Wyllie's treatment of epilepsy : principles and practice / editor-in-chief, Elaine Wyllie; associate editors, Barry E. Gidal, Howard P. Goodkin, Tobias Loddenkemper, Joseph Sirven. — Sixth edition.
p.; cm.
Other title: Treatment of epilepsy
Includes bibliographical references and index.
ISBN 978-1-4511-9152-3
I. Wyllie, Elaine, editor.II. Gidal, Barry E., editor.III. Goodkin, Howard P., editor.IV. Loddenkemper, Tobias, editor. V. Sirven, Joseph I., editor. VI. Title: Treatment of epilepsy.
[DNLM:1. Epilepsy—therapy.2. Epilepsy—diagnosis.WL 385]
RC372
616.8'53—dc23
2014028715

Cover Art: Exciting new research demonstrates that MRI post-processing analysis using first-order texture models may enhance localization of subtle focal cortical dysplasia, as in this illustrative case adapted from Figure 2, Chapter 77.

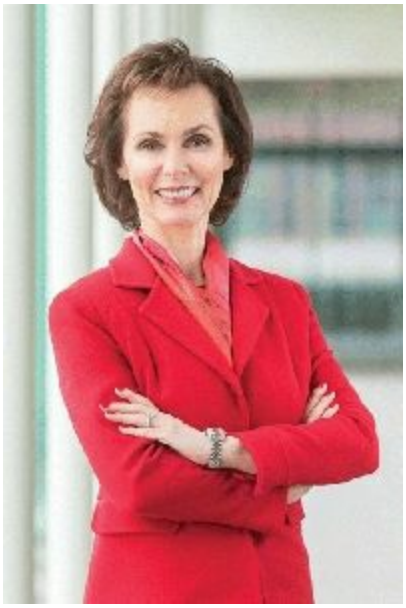
With thanks to Dr. Andrea Bernasconi for sharing this case, and to Mr. Jeffrey Loerch for his artistic rendition.

DEDICATION

To my dance partner, Dr. Robert Wyllie, our choreographer, Mr. Dick Blake, and all the outstanding caregivers at Cleveland Clinic.

In the pursuit of both of my two passions, medicine and dance, I have been privileged to study and practice with the very best.

ABOUT THE AUTHOR



Dr. Elaine Wyllie, Professor, Lerner College of Medicine, is a pediatric epilepsy specialist at Cleveland Clinic. Presenting six editions of Wyllie's Treatment of Epilepsy is one of her proudest achievements. She has also published over 250 reports on her research in epilepsy in scientific journals and received many honors including the prestigious Epilepsy Research Award from the Milken Family Foundation and the American Epilepsy Society. Now that her two sons are grown and pursuing their own scientific careers, Dr. Wyllie's hobby is ballroom dancing with her husband on a professional level.

CONTRIBUTING AUTHORS

Nicholas S. Abend, MD

FOREWORD

Epilepsy is one of the most common of all chronic neurologic disorders. An Institute of Medicine of the National Academies consensus report, Epilepsy Across the Spectrum: Promoting Health and Understanding, released on March 30, 2012, indicated that one in 26 individuals during their lifetime will develop a seizure disorder. The prevalence of epilepsy appears to be increasing and is twice the number of patients with multiple sclerosis, Parkinson disease, and autism spectrum disorders combined. Approximately 2.2 million people in the United States and 65 million individuals worldwide have epilepsy. One hundred and fifty thousand individuals develop a seizure disorder each year in the United States, the highest risk groups being in the most vulnerable people, that is, the very young and very old.

The toll of this common neurologic disorder is enormous. In addition to seizures, other comorbid conditions impacting patients' quality of life include depression and anxiety, cognitive impairment, psychosocial debilitation, lack of employment and educational opportunities, social isolation, and inability to operate a motor vehicle. These concerns are most prominent in patients with drug-resistant epilepsies that may be physically, medically, and socially disabling. Practical considerations for selected individuals with epilepsy include the cost of medications, access to appropriate epilepsy care, and limited health insurance. Finally, the care of people with epilepsy in many developing and resource-poor countries, an estimated 80% of the 65 million patients worldwide, is largely unsatisfactory and almost nonexistent.

There are still important gaps in knowledge regarding diagnosis and management of individuals with recurrent seizures, even though epilepsy has been recognized as an important illness for over 3000 years. It was first referred to as the "falling down disease" in the ancient Babylonian cuneiform medical text, the Sakikkū. Hippocrates, considered the father of medicine, made the seminal observation in the 5th century BCE that epilepsy was not a divine illness, but a malady involving the brain that may have a hereditary association. Our present understanding of epilepsy began with the pivotal studies of John Hughlings Jackson (1835–1911) and his colleagues at the National Hospital for Diseases of the Nervous System including Paralysis and Epilepsy in Queen Square, London. Jackson proposed that the cerebral cortex was an essential structure for epileptogenesis and introduced the basic tenets of focal epilepsy. The writings and teachings of Jackson in the last two decades of the 19th century (summarized in the two volume series edited by James Taylor, Selected Writing of John Hughlings Jackson, Staples Press, London, 1958) remain the foundation and cornerstone of our current understanding of clinical epileptology.

The 20th century witnessed enormous changes in our knowledge of epilepsy and in the development of diagnostic techniques and potential therapeutic modalities. Students of epileptology know well the history of the introduction and advances in EEG, antiepileptic drug therapy, neuroimaging, and epilepsy surgery in the past century. Unfortunately, despite these important contributions, approximately one-third of patients at present have drug-resistant epilepsy that may be debilitating to the people with epilepsy, their families, and caregivers. Adverse effects of therapy further may comprise the individual's quality of life.

The sixth edition of Wyllie's Treatment of Epilepsy will serve as an outstanding testimony to the

enormous progress in the evaluation and treatment of people with epilepsy that has been made by the individuals at the forefront of experimental and clinical research. Significant changes both in content and authors have been made since the fifth edition. The 95 chapters represent an international effort with the pioneers in epilepsy research and leading figures in patient care providing contemporary reviews of pivotal information as well as a glimpse into future advances. A virtual "Who's Who" in epilepsy that includes both relatively junior up-and-coming investigators and senior well-established individuals represents the contributing authors for this comprehensive textbook. The editor-in-chief and associate editors should be congratulated for identifying and properly motivating this distinguished group of experts to share their knowledge and experience in their chapters.

As has been true with prior editions of Wyllie's Treatment of Epilepsy, the volume is superbly organized into six parts each with multiple sections. Impressive leaders in epilepsy who are also prolific investigators serve as the associate editors. The reader is able with minimal effort to navigate through the textbook and identify a subject of interest and read a comprehensive but concise chapter on a wide range of material. This volume is essential for individuals involved in clinical research and patient care both in the community as well as academic centers. This should serve as a "go to" source of information in clinical epileptology. The broad contents of the sixth edition will have a putative beneficial effect on the care and management of people with epilepsy.

I am extremely honored and privileged to be invited to present the sixth edition of Wyllie's Treatment of Epilepsy and recognize that this excellent book will superbly serve the needs and goals of our patients. One century ago phenobarbital (introduced for epilepsy in 1912) was the only appropriate treatment available for the treatment of seizure disorders, and many people with epilepsy were relegated to epilepsy colonies. This textbook will both document the tremendous advances in our understanding and management of seizure disorders and also indicate ongoing areas of investigation that may result in effective therapeutic modalities. The existing gaps in knowledge in the diagnosis and treatment of epilepsy are significantly narrowed in this outstanding international effort that will inspire future research endeavors and advance the cause of patient care. The care and management of people with epilepsy must go beyond reducing seizure tendency, also attempting to enrich the lives of our patients and allowing the individuals to become productive and participating members of our society. Wyllie's Treatment of Epilepsy will assist in this task.

