malleable shaft, and a tip that is 4-mm long (paralleling the cortical width) and 1-mm wide. If the 4-mm tip is introduced just below the pia, it should remain in the gray matter layer, leaving the white matter undisturbed. The tip is angled at 105 degrees and is blunt. These two features make snagging or injuring a vessel less likely. However, it is important to avoid crossing a sulcus where buried vessels are unprotected. While this procedure is simple in principle, we have found that to master it requires considerable experience.

After the first transection is completed, bleeding from the pial opening is controlled with small pieces of Gelfoam and a cottonoid. The 4-mm tip is then placed up against the cortex next to the transection so as to select the next transection site 5 mm from the first. This is repeated until the identified epileptogenic zone is transected. Over a few minutes, the lines take on a striped appearance from the petechial hemorrhages along the lines. Minimal bleeding is encountered if the transections are done properly. ECoG is repeated at the conclusion of the transections. The transected area displays a significant attenuation of the background activity with elimination of the spikes. In cases of persistent epileptiform activity, the possibility that activity is coming from the depth of a sulcus or from remote areas must be considered. On rare occasions, when persistent activity is clearly identified as originating in an area that has been transected, transecting down into the sulcus may be done. In order to perform this safely, the tip of the probe should be turned away from the sulcus as the instrument is advanced.

Favorable outcomes using alternative instruments and methods of transection have been described by neurosurgeons (73,74). Ntsambi-Eba et al. (75) reported a large series utilizing radial MST from a single cortical entry point.

Seizure Outcome

Evaluation of seizure outcome should be carried out in patients who underwent MST without additional cortical resection. We have previously reported our series of patients with partial epilepsy with 37.5% of patients becoming seizure-free at 2-year follow-up with an additional 37.5% having a worthwhile outcome (class II–III). However, as has been reported by other centers, there is a late reoccurrence rate in seizures following MST (76). Orbach et al. (77) reported a relapse rate of 18.6% over several years. Schramm et al. reported on the efficacy of MST alone in 20 patients with drug-resistant epilepsy. One patient had a previous temporal resection; there were two cases each of LKS and electrical status epilepticus of sleep (ESES). In this series, 10% had a class I outcome and 45% had a class II–III outcome. They also noted the relapse in seizures over time (78). Zhao et al. reported on 80 patients treated with MST alone as part of his larger series. He reported 51.7% seizure freedom in patients with at least 1-year follow-up (79).

Ntsambi-Eba et al. reported on 62 patients, using radial MST. Twelve patients were MST alone. Reduction in seizures by 50% was seen in 79%. Forty-two became seizure free and 33% of the MST alone group (75).

In a meta-analysis of MST with or without additional cortical resection, Spencer reviewed 211 patients who underwent MST for intractable epilepsy and found an excellent outcome (>95% reduction in seizure frequency) in 87% of patients who had generalized seizures and 68% of patients with simple and complex partial seizures (80). Zhao et al., in the largest series reported to date, reported on 200 patients (80 MST alone) treated with MST for intractable partial epilepsy involving eloquent cortex between 1991 and 2000. They found complete control of seizures in 62.5% with another 20% of patients having a significant reduction (>75%), with 160 patients having at least 1-

year follow-up (79).

Pondal-Sordo et al. published the neurosurgical experience of London, Ontario, with perirolandic epileptic foci with cortical resection with or without additional MST. The most common etiology was neoplastic. Average follow-up was 4.2 years. At follow-up, 46% had worthwhile outcome (Engel class I, 31%; Engel class II, 15%). Residual deficits were seen in 50% but were mild in half. Those patients whose postoperative ECoG showed infrequent or no epileptiform activity had better surgical outcomes (81).

In pediatric patients, Shimizu and Maehara (82) analyzed 25 cases where MST was utilized with 10 out of 25 having an Engel class I or II outcome. In 2006, Benifla et al. reviewed two studies of MST efficacy that included 60 patients (10 MST alone). They found that between 33% and 46% of patients in the respective series had Engel class I or II outcomes (83).

MST had been used to treat hippocampal epilepsy and preserve verbal memory. Shimizu and Maehara reported a case series of 21 patients who underwent multiple transections of the pyramidal layer of the hippocampus under the alveus using a modification of the MST procedure. Of the 21 patients, 17 were followed for more than 1 year. Fourteen patients (82%) became seizure-free and two (12%) had rare seizures. Eight patients underwent a full postoperative battery of neuropsychological testing of verbal memory. Verbal memory was completely spared in seven, with one patient having a transient worsening that cleared over 6 months (84). The authors were encouraged with the above results; however, a longer follow-up and greater numbers of patients are required before transection of hippocampus is confirmed to be efficacious and sparing of verbal memory function.

Patil and Andres assessed 15 patients with 2- to 5-year follow-up who underwent multiple hippocampal transection. In this series, a transcortical approach exposed the hippocampus and shallow transections were made on the hippocampus. Further transections were also performed on the temporal lobe in some patients. Results were excellent with 94.7% class I and 5.3% class II. Verbal memory was preserved (85).

MST had been used to treat LKS for the past 15 years at our institution. Kanner et al. reviewed the outcome of 24 patients with classic LKS. Thirteen of the 24 had MST alone and 7 had resection and MST (86). All had continuous spike and wave in slow-wave sleep from a unilateral perisylvian source, and all had been mute for at least 2 years. After MST of the perisylvian epileptic abnormality, follow-up revealed that two-thirds of children speak in complex sentences at their last formal speech evaluation with significant improvement of language coming within the first 6 months postoperatively. Nine of these children had achieved complete recovery of language and were not requiring any speech therapy (86).

Irwin et al. reported five cases of classic LKS who underwent MST. All had ESES, clinical seizures, severe language dysfunction or no language, and a behavioral disorder. The frequency of seizures and behavioral disorders were significantly improved in all; however, improvement in language function was not dramatic. This might be related to the duration of the epileptic abnormality prior to surgery (87). The mean duration was 4.6 years, and studies have suggested that duration over 3 years is a predictor of the severity of chronic language disturbance, even with treatment (87).

MST with cortical resection has also been used in patients with multifocal multilobar epilepsy with clinical seizures and developmental regression. In reports by Patel and Devinsky (88), a moderate improvement in language, social, and behavioral function with a significant improvement in seizure frequency was found.

MST had been used in Rasmussen encephalitis in seven patients from Morrell's series. In four

patients, the targeted seizures were eliminated but the progression of the disease continued. In three of seven, MST did not eliminate the epileptic process due to the fact that it arose from the depth of the sulcus (63). MST had also been used in patients with refractory status epilepticus that involved eloquent cortex. In both cases, MST successfully stopped the status epilepticus (89,90). MST has also been utilized in intractable infantile spasm with some improvement in seizures and developmental delay. (91)

Surgical Morbidity

Acute Postoperative Morbidity

Cerebral edema is expected after MST, peaking on the 3rd to 4th postoperative day. Consequently, patients are expected to experience transient dysfunction of transected cortex, with ensuing neurologic deficits lasting for 2 to 3 weeks. Sometimes, mild deficits may persist for several months. Similar observations have been made at the other centers where MST is performed (see the following section).

Chronic Morbidity

The incidence of chronic morbidity varies, in part, with the experience of the neurosurgeon performing the MST procedure. We have reported previously a neurologic complication rate of 15% with 7% suffering a permanent deficit. These included foot drop in 2%, language deficit in 2%, and a parietal sensory loss in 1%. Mild, but clear, diminution in rapid skilled movements was seen in the majority of those undergoing MST of the parietal sensory cortex.

In the meta-analysis of 211 patients by Spencer, the highest morbidity with new neurologic deficits was found in 19% of those with pure MST including 4 with memory decline, 5 with hemiparesis, and 1 with partial visual field defect. A total of 23% of the patients with resection and MST had persistent neurologic deficit (80). Schramm reported transient neurologic deficit in 29% of the 20 cases of pure MST, but all deficits resolved to the point that they would not be noted on standard clinical exams (78). In Zhao et al.'s (79) larger series of 200 patients, 80 MST alone, he reported transient neurologic deficits in just 3%. Likewise, in review of pediatric MST, Benifla et al. (83) reported no permanent language or motor disabilities after MST. Ntsambi-Eba et al. (75) using the modified radial MST had permanent neurologic deficits in 64% with 3.2% permanent deficits, directly attributed to the MST.

CONCLUSIONS

Corpus callosotomy and multiple subpial transaction are different surgical techniques, yet both are fundamentally disconnection procedures. Both offer therapeutic options in patients previously rejected for more traditional resective surgery. The efficacy of corpus callosotomy has now been demonstrated in multiple centers around the world. MST, while used with increasing frequency in epilepsy centers worldwide, has yet to gain universal acceptance. Additional experimental and clinical studies are needed before this surgical procedure is fully integrated into the therapeutic armamentarium at all major epilepsy centers. Much of the success of both procedures depends on the proper selection of patients and the experience of the neurologic and neurosurgical teams. A learning

curve should be expected whenever these procedures are newly implemented at a center.

CHAPTER 89 SPECIAL CONSIDERATIONS IN CHILDREN

AJAY GUPTA AND ELAINE WYLLIE

Surgery is a well-established treatment for children with medically intractable seizures (1–5). With training of pediatric neurology practitioners, broad acceptance of surgery as a therapeutic option, and improved safety of pediatric anesthesia, neurosurgery, and intensive care techniques, pediatric epilepsy surgery has truly emerged to be a mature discipline with growth of academic programs in most developed and some developing countries (6–8). There have been collaborative efforts to study pediatric epilepsy surgery outcomes from programs in the United States, Europe, and Australia (9) as well as health system studies to improve children's access to epilepsy surgery (6). Consequently, surgical experience and seizure outcome data after surgery in children have now been published from several centers around the world, and results are encouraging from pediatric series involving infants and young children (1,10–18) and adolescents (19–24). However, identification of appropriate pediatric surgical candidates, especially infants and children, remains a challenge because of complex interactions of several unique and age-related factors (3,10,25).

In this chapter, we focus on these unique and age-related differences that interplay in the management of children who are likely to benefit from the surgical treatment of epilepsy. The step critical to surgical strategy in children as well as adults is the identification of a focal, resectable epileptogenic zone. Clues to the epileptogenic zone are found in seizure symptomatology, electroencephalography (EEG), and neuroimaging results. Some aspects of these features are similar to those in adult candidates, whereas others are unique to infants and children.

Table 89.1 compares common findings during diagnostic evaluation of pediatric and adult patients for epilepsy surgery.

Table 89.1 Commonly Encountered Differences During Diagnostic Evaluation and Surgical Decision Making in Pediatric and Adult Patients

Characteristic findings	Infants/young children	Adult patients
History, seizure semiology, and examination		
Specific auras	Rare (unable to communicate)	Common
Seizure semiology	Stereotypic (like "epileptic spasms" or "bland stare")	May indicate symptomatogenic zone
Clinical seizure onset, ictal examination, postseizure recall	Unable or difficult to confirm	Easier
Ictal lateralizing features	Uncommon or unreliable	Common and reliable
Neurologic deficit on examination	Difficult to elicit (mild hemiparesis, visual fields)	Easy to elicit
Neuropsychological testing for surgical risk	Less objective (due to age, severe cognitive and behavioral difficulties)	Helpful in pointing to specific deficits
Scalp EEG patterns		
Confounding factor of developmental EEG evolution	Present	Absent
Stereotypic and nonlocalizing interictal and ictal patterns	Common (hypsarrhythmia, generalized discharges)	Absent or uncommon
Imaging and pathologic substrates		
Confounding factor of developmental brain MRI changes	Present	Absent
Ictal SPECT	Difficult (brief frequent seizures, clusters, difficult ictal onset)	Easier
Common location and extent of lesions	Extratemporal large lesions	Temporal, smaller lesions
Common etiologies	Congenital (cortical dysplasia, malformation, tumor, perinatal stroke)	Hippocampal sclerosis, focal cortical dysplasia
Surgical considerations		
Morbidity and mortality	Higher (due to age, weight, larger resections, coexisting disabilities)	Lower
Timing and best techniques for surgery	More controversial and require planning and experience	Less controversial
Invasive mapping (intracranial grids or depth electrodes)	Not practical in most infants and young children	Possible
Intraoperative neurophysiologic techniques	Limited utility, more challenging in infants	Very useful
Goals of surgery/successful seizure control	Cognitive improvement, schooling, behavior, productive adult life	Job, driving, independence

SEIZURE SEMIOLOGY DURING VIDEO–EEG IN INFANTS AND CHILDREN

Clinical features of focal seizures may differ in pediatric and adult surgical candidates. Independent studies (26–29) of videotaped seizures from patients at separate institutions indicated that the classification of epileptic seizures of the International League Against Epilepsy (29), originally reflecting experience in older patients, was not applicable to infants younger than 3 years of age. In one study (26), only 3 of 21 infants had unmistakable characteristics of localized seizure onset, including clonic jerking of one extremity. In the remaining patients, seizures consisted of a decrease in motor activity with indeterminate level of consciousness and minimal or no automatisms, arising from temporal or temporoparietal regions, or bilateral tonic stiffening sometimes preceded by bilateral eyelid blinking, arising from frontal or frontoparietal regions. In another study of 77 children with temporal lobe epilepsy examining the relationships between etiology, age at onset, and electroclinical findings, auras were typically clear after the age of 6 years, and initial ictal symptomatology consisted of staring with behavior arrest, lip cyanosis, and bland or subtle oral

automatisms again reiterating the lack of clear lateralizing or localizing semiology (30). Other authors (27,31) have also noted bilateral motor phenomena during partial seizures in infants. The mechanism is unknown but may include ictal activation of subcortical regions or of the supplementary sensorimotor area. A localized EEG seizure pattern clarifies the focal nature of the epileptogenic process.

Seizure characteristics signaling localized onset in older patients may be absent or unidentifiable in infants. For example, an aura is an important clue to focal onset in older children and adults, but sensory phenomena are difficult to detect and are rarely observed during video–EEG studies in infants (26). Clinical seizure onset may be difficult to notice, especially in mentally impaired young children, and this may create a challenge during diagnostic evaluation like video–EEG and ictal single photon emission computer tomography (SPECT) (32,33). Complex gestural automatisms and altered awareness are hallmarks of many partial seizures in older patients, but assessment of the ictal level of consciousness in infants is fraught with problems, and automatisms, when present, tend to be simple, bland, and predominantly oral. In infants, distinguishing automatisms from normal background behavioral activity can be difficult (26,27).

SCALP EEG PATTERNS, INFANTILE SPASMS, AND FOCAL CORTICAL LESIONS

Within the first 2 years of life, focal cortical lesions may manifest as infantile spasms and hypsarrhythmia (12,34–36). The spasms may be intermixed with partial seizures (Fig. 89.1) or may replace a previous partial seizure type altogether, becoming the only active seizure type (Fig. 89.2). The mechanism is unknown, but a clue may be the relationship between age of onset of spasms and location of the lesion. Koo and Hwang (37) found that spasms began earliest in patients with occipital lesions (mean age, 3 months), appeared later in patients with centrotemporoparietal lesions (mean age, 6 months), and occurred latest in patients with frontal lesions (mean age, 10 months). This timing coincides with maturation in those regions, rapid increases in synaptic density, and sequential myelination that proceed from the back to the front of the brain. Infantile spasms appear to result from an age-related pathologic interaction between a focal cortical lesion and normal developmental processes.

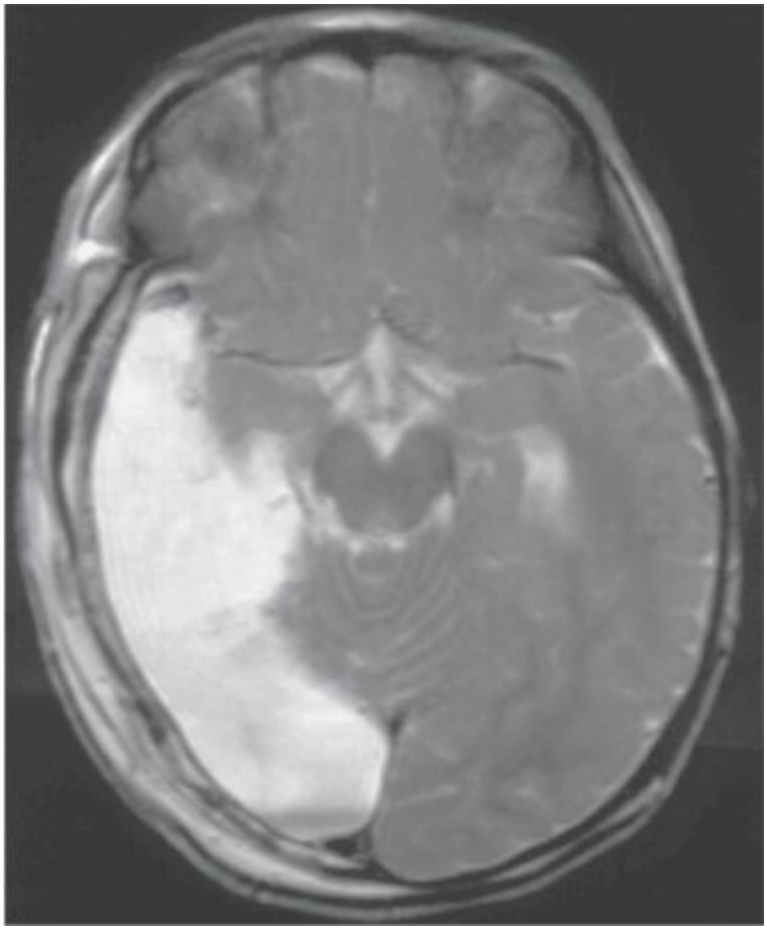

Figure 89.1. Case 1. (All images are of the same patient.) **A:** Axial magnetic resonance image from an 8-month-old boy, showing focal malformation of cortical development in the right temporo-occipital region (arrows). Findings were subtle and included decreased arborization of the white matter and thickened, poorly sulcated cortex. Seizures began 14 hours after an unremarkable term birth and occurred 20 to 30 times per day. The boy was otherwise normal except for developmental delay. **B:** 2-[^{18}F]fluoro-2-deoxy- D-glucose PET scan at age 8 months, showing glucose hypometabolism in the right temporo-occipital region (arrows) . **C:** Interictal electroencephalogram at age 8 months, showing right posterotemporal sharp waves (maximum at the T8 and P8 electrodes), slowing, and decreased background activity. **D:** Ictal electroencephalogram at age 8 months with seizure pattern maximum in the right posterior temporal region (T8 electrode). Seizures involved bilateral clonic eyelid blinking, rhythmic interruption of crying, and bilateral clonic arm twitching. **E:** Ictal electroencephalogram at age 8 months, showing diffuse electrodecrement (arrow, preceded and followed by movement artifact) during an asymmetric spasm with extension and elevation of both arms (left more than right) and tonic closure of the left eyelid. **F:** Magnetic resonance image showing the right temporo-occipital resection performed at age 22 months. Fourteen months later, the child still has developmental delay but remains free of seizures off all antiepileptic medication. (**A** and **C–F** are from Wyllie E. Surgical treatment of epilepsy in infants and children. Can J Neurol Sci. 2000;27:106–110, with permission.)

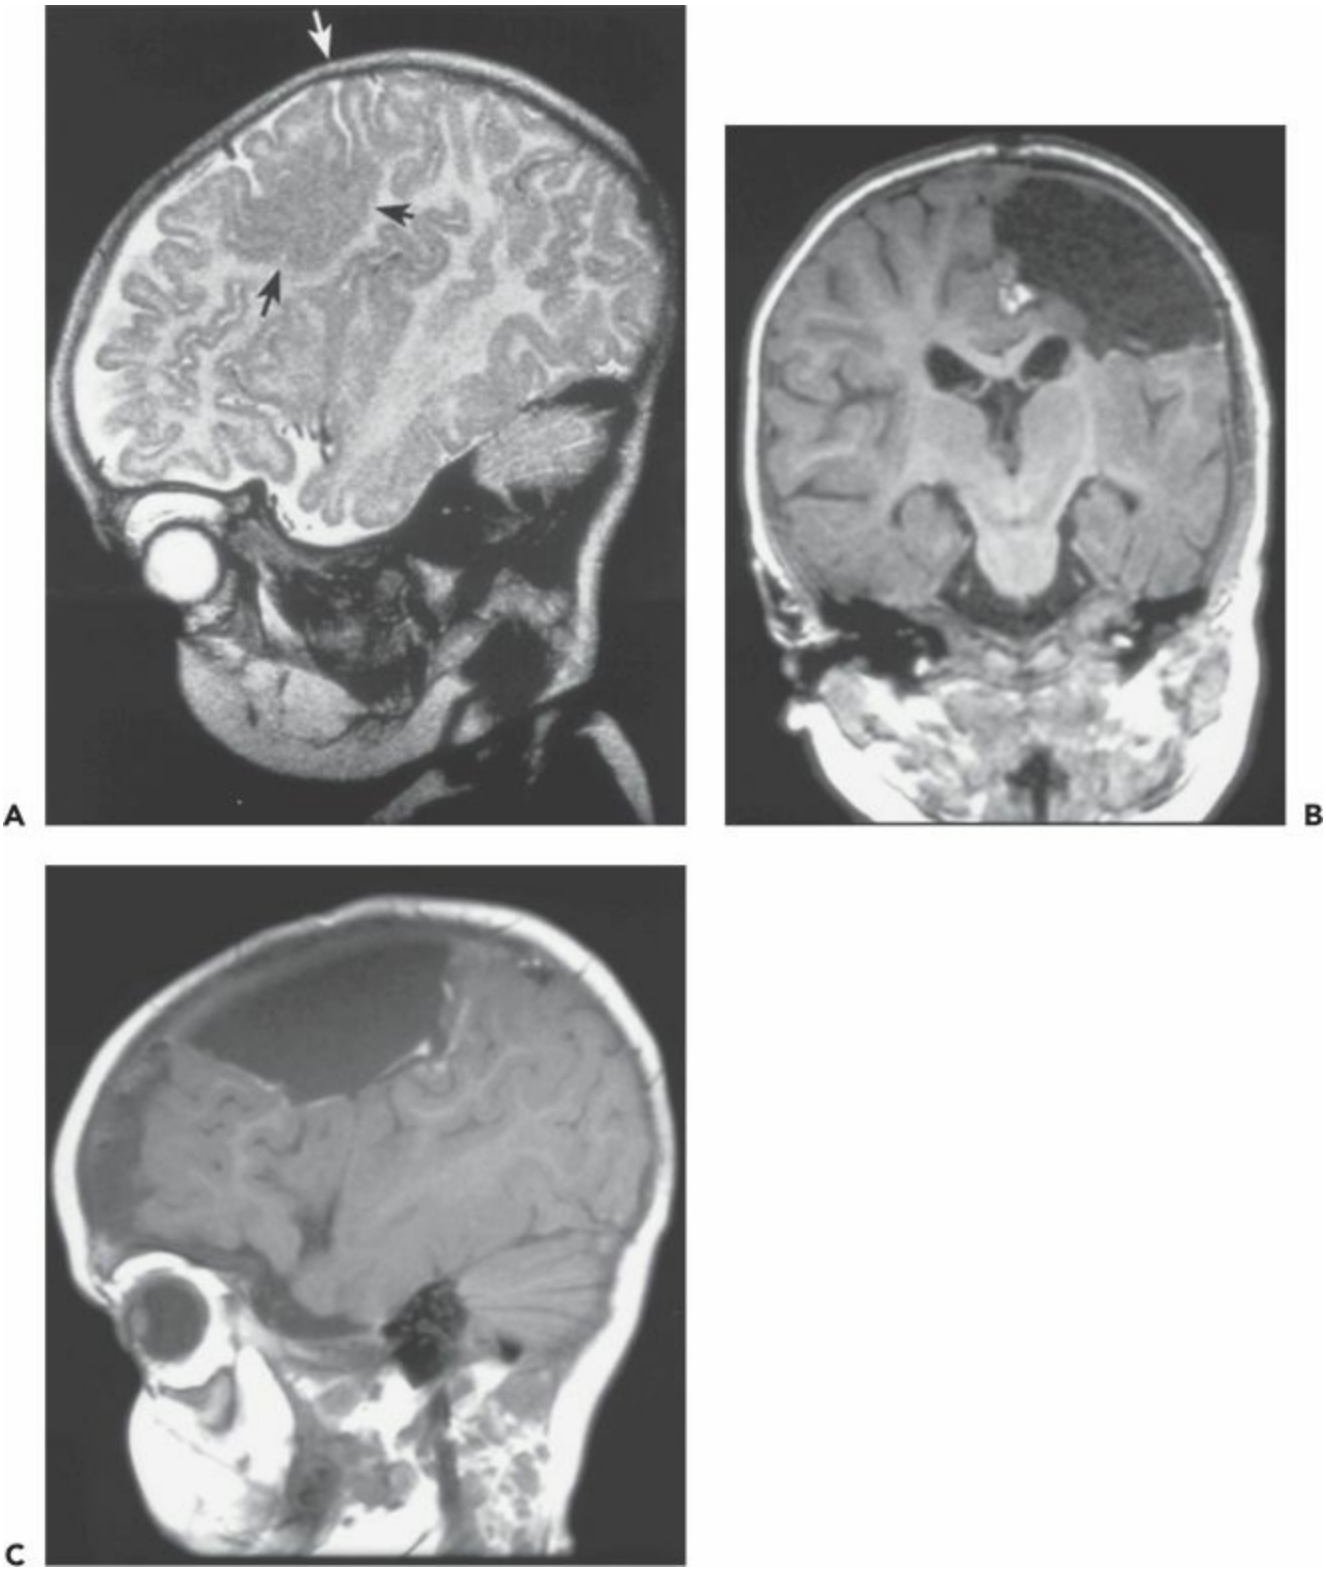

Figure 89.2. Case 2. **A:** Sagittal magnetic resonance image showing focal malformation of cortical development cerebral dysgenesis (black arrows) in the left posterior frontal lobe extending across the central sulcus (white arrow) into the anterior portion of the postcentral gyrus. The boy was 4 months old at the time of the MRI, with intractable daily seizures since the first day of life after an uncomplicated full-term delivery. Seizures involved clonic jerking of the right arm and leg, with eye deviation toward the left, or opisthotonic posturing with stiffening and extension of all extremities. Ictal and interictal epileptiform discharges were localized to the left central region. Moderately severe right hemiparesis and mild developmental delay were also present. **B:** Coronal and **(C)** sagittal scans performed 2 days after cortical resection at age 9 months. Prior to resection, electroencephalographic seizure was recorded over the lesion with intraoperative electrocorticography, and primary hand motor cortex was identified in the same area by intraoperative cortical stimulation. Postoperatively, the hemiparesis was transiently minimally worse, returning to preoperative baseline within days. Twenty-two months later, the child is making developmental progress and has had no seizures on a reduced dose of antiepileptic medication. (A from Wyllie E. Surgical treatment of epilepsy in children. Pediatr Neurol. 1998;19:179–188, with permission.)

Chugani et al. (13,38,39) first emphasized the role of positron emission tomography (PET) and magnetic resonance imaging (MRI) in identifying focal cortical lesions in children with infantile spasms and hypsarrhythmia, describing several patients with cessation or dramatic reduction of seizures after cortical resection or hemispherectomy. Their experience has been replicated elsewhere (2,35,40). Sixty-five percent of affected children are free of seizures after surgery (12), and infantile spasms are not predictive of poor outcome. However, the identification of appropriate surgical candidates may be complicated by the absence of focal EEG seizure patterns in the setting of spasms with diffuse electrodecrements (17,40).

The goal of the presurgical evaluation in patients with infantile spasms is to identify a region of cortical abnormality. The most common finding for surgical planning in this setting is a unilateral lobar, multilobar, or a hemispheric epileptogenic lesion on MRI or PET, usually a malformation of cortical development or encephalomalacia following perinatal cerebral infarction or ischemia. Helpful EEG findings may include a predominance of interictal sharp waves over one region; localized slowing, decreased background activity, or absent sleep spindles over the affected region or hemisphere; unilateral electrodecremental events; asymmetric EEG seizures; or a history of partial seizures (3). Neurologic examination may show evidence of unilateral hemispheric dysfunction with decreased spontaneous movement of one arm (hemiparesis) or gaze preference to one side (homonymous hemianopia).

Generalized epileptiform discharges on scalp EEG in the presence of a congenital or early-acquired focal lesion are not limited to infants. Recently, two reports from Cleveland Clinic described older children and adolescents with a unilateral or strongly asymmetric focal or hemispheric epileptogenic lesion who presented with generalized interictal abnormalities and ictal scalp EEG patterns (41,42). Initially, many of these children were rejected for surgical treatment owing to the presence of generalized EEG findings and lack of localizing EEG data. Because of a high burden of seizures, failure of most treatment modalities, and minimal risk of new postoperative side effects, surgical treatment was generally offered as a last resort with resection of the brain MRI lesion or hemispherectomy in each case. Seizure-free outcome was obtained for 70% of these children with generalized or contralateral EEG abnormalities, and these results were similar to those in a comparison group of children with similar MRI lesions and localized EEG findings. On further analysis of the group with generalized video–EEG abnormalities, the rate of seizure freedom after resection of the lesion was invariable regardless of the presence or absence of focal ictal semiology, generalized slow spike-and-wave complexes, and proportion (30% to 100%) of the generalized or contralateral ictal and interictal epileptiform discharges (42). Postoperative EEG in seizure-free children typically showed resolution of the generalized or contralateral epileptiform discharges, which were often nearly continuous on preoperative EEG, especially during sleep (Fig. 89.3).

Figure 89.3. Case 3. (All images are of the same patient.) **A:** MRI showing left anteromedial temporal malformation of cortical development in an 11-year-old girl with history of left temporal lobe seizures from 5 to 7 years of age and then severe epileptic encephalopathy. **B:** FDG–PET showing severe left anteromedial hypometabolism in the region of the malformation seen in **A**. **C:** EEG at 11 years of age showing nonlocalized slow spike-and-wave complexes, nearly continuous during sleep (CSWS pattern). After left anteromedial temporal resection, she was free of seizures with resolution of her epileptic encephalopathy. Postoperative EEG showed no epileptiform discharges while awake or asleep.

A unifying feature in the Cleveland Clinic studies with generalized EEG was the early timing of the occurrence of the lesion seen on MRI, most commonly a malformation of cortical development or encephalomalacia following ischemia, infection, or trauma (41,42). Lesions were congenital or perinatal in 75% of patients and acquired within the first 2 years of life or earlier in 90%. The latest timing of lesion acquisition in the series was at age 5 years. In contrast, the age at evaluation for surgery ranged widely from infancy through young adulthood, with median at 8 years (42). Although mechanisms are unknown, the generalized epileptiform discharges seen later in childhood appear to result from complex early interactions between the epileptogenic lesion and the developing brain (41,42). These studies (41,42) highlight the limitations of scalp video–EEG in children, emphasize the importance of a brain MRI lesion, and show practical difficulties in establishing proof of focal epileptogenicity in some children before surgery. Therefore, in every child, the location of the focal epileptogenic zone must be preoperatively defined, whenever possible, by a convergence of results from clinical examination, video–EEG, anatomic and functional neuroimaging, and other testing, while recognizing that in carefully selected cases with early MRI lesions, generalized EEG patterns may not contraindicate surgery (3,25).

ANATOMIC AND FUNCTIONAL NEUROIMAGING

Neuroimaging is a critical component of surgical strategy at every age. A focal epileptogenic lesion on the MRI seems to indicate a better prognosis for seizure-free outcome. In the Cleveland Clinic pediatric series from 1990 to 1996 (2), 54% of patients were seizure free and 19% had only rare seizures after extratemporal or multilobar resections. In contrast, in the Montreal Neurological Institute pediatric series (43) (excluding tumor cases) during the pre-MRI era between 1940 and 1980, only 27% had few or no seizures after frontal resection. The more favorable results from the Cleveland Clinic may be due to identification of a focal epileptogenic lesion on preoperative MRI in 85% of patients. Almost identical results were reported in an adult series of extratemporal resections performed in Bonn, Germany, from 1987 to 1993, with 54% of patients free of seizures after surgery (44). Seizure-free outcome in that series was significantly more common in lesional than nonlesional cases, with 82% of lesions identified preoperatively by MRI. The absence of MRI localization appears to be an unfavorable prognostic sign, although some patients may have good outcome after EEG-guided cortical resection. The yield of brain MRI, particularly in neocortical frontal and temporal lobe epilepsy, could be enhanced by use of high-resolution imaging with 3-T magnets, specialized protocols with thin sections and surface coil MRI, and experience of the reader (5,45).

PET is also an important neuroimaging tool for pediatric epilepsy surgery. Chugani et al. found that a localized region of hypometabolism may identify focal cortical dysplasia even without abnormal features on MRI (12). This is especially helpful in infants because immature myelination challenges identification of subtle dysgenetic abnormalities of the gray–white junction on routine brain MRI protocols. In a recent study, brain PET was also found to be a useful predictor of seizure outcome after hemispherectomy, with bilateral PET abnormalities being associated with postoperative seizure recurrence (46). PET scans using special tracers have been reported to be useful in some children with tuberous sclerosis (47). Ictal SPECT remains a challenging modality to use in children; however, it has been increasingly used in many centers in selected pediatric cases (32,48,49). Acquisition and interpretation of ictal SPECT in children are complicated as a result of several factors (32). First, interictal SPECT may be difficult to obtain owing to multiple daily seizures in this group of patients. Second, difficulty in promptly recognizing the clinical onset of ictal behavioral changes because of age and coexistent mental retardation may result in a late injection for an ictal SPECT. Third, some extratemporal seizures may be brief and spread rapidly. Fourth, children may require sedation on two occasions to obtain interictal and ictal scans. Newer noninvasive presurgical procedures, such as magnetoencephalography and functional MRI (fMRI), are increasingly being used in children for source localization of interictal spikes (50–53) and mapping of language and motor function (fMRI) using standardized protocols (54,55). However, it remains to be seen if these techniques will independently expand the selection of pediatric surgical candidates, obviate the need for invasive video–EEG recordings, and improve the long-term surgical outcome in children.

ETIOLOGIES AND PATHOLOGIC SUBSTRATES OF EPILEPSY IN PEDIATRIC PATIENTS

Causes of epilepsy differ in children and adults. Figure 89.4 depicts the usual age of onset and common etiologies/pathologic substrates encountered in children with epilepsy. Hippocampal sclerosis, the most common etiologic factor in adult candidates for epilepsy surgery, is uncommon in children. In contrast, in a pediatric epilepsy surgery series from the Cleveland Clinic Foundation (2),

hippocampal sclerosis was the cause in only 12% of 62 children (3 months to 12 years of age) and in 15% of 74 adolescents (13 to 20 years of age). Although hippocampal sclerosis may begin in childhood, the typical presentation for surgical evaluation is in early adulthood. When hippocampal sclerosis occurs in pediatric candidates for epilepsy surgery, the clinical and EEG features may be similar to those in adults (56). However, pediatric patients appear to have an especially high incidence of dual pathology with cortical dysplasia in addition to the hippocampal sclerosis (56).