Preface

Since the conception of our first edition in 1991 through our current sixth edition, we have been working diligently to perfect this text. It is considered the book with no peers, because its diverse authors are the most influential experts on the world stage today. Their informative chapters present the latest advances and authoritative research in epilepsy medicine, giving us the current state of scientific knowledge and the most up-to-date approach to clinical treatment.

It is our privilege to announce a new concept introduced with this edition. The esteemed authors have collaborated to create an electronic bank of over 500 board review-style questions spotlighting key concepts for active learning. Whether you are studying for a board examination or sharpening your clinical skills for daily practice, completing these skillfully crafted questions on-line will afford great insight and understanding.

We are honored to present this sixth edition, and trust you will find it both practical and enlightening.

Elaine Wyllie, MD
Professor of Medicine
Cleveland Clinic Lerner College of Medicine
Epilepsy Center, Neurological Institute
Cleveland Clinic
Cleveland, Ohio

ACKNOWLEDGMENTS

Any project of this magnitude is the result of extraordinary teamwork. At the core, of course, were the internationally renowned authors. Also indispensable were the brilliant associate editors, Dr. Barry E. Gidal, Dr. Howard P. Goodkin, Dr. Tobias Loddenkemper, and Dr. Joseph I. Sirven, who guided each chapter into its final form with skill and grace. Dr. Loddenkemper also edited the 500-plus board review-style questions, bringing the book into a new dimension. Ms. Andrea Vosburgh provided impeccable editorial assistance, and Ms. Vedhapriya Ramesh Babu meticulously transformed the manuscript to final printer files. And I owe everything to Dr. Robert Wyllie III, Chief Medical Operations Officer of Cleveland Clinic—my husband, dancing partner, and father to our sons, Mr. James Wyllie and Dr. Robert Wyllie IV, who make us proud.

PART I PATHOLOGIC SUBSTRATES AND MECHANISMS OF EPILEPTOGENESIS

SECTION A EPIDEMIOLOGY AND NATURAL HISTORY OF EPILEPSY

ASSOCIATE EDITOR: HOWARD P. GOODKIN

CHAPTER 1 EPIDEMIOLOGIC ASPECTS OF EPILEPSY

CHRISTINE LINEHAN AND ANNE T. BERG

INTRODUCTION

Epidemiology is the primary research branch of public health. As such, the goal of epidemiologic investigations is to provide information about the frequency in the population of various diseases and conditions, to identify high-risk groups, to provide leads into causation and prevention, as well as to monitor trends over time and across regions or countries.

Estimations of the frequency of epilepsy within the population have recently been revised upward from an estimated 50 million people worldwide (1) to approximately 69 million people (2). The disparity in these figures may be partially explained by the fact that while the lower estimate is derived from a "best guesstimate" by key informants in 160 countries, the higher estimate is based on a meta-analysis of 65 prevalence studies, conducted in 37 countries, which met a predefined inclusion criterion. The meta-analytic study may be deemed to have a stronger empirical basis and may therefore provide a more accurate estimate of the true numbers of people worldwide with epilepsy.

A breakdown of these data by geographical location highlights the uneven distribution of epilepsy throughout the globe. Of the estimated 69 million persons worldwide who have epilepsy, 45 million (65%) are estimated to live within rural regions of countries classified by the World Bank as "developing," with a further 17 million (25%) living within urban areas of these countries. Just 7 million individuals, approximately 10% of all those with epilepsy worldwide, are estimated to live in "developed" countries (2).

The greater burden of epilepsy observed in developing regions is multifaceted, but a major contributor is the "treatment gap," that is, the difference between the number of individuals with active epilepsy on the one hand and the number who have difficulty accessing or adhering to treatment on the other. Estimates suggest that the treatment gap may exceed 75% in low-income countries, a figure that compares unfavorably with the estimated 10% gap observed in countries of high income (3). Despite the considerable skewing of prevalence within developing countries and the challenges of delivering optimal health care, epidemiologic research is hampered in these jurisdictions, most particularly given the challenges of sourcing accurate population-based denominators that are typically available in the developed world (4).

Prevalence estimates provide an important indicator of the burden of epilepsy worldwide. Mortality data are similarly used to quantify, albeit crudely, the impact of the condition within populations. The Global Burden of Disease (GBD) study, pioneered by the World Health Organization, the World Bank, and the Harvard School of Public Health and supported by the Bill and Melinda Gates Foundation (5), gathers cause of death data across the globe. Mortality data from GBD 2010 indicate that 117,600 persons with epilepsy die annually, equating to 0.3% of all deaths

worldwide. Mortality statistics, however, mask the burden of disease among those living with epilepsy. Acknowledging the need to define burden beyond mortality, the GBD study introduced a new metric to measure the burden of diseases, injuries, and risk factors—the DALY (disability-adjusted life year). DALYs were calculated in GBD 2010 as the sum of years of life lost and years lived with a disability (6). Using this algorithm, epilepsy is estimated to contribute 17,429,000 DALYs (0.7%) to the GBD.

While the GBD data provide valuable insights into the global burden of epilepsy, commentators have called for more detailed information that would breakdown these data by type of epilepsy and seizure frequency, factors that are strongly associated with quality of life (7). GBD's own disability weightings, which quantify the health loss associated with epilepsy, reflect the strong association between severity and impact. The weighting for treated epilepsy, where an individual is seizure free, is 0.072. In contrast, the weighting of "severe" epilepsy is 0.657 (8). This latter weighting was almost the highest rating allocated to any of the disabilities assessed in GBD 2010 and can be interpreted within the context of a DALY weighting of one "essentially meaning dead" (9).

The burden of epilepsy, however, extends beyond physical health status. Stigma and discrimination are common features of the condition worldwide (10,11). Profound social isolation (12), feeling of shame and discomfort (13), and higher risk of psychiatric disorder (14) are among a host of variables contributing to a compromised quality of life. Poor employment opportunities, lost work productivity, and out-of-pocket health care expenses contribute to the economic burden of epilepsy not only for the individual with epilepsy but also for the family and the wider community (15). In combination, these findings leave little doubt regarding the substantial burden of epilepsy.

The first epidemiologic study of epilepsy was conducted in 1959 by Leonard T. Kurland and reported population-based data from Rochester, Minnesota, over a 10-year period. Kurland acknowledged that data existed from "numerous reports based on proportionate hospital admission rates and selected case series" but observed that "these data are not necessarily representative of a population from which the patients are drawn" (16; p. 143). This observation was to profoundly impact not only the future of epidemiologic studies in the field but moreover the prevailing view of epilepsy and its prognosis. What Kurland had observed was that studies based on institutionalized patients suffered an inherent bias whereby those with more severe levels of epilepsy were overrepresented. Those with milder forms of epilepsy were less likely to attend specialist referral centers and were therefore less likely to be identified in these studies. The consequence of failing to include those with milder forms of epilepsy in epidemiologic studies was that epilepsy appeared an unremitting and chronic condition affecting a somewhat smaller proportion of people with epilepsy in the population (17).