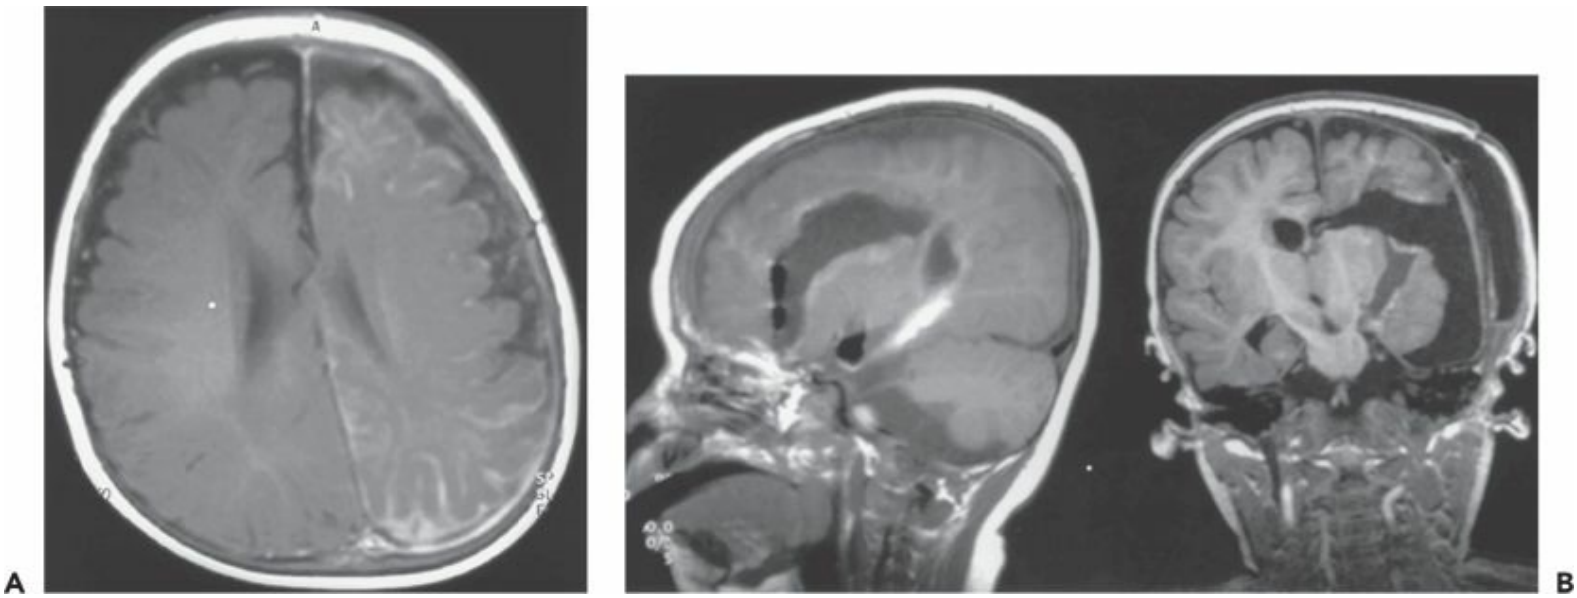

Figure 89.4. Case 4. **A:**Axial magnetic resonance image at age 12 months, showing Sturge–Weber malformation with left hemispheric atrophy and pial angiomatosis. Starting at age 2 months, seizures occurred once or twice per day characterized by jerking of the right arm or decreased behavioral activity with bilateral eye blinking and lip smacking. Physical examination revealed right hemiparesis, right hemianopia, and developmental delay. Ictal and interictal epileptiform abnormalities were seen in multiple areas of the left hemisphere. **B:**Sagittal (**left**) and coronal (**right**) magnetic resonance images showing the left hemispheric disconnection performed at age 12 months. No seizures occurred during the 8 months since surgery on a reduced dose of antiepileptic medications. Surgery did not worsen neurologic deficits, and the child has progressed developmentally.

In pediatric candidates, the predominant etiologic factors are focal, multilobar, or extensive hemispheric malformation of cortical development (cortical dysplasia) (Figs. 89.1, 89.5, and 89.6) and low-grade tumor (2,3,57). These were the cause of the epilepsy in 57% of adolescents, 70% of children, 90% of infants younger than 3 years in the Cleveland Clinic series (2), and 90% of infants treated surgically in the series of Duchowny et al. (1). Less common causes are vascular malformation, arachnoid cyst, and localized injury due to infarction, trauma, or infection (1,2,57).

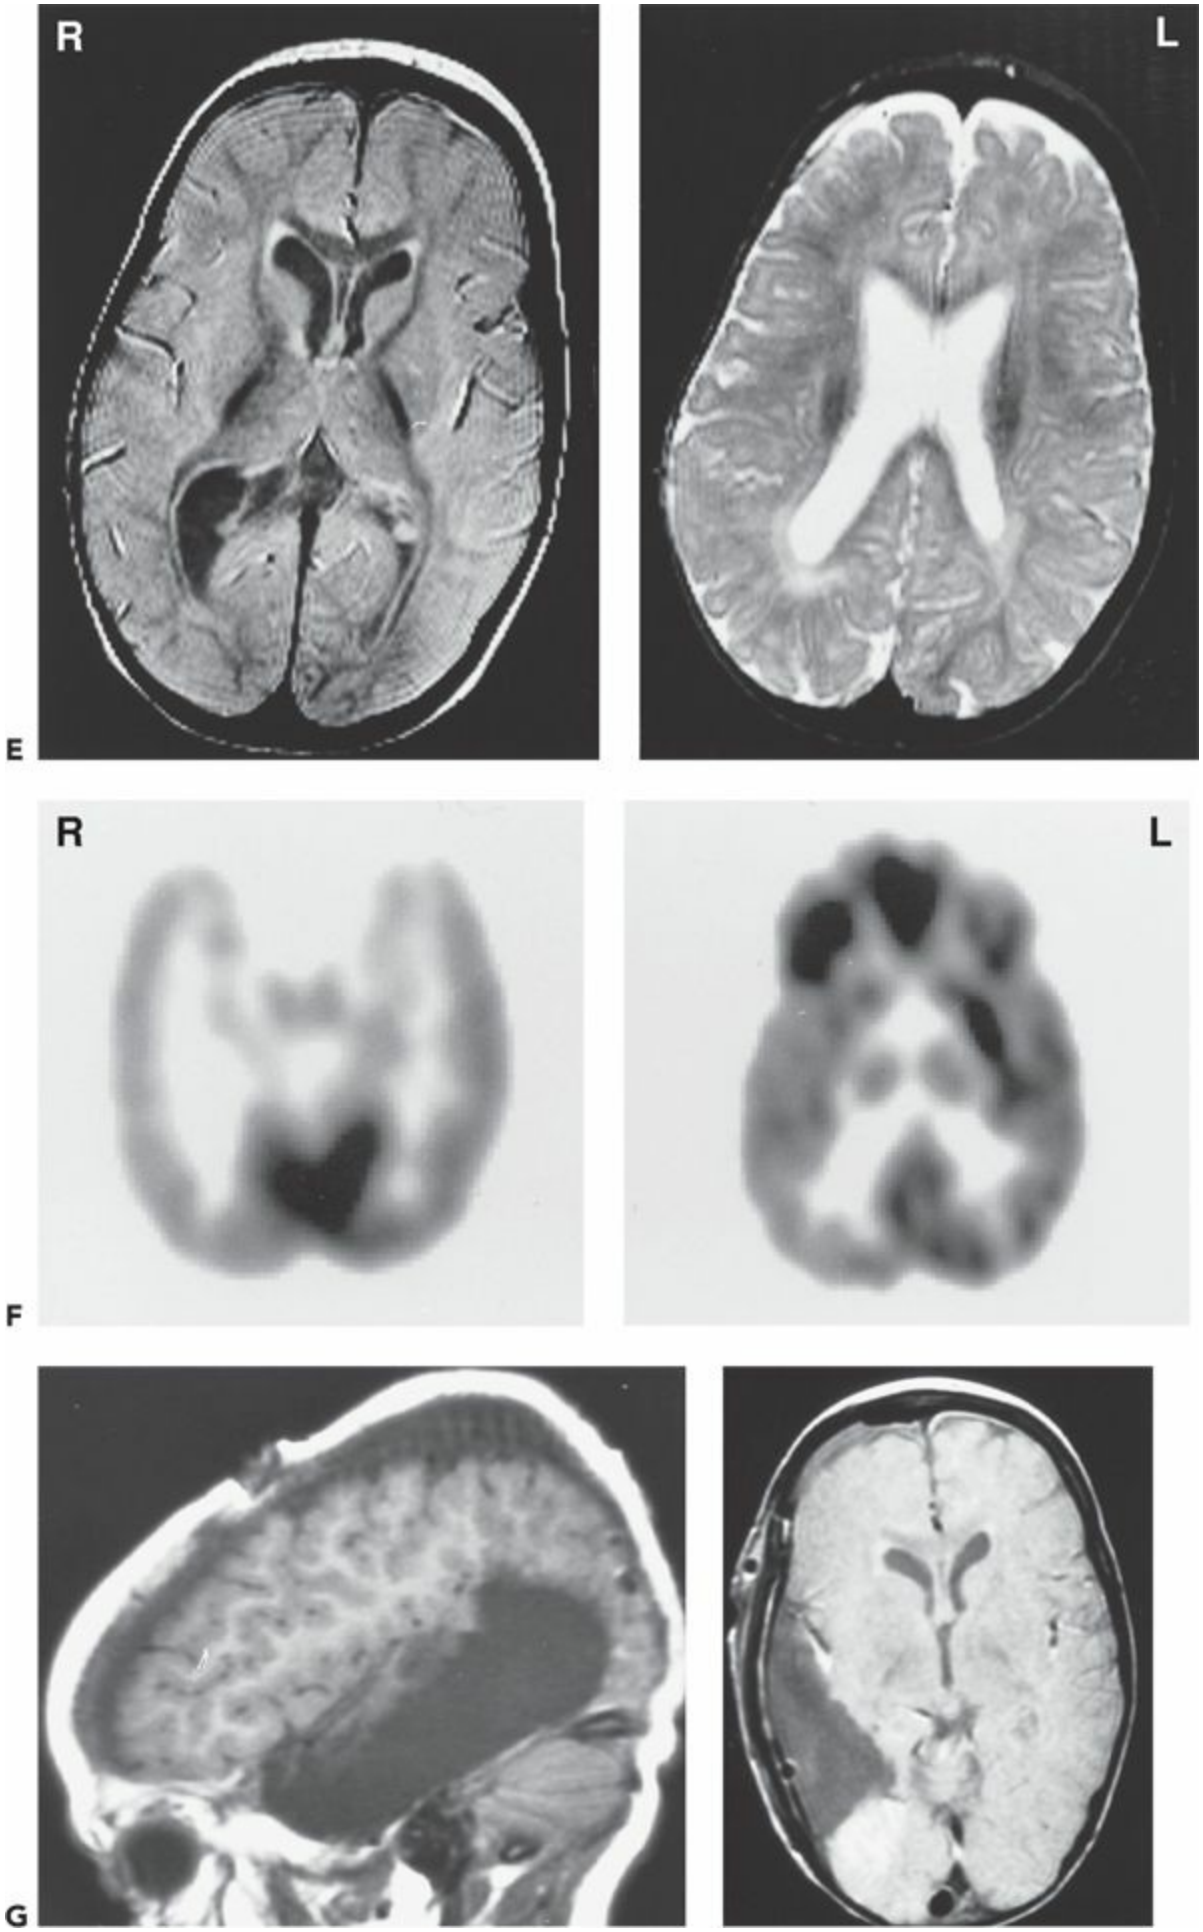

Figure 89.5. Case 5. (All images are of the same patient.) **A:** Ictal electroencephalogram from a 4.5-month-old infant (patient 2089) showing right parietal onset of a partial seizure (arrow). Seizures began at age 2 months and occurred several times a day. **B:** Ictal electroencephalogram at age 13 months, showing hypsarrhythmia with diffuse electrodecrement at the onset of an infantile spasm

(arrow). Evolution from partial seizures to infantile spasms occurred at age 7 months. The infant had delayed cognitive development and reduced visual attentiveness but no motor deficits. **C:** Sleep spindles were consistently reduced over the right hemisphere, providing further evidence of right hemisphere dysfunction. **D:** This carefully selected segment of the interictal electroencephalogram shows that spikes were sometimes predominant over the right parietal region, despite the diffuse hypsarrhythmic pattern during most of the recording. Normal faster frequencies were reduced in that area. **E:** Magnetic resonance imaging (MRI) at 13 months showed bilateral periventricular leukomalacia, worse in the right parietal region. The findings could have resulted from intrauterine right germinal matrix hemorrhage several weeks before the uneventful term birth. No cortical dysplasia or gyral abnormality was evident on MRI. **F:** Interictal 2-[^{18}F]fluoro-2-deoxy-D-glucose PET at 13 months showing right parietooccipitotemporal hypometabolism. **G:** Postoperative MRI showing the right parietooccipitotemporal resection performed at age 15 months. Histopathologic analysis of resected tissue revealed microscopic cortical dysplasia, possibly as a result of disturbance of late neuronal migration at the time of the intrauterine intraventricular hemorrhage. The infant remains free of seizures 17 months after operation and has made "catch-up" developmental progress. (**A**, **B**, **E**, and **F** are from Wyllie E, Comair Y, Ruggieri P, et al. Epilepsy surgery in the setting of periventricular leukomalacia and focal cortical dysplasia. Neurology. 1996;46:839–841, with permission; **A** and **G** are from Wyllie E, Comair YG, Kotagal P, et al. Epilepsy surgery in infants. Epilepsia. 1996;37: 625–637, with permission.)

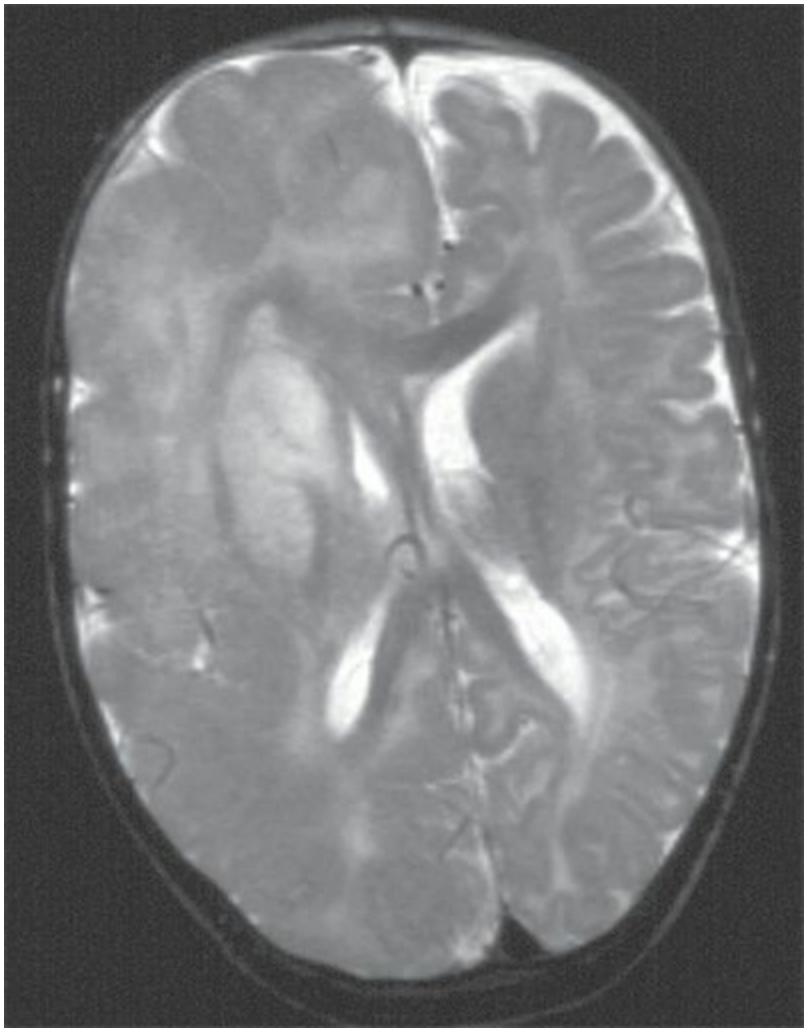

Figure 89.6. T2-weighted sagittal image of "typical" hemimegalencephaly showing diffuse right hemispheric enlargement and dysplasia. Midline shift with bulging of anterior falx to the left and compression of the right lateral ventricle suggests a mass effect as a result of increased volume of the brain parenchyma. Dysplastic changes are diffuse, with thick and disorganized cortex, poor gray–white matter differentiation, and abnormal signal in the white matter. Note that the basal ganglia are also dysplastic with abnormal increased signal.

Hemispheric syndromes are also important etiologies in children undergoing epilepsy surgery in the form of hemispherectomy (46,58). Hemispheric malformations of cortical development like hemimegalencephaly (see Fig. 89.6), Sturge–Weber syndrome, and perinatal unilateral cerebral ischemic insults are the most common etiologic factors in children and adolescents who had

hemispheric ablation procedures, with Rasmussen chronic focal encephalitis occurring less frequently (46,58,59).

The age-related differences in etiology result in an age-related spectrum of surgical procedures. Anteromesial temporal resections predominate in adults but not in children. In pediatric series, extratemporal or multilobar resections or hemispherectomies composed 44% of the surgeries in adolescents, 50% in children, and 90% in infants (1,2).

SURGICAL CONSIDERATIONS IN PEDIATRIC PATIENTS

Identification of Candidates: The Timing of Surgery

Critical features of surgical candidacy at any age include intractable epilepsy interfering with quality of life or development, clear identification of a localized epileptogenic zone, and low risk for new postoperative neurologic deficits. However, for each of these factors, age-related issues must be considered in light of results from an extensive presurgical evaluation. The risk of proceeding with surgery must be weighed against the risk of continuing with uncontrolled seizures treated medically. If careful analysis yields a favorable risk–benefit ratio for surgery, then the available data suggest that it is appropriate to proceed regardless of age.

The usual delay from onset of seizure intractability to surgery is still in the range of 12 to 15 years at most centers, reflecting a reluctance to consider surgery during childhood. Results from pediatric series do not justify this reluctance but instead suggest that children should be referred for surgical evaluation at whatever age they present with severe focal epilepsy. Complicated cases warrant referral to specialized centers with extensive pediatric experience. Improving access to centers with pediatric epilepsy surgery experience is also critical (6). Evidence is also emerging to support the long-held notion—"sooner the epilepsy surgery in children better is the prognosis for seizure outcome" (60).

Goals of Epilepsy Surgery in Children and Adolescents

The goals of epilepsy surgery may vary according to age. In adolescents and adults, the main goals are usually related to driving, independence, and employment, and their achievement requires complete postoperative freedom from seizures. For infants and children, the goals often center on relief of catastrophic epilepsy, resumption of developmental progression, and improvement in behavior. These goals may sometimes be reached even in the absence of complete freedom from seizures. For infants and young children with many daily seizures and developmental stagnation or regression, a postoperative outcome with rare or infrequent seizures and resumption of developmental progression may be gratifying. Even in the less-favorable-outcome group with malformation of cortical development, 68% of patients in the Cleveland Clinic series had few or no seizures after surgery (2).

In pediatric practice, developmental outcome is of paramount importance. Developmental delay is common in pediatric epilepsy surgery candidates, especially infants. Duchowny and associates noted normal preoperative development in only 20% of infant candidates for epilepsy surgery, whereas the remainder had moderate (52%) or severe (28%) delay (1). Postoperatively, the

developmentally normal infants remained normal after surgery, whereas the severely delayed infants remained severely delayed. Parents reported cognitive and social gains in children with seizure-free outcome, although these were difficult to appreciate on examination (1). Other researchers have made similar observations (12,36,61,62).

In a series of infants who had epilepsy surgery at the Cleveland Clinic (63), the developmental quotient indicated modest postoperative improvement in mental age. Developmental status before surgery predicted developmental function after surgery, and patients who were operated on at younger age and with epileptic spasms showed the largest increase in developmental quotient after surgery (63). In a recent large series on long-term functional outcome of patients after hemispherectomy, seizure recurrence after hemispherectomy and contralateral hemisphere abnormalities on MRI were the major predictors of poor outcome in ambulation, spoken language, and reading abilities (64). These results suggest that early surgery for refractory epilepsy as well as postoperative seizure freedom may offer an opportunity for improved developmental outcome.

Seizures that begin in the first few years of life, regardless of etiology, constitute a risk factor for mental retardation (65,66). Early surgical intervention may reduce this risk, but quantitative and prospectively collected data are scant. Asarnow et al. (67) studied results of the Vineland assessment in 24 patients with infantile spasms who underwent focal cortical resection or hemispherectomy at a mean age of 21 months (67). Raw scores 2 years after surgery increased significantly compared with preoperative levels, although only four children had a normal rate of development. The Adjusted Behavioral Composite scores were significantly higher for children who had higher preoperative scores or earlier surgery. Surgery within the first year of life may therefore maximize developmental outcome by allowing resumption of developmental progression during critical stages of brain maturation (67). Another study (68) on cognitive outcome of hemispherectomy in 53 children who underwent presurgical and postsurgical testing reported moderate cognitive and behavioral improvement in most patients. The most significant predictor of cognitive skills after surgery was etiology, with dysplasia patients scoring lowest in intelligence and language but not in visual–motor skills (68). Other studies have also reported similar improvements in the cognitive and behavioral spheres after hemispherectomy (64,69–71).

Psychosocial outcome may also be better after earlier surgery. At the advent of epilepsy surgery, Falconer urged that adolescents be considered for operative treatment before the end of secondary school so that they could pass more normally through the maturational stages of early adulthood (20). In patients who had temporal resection for childhood-onset epilepsy and were studied after a mean interval of 15 years, Mizrahi et al. noted that later surgery was associated with greater permanent psychosocial, behavioral, and educational problems (72). Delaying surgery for childhood-onset epilepsy may have disadvantages.

Age-Related Risks of Epilepsy Surgery

The extensive multilobar and hemispheric surgeries performed in children and adolescents may carry some risk. In the Cleveland Clinic series (2), two of 149 patients (1.3%) died immediately after surgery, and Paolicchi et al. (16) reported one postoperative death among 83 patients (1.2%) in a pediatric series from Miami Children's Hospital. Mortality may be slightly higher for infants, in part because of their small blood volumes. One or two infant deaths were reported in surgery series from UCLA (38), Johns Hopkins Medical Center (73,74), and Miami Children's Hospital (1,16). These results emphasize the need to reserve surgery for infants with severe epilepsy. Risk may be reduced

by a dedicated team of pediatric anesthesiologists, intensivists, and surgeons.

At any age, the mortality from epilepsy surgery must be weighed against the mortality from uncontrolled seizures treated medically. Nashef et al. (75) found this risk to be 1:295 per year in children and adolescents with severe epilepsy and learning disabilities. In a population-based cohort study in children (76) (1 to 16 years of age) who developed epilepsy between 1977 and 1985, 26 (3.8%) of 692 children died by the year 1999. The majority (13/26) who died had secondarily generalized seizures. Neurologic deficit was the only independent factor that determined mortality. In this study, mortality in children with comorbid neurologic deficits (15/1000 person-years) was higher than in those without any deficits (0.7/1000 person-years). Mortality in the children with seizures and no neurologic deficits was no different from that in the reference nonepileptic population. A Dutch study has reported similar results (77,78). These epidemiologic data reinforce consideration for early surgical intervention, as children with catastrophic partial epilepsy who are candidates for surgery often have neurologic deficits and secondarily generalized seizures. The increased long-term mortality from epilepsy in children can also be seen in outcome studies of epilepsy surgery. During long-term follow-up, late death occurred in 2% of the Cleveland Clinic series (2) and in 11% of a series from Guldvog et al. (21) involving patients with persistent seizures.

Other risks of epilepsy surgery, including new postoperative neurologic deficits (e.g., hemiparesis or language impairment), may be reduced in pediatric patients as a result of developmental plasticity. Language may transfer to the right hemisphere during the course of destructive processes such as Rasmussen chronic focal encephalitis or may develop in an unusual region of the left hemisphere in a congenital left frontal or posterotemporal tumor (79,80). In these cases, the epileptogenic lesion may be resected or disconnected without producing new language deficits. Motor function may also partially develop outside a damaged or malformed rolandic region, so that resection of a peri-rolandic lesion results in little or no additional postoperative motor deficit (see Fig. 89.5). Factors favoring developmental plasticity include early onset of the lesion (e.g., perinatal infarction or congenital malformation) and surgery performed within the first few years of life.

Decrements in postoperative verbal memory scores may follow left mesial temporal resection in adults, especially in individuals with high preoperative scores (81,82). Little is known about this potential complication in children, although similar risk factors were identified in a small pediatric series examining cognitive outcome after temporal lobe resection (83). It is not known whether the intracarotid amobarbital procedure can accurately predict this complication in children. Low memory retention scores may occur during this testing in a significant proportion of children (84), and withholding mesial temporal resection from otherwise favorable candidates on the basis of this finding alone may not be appropriate.

Seizure Outcome after Epilepsy Surgery

Published studies on surgical outcome are reliable but difficult to compare owing to the inclusion of patients with diverse pathologic conditions, use of different evaluation and surgical techniques, and variable definitions of postoperative outcome and follow-up. Good postoperative outcomes with rare or no seizures occur with similar frequencies at all ages, according to recent series in infants, children, adolescents, and adults, despite age-related differences in causes and surgery types (1,2,16,36,85). The likelihood of a favorable seizure outcome postoperatively does not diminish significantly, even in infancy. These results compare favorably with those achieved during controlled

trials of new antiepileptic drugs, in which the rate of "responders" (at least 50% improvement in seizure frequency) was 20% to 40% and seizure freedom was fairly rare (86). More recent studies show only modest chances of seizure freedom (<5%) after failure of two antiepileptic medications and report no difference between established and newer antiepileptic drugs used as initial monotherapy (87).

Certain subgroups appear especially likely to be free of seizures after surgery. In the Cleveland Clinic pediatric series (2), this outcome was significantly more common in patients who had temporal resection (78%) than in those who had extratemporal or multilobar resection (54%). However, this difference based on surgery type disappeared when results were analyzed by etiologic factors. Significantly more patients with low-grade tumor (82%) than patients with malformation of cortical development (52%) were seizure free, regardless of whether the surgery was temporal (86% for tumor vs. 56% for dysplasia) or extratemporal/multilobar (75% for tumor vs. 50% for dysplasia). Duchowny et al. (1) noted that it is relatively meaningless to consider pediatric patients treated with temporal resection as a special outcome subgroup because of the varied etiologic factors in younger patients. In children, surgically managed temporal lobe epilepsy is not synonymous with hippocampal sclerosis. However, in the pediatric patients who have hippocampal sclerosis, postoperative seizure outcome appears similar to that in adults. In a series of 34 children and adolescents with hippocampal sclerosis who had anteromesial temporal resection at the Cleveland Clinic for intractable temporal lobe epilepsy, 78% of patients were free of seizures after surgery (56). Published series (46,59,69,70) in children who underwent hemispherectomy for any indication report seizure freedom rates in the range of 50% to 65% after a postoperative follow-up of 3 months to 22 years (Chapter 84).

CONCLUSIONS

All children with catastrophic epilepsy, regardless of age, must be promptly evaluated for diagnosis and surgical candidacy. The risk–benefit ratio should then be cautiously weighed for every child in light of several complex age-related issues discussed in this chapter. Young age entails special challenges for presurgical evaluation, but it also provides a great opportunity to attain early freedom from daily seizures and to achieve the maximum cognitive potential. Even in some older children, it is now evident that surgically treatable epilepsy due to focal congenital or early-acquired lesion may manifest with a "generalized EEG phenotype" and global epileptic encephalopathy posing challenges for surgical selection. Evaluation and treatment of complex cases are best done at specialized centers with extensive experience in pediatric epilepsy surgery.

CHAPTER 90 OUTCOME AND COMPLICATIONS OF EPILEPSY SURGERY

LARA JEHI, JORGE ALVARO GONZÁLEZ-MARTÍNEZ, AND WILLIAM E. BINGAMAN

The effectiveness of epilepsy surgery in the treatment of intractable focal epilepsy is currently widely accepted. With Engel class I evidence showing obvious therapeutic superiority of temporal lobectomy (TL) over medical treatment with comparable complications (1), and multiple series replicating similar results with up to 50% to 55% of patients remaining seizure free as late as a decade after surgery (2,2–9), little doubt remains that once the determination of medical intractability has been made, a patient with temporal lobe epilepsy (TLE) should undergo an evaluation for surgical candidacy (10). Several studies have also shown encouraging, albeit less dramatic, results following extratemporal epilepsy surgery with chances of seizure freedom at 5 to 10 postoperative years ranging from 30% to 50% (11–22).

Our understanding of "favorable" surgical outcomes has evolved significantly over time. We know now that postoperative seizure outcome is a dynamic state with chances of ongoing seizure freedom dropping steadily after surgery (3,6,8,23). Conversely, up to 20% to 30% of TL patients have intermittent seizures within the few months following surgery only to become seizure free later (3,7,24–26). So, assessing the "success" of surgery few months postoperatively represents a simplistic approach of limited long-term usefulness. Furthermore, while seizure outcome is indeed the most important determinant of quality of life (QOL) after surgery (27), it is not the only one, such that a comprehensive view of a surgical outcome should include consideration of neurocognitive, social, psychiatric, and functional implications of surgery, as well as its potential complications. Lastly, recent clinical research on postoperative seizure outcomes has generated the conceptual framework for translational research aimed at understanding and modifying the mechanisms of seizure recurrence after surgery (20,28–30).

This chapter provides an overview of the currently available information on surgical outcomes following the most commonly performed types of epilepsy surgery.

AVAILABLE OUTCOME MEASURES AND PITFALLS OF OUTCOME STUDIES

Definitions of "seizure free" vary. Two major seizure outcome classification systems are currently available. Traditionally, most studies have used Engel's classification (Table 90.1), reporting favorable seizure outcomes as being either "excellent," reflecting freedom from disabling seizures (Engel class I), or "good" with the additional inclusion of patients having rare seizures (Engel classes I and II). Disadvantages of this system include the following: (i) Certain outcome criteria, such as "worthwhile improvement," are very ambiguous, leading to variation in interpretation among different centers; (ii) comparison to antiepileptic drug (AED) trials is virtually impossible as those

typically use "≥50% seizure reduction" as their outcome measure; and (iii) the "seizure-free" category (Engel class I) is not restricted to patients who are truly completely seizure free after surgery (Engel class IA); it also includes those with persistent auras, simple partial seizures, and generalized convulsions upon AED withdrawal (Engel classes IB to ID). Because most studies do not usually report outcome using Engel's classification subcategories, the independent evaluation of truly seizure-free patients is not always possible.

Table 90.1 Engel's Classification of Postoperative Outcome

Class I: Free of disabling seizures[a]
A: Completely seizure free since surgery
B: Nondisabling simple partial seizures only since surgery
C: Some disabling seizures after surgery, but free of disabling seizures for at least 2 y
D: Generalized convulsions with AED discontinuation only
Class II: Rare disabling seizures ("almost seizure free")
A: Initially free of disabling seizures but has rare seizures now
B: Rare disabling seizures since surgery
C: More than rare disabling seizures since surgery, but rare seizures for the last 2 y
D: Nocturnal seizures only
Class III: Worthwhile improvement[b]
A: Worthwhile seizure reduction
B: Prolonged seizure-free intervals amounting to greater than half the followed-up period, but not <2 y
Class IV: No worthwhile improvement
A: Significant seizure reduction
B: No appreciable change
C: Seizures worse

[a]Excludes early postoperative seizures (first few weeks).
[b]Determination of "worthwhile improvement" will require quantitative analysis of additional data such as percentage seizure reduction, cognitive function, and QOL.

To address the above issues, the International League Against Epilepsy (ILAE) issued a commission report proposing a new outcome classification scheme (Table 90.2). Completely seizure-free patients are classified separately; seizures are quantified in each category and compared to a well-defined baseline frequency, and results can be easily compared to AED trials. To date, only one study (26) compared both systems in its outcome assessment and found similar results at the last available follow-up.

Table 90.2 Proposal for a New Classification of Outcome with Respect to Epileptic Seizures

Outcome classification	Definition
1	Completely seizure free[a]; no auras
2	Only auras[b]; no other seizures
3	1–3 seizure days per year; ± auras
4	4 seizure days[c] per year to 50% reduction of baseline seizure days[d]; ± auras
5	Less than 50% reduction of baseline seizure days to 100% increase of baseline seizure days; ± auras
6	More than 100% increase of baseline seizure days; ± auras

[a]"Neighborhood seizures" in the first postoperative month are not counted.
[b]Auras are only counted if they are short in duration, and similar or identical to the preoperative ones.
[c]A "seizure day" is a 24-hour period with one or more seizures. This may include an episode of status epilepticus.
[d]"Baseline seizure days" are calculated by determining the seizure-day frequency during the 12 mo before surgery, with correction for the effects of AED reduction during diagnostic evaluation.

Some centers reported their outcomes using internally validated scoring systems (24,31,32). Others chose a prespecified period of seizure freedom—usually 12 to 24 months—as reflecting a favorable outcome (4,33,34).

This wide variation in outcome measures is only one of many pitfalls complicating the interpretation and comparison of the results among different surgical series. Other issues comprise (i) including patients with heterogeneous disease pathologies and surgeries in the same study limiting the validity of the results for any one group; (ii) using cross-sectional methods of analysis, which, by definition, are inaccurate in analyzing longitudinal dynamic time-dependent outcomes like postoperative seizure freedom; and (iii) the lack of studies comparing the usefulness of various surgical diagnostic (e.g., invasive subdural vs. depth recordings) or treatment techniques (e.g., resective vs. radiosurgery vs. thermo- or laser ablation). The final limitation of our current outcomes understanding remains our inability to "individually" predict the chances of success for potential surgical candidates.

TEMPORAL LOBE SURGERY

Rate and Stability of Postoperative Seizure Freedom

TL is the most common type of resective epilepsy surgery performed. One randomized controlled trial (1) showed that only two intractable epilepsy patients need to be treated surgically for one patient to become free of disabling seizures. Table 90.3 summarizes the seizure outcomes of most major centers, showing relatively comparable results with about two-thirds of the patients becoming seizure free postoperatively, compared to 5% to 8% with medical therapy. More than 50% of patients remain seizure free beyond 10 years after anterior temporal lobectomy (ATL) reflecting a sustained

benefit (3,5,35–38).