Early epidemiologic studies that followed from Kurland's work contributed substantially to our current understanding of epilepsy. Additional studies exploring the Rochester longitudinal population-based datasets, for example, illustrated that the occurrence of epilepsy and isolated seizures was relatively common (18). These datasets also revealed that the probability of being in remission, as defined by 5 consecutive years of seizure freedom, was also more common than previously thought (19), an important consideration for investigators determining prevalence estimates (Fig. 1.1). These early epidemiologic findings provided an evidence base of the occurrence and prognosis of epilepsy that contributed to advances in the treatment and management of seizures (17).

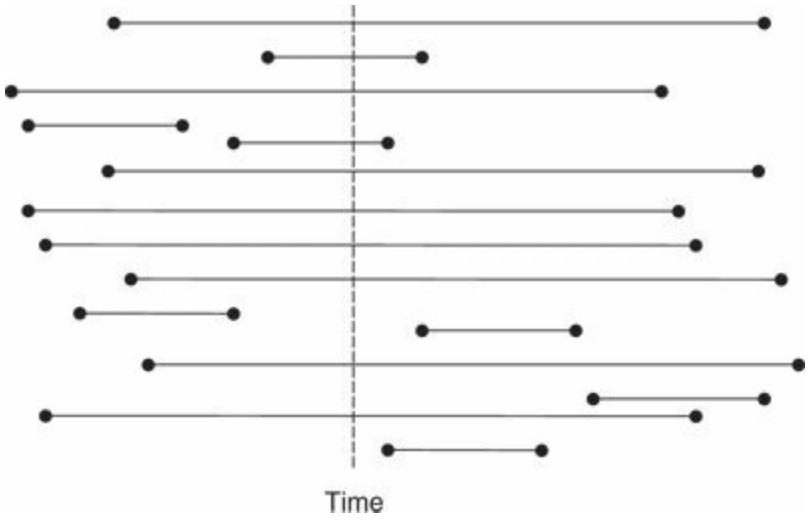

Figure 1.1. Prevalence bias. Each horizontal line represents a case with active disease (i.e., a prevalent case). The length of the line represents the time of the active disease, with onset to the left and offset or death to the right. The dashed vertical line represents the day on which prevalence is measured. Long-duration cases are oversampled (8 of 8 are ascertained on the prevalence day) relative to short-duration cases (2 of 7 are ascertained on the prevalence day).

Epidemiologic investigations since these early studies continue to inform and challenge our understanding of epilepsy. This chapter aims to outline current definitions and distinctions in epidemiologic research. In addition, findings from more recent studies and the challenges presented to investigators conducting these studies are outlined.

FREQUENCY MEASURES OF INCIDENCE AND PREVALENCE

Incidence is expressed as the number of new cases of disease in a standard-sized population per unit of time—for example, the number of cases per 100,000 population per year. Prospective studies of incidence are advocated as they permit observation of any changes in the incidence rate (20) and may therefore identify risk factors that play a causal role in the development of epilepsy (21,22). Ongoing surveillance studies of this type, however, are time consuming and costly (20,23) and are therefore less common than prevalence studies (20,23) and less likely to be conducted in resource-poor countries (24). Incidence rates for epilepsy are typically between 30 and 80 per 100,000 population per year in developed countries but have been observed to exceed these figures. Table 1.1 presents a selection of studies illustrating this trend.

Table 1.1 Incidence and Prevalence of Epilepsy as Reported in Selected Population-Based Studies Throughout the World

	First author/year	Country/region	Methodology	Age group (years)	Incidence/100,000/year	Prevalence/1000
Africa	Houinato et al. (2013) (25)	Benin	Door-to-door survey screening with confirmatory examination of those screening positive for epilepsy followed by capture–recapture method	All ages	69.4	38.4 lifetime following capture–recapture
	Mung'ala Odera et al. (2008) (26)	Kenya	Combined data from two door-to-door studies	Children	187	41 lifetime 11 active
	Dozie et al. (2006) (27)	Nigeria	Door-to-door survey screening with confirmatory examination of those screening positive for epilepsy	All ages	—	12 active
Latin America	Chong et al. (2013) (28)	Arizona–Mexico Border	Door-to-door survey screening with confirmatory examination of those screening positive for epilepsy	All ages	—	14.3 lifetime 11.8 active
	Noronha et al. (2007) (29)	Brazil	Door-to-door survey screening with confirmatory examination of those screening positive for epilepsy	All ages	—	9.2 lifetime 5.4 active
	Melcon et al. (2007) (30)	Buenos Aires	Door-to-door survey screening with confirmatory examination of those screening positive for epilepsy	All ages	—	6.2 lifetime 3.8 active
Europe	Dura-Trave et al. (2008) (31)	Spain	Cases referred to neuropediatric reference centre	Children under 15 y	62.6	—
	Christensen et al. (2007) (21)	Denmark	Data Linkage (Civil Registration and Hospital Register Databases)	All ages	68.8	5.7 lifetime
	Olafsson et al. (2005) (32)	Iceland	Cases identified via countrywide surveillance system in health care facilities with confirmatory review by neurologists	All ages	56.8 all unprovoked seizures; 23.5 single unprovoked seizures; 33.3 epilepsy	—
North America	Kaiboriboon et al. (2012) (33)	Ohio	Cases identified via Medicaid claims database	18–64 y	362	13.2 lifetime
	Benn et al. (2008) (34)	New York	Cases identified via review of local hospital and nursing home registers with follow-up interviews	All ages	41.1[a]	—
	Kobau et al. (2008) (35)	USA	Self-report omnibus health survey	Over 18 y	—	16.5 lifetime 8.4 active
Asia	Fong et al. (2008) (36)	Hong Kong	Population-based phone screening followed by neurologic validation	All ages	—	8.49 seizure disorders 3.94 active
	Tran et al. (2006) (37)	Central Lao	Door-to-door survey screening with confirmatory examination of those screening positive for epilepsy	All ages	—	7.7 active
	Mani et al. (1998) (38)	Rural South India	Door-to-door survey screening with confirmatory examination of those screening positive for epilepsy	All ages	49.3	4.19 lifetime 3.91 active

[a]First unprovoked seizure and newly diagnosed epilepsy.

Worldwide, rates vary across regions, with rates being typically higher in resource-poor countries (22), most especially in Africa and Latin America, where figures can exceed 100 per 100,000 population (39–41). Rates also differ by age, but differentially in developed and resource-poor countries. In developed countries, rates are highest among infants and older persons (31,42–44). Although incidence rates among children have fallen over the last three decades in developed countries, this decrease has been offset by an increase among older persons (45). A different age-related pattern emerges in developing countries, however, where a decrease in incidence is observed with age (22). The larger proportion of children in the population in developing countries is thought is to contribute to the higher overall incidence rates when compared with developed countries (21,22).

Prevalence studies measure the total number of persons with epilepsy at a specific moment in time. Prevalence rates are usually expressed as the number of persons with epilepsy per 1000 population. Estimates of active epilepsy are typically the focus of prevalence studies, with those in remission or who are not receiving treatment at the time of case ascertainment being excluded. A

"plethora of studies" that consistently report prevalence estimates of active epilepsy in developed countries of between 4 and 10 per 1000 population suggest that there is "little justification for further cross-sectional studies of prevalence" (46, p. 168) in these countries. Recent findings from Norway, however, of 12 per 1000 treated epilepsy and 7 per 1000 active cases in a population that excluded high-risk groups such as older persons have led investigators to suggest that the true prevalence of epilepsy in developed countries may be higher than previously reported (47). Prevalence estimates typically increase with age and are generally higher among males than females (20) although this difference may not always reach statistical significance.

Prevalence estimates in resource-poor countries are generally higher than in developed countries (46). Median prevalence of active epilepsy in Latin America is reported as 12.4 per 1000 population; however, this finding conceals widely varying findings from individual studies ranging 5.1 to 57 per 1000 population (48). This wide variation in estimates is also observed in Africa where estimates have been reported ranging from 5.2 to 58 per 1000 (49,50). While researchers note that known risk factors, such as environment, contribute to the high prevalence estimates on the African continent (26), some authors suggest that the true prevalence estimate may actually be higher again as disclosure of the condition is particularly problematic (51). Reviews of studies conducted in Asia, perhaps surprisingly, report findings aligning more closely with those in developed countries. This has led some investigators to speculate whether there is a specific protective factor as yet unknown in Asia or whether the finding reflects specific risk factors in Latin America and Africa (23). Table 1.1 presents findings from some recent studies worldwide.

Several recent studies have examined the relative frequency, if not absolute incidence, of different forms of epilepsy in well-characterized series of incident patients who were reasonably representative of the populations from which they were drawn (Table 1.2). Apart from the obvious difference between adults and children, there is a degree of variation among the studies just of children as well. Whether this represents real differences across populations or methodologic difference between studies is not clear. Certainly, patterns of referral to recruitment sources as well as diagnostic ability of the physicians who evaluate the patients could create apparent difference between studies where none exist. Such concerns aside, a few generalities can be drawn. Fewer children than adults are likely to have an unclassified form of epilepsy. In children, idiopathic focal epilepsies (largely dominated by benign rolandic epilepsy) comprise about 5% to 10% of childhood-onset epilepsy. The idiopathic generalized epilepsies comprise 20% to 40%. Finally, between 10% and 20% of childhood-onset epilepsy falls into the category of secondary generalized. These are some of the most devastating and intractable forms of epilepsy and include West and Lennox–Gastaut syndrome.

Table 1.2 Distribution of Epilepsy Syndromes in Newly Diagnosed Patients from Eight Different Countries

Syndrome	Connecticut[a] (52)	France[b] (53)		The Netherlands (54)	Italy[c] (55)	Columbia (56)	Sweden (57)	Japan (58)	Iceland (32)
	Children <16 years	Children <14 years	Adults ≥25 years	Children <16 years	Children	All ages	Children <16 years	Children <16 years	All ages
	N (%)	*N* (%)	*N* (%)	*N* (%)	*N* (%)	*N* (%)	*N* (%)	*N* (%)	*N* (%)
11 idiopathic focal	61 (10%)	47 (9%)	1 (<1%)	31 (7%)	21 (9%)	2 (2%)	46 (23%)	55 (5%)	16 (6%)
12 symptomatic focal	71 (12%)	34 (7%)	81 (27%)	74 (16%)	92 (38%)	27 (29%)	9 (4%)	345 (29%)	74 (26%)
13 cryptogenic focal	227 (37%)	121 (24%)	107 (35%)	87 (19%)	0 (0)	45 (49%)	49 (24%)	507 (42%)	78 (27%)
21 idiopathic generalized	126 (21%)	199 (40%)	15 (5%)	195 (42%)	67 (28%)	9 (9%)	37 (18%)	95 (8%)	30 (10%)
22 cryptogenic/ symptomatic generalized	43 (7%)	39 (8%)	0 (0)	29 (6%)	50 (21%)	2 (2%)	47 (23%)	173 (14%)	6 (2%)
23 symptomatic generalized	9 (1%)	14 (3%)	7 (2%)	41 (9%)	1 (<1%)	0 (0)	0 (0)	0 (0)	1 (<1%)
31 generalized and focal features	5 (1%)	13 (3%)	0 (0)	1 (<1%)	1 (<1%)	0 (0)	0 (0)	0 (0)	8 (3%)
32 unclassified	71 (12%)	34 (7%)	94 (30%)	2 (<1%)	19 (8%)	6 (7%)	17 (8%)	21 (2%)	77 (27%)
Total number of patients	613	501	305	462	251	92[d]	205	1196	290

[a]The cryptogenic and symptomatic localization–related categories were redefined to be consistent with the interpretation of other authors and to facilitate comparisons.

[b]Limited to children <14 y of age.

[d]Listed as "special syndrome."

CURRENT DEFINITIONS AND DISTINCTIONS USED IN EPIDEMIOLOGIC EPILEPSY RESEARCH

Epilepsy (recurrent, unprovoked seizures) must be distinguished from many other conditions and situations in which seizures may occur. The following definitions are generally accepted and are in widespread use.

Epileptic Seizure

An epileptic seizure is a "transient occurrence of signs and/or symptoms due to abnormal excessive or synchronous neuronal activity in the brain" (59). Epileptic seizures must be distinguished from nonepileptic seizures and from other conditions that may produce clinical manifestations that are highly similar to those caused by epileptic seizures.

Acute Provoked Seizure

An acute provoked seizure is one that occurs in the context of an acute brain insult or systemic disorder, such as, but not limited to, stroke, head trauma, a toxic or metabolic insult, or an intracranial infection (60).

Unprovoked Seizure

A seizure that occurs in the absence of an acute provoking event is considered unprovoked (60). A history in the past of stroke, trauma, or other condition may be present; however, at the time of the seizures, no specific acute insult has occurred.

Epilepsy

The widely accepted operational definition of epilepsy requires that an individual has at least two unprovoked seizures on separate days, generally 24 hours apart. An individual with a single unprovoked seizure or with two or more unprovoked seizures within a 24-hour period is typically not at that time considered to have met the criteria for the diagnosis of epilepsy per se (60). An International League Against Epilepsy (ILAE) document from 2005 attempted to provide a conceptual definition of epilepsy, which entailed the notion of an enduring underlying predisposition to unprovoked seizures (59). The definition was presented, however, as an operational definition and engendered considerable controversy and response (61–63) precisely because there was no way to ensure that it would be consistently and validly applied across different settings by different investigators, a quality that is a prerequisite for meaningful research. A new practical clinical definition of epilepsy has now been agreed upon. Epilepsy is defined as any one of the following conditions: (a) at least two unprovoked (or reflex) seizures occurring >24 hours apart; (b) one unprovoked (or reflex) seizure and a probability of further seizures similar to the general recurrence risk (at least 60%) after two unprovoked seizures, occurring over the next 10 years; or (c) diagnosis of an epilepsy syndrome. Epilepsy is considered to be resolved for individuals who either had an age-dependent epilepsy syndrome but are now past the applicable age or have remained seizure free for the last 10 years and off antiseizure medicines for at least the last 5 years (63). As this definition was just published in 2014, few studies have used it, and most of the literature is based on the earlier definition of two or more unprovoked seizures.

A first seizure often is the first identifiable sign of epilepsy, and in some cases, it is possible to recognize the specific underlying disorder (form of epilepsy) at its earliest presentation (53). In the case of Dravet syndrome, the first definitive sign may be a febrile seizure—typically hemiclonic and prolonged—and, with a genetic test, the epilepsy may be diagnosed before "unprovoked" seizures emerge (64). Such situations may be rare and are difficult to ascertain and handle well in many epidemiologic studies because of the relatively crude diagnostic information used. For the field of epilepsy, however, they are increasingly important and should not be ignored.