If a patient is seizure free at 1 year postoperatively, the likelihood of remaining seizure free is 87% to 90% at 2 years, 74% to 82% at 5 years, and 67% to 71% at 10 years (3,5, 35–39). If a patient is seizure free for 2 years postoperatively, chances of seizure freedom increase up to 95% at 5 years, 82% at 10 years, and 68% at 15 years (8,40). So, seizure freedom for 2 years might be a better predictor of long-term outcome, although both the 1-year and the 2-year conditions correlate fairly well with subsequent seizure-free status.

In surgical failures, more than half of seizure recurrences start within 6 postoperative months, and more than 95% recur within 2 to 5 postoperative years (8,41). There is therefore an initial phase of steep recurrence, followed by a relapse rate of 2% to 5% per year for 5 years with subsequent more stable seizure freedom (6,8,36). Recent data suggest that prognostic factors affecting those two phases of recurrence are distinct (8,28,29,33,42,43), possibly reflecting different mechanisms for early versus late relapses. "Early recurrences" occurring within 6 to 12 months of surgery may be due to incomplete removal of the initial epileptogenic zone, whereas later relapses may reflect an underlying diffuse epileptogenicity or progression of an "age-dependent" etiology such as mesial temporal sclerosis (2,4,28,29,36,39,44,45). The main implication of this mechanistic perspective is the idea that improving seizure outcomes necessitates both optimal localization and resection of the epileptic focus AND strategies aimed at preventing future epileptogenesis.

The counterpart of late seizure relapses also exists. In the "running-down" phenomenon, defined as the late remission of postsurgical seizures and occurring in 3.2% to 20% of TLE surgery cases, the frequency of seizures during the running-down interval may be up to several per month, but a seizure-free state is usually achieved within 2 years (44,46). The most accepted explanation for this phenomenon is a dekindling effect, the converse process to secondary epileptogenesis, where the induced synaptic dysfunction gradually declines in the surrounding epileptogenic cortex after pacemaker resection, and eventually "runs itself down" (46).

Predictors of Recurrence

Clinical Variables and Seizure Outcome

Age at Onset of Epilepsy.

Patients with an earlier age at onset of epilepsy (usually <5 years) or at the time of the initial neurologic insult may be up to three times more likely to have a favorable postoperative outcome (5,37). However, some investigators proposed that this variable actually predicts hippocampal sclerosis (HS), which is the actual good prognostic indicator (34,47). This hypothesis is supported by the observation that those patients were more likely to have features typical of HS such as unilateral hippocampal atrophy on MRI (48) and focal ictal electroencephalogram (EEG) with predominantly partial seizures (37) and by the fact that age at onset per se was of no prognostic value in studies evaluating pure cohorts of HS (34,47) or controlling for pathology (4,6,8).

Duration of Epilepsy.

A long history of seizures correlated with worse outcome in multiple studies on univariate analysis (24,41,44). In some of those same cohorts, this influence disappeared when multivariate analysis was performed adjusting for other more solid indicators of outcome (6,7). Furthermore, many more recent studies found no correlation of epilepsy duration with outcome (4–6,34,47,49). Various hypotheses have been proposed to explain those findings, including secondary epileptogenesis occurring with a long seizure history, varying degrees of maturation of different epileptogenic foci, and the increased development of generalized seizures with longer epilepsy duration (44).

Age at Surgery.

Most studies found no correlation between age at surgery and seizure outcome (5,6,8,34), although one longitudinal study in HS patients found that patients who were ≤24 years old at surgery were about four times more likely to be seizure free at 5 postoperative years when compared to the older surgical group (36 years or older) (7). Few other studies found similar results (44).

One should note here that successful and safe ATLs have been performed in the elderly (>50 years old), with few reports suggesting slightly lower chances of seizure freedom albeit without increased risks of neuropsychological deficits (44). Therefore, older age by itself should not be a deterrent from surgery.

Absence of Secondarily Generalized Tonic–Clonic Seizures.

Only 57% of mesial TLE patients with secondarily generalized tonic–clonic seizures (SGTCS)

achieved a 1-year remission compared to 80% remission rate in those who had only partial seizures in one study (34). Patients who had no generalized tonic–clonic seizures (GTCS) were 2.2 times more likely to be seizure free 5 years after surgery in another study (7). This effect may be most significant when GTCS are frequent (more than two per year) and occurring within 3 years of surgery (6). The prognostic significance of SGTCS was confirmed in a prospective multicenter trial (4).

The occurrence of SGTCS in TLE correlates with more extensive HS, multifocal irritative areas, and extended positron emission tomography (PET) hypometabolism suggesting a diffuse potential epileptogenic zone with worse expected surgical outcome (44).

Other.

Clinical variables where some studies suggested a favorable prognostic significance include low baseline seizure frequency and a history of febrile seizures. This, however, was not consistently confirmed. No correlation between occurrence of auras and outcome was proven (8).

Imaging Variables and Seizure Outcome

Magnetic Resonance Imaging.

A consistently identified favorable outcome predictor has been the presence of a unilateral temporal lobe abnormality on MRI (4,44,47). Patients with MRI evidence of unilateral HS had a 54% chance of seizure freedom at 10 years after ATL compared to 18% if MRIs were normal in one longitudinal study (6). However, recent data suggest that such a favorable prognostic significance is actually conferred by ANY unilateral temporal MRI lesion, and not necessarily by HS, especially with concordant ictal and interictal EEG findings (44).

Although a normal MRI was traditionally considered an automatic correlate to surgical failure (40,41), recent data have actually shown seizure-freedom rates of up to 41% to 48% as long as 8 years after ATL (18,50–54). While some data suggest that these patients may actually have "MRI-negative" or undetected HS (44), other studies concluded that most cases of normal-appearing hippocampi on high-resolution MRI have neocortical TLE since they had less febrile seizures, more delta rhythms at ictal onset, and more extensive lateral neocortical changes on PET with surgical outcomes still comparable to those of HS obvious in MRI (51,53). It should be emphasized, though, that surgery was successful in nonlesional patients typically when performed in context of concordant EEG and PET data (18,51,53). "Normal" MRIs correlating with bad outcomes in older studies using lower quality imaging may have included patients with extratemporal or contralateral pathology, findings that would currently exclude viable surgical options (18,51,53). Lack of SGTCS and low preoperative seizure frequency correlate with more favorable surgical outcomes in nonlesional TLE, similar to lesional TLE (18).

Bilateral MRI lesions, including grossly bilateral HS, reflect multiple potentially epileptogenic foci and correlate with a worse surgical outcome: 58% seizure free at 2 years compared to 78% when compared to unilateral lesions or even normal MRI (8,44). Subtle hippocampal asymmetries only detected using volumetric analyses were less predictive of outcome (44).

Nuclear Imaging.

Unilateral temporal hypometabolism on FDG-PET is a good predictor of seizure freedom in patients with mesial TLE, independent of pathologic findings and regardless of whether the MRI is normal

(55). In a recent review of the literature, Casse (55,56) found that 86% of patients with unilateral temporal hypometabolism ipsilateral to the side of surgery had a good outcome as defined by more than 90% reduction in seizure frequency or Engel class I or II, with those chances slightly reduced to 82% if the MRI was normal. This number significantly dropped to 62% when PET was normal and to 50% when it showed bitemporal hypometabolism (56). With extratemporal hypometabolism, chances of seizure freedom are even worse: Complete seizure freedom at last follow-up (mean 6.1 years) was seen in 45% of patients with extratemporal cortical hypometabolism confined to the ipsilateral hemisphere and only 22% with contralateral cortical hypometabolism (57).

Abundant data support the usefulness of ictal SPECT in localizing the epileptogenic zone in TLE, with 70% to 100% of ictal SPECTs being correctly localizing and only 0% to 7% incorrectly localizing (44). However, while the prognostic value of such localized SPECT findings is clear in extratemporal or poorly localized nonlesional temporal epilepsy (58,59), its role in clear lesional TLE cases is less defined. In a recent analysis of patients with unilateral HS visible on MRI, surgical outcome was not influenced by contralateral increased flow on ictal SPECT (60). One hypothesis is that due to their low temporal resolution, ictal SPECT hyperperfusion patterns often contain both the ictal-onset zone and propagation pathways. These patterns often have a multilobulated "hourglass" appearance with the largest and most intense hyperperfusion cluster often representing ictal propagation and not necessarily requiring resection to render a patient seizure free (61,62). Results for interictal SPECT suggest that it is relatively poor at localizing the seizure focus (44).

Neurophysiologic Variables and Seizure Outcome

Noninvasive EEG.

Focal interictal EEG predicts a favorable outcome when lateralized to the side of surgery or when highly localized to the resected temporal lobe. Patients whose interictal EEGs showed ≥90% predominance on the operated-on side had an 80% chance of complete seizure freedom after a mean 5.5 years of follow-up versus 54% in those with lesser degrees of lateralization in one prospective study (5). In general, interictal evidence of a diffuse irritative zone predicts a worse outcome: Postoperative seizure freedom is worse when interictal spiking was posterior temporal, extratemporal, or bitemporal (44). Posterior temporal and extratemporal spiking in patients with pathologically confirmed HS may reflect diffuse epileptogenicity or "dual pathology" with associated neocortical epileptogenic zones, thereby explaining the associated worse prognosis (34,63). However, prognostic implications of bitemporal interictal spiking on surface EEG deserve more careful consideration, as it does not automatically preclude postoperative seizure freedom. One study found that if ≥90% of surface interictal bitemporal spikes arise from one temporal lobe, excellent outcome is possible (92% seizure free in the second postoperative year vs. 50% if <90% lateralization), and further evaluation with depth EEG electrodes may not even be indicated (64). With a unilateral MRI temporal lesion, and with lateralizing WADA or neuropsychiatric testing, up to 64% of patients with bilateral interictal spikes achieved complete seizure freedom at ≥1 year postoperatively when seizure onset was strictly unilateral on invasive evaluation (65). Other findings consistent with unilateral HS, such as a history of febrile seizures or early onset of epilepsy (prior to age 3 to 6 years), also correlated with favorable outcome in patients with bitemporal interictal spikes suggesting that contralateral spiking may simply be spread from a surgically treatable hippocampus (44). However, if the MRI is normal or shows widespread abnormalities, then seizure recurrence is

the rule as either an extratemporal focus spreading to both temporal lobes or bitemporal epilepsy becomes more likely (65).

Similar concepts apply to the prognostic value of ictal EEG. Again, focal or anterior ictal EEG correlates with a more favorable outcome, and patients who had bitemporal ictal onsets on surface EEG still achieved seizure-freedom rates of up to 64% at 1 postoperative year if seizures were exclusively unilateral with depth recordings and imaging or neuropsychological testing were also consistent with unilateral temporal dysfunction (44,65).

Intracranial EEG.

Depth electrode evaluations have traditionally been used to clarify lateralization of the epileptogenic zone in patients with suspected bitemporal or falsely lateralized TLE, whereas subdural recordings and stereoelectroencephalography (SEEG) are useful in neocortical epilepsy for extraoperative functional mapping and definition of the extent of the epileptogenic zone. Those modalities are therefore reserved for patients with a poorly defined epileptogenic zone, which may explain poorer outcomes seen in cases that required invasive recordings preoperatively compared to those that did not (8,38,44,66). Outcomes are particularly worse in patients who had prior temporal lobe resections (67). Yet, specific findings obtained with such invasive evaluations may provide useful prognostic information. During depth recordings, more favorable outcomes are seen with exclusively unilateral seizure onset and ictal spiking as opposed to low-voltage fast activity, electrodecrement, or any other rhythmic sustained activity at seizure onset, whereas evolution into distinct contralateral electrographic seizures lowered seizure freedom from 84% to 47% at 1 postoperative year (44). Short interhemispheric propagation times ranging from <1 second to <8 second, a short duration between EEG and clinical seizure onset, and diffuse or posterior temporal onset as opposed to anterior and/or middle basal temporal ictal onset have all been also identified as predictors of seizure recurrence after surgery (44).

Surgical Technique and Seizure Outcome

Similar seizure-freedom rates have been observed with selective amygdalohippocampectomy and anterior TL (8,68,69). Many studies failed to correlate the extent of temporal resection (37), the extent of hippocampal resection (38), or having a mesial versus neocortical resection (8,70) to outcome. Those studies, however, did not evaluate patients with mesial TLE separately. In the presence of unilateral mesial TLE with HS, the extent of mesial resection becomes a more significant predictor of postoperative seizure freedom (44). In a prospective, randomized, blinded clinical trial, Wyler et al. (71) found that only 38% of patients in whom the hippocampal resection was limited posteriorly by the projection of the lateral mesencephalic sulcus (partial hippocampectomy) were seizure free at 1 year, compared to 69% of those in whom the hippocampus was removed further, to the level of the superior colliculus (almost complete resection). The amount of amygdala that must be resected to achieve seizure freedom is unclear, although one study found no correlation between residual amygdalar tissue and surgical outcome (72). The ideal extent of lateral temporal resection also remains to be defined with conflicting data currently available (44).

In the presence of a well-circumscribed lesion, such as a tumor or a vascular malformation, a lesionectomy plus resection of the nearby adjacent cortex might suffice unless there is associated hippocampal atrophy. In such cases of dual pathology, complete seizure freedom after a mean follow-up of 37 months was lowered from 73% with lesionectomy plus mesial temporal resection to 20%

with mesial temporal resection alone and 12.5% with lesionectomy alone (44,73,74).

Etiology, Pathology, and Seizure Outcome

When pathologic findings in the resected temporal lobe were restricted to nonspecific gliosis, poor short- and long-term outcomes have consistently been observed (44). In a longitudinal study of 371 ATL patients, 44% of cases who only had gliosis were seizure free 8 years after surgery, compared to 64% if a specific pathologic diagnosis was identified (8). However, once a specific pathologic abnormality is identified, it is not entirely clear that its nature is relevant for seizure outcomes. While the older literature has suggested more favorable outcomes with HS, seizure-freedom rates were similar between HS and other types of lesions in many recent (6,8) or prospective studies (4,70,75). One hypothesis is that outcome depends not only on the presence of HS but also on its severity: Worse disease may predict better outcome. One group found that 84% of patients with classical HS, as defined by neuronal loss and sclerosis in CA1, CA4, and the granule cells of the dentate gyrus, achieved at least 95% seizure reduction at last follow-up, compared to only 29% of those where cell loss was restricted to the dentate gyrus and/or CA4 (53). Another group also found that rates of Engel class I outcomes at last follow-up increased from 60% to 76% to 89% as the pathologic severity of HS ranged from mild to moderate to severe (26).

FRONTAL LOBE SURGERY

Rate and Stability of Postoperative Seizure Freedom

Frontal lobectomy (FL) accounts for 6% to 30% of all epilepsy surgeries and represents the second most common procedure performed to treat intractable focal epilepsy after TL. However, reported seizure-freedom rates with frontal resections have varied from 13% to 80% (11,15,17,54, 76–82), suggesting, in general, significantly lower success rates than those observed with temporal resections. Only few studies evaluated seizure freedom after FL longitudinally and can therefore provide useful information related to rate and stability of seizure outcome over time (11,77,83). In a retrospective study evaluating 97 adults who underwent resective FL surgery between 1991 and 2005, Elsharkawy et al. (77) found that the probability of an Engel class I outcome was 54.6% at 6 months, 49.5% at 2 years, 47% at 5 years, and 41.9% at 10 years. In a study reviewing patients operated at Cleveland Clinic between 1995 and 2003, and using a stricter "favorable outcome" definition (complete seizure freedom since surgery), we had previously identified a seizure-freedom rate of 55.7% at 1 postoperative year, 45.1% at 3 years, and 30.1% at 5 years and beyond (11). Outcomes were somewhat more favorable, closer to the 40% seizure-free range in a more recent series (20). Eighty percent of seizure recurrences occur within the first 6 postoperative months, and although late remissions and relapses may occur, those are usually rare (11). One study showed that although a postoperative reduction in seizure frequency often occurred in patients who failed to become completely seizure free after surgery, this improvement was sustained until the last follow-up in only 35%, with seizure frequencies eventually returning to preoperative levels in the remainder (11). The running-down phenomenon previously described may occur following FL, but at a rate of <15%, also significantly less than that seen after TL (77).

Similar to TL, however, seizure freedom at 6 months to 2 postoperative years seems to be a very good predictor of a long-term seizure-free state. If a patient is seizure free at 2-year follow-up, the

probability of remaining seizure free up to 10 years may increase up to 86% (77).

Predictors of Seizure Recurrence

Mechanistically, proposed hypotheses to explain the generally lower rates of seizure freedom following FL include (i) difficulty localizing the epileptogenic zone with EEG data secondary to rapid ictal spread through the frontal lobe, (ii) difficulty achieving a complete surgical resection secondary to proximity of functional/eloquent cortex, and (iii) a preponderance of cortical dysplasia, often invisible on MRI, as the epilepsy etiology in the frontal lobe as opposed to clearly localized HS in the temporal lobe (14,79,84). Practically, identified predictors of postoperative seizure recurrence have included incomplete resection of the epileptic lesion (11,22,77,85,86), the need to perform an invasive EEG evaluation (11,77), the occurrence of acute postoperative seizures (11), the persistence of auras postoperatively (11,77), a history of febrile seizures (79), predominantly generalized or poorly localized ictal EEG patterns on surface EEG prior to surgery—especially in the adult population (11,13,17,77) —and the lack of a distinct single MRI lesion (11,13,77,85). Of all the above prognostic indicators, the two most consistently reported and strongly predictive of postoperative seizure freedom are the presence of an MRI lesion and completeness of resection (Figs. 90.1 and 90.2). A short epilepsy duration (<5 years) is associated with significantly improved outcomes, regardless if patients are lesional or not, a finding that highlights the urgency and importance of early surgical referral in patients with FLE (20).

MRI and Seizure Outcome

A normal MRI in a patient undergoing FL has consistently been found to predict a worse outcome. Twenty-five percent of the patients with negative MRI studies and 67% of those with neuroimaging abnormalities restricted to the frontal lobe were seizure free at a minimum duration of follow-up of 1 year in one study (87). A focal MRI abnormality was the only variable significantly associated with a favorable surgical outcome in another report (88). Only 41% of nonlesional FLE patients had an excellent outcome versus 72% when MRI abnormality was present in yet another retrospective analysis (79). Most such "nonlesional" FLE cases are thought to have an underlying malformation of cortical development (MCD) (13,85). In one series, all patients with normal MRI and pathologically proven MCD had recurrent seizures by 3 postoperative years (11). Knowing that milder forms of MCD such as microdysgenesis, cortical dyslamination, or focal MCD are often missed, even on high-resolution MRI may explain why one cannot "see" the extent of the epileptogenic tissue in those MRI-negative MCD cases making adequate surgical treatment harder. The particular pathologic MCD substrate in fact was critical in determining surgical outcome in another more recent series with the worst outcomes in type I MCD (19).

Techniques such as ictal SPECT imaging, FDG-PET, and subdural grid or SEEG monitoring are often used to better localize the epileptogenic zone in nonlesional FLE cases. A study reporting on 193 patients with neocortical focal epilepsy (including 61 with FLE) showed that correct localization by FDG-PET was an independent predictor of a good outcome (13), and other case reports highlighted the usefulness of ictal SPECT in identifying a potential epileptogenic zone in nonlesional FLE (84). A recent analysis, however, found that while MRI, PET, and ictal SPECT all had good positive predictive values with correspondingly acceptable negative predictive values in correlating with the ictal-onset zone as later defined by invasive EEG recording, there was no significant relationship between the diagnostic accuracy of any of these modalities and surgical outcome, with the exception of MRI ($P = 0.029$) (15). So, the translation of "accurate" and "correct localization" of epileptic foci using either PET or SPECT into actual improvements in seizure outcome for nonlesional FLE has not always been consistently reproducible. The interpretation of the role of intracranial EEG monitoring is another delicate issue. In a cross-sectional study of 51 nonlesional,

mostly FLE, cases operated on between 1992 and 2002, Wetjen et al. (76) found that 35.7% of the 28 patients who eventually underwent a focal resection after intracranial EEG recording became seizure free with high-frequency oscillations at ictal onset being predictive of seizure freedom. Since this study's patient population included cases operated on prior to the advent of FLAIR imaging and other high-resolution neuroimaging techniques, an unknown proportion of its cases may have had subtle structural abnormalities, which potentially could have been detected using current imaging modalities. A longitudinal study of FLE patients imaged and operated on more recently found that 66% were seizure free at 1 postoperative year, and 44% (95% CI = 39 to 49) at 5 years and beyond, including nonlesional cases (20). In summary, while nonlesional FLE cases seem to be as a whole less than ideal surgical candidates for resective epilepsy surgery, efforts to identify the specific subgroup that might benefit from surgery while pursuing nonsurgical treatment options for the rest are still required. Early referral for a presurgical evaluation is essential (20).

Any extrafrontal MRI abnormality also confers a poor prognosis. Favorable outcomes occurred in either none of the patients with multilobar MRI abnormalities (87) or at best in 10% to 14% (11,89). Tumors, well-circumscribed pathologies, usually have the best outcome with up to 62% seizure free at last follow-up in one report (11) and 65% Engel class I or II at last follow-up in another series (14).

European series from centers using stereo–EEG evaluations report more favorable outcomes in nonlesional extratemporal epilepsy (90,91), highlighting the importance of adequately developing a preimplantation hypothesis prior to exploration of these patients for resective surgery.

Extent of Resection and Seizure Outcome

Complete resection of the epileptogenic lesion has consistently been found to predict seizure freedom. In one report, of patients who had complete removal of their epileptogenic lesions, 81% were seizure free at 1 year and 66% at 3 years, compared to 13% and 11%, respectively, of those who did not (11). Complete removal of neuroimaging abnormalities (76,85,92) and abolition of residual ECoG spiking (93) or seizures (94) have also been linked with the most favorable outcomes following FLE surgery. Major challenges that hinder a complete resection in all cases include frequent proximity or overlap with eloquent cortex and difficulties identifying the true edges of the "abnormal" tissue in MCD cases where the MRI-visible portion of the dysplasia may be surrounded by microscopically abnormal tissue that seems normal on imaging (11).

In summary, while the rates of seizure freedom are low, in general, following frontal resections, very successful seizure outcomes are possible in a selected group of patients, mainly those with a clear MRI lesion that is completely resectable.

POSTERIOR CORTEX SURGERY

Rate and Stability of Postoperative Seizure Freedom

Resections in the posterior cortex represent <10% of all epilepsy surgeries, with reported postoperative seizure- freedom rates varying from 25% to 90% (12,85,95–98). In a longitudinal analysis of a cohort of posterior cortex resections, the estimated chance of seizure freedom was 73.1% at 6 postoperative months, 68.5% at 1 year, 65.8% between 2 and 5 years, and 54.8% at 6 years and beyond. The median timing of recurrence was 2.0 months with 75% of the seizure

recurrences occurring by 6.4 months, and late recurrences were rare with the latest being at 74 months (12). Similar rates of seizure freedom have been reported in another longitudinal analysis of 154 adult patients who underwent various types of extratemporal resections (about 40% frontal and the remaining being posterior cortex surgeries), with an Engel class I at 2 postoperative years being correlated with an 88% chance of remaining seizure free 14 years after surgery (83). These findings suggest that in posterior cortex resections, we can expect an initial rate of seizure recurrence that is as fast as following FL, allowing a relatively early identification of surgical failures, but with a more optimistic long-term outlook with late seizure-free rates comparable to those following temporal resections. Figure 90.3 illustrates the longitudinal rates of seizure freedom in posterior quadrant resections in a cohort evaluated at Cleveland Clinic recently.

Predictors of Seizure Recurrence

Patients with well-circumscribed focal lesions (tumors or MRI-visible MCD), who have more extensive resections (lobectomies or multilobar resections as opposed to lesionectomies), no preoperative evidence of extralobar epileptogenicity extending to the ipsilateral temporal lobe (temporal spiking or auditory auras), and no postoperative evidence of residual epileptogenicity (spiking on 6 months postoperative EEG) had the most favorable outlook in most series of posterior cortex resections (12,83,85,95–98).Other less consistently reported predictors of seizure freedom include lateralizing seizure semiology (95), focal ictal EEG (99), and shorter epilepsy duration (100).

In a series of 57 patients with posterior cortex resections, only a quarter of patients with either a tumor or lesional MCD had postoperative seizure recurrence, as opposed to more than half of the patients who had other pathologies after a mean follow-up of 3.3 years (12). Completeness of resection of such epileptogenic lesions was identified, among others, by Barba et al. (99) in 2005 to be the strongest predictor of postoperative seizure freedom. The challenge though is that while it is easily understood that larger resections have a better chance of achieving seizure freedom, this may not always be possible secondary to risks of injury to eloquent cortex, especially in the dominant hemisphere. We found that a lesionectomy achieved seizure freedom in 67% of cases in tumor or

MCD but in only 20% of other etiologies, suggesting that attempting a "smaller surgery" to avoid injuring eloquent cortex may be appropriate in selected cases of tumor/MCD but is rather ill-advised with other "unfavorable etiologies" (12). Invasive EEG recordings with subdural grids or depths or the use of stereo–EEG are more extensively used for better delineation of the epileptogenic zone and for extraoperative functional mapping optimizing resections with multiple reports showing very promising seizure outcome data. Caicoya et al. (101) found that five of seven occipital lobe epilepsy patients who underwent tailored resections guided by subdural EEG data were seizure free after a mean follow-up of 24.3 months. Cukiert et al. (102) reported on 16 patients with intractable extratemporal epilepsy who had either normal or "nonlocalizing" MRI, finding that 13/14 were rendered seizure free with resections that used subdural EEG information. The use of preoperative invasive monitoring has even been shown in one report to actually correlate with a more favorable outcome in a large cohort of extratemporal resections, consisting mostly of posterior cortex surgeries (83).

PSYCHIATRIC OUTCOMES AFTER EPILEPSY SURGERY

Epilepsy surgery, especially when successful, appears to reduce the prevalence of commonly observed psychiatric comorbidities of epilepsy, including depression and anxiety. Kanner et al. (103) reported a total remission rate off psychotropic medication in 45% of patients who underwent epilepsy surgery. The impact on psychotic disorders, however, is less clearly defined: It varied from unchanged in most cases to improved psychotic status/and or level of functioning (103). Conversely, patients may undergo an exacerbation of an underlying psychopathology or develop de novo psychopathology after surgery. In a study by Wrench et al. comparing the psychiatric outcomes following temporal versus extratemporal resections over a 3-month period, it was found that although both groups had similar baseline rates of depression and anxiety, and more patients were seizure free after a temporal than after an extratemporal resection, the psychiatric outcome was significantly worse in the temporal resections group: At 1 month after surgery, 66% of TL versus 19% of ETL patients reported symptoms of anxiety or depression, which persisted until the 3-month follow-up in 30% of TL and 17% of ETL. In addition, by the 3-month follow-up, 13% of ATL patients had developed a de novo depression as opposed to none in the ETL group. More notably, the occurrence of any of those psychiatric comorbidities was not related to seizure freedom (104). This reinforces the need to carefully evaluate and consider psychiatric outcomes after epilepsy surgery as an independent—albeit intimately connected—entity to the seizure outcomes.

PSYCHOSOCIAL OUTCOMES AFTER EPILEPSY SURGERY

The goals of surgery, as identified by epilepsy patients, extend beyond seizure control, to include driving, regaining or improving employment, and overall independence (104). Intimately linked to these goals is the absence of any "functional" worsening due to surgery, as might occur with a new neurologic deficit, memory loss, or language disturbance. A "successful" surgery is one where seizures are controlled and where the patients' psychosocial goals materialize into an improved QOL. Several studies have found that for optimal improvement in QOL measurements, complete

seizure freedom (even from auras) is required (41,105). Other possible predictors of an improved QOL include a higher presurgical IQ score, younger age at surgery, and a more stable mood at baseline (105). Studies evaluating the psychosocial and educational impacts of surgery in the pediatric population are very limited, but do suggest meaningful improvements in educational attainments and later employment (105).

SURGICAL COMPLICATIONS AFTER FOCAL EPILEPSY SURGERY

The main goal of the pre- and intraoperative evaluation for epilepsy surgery is to identify possible candidates in whom surgical intervention will totally or partially control seizures without increasing neurologic deficits or general morbidity.

In general, we can divide complications in focal neocortical epilepsy surgery based on pathophysiologic mechanisms into

Surgical Complications:

- Infection
- Hematoma
- Brain swelling
- Hydrocephalus
- Vascular compromise (arterial or venous)

Injury to Eloquent Areas of the Brain Causing Neurologic Impairment:

- Hemiparesis
- Hemiplegia
- Visual field defect
- Aphasia
- Alexia
- Neuropsychological impairment (deficits in cognition, memory, language, attention, and concentration)

Psychosocial Impairment:

- Family and interpersonal relationships
- Self-esteem
- Vocational/educational

Psychiatric Impairment:

- Depression
- Anxiety
- Psychosis

In regard to surgical procedures related to neocortical focal epilepsy, we can classify complications

due to focal neocortical resections as follows:

Diagnostic Procedures:

- Complications associated with subdural grid and strip electrodes, depth electrode, and SEEG

Therapeutic Procedures—Resective Surgery:

- Complications associated with frontal (mesial and lateral) resections
- Complications associated with temporal lobe resections
- Complications associated with parietal and occipital resections

Diagnostic Procedures

Subdural Grids/Strip Electrodes, Depth Electrode, and SEEG Complications

When noninvasive studies remain nonconcordant or inconclusive regarding the localization and the extent of the seizure- onset zone and/or the eloquent cortex, invasive studies using subdural grids, strips, or depth electrode may be needed (106). Jayakar et al. proposed the following relative indications for the evaluation with invasive monitoring: Normal structural imaging, extratemporal location, divergent noninvasive data, and encroachment on eloquent cortex, tuberous sclerosis, and cortical dysplasia (106). Rosenow and Lüders (107) recommended the use of invasive monitoring only in patients with focal epilepsy (single focus) in whom there is a clear hypothesis regarding the location of the epileptogenic zone (derived from noninvasive studies).

The intracranial placement of subdural grid electrodes via craniotomy has received increasing acceptance over the past decade. Invasive EEG monitoring by subdural grid electrodes facilitates prolonged electrographic assessment as well as extraoperative functional brain mapping of the superficial cortex. Also, it is particularly important in pediatric cases in which awake surgery and intraoperative functional mapping are often difficult.

The principal complications of grid electrode implantation include infection and subdural hematoma formation, which may be associated with neurologic deficits, elevations of intracranial pressure (ICP), and even death (108–110). Other complications may include brain swelling and arterial or venous infarctions (Fig. 90.4). In a recent series, of the 228 cases from 9 centers, the reported complications included infection, hemorrhage with transient deficit, increased preexisting hemiparesis, aseptic necrosis of the bone flap, and transient elevations in ICP (111). In an individual series from the Cleveland Clinic, an initial infection rate of 22% declined to 7% when subcutaneous tunneling of electrode cables was instituted (112). More recently, routine use of perioperative antibiotics and watertight dural closure with sutures at cable exit sites has been advocated in our group (Awad, personal communication, 1992). Since these modifications were introduced, the infection rate has declined markedly.

Figure 90.4. Complication of subdural grid placement: Venous infarction located in the left frontal lobe region after subdural grid placement. Postoperative CT after subdural grid removal and bone decompression.

In the absence of a multicenter, prospective complications survey, anecdotal reports of subdural hematoma formation, increased ICP, and death following grid placement have been documented in the literature. Some centers recommend routine, perioperative dexamethasone, and mannitol administration over 2 to 3 days after surgery, dural grafting, or leaving out the bone flap during the period of monitoring as responses to the threat of increased ICP. Circumferential dural incision, lining of the outer grid surface with hemostatic agents, and tapering of valproic acid are also recommended to reduce hematoma formation. There is no data with respect to the relative value of any of these practices in preventing individual complications.

Regarding subdural strip electrodes, epilepsy surgery literature suggests that insertion may be safer than depth electrode placement (109,113). No examples of significant hemorrhagic complications associated with prolonged neurologic deficit or death have been reported so far. Localized infections occur at a slightly lower frequency when compared with depth recordings and usually respond to antibiotic therapy alone. In a recent series of 350 patients, 2 cases of meningitis, 1 brain abscess associated with hemiparesis, and 3 superficial wound infections were reported (114). In two additional reports studying 122 patients, no hemorrhagic, neurologic, or infectious complications occurred following strip electrode placement (115).

Regarding the SEEG method, the total complication rate was 3% in a recent report from the Cleveland Clinic (116). Other groups reported similar results. Cossu et al. (90) reported a morbidity rate of 5.6%, with severe permanent deficits from intracerebral hemorrhage in 1% (90). In our reported series, all complications were hemorrhagic, which has been reported in several studies to be the most common complication in depth electrodes placement (90,116). Other published series reporting complications across invasive monitoring procedures (subdural grids and depth electrodes) reported rates ranging from 0% to 26% (114,117,118). Subdural grid electrodes implantation has historically been shown to have low permanent morbidity (0% to 3%) compared with depth electrodes (3% to 6%) since there is no intraparenchymal passage. Although it is difficult to compare

morbidity rates between subdural grids and SEEG due to the variability in patient selection, institutional preferences, and variable numbers of implanted electrodes, our experience suggests that the SEEG method provides at least a similar degree of safety when compared with subdural grids or strips; an impression also shared by others (90,119,120).

Different techniques of invasive monitoring exist, and each has its advantages and disadvantages. Chronically implanted subdural electrodes allow recording from large superficial cortical areas, but they provide limited coverage of deeper structures, such as the hippocampus, the interhemispheric region, or the cortex within sulci. Intracerebral electrodes have the advantage of excellent sampling from mesial structures and from deep cortical areas, providing a three-dimensional view of the epileptogenic network, with the disadvantage of providing information from a limited volume of tissue. Combined use of subdural and intracerebral electrodes also has been advocated. In a recent publication, Cossu et al. presented a retrospective study of a large series of patients (211 patients) who underwent SEEG evaluation. SEEG provided additional guidance toward epileptic focus resection in 183 patients (87%), resulting in seizure-free outcome in 44% of the cases and an overall significant improvement in 82%.

As highlighted by others, important issues relating to the stereotactic placement of depth electrodes and associated complications include (i) the relative safety of lateral, parasagittal, and tangential methods of insertion; (ii) the relative safety of flexible versus rigid electrodes; (iii) the role of computer- assisted work stations in the improvement of stereotactic accuracy and the reduction of vessel injury; and (iv) the effect upon infectious complications of length of monitoring, antibiotics prophylaxis, tunneling of electrode leads, and methods of electrode removal.