Etiology

Terminology for referring to etiology has evolved considerably in the last several years. The old, traditional terms, idiopathic, cryptogenic, and symptomatic, are gradually being abandoned in favor of clearer more descriptive language. The 2010 ILAE Commission report recommended as an initial starting point the terms "genetic," "structural–metabolic," and "unknown" to refer to classes of causal factors. Note, these are categories for causes, not the form (syndrome) of epilepsy per se. Each was carefully defined: genetic refers to causes for which, to our best understanding, the seizures are a direct result of the genetic error and seizures are the core symptom of the disorder. Evidence concerning a genetic role may come from molecular studies but may also be derived from well-conducted clinical studies (e.g., twin studies). This differs from the old idiopathic (meaning "presumed genetic") as a basis for the genetic inference is stated, and, unlike idiopathic, genetic includes disorders that do not necessarily have a "benign" outcome. The unwieldy term "structural–metabolic" is intended to identify people with known underlying brain disorders that are primary contributors to their epilepsy. As most metabolic and many structural disorders have a genetic basis, the distinction between genetic–structural–metabolic may seem fuzzy. The distinction focuses on the mechanism by which the genetic defect influences epilepsy as well as the constellation of symptoms presented by the patient, primarily seizures or seizures secondary to some other medical condition.

The role of autoimmunity, an extremely important contributor to some epilepsies is not adequately evoked by the term structural–metabolic either (65,66). As the mechanisms linking the precipitating cause to development of epilepsy become better understood, it becomes more difficult to pigeonhole some causes. For example, recent evidence suggests that some forms of cortical malformations that cause epilepsy are themselves due to viral infections in utero (67). Finally, for referring to situations in which the cause is simply unknown, the term "unknown" was suggested. This was meant to be considered as a true statement of uncertainty or ignorance, without assumptions.

The ability to identify the likely causes of epilepsy has changed dramatically over time with the introduction and increasing sophistication of neuroimaging and genetic testing. These changes are not uniformly implemented across countries or even across subpopulations within a country. Consequently, the unevenness of precision raises problems for cross population (including across time period) comparisons. For epidemiologic purposes, especially on the global level, a very pragmatic distinction could be made between what might be called complicated and uncomplicated epilepsy. Complicated epilepsy would include any epilepsy associated with a factor that is presumed to cause epilepsy (stroke, trauma, tuberous sclerosis, etc.) or any evidence of neuroimpairment (substantial developmental delay, intellectual impairment, abnormal motor or sensory exam) that can result from a cortical insult. Implicitly, uncomplicated would refer to epilepsy in which there is no clear insult or condition to which the occurrence of the epilepsy can be attributed and the individual is neurotypical (normal exams and cognition).

Grey Areas

Neonatal seizures (i.e., those occurring in an infant <28 days old) are usually differentiated from epilepsy for a variety of reasons; however, this approach makes little sense as several specific forms of epilepsy have been reported in this age group (68), and there is no good reason that factors that would be considered structural or metabolic causes of epilepsy in an older individual would be treated differently in the neonate. Unfortunately, epidemiologists often do not have the detailed information needed to distinguish the child with a seizure secondary to transient hypoglycemia from a child who seizes because of a KCNQ2 encephalopathy (69) or a brain malformation. Febrile seizures are a well-described and recognized seizure disorder, which, for historical reasons, has been distinguished (both clinically and in research) from epilepsy. For those involved in detailed genetic investigations, this may be an inappropriate distinction. For the epidemiologist, however, who may not always have the necessary clinical and particularly the genetic detail, the distinction is of value. It also has important clinical implications for the treatment of most of these children with such seizures.

Epilepsy Syndromes

Epilepsy syndromes have been alluded to above and are presented in greater detail in subsequent chapters of this book. Epilepsy, like cancer, is not a single disorder, and the efforts to identify specific forms of epilepsy reflect the importance of the diversity within the epilepsies. The epilepsy syndromes represent forms of epilepsy that have different causes, different manifestations, different implications for short- and long-term management and treatment, anticipatory guidance, genetic counseling, and long-term outcomes. Many epidemiologic studies do not attempt to identify specific forms of epilepsy; however, in large-scale population- and community-based studies, it is possible to do so, provided the investigators have access to the necessary information and the expertise needed to

diagnose these syndromes (52–54). As the questions in epileptology become increasingly sophisticated, including precise characterization of specific causes, types of seizures, and types of epilepsy, the gap between what typical epidemiologic studies can do versus the types of information needed from them has been widening.

Seizure Types

Perhaps the greatest and most relevant distinction for broad-scaled epidemiologic investigations is between convulsive and nonconvulsive seizures as a very crude marker of severity. The term tonic–clonic should generally be eschewed in epidemiologic studies as it is often misused to refer to any "big" seizure regardless of whether tonic and clonic components are both present. Diagnostic precision to identify other seizure types is generally inadequate in epidemiologic studies, and the basis of identifying other seizure types requires significant scrutiny.

EPIDEMIOLOGIC CHALLENGES

Epidemiologic studies have provided valuable insights into the frequency of seizures within the population and have provided the initial impetus for some of the distinctions outlined above. As Kurland noted, however, epidemiologists need to be vigilant to potential sources of bias that threaten the validity of their findings. The ability of diagnosticians to appropriately identify cases and the capabilities of epidemiologists to identify those cases within the population are fundamental issues within the field of epidemiology. We also note that, as the clinical and scientific field of epilepsy has grown much more sophisticated, epidemiologists must work to keep up with important diagnostic and lexical distinctions.

Diagnostic Issues and Considerations in Ascertaining Cases

Seizures and epilepsy present a complex situation because the diagnosis is not based on a single source or type of information. Rather, epilepsy is a clinical diagnosis supported to a greater or lesser extent by a wide range of data obtained from several sources: the history (both from the patient and witnesses) of the events believed to be seizures, the circumstances under which the events occur, the past medical history, medications, a neurologic examination, reliable EEG, and increasingly neuroimaging (70). To have a valid diagnosis, one must also be able to rule out many other conditions that mimic seizures. These disorders include, but are not limited to, movement disorders, parasomnias, attention deficit/hyperactivity disorder, pseudo- or nonepileptic seizures, transient ischemic attacks, and syncope (71,72).

Ideally, a diagnosis of epilepsy should be undertaken by medical practitioners with expertise in epilepsy (73). Unfortunately, access to neurologists and epilepsy specialists is generally poor in developing countries and often poor in developed countries as well. Consequently, diagnoses may be made by those with only minimal expertise in the field (35,74). Estimates of misdiagnosis rates suggest that over one-fifth of persons with a diagnosis of epilepsy may be misdiagnosed (75,76). Reevaluation of initial diagnosis of epilepsy in epidemiologic studies reports rates of 23% (77,78) with diagnostic doubt among patients diagnosed by neurologists and nonspecialists reported at 5.6% and 18.9%, respectively (79). In 2007, a UK All Party Parliamentary Group on Epilepsy convened to determine the "human and economic cost of epilepsy" in England. The report estimates that 74,000

people in England are misdiagnosed with epilepsy and are therefore receiving inappropriate treatment. The financial cost of unnecessary or incorrect treatment combined with lost employment was estimated in 2007 at £134 million per annum (80).

Epidemiologic studies that rely on medical registers for case ascertainment provide valuable insights into levels of misdiagnoses. Christensen et al. (21), for example, randomly selected 200 patients with an ICD diagnosis of epilepsy from the Danish National Hospital Register, a national register of all discharges and outpatient cases from Danish hospitals. The authors found that almost one in five (19%) of the sample did not fulfill the ILAE criteria for an epilepsy diagnosis. In fact, approximately 7% of patients were given an epilepsy diagnosis on the basis of one seizure. Christensen et al. (81) also noted that while the validity of epilepsy diagnosis from the register was moderate to high, there was low predictive value for epilepsy syndromes.

Primary care registers, a common source of case ascertainment in epidemiologic research, have also been found to include persons incorrectly diagnosed with epilepsy. Gallitto et al. (82) gathered population-based data from general practitioners (GPs) in the Aeolian Islands. All established or suspected cases of epilepsy were evaluated by epileptologists in the local outpatient services with the support of the local GPs or, for those with additional disabilities, within the family home. The evaluations comprised a review of medical notes and where necessary EEG or neuroradiologic investigation. Following the epileptologic evaluation, 30% of established and suspected cases were identified as not fulfilling the diagnostic criteria for epilepsy.

These high levels of misdiagnosis have resulted in calls for a gold standard diagnostic criterion to distinguish epilepsy from other conditions with similar clinical features (75). The UK National Institute for Health and Clinical Excellence (NICE) provides support to diagnosticians via its recently updated guidelines “The epilepsies; the diagnosis and management of the epilepsies in adults and children in primary and secondary care” (83). The NICE recommends that all individuals with a recent-onset suspected seizure be seen within a 2-week period by a specialist, defined as a medical practitioner with expertise in epilepsy. The implementation of these guidelines for children is currently being monitored by Epilepsy12, a nationwide audit aiming to ensure a standardized level of provision across the United Kingdom (84).

In addition to the determination of whether or not someone has epilepsy, adequate information is needed to identify the specific form of epilepsy and its underlying cause. While this level of detail is frequently absent from traditional epidemiologic studies, it must be incorporated in the future if epidemiologic studies are to continue to inform scientific and clinical endeavors relevant to epilepsy as it is understood and treated today. Without a meaningful diagnostic evaluation, epidemiologic studies can do little more than provide an approximate head count, which previous work has shown to be rather error prone. The lumping together of highly diverse disorders that share the diagnostic label “epilepsy” also limits the ability of epidemiologic studies to provide meaningful prognostic information.

The case ascertainment options described above, based on medical registers, may not be suitable for all epidemiologic studies. Where these registers are unavailable, or may be considered unrepresentative, other more population-based methods may be used to identify people with epilepsy. As was observed for medical registers, these methods also have their own unique challenges. Screening questionnaires, for example, are a common tool used in epidemiologic studies. Methodologies employing screening questionnaires typically comprise two phases. In the first phase, a screen is used to identify positive cases. In the second phase, these positive cases are evaluated clinically to confirm the presence of epilepsy. Noronha et al. (29), for example, used a screening tool

developed by Borges et al. (85) in the first phase of their study to determine the prevalence of epilepsy in Brazil. The screening tool reported sensitivity and specificity at 96% and 98%, respectively. Similarly, Melcon et al. (30) used a modified version of a screening tool from the Copiah County study (86) to identify potential cases for inclusion in their prevalence estimate of epilepsy in Argentina. This screening tool also reported acceptable levels of sensitivity and specificity at 95% and 80%, respectively. More recently, a three-stage survey methodology has been proposed that comprised a two-item first survey, a more extensive second survey, and a third-stage clinical validation. This methodology reported a sensitivity of 49% and specificity of 100% and was found to be 37% less expensive than the more traditional two-stage process (87).

Screening tools are advocated by the World Health Organization, whose "Global Campaign Against Epilepsy" supports those undertaking epidemiologic research in resource-poor countries. Demonstration projects managed under this program, in addition to assessments of local knowledge, attitude, and health service provision, undertake epidemiologic door-to-door studies to determine prevalence estimates. Screening tools developed by WHO (88) have been used in large-scale national epidemiologic studies (56). Notwithstanding the successful application of screening tools in many studies, the diagnostic sensitivity and specificity of these tools can, however, be poor, and the training of physicians or other health care professionals charged with validating positive screens may be compromised by poor access to such basic diagnostic tools as EEGs.

Other case ascertainment sources used in epidemiologic studies include prescription databases recording antiepilepsy drug usage. By definition, these epidemiologic studies estimate "treated epilepsy" and are more common in developed countries where the treatment gap is minimal. Prescription databases have been found to offer a suitable means by which the prevalence of epilepsy can be determined in community samples (89) as the coverage of the databases is typically far broader than medical registers. Purcell et al. (90), for example, examined rates of treated epilepsy in the United Kingdom using the General Practitioner Research Database, which provided data on prescription use of over 1.4 million persons. More recently, D'Souza et al. (91) estimated rates of treated epilepsy in Tasmania via a two-stage process of firstly, identifying all residents in Tasmania who were supplied with at least one antiepilepsy drug prescription recorded on the national prescription database over a given time period and secondly, by following up on these individuals by a postal survey to determine whether or not they were receiving this treatment for epilepsy.

A potential source of bias in identifying persons with epilepsy from prescription databases is that cases cannot be clinically validated (90,92). This bias is magnified in situations where diagnosis is not recorded on the database and where "estimates" of drug use among people with epilepsy are applied (93,94). While antiepilepsy drugs have been previously identified as "tracers" of epilepsy due to their chronic and highly specific usage (94), the growing use of antiepilepsy medication for indications other than epilepsy, such as pain, migraine, bipolar disorders, agitation, hormonal imbalance, and weight reduction, must be now considered. In general, reliance on prescription data alone is an inadequate case ascertainment method for epilepsy.

A methodology for case ascertainment that is becoming more frequently used in North American studies is the self-report survey. These studies typically include epilepsy-specific items in large population-based health surveys (95–98). The coverage of these surveys is extensive. The Canadian Health Survey, for example, was completed by over 130,000 persons, all of whom were questioned as to their health status, health care utilization, and determinants of health (95). The California Health Interview Survey 2003 provided similar data on over 41,000 persons (98).

The Behavioural Risk Factor Surveillance System (99) provides an example of the typical type of

epilepsy-specific items that can be included in these surveys: "Have you ever been told by a doctor that you have a seizure disorder or epilepsy?" A distinct advantage of this methodology is the opportunity it affords to examine not only the frequency of self-reported epilepsy among very large representative populations but also the impact of epilepsy on their health-related quality of life. Issues such as employment, education, and comorbid conditions can be examined. Most recently, the 2008 HealthStyles Survey in the United States was used to examine life satisfaction among a representative sample of community-dwelling adults with self-reported epilepsy (100).

Where these items are common to both those with and without a self-report of epilepsy, important disparities can be identified. Without doubt, this method differs from more rigorous epidemiologic studies (97). A selection bias may exist whereby, despite the broad community-dwelling population from which samples are drawn, those who agree to participate in surveys may differ in some fundamental way from those who decline. This method also faces the challenge previously observed among studies examining prescription databases whereby cases are not clinically validated. Whether those who self-disclose epilepsy do in fact have the condition cannot be determined, no more so than those who have epilepsy but chose not to disclose it. Despite these challenges, population-based surveys that are conducted on an ongoing basis as part of a health surveillance system have recently been strongly endorsed by a cross-party report published by the U.S. Institute of Medicine of the National Academies (101).

Each of the methods outlined above has its own benefits and challenges. This has led some researchers to propose that the most valid method to identify cases of epilepsy is to access multiple sources of case ascertainment (20). Data linkage studies, for example, provide opportunities to simultaneously examine both population-based and hospital-based registers (102,103). These multicase ascertainment studies make it possible "not only to estimate the number of cases missed by each source but also to indirectly estimate the number of cases missed by the combined dataset" (104, p. 134). Choice of case ascertainment, however, may not always be at the discretion of the epidemiologist. Resources of appropriately trained personnel and funding and sophistication of health care services are some of the many factors that influence how the same study might be conducted differently in different jurisdictions.