Therapeutic Procedures

Complications of Temporal Neocortical Focal Resections

In general, there are at least four different surgical approaches to treat mesial TLE. These approaches include (i) en bloc temporal resection or standard TL, (ii) awake TL with tailored resection, (iii) amygdalohippocampectomy, and (iv) radical hippocampectomy. Each technique represents a different approach to the identification and resection of the epileptogenic zone. Because this chapter is focused on complications in neocortical epilepsy surgery, complications related to amygdalohippocampal resections will not be discussed.

In an extensive review of the literature performed by Pilcher and Ojemann regarding complications of anterior TL, mortality occurred in <1%, mainly caused by hemorrhage, infarction, pulmonary complications, and sudden death. Other complications included hemiparesis (transient or permanent) in 2% to 4%, minimal visual field defects in more than 50%, and severe field defects (hemianopsia) in 2% to 4%. Infections (meningitis, abscess), epidural hematoma, and III nerve palsy (transient) occurred in <2%. Neurobehavioral complications included transitory anomia (<1 week) in 20% of the patients, persistent dysphasia in 1% to 3%, and transitory psychosis/depression in 2% to 20%.

Penfield reported a 2.5% hemiplegia in an early Montreal Neurological Institute (MNI) series. He attributed this complication to excessive manipulation of branches of the middle cerebral artery during the transsylvian resection of insular cortex (121). Alternative explanations included direct capsular injury with insular resection as well as compromise of the lenticulostriate vessels and the anterior choroidal artery.

Visual field deficits occur following temporal lobe resections in approximately 50% of operated patients. These deficits are often incongruous or worse in the ipsilateral eye, due to the anterolateral location of ipsilateral fibers overlying the anterior portion of the temporal horn (Meyer loop). Severe visual field deficits considered disabling by patients are less frequent and were reported in 8% in our previous series (112). Rasmussen et al. suggested that by limiting the extent of the superolateral ventricular opening to 1 cm, quadrantic deficits could be avoided entirely. Other studies also suggested that the magnitude of the visual field deficit was entirely related to the extension of the ventricular opening, mainly in the ventricular roof in the temporal horn. Alternatively, direct surgical injury to the optic tract, lateral geniculate nucleus, or optic radiation in the posterior temporal lobe white matter can also cause visual field deficits.

Postoperative anomia or dysphasia is not uncommon following dominant TL. These aphasias are largely resolved after 1 week. Transitory dysphasias are reported in up to 30% of operated patients in the setting of awake surgery with intraoperative language mapping. Removal of the anterior temporal or inferior basal language sites may explain this phenomenon (122). Other explanations include resection of cortex within 1 to 2 cm from essential language areas, brain retraction, and disruption of white matter pathways connecting language areas. According to Crandall et al., persistent language disorders were found in three of 53 patients undergoing temporal lobe resection. In another series, 5 of 25 patients were aphasic at the time of discharge (123). In the MNI series, using intraoperative language mapping, 2 of 250 patients were reported to have long-lasting aphasia after surgery (124,125). In both cases, aggressive resection near essential speech areas was performed. In the Seattle series, removal of brain within 1 to 2 cm of essential sites established by intraoperative mapping was associated with mild language deficits (126,127).

The “tailored operation” is designed to use language-mapping techniques to identify and protect neocortical language sites. In a comparison of “standard” versus tailored TLs performed by a single surgeon, a slight increase in postoperative dysnomia was identified 6 months after surgery following a “standard” operation (128).

Complications of Extratemporal Neocortical Focal Resections

The extratemporal epilepsies considered for resective therapy are less frequent, more variable in their presentation, and the epileptogenic zone is more likely to involve eloquent cortex, and intraoperative or extraoperative brain mapping is often necessary. All of these facts have a direct impact upon the complications of extratemporal neocortical focal resections, most important of which are the functional consequences of adequate removal of the epileptogenic zone in a particular brain area. In a systematic fashion, we can divide extratemporal focal resections in frontal, central, parietal, and occipital resections.

Frontal Resections.

Anatomically, Broca area is located in the inferior frontal gyrus at pars triangularis and pars opercularis of the dominant frontal lobe, and this region is generally avoided when dominant frontal resections are performed under general anesthesia. The pattern of frontal language localization may be quite variable, and many centers rely upon brain-mapping techniques to tailor frontal resections and avoid language complications. These investigations may identify zones of language cortex quite separate from Broca area within the middle, superior, and even parasagittal frontal cortex in the region of the supplementary motor area (SMA).

Transitory aphasic syndromes are often caused when resections are carried within 1 to 1.5 cm of these essential language areas (126,127). Long-lasting expressive aphasia can follow resection of language sites in the posterior inferior frontal gyrus or vascular compromise with postoperative ischemic injury to the region. Resections involving frontal cortex (superior frontal gyrus) may cause compromise of draining frontal veins with associated postoperative edema, venous infarction, as well as potential language and motor deficits.

The SMA is located in the mesial surface of the superior frontal cortex, superior to the cingulate gyrus. Functional studies have shown that this area is activated during initiation of movement and vocalization. Stimulation of this area leads to a fencing posture with bilateral motor movement. Unilateral responses are rare. The SMA is extensively and somatotopically connected through the corpus callosum, resulting in fast spread of the ictal discharges to the contralateral side, making lateralization of the ictal-onset zone difficult (129). Resection of the SMA located in the mesial frontal lobe may produce supplementary motor cortex syndrome characterized by mutism, contralateral neglect or hemiparesis, and diminished spontaneous movement, which gradually resolves over several weeks (130). On long-term follow-up, gross motor deficits are rare.

The orbitofrontal area is limited laterally by the horizontal ramus of the sylvian fissure, medially by the olfactory sulcus, and posteriorly by the anterior perforated area. The orbitofrontal cortex is extensively connected with the anterior and mesial temporal lobes, cingulum, and opercular area and, for this reason, frequently misdiagnosed as anterior temporal seizures (131). Adequate sampling of these structures using invasive electrodes is recommended. The cognitive effects of extensive nondominant frontal resections are thought to be of minimal consequences in daily life activities (132). Furthermore, provided that a careful subpial technique is employed, with preservation of the vascular supply to motor cortex, frontal excisions may be safely carried up to the pial bank of the precentral gyrus. Care must be taken, however, not to undermine the motor cortex if the resections are extended into the white matter.

Central Resections.

Central-type epilepsy or seizures arising from the primary motor and sensory area are infrequent. Patients with preserved motor function present considerable challenges. A more aggressive approach to the peri-Rolandic epilepsies is gaining acceptance in which extraoperative functional mapping of central cortex is supplemented by intraoperative remapping of this area by direct cortical stimulation, often under awake conditions.

Resection of the facial motor cortex.

The partial resection of the nondominant face motor cortex may be safely performed, resulting in a transitory contralateral facial asymmetry. Complete removal may be associated with perioral weakness in some patients. The superior resection margin should extend no higher than 2 to 3 mm below the lowest elicited thumb response. In the dominant hemisphere, some surgeons report postoperative dysarthrias and dysphasias following face motor cortex excision. Nevertheless, Rasmussen et al. reported that complete removal of dominant face motor and sensory cortex may be safely performed, provided that manipulation of underlying white matter or ascending vascular supply is avoided (124,125).

Resection of the hand/leg motor cortex.

The resection of the primary hand motor cortex produces a permanent deficit of fine motor control and should be avoided if useful hand function is present preoperatively. Resection of the primary leg motor cortex will elicit an immediate flaccid leg paralysis followed by gradual partial recovery of ambulatory capacity over months (124,125). Proximal limb function is likely to recover; however, distal ankle and foot permanent weakness are often present, requiring use of orthoses for safe ambulation.

Resection of the sensory cortex.

The resections of leg or face sensory cortex cause permanent but clinically insignificant deficit of proprioception in the leg or two-point discrimination in the lower face (132). In contrast, resection of hand sensory cortex is followed by important functional impairment, with the majority of patients showing deficits of pressure sensitivity, two-point discrimination, point localization, position sense, and tactual object recognition, which makes functional use of the involved hand difficult (132).

Parietal Resections.

Very few articles reporting complications in parietal resections are available in the literature. Salanova et al. (97) reported the MNI experience of 79 patients with nontumoral parietal lobe epilepsy. Of these, 45.5% were seizure free, 19% had rare seizures, and 21.5% had worthwhile improvement. Persistent dysphasia was noted in two patients, Gerstmann syndrome in one patient, and contralateral weakness in three patients.

Large parietal resections may be undertaken posterior to the central cortex in the nondominant hemisphere without causing a sensorimotor deficit and with a rate of hemiparesis of approximately 0.5% (124,125). A nondominant parietal syndrome may follow these resections in some individuals. In the dominant hemisphere, language mapping must be used to avoid postoperative language deficits if resections extend to the inferior parietal lobule. When resections are extended into the parietal operculum, contralateral lower quadrantic or hemianopic visual field deficits (rare) may occur as resections are performed beyond the depths of the sulci into the white matter (111,124,125).

Occipital Resections.

In patients with hemianopsia, resective occipital surgery carries minimal risk. On the dominant hemisphere, the speech-related cortex should be identified and spared. The management of patients with intact vision is challenging. When a circumscribed lesion is found, lesionectomy can yield satisfactory results. In nonlesional cases, the ictal-onset area should be precisely localized using invasive electrodes (80,133). These are used in addition to mapping of the calcarine cortex and speech-related cortex. With this strategy, visual deficits can be minimized. Resections of the dominant basal temporal lobe should be carefully planned as this can yield to an alexia without agraphia deficit (122).

Contralateral homonymous hemianopsia may follow resections in this area. If vision is intact preoperatively, calcarine cortex and optic radiations must be spared as much as possible. The use of intraoperative visual evoked potential, intraoperative direct stimulation, and radiologic techniques as diffuse tensor images is still under investigation.

If adequate data from invasive monitoring are available to suggest that the superior calcarine gyrus may be spared, an inferior calcarine gyrus resection with or without an aggressive resection of mesial temporal lobe structures will result only in a superior quadrantic deficit associated with

minimal disability. Excision to within 2 cm of Wernicke area in the dominant hemisphere may elicit persistent dyslexia (124,125). Therefore, exposure at craniotomy should be adequate to provide access to the postcentral gyrus and parietotemporal language areas, which will serve as the anterior limits of resection.

CONCLUSIONS

A valid appreciation of the complications of epilepsy surgery is fundamental to balance the risks and benefits of diagnostic and therapeutic procedures. Unfortunately, the actual literature available in this topic does not reflect contemporary surgical practice. Available data are derived from the surgical experience of a few highly experienced surgeons who worked in a few well-established comprehensive epilepsy centers and used patient selection criteria and operative approaches, which have since been modified or radically changed. A prospective multicenter study is necessary to determine the contemporary risks for invasive monitoring, the role of awake craniotomy with intraoperative mapping for speech mapping, and the complications rate in the epilepsy population.

CHAPTER 91 ELECTRICAL STIMULATION FOR THE TREATMENT OF EPILEPSY

WEI HU, S. MATTHEW STEAD, AND GREGORY A. WORRELL

Electrical stimulation has a long history as a diagnostic and therapeutic modality for epilepsy (1,2). The application of electrical stimulation for mapping cortical function in animals was first reported by Fritsch and Hitzig in 1870 (3), and the first report in humans by Bartholow (4) followed in 1874. Krause and Foerster extended the clinical application of electrical stimulation for localization of brain function in patients undergoing surgery for epilepsy (5). These studies culminated in the seminal work of Penfield and Jasper (6) who established the routine clinical use of electrical stimulation for localization of cortical function in epilepsy surgery. In the 1970s, the concept of therapeutic electrical stimulation for epilepsy emerged and has remained an area of active clinical research. Only recently, however, have well-designed clinical trials yielded class I evidence for efficacy.

THERAPEUTIC STIMULATION FOR THE TREATMENT OF EPILEPSY

Cooper first began implanting cerebellar stimulators in patients with intractable epilepsy in the 1970s (7,8), but the idea of electrical stimulation as a treatment for epilepsy is much older (2). Cooper et al. (7,9) reported significant reductions in the number of seizures with chronic cerebellar stimulation. However, later controlled trials did not confirm a dramatic therapeutic effect (10). The failure of a controlled trial to confirm the efficacy reported in an uncontrolled trial was later repeated for centromedian nucleus (CMN) of thalamus stimulation (11). These examples underscore the need for well-designed clinical trials to establish the efficacy of electrical stimulation before they can be recommended in routine clinical practice. Recent reviews have summarized the research in humans and animal models and have laid the framework for future research and clinical trials of brain stimulation for the treatment of epilepsy (2,12). Advances in neural engineering are now poised to deliver new treatments for a range of neurologic diseases. In epilepsy, active areas of research include the development of devices that modulate epileptogenic brain to prevent seizures, devices that directly detect seizures and deliver electrical stimulation to abort seizures, and devices that identify periods of increased probability of seizure occurrence (2,8). Two first-generation devices using electrical stimulation for the treatment of epilepsy have been recently completed in multicenter trials and are discussed below in detail.

Clinical Trial Design

Determining the efficacy of an epilepsy therapy is challenging. Epilepsy is characterized by unprovoked, paroxysmal, seizures that leave no lasting objective evidence of their occurrence. This can be contrasted with other neurologic diseases or disorders that have clear magnetic resonance

imaging (MRI) abnormalities or neurologic exam findings that can be tracked, for example, brain tumor, stroke, multiple sclerosis, amyotrophic lateral sclerosis, and peripheral neuropathy. Determining the efficacy of an epilepsy therapy requires tracking the occurrence of seizures. Unfortunately, until recently, this has only been possible with self- (or observer) reporting of seizures. Patient diaries, however, are imperfect, and their limitations are well known (13). A recent study showed very poor correlation between recorded seizures and patient diaries in 15 patients implanted with a device recording continuous intracranial electroencephalographic (iEEG) (14). Clinical trials investigating treatment efficacy of medications or brain stimulation typically use reduction in seizure frequency as the primary outcome measure. Well-designed clinical trials have control and active therapy arms (Fig. 91.1) with patients randomized to therapy ON or OFF. The patient and treating physicians are blinded to this information in order to limit bias. Nonetheless, because seizures occur sporadically without lasting objective evidence of their occurrence, the measure of treatment success has depended on the seizure diaries.

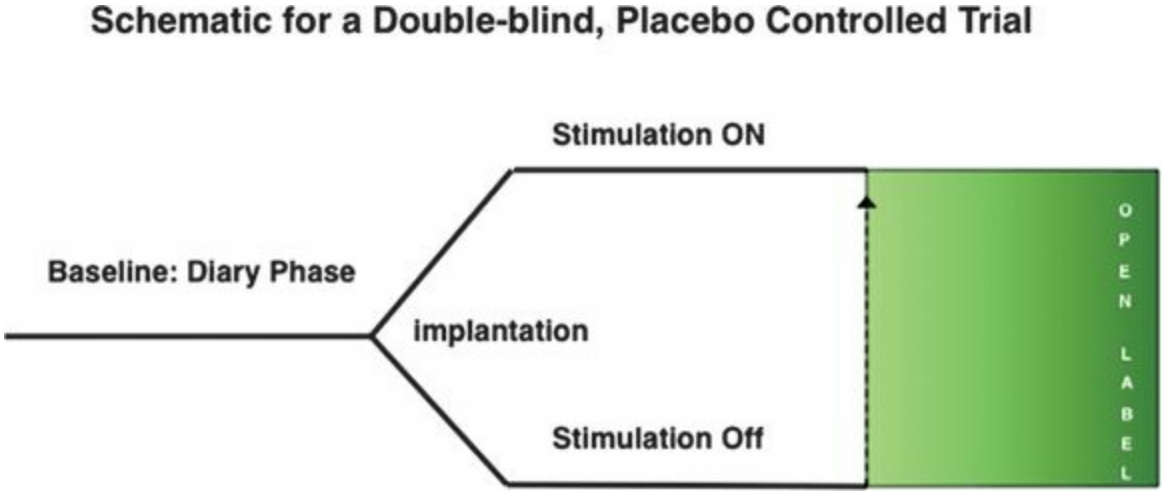

Figure 91.1. A schematic for a double- blind, placebo-controlled trial that has been adopted for two recent multicenter brain stimulation trials (Medtronic stimulation of the anterior nucleus of the thalamus [SANTE] trial and NeuroPace responsive neurostimulator system [RNS] trial). Specifically, well-designed clinical trials have control and active therapy arms with patients randomized to therapy ON or OFF. The patient and treating physicians are blinded to this information in order to limit bias.

To determine the efficacy of a particular brain stimulation paradigm (target of stimulation, timing of stimulation, stimulation parameters, etc.) for the treatment of epilepsy requires an appropriate study design. Pilot studies in a small number of patients are often used to initially investigate the safety, feasibility, and evidence of possible efficacy. Pilot and feasibility studies are not adequately powered to prove efficacy but should also use an appropriate design with controls and blinding. Figure 91.1 is a schematic for a double-blind, placebo-controlled trial that has been adopted for two recent multicenter brain stimulation trials (Medtronic stimulation of the anterior nucleus of the thalamus [SANTE] trial and NeuroPace responsive neurostimulator system [RNS] trial; see Figs. 91.2–91.4). As discussed in the following sections, a number of studies that reported positive results have not held up in better designed, more rigorous studies with a placebo-controlled arm.

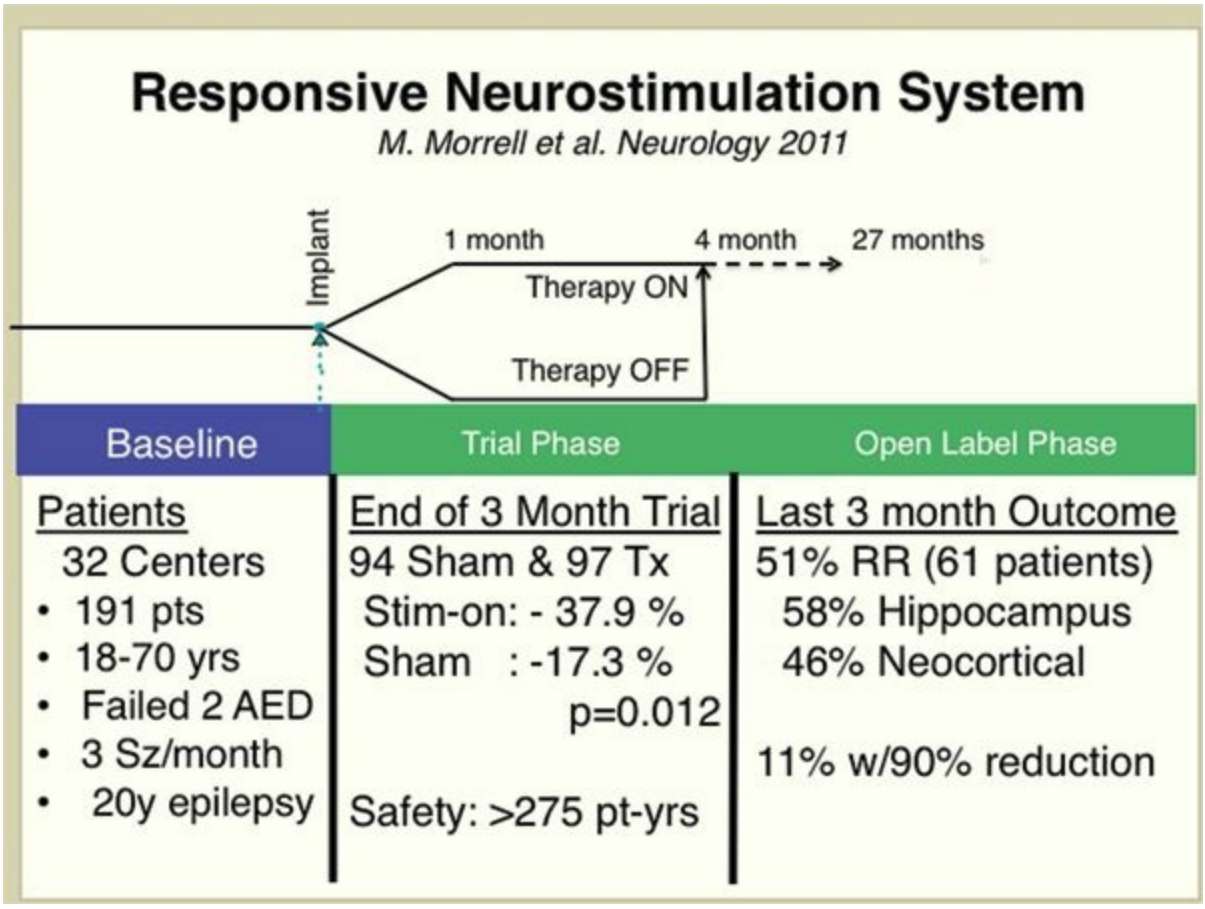

Figure 91.4. The results from a large multicenter, randomized, controlled trial for hippocampal and neocortical responsive stimulation using the NeuroPace RNS device (16).

Baseline

The baseline seizure frequency is determined from the patient diary in a defined period prior to the intervention under investigation. Studies of epilepsy, whether they are drug studies or brain stimulation, typically rely on the patient diary for determining seizure frequency. The reliability of patient reporting is a recognized weakness. Although there are currently no tools for reliably counting seizures in the outpatient setting, a recent study presented data from an implanted seizure advisory system (SAS), which could potentially be used for seizure counting (14).

Implantation

The device is implanted in patients who have met the enrollment criteria of the study. For example, only patients who had the required number of seizures in the 3-month baseline seizure frequency phase are implanted. In order to minimize the acute effect of implantation, there is typically a period of time (approximately 1 month) prior to randomization to stimulation ON/OFF and commencing the blinded treatment phase.

Randomization and Placebo Control

In order to rigorously differentiate the effect of electrode implantation, placebo, and stimulation, a sham surgery arm would be required. In most cases, it is not ethically possible to include sham implantation surgery. The placebo response and efficacy of stimulation are determined by randomization of patients to therapy ON or OFF. In effect, a coin toss (heads/tails) determines whether stimulation is activated or remains inactivated after surgery. In this way, approximately half the patients in the trial are randomized to therapy ON or OFF.

Double-Blind Design

The placebo response is well established in clinical trials and can have a powerful impact on the patient and physician's perception of treatment efficacy. By blinding the patient and physician to the treatment information, that is, stimulation ON or OFF, the placebo response can be determined. The efficacy of stimulation can be evaluated by directly comparing seizure frequency with stimulation ON versus OFF. A statistically significant reduction in seizures in the stimulation arm versus placebo (i.e., control) can be attributed to the stimulation therapy. Any seizure reduction occurring in the control arm is attributed to placebo response, chance, or possibly implantation effect. As mentioned in the two completed device trials (Medtronic SANTE and NeuroPace RNS), the implantation of the electrodes could conceivably create a therapeutic lesion. Yet, the acute therapeutic effect of electrode implantation appears to wear off with time.

Crossover

A crossover design allows patients who were initially randomized to therapy OFF to receive stimulation after completion of the double-blind study phase. The multicenter trials discussed in the following sections have utilized this single crossover design. In a double crossover study design, patients receiving therapy (ON) are crossed over to no therapy (OFF). In this study design, the

possible carryover effects of brain stimulation could confound the interpretation of the results. The "wash-out" period for anticonvulsant medications can be easily obtained, but the time required for "wash-out" of the effect of months of brain stimulation is not known.

Open-Label Extension

In the open-label portion of the trial, all patients receive stimulation without blinding. Often in the open-label phase, medications are adjusted or added, so interpretation of results requires caution. In addition, the patients and physician are no longer blinded to the therapy. Interestingly, the two large-scale multicenter clinical trials (see SANTE and RNS studies discussed below) have all shown evidence for increasing efficacy of brain stimulation with duration of time of receiving stimulation. These results must be interpreted with caution since they come from the open-label portion of the trial, but raise the possibility that brain stimulation has a cumulative therapeutic benefit.

Measures of Efficacy

Commonly reported outcome measures are (i) responder rate (RR), defined as the percentage of patients with a 50% or greater reduction in seizures, (ii) mean reduction in seizures from all patients, and (iii) number of seizure-free patients (defined over a specific duration of the trial, e.g., the most recent 3 months of the open-label phase of the trial). In addition, quality-of-life measures are often assessed, for example, Quality of Life in Epilepsy (QOLIE)-89 scale (17).

Measures of Safety

Side effects are categorized as serious or minor and anticipated or unanticipated. For example, an intracranial hemorrhage associated with electrode placement would be a serious, but anticipated, complication.

Electrical Stimulation Paradigms

The parameter space defining the range of stimulation variables is large and includes the type of stimulation (constant current vs. constant voltage), amplitude, stimulation waveform, frequency, duration, etc. The paradigms of stimulation can be broadly categorized as follows.

Open-Loop Stimulation (Duty Cycle Stimulation)

To date, the majority of stimulation systems utilize duty cycle stimulation. The stimulation is given regardless of the occurrence of seizures or brain activity. For example, deep brain stimulation (DBS) for tremor and open-loop stimulation protocols for the SANTE trial.

Closed-Loop Stimulation (Automated or Responsive Stimulation)

Recently developed systems utilizing implantable microprocessors make it possible for programmable stimulation to be delivered in response to recorded electrophysiologic signals. The NeuroPace RNS system is a closed-loop device capable of recording continuous iEEG and delivering therapeutic stimulation based on automated detection of pathologic activity and seizures.

Control Law Stimulation (Feedback Control Stimulation)

Based on the hypothesis that seizures occur out of a particular brain state that can be characterized by some observable (e.g., features of iEEG), it may be possible to actually prevent seizures by continuously adjusting a therapy (such as stimulation) that is determined by the measured observable. This approach is commonly used in a wide range of engineering applications and has been applied to animal models of epilepsy (18–20).

STIMULATION TARGETS IN THE HUMAN NERVOUS SYSTEM

Intracranial Stimulation

The idea of using electrical stimulation to treat epilepsy has a long history (1,2,21). The following is a discussion of earlier studies with a focus given to studies with good clinical design. The ability to accurately and safely implant electrodes into human brain has led to dramatically successful therapies for some neurologic disorders such as tremor (1). Less successful has been the application of DBS, hippocampus stimulation, and neocortical stimulation for the treatment of epilepsy. Nonetheless, the field has advanced. Two well-designed multicenter clinical trials (Medtronic SANTE and NeuroPace RNS) investigating the feasibility, safety, and efficacy of brain stimulation for treatment of medically resistant focal epilepsy have recently been reported and will be discussed in the following sections.

Cerebellar Stimulation

The cerebellum provides inhibitory outflow and for this reason was an early candidate target for electrical stimulation to treat epilepsy (7,22). In early uncontrolled studies, cerebellar stimulation was reported to yield significant reductions in seizures. An early uncontrolled trial of 115 patients reported 31 patients became seizure free and 56 improved significantly (23). This was a remarkable result and generated considerable interest. However, in a later controlled, double-blinded study of 12 patients, only 2 patients showed improvement (10). The small number of patients studied in the trial limits the ability to draw conclusions.

Caudate Nucleus Stimulation

Chkhenkeli and Chkhenkeli (24) reported a decrease in “interparoxysmal activity” in neocortical and mesial temporal epileptic foci in patients with stimulation of caudate nucleus, but clinical seizures were not investigated.

Mammillary Nuclei

Mirski and Fisher (25) reported an increase in the seizure threshold for pentylenetetrazol-treated rats. However, trials have not been performed in humans.

Centromedian Nucleus of the Thalamus

The CMN is implicated as part of the circuit involved in the generation of spike-and-wave discharges in generalized epilepsy (26). Early studies from Velasco et al. reported significant reductions in seizures for patients with generalized convulsive seizures and atypical absence seizures, but no benefit in patients with complex partial seizures (27,28). Fisher et al. (11) reported the first randomized, controlled trial of CMN stimulation in seven patients. The trial did not show a statistically significant difference between the stimulation ON versus OFF (although one patient showed marked improvement). The trial was a rigorous double-blind, placebo-controlled, crossover design. One patient experienced dramatic benefit, which prevented his crossover to the OFF arm. In addition, in this double crossover design, the possible "carryover" benefit from 3 months of stimulation may have confounded the results. Unfortunately, it is not known if there is a carryover effect from stimulation and if there is the "wash-out" time required for its elimination.

Subthalamic Nucleus

Stimulation of the subthalamic nucleus (STN) for the treatment of essential tremor and Parkinson disease is safe and effective (29). The use of stimulation of STN for epilepsy is based on evidence for a subcortical control network that influences cortical excitability (29). Loddenkemper et al. (30) reviewed the studies supporting the existence of the nigral control of epilepsy system and preliminary results of STN stimulation in animals and humans. There are no controlled trials.

Anterior Nucleus of the Thalamus Stimulation

The antiepileptic effect of stimulation of the anterior nucleus of the thalamus is thought to be mediated by its integral role in the circuit of Papez (2). Sectioning the connection between the mammillary bodies and the anterior thalamus markedly increased the threshold for pentylenetetrazol-induced seizures in guinea pigs (31). Later studies showed that high-frequency electrical stimulation of the anterior thalamus in rats also significantly increased the threshold for pentylenetetrazol-induced seizures (25).

Upton et al. (32) reported an antiepileptic effect associated with stimulation of the anterior nucleus of thalamus. Hodaie et al. (33) reported on five patients who underwent bilateral anterior thalamus stimulation. The patients experienced a 54% mean reduction in seizure frequency, with two patients having approximately 75% reduction. Interestingly, however, there was not a significant difference between the stimulation ON and OFF arms of the trial, perhaps indicating a strong placebo component, carryover confound, or therapeutic lesion from implantation.

Medtronic SANTE Trial

The results from a large multicenter, randomized, controlled trial for SANTE using the Medtronic deep stimulator were reported in 2010 (Figs. 91.2 and 91.3) (15). The SANTE trial investigated the safety, feasibility, and efficacy of duty cycle stimulation of the anterior nucleus of the thalamus. In this well-designed, industry-funded (Medtronic, Inc.) trial, 110 patients were enrolled from 17 centers. Baseline diaries were kept for 3 months, and patients with 6 or greater partial, complex partial, or secondary generalized seizures per month were implanted with bilateral thalamic DBS electrodes and a subclavicular generator. One month after implantation, the patients were randomized to stimulation

ON or OFF. Patients and treating physicians were blinded to whether stimulation was ON or OFF. After 3 months of the blinded trial, all patients entered an open-label trial with stimulation ON. The results showed a 40.5% mean reduction in seizures for the stimulation ON arm compared to 14.5% reduction with stimulation OFF. Significantly, by 2 years, a greater reduction in seizures was seen in the open-label phase of the trial with a 54% responder rate (50% or greater reduction in seizures); 14% of patients were seizure free for at least 6 months (15). Importantly, patients refractory to vagal nerve stimulation (VNS) or epilepsy surgery had the same favorable response to DBS as did the overall group (34). There were no unanticipated side effects, but 5 patients had asymptomatic brain hemorrhage as revealed by neuroimaging. Neuropsychological tests showed no difference in cognition and mood tests, although patients in the stimulated group were more likely to complain of depression or memory impairment. These rates of complication are consistent with other studies that DBS has been used for movement disorders (34). Taken together, this study demonstrated that DBS of the anterior thalamus is useful for some people with medically refractory partial and secondarily generalized seizures.

Hippocampus Stimulation

Velasco et al. (35) reported on 9 patients with a 3-month-baseline seizure count, after which they underwent bilateral hippocampal diagnostic electrode implantation to establish epileptogenic focus laterality and location. Three patients had bilateral, and six patients had unilateral foci. Electrodes were implanted directly into the hippocampal epileptogenic foci. Duty cycle stimulation was delivered using the Medtronic DBS system. Follow-up ranged from 18 months to 7 years. Patients were divided in two groups with normal MRI and MRI consistent with mesial hippocampal sclerosis. Patients with normal MRIs had seizure reductions of >95%, while the four patients with hippocampal sclerosis had seizure reductions of 50% to 70%. Vonck et al. (36) reported on 10 patients with temporal lobe epilepsy and normal MRIs who received duty cycle stimulation to unilateral amygdalohippocampal stimulation. All patients had a >50% reduction in seizures at 5 months.

Tellez-Zenteno et al. (37) reported on a well-designed controlled trial of four patients who had hippocampal stimulation with the Medtronic DBS device and only achieved a 15% median reduction in seizures. All but one patient's seizures improved; however, the results did not reach significance. The authors concluded that there are beneficial trends, some long-term benefits, and absence of adverse effects of hippocampal electrical stimulation in mesial temporal lobe epilepsy. However, the effect sizes observed were much smaller than those reported in nonrandomized, uncontrolled, nonblinded studies. Again, the above results were from small groups of patients. More recently, the results of hippocampal stimulation in the RNS trial were reported to show benefit (see below).

Neocortical Stimulation

The responsive neurostimulator system (RNS NeuroPace) was approved on November 2013 by the FDA for adults with medically resistant focal epilepsy. The RNS includes a cranially implanted programmable device, depth or subdural electrodes, physician programmer, patient data transmitter, and a web-based interactive data repository. A multicenter, double-blind, randomized, controlled trial provided class I level of evidence for safety and efficacy (16). One hundred and ninety-one patients with medication-resistant focal epilepsy were implanted with an RNS. Patients were randomized to receive active or sham stimulation. Specifically, efficacy and safety were assessed

over a 3-month blinded period and a subsequent open-label period during which all subjects received responsive stimulation. Similar to the SANTE study, the RNS device significantly reduced seizure frequency relative to baseline for the actively stimulated group versus sham group (see Figs. 91.2 and 91.4). Moreover, the implant-associated seizure reduction in the stimulated group was sustained in subsequent months and improved over time. The median reduction in seizures at 1 year was 44% and at 2 years was 53%, respectively. The authors also reported that the overall quality of life was significantly improved, and there was no deterioration in any mood or neuropsychological measurement. Importantly, stimulation was well tolerated and also beneficial for the patients who were even intractable to VNS or epilepsy surgery (16).

Seizure Forecasting

Seizure forecasting may prove useful in improving patient safety and guiding acute treatments. Recently, a multicenter clinical study in Australia evaluated safety and feasibility of a long-term implanted SAS designed to predict seizure likelihood and quantify seizures in patients with medically resistant focal epilepsy (Fig. 91.2). Fifteen patients were implanted with the SAS, and a seizure forecasting algorithm was trained on each patient's EEG during a training phase that included at least four seizures and lasted several months. In 11 patients, the device met enabling criteria, that is, the algorithm demonstrated prediction that was better than expected by chance. These patients advanced to an advisory phase, during which the warning device prospectively indicated the likelihood of seizure occurrence. No serious system-related adverse effects were reported in these patients. This small proof-of-concept study demonstrated that seizure prediction is possible and could eventually lead to new therapeutic strategies for epilepsy (14,38).