Variations in methodology have traditionally been identified as producing highly varying estimates of epilepsy (46,105). Recent research suggests that the influence of methodology on variation may have been somewhat overstated (2). Irrespective, the lack of harmonized definitions employed across studies is a cause for concern. Despite the ILAE's Commission of Epidemiology and Prognosis (60) and more recently the ILAE's Standards of Epidemiologic Studies of Surveillance of Epilepsy (106) issuing guidelines for definitions employed in epidemiologic studies, specific definitions of what constitutes "epilepsy," "active cases," and "cases in remission" differ markedly among studies. Definition of "active epilepsy," for example, vary in terms of their stated duration since last seizure, with some studies using the ILAE-recommended definition of one seizure or use of AEDs within the previous 5 years (107) and others truncating this duration to the previous 3 months (97,98). Harmonization of definitions is encouraged as it would permit valuable comparisons of findings across studies.

While the use of large-scale studies and attempts to harmonize definitions should ideally result in comparability across studies, all endeavors in clinical epilepsy research must face the challenges of epilepsy diagnosis. These are not trivial. Repeated studies from tertiary centers find that a substantial proportion of adults referred for refractory epilepsy do not have epilepsy but have nonepileptic seizures (108). These are patients who have been diagnosed by physicians, often neurologists, even

epileptologists, yet they do not have epilepsy. Nonepileptic seizures are a form of conversion disorder, a psychiatric condition. Unfortunately, distinction of nonepileptic seizures from true epilepsy requires either superb clinical acumen or admission to a monitoring unit where the events can be recorded simultaneously with EEG. The EEG, while a key tool in diagnosis, is not a test for epilepsy and is often greatly misused and misread (109–111). Without knowing the qualifications of those evaluating a patient and interpreting an EEG, the figures regarding the frequency of epilepsy in the population need to be taken with a healthy dose of skepticism. This raises further concerns regarding the epidemiologic studies that repeatedly find a relationship between other psychiatric disorders (depression, anxiety, schizophrenia, and even suicidal ideation and suicide) and epilepsy. If the epilepsy is actually a psychiatric disorder and not epilepsy, that could explain a substantial proportion of this literature. Replication of findings, if based on the same diagnostic error, should not be taken as evidence that the association is necessarily real. No obvious solution to this problem is evident at this time; however, it is a strong reminder that population-based studies may contain considerable diagnostic error, and their findings should be interpreted cautiously.

SUMMARY

Epidemiology has been key in demonstrating the relatively high frequency of seizures in the population and in challenging long-held beliefs about the uniformly poor seizure outcomes associated with seizures. Research pursuits within the epidemiology of epilepsy have come a long way from the days of simply counting how many people in a given population had seizures. Some studies are providing estimates of the frequency of specific types of epilepsy with some relatively clear patterns emerging across studies. As diagnostic technology has become more sophisticated, the methods used for ascertaining cases in a population have become appropriately more complex. Representativeness and diagnostic accuracy are increasingly at odds, especially in underdeveloped areas; however, the problem clearly exists and affects an important proportion of people considered to have “refractory” epilepsy. If these issues can be adequately addressed, cross-regional or cross-national comparisons of similarly conducted studies may help identify forms of epilepsy and causes of epilepsy that are unusually common in certain areas. This may, in turn, lead to insights into prevention. Combining the strengths of epidemiologic methods with the sophistication of new medical diagnostic technology and our growing understanding of epilepsy has the promise of advancing our knowledge of the causes, consequences, and possibly prevention of this common set of disorders.

CHAPTER 2 THE NATURAL HISTORY OF SEIZURES

DING DING AND W. ALLEN HAUSER

It was not long ago that epilepsy was considered a lifelong condition with a low likelihood of seizure control, much less remission. This view was based largely on reports drawn from highly selected, tertiary-care center populations. However, recent retrospective and prospective epidemiologic studies based on community and hospital populations have provided more favorable information regarding the natural history of epilepsy. Appropriate counseling of people with epilepsy and their families at crucial stages during the epilepsy requires knowledge of the natural history after a first seizure, at the time of diagnosis, after a prolonged period of seizure freedom, and at time of failure of a first or second medication, which may herald the eventual onset of drug resistance or intractability. Specific important predictive factors include age of onset, gender, etiology, seizure type, electroencephalogram (EEG) pattern, number of seizures prior to treatment, early response to treatment, medication withdrawal, and epilepsy surgery. For the individual, the outcome of epilepsy strongly reflects the individual's syndromic classification and underlying etiology of the epilepsy (1).

A seizure may be the result of an acute precipitant such as a stroke or toxin (i.e., acute symptomatic) or occur in the absence of precipitating factors (i.e., unprovoked). Seizures with fever, an event occurring in 3% to 9% of children, represent a subcategory of acute symptomatic seizure. Each of these subgroups has a specific and predictable prognosis.

Seizures provoked by fever (Chapter 34), metabolic disturbance (Chapter 31), or traumatic brain injury (Chapter 28) are discussed elsewhere in the book. This chapter focuses on prognosis in persons with unprovoked seizures.

PROGNOSIS AFTER A FIRST UNPROVOKED SEIZURE

Epilepsy is a condition in which an individual has the tendency to experience recurrent unprovoked seizures. Typically, epilepsy is defined once a person experiences a second unprovoked seizure. Overall, the population risk for seizure recurrence following a first unprovoked seizure is 40% to 50% (2); however, the individual risk can vary between as low as 20% in the subsequent 5 years to higher than 80% (3–5). In one study (Table 2.1), the recurrence risk at 2 years varied from <15% in those with no identified risk factors to 100% in those with a combination of two or more risk factors (3) (Table 2.1).

Table 2.1 Seizure Recurrence After a First Unprovoked Seizure: An Extended Follow-Up

Risk factor	Recurrence in subgroups, % months of follow-up		
	12 months	24 months	36 months
Baseline ($N = 78$)	7.0	13.0	16.7
Idiopathic or cryptogenic with an affected sibling ($N = 10$)	20.0	20.0	31.0
Idiopathic or cryptogenic with a generalized spike-and-wave EEG pattern ($N = 10$)	10.0	55.0	55.0
Idiopathic or cryptogenic with prior acute seizures (all febrile) ($N = 7$)	0.0	14.0	28.6
Idiopathic or cryptogenic with abnormal neurologic examination ($N = 13$)	9.3	15.4	20.3
Idiopathic or cryptogenic with abnormal examination and additional feature ($N = 23$)	14.3	14.3	22.7
Idiopathic or cryptogenic with two or more features and normal examination ($N = 5$)	40.0	40.0	70.0
Remote symptomatic with no other features ($N = 32$)	15.9	15.9	24.8
Remote symptomatic with Todd paresis ($N = 4$)	0.0	25.0	50.0
Remote symptomatic with prior acute symptomatic seizures ($N = 3$)	100.0	100.0	100.0
Remote symptomatic with multiple seizures or SE at presentation ($N = 8$)	25.0	37.5	37.5
Remote symptomatic with two or more risk factors ($N = 12$)	41.7	75.0	75.0

EEG, electroencephalogram.
From Hauser WA, Rich SS, Annegers JF, et al. Seizure recurrence after a first unprovoked seizure: an extended follow-up. *Neurology*. 1990;40:1163–1170, with permission.