CONCLUSIONS

Despite the development of numerous new anticonvulsant medications, the number of patients that continue to have seizures with the optimized medical therapy is significant. Devices can provide clinically meaningful benefits in people who have failed medications and less invasive therapies. The potential for therapeutic brain stimulation has attracted considerable attention over the past decades, and the technology is now matured to the point that devices have been studied in clinical trials. There are two well-designed multicenter trials investigating electrical stimulation for the treatment of epilepsy. The results from both trials, SANTE (Medtronic) and RNS (NeuroPace), showed promise as viable therapies for medically resistant focal epilepsy. The safety record from both these device trials of long-term brain stimulation is also very encouraging. Currently, Medtronic device for anterior thalamic stimulation is approved in Europe and Canada, but not in the United States. The NeuroPace RNS device for closed loop stimulation was approved in the United States in late 2013. The next decade will hopefully see the emergence of FDA-approved viable therapeutic devices for patients with epilepsy.

PART VI PSYCHOSOCIAL IMPACT, QUALITY OF CARE, COMORBIDITIES, AND ECONOMICS OF EPILEPSY

CHAPTER 92 COGNITIVE EFFECTS OF EPILEPSY AND ITS TREATMENTS

KIMFORD J. MEADOR

COGNITIVE DEFICITS IN EPILEPSY

As a group, individuals with epilepsy have impaired cognitive performance in comparison to healthy subjects matched for age and education (1); however, considerable intersubject variability exists. Most persons with epilepsy have intelligence in the normal range, and some have superior cognitive abilities. Various factors can have a detrimental effect on cognition in epilepsy patients, including (a) etiology of seizures, (b) cerebral lesions acquired prior to onset of seizures, (c) seizure type, (d) age at onset of epilepsy, (e) seizure frequency, (f) duration and severity of seizures, (g) physiologic dysfunction (intraictal, interictal, or postictal) resulting from seizures, (h) structural cerebral damage as a consequence of repetitive or prolonged seizures, (i) hereditary factors, (j) psychosocial factors, (k) sequelae of epilepsy surgery, and (l) untoward effects of antiepileptic drugs (AEDs).

Patients with new-onset epilepsy may have impaired cognition (1). The etiology of seizures may be one of the strongest factors influencing cognitive abilities (2). Patients with seizures attributable to progressive cerebral degeneration usually exhibit dementia, those with mental retardation have an increased incidence of epilepsy, and those with seizures caused by a focal brain lesion may exhibit a specific neuropsychological pattern of deficits. In contrast, patients with idiopathic epilepsy are more likely to have normal intelligence (2). Seizure syndrome may be strongly associated with cognition. Patients with juvenile myoclonic epilepsy usually have normal intelligence, but children with infantile spasms have a poor prognosis. In general, the earlier the age of seizure onset, the more likely it is that a patient will have cognitive impairment. Additionally, patients with mental retardation are more likely to have refractory epilepsy.

Seizure type, frequency, duration, and severity may affect cognition in several ways. Obviously, cognition is impaired intraictally when consciousness is altered during generalized or complex partial seizures. Epileptiform discharges and postictal suppression may impair cognition interictally. Recent temporal lobe seizures impair memory consolidation, and hippocampal interictal discharges can impair memory recall (3,4). Classic postictal Todd paralysis lasts <24 hours, but postictal cognitive dysfunction, such as dysphasia, may persist for several days. Chronic physiologic dysfunction may also exist well beyond the zone of epileptogenesis. For example, positron emission tomography (PET) scans reveal interictal hypometabolism extending to the lateral temporal cortex in patients with epilepsy caused by mesial temporal lobe sclerosis. Although not true for all seizure types (e.g., absence seizures), repetitive or prolonged seizures may permanently damage the cerebral substrate via anoxia, lactic acidosis, or excessive excitatory neurotransmitters. Even temporal lobe seizures of relatively modest frequency over several decades can increase the severity of hippocampal atrophy and reduce cognitive abilities (5). Although many factors contribute, memory problems are common in patients with epilepsy. Interestingly, the molecular mechanisms of animal

models for epilepsy (i.e., kindling) and memory formation (i.e., long-term potentiation) are very similar (6).

Factors indirectly related to epilepsy may also affect cognition. Hereditary factors strongly influence intelligence; maternal intelligence quotient (IQ) is the most influential factor overall in predicting a child's intelligence. Psychosocial factors may adversely affect cognition through such mechanisms as depression or restriction of environmental influences. Finally, surgical or pharmacologic treatments of seizures may produce adverse cognitive effects.

EPILEPSY SURGERY

Patients who become seizure free from epilepsy surgery have a significant improvement in their emotional well-being and perceived quality of life (QOL), but those who fail epilepsy surgery are at risk for depression and poor QOL. Epilepsy surgery usually does not cause a general cognitive decline because dysfunctional tissue is primarily removed. Surgery may even improve cognition because of reduction in seizures and AEDs. However, clinically significant postoperative cognitive deficits may occur (7). For example, left temporal lobectomy may lead to declines in naming and in verbal memory. However, the risks are largely predictable (7). Risks are greater if the following are present: older age of epilepsy onset, absence of hippocampal gliosis/atrophy, temporal lobectomy in language-dominant hemisphere, high baseline verbal memory for resection on language-dominant side, or absence of ipsilateral dysfunction (e.g., PET, Wada, functional magnetic resonance imaging [fMRI]). Thus, a patient undergoing left temporal lobectomy is at particular risk if the patient has high baseline verbal memory with left cerebral language dominance and lack of evidence of left temporal lobe lesion or dysfunction. High memory performance with right intracarotid amobarbital injection and low with left injection on the Wada test, absence of left temporal lobe PET hypometabolism, or robust left temporal lobe activation on fMRI memory task all suggest increased risk. In contrast, a decline in visuospatial memory is inconsistent following right temporal lobectomy. Rarely, unilateral temporal lobectomy has resulted in a severe global anterograde memory disorder. Fortunately, modern advances in preoperative evaluation techniques have minimized this risk. In addition, selective resections (e.g., amygdalohippocampectomy) may reduce the risk for memory loss compared with standard anterior two-thirds temporal lobectomy, but the effect of selective approaches may be affected by collateral white matter damage (8). Recently, new deficits following anterior temporal lobectomy have been recognized, which include naming of proper nouns (left resection) and recognition of famous faces (right resection) (9). Preliminary data using a new surgical approach (i.e., stereotactic laser ablation of the amygdala and hippocampus) suggest that this technique reduces these deficits as well as classic deficits compared to standard anterior temporal lobectomy and selective amygdalohippocampectomy via craniotomy (10).

STIMULATION THERAPIES

No consistent negative or positive effects of vagal nerve stimulation (VNS) have been seen in patients with epilepsy (11). Fewer studies exist, but no adverse cognitive effects have been found for other stimulation therapies (i.e., anterior thalamic and responsive neural stimulator) (12,13).

ANTIEPILEPTIC DRUGS

AEDs reduce neuronal irritability and thus may reduce neuronal excitability and impair cognition. Because AEDs are the major therapeutic intervention in epilepsy, their cognitive effects are of particular concern to physicians, who must consider the risk–benefit ratio of any treatment. Therefore, differentiating the cognitive effects of AEDs and placing them in the proper perspective are critical to clinical decisions and informed consent.

The most typical cognitive side effects of AEDs include reductions in psychomotor speed, attention (especially sustained or complex attention), dual processing, memory, and for some AEDs naming or word finding. Although all AEDs may impair cognition, such side effects are generally modest, as assessed by neuropsychological tests in patients on monotherapy in whom anticonvulsant blood levels are within standard therapeutic ranges. Furthermore, the cognitive effects may be partially offset by the reduction in seizures. The risk of cognitive side effects rises with rapid initial titration, lack of time for habituation (especially the first several weeks of therapy), polypharmacy, and increasing AED dosages and anticonvulsant blood levels. Decreasing the number of AEDs frequently improves cognition and may reduce the number of seizures. However, the best drug regimen for an individual patient is the one that best controls seizures with the fewest side effects, and for some patients, this regimen may involve polytherapy. The cognitive effects of AEDs can be clinically pertinent, as evidenced by the highly significant inverse correlation of neurotoxicity symptoms and QOL scores (14). Despite the absence of overt toxicity on neurologic exam, patients who have more subjective symptoms of neurotoxicity exhibit lower perceived QOL. Further evidence of the clinical impact is the fact that certain AEDs can impair verbal paragraph memory by 15% to 20% (15) and withdrawal of some AEDs can produce an 11% to 28% improvement on neuropsychological tests (16).

Methodologic Issues

The literature examining the cognitive effects of AEDs must be viewed cautiously, because flaws in experimental design, analysis, and interpretation occur frequently (17). The magnitude of AED effects on standard neuropsychological measures is generally modest and may be missed if appropriate study designs are not used. Errors in experimental design include subject selection bias, nonequivalence of clinical variables, and nonequivalence of dependent variables. Selection bias is a problem when subjects are not randomly assigned to a treatment group or inadequately matched, or if the sample size is inadequate for a parallel-group design. Examples of nonequivalence of clinical variables include the failure to control for anticonvulsant blood levels or seizure frequency. Nonequivalence of dependent measures may occur when there is no assurance that treatment groups performed similarly on dependent measures prior to treatment. Additional design issues include sample size, test–retest effects, characteristics of behavioral tests, and effects of changes in seizures. Issues related to statistical analysis and interpretation include type I and II errors, use of inappropriate statistics, nonorthogonal contrasts, and comparison of studies with nonequivalent designs/statistics. Even when statistically significant findings are apparent, the magnitude and impact of the findings have to be interpreted in terms of clinical significance, taking into account the overall risk–benefit ratio of the AED and the severity of the seizure disorder in question.

Older Antiepileptic Drugs

No cognitive differences were observed between carbamazepine and phenytoin in two studies of

patients with epilepsy using a double-blind, randomized, crossover, monotherapy design, controlling for anticonvulsant blood levels (18,19), but one of these studies also examined phenobarbital and found worse performance for it compared to the other two AEDs. Using randomized, double-blind, crossover designs in healthy volunteers, which controls for the confounding effects of seizures and preexisting brain abnormalities, investigators found no overall difference between carbamazepine and phenytoin (20), but 52% of the variables were significantly worse with AEDs than with nondrug. Other studies have confirmed modest negative effects on cognition with both carbamazepine and phenytoin, but few differential effects (e.g., 21). In a healthy volunteer study (22), 32% of the variables were significantly worse with phenobarbital than with phenytoin or valproate, with the latter two agents being similar to each other, and about half of all variables significantly worse than nondrug condition. Overall, phenobarbital has greater untoward cognitive effects versus other older AEDs, while carbamazepine, phenytoin, and valproate have similar cognitive effects.

Newer Antiepileptic Drugs

Although data are incomplete, the cognitive/behavioral effects for selective studies of the newer AEDs are reviewed.

Gabapentin

Using a double-blind, placebo-controlled, dose-ranging (1200 to 2400 mg/day), add-on, crossover design in patients with partial epilepsy, Leach et al. (23) found no substantial effects of gabapentin. A double-blind, randomized, crossover study of healthy volunteers found significantly better performance with gabapentin versus carbamazepine on 26% of the variables, carbamazepine was worse than nondrug on 48% of the variables, and gabapentin was worse than nondrug on 19% (24). These results have been supported by a subsequent double-blind study in healthy volunteers comparing treatment with carbamazepine and gabapentin (25).

Lacosamide

A retrospective, nonrandomized, open-label study comparing adjunctive lacosamide to lamotrigine and topiramate in patients with epilepsy found that the cognitive effects of lacosamide were comparable to lamotrigine and better than topiramate (26).

Lamotrigine

Several studies with healthy adults demonstrated fewer cognitive side effects with lamotrigine compared with carbamazepine, diazepam, phenytoin, placebo, topiramate, and valproate (27–31). In a clinical trial, lamotrigine had less adverse cognitive effects than topiramate (32). Lamotrigine has positive psychotropic properties as evidenced in bipolar disorder patients and patients with epilepsy (33).

Levetiracetam

A double-blind, randomized, crossover healthy volunteer study found significantly less neuropsychological effects of levetiracetam versus carbamazepine on 44% of variables (34).

Levetiracetam has been noted to have more adverse behavioral side effects compared to gabapentin and lamotrigine (35,36).

Oxcarbazepine

No substantial differences in cognitive effects were found between oxcarbazepine and phenytoin in randomized, double- blind, studies in patients with new-onset epilepsy (37) and in healthy subjects (38).

Rufinamide

A double-blind, randomized, parallel, placebo-controlled, multidose study found no statistically significant cognitive changes for rufinamide (39).

Tiagabine

No significant cognitive effects were reported in a large, randomized, double-blind, add-on, placebo-controlled, parallel- group, dose–response study in patients with epilepsy (40).

Topiramate

In clinical trials, topiramate produced somnolence, psychomotor slowing, memory difficulties, and language problems (e.g., difficulty with word finding and fluency). Factors affecting these adverse effects include titration rate, maintenance time, dose, polytherapy, and individual susceptibility. In a study of patients with epilepsy tested on/off or off/on topiramate, declines in verbal fluency, attention, processing speed, and working memory, but not retention, were seen with topiramate (41). Two randomized, multicenter, double-blind studies of topiramate versus valproate as adjunctive therapy in patients with epilepsy found less-profound neuropsychological effects after slow titration and 8 weeks' maintenance; 1/17 variables (i.e., verbal memory) in one study (42) and 2/30 variables (i.e., verbal fluency and a graphomotor task) in another study (43) were significantly worse with topiramate. A double-blind, randomized, placebo-controlled, 12-week treatment, parallel- group study in healthy adults found that gabapentin had less adverse effects on 50% of the variables compared to topiramate (44). A double-blind, randomized, crossover study in healthy adults with 12-week treatment arms noted worse effects for topiramate on 88% of variables compared to lamotrigine (28). Similarly, a multicenter, double-blind, randomized, adjunctive therapy reported more adverse neuropsychological effects for topiramate versus lamotrigine (32). A double-blind, randomized, placebo-controlled, parallel- group, dose-ranging (64, 96, 192, or 384 mg/day) investigation of weight effects in obese subjects analyzed cognitive effects in a 24-week study (45); significant declines were seen in 12% (64 mg), 8% (96 mg), 15% (192 mg), and 35% (384 mg) of subjects compared to 5% in the placebo group.

Vigabatrin

In several double-blind, randomized, add-on studies of patients with epilepsy (e.g., 63,65), vigabatrin had few adverse effects on cognition or QOL compared to placebo. Abnormal behaviors, including depression and psychosis, have been reported in 3.4% of adults in controlled clinical trials (48).

Zonisamide

Zonisamide impaired cognition, but some tolerance appeared to develop over 24 weeks in a small, preliminary add-on study in patients (49). Long-term cognitive and mood effects of zonisamide were investigated in a randomized, monotherapy, multidose (100, 200, or 400 mg/day), open-label, 1-year investigation (50); after 1 year, 47% complained of cognitive deficits, and dose-related negative effects were seen on delayed word recall, Trail-Making Test, and verbal fluency.

Other Newer AEDs

The data on the cognitive effects of other newer AEDs (e.g., clobazam, ezogabine, perampanel) are inadequate at this time to draw conclusions.

Effects of Antiepileptic Drugs at Age Extremes

Fewer AED studies have been conducted at the extremes of the age spectrum.

Elderly

The increased susceptibility of the elderly to the cognitive effects of a variety of agents is attributable to both pharmacokinetic and pharmacodynamic factors. One study reported comparable cognitive effects of phenytoin and valproate in elderly patients (51). Reanalysis of the original VA Cooperative Study comparing carbamazepine, phenobarbital, phenytoin, and primidone revealed that elderly patients were easier to control but had greater cognitive side effects (52). The results from a VA Cooperative Study in elderly patients with new-onset epilepsy revealed that patients are more likely to remain on gabapentin or lamotrigine compared to carbamazepine (53); this finding was the result of greater CNS side effects with carbamazepine.

Children

Because the cognitive effects of AEDs might be additive over the long-term during neurodevelopment, children may be at higher risk. Unfortunately, investigations in children are inadequate (54). A double-blind, randomized, crossover, monotherapy study conducted in children with epilepsy found performance on phenobarbital was worse than valproate (55). Adverse cognitive effects of phenobarbital have also been found in a placebo-controlled, parallel-group study of children with febrile convulsions (56). Similar to the outcomes of adult studies, comparisons of carbamazepine, phenytoin, and valproate in children have yielded few differences (e.g., 57,58). No statistically significant differences in cognition were observed between oxcarbazepine, carbamazepine, and valproate in an open-label, randomized, parallel-group study in children and adolescents with newly diagnosed partial seizures (59). A randomized, double-blind, placebo-controlled study of adjunctive levetiracetam in children with epilepsy found no cognitive effects of levetiracetam at 12 weeks (60). Children are susceptible to adverse behavioral effects of AEDs. This is best known for phenobarbital, but can be seen with newer AEDs (e.g., gabapentin, lamotrigine, levetiracetam) (61–63).

NEURODEVELOPMENTAL EFFECTS OF IN

UTERO AED EXPOSURE

Multiple factors may contribute to neurodevelopmental deficits in children of mothers with epilepsy, but animal and human data suggest that AEDs play an important role in this regard.

Animal Studies

AED-induced cognitive/behavioral deficits (i.e., behavioral teratogenesis) have been observed in animals at dosages lower than those associated with somatic malformations (64). Phenobarbital produces neuronal deficits, reduces brain weight, and impairs development of normal behaviors and reduces brain catecholamine levels. Prenatal phenytoin produces dose-dependent, long-term, impaired coordination and learning. Significant neurobehavioral effects have been seen with trimethadione and valproate. A recent study has shown a range of behavioral deficits for phenobarbital and phenytoin, but also impaired rotarod performance for adult rats with neonatal exposure to lamotrigine (65).

AED-induced functional and anatomical defects may involve different mechanisms since anatomical risks are related to first trimester exposure, and functional deficits may be related primarily to third trimester exposure. Proposed possible mechanisms underlying functional teratogenicity of AEDs include folate, reactive intermediates (e.g., epoxides or free radicals), ischemia, apoptosis-related mechanisms, and neuronal suppression.

Similar to alcohol, exposure of the immature brain to some AEDs (i.e., clonazepam, diazepam, phenobarbital, phenytoin, vigabatrin, or valproate) can produce widespread neuronal apoptosis (66). The associated cognitive deficits are likely more related to dysfunction in the surviving neurons than the actual neuronal loss. The effect is dose dependent, occurs at therapeutically relevant blood levels, and requires only relatively brief exposure in monotherapy. Valproate's increased risk may occur because apoptosis begins below its typical therapeutic range. Many AEDs have not been tested in this model, but similar apoptotic effects were not seen at therapeutic dosages for carbamazepine, lamotrigine, levetiracetam, or topiramate in monotherapy. However, addition of these AEDs (except for levetiracetam) to an AED that produces apoptosis in monotherapy will increase the apoptotic effect, which may suggest polytherapy risk. These observations in animals raise serious concern that certain AEDs, which are commonly used in women of childbearing potential, could produce similar adverse effects in children exposed in utero or in the neonatal period. Additional studies are needed to examine effects of other AEDs in animal models and determine if a similar mechanism occurs in humans.

Human Studies

Although the risks for birth defects and neurodevelopmental deficits are increased in children of women with epilepsy, the role of AEDs and differential risks of AEDs have been unclear and remain only partially delineated (67). Disparities across studies are partly a result of differences in methodology and patient populations. Formal assessments of mental performance were made in most studies, but in many, it is unclear whether investigators were blind as to AED exposure when assessments were made. In many prospective studies, follow-up began postnatally rather than during pregnancy. In many studies, the influences of possible confounding factors have not been addressed in an empirical fashion (e.g., parental IQ and education, seizure type and frequency, AED dose/blood levels, maternal age/parity, socioeconomic status, and home environment).

The majority of investigations report an increased risk for developmental delay in children of mothers with epilepsy (67). The incidence of mental retardation is increased in children of mothers with epilepsy versus children of mothers without epilepsy, but not in children of fathers with epilepsy versus controls. Animal studies suggest that AEDs play at least a partial role. The risk for mental impairment in children of mothers with epilepsy has been related to intrauterine growth retardation, reduced head circumferences, major malformations, numerous (nine or more) minor malformations, and in utero AED exposure, although contradictory findings have been reported (67).

Two retrospective studies from Denmark (68) examined the effects of in utero phenobarbital exposure on intelligence in adult men of mothers without epilepsy. Men exposed prenatally to phenobarbital had significantly lower verbal IQ scores (about seven points) than predicted in both studies. Lower socioeconomic status and being the offspring of an "unwanted" pregnancy markedly increased the magnitude of negative effects (about 20 IQ points).

A retrospective study of school-aged children exposed in utero to AEDs found that special education was required in 30% of children exposed to valproate monotherapy, compared with 3% to 6% for other monotherapies, and 11% with no drug (69). A prospective study (70) found no effect of carbamazepine; however, the mean IQ of children exposed in utero to valproate was 83, compared to 96 for children exposed to carbamazepine, which did not differ from no drug exposure (IQ = 95), but the monotherapy valproate group was small and maternal IQ was not measured. A long-term prospective study, which controlled for multiple possible confounding factors including maternal IQ, confirmed the increased risk for impaired cognition from in utero valproate exposure (71,72); the IQ of children exposed to valproate was reduced 7 to 10 points compared to children exposed to carbamazepine, lamotrigine, or phenytoin. Valproate also exhibited dose- dependent adverse effects on IQ, language, nonverbal, memory, and executive functions (72). A recent population-based study confirmed prior reports of an increased risk for autistic spectrum disorder in children exposed to valproate (73). Although it is clear that in utero valproate exposure poses a greater risk for both anatomical and behavioral teratogeneses, the risks for other AEDs remain to be fully delineated.

CONCLUSIONS

Patients with epilepsy have increased risk for cognitive impairment. Various factors may contribute, but AEDs are of special concern as the major therapeutic modality for epilepsy. All AEDs can produce some cognitive side effects, which are increased with polypharmacy and higher dosage/blood levels. For an individual patient, the best risk–benefit ratio may be obtained with judicious use of polypharmacy or with anticonvulsant blood level above "standard therapeutic ranges," but physicians should be alert to increased risk under these circumstances. Further, they should be aware that certain AEDs have higher risk to produce adverse cognitive effects (e.g., benzodiazepines, phenobarbital, topiramate) while others have lower risk (e.g., gabapentin, lamotrigine, levetiracetam). Differential behavior effects are also seen (e.g., mood stabilization, depression, irritability/agitation, psychosis) with some AEDs having positive psychotropic effects (e.g., carbamazepine, lamotrigine, valproate) while others have higher risk of adverse effects (e.g., levetiracetam, phenobarbital, topiramate). However, age differences and individual variability occur.

When AEDs are used in monotherapy with blood levels within standard therapeutic ranges, their cognitive effects on formal neuropsychological tests of cognition are generally modest, but can still be clinically significant. Cognitive impairments induced by AEDs may be of particular concern for adults with jobs requiring speed or sustained vigilance and for children in whom the additive effects

during neurodevelopment may have long-lasting consequences. Further studies are needed to examine the relative effects of epilepsy therapies and to delineation cognitive effects for all AEDs, especially at age extremes (fetus, young children, and elderly).

CHAPTER 93 PSYCHIATRIC COMORBIDITY OF EPILEPSY

BETH A. LEEMAN-MARKOWSKI AND STEVEN C. SCHACHTER

Epilepsy is a model for brain–behavior relationships. Seizures affect behavior, and behavior affects seizures. Psychiatric comorbidity is common among patients with epilepsy, the clinical presentation is frequently atypical, and there is often a temporal relationship with seizures. This chapter reviews four of the most commonly encountered psychiatric illnesses in patients with epilepsy: depression, anxiety, psychosis, and personality disorders.

DEPRESSION

Epidemiology

Depression is the most frequently occurring comorbid psychiatric disorder in patients with epilepsy, with a prevalence of 10% to 20% among patients with controlled seizures and 20% to 60% among those with refractory epilepsy (1,2). These rates are significantly higher than in controls, with major depressive disorder (MDD) diagnosed in 4.9% to 17% of the general population. The relationship between seizures and depression is bidirectional, in that the presence of one predicts the other (3,4). Those with depression have a 1.7- to 6-fold higher risk of developing seizures than controls (5,6).

Depression is a better predictor of quality of life in patients with epilepsy than are verbal memory, psychomotor function, cognitive processing speed, mental flexibility, seizure frequency, and seizure severity (7,8). Depression has a negative effect and is associated with more disability, greater social difficulties, more drug side effects, lower employment rates, cognitive dysfunction and subjective memory complaints, and greater use of the medical system (9,10). In patients with epilepsy, morbidity, mortality, and overall prognosis are poorer in those with comorbid depression. Those with psychiatric disease are less likely to attain seizure freedom with antiepileptic drugs (AEDs) or anterior temporal lobectomy (11,12).

Potential risk factors for depression in patients with epilepsy include frequent seizures (>1 per month), symptomatic focal epilepsy, younger age, psychosocial difficulties with learned helplessness, and polypharmacy (13). Depression ratings negatively correlate with the presence of idiopathic generalized epilepsy (IGE) as opposed to other types of seizures (13). Mesial temporal sclerosis (MTS) is a better predictor of the presence of depression compared to other forms of temporal lobe epilepsy (TLE). The effect in focal epilepsies appears to be independent of lateralization of the seizure focus, although studies are conflicting, with some indicating left predominance (14). Frontal dysfunction may have etiologic significance as well. Unlike idiopathic depression, female predominance is not a consistent finding.

Clinical Features

Depression is categorized into MDD, persistent depressive disorder (dysthymia), and other forms such as "other specified depressive disorder" and "unspecified depressive disorder." Criteria for major depression include low mood, feelings of worthlessness, guilt, loss of energy and interest, insomnia or hypersomnia, changes in appetite, psychomotor retardation or agitation, decreased concentration, and suicidal ideation (SI). Approximately 17% to 30% of depressed patients with epilepsy will meet formal criteria for MDD. In persistent depressive disorder, symptoms are more chronic but may be less severe. Other specified depressive disorder and unspecified depressive disorder are diagnosed when presentations do not meet full Diagnostic and Statistical Manual of Mental Disorders (DSM-5) criteria for MDD, persistent depressive disorder, or the other disorders of this diagnostic class.

The clinical presentation in 25% to 71% of depressed patients with epilepsy does not meet DSM Axis I category criteria (15) and may be considered an "other specified" or "unspecified" depressive disorder. Atypical presentations are particularly common in children. The concept of an atypical depression in epilepsy, first noted by Kraepelin and later formalized by Blumer, has been termed "interictal dysphoric disorder" (IDD) (16) or "dysthymic-like disorder of epilepsy" (17). Symptoms resemble those of dysthymia (now termed "persistent depressive disorder"), but occur intermittently, precluding the formal diagnosis of persistent depressive disorder. Patients may have intermittent irritability, depressed or euphoric moods, anergia, insomnia, atypical pains, anxiety, and fears in the setting of clear consciousness. Episodes begin and end abruptly. They may recur every few days to every few months and last from a few hours up to 2 days or more. Onset generally occurs 2 years after the diagnosis of epilepsy. Data suggest an association with mesial TLE. A similar presentation in the setting of limbic lesions, but without overt seizures, has been termed "subictal dysphoric disorder." Depression in epilepsy may represent a continuum, perhaps with persistent depressive disorder, intermittent episodes of IDD, and occasional worsening of symptoms meeting criteria for MDD (18). While IDD may be evident preictally, postictally, premenstrually, or in the setting of forced normalization, symptoms are typically independent of seizure occurrence. Many patients experience an increase in dysphoria over the 12 to 18 months following temporal lobectomy, after which symptoms resolve.

The Seizure Questionnaire (16) may be used to screen for IDD; presence of at least three of the key symptoms warrants the diagnosis. Ongoing treatment is often necessary. Patients with IDD tend to be sensitive to antidepressants, in that drugs are rapidly effective for their broad array of symptoms at low doses.

Major depressive symptoms vary according to the temporal relation to seizure activity. Symptoms may arise prior to seizure onset (preictal), as an expression of the seizure (ictal), following seizures (postictal), or, most commonly, unrelated to seizure occurrence (interictal). Preictal depression is characterized by a dysphoric mood that precedes a seizure by hours or days (19) and usually ends with the seizure. Ictal depression may manifest as a simple partial seizure (SPS) in which depression is the sole symptom or as an aura leading to a complex partial seizure (CPS). Psychiatric symptoms occur in 25% of auras, 15% of which involve affective changes (20). Ictal depression is the second most common, after ictal anxiety or fear, and consists of anhedonia, guilt, and SI. In dacrystic seizures, auras consist of unprovoked and inappropriate crying. The mood alterations with ictal depression are stereotypical and occur out of context. Postictal depression has long been recognized, but its frequency is unknown. In one series, postictal depression was evident in 43% of patients with

partial seizures. Postictal symptoms often persist for hours to several days and may be severe, including SI (21).

Major depression may also develop paradoxically as seizure control or EEG abnormalities improve through medication or surgery, a sequence of events termed "forced normalization." Although many of those with depression will have resolution of their symptoms after epilepsy surgery (22–24), depression may also worsen or occur de novo posttemporal lobectomy (24,25). Postoperative depression often begins acutely within the first month after surgery. In 80% of patients, symptoms will begin within the first year. Risk factors include fear auras. The effect of laterality is controversial, although Quigg et al. (26) suggest higher risk with right-sided resections.

Recent 5-year surgical resection outcome data, however, indicate that long-term, sustained improvement in mood may be attained in those with good seizure control (23). In addition, initial data suggest that radiosurgery and deep brain stimulation (DBS) do not have deleterious effects on mood. No overall mean change in depressive symptoms was evident 2 years after gamma knife radiosurgery for mesial TLE (27). While approximately 15% of patients, nearly all with a prior history of depression, reported depression as an adverse event with DBS of the bilateral thalamic anterior nuclei, there was no difference in mood between control and treated groups on formal testing at 3 months (28). In general, preexisting depression should not be a contraindication for surgical management or device implantation (i.e., vagal nerve stimulation).

Treatment

Depression is both underrecognized and undertreated in patients with epilepsy. An estimated 80% of neurologists (29) do not screen for depression in patients with seizure disorders, perhaps due to unease with its management. Difficulty in recognition of symptoms may also play a role, as many patients present atypically or have confounding side effects of medications. A further limiting factor is the lack of controlled trials for depression in patients with epilepsy. Wiegartz et al. (30) found that 38% of patients with a lifetime history of MDD had never received treatment, and Kanner and Palac (15) observed that treatment was delayed by more than 6 months in 66% of patients with epilepsy and concomitant mood disorders of >1-year duration.

When screening for depression, an initial, simple step is to inquire about anhedonia, which is the inability to experience pleasure. This is an excellent indicator of depression and generally unaffected by drug side effects or underlying medical issues. Consensus guidelines established by the International League Against Epilepsy (ILAE) recommend screening for depression using the Neurological Disorders Depression Inventory for Epilepsy (NDDI-E), Patient Health Questionnaire (PHQ-2), or equivalent measure at the time of diagnosis and yearly thereafter (31). Referral to a psychiatrist, especially one who is knowledgeable about epilepsy, is advisable for diagnosis and treatment, particularly in the setting of bipolar disorder, psychotic features, SI, or symptoms refractory to two antidepressant trials (32).

Before initiating treatment, iatrogenic factors should be considered, such as the recent discontinuation of an AED with mood-stabilizing properties (e.g., carbamazepine [CBZ], lamotrigine [LTG], valproate [VPA], and vagus nerve stimulation [VNS]). Many of the recently approved anticonvulsants also have positive effects on mood. Rufinamide was reported to have mood-stabilizing properties in isolated cases (33), and lacosamide, ezogabine, and perampanel have produced euphoria, particularly at high doses. While clobazam has been associated with depression in some patients, others have reported a "feeling of well-being" with use of this agent (34,35). The

recent introduction or dosage increase of an AED with potential negative psychotropic properties must also be considered (e.g., primidone, phenobarbital [PB], topiramate [TPM], vigabatrin, tiagabine, felbamate, gabapentin, levetiracetam [LEV], or zonisamide [ZNS]), as well as the recent remission of seizures (i.e., "forced normalization"). Phenobarbital exerts particularly negative effects on mood, with 40% of those treated developing depression (36). Risk factors for AED-induced depressive episodes include a personal or family history of mood disorders, anxiety, or alcoholism; severe epilepsy; febrile seizures; polytherapy; rapid titration; and high doses. Addition of an enzyme-inducing AED may also increase clearance of concurrently administered antidepressants, leading to breakthrough depressive symptoms (Table 93.1). If iatrogenic issues are a factor, their correction should be the first step in management. If it is not possible to alter the AED regimen, an antidepressant may be added. In addition, prior to initiation of therapy, patients should be screened for evidence of bipolar disorder to avoid precipitating a manic episode.

Table 93.1 Antidepressants Commonly Used in Patients with Epilepsy

Medication	Initial monotherapy	Hepatic enzyme effects	Interactions with AEDs/ antidepressants	Seizure risk (percent incidence in general population)	Notes
SSRI					
Citalopram	Depression Adults Children	Little effect	↑ TCA levels Levels decreased by CBZ	0.1–0.3 18.0 at 600–1900 mg	Toxicity increased by concurrent LMT Increased risk of prolonged QT with concomitant ezogabine
Escitalopram	Depression Adults Children[a]	Little effect	Levels increased by oxcarbazepine Levels decreased by phenobarbital, primidone	0–0.04	Myoclonus reported with concurrent LMT Increased risk of prolonged QT with concomitant ezogabine
Fluoxetine	Depression—children[b,c]	Inhibitor	↑ DPH levels ↑ Ethotoin levels ↑ CBZ levels ↑ Lacosamide levels ↑ TCA levels ↑ VPA levels (rare) Levels increased by clobazam	0–0.3	Possible anticonvulsant effects Serotonin syndrome; isolated case of Parkinsonian syndrome with concurrent CBZ Long half-life, less withdrawal Toxicity increased by concurrent LMT Increased risk of prolonged QT with concomitant ezogabine
Fluvoxamine	Depression—children[c]	Inhibitor	↑ DPH levels ↑ CBZ levels ↑ Clobazam levels ↑ Ethotoin levels ↑ Lacosamide levels ↑ ZNS levels ↑ TCA levels Levels increased by clobazam	0.05–0.2	Toxicity increased by concurrent LMT
Paroxetine		Little effect	↑ TCA levels Levels increased by clobazam	0.07–0.1	Increased risk of weight gain Short half-life, withdrawal syndrome Toxicity increased by concurrent LMT Not recommended for children
Sertraline	Depression—children[c]	Little effect	↑ CBZ levels ↑ DPH levels (rare) ↑ TCA levels	0–0.3	Increased risk of weight gain Toxicity increased by concurrent LMT
SNRI					
Venlafaxine	Depression—adults		↑ TCA levels Levels increased by clobazam	0.1–0.3 0 with XR formulation 5.0 with overdose	Not for use in young children; may use in older adolescents and those with resistant depression Higher remission rates than SSRI Faster onset of action For somatic symptoms; wide spectrum of action More complicated titration Significant withdrawal Use extended release May cause lethargy, irritability, hypertension Use at half starting dose in elderly
Tetracyclic					
Mirtazapine	Depression—adults		Levels increased by clobazam	0.04	Not for use in young children; may use in older adolescents and those with resistant depression For melancholic features May cause sedation, weight gain Lacks SE of nausea, sexual dysfunction May cause agranulocytosis; do not use with CBZ

For those with peri-ictal depression, improved seizure control may be a sufficient treatment. For patients with resistant peri-ictal depression, interictal MDD, persistent depressive disorder, or IDD, antidepressant treatment is indicated. Antidepressant medications tend to be less effective, however, for peri-ictal episodes. In the absence of controlled trials, the choice of antidepressant should be based upon safety, tolerability, and ease of use (e.g., frequency of dosage, likelihood of drug–drug interactions). If a particular antidepressant was successful in the past for the patient or a family member, another trial of this agent should be considered.

A common misconception is that all antidepressants significantly lower seizure threshold and should be avoided. These fears are largely based upon seizures associated with overdoses, which have little predictive value when levels are within therapeutic range (37,38). Lower doses of antidepressants may in fact have anticonvulsant properties (39). Rate of escalation and duration of treatment may also play a role. Patients with primary generalized epilepsy may have a greater propensity for seizure exacerbation secondary to antidepressants; depression in such patients appears to respond well to low doses of these agents (16).

The medications with substantial risk are few; however, it is prudent to avoid bupropion, maprotiline, clomipramine, and amoxapine because of their potential for exacerbating seizures (39). Seizures due to bupropion are classically generalized tonic–clonic convulsions (GTC), as may be seen particularly in patients with bulimia. The immediate-release preparation presents the greatest concern, with a seizure incidence of 0.36% to 5.8%. The seizure-inducing potential is dose related, and the therapeutic index is low. Maprotiline induces seizures in 12.2% to 15.6% of patients; higher serum levels and longer durations of treatment are the risk factors. The epileptogenicity of clomipramine varies by dose, with seizures in up to 3% of patients taking >250 mg/day. Risk also increases with concomitant VPA, with status epilepticus occurring in some cases. Although the propensity for seizures is lower (0.5%) with doses <250 mg/day, clomipramine is best avoided. Likewise, seizure risk with amoxapine is 36.4%, with reports of status epilepticus.

In contrast, selective serotonin reuptake inhibitors (SSRIs; citalopram, escitalopram, fluoxetine, fluvoxamine, paroxetine, sertraline) are unlikely to worsen seizure frequency or severity and are generally effective for dysthymic disorders, symptoms of irritability, and poor frustration tolerance. Furthermore, an overdose of an SSRI is unlikely to be fatal, interactions with AEDs are minimal, and side effects are manageable. For these reasons, SSRIs are first-line treatments in adults and children with depressive disorders. Women tend to be more responsive than men, however, and sexual dysfunction and weight gain are common adverse reactions. Sexual dysfunction may occur in 70% of those treated with SSRIs. Weight gain is of particular concern when SSRIs are used in combination with AEDs that cause the same effect, including gabapentin, VPA, CBZ, and pregabalin.

Among the SSRIs, sertraline has been best studied. Kanner et al. (17) used sertraline to treat depression in 100 patients with epilepsy. Depressive symptoms improved in the majority of subjects, with seizures definitely worsening in only one patient. Clinicians favor the use of the newer SSRIs, citalopram and escitalopram, due to their lack of hepatic enzyme effects. Fluoxetine and fluvoxamine, in contrast, have enzyme-inhibiting effects that may elevate AED levels. Starting with the lowest dose of an SSRI is recommended, with a gradual dose increase at 1- to 2-week intervals. If a more rapid increase is necessary due to severe symptoms, closer observation is required.

Vortioxetine, approved in 2013, acts as an SSRI, but with additional serotonergic effects, including 5-HT_3 receptor antagonism and 5-HT_{1A} receptor agonism. Seizure induction rates have not yet been published, and data in epilepsy populations are lacking. Vortioxetine levels are decreased

by CYP inducers, including CBZ and phenytoin (DPH). Vilazodone, a newly approved SSRI and partial serotonin 5-HT_{1A} receptor agonist, has not yet been studied in patients with epilepsy. Prescribing information notes that "seizures can occur with treatment," although induction rates were not specified. An isolated case of generalized tonic–clonic status epilepticus was reported in a young child with a toxic ingestion (40). Given such limited seizure-related data and overall experience, vortioxetine and vilazodone are unlikely to be prescribed for epilepsy patients at present.

The tricyclic antidepressants (TCAs; amitriptyline, amoxapine, clomipramine, desipramine, doxepin, imipramine, nortriptyline, protriptyline, trimipramine) are not recommended as first-line agents in patients with epilepsy because of a greater likelihood of side effects and drug–drug interactions. Weight gain and sexual dysfunction are common. Also of concern are the potential for cardiac conduction abnormalities and the greater tendency to induce mania. The anticholinergic effects may exacerbate memory dysfunction in patients with Alzheimer disease as well. Finally, these medications have been shown to increase the risk of seizures in the general population in up to 0.1% to 4% at therapeutic levels and 8.4% to 22% in the setting of overdose (levels >1000 mg/mL). This class of medications is contraindicated in children with epilepsy due to the seizure risk. Imipramine and amitriptyline at dosages ≤200 mg/day, however, do not generally provoke seizures in adults. Imipramine, amitriptyline, and trimipramine may cause epileptiform EEG changes at high doses, although this is not generally accompanied by clinical seizures.

For these reasons, monitoring TCA levels may be helpful, particularly in the setting of polypharmacy or to identify slow metabolizers. Enzyme-inducing AEDs (e.g., phenytoin [DPH], PB, primidone, CBZ) may cause low TCA levels, while enzyme inhibitors (i.e., VPA) may increase TCA levels. Conversely, imipramine and nortriptyline may increase concentrations of DPH, CBZ, and PB, and amitriptyline may increase the volume of distribution of VPA. Drug–drug interactions may be quite complex, at times with increased formation of toxic metabolites but decreased activity of parent compounds. The common recommendation to start at a low dose and increase slowly applies.

The monoamine oxidase inhibitors (MAOIs; rasagiline, selegiline, isocarboxazid, phenelzine, tranylcypromine) are generally safe in patients with epilepsy. They are not often prescribed due to their side effect profile, however, which includes hypertensive crises due to interactions with tyramine-containing foods. The potentially fatal serotonin syndrome may also occur when an MAOI is combined with an SSRI or a TCA, with symptoms including restlessness, myoclonus, diaphoresis, tremor, hyperthermia, and seizures. Although useful for atypical features of depression, these are third-line agents and should be prescribed only by psychiatrists.

Of the selective norepinephrine reuptake inhibitors (SNRIs; duloxetine, venlafaxine), venlafaxine is a first-line agent in adults with depression, particularly for those with melancholic features. Dosages as high as 225 mg/day have been demonstrated to be safe in depressed patients with epilepsy. Lethargy, irritability, and hypertension are the main side effects. Blood pressure elevations are typically seen at higher doses, above 300 mg/day.

Levomilnacipran is a new serotonin and norepinephrine reuptake inhibitor, FDA approved in 2013. An isolated case of seizure activity was reported in premarketing clinical studies, but data regarding use in epilepsy patient populations are not yet available. As with many new psychiatric medications, the drug is not commonly used in epilepsy patients, pending further experience and less expensive generic formulations.

The goal of treatment for depression is symptom remission; those with any residual symptoms have a greater likelihood for relapse. A full response should be evident in 6 to 12 weeks. Continuation of medication is generally indicated for 4 to 9 months. The ILAE consensus guidelines

recommend continuation of treatment for 6 months after recovery from the initial episode and for at least 2 years after recovery from any subsequent episodes (31). If a patient has three or more episodes of depression, residual symptoms, suicidality, psychosis, or an otherwise severe episode, long-term prophylaxis is indicated. Children tend to have high relapse rates, with continuation of symptoms into adulthood (41).

In the elderly, SSRIs and venlafaxine may be used, but dosages should begin at one-half the usual starting dose, and treatment should be continued for at least 2 years in those with frequent or severe episodes (20).

In addition to pharmacotherapy, evidence supports use of cognitive–behavioral therapy (CBT) and interpersonal therapy in those with mild to moderate symptoms, and additional benefit may be attained from combined approaches with therapy plus medication. Psychotherapy can help patients cope with limitations imposed by epilepsy and may result in significant improvements in rating scales of depression and anxiety, as well as seizure frequency (42). Psychoeducation and therapy (e.g., CBT, interpersonal psychotherapy, or supportive therapy) are strongly recommended for children (43).

For refractory depression, alternative regimens may include dopamine agonists and electroconvulsive therapy (ECT), which is particularly useful for refractory depression or acute, severe episodes (e.g., including suicidality, psychosis). ECT is not contraindicated in epilepsy. Dose reduction of AEDs may be required during a course of ECT, and AEDs should be withheld the morning of a treatment unless there is concern for status epilepticus.

The Epilepsy Foundation's Mood Disorders Initiative has made the following recommendations regarding treatment of depression in adults with epilepsy (20):

Stage 1: Monotherapy with an SSRI (citalopram, escitalopram), venlafaxine or mirtazapine, and/or CBT is first-line treatment. If there is an incomplete response, proceed to stage 2.

Stage 2: Monotherapy with a different agent is recommended (another SSRI, a TCA, venlafaxine, or mirtazapine). If there is an incomplete response, proceed to stage 3.

Stage 3: Monotherapy with an SSRI, a TCA, venlafaxine, mirtazapine, or an MAOI is recommended. A medication from a different class than that used in stages 1 or 2 should be administered. Alternatively, combination therapy may be used (TCA with SSRI, TCA with venlafaxine, TCA with mirtazapine, venlafaxine with mirtazapine). If there is an incomplete response, proceed to stage 4.

Stage 4: Combination therapy is recommended (TCA with SSRI, TCA with venlafaxine, TCA with mirtazapine, venlafaxine with mirtazapine). If there is an incomplete response, proceed to stage 5.

Stage 5: ECT.

When transitioning between drugs, an overlap and taper strategy should be used to avoid withdrawal symptoms.

The Canadian Network for Mood and Anxiety Treatments (CANMAT) recently issued general recommendations for the treatment of mood disorders in epilepsy (44), which vary somewhat from the Epilepsy Foundation's guidelines. CANMAT recommendations, for example, suggest lamotrigine as a second-line treatment for depression in epilepsy patients. They also consider the use of folate supplementation, given the concern that AED-associated folate deficiency may contribute to depression. Furthermore, in refractory depression, the authors propose possible VNS implantation.

Suicidality

Though estimates vary, the lifetime prevalence of SI in patients with epilepsy is approximately twice that of the general population, occurring at a rate of about 12%. Suicide attempts occur in 4.6% to 30% of patients with epilepsy, compared to 1.1% to 7% of controls. Patients with seizures are also at greater risk of completing suicide compared to controls: 2.32% to 14% and 0.74% to 1.4%, respectively (45). Elevated risk occurs in children and adolescents with epilepsy as well, with 20% of such children experiencing SI (46).

The prevalence of suicide in epilepsy increases with comorbid psychiatric diagnoses, including depression, psychosis, anxiety, personality disorders, and bipolar disorder (45). Ictal and postictal depression, mania, postictal psychosis (PIP), and command hallucinations present particular risks. In 90% to 95% of patients who commit suicide, prior psychiatric diagnoses were present (45).

Other risk factors include psychosocial stressors, poor physical health, young age in men (25 to 49 years), early age of seizure onset (<18 years, particularly during adolescence), presence of brain lesions, inadequate follow-up or treatment of seizures, access to firearms or other methods of self-harm, and interictal behavioral disorders (i.e., viscosity) (45,47). In TLE, the suicide rate is 25 times higher than in the general population, and a history of epilepsy surgery presents a risk five times of that presented by medical management. Furthermore, cognitive impairment carries a 10 to 25 times greater risk than normal cognition. The degree to which these factors are predictive, however, may differ between men and women (48).

Time periods for particular concern are in the first 6 months after the diagnosis of seizures (49) and within a few months to years of attaining good seizure control after a long history of refractory epilepsy (50). SI may also occur with a temporal relationship to seizure activity. Among patients with refractory seizures, 13% experience postictal SI, lasting 24 hours on average.

Of concern is suicidality associated with AEDs, especially PB (36,48). The risk of SI is 47% in those treated with PB compared to 4% in those treated with CBZ (36). The relationship may be related to dose (48). Patients taking PB should be specifically monitored for the development of SI, and use of the drug should be avoided in those with depression or cognitive dysfunction.

In early 2008, the FDA issued an alert regarding suicidality and use of AEDs (51). Based upon a meta-analysis of 199 placebo-controlled trials including 11 AEDs, they found approximately twice the risk of suicidal thoughts or behavior in those taking AEDs compared to placebo (0.43% vs. 0.22%, respectively). The FDA interpreted the findings as likely representing a class effect, generally consistent across medications. Rates differed, however, between the studied AEDs, and older AEDs were not included in the analysis. The risk began as early as 1 week, and continued to at least 24 weeks, at which time most trials ended. Demographic factors (i.e., age) did not clearly influence risk, although those using the drugs for seizure control had the highest relative risk of suicidality (3.6) when compared to groups taking these agents for other indications. These findings prompted labeling changes. Physicians are encouraged to discuss this issue with their patients and closely monitor those receiving AEDs for onset or worsening of depression.

Assessment should include direct questioning regarding risk factors. Risk for suicide may also be assessed by the suicidality modules of the Mini International Neuropsychiatric Interview (MINI), the Beck Depression Inventory-II (BDI-II), and the Children's Depression Inventory (CDI) (20,45). Physicians need to document the level of risk, interventions, and plans for monitoring. The patient must be kept safe, including the removal of firearms from the home, and may be provided hospitalization until the SI resolves. The clinician should also consider the patient's access to AEDs

and the potential for overdose. The availability of PB, for example, poses great safety concerns. Antidepressants and psychotherapy are helpful, and referral to a psychiatrist is indicated.

ANXIETY DISORDERS

Anxiety disorders include generalized anxiety disorder (GAD), panic disorder (PD), obsessive–compulsive disorder (OCD), phobias, and posttraumatic stress disorder (PTSD). Studies suggest an increased prevalence of GAD, PD, OCD, and phobias in patients with either partial or primary generalized epilepsy, with prevalence estimates of 3% to 66% in patients with seizures and up to 29% in the general population (2). Symptoms of anxiety may be more severe in patients with localization-related epilepsy (52,53), and recent data suggest a particularly high frequency of anxiety disorders in patients with left MTS (66.7%) (32). The association between anxiety and epilepsy is bidirectional, with the incidence of anxiety increased in the years pre- and postepilepsy diagnosis (4). Patients may also have symptom complexes that overlap defined categories. Anxiety may lead to significant distress, and the presence of anxiety in a depressed patient with epilepsy increases the risk of suicide (45).

Generalized Anxiety Disorder

GAD is characterized by excessive anxiety and worry about many issues, occurring almost daily. Patients with GAD may also experience restlessness, fatigue, poor concentration, irritability, muscle tension, and sleep dysfunction. Anxiety in epilepsy most commonly presents as GAD, seen in an estimated 21% of patients with refractory TLE (54).

Anxiety may occur prior to (preictal), during (ictal), or after (postictal) seizure onset. Preictal anxiety may precede the seizure by hours to days. Ictal anxiety is often described as “fear,” occurring as part of the aura in approximately 15% of patients with partial seizures and 33% of patients with TLE. Ictal fear is more common with medial foci than with lateral regions of onset. It has been suggested that ictal fear may signify well-localized anterior TLE and predict a favorable surgical outcome compared to those without ictal fear. Ictal anxiety may also be present, however, with frontal, cingulate, or other limbic-onset seizures. While some authors suggest that fear lateralizes to the nondominant hemisphere (55), this is not entirely clear. Postictal anxiety occurs in an estimated 45% of those with refractory partial seizures. Symptoms last an average of 24 hours and have been likened to a “psychiatric Todd phenomenon.” Those at greatest risk for postictal anxiety include patients with a psychiatric history (21).

Up to 66% of patients with epilepsy report interictal anxiety. While data are conflicting, interictal anxiety does not necessarily correlate with seizure frequency (56,57), and symptoms may develop paradoxically with seizure freedom or reduction (i.e., postoperatively). A shorter duration (<2 years) of epilepsy may correlate with increased anxiety.

Contributing factors include the unpredictability of seizures, psychosocial difficulties, and iatrogenic effects. More specifically, the use of felbamate, vigabatrin, LTG, or TPM may predispose to anxiety, particularly with rapid titration. The withdrawal of AEDs, such as benzodiazepines or PB, may also precipitate GAD, particularly in those with ictal anxiety. Increased anxiety can occur as a paradoxical reaction to SSRIs as well.

GAD may affect quality of life even more than seizure frequency. Anxiety prior to epilepsy surgery is a marker of poorer postresection psychosocial adjustment, perceived memory function, and

health-related quality of life. Hence, the importance of screening should be emphasized to aid in appropriate treatment and presurgical counseling. A number of assessment tools are available, including the State–Trait Anxiety Scale (STAI, revised scale Form Y), Goldberg Depression and Anxiety Scales, the Beck Anxiety Inventory (BAI), the Symptoms Checklist (SCL-90-R), the Hospital Anxiety and Depression Scale, and the Hamilton Anxiety Rating Scale (HAM-A or HARS) (58).

Treatment in patients with epilepsy currently varies little from that of the general population, although no controlled studies have been conducted to date. SSRIs, specifically paroxetine and escitalopram, are first-line agents (Table 93.2). Data also demonstrate efficacy of venlafaxine. Benzodiazepines may be used for insomnia and acute, severe distress, although continuous use should probably be limited due to their addictive properties. Pharmacologic treatments used empirically also include TCAs (i.e., imipramine), trazodone, propranolol, and AEDs. AEDs with anxiolytic effects include VPA, tiagabine, benzodiazepines, barbiturates, gabapentin, pregabalin, phenytoin, oxcarbazepine (OXC), and possibly rufinamide. Mula (59) suggested pregabalin as a first-line agent for acute and long-term maintenance therapy, with paroxetine, imipramine, and venlafaxine as second choices. While buspirone is effective in the general population, this agent should be avoided in patients with epilepsy due to the risk of exacerbating seizures.

Table 93.2 Preferred Agents for the Treatment of Anxiety Disorders

	GAD	PD	OCD	PTSD	Social anxiety
Antidepressants	SSRI Paroxetine Escitalopram	SSRI Sertraline Paroxetine Fluoxetine	SSRI Sertraline Paroxetine Fluoxetine Fluvoxamine	SSRI Sertraline Paroxetine	SSRI Sertraline Paroxetine
	Venlafaxine	Venlafaxine			Venlafaxine
Benzodiazepines	Clonazepam Alprazolam	Clonazepam Alprazolam			
Other anticonvulsants		Valproic acid Gabapentin Oxcarbazepine	Carbamazepine		
Additional agents	Propranolol				

Medications in bold are FDA approved for that indication.

Nonpharmacologic treatment may be helpful in individual cases, including family counseling, supportive psychotherapy, psychoeducational programs, and self-help groups. Although data regarding efficacy are conflicting, CBT may be useful, either adjunctive to anxiolytics or alone, in patients with mild to moderate symptoms. CBT addresses the negative thought patterns that lead to anxiety, followed by desensitization to anxiety-provoking stimuli. In severe cases, anxiety may also be treated by ECT.

Panic Disorder

Panic attacks consist of episodic symptoms including light-headedness, tremor, fear of loss of control or death, paresthesias, shortness of breath, chest pain, palpitations, perspiration, chills, abdominal upset, sensation of choking, derealization, and persistent worry about future attacks. Clinicians must distinguish between seizures manifesting as panic ("ictal panic"), a primary panic disorder (PD), and comorbid epilepsy and PD. Factors favoring the diagnosis of PD include a gradual onset of

symptoms, duration from minutes to hours, and lack of postepisode confusion (Table 93.3). Making the distinction, however, may be difficult. Sazgar et al. (60) identified 4.5% of patients with intractable TLE as having been initially misdiagnosed as PD. Mintzer et al. (61) have adapted the MINI with an "Epilepsy Addendum" that attempts to aid in the distinction between PD and ictal fear. Anecdotally, patients often report that they sense the difference between the two types of spells. Still, seizures may be diagnosed only after a long delay, when progression to more clear complex partial events occurs.

Table 93.3 Differentiation of Panic Attacks and Partial Seizures

	Panic attacks	Partial seizures
Duration of episode	Longer duration, last at least 5–15 min up to several hours	Brief, typically lasting 30 s–2 min
Variability of symptoms	Variable symptoms and sequence	More stereotyped
Consciousness	Preserved	May progress to alteration/loss of awareness
Postevent symptoms	No confusion/amnesia	May have confusion/amnesia
Symptom onset	Slow building of symptoms	Rapid shifts of symptoms
Déjà vu, olfactory or gustatory hallucinations	Rare Hallucinations in psychiatric disease perceived as internal to self, often with associated paranoia	>5% Hallucinations perceived as external to self, without paranoia
Smothering or choking sensation, tachypnea	Common	Rare
Anticipatory anxiety	Common	Uncommon
Associated symptoms (aphasia, gustatory hallucinations, behavioral arrest, automatisms)	Uncommon	May be associated as progress to CPS
Treatment	Response to benzodiazepines, antidepressants; other AEDs occasionally helpful	Response to AEDs, resection May rarely worsen with certain antidepressants (i.e., tricyclics)
Recurrence	More associated with periods of emotional upset; occur in wakefulness	Sporadic; may occur during sleep
Agoraphobia	50%	No association
Family history	25.1% first-degree relatives with panic disorder	Uncommon
Palpitations	Tachycardia	Brady- or tachycardia
Paresthesias	Perioral, distal extremities associated with hyperventilation	May be generalized although bilaterality rare; often focal, unilateral
EEG	Usually normal	Often abnormal
MRI	Usually normal	Lesions common
Age of onset	Most often 20–30 y	Any age

An estimated 21% of patients with epilepsy have comorbid PD (62), in contrast to a prevalence of PD in 1% to 3.5% of the US general population. The comorbidity may occur in up to 33% of patients with ictal fear (61). PD may emerge or worsen after epilepsy surgery, particularly in those with ictal fear. The incidence of PD in epilepsy appears to increase with age.

Seizures manifesting as panic are uncommon. When present, ictal panic is most often associated with right midanterior temporal lobe onset. One study suggested that ictal panic is particularly rare in patients with extratemporal lobe seizures, with no cases observed in a series of 72 such patients (60). Isolated case reports, however, suggest that ictal panic may occur with left parietooccipital lobe– (63), right parietal lobe– (55), and left temporal lobe–onset seizures (64).

Panic attacks may also present as a postictal phenomenon. Like other forms of postictal anxiety, symptoms last 24 hours on average and are predicted by psychiatric history and relatively low

seizure frequency.

PD can cause significant distress, and proper treatment should be initiated upon diagnosis. Serotonergic medications and benzodiazepines are the agents of choice (65). FDA-approved medications for the treatment of panic include sertraline, paroxetine, fluoxetine, venlafaxine, clonazepam, and alprazolam. The role for other anticonvulsants in the treatment of PD is unclear, although VPA, gabapentin, and OXC may be helpful. In a recent review, Mula (59) recommended an SSRI and CBT in combination during the acute phase, with a TCA and CBT as a second choice. For long-term maintenance, either SSRI–CBT combination therapy or CBT alone was suggested. Of note, hyperventilation/deep breathing during CBT is contraindicated in patients with PD and epilepsy, per ILAE guidelines (31).

Obsessive–Compulsive Disorder

OCD manifests as obsessive thoughts or repetitive, ritualistic behaviors, typically carried out in order to neutralize anxieties or prevent imagined negative events. The prevalence of OCD in the general population is estimated at 1% to 3%. Limited data suggest an increased frequency of OCD in patients with seizures, with studies demonstrating prevalence between 10% and 22% in patients with TLE (32,66,67). Several case reports also document the co-occurrence of OCD and epilepsy in patients with temporal lobe (68,69), anterior cingulate (70), frontorolandic (71), and primary generalized (72) seizures. Data regarding an association with lateralization of the seizure focus, however, are conflicting. In a study of patients with TLE and IGE, common obsessions included those related to symmetry or exactness, contamination, and aggressiveness, while common compulsions included ordering, washing, and checking (67). Interictal personality characteristics associated with TLE, such as attention to detail or hyperreligiosity, may also be viewed as a mild form of obsessions or compulsions.

OCD in the setting of epilepsy, however, remains underrecognized. In a series of nine patients with TLE meeting criteria for OCD, only one had been previously diagnosed (66). Barbieri et al. (68) described a patient who experienced symptoms of OCD for 17 years and never informed her physicians. These cases underscore the importance of screening and the involvement of neuropsychiatrists in epilepsy clinics. Depression and anxiety are common in patients with epilepsy and obsessive–compulsive symptoms (73), and it is important that these comorbid conditions do not obscure the diagnosis of OCD.

Male sex, older age, earlier age of seizure onset, longer duration of epilepsy, focal-onset seizures, and poor seizure control have been associated with more severe symptoms (73), although the effect of epilepsy duration is controversial. Surgical resection may either ameliorate or worsen symptoms of OCD. Rare cases of postsurgical de novo OCD have also been reported (74).

No controlled trials have evaluated the treatment of OCD in patients with epilepsy, and no consensus regarding management exists. Patients are best managed by an experienced psychiatrist. Idiopathic OCD may be treated with psychotherapy and antidepressants, with SSRIs as first-line medications. When using antidepressants, high doses are often required, with monitoring for seizure exacerbation, side effects, and drug interactions. Although one case report documented a 50% improvement in symptoms, many attempts at nonpharmacologic, behavioral treatments have met with limited success in patients with comorbid seizures (69). Nevertheless, Mula (59) recently recommended CBT as the first choice for acute and long-term treatment in epilepsy patients, with the second choice being CBT with sertraline, followed by CBT with clomipramine, when drug treatment

is needed in severe or refractory cases. Successful treatment with CBZ or OXC has also been reported (72). Koopowitz and Berk (72) suggested that comorbid epilepsy may predict better response of OCD symptoms to AEDs than antidepressants, although many other case reports document a lack of effect.

Phobias

Phobias occur in 20% of patients with epilepsy. An estimated 8% to 9% of patients with refractory TLE have agoraphobia and 29% have social phobia (54). Underlying cognitive deficits, low self-esteem, depression, family psychiatric history, and lack of social support may predispose to phobias.

Rare, and perhaps unique to epilepsy, is a "seizure phobia" in which patients fear future seizures. Patients may specifically fear resultant death or brain damage and relive prior seizures. Patients may develop agoraphobia or social phobia, stemming from fear that others would observe their seizures if they were to occur in public. While phobias are typically an interictal phenomenon, some patients experience postictal agoraphobia. The degree of anxiety may parallel the perceived severity of seizures.

Such phobias may be successfully treated by CBT in addition to other forms of counseling and seizure education (75). Caution should be used in the prescription of benzodiazepines, given concerns that they may lead to dependence and avoidance of the deeper cognitive–behavioral issues.

PSYCHOSIS

Epidemiology

The risk of psychosis varies with epilepsy syndrome, seizure severity, and seizure frequency. Incidence rates of psychosis are increased in patients with epilepsy, both before and after the onset of seizures, suggesting a bidirectional relationship (4). Psychosis is reported in 0.6% to 7% of patients with epilepsy in the community and in 19% to 27% of hospital-derived populations (76). The overall frequency of psychosis among patients with epilepsy is approximately 7% to 14%. Most studies indicate a predilection for those with TLE (15.8%), particularly those with left MTS (77,78). Reports of an association with other localization-related epilepsies indicate, less commonly, a relationship with left frontal lobe–onset seizures (79). In addition, a prevalence of 3% to 5% has been documented in patients with IGE.

Diagnosis

Preictal or ictal psychosis is rare. Shukla et al. (80) described a series of patients with intractable right temporal or frontotemporal seizures and preictal psychosis. Symptoms consisted of hallucinations, delusions, affective changes, heightened religiosity, and abusive behavior lasting from 12 hours to 15 days prior to habitual seizures. The psychotic features resolved after each seizure.

During seizures, patients may experience visual or auditory illusions and hallucinations, paranoia, depersonalization, derealization, autoscopy, or a sense of someone lurking behind them. As with most partial seizures, symptoms typically last <3 minutes duration. Prolonged ictal psychosis is rare but may be evident in the setting of nonconvulsive partial or absence status. Often, such patients have a corresponding central nervous system (CNS) lesion (i.e., tumor) (81). Prolonged psychosis and

seizures in the setting of unresponsiveness, dyskinesias, autonomic instability, and hypoventilation, particularly in women, should prompt consideration of an anti–NMDA receptor antibody encephalitis.

The most common form of psychosis occurs between seizures (interictal) (82). Interictal psychosis is present in up to 9.4% of patients with MTS. Average age of onset is approximately 25 to 30 years (83,84), at a mean of nearly 15 years after the first unprovoked seizure (83). Earlier onset of psychosis is associated with generalized epilepsy and a positive family history of psychosis (83). Symptomatology appears to be similar across epilepsy syndromes (78). Features resemble that of schizophrenia, with persistent or recurrent positive symptoms, such as delusions and visual or auditory hallucinations, in the setting of otherwise clear consciousness (85,86). Themes are often persecutory or religious and may have strong affective components. Common associated affective changes include irritability, depression, and aggressive behavior. As in schizophrenia, symptoms may be insidious in onset. Episodes tend to be long-lasting, but may vary in duration, from minutes to years. The mean duration in a study of 155 patients was approximately 80 weeks, with half of the episodes lasting 4 months or longer. The duration tends to be shorter with advancing age (84).

Many key differences to schizophrenia, however, have prompted the term "schizophrenia-like psychosis" of epilepsy (86). Compared with the psychosis of schizophrenia, patients with interictal psychosis often have an absence of negative symptoms or formal thought disorder, better premorbid states, and less deterioration of personality (87), although more recent data suggest that most patients with epilepsy and psychosis will have at least one negative symptom (78). Patients with psychosis related to epilepsy also have a slightly older age of onset compared to those with schizophrenia, with symptoms beginning in the mid-20s to mid-30s (83,84,87,88). Those with epilepsy-related psychosis are more likely to be male, as opposed to patients with schizophrenia (87). Patients with interictal psychosis may also have a better prognosis, with a tendency for remissions and positive responses to treatment (87).

In some patients, a positive correlation exists between overall seizure frequency and psychotic symptoms. A notable exception to this pattern, however, is the concept of "forced normalization" or "alternative psychosis" introduced by Landolt in 1953 (85). Although evident with other psychiatric disorders as noted above, forced normalization is classically associated with psychotic behavior. The patient may have periods of psychosis coinciding with improved seizure control or reduced epileptiform discharges on EEG, often seen with the addition of a new AED. Such periods may alternate with epochs of improved psychiatric function in the setting of a paradoxical increase in seizure frequency or abnormalities on EEG. The underlying pathophysiology is unclear. As Nadkarni et al. (81) note, the psychosis may also be a reaction to the new drug, with improved EEG patterns representing an epiphenomenon. AEDs associated with psychosis include DPH, LEV, TPM, ZNS, tiagabine, ezogabine, perampanel, and vigabatrin (82,89–93). Although generally well tolerated, a case of lacosamide-induced psychosis was also recently reported (94). Forced normalization has been documented with other treatments as well, including VNS (95).

De novo psychosis after epilepsy surgery has also been reported, with rates varying from <1% to 28.5%. Symptoms most often occur transiently after surgery, and the diagnosis may be easily missed. The time period of greatest concern is the first 6 months after resection. Risk factors include a family history of psychosis and surgery after 30 years of age. Some authors suggest an increased incidence in those undergoing nondominant temporal resections, although this is not a consistent finding. Etiology of epilepsy does not appear to affect risk assessment (81). While preoperative psychosis is a risk factor for postoperative psychosis, it should not pose a contraindication for surgery, as long as the

patient has appropriate psychiatric care, can cooperate with evaluation and treatment, and understands associated risks and benefits (31).

PIP is less common, occurring in 6.4% of patients with MTS (77). It typically presents after a cluster of seizures or status epilepticus, oftentimes in someone whose seizures were otherwise well controlled. PIP after a single seizure is rare. Symptoms often begin after 24 to 48 hours of normal baseline behavior, a period termed the "lucid interval." Episodes may last a few days to several weeks, terminating within 1 to 2 weeks on average. Approximately 95% of episodes will resolve within 1 month. A history of interictal psychosis, a family history of psychosis, and low intellectual functioning predict a longer duration of symptoms (96). Symptoms may include visual or auditory hallucinations, paranoia, delusions, confusion, affective changes, violence (i.e., suicidal acts), and amnesia (76,97,98). Religious or grandiose themes among hallucinations and delusions are common, while thought insertion, commenting/command hallucinations, and negative symptoms are rare. Most religious conversions occur during this period.

It is important to distinguish between PIP and postictal mania, as treatment options differ (Table 93.4). The two entities may be easily confused, as both may involve manic features and exhibit a similar lucid period. Logsdail and Toone (97) suggested the following diagnostic criteria for PIP:

1. An episode of psychosis developing within 1 week of a seizure or cluster of seizures
2. Lasting ≥24 hours and ≤3 months
3. Characterized by disorientation, delirium, delusions, or hallucinations in clear or clouded consciousness

4. Without AED toxicity, nonconvulsive status on EEG, prior interictal psychosis, recent head trauma, or alcohol/drug intoxication

Possible risk factors for PIP include age >30 years; male gender; focal-onset seizures; bilateral onset (often bitemporal) or spread of seizures (i.e., secondary generalization); a history of status epilepticus; prior encephalitis or other widespread CNS injury, borderline intelligence; EEG slowing; psychiatric illness; clusters of seizure activity; presence of ictal fear; and a family history of mood disorders, alcohol use, or epilepsy (98–101). Age at seizure onset and seizure frequency may not be predictive, although data are conflicting. These patients tend to have complex presentations, in that bitemporal dysfunction on neuropsychological testing may be greater than expected based upon structural imaging, and seizure onsets on video–EEG monitoring are often nonlateralizing (101). Postictal psychoses typically develop after at least 10 years of epilepsy and occur almost exclusively in adults, with the mean age of onset 32 to 35 years. Recurrent episodes have been documented in 12% to 50% of cases. As the frequency of psychotic episodes increases, the risk for developing chronic interictal psychosis becomes greater (81). In a series of 18 patients with PIP, 39% also experienced interictal psychosis (102).

Treatment

The first step in treatment is identification of the problem. Patients may not report their symptoms; hence, direct questioning is necessary. As "psychotic episodes may beget psychotic episodes," once identified, symptoms should be treated immediately (81). On average, earlier antipsychotic administration significantly shortens episode duration (84).

For those with peri-ictal psychosis, optimal seizure control is advised. Symptoms may resolve with treatment of the seizures (i.e., with resection) (79). Antipsychotic medications are the mainstay of management for both acute episodes and prevention, as long-term treatment may be necessary for patients with interictal or frequent peri-ictal episodes (Table 93.5). The ILAE guidelines make specific recommendations regarding the duration of treatment, suggesting a taper after 5 days for brief postictal psychotic episodes, a taper after 1 to 2 months when PIP lasts more than a few days, and long-term continuation for interictal psychosis (31). Some patients require psychotherapy, day treatment programs, case managers, or assisted living facilities, as well (81). ECT may be helpful in refractory cases. Patients with psychosis are best referred to epilepsy centers with teams that include psychiatrists and social workers.

The "positive symptoms," such as delusions, hallucinations, and disordered thinking, respond best to medications. The "negative symptoms," such as apathy, social withdrawal, and catatonia, are notoriously difficult to treat but may respond to the newer, atypical antipsychotics. In general, patients with psychosis associated with epilepsy have better response rates than patients with schizophrenia, with lower initial and maximum doses. These findings were likely due in large part, however, to better compliance (87).

The older, typical antipsychotics carry a greater risk of seizure exacerbation, with seizure induction rates of 0.5% to 1.2% in the general population. Risk is increased by a history of seizures or abnormal EEGs, CNS disorders, rapid titration, high doses, and the concomitant use of other drugs that lower the seizure threshold (103). Hence, the atypical antipsychotics, with lower epileptogenic potential, are preferred. Due in part to a lack of controlled studies, specific treatment decisions are individualized and based upon side effect profiles. Of note, all of the atypical antipsychotics carry some risk of weight gain, hyperlipidemia, and type 2 diabetes mellitus. New data also suggest an increased risk of sudden cardiac death (104). Blood glucose and lipid profiles must be followed, particularly in those taking AEDs that are associated with weight gain (e.g., VPA, gabapentin, pregabalin, and CBZ). One may also consider checking pre- and posttreatment EKGs for evidence of prolonged QT intervals (105).

Ziprasidone is the most common agent used to treat postictal and interictal psychosis, followed by quetiapine and aripiprazole (81). Although an isolated case of frequent GTC seizures associated with aripiprazole was recently reported (106), the drug has an overall low seizure-inducing potential. Other options with relatively low rates of seizure induction include risperidone (107) and olanzapine. The new atypical antipsychotics, lurasidone, iloperidone, and asenapine, have low rates of associated seizures but are not often prescribed. Older agents are generally preferred as they have equal efficacy, but are more familiar, available as low-cost generics, and included on hospital formularies. In addition, lurasidone is contraindicated in the setting of many AEDs due to drug–drug interactions, which may limit its use. Among the typical antipsychotics, haloperidol appears to be the safest. Other typical agents with lower seizure-inducing potential include molindone, fluphenazine, perphenazine, and trifluoperazine (103). Lorazepam may also be used in conjunction with an antipsychotic for acute exacerbations and reinforcement of sleep schedules.

Clearly, psychotropic agents that are associated with a high incidence of seizures in nonepileptic patients should be avoided. These include the antipsychotics clozapine, chlorpromazine, and loxapine. Many antipsychotics can cause slowing of the EEG waveforms, particularly at higher doses. Clozapine, however, can cause frank epileptiform discharges. While these spikes and sharp waves are not predictive of seizure occurrence, severe disorganization of the EEG background may be a harbinger of seizures. Whether concurrent use of AEDs will protect against seizure-inducing potential is unknown. The adage "start low, go slow" applies to all antipsychotics.

Forced normalization is a unique entity, in that a breakthrough seizure may resolve the psychotic symptoms. In such patients, the goal of seizure freedom must be balanced by the risk of potentially disabling psychiatric disease. Seizure freedom may not be ideal for such patients. As Landolt stated, "there would seem to be epileptics who must have a pathological EEG in order to be mentally sane." For those with forced normalization due to VNS, decreasing the pulse intensity can improve symptoms (95). In the setting of forced normalization or drug-induced psychosis, gradual withdrawal of medications may be necessary, and antipsychotics, antidepressants, and anxiolytics may be used.

PERSONALITY DISORDERS

The association between epilepsy and certain personality characteristics dates back to Hippocrates in 400 BC. Reports suggest that up to 69% of patients with TLE and 72% of patients with generalized epilepsy suffer from personality disorders (PSD) (108). DSM-5 cluster B and C disorders, particularly borderline, dependent, and avoidant PSD, are typically cited as the most common. In a series of patients with juvenile myoclonic epilepsy (JME) (109), 14% had PSD, including borderline (6%), dependent (3%), histrionic (1%), and obsessive–compulsive (0.6%) PSD, as well as 3% with PSD not otherwise specified.

Perhaps more controversial is the notion of a specific personality type in the setting of TLE, thought to occur in 7% of TLE patients (110,111). In 1975, Waxman and Geschwind formalized the concept of an "interictal behavioral syndrome," alternatively termed "Geschwind syndrome" or "Gastaut–Geschwind syndrome," which consisted of deepened emotions, circumstantiality, hyperreligiosity, hyposexuality, and hypergraphia. Gastaut suggested that this cluster of personality traits was the opposite of that exhibited by patients with Kluver–Bucy syndrome. Bear and Fedio later expanded the cluster of traits to include the 18 items listed in Table 93.6. The most significant differences in patients with TLE compared to nonneurologic controls were in humorlessness, circumstantiality, dependence, and sense of personal destiny. These are not necessarily negative, pathologic, or maladaptive traits, but rather a constellation of often subtle behavioral changes. The alterations in personality tend to develop gradually, after at least 2 years of seizures (111).

These behavioral characteristics may correlate with mild intellectual impairment and AED

levels. The effect of laterality in TLE is likely minor, with mixed results (112,113). An observed trend is for those with right temporal foci to report more emotional traits and minimize their difficulties, while those with left temporal foci endorse more aberrant behaviors thereby "tarnishing their image" (110).

While much of this discussion focuses on patients with TLE, those with other localization-related epilepsies or IGE may have personality changes as well (110). Patients with anterior cingulate seizures can demonstrate aggressive, sociopathic, irritable, obsessive–compulsive, or impulsive traits (110). Orbitofrontal epilepsy may be characterized by abnormal emotionality, aggression, disinhibition, and confabulation. Patients with typical absence epilepsy may have poor social relationships, particularly in the setting of ongoing seizures. Patients with JME may exhibit irresponsibility, poor impulse control, self-interest, emotional instability, exaggeration, denial, inconsiderate behaviors, and distractibility (110,114,115). These characteristics in a patient with JME may lead to indifference toward illness, poor lifestyle choices, and a failure to learn from past mistakes, leading to perpetuation of the seizure disorder.

Not all studies, however, have found specific personality traits or disorders related to seizure localization. Although scores on PSD inventories are often higher in TLE than in generalized epilepsy, this is not a consistent finding. Nor are there consistent differences in personality measures between patients with temporal and extratemporal lobe seizures (113). The development of specific personality traits and disorders is clearly multifactorial, and while data are often conflicting, factors including prior psychiatric diagnoses, family psychiatric history, female sex, lower educational level, greater seizure frequency, occurrence of CPS and auras, longer duration of epilepsy, earlier age of seizure onset, and AED polytherapy likely play roles as well (112,116–118).

Symptoms of presurgical PSDs typically fail to improve postoperatively, and PSDs may also develop de novo after epilepsy surgery (116). In addition, preoperative PSD may herald the development of other postoperative psychiatric complications, that is, de novo affective disorders. Identification of preoperative PSD may also be important with respect to prediction of seizure outcomes, as their presence in patients with MTS correlates with the persistence of auras (Engel class 1B) and initial disabling seizures followed by seizure freedom (Engel class 1C) after temporal lobectomy (119).

A number of instruments are available for the evaluation of PSD. Administered most commonly is the Minnesota Multiphasic Personality Inventory-2 (MMPI-2). The Bear–Fedio Inventory (BFI), evaluating the characteristics outlined in Table 93.6, has been used less often in recent years. Other self- report batteries include the Questionnaire on Personality Traits, Neurobehavioral Inventory (NBI, a revised version of the BFI), Neurobehavioral Rating Scale (NBHRS), Overt Aggression Scale, Freiburg Personality Inventory/Form A (FPI-A), Index of Personality Characteristics (IPC), and Millon Behavioral Health Inventory (MBHI) (110).

When personality traits impair function and quality of life, treatment should be considered. Unfortunately, treatment options for PSD are limited. Patients may be referred for long-term psychotherapy, although little data formally support its use in epilepsy patients (110). Therapy is often challenging, and complicated by a lack of patient insight. Empathy and reassurance during clinic visits will aid in developing rapport and ensuring adherence to treatment regimens. In patients with JME, the need for self-control, treatment compliance, and healthy lifestyle choices should be stressed (120).

It is important, though difficult, to distinguish those behavioral components due to psychological comorbidities of the epileptic disorder from effects of underlying lesions, medications, or other

behavioral issues. It may also be challenging to differentiate between the ictal, preictal, interictal, and postictal states, as boundaries may be indistinct. Studies are further confounded by difficulties in identifying the focus of onset and degree of spread of abnormal activity, particularly when using routine scalp recordings. Differing criteria for the diagnosis of a behavioral disorder, varying definitions of the epilepsy or control populations, and small sample sizes make studies complicated to interpret or compare. Furthermore, none of the symptoms above are pathognomonic for any one seizure subtype or even to epilepsy as a whole. For these reasons, identification of a personality syndrome specific to TLE has met with criticism (121).

Aggression

Aggression and hostility have been documented in approximately 5% of patients with epilepsy (110,122). In more selected groups and prisoners with TLE, interictal aggressive behavior is present in up to 56% of patients. Nevertheless, aggressive behavior is likely underdiagnosed due to underreporting and a lack of appreciation that the behavior may constitute a treatable disorder.

Although classically associated with TLE and lesions of the amygdala, patients with JME, Lennox–Gastaut syndrome, anterior cingulate seizures, and orbitofrontal epilepsy may also demonstrate interictal aggression. Such behavior is more likely in men and children. Onset of epilepsy before 10 years of age, disability, traumatic brain injury, psychosis, cognitive deficits, fewer years of formal education, lower IQ, and lower socioeconomic status are possible risk factors (123–125).

The association between aggression and epilepsy may relate to common limbic pathways or psychosocial factors. Seizure treatments are also important contributors. Because AEDs may indirectly cause aggressive behavior as a consequence of forced normalization (126) or disinhibiting, anxiogenic side effects, iatrogenic causes should first be considered. Agents causing irritability or aggression include PB, LEV, perampanel, clobazam, and gabapentin, particularly in children and patients with learning disabilities. Effects of LTG, vigabatrin, and TPM are variable, with reports indicating either increased or decreased aggression with use of these agents. Aggressive behavior has also been noted after resection for refractory TLE (127).

Interictal aggression may be evident as a symptom of depression, psychosis, or the more controversial IDD in which patients have “paroxysmal affects” ranging from mild irritability to rage. When in association with interictal psychosis, the aggression is often directed toward imaginary enemies resulting from hallucinations and delusions, rather than surrounding bystanders.

Aggressive behavior may also occur with a temporal relationship to seizures. Some patients exhibit irritability and aggression in the minutes, hours, or days leading up to a seizure (preictal) (19). Ictal automatisms may include stereotyped kicking, boxing, biting, scratching, or other forceful movements. Directed, purposeful, violent behavior during seizures (ictal), however, is rare (122,128,129). Violent crimes are typically too complex to result from the simple, brief automatisms associated with ictal activity. In 1981, an international panel established five criteria to determine whether a crime may result from seizure activity, which are still referenced today (128). These include the following:

1. The diagnosis of epilepsy, established by at least one neurologist with competence in epilepsy
2. Epileptic automatisms documented by history and video–EEG monitoring

3. Aggressive behavior during the epileptic automatisms, confirmed by a video–EEG recording demonstrating ictal discharges
4. Aggressive behavior characteristic of the patient's typical seizures during the ictal EEG
5. Determination by a neurologist that it was possible for the crime to result from a seizure

Postictal aggression is the best recognized entity. Postictal violent behavior may result from attempts at physical restraint, termed "resistive violence" (130). The behavior is typically associated with impaired consciousness or confusion and is most frequently seen in those with CNS pathology (e.g., prior head injury or CNS infection), mental retardation (MR), and psychiatric illness. Self-injury is more often evident in patients with developmental disabilities. Violent behavior may also occur in association with PIP (131,132), during which aggression may be more purposeful and directed toward those nearby in response to hallucinations or delusions.

Subacute postictal aggression (SPA) consists of stereotyped, directed violent or verbally abusive behavior beginning several minutes to hours after a seizure (133). Episodes may occur after waking from postictal sleep and are unrelated to ictal discharges or postictal confusion. The episodes are brief, lasting 5 to 30 minutes. Curious features include at least partially retained awareness and remorse after the episode. SPA tends to occur many years after the onset of epilepsy, in patients with long-standing refractory partial seizures and extensive neural dysfunction. These episodes are more common in men and in patients with TLE and secondary generalized seizures. SPA is not a well-recognized clinical entity and must be differentiated from the more common PIP.

Treatment depends upon the severity of the behavior and the temporal relationship to seizures. Ictal aggression should respond to AEDs. Postictal resistive violence is best treated by avoiding or limiting physical restraint during the postictal period (130). The treatment of interictal aggression is less certain, as it does not necessarily improve with seizure freedom and controlled studies are lacking. AEDs (particularly CBZ, LTG, and VPA), antidepressants (i.e., SSRIs), and atypical neuroleptics (e.g., olanzapine, risperidone, quetiapine, and ziprasidone) have been used empirically. Valproic acid, however, may also cause paradoxical irritability. Beta-adrenergic receptor blockers, including propranolol, nadolol, and pindolol, provide alternative treatment options. Drug interactions are of concern, however, as beta blockade may be increased by SSRIs and decreased by CBZ. Amphetamines may be effective for the treatment of impulsivity and aggression, and are generally safe for use in epilepsy, although methylphenidate has been reported to increase seizure frequency in isolated cases. Lithium may be used for treatment of aggression and agitation, although patients with brain injuries are particularly sensitive to its neurotoxic side effects. Encephalopathy has also been noted with concomitant use of CBZ. While lithium has been used safely in patients with epilepsy and bipolar disorder, it is not generally recommended as initial therapy because of its potential for seizure exacerbation and induction. Similarly, while buspirone is effective for aggression in the general population, its use is discouraged in patients with epilepsy. Removal of anxiogenic agents and treatment of coexisting mood disorders should be pursued. Behavioral therapy may also be helpful, and psychiatric hospitalization should be considered for patients at risk for impulsive, potentially self-injurious behavior (130). For acute episodes, benzodiazepines and antipsychotics are recommended.

SUMMARY

Psychiatric disease is common and significantly impacts quality of life in patients with seizures.

Physicians must actively screen for these disorders, and proper treatment is essential.

Depression, the most common comorbid psychiatric disorder in epilepsy, negatively affects quality of life and increases the risk for suicide. Unfortunately, depression in epilepsy remains underrecognized and undertreated. Many patients present with atypical symptoms, and establishing a diagnosis may be challenging. The importance of screening and treatment for depression in this population, however, should be emphasized. The myth that all antidepressants significantly lower seizure threshold and should be avoided must be dispelled.

Anxiety disorders also occur more commonly in patients with seizures than in the general population. Symptoms typically manifest as GAD and may occur inter- or peri-ictally. Comorbid PD may be present in the setting of epilepsy and must be distinguished from seizures manifesting as panic attacks. Anxiety may also present as OCD or phobias. Common phobias in patients with epilepsy include agoraphobia, social phobia, and a fear of having seizures. Anxiety disorders can be a source of significant distress, and proper treatment is essential.

Patients with epilepsy may also experience comorbid psychosis. Psychotic symptoms generally occur during the interictal state with features similar to that of schizophrenia (e.g., delusions and hallucinations). In contrast to schizophrenia, however, patients with epilepsy and psychosis often have fewer negative symptoms and lack deterioration of personality. Psychosis may also occur as a peri-ictal phenomenon. As an increased frequency of postictal psychotic episodes may evolve to chronic interictal psychosis, immediate treatment is indicated. Atypical antipsychotics and psychiatric consultation are the cornerstones of management.

Finally, clinicians should note the frequent presence of comorbid PSD in this patient population. Perhaps more controversial is the notion of a specific “interictal behavioral syndrome” in patients with TLE, including such traits as viscosity, hyperreligiosity, and hyposexuality. Aggression may also be evident in patients with seizures and should be recognized as a treatable disorder.

CHAPTER 94 DRIVING AND SOCIAL ISSUES IN EPILEPSY

AMY Z. CREPEAU AND JOSEPH F. DRAZKOWSKI

A person with epilepsy faces many social concerns that are taken for granted by those without the disorder (1,2). The 2012 Institute of Medicine Report on epilepsy "Epilepsy Across the Spectrum" utilized published data and patient testimonies to assert that everyday limitations placed upon persons with epilepsy can have as significant an impact on quality of life as seizures. The report identified a list of needs, ranging from education regarding the disease to local resources, employment, and transportation needs (3). Quality-of-life (QOL) surveys have identified driving a motor vehicle as the number one concern for a person with epilepsy (1). In addition, other important social issues repeatedly identified by persons with epilepsy include obtaining and maintaining employment and participating in athletic and recreational activities (2,4). This chapter explores important social issues that can influence the QOL of a person with epilepsy.

EVALUATION OF THE RISK OF ENGAGING IN A DESIRED ACTIVITY

Engagement in any activity requires some analysis of the risks of desired activity against the potential benefits of that activity. For a person with epilepsy, there is additional significance to considering this cost-to-benefit analysis. A person with epilepsy must conduct the analysis in the context of a specific situation, with the consideration that a seizure-related injury might occur during the specific activity. To determine potential risk, a person with epilepsy needs to understand all aspects of the activity and try to anticipate the potential exposure to injury should a seizure occur during participation. The risk of seizure recurrence will determine, at least in part, how safe it is to participate in a desired activity. Factors that influence seizure recurrence have been reported (5) and may provide important insight into determining the risks associated with a desired activity. These factors include the presence of an abnormal electroencephalogram (EEG), initial seizure type, and etiology of the seizure. Seizures due to structural etiologies are twice as likely as seizures related to unknown causes to recur (6–8). Focal seizures are also more likely to recur compared with an initial major motor seizure (6,9). If the etiology of a seizure disorder is head injury, the risk for recurrence may be higher. In patients with severe head injury, the recurrence rates for seizures are 7.1% and 11.5% at 1 and 5 years, respectively (10), with severe head injury defined as amnesia and/or loss of consciousness for more than 24 hours, or the presence of an intracranial hematoma. Structural lesions, such as brain tumors, stroke, abscesses, and penetrating head wounds, all carry an increased risk for recurrent seizures. After a new-onset major motor seizure in a patient with a normal examination and workup, including magnetic resonance imaging, electroencephalography, and blood tests, seizure recurrence is estimated to range between 25% (7) and approximately 70% (11) at 3 years. The period

of seizure freedom can predict future risk of seizure recurrence. After a single seizure and a 6-month seizure-free interval, the risk of seizure recurrence in those treated with antiepileptics is 14% and 18% in those not treated (12). If one remains in remission (i.e., seizure free) for 2 years or longer, a good prognosis is possible (13).

The danger period for a particular activity should also be considered when evaluating potential risk. The person with epilepsy is exposed to less risk when the danger period for an activity is brief. Activities with inherent danger must also be factored into the decision of whether to participate. Finally, other factors, such as medication compliance, medication side effects, age, concomitant medical problems, use of safety equipment, seizure triggers, and a prolonged and consistent aura, can all influence the risks faced by a person with epilepsy when engaging in a specific activity.

DRIVING AND THE PERSON WITH EPILEPSY

Driving is a privilege that many adults take for granted yet rely upon in order to go to work, complete errands, and travel. For many individuals with first-time seizures, loss of driving privileges is the most burdensome consequence of the seizure. In a survey of persons with epilepsy, sadness was the most common reaction to driving restrictions, while those who drove despite restrictions most commonly reported anger (14). Governing bodies have increasingly attempted to critically assess risk to make the most reasonable driving regulations for persons with epilepsy.

The Risks

A person with epilepsy faces a risk of injury and a risk of causing injury if a seizure should occur while operating a motor vehicle. Individual country, state, or territorial governments govern this privilege (15). There are approximately 225 million registered vehicles in the United States. In 2011, an estimated 5.3 million motor vehicle crashes occurred in the United States. These crashes resulted in approximately 1.5 million injuries and nearly 30,000 deaths (16). It is estimated that approximately 0.5% to 1.0% of the US population has epilepsy (5), potentially placing up to than 3 million drivers with epilepsy on the roads of the United States. However, the actual number of persons with epilepsy who drive with or without a valid license is unknown. Applicants for a motor vehicle license must answer questions about their medical status and affirm that they are healthy and fit to drive before they are allowed to operate a motor vehicle. One study suggested that only 14% of individuals had answered truthfully on their driving application when asked about the presence of epilepsy (17). In a prospective survey of 367 patients with focal epilepsy pooled from a consortium of comprehensive epilepsy programs, approximately 30% of the respondents had operated a motor vehicle in the previous 12 months (18). A recent Brazilian study identified male sex, occurrence of focal seizures without dyscognitive features, epilepsy onset over 18 years of age, and monotherapy treatment as being associated with driving after the diagnosis of epilepsy, despite local laws (19). In a Korean study of patients with uncontrolled epilepsy, being male, married, employed, and on fewer antiepileptic drugs (AEDs) were risk factors for continuing to drive despite being instructed not to (20). The paucity of available data makes it difficult to definitively establish the number of automobile crashes caused by persons with epilepsy who have a seizure while driving. Reports suggest that persons with epilepsy account for approximately 0.02% to 0.04% of all reported automobile car crashes (21,22). In comparison to healthy controls, an evidence-based review found that epilepsy is probably not predictive of motor vehicle accidents. In addition, epilepsy surgery, few

non-seizure–related crashes, regular medication adjustments, and longer seizure-free intervals are probably protective against crashes (23). However, these data were largely based upon patient surveys, which may underestimate risk.

Seizures are unpredictable, and the presumption is that longer seizure-free intervals translate into a decreased likelihood of seizure-related crashes. However, verifying this fact is difficult, as individual driving records are generally not available for review. A retrospective survey of patients in several Maryland outpatient epilepsy clinics suggested that the risk of motor vehicle crashes was reduced by 85% and 93% if the patient did not have a seizure at 6 and 12 months, respectively (24). This survey relied on self-reported crashes.

It is challenging to determine what factors are likely to predict seizure freedom in an individual. In those patients who report being seizure free, there is concern they may be unaware of brief seizures they experience, placing them at risk while driving. It has been suggested that using medium- or long-term video EEG or ambulatory EEG may assist in estimating risk of seizure relapse (25,26).

Moreover, self-reporting of crashes by respondents in surveys is often considered unreliable (27,28). Drazkowski et al. (22) reviewed actual accident reports in Arizona from crashes caused by seizures before and after the seizure-free interval was reduced from 12 to 3 months (Table 94.1). Although no significant increases in seizure-related crashes were reported, the retrospective study provided some objective data on these crashes. To date, no controlled prospective data are available to guide regulating authorities as to the optimum seizure-free interval for the protection of both the person with epilepsy and the public.

The Regulatory Requirements

The first seizure-related car crash was reported near the turn of the 19th century. Since then, regulatory authorities have placed restrictions on driving for a person with epilepsy. In the early

1990s, the American Academy of Neurology, the American Epilepsy Society, and the Epilepsy Foundation of America convened a conference of thought leaders to issue guidelines on the topic of driving and the person with epilepsy (29). Recommendations from the conference included (i) a seizure-free interval of 3 months, (ii) allowances for purely nocturnal seizures, and (iii) a provision allowing driving when there is an established pattern of a prolonged and consistent aura (29).

It is challenging to determine the duration of seizure freedom that should be required to appropriately balance public safety and overly arduous restrictions on a person with epilepsy. Seizure-free intervals adopted by jurisdictions vary widely and have many unique exceptions (31). State regulatory agencies and the Epilepsy Foundation of America Web site (www.epilepsy.com) can be contacted for current laws governing driving and epilepsy, which has been recently updated (32). Though there is a range of restrictions among states, it has yet to be shown whether tighter restrictions are associated with decreased driving and accidents by persons with epilepsy.

In an editorial, Krumholz suggested that it is time to consider uniform laws governing epilepsy and driving throughout the United States (33). International rules on driving have been reviewed, and because of the high variability among individual countries, the appropriate national authority should be consulted to determine current local laws regarding driving before traveling to these nations (34).

Six states currently have laws that require health care providers to report persons with epilepsy to the appropriate state driving authorities. The rationale behind physician reporting is the concern that a person with epilepsy will not reliably self- report the presence of active or recurrent seizures to the proper authority. Laws that require a health care provider to report a person with epilepsy to authorities are criticized as impairing the physician–patient relationship and thus compromising optimal medical care. The premise is that when physicians are required to report epilepsy to driving authorities, persons with epilepsy may conceal information about their seizures to avoid being reported and potentially losing their license (27). Of persons with epilepsy who had been counseled about driving laws, only 27% reported their condition to the appropriate authorities (28). The low percentage of self-reporting may partially be attributed to lack of counseling on behalf of the health care professional. In a recent review of ER visits requiring self-reporting to the driving authorities, <10% were counseled in a major metropolitan city in the southwest (35); in another survey, only 13% of providers knew the appropriate requirements in any event (36). In California, which is the most populous state requiring physician reporting, a survey again suggested that the physician reporting requirement impaired medical care and the doctor–patient relationship (37). There are no available studies showing that physician reporting reduces seizure-related automobile crashes. In Canada, a conference of invited experts concluded that the laws requiring health care professionals to report persons with epilepsy to authorities should be abolished and suggested that driving laws be uniform across Canada (38). McLachlan et al. reported on the impact of mandatory reporting to driving authorities in one province requiring reporting compared to a province that does not. Their conclusion was that mandatory reporting of the person with epilepsy to the driving authorities by physicians did not reduce accident risk. They go on to suggest that the reporting requirements may be excessive compared to other medical conditions or nonmedical risk factors (39). In a comparison between one state with mandatory reporting and one without, there was no difference found in rate of physician counseling regarding driving, driving despite between told not to, or automobile accidents (40). An editorial by emergency department physicians suggested that mandatory reporting of seizures be abolished in the United States (41). This editorial highlighted several other medical conditions and situations that are associated with a similar or higher relative risk of a car crash compared with epilepsy, such as sleep, apnea, diabetes, dementia, and cell phone use (38).

EMPLOYMENT AND THE PERSON WITH EPILEPSY

QOL surveys have identified employment issues and concerns of persons with epilepsy as significant (1,2). The economic impact that epilepsy has on society is huge (more than $10.8 billion/year) and is largely attributable to indirect employment- related costs, which account for 85% of all epilepsy costs (42). Persons with epilepsy have a lower prevalence of employment (43). They are also reported to have lower household incomes, which are estimated to be 93% of the US median income (44), compared with the general population.

In the United States, the rate of unemployment for persons with epilepsy is reported to be between 25% and 69% (44,45). Although many factors are likely to contribute to the high rate of unemployment among persons with epilepsy, poorly controlled epilepsy is associated with a high level of unemployment (45). Age of epilepsy onset also impacts employment status, with an earlier age of onset correlating with work difficulties later in life (46). In patients with adult-onset epilepsy, initial seizure control or lack of control does affect work status. Newly diagnosed, unprovoked seizures in adults do not seem to negatively impact employment rates. The same study associated the development of refractory seizures in adults with reduced income (47).

Many persons with epilepsy have to deal with the reality of employment discrimination. A survey of young persons with epilepsy enrolled in a job training program in Ireland indicated that 50% of the participants believed they were being actively discriminated against when seeking employment (48). A similar percentage of employed persons with epilepsy in Australia felt they were discriminated against (30). Widely available public education regarding epilepsy has the potential of reducing stigma within the community and, hopefully, within workplaces (49,50).

The Americans with Disabilities Act (ADA) (51) was enacted in 1990 to combat job discrimination against individuals with illnesses. The law was intended to help persons with epilepsy and persons with other disabilities obtain and retain employment. A prominent feature of the ADA is that a person with a covered malady cannot be discriminated against if "reasonable accommodations" can be made that would allow the covered individual to obtain or remain in a specific job. But the ADA exempts employers with 15 or fewer employees, thereby eliminating many small businesses. Furthermore, what constitutes a reasonable accommodation was left open to interpretation. The standard may be based on the actual cost of any modifications required that allow a person to keep a specific job. Finally, the employee must be able to perform the "essential" tasks of the job. Administrative and court rulings have made it clear that the protection sought has not been achieved (52). In a unanimous U.S. Supreme Court opinion, Justice O'Connor wrote that for an individual to be considered disabled, the person's disability must be "permanent or long-term," and the impairment must "prevent or severely restrict the individual from doing activities that are of central importance to most people's daily lives" (53). The following statement summarizes the court's opinion: "Merely having an impairment does not make one disabled for the purposes of the ADA." This ruling and others like it have changed the thinking on what defines disability for many patients. These uncertainties and restrictive rulings by the court have prompted a reevaluation of the issue by the US Legislature, which resulted in the passage of the "ADA Restoration Act of 2008." The law took effect on January 1, 2009. The law was passed in an effort to clarify and be more inclusive on what constitutes disability under the law. It still covers business and governmental agencies of 15 or more employees. The U.S. Equal Employment Opportunity Commission has reviewed and published

guidelines for person with epilepsy and employers regarding employment and epilepsy issues (http://www.eeoc.gov/facts/epilepsy.html). Major life activities specifically covered in the law are highlighted in Table 94.2. The major life limitations due to epilepsy can result from seizures or the complications and side effects of medications used to treat the seizures. Specific examples of hiring practices' do's and don'ts for the person with epilepsy determinations about disability are fraught with complexities and should be considered on a case-by-case basis, taking into account the unique facts involved. Individual cases may require specialized legal advice. All the possible accommodations that may affect the person with epilepsy would be lengthy. A potentially helpful website, the Job accommodation network (3), with common examples of accommodation is http://www.jan.wvu.edu/media/epilepsy.html. Readily accessible social service resources can assist patients in navigating employment accommodations and disability eligibility in regard to their epilepsy (54).

Certain jobs may be perfectly safe for many persons with epilepsy but other jobs may impose unacceptable risk. A person with epilepsy must carefully evaluate jobs involving dangerous machinery, or equipment heights, or situations in which there is a possibility for injury or death because of potentially dangerous conditions in the event of a seizure. Persons with epilepsy also face regulatory-imposed restrictions for some jobs. For example, a person with epilepsy's pursuit of a commercial pilot's license is severely limited by the Federal Aviation Administration (FAA) (55). Similarly, a person with epilepsy wishing to obtain a commercial driver's license (CDL) to operate a truck in interstate commerce must overcome significant hurdles imposed by the Federal Department of Transportation. The diagnosis of epilepsy and the use of AEDs generally disqualify an applicant or current driver from obtaining a CDL. A CDL is required to operate a truck with a gross weight >24,000 pounds. Although many states have mirrored the federal regulations with regard to state commercial driving laws, individual state regulations should be reviewed for accuracy. Internationally, laws vary regarding CDLs. For example, in Norway, bus and taxi drivers may not have had a seizure after age 18 (56). Tailoring the specific job to the person with epilepsy, based on the person's unique, individual situation, should be emphasized.

Under Social Security Administration (15) regulations, epilepsy is covered by specific listings (57). These listings, which define what constitutes a disability for the person with epilepsy, are used in determining who is eligible to receive disability payments. Persons with epilepsy are required to provide specific evidence, through medical records documenting that they "meet the listing," as featured in Table 94.3. Other factors, such as postictal effects of seizures and side effects of prescribed medications, may be considered in determining disability, especially during a hearing or an appeals process for a denied claim. The specific listings for epilepsy are sections 11.03 and 11.02 for minor motor and major motor seizures, respectively (57). Decisions regarding SSA for epilepsy based upon the listings have been shown to be inconsistent and without evidence-based guidelines, potentially requiring further guidelines in the future (4,58).

SPORTS AND RECREATIONAL ACTIVITIES

Persons with epilepsy are often excluded or discouraged from participation in sports and recreational activities because of fear of what might occur during the activity. Since the 1960s, official recommendations regarding limitations in the participation of physical activity have been significantly liberated, and at this point, physical activity is recognized as being beneficial for persons with epilepsy. In addition, lack of leisure time and physical activity may be a detriment to persons with epilepsy. It has been shown that a low level of physical activity is a risk factor for depression in epilepsy (59) and that greater physical activity is associated with fewer days where their health limited their routine (60). However, engagement in leisure and physical activity require certain considerations.

Epilepsy and Recreational Vehicles

Motorized vehicles can potentially cause serious injury or death even in persons without epilepsy. The unpredictability of uncontrolled seizures might pose a serious threat should a seizure occur at the wrong time. Operating motorized vehicles is associated with a prolonged danger period.

A seizure that occurs while a person is piloting a private plane is likely to have disastrous consequences. Noncommercial aviation is at least partially regulated by the FAA. A third-class pilot's license is required for all general noncommercial aviation (55). If an individual has experienced a single unprovoked seizure with no EEG abnormalities, normal brain imaging, and no additional risk factors, that person can be considered for a third-class license if he or she has not taken an AED for 4 consecutive years. The FAA uses certified examiners to assist in the decision-

making process for granting licenses when there is a potential medical problem. Piloting ultralight aircraft, hang gliders, and other small aircraft may not require a license, but these are unlikely to be any safer than a private plane should a mishap occur.

Other motorized vehicles, such as motorcycles, personal watercraft, all terrain vehicle (four wheel), and boats, may pose less of a threat to a person with epilepsy than does flying. If the person with epilepsy operating the vehicle has a prolonged and consistent aura, it may allow that person the opportunity to stop and protect ones self. However, a person with epilepsy when contemplating sports activities should consider other factors. For example, drowning is a common accident among persons with epilepsy (61). The use of a personal flotation device at all times when operating or riding in any watercraft should be considered. When operating off-road vehicles, safety equipment should also be considered, especially the use of boots, shoulder pads, protective clothing, and helmets. Although a person operating such a vehicle does not require a license, specific training courses are available and are highly recommended.

In contrast, organized motor sports generally require some form of medical clearance before participation (53). The different motor sport sanctioning bodies, such as the Sports Car Club of America, the National Association of Stock Car Racers, and the Indy Car Series, all have specific requirements for a person to be allowed to drive in sanctioned events. Each series requires approval from a qualified health care professional before driving, and therefore, specific rules should be reviewed.

The Person with Epilepsy and Athletics

The decision to participate in individual (i.e., one-on-one) and team sports should follow those principles outlined above in order to ensure maximum benefits (and thus satisfaction) and safety. The extent to which a person with epilepsy wishes to pursue athletics is an individual decision that should be based on individual circumstances. Table 94.4 classifies risks to the person with epilepsy according to the sport.

Participation in team sports should also be determined on an individual basis. Football could be dangerous if a player is unable to protect him or her during a play, whereas basketball is less likely to be dangerous. Noncommercial scuba diving is also not regulated from a medical standpoint, but good judgment is required on the part of the participant. Hyperventilation techniques and the high concentration of inspired oxygen used during scuba diving have the potential to provoke seizures, and seizures that occur during a dive can have a fatal outcome. Scuba diving organizations vary in their recommendations. These recommendations range from considering seizures to be an absolute contraindication to requesting an individual be seizure free for several years before diving (62). If a person with epilepsy does engage in scuba diving, it is crucial that person notifies the diving group and has a strong diving partner that is ready to assist in the instance of an underwater seizure. Water sports and drowning pose a likely threat to the person with epilepsy. A review of drowning deaths found that 40% of seizure-related drownings occurred during recreational activities (61). A study by Gotze (63) found no increase in seizure occurrence during strenuous swimming.

Evidence suggests that regular exercise has a beneficial effect in the control of epilepsy and regular physical activity may reduce seizure occurrence (63,64). Recent opinion has encouraged sports participation for the person with epilepsy despite the potential risks (65,66) and it has even been suggested that exercise may be a non-pharmacologic intervention in epilepsy (67). Engagement in physical activity and sporting activities have benefit in persons with epilepsy, but individual considerations need to be made to ensure safety.

Often overlooked are the possible AED-associated side effects that may interfere with participation in sports. For example, zonisamide reduces sweating in children and could potentially

lead to heat-related injury in hot climates. Tremor associated with the use of valproic acid could be dangerous when shooting target pistols. Phenytoin-induced ataxia could potentially be deadly while riding a motorbike (68). Many more potential examples could be conceived and listing all the potential combinations is beyond the scope of this chapter; thus, the health care professional should be knowledgeable of the person with epilepsy's history, desires, and a basic understanding of the recreational activity considered. Individualizing the specific drug side effect profile, patient characteristics, and particular recreational activity generally should all be considered when advising the person with epilepsy about participation in recreational and sporting activities.

CONCLUSIONS

The patient with epilepsy faces many challenges beyond seizures. Seizures have the potential to impact aspects of daily life, which are otherwise taken for granted, including transportation, employment, and leisurely activities. These issues, among others, have a significant impact on quality of life, but also need to be balanced with safety. It must be emphasized that each patient has individual characteristics requiring knowledge of the specific activity in which the person with epilepsy wishes to participate. Recent changes to the U.S. laws governing disability and employment may prove helpful for the person with epilepsy.

CHAPTER 95 QUALITY OF LIFE WITH EPILEPSY

TATIANA FALCONE AND ALLYSON M. PALOMBARO

According to the World Health Organization Quality of Life Group, quality of life (QoL) is defined as the individual perception of position in life in the context of value system, goals, expectations, standards, and concerns (1). As for any chronic disease, there is a component of psychosocial adjustment when living with epilepsy. The stigma and misconceptions that surround epilepsy come from the general public's lack of understanding about the condition. This includes response to seizures and to individuals who have them. People with epilepsy have limitations that affect how they think of themselves as individuals. This stigma badly affects the health and well-being of these individuals as a whole. In addition, comorbidities, seizure frequency, and antiepileptic drugs (AEDs) affect QoL in epilepsy.

HISTORICAL OVERVIEW

QoL is not a new concept and can be traced back to the days of Greek philosopher Aristotle (2). According to the Center for Disease Control "health" includes physical, mental, and social dimensions (2,3). In much the same way, epilepsy is a multidimensional disease affecting individuals physically, mentally, and socially (4). QoL is subjective and is thereby defined differently by a number of groups and populations (5). For this reason, it is hard to measure. The U.S. Department of Health and Human Services states that QoL is synonymous with well-being and can be defined by both positive and negative emotions in one's life (6). QoL is influenced not only by a person's health but also by his or her day-to-day functioning. Health-related quality of life (HRQOL) is a disease-related measure that explores how one's health status affects one's QoL (3). It is important in epilepsy to be cognitive of how the condition is interfering with daily tasks (3).

QUALITY OF LIFE IN EPILEPSY

In children with epilepsy (CWE), lack of accurate knowledge about the condition has been associated with social anxiety and poor self-esteem (7). Disruption of normal tasks required to be attained by different developmental stages impacts the social functioning of the individual with epilepsy (7).

In Early and Middle Childhood

In this stage, children are learning tasks to become independent. They need a family environment that facilitates their development and is conducive to exploration of the world around them. Parents of CWE are distressed about seizure probability, hence restricting child social interactions and potentially hindering their development both socially and emotionally. Studies looking at level of

parental anxiety and socialization in CWE describe that anxious parents are more likely to have children with poor socialization skills. Parental skills are another important issue in CWE; because the child has a chronic illness, parents feel guilty enforcing family rules, which consequently impacts negative behaviors (7).

In Adolescence

One of the most important developmental tasks of adolescence is the formation of identity. In this stage, adolescents build a sense of emotional and physical competence. Epilepsy impacts the ability to feel confident about emotional and physical well-being, and feeling unable to perform some tasks impacts self-esteem. Bullying is frequent in this stage and impacts the way adolescents perceive themselves and their world. In a study examining adolescents' attitudes toward peers with epilepsy, three-quarters of the adolescents in the general population believed that peers with epilepsy were more likely to be bullied. Also, less than one-third of adolescents reported that they would date someone with epilepsy (8). A separate study found that adolescents with epilepsy felt that the stigma of having a chronic debilitating condition set them apart from their peers. They also felt that the uncontrollability of the seizures made it hard to become independent (9). In addition, driving is an important developmental task in late adolescence, and people with epilepsy feel that the inability to drive limits opportunity for participation in social activities (7).

In Adulthood

Most of the studies on psychosocial function on adults with epilepsy were conducted in clinical population samples, limiting their generalization. Employment is key in the personal development of adults and is a predictor of QoL in patients with epilepsy (10). Many studies have reported on the struggles that patients with epilepsy face gaining and maintaining employment. The unemployment rates for people with epilepsy are reported to be around 42% to 50% and are higher than in the general population. Patients feel the epilepsy is an important barrier to gaining employment (11).

Important cultural differences have been reported on rates of marriage in people with epilepsy. In developed countries, rates of marriage are around 66.2% overall (10), 32% for men and 58% for women (11). In a British study, 50% of people with epilepsy were married. In India, laws that prohibited people with epilepsy from getting married were only recently repealed (12). Other developing countries still have negative connotations associated with epilepsy, which limits the potential for people with epilepsy to get married.

Woman with epilepsy are affected differently than men with epilepsy. It is vital that this be addressed early on in the diagnosis of epilepsy in females. Health needs unique to the female and her sexuality extend beyond pregnancy, and it is never too early to start counseling (13). In the prepubescent and pubescent female and throughout the rest of female adult life (including menstruation years, pregnancy, and menopause), seizure frequency, severity, and duration are affected. Seizure frequency may be directly related to the menstrual cycle in the pattern known as catamenial epilepsy (13). Folic acid supplementation should be discussed at the start of AEDs in the menstruating woman of any age (13). In addition to other potential side effects of AEDs, their cosmetic side effects need be considered when starting treatment in the female. Cosmetic effects of AEDs, such as acne, weight gain/loss, and hirsutism, affect a woman's self-image and thereby affect her QoL. It is important to know that what is acceptable to the clinician is not always acceptable to

the patient (14,15). Communication between the patient and the provider is very important, as sometimes the deleterious side effects of higher doses of AEDs could worsen the QoL more than the lesser seizure control previously attained with the lower dose of the medication. Patients might also neglect to share with the provider the dose of the AED that they are actually taking.

The Role of Stigma and Quality of Life

The negative social perception of epilepsy dates back to the Biblical New Testament where epilepsy is mentioned as "a madness." Early primitive societies attributed the cause of epilepsy to demonic possession or as a consequence of negative karma by the individual or family (8). In some ancient cultures, people with epilepsy were segregated in a remote location to prevent "contagion" of the illness. The evolution of the concept of epilepsy from "badness to sickness" has potential important correlations with the role of stigma (16). Early studies reporting increase of aggressive behavior, criminal behavior, sexual misconduct, and negative personality characteristics have certainly perpetuated the stigma that patients with epilepsy face. Scambler (17) describes how people with epilepsy exposed to negative perceptions about the disease develop a "special identity" that is certainly related to the exposure to stigma.

Cultural beliefs have an important role in societal stigma against epilepsy. In the highly educated population, the lack of understanding about the disease impacts societal views about epilepsy. In the United States, Austin et al. (8) stated 22% of adolescents reported uncertainty about epilepsy being contagious. Westbrook et al. (18) remarked how up to 50% of the families studied decided to keep the condition secret from others. Falcone et al. (19) identified that 50% of families decided not to disclose the epilepsy diagnosis to the school. Bauman et al. (20) reported that one out of four of the families surveyed believe that having a child with epilepsy in the classroom deteriorates the learning environment.

PSYCHOSOCIAL ADJUSTMENT OF PEOPLE WITH EPILEPSY

McQueen et al. (21) described two different models to understand the psychosocial adjustment in people with epilepsy. The medical model focuses on severity of epilepsy and is the driver of the psychosocial adjustment. The sociologic model attributes the adjustment to the perception of the individual's condition or social stigma.

Seizure frequency has been reported by many studies as the most important predictor of psychosocial functioning. The better seizure control, the better the QoL. QoL directly relates to seizure frequency and severity. What may be a medically safe frequency to the provider may not be defined the same by the patient who is having the seizures, and the same goes for seizure severity (14). In addition, frequency and severity and how both affect QoL may vary from the caretaker's opinion to the epilepsy patient's opinion.

Chronicity is another important factor; newly diagnosed people usually adjust better than do patients with chronic epilepsy. The age of onset of epilepsy may also have a key role in psychosocial adjustment (19). For example, the first 8 years of life are key in the development of social skills; when epilepsy starts in this important developmental period, it might also have important repercussions in the development of social skills. Parents also play a very important role in the development of social skills, and overprotective parents or social isolation might also have an

important role in the inability of youth with epilepsy to develop appropriate social interaction with peers (19). A patients' perception of his or her own ability has an important key role in QoL, and good self-perception was correlated with better QoL in epilepsy. Some have suggested that the patient's own perception of disability was a stronger predictor than was seizure frequency in affecting different domains of QoL such as employment or social interaction (19).

In a study attempting to elucidate the effect of the different factors on QoL, Suurmeijer et al. (10) reported that <5% of QoL was related to the clinical aspects of epilepsy (onset, seizure frequency, and side effects of the medication) and only 15% to clinically related aspects such as perception of epilepsy and health perception. Social functioning, self-efficacy, and psychological functioning contributed twice as much to the QoL compared to the clinical aspects of epilepsy. Social support was reported as a key factor in the emotional adjustment to having a chronic illness such as epilepsy.

THE ROLE OF PSYCHIATRIC COMORBIDITIES IN QUALITY OF LIFE IN PATIENTS WITH EPILEPSY

Psychiatric comorbidities are frequent in patients with epilepsy. Among psychiatric comorbidities in patients with epilepsy, depression is one the most frequent. In fact, the prevalence of depression in epilepsy appears to be higher than in other chronic illnesses. In a population-based study involving 18,000 individuals, the prevalence of depression for patients with epilepsy was 29% compared to 17% in those with diabetes and 16% in those with asthma (22). Epidemiologic studies indicate that 10% to 20% of patients with epilepsy and 20% to 60% of patients with recurrent seizures have depression (23). Likewise, rates of psychopathology are very high, ranging from 37% to 77% in children and adolescents with epilepsy (23–25). A meta-analysis of 29 cohorts of epileptic patients demonstrated increased suicidality as compared with the general population (26). Despite continued progress in the treatment of epilepsy, the psychosocial outcome in adults is reported as poor, even in patients who reach seizure freedom (23). Patients with epilepsy and depression have some of the lowest scores on QoL, even when seizures are under control (23).

In addition, psychosocial adaptation has not been investigated extensively in this population. Some studies suggest that psychosocial adaptation in CWE might be lower than in healthy children, which may be due to the stigma of having a chronic disorder that subsequently lowers their self-esteem. CWE have been reported to have poorer self-concepts than children with other chronic medical conditions and to frequently struggle in school and other social settings. These experiences may lead to poor self-esteem and symptoms of depression. Studies have reported that female CWE with low IQ are especially at risk for poor self-concept and the development of depression (25).

Some stressors, such as stigma, language and cultural barriers, financial difficulties, stressful life events, decreased expressed emotions, and poor family coping skills, have been reported in depressed epileptic patients. A positive attitude toward epilepsy has been correlated with less depression (25,27,28). Population surveys of mental health problems in CWE in the United Kingdom reported the rate of psychiatric comorbidities to be 37%, compared to 11% in diabetes and 9% in healthy children. This is comparable to the landmark study from the Isle of Wight, where Rutter (29) reported psychiatric comorbidities as high as 29% in CWE compared with 12% in those with other chronic clinical conditions and 7% in the general population. The associations between these two disorders point to the importance of early recognition and treatment (29).

In a meta-analysis involving 29 selected studies comprising 50,814 patients and 187 who

committed suicide, Pompili et al. (26) calculated the mean number of suicides per 100,000 individuals with epilepsy and showed that suicide is more frequent in patients with epilepsy than in the general population. Likewise, in a population-based case–control study in Denmark from 1987 to 1997, a threefold higher risk of suicide was found among people with the diagnosis of epilepsy (26). However, there are studies that did not find any difference in the suicide rate between patients with or without epilepsy (26).

Patients, and sometimes care providers, decide to wait to access mental health treatment for patients with epilepsy. The common belief is that when the epilepsy will improve, all the other issues will also improve. However, evidence has demonstrated the contrary. The longer that the mental health symptoms persist, the more difficult they are to treat and the greater the risk of suicide. There is an important correlation between depression and anxiety with QoL, independent from seizure rates. In patients with epilepsy, depression has been related to poor seizure control, poor health care utilization, lower scores on the QoL scales, and increased cost in patients with epilepsy.

OTHER COMORBIDITIES

Tellez-Zenteno et al. (30) reported that people with epilepsy had two to five times higher rates of somatic comorbidities such as stroke, headache, and gastrointestinal problems among others. More evidence is needed to further understand the role of epilepsy in these comorbidities.

Sleep

Sleep disorders and epilepsy have a bidirectional relationship. Having sleep problems can certainly impact epilepsy, but also having epilepsy will worsen sleep problems. Many of the medications used to treat seizure disorders have deleterious impact on sleep efficiency. Some studies have reported sleep apnea in up to 30% in patients with epilepsy (31).

In a study comparing sleep disorders in epilepsy with controls, the patients with epilepsy had double the probability to have any sleep disorder. In addition, having a comorbid sleep disorder was associated with an important decrease on QoL in the previous 6 months in patients with epilepsy (31). In a study of patients with epilepsy in Mexico, one of the most important negative predictors of QoL was sleep disturbance, and this was unrelated to any of the other predictors of QoL in adults with epilepsy (32). The authors concluded that insomnia was an independent negative factor in QoL. Insomnia impacted emotional well-being including energy, cognitive function, and social functioning (33). In a group of 130 CWE and 161 matched controls, the group of CWE had worse sleep than did children with no epilepsy. Sleeplessness also impacts cognition and behavior (34).

Migraine

The relationship between epilepsy and migraine has been extensively reported. Patients with history of one of the illnesses double the risk of the other. In a population-based study, Ottman and Lipton (37) reported that migraines were frequent in patients with epilepsy, seen in up to 24%. Depression has also been reported as increased in patients with migraines, with an associated deleterious impact on the HRQOL scores. In a study evaluating the impact of migraines on seizure variables, Veliogu et al. (36) reported that patients with migraines have poorer seizure control, higher proportion of intractable seizures, longer duration of illness, and poorer treatment response (37).

Studies continue to report the importance of recognizing, diagnosing, and addressing all the other issues that impact the QoL in epilepsy. Becoming seizure free is an important goal, but if the comorbidities are not addressed, even after seizure freedom is reached, the QoL may not improve (38).

QUALITY OF LIFE AND ANTIEPILEPTIC DRUGS

A goal of epilepsy treatment with AEDs is the best seizure control with the least amount of side effects and the best QoL. Although this is often said to the patients, it is more difficult to implement than providers realize, mainly because of the effect both have on QoL (14,15). Lifestyle, compliance, income level, and AED side effects also play a role in the mainstream goal of epilepsy treatment (14). Elliot et al. (39) reported that compliance is a serious problem among epilepsy patients who live in poverty. Pharmaceutical companies do offer patient assistance programs; however, extensive time and effort on the part of the provider and the patient are involved to set up the assistance (39).

Just as there are misconceptions about epilepsy, there are also misconceptions about its treatment. Patients may or may not ask questions that reveal their lack of understanding. Many fear what the medications can do to the organs in the body and what the long-term effects of use may be (14). This misinformation or lack of information may also contribute to compliance and negatively impact QoL.

The number of medications and their dosages is important to how an epilepsy patient rates his or her QoL. Some patients are on polytherapy with subtherapeutic dosing, side effects, and inadequate seizure control. AEDs affect each individual; one patient may be on a low dose of AEDs with side effects at subtherapeutic serum levels, while another patient may be on a high dose of AEDs with a high serum level and no side effects (15).

QUALITY-OF-LIFE INSTRUMENTS IN EPILEPSY

The best definition for QoL is defined by the tool you are using to measure it (15). The National Institutes of Neurological Disorders and Strokes (NINDS) lists QoL tools in the Epilepsy Common Data Elements such as the Quality of Life in Epilepsy (QOLIE). It is used to measure QOL in epilepsy and has both research and clinical versions in addition to an adult and adolescent version (15,40). This tool was designed to explore how epilepsy and its treatment affect activities of daily living (15).

The original version is the QOLIE-89, which was designed in 1995 for research purposes (15). From it, the QOLIE-10 was derived (15). It is a shorter version containing a 10-item evaluation that takes only minutes to complete, thus ideal for the clinical setting (40). One item was selected from the scales of seizure worry, emotional worry, energy/fatigue, cognition, and overall QoL (15). In addition, two items were selected from AED side effects and three items from the social function scale (15). It is easy to complete and simple to score. According to the NINDS Common Data Elements report, the test-retest reliability ranged from 0.48 to 0.58 for different items and from 0.55 to 0.77 for different subscales, and the validity score was established for seizure frequency, AED polytherapy, and sleep disturbance (40). It is available in Spanish, English, and Dutch (40).

The QOLIE-AD-48 was developed in 1999 by the QOLIE Development Group for adolescents (11 to 17 years old) (15). Items address epilepsy impact, memory/concentration, attitudes toward epilepsy, physical functioning, stigma, social support, school behavior, and health perceptions and have a total summary score (15). The 15-minute self-administered questionnaire has no parent version (14,40). According to the NINDS Common Data Elements report, validity is statistically

significant at the $P < 0.05$ level and test–retest reliability is good at 0.83 (40). It is available in Chinese, English, Serbian, Portuguese, and Spanish (40).

For children, the NINDS recommends the Quality of Life in Childhood Epilepsy that covers physical function, emotional well-being, cognitive function, social function, and behavior (40). It is done by the parent and takes approximately 30 minutes to complete (40). The length of time for completion is not ideal, but it is an epilepsy-specific quality-of-life tool. According to the NINDS Common Data Elements report, reliability is ranged from 0.72 to 0.93 (40). Its weakness is that the validation was done with caretakers of children with refractory epilepsy, and it is only available in English (40).

FINAL NOTE A MOTHER'S PERSPECTIVE

SUSAN AXELROD

It had to be one of the coldest Januarys on record in Chicago. The year was 1982, and my daughter Lauren was just 7 months old.

She was a remarkably beautiful baby. She was sick for the first time in her short life. A cold. No fever. Because of her nasal congestion, she had not slept well in 3 nights, and so her pediatrician advised me to give her a small dose of Triaminic. I did so, put her to bed, and we each slept well.

Or, at least, I did. I thought she was sleeping well too. But, when I entered her room in the morning, I found her lying limp and grayish blue in her crib. I thought she had died. I whisked her out of bed, and her body then stiffened, her beautiful blue eyes rolled back in her head, and bubbles of saliva collected around her lips.

It was the first of thousands of seizures I would come to witness. But, at that point, I had never seen a single seizure. I hadn't the slightest idea what was happening.

The emergency room nurse grabbed her from me when she witnessed her displaying another of these strange behaviors, identified it as a seizure, and I'm not even sure what happened next. Needle sticks. IVs. Spinal taps. Medications we had never even heard of poured into her tiny body.

A month later, we brought her home from the hospital on megadoses of phenobarbital and phenytoin. She had lost many of her developmental milestones. She was still having at least six seizures a day. She was alternately groggy, hyperactive, irritable, and moody. We couldn't recognize our child—she bore very little resemblance to the Lauren we knew before.

With no warning, no preparation, and certainly without our consent, epilepsy blasted into our lives with a vengeance. Over the next 18 years, Lauren had clusters of seizures that could last for days on end. Uncountable visits to the ER and hospitalizations that could each last for weeks. Over 20 anticonvulsants, in combinations of up to 5 at a time, failed to control her seizures. The ketogenic diet was ineffective, as was vagal nerve stimulation and surgery. We saw numerous specialists, none of whom could offer us answers or relief.

Sadly, Lauren's story is not unique. Certainly, many children with epilepsy are not nearly as refractory to treatment and don't experience the same degree of psychosocial and cognitive impact that she has. And too many more, sadly, have a much rougher, tougher ride, including those who succumb to the very worst consequence of epilepsy—loss of life.

Our federal agencies now recognize the spectrum of syndromes, forms, and severity of recurrent, unprovoked seizures as “the epilepsies.” It would behoove us all—physicians, caregivers, and patients alike—to also acknowledge that there is not one epilepsy. The epilepsies are a significant public health problem with a myriad of complex causes, effects, and outcomes that are yet to be well understood.

And so, treating children is far from a “one size fits all” proposition. And interacting with and supporting parents and caregivers are perhaps as complicated and multifaceted as the epilepsies

themselves.

Simplistic as it may sound, it comes down to building and nurturing a mutually respectful relationship, one that can only be built on a foundation of trust. It has to go both ways—the family needs to be as fully honest and respectful as the physician and his/her team.

No parent or caregiver should be denied the complete truth about their child's diagnosis and prognosis. Parents—particularly those just entering the world of epilepsy—rely on their child's doctors to steer them to the best information available. Even if physicians feel that the answers may not be what a parent wants (or is ready) to hear. Or, even if the best that can be done is to admit that the answers do not yet exist.

This doesn't require that all of the harshest potential outcomes be addressed immediately—particularly if the patient is not at high risk. But it is the responsibility of the physician's team to steer families toward reliable information and resources—hopefully as soon as possible, with as much encouragement as possible.

In 1982, the Internet did not exist. We were sent home from that first hospitalization with an incredibly sick child, powerful cocktails of daily medications, no answers to our questions, and no resources for either support or information. We were desperately alone.

Although information from the Internet may often not be optimal, health care professionals need to help families find the best resources and filter out what is not helpful. This needs to be done in a manner that acknowledges that people seek information because they are desperate to know. They should not be discouraged from doing so, because to do so is both empowering and inevitable.

In addition, just as parents are more likely to witness their child's seizures than their physicians, they—along with other professionals in their child's life—are the ones in the best position to notice changes in mood, behavior, cognition, and social skills.

When we began this journey, we were never once asked to monitor and record seizures or medication side effects. We contacted Lauren's doctor only when things reached what seemed to us like an emergency. But, equally disturbing, there was absolutely no conversation around how this barrage of electrical storms in her developing brain—not to mention the high-powered medications she was taking—were impacting her life.

Consequently, we soon felt that everything we witnessed in her—apart from the seizures—was somehow irrelevant. This caused a significant breakdown in our working relationship with her doctors. Later, I came to believe that this dismissal of our concerns was due to the fact that answers did not exist. Because we weren't told that, we sought other opinions and became increasingly frustrated and mistrustful.

Sadly, many of the answers we need are still unavailable to us. We have a long way to go in our understanding of causes, prevention, optimal treatments, sequelae, and long-term outcomes. This is what drove me, along with other desperate and frustrated mothers, to found CURE, Citizens United for Research in Epilepsy, in 1998.

One of the most significant results of our advocacy efforts was to open up a long overdue conversation about what had become, along with the diagnosis of epilepsy, an acceptance of both repeated seizures and intolerable treatment side effects, particularly in the 30% or more of patients whose seizures are not controlled on the first few medications.

Our work has been with the epilepsy research community—shifting their focus from simply seizure control to improving our understanding of causes and underlying mechanisms, so that antiepileptogenic therapies may one day be the standard course of treatment, in lieu of the arsenal of anticonvulsant treatments available today.

I hope that this shift has also been reflected in clinical care and that physicians who treat patients with epilepsy—along with patients and their loved ones—are no longer willing to accept the status quo. We all need to be as vigilant as possible at preventing and stopping all seizures. The inherent danger of each and every seizure means that they are not something we can continue to accept as a "given" of this diagnosis. The often-debilitating side effects of current treatments are unacceptable.

Amazingly, it wasn't until Lauren was almost 3 years old that I learned she had epilepsy. I read the dreaded "E" word on an EEG report and panicked. No doctor had ever used the word before in reference to Lauren.

She had been sent home from that first hospitalization with the diagnosis of "idiopathic seizure disorder." We were told that she was likely to outgrow the seizures by the time she was the magical age of 5. We were told that her seizures—during which her lips often turned a disturbing bluish gray color—were not damaging her developing brain. We were told that the cocktail of medications, we had no choice but to give her, would have no lasting negative effect. We were never told she had epilepsy.

I hope that no physician avoids using that word again. To call it anything else can delay a family from finding the information and resources they need. And, rather than destigmatizing, it continues the secrecy and shame that increase—not decrease—society's misperceptions about what epilepsy is.

I hope that doctors will no longer sugarcoat what we know or pretend we know something we don't. This is not the foundation on which trust and partnership are built.

I hope that physicians will encourage their patients to seek support and knowledge. And, that they will respect and honor them for those pursuits. They want and need knowledge. They want an end to epilepsy and all that it entails for their loved ones.

I hope that physicians will refer families to specialists whenever indicated and available. This includes epileptologists as well as specialists who may be in the best position to address the comorbidities that are increasingly recognized as accompanying epilepsy in so many children. Particularly in children diagnosed with epilepsy, a whole-patient perspective is essential to ensuring as promising a future for the child as possible.

I hope that patients will recognize—and that physicians will help them do so—that they are equal partners in this journey.

I also hope, for the sake of future generations, that physicians will help their patients understand the value of biomedical research and that stakeholders have an invaluable role to play in advancing research toward better therapies and cures.

Epilepsy—by its very nature—causes an enormous loss of control. Children and their families are dealing with this on a day-to-day, moment-to-moment basis. They need the stability of a relationship with their physician, which includes honest discourse, mutual respect, and trust.

Finally, we must ensure that nobody in this community—stakeholders or professionals—continues to be tolerant of continued seizures and debilitating, ineffective side effects from treatments. If we continue to be complacent and accepting of the status quo, then the rest of society—who may know nothing about epilepsy—will certainly not expect anything more. If we aren't our own self-advocates—beginning in the setting of a doctor's office and expanding beyond to schools, workplaces, and community—epilepsy will continue to be a major public health problem that has plagued mankind for far too long.

Indications for Antiepileptic Drugs Sanctioned by the United States Food and Drug Administration

KAY C. KYLLONEN

Authors in this text have described uses of antiepileptic drugs based on clinical experience and results of clinical trials. In some cases, these clinical indications are broader than those sanctioned by the U.S. Food and Drug Administration (FDA) for product labeling.

To obtain specific FDA-approved indications, pharmaceutical companies present efficacy data from controlled clinical trials. If the data are judged scientifically sound, then the FDA may approve use of the drug for the specific types of patients and seizures studied in the trials. The approved indications are based only on the data presented by the pharmaceutical manufacturer and may not reflect all of the available research information. Once the indications are authorized by the FDA, the pharmaceutical manufacturers may not promote use of the drug for indications other than those specifically delineated in the labeling. However, this does not preclude the "off-label" use of these medications for other indications, including those discussed in this clinical text. By necessity, certain patient populations—most notably, children—are often treated outside of the labeled indications, because prior to recent FDA regulations, they were infrequently included in controlled clinical trials.

Antiepileptic medications mentioned in this text are listed in the following table with their FDA-approved epilepsy- related indications from the 2013 online editions of the Pediatric Lexi-Drugs Online (1), DailyMed (2), or Drug Facts and Comparisons (3), standard references for pharmacists. Some of the listed indications use outdated terminology because they were designated prior to the adoption of international standards for seizure and epilepsy classification. Drugs not yet in any part of the U.S. federal approval process have been marked as "not listed" in the table.

Only four antiepileptics had specific FDA-approved pediatric indications listed in the 1999 Physicians' Desk Reference (4) or Drug Facts and Comparisons (5). At this writing, over 20 medications carry specific FDA approval for pediatric indications. For many other antiepileptic drugs, use in children is implied in the approved product information by mentioning use in specific pediatric syndromes (e.g., infantile spasms or febrile seizures), by listing pediatric formulations (chewable tablets or elixirs), or by describing dosage schedules based on pediatric ages or body weights. The table also notes whether pediatric doses are listed in the any of the following—The

Pediatric Lexi-Drugs Online, DailyMed, or Drug Facts and Comparisons—regardless of whether or not the drug carries a specific FDA-approved pediatric indication. Dosing schedules are further discussed in "Part IV: Antiepileptic Medications" of this textbook; however, it is advisable to consult full prescribing information before clinical use.

Drug	Listed indications: seizure or epilepsy type	Pediatric dose	Pediatric labeling indication
Acetazolamide	Centrencephalic epilepsies (petit mal, unlocalized seizures)	Yes	
Carbamazepine	Epilepsy—partial seizures with complex symptomatology (psychomotor, temporal lobe), generalized tonic–clonic seizures (grand mal), mixed seizures	Yes	Yes
Clobazam	Lennox–Gastaut syndrome	Yes	>2 y
Clonazepam	Lennox–Gastaut syndrome (petit mal variant), akinetic and myoclonic seizures	Yes	
Clorazepate	Adjunctive therapy; management of partial seizures	Yes	>9 y
Corticotropin	Infantile spasms	Yes	Yes
Diazepam	Status epilepticus, severe recurrent convulsive disorders	Yes	Yes
Eslicarbazepine	Not available in the United States		
Ethosuximide	Absence (petit mal) epilepsy	Yes	Yes
Ethotoin	Tonic–clonic (grand mal) and complex partial seizures	Yes	Yes
Felbamate	Adjunctive therapy in Lennox–Gastaut syndrome, monotherapy for partial seizures in adults with epilepsy	Yes	Yes (age >2 y)
Fosphenytoin	Short-term treatment of acute seizures, including status epilepticus; prevention of seizures during and after neurosurgery; substitute for oral phenytoin	Yes	
Gabapentin	Adjunctive treatment of partial seizures with or without generalization	Yes	Yes (age >3 y)
IVIG—intravenous	Intractable epilepsy (possible due to IgG2 subclass deficiency) immunoglobulin, infantile spasms	Yes	
Lamotrigine	Adjunctive treatment of partial seizures and Lennox–Gastaut syndrome	Yes	Yes (≥2 y)
Lacosamide	Partial-onset seizures		
Levetiracetam	Neonatal seizures, partial seizures, and primary generalized epilepsy	Yes	Yes (≥4 y)
Lorazepam	Status epilepticus	Yes	
Mephenytoin	Not available in the United States		
Methsuximide	Absence seizures refractory to other drugs	Yes	Yes
Midazolam	Refractory seizure; status epilepticus	Yes	
Nitrazepam	Not available in the United States		
Oxcarbazepine	Adjunctive therapy partial seizures	Yes	Yes (≥2 y)
Paraldehyde	Not available in the United States		
Paramethadione	Not available in the United States	Yes	
Perampanel	Refractory seizures; partial-onset seizure		Yes (>12 y)
Phenobarbital	Generalized and partial seizures, febrile seizures, status epilepticus	Yes	Yes
Phenytoin	Generalized tonic–clonic (grand mal) and complex partial (psychomotor, temporal lobe) seizures; prevention and treatment of seizures occurring during or following neurosurgery; status epilepticus	Yes	Yes
Pregabalin	Partial-onset seizures in adults		
Primidone	Grand mal, psychomotor, and focal epileptic seizures	Yes	Yes (age > 8 y)
Pyridoxine	Pyridoxine-dependent seizures	Yes	
Remacemide	Not available in the United States		
Rufinamide	Lennox–Gastaut, complex partial-onset seizures	Yes	Yes (>4 y)
Stiripentol	Not available in the United States		
Tiagabine	Adjunctive therapy for partial seizures	Yes	Yes (age ≥12 y)
Topiramate	Adjunctive therapy for partial seizures	Yes	Yes (age > 2 y)
Trimethadione	Withdrawn from US market		
Valproate	Simple and complex absence seizures; adjunctive therapy in multiple seizure types, including absence and complex partial seizures	Yes	Yes (age > 2 y)
Vigabatrin	Adjunctive therapy for complex partial seizures	Yes	Yes (age > 1 mo)
Zonisamide	Adjunctive therapy for partial seizures	Yes