A prior neurologic insult, indicated by features such as neurologic deficits from birth (intellectual disability and cerebral palsy) or history of traumatic brain injury (TBI) or other brain injuries leading to a static lesion, is the most powerful and consistent predictor of recurrence after a first seizure (3). Other factors include an epileptiform EEG abnormality, the occurrence of previous acute symptomatic seizures, nocturnal occurrence of the seizure, and a Todd paralysis (3,6). Status epilepticus (SE), focal seizures, and a family history of epilepsy have also been identified in some but not all studies.

The risk of subsequent seizures decreases with time, with up to 80% of recurrences occurring within 2 years of the initial seizure; recurrence rates are 36% in prospective studies and 47% in retrospective studies at 2 years (7). In the National General Practice Study of Epilepsy (NGPSE) conducted in the United Kingdom, 67% of those with a single seizure had a recurrence within 12 months and 78% within 36 months (8).

There remains debate regarding the similarities between acute symptomatic seizures associated with acute brain insults and unprovoked seizures. There are many differences in terms of subsequent morbidity and mortality, and the difference in seizure recurrence among those with unprovoked seizures and individuals with a first acute symptomatic seizure is also striking. People with an acute symptomatic seizure are 80% less likely to experience a subsequent unprovoked seizure than are individuals with a first unprovoked seizure. An MRI is appropriate in the evaluation of a first presumably unprovoked seizure, but the usefulness in predicting seizure recurrence is uncertain.

In two randomized clinical trials, use of antiepileptic drugs (AEDs) in doses to maintain serum levels in the therapeutic range was associated with a reduction in the proportion of patients who experienced seizure recurrence after a first seizure (9,10). There was no benefit in terms of long-term prognosis for seizure freedom. In a prognostic model that was based on the Medical Research Council's (MRC) "Multi-center trial for Early Epilepsy and Single Seizures (MESS)" data, the estimated probability of a second seizure at 1, 3, and 5 years for individuals treated immediately following a first seizure was 26%, 35%, and 39%, respectively. In this study, no significant difference was observed between the immediate treatment group and delayed treatment group with respect to being seizure free between 3 and 5 years after randomization, quality of life outcomes, and serious complications (11). In summary, drug initiation after a first seizure decreases early seizure

recurrence but does not affect the long-term prognosis in terms of remission.

PROGNOSIS AT THE TIME OF DIAGNOSIS OF EPILEPSY

The entire natural history is modified when a diagnosis of epilepsy (recurrent unprovoked seizures) is made. Unlike the relatively low risk of a second seizure after a first unprovoked seizure (on average 40%), the risk for subsequent seizures following a second unprovoked seizure is closer to 100%, which moves the cost–benefit toward medical treatment and preparation for a much longer period for lifestyle modification. Predictors that the initial response to antiepileptic medication may be poor include multiple seizure types, a high number and density of seizures prior to treatment, and history of depression.

Initial response to treatment also provides clues to long-term prognosis. About half of newly diagnosed persons with epilepsy will obtain complete seizure control with the first antiepileptic medication, often at low doses. If failure of the first medication is related to side effects, the likelihood of control with a second medication is again excellent. However, if the failure is related to apparent ineffectiveness of the first medication, the likelihood of control with a second medication is considerably lower. Overall, about two-thirds of newly diagnosed persons with epilepsy will obtain control of seizures by either a first or a second medication. After that, changing therapy will provide control of seizures in only an additional 3% to 5% of people (12). As a corollary, the number of seizures after initiation of treatment can predict the long-term course.

It should be pointed out that failure to respond to two medications, the criteria set by the International League Against Epilepsy (ILAE) for "drug-resistant epilepsy" (13), is not tied to number of seizures or seizure density. One may have a seizure once a year or less and still qualify as "drug resistant" by this definition.

PROGNOSIS OF ESTABLISHED EPILEPSY

A community-based study of the natural history of treated epilepsy performed in Rochester, Minnesota, reported that the probability of attaining "terminal remission" (seizure free for 5 years) at 20 years after diagnosis was 75% (14). More importantly, almost 50% of the persons with epilepsy in this community-based study had entered remission at 6 years of follow-up following initial diagnosis of epilepsy, the earliest point they could be considered to be in remission. Similar data have been provided from the NGPSE. In that study, 60% of people with newly diagnosed epilepsy achieved a 5-year remission by 9 years of follow-up (15). Studies of newly diagnosed patients followed for long periods also tend to suggest a remission rate of 60% to 90% (16) (Table 2.2).

Table 2.2 Terminal Remission Data from Selected Studies

Reference	Study setting	Special study features	No. of patients	Median follow-up (years)	Years in remission	% in remission at median follow-up
Elwes et al. (17)	Hospital		106	5.5	2	79
Shafer et al. (13)	Community		432	17	5	66
Collaborative Group (18)	Hospital		280	4	1	70
Cockerell et al. (4)	Community	Definite epilepsy	564	7	5	68
Sillanpaa et al. (19)	Hospital	Children only	176	40	1	93
Lindsten et al. (20)	Community	≥1 baseline seizure	107	9	5	64
		≥2 baseline seizures	89	9	5	58

From Kwan P, Sander JW. The natural history of epilepsy: an epidemiological view. *J Neurol Neurosurg Psychiatry*. 2004;75:1376–1381, with permission.

PREDICTORS OF REMISSION IN PERSONS WITH EPILEPSY

Many studies have looked at potential predictors of seizure prognosis, including age of onset, gender, etiology, seizure type, EEG patterns, number of seizures prior to treatment, and early response to treatment (21). A diagnosis of remote symptomatic etiology, or the presence of a neurologic deficit prior to the onset of the epilepsy, has consistently been shown to be associated with a poor prognosis (19).

The number of seizures and seizure patterns in the first 6 months or first year after diagnosis has been found to be a strong determinant of the probability of subsequent remission, with 95% of those with two seizures in the first 6 months achieving a 5-year remission compared with only 24% of those with more than 10 seizures during this same time period (22). Children who experience clusters of seizures during treatment are less likely to achieve 5-year terminal remission (23). Children who continue to have weekly seizures during the first year of treatment had an eightfold increase in the risk of developing intractable epilepsy and a twofold increase in the risk of never achieving 1-year terminal remission (18).

Seizure type has not been a consistent prognostic factor (14), although persons with multiple seizure types, as is typical in the catastrophic epilepsies of childhood, have a poorer prognosis (24).

MEDICATION WITHDRAWAL IN PERSONS WITH SEIZURE REMISSION

The most comprehensive study to evaluate the success of medication withdrawal was the MRC's randomized Antiepileptic Drug Withdrawal Study. In this study, people who had been seizure free for at least 2 years were randomized to either slow withdrawal of medication or continued therapy. In the withdrawal group, 40% experienced seizure recurrence in the subsequent 2 years. The highest rate of recurrence was in the first year after the withdrawal was started. In the group continuing treatment, 25% experienced seizure recurrence by 2 years. The relapse rate was similar in the two groups after 2 years (25). The results suggest that people who need antiepileptic medication declare themselves early in the withdrawal period. The recurrence in those continuing therapy suggests that a relapse cannot be attributed solely to medication withdrawal. Even though a substantial proportion of patients in the MRC study remained seizure free after medication withdrawal, there were no powerful predictors that allowed for the identification of these individuals. In a multivariable analysis, factors

that increased recurrence risk included history of focal seizures, myoclonic seizures, and tonic–clonic seizures (primary or secondary) as well as seizures after therapy initiation. In contrast, being seizure free for over 3 years at the time of randomization decreased the risk (25).

There seemed to be little impact on quality of life associated with withdrawal, although a seizure recurrence was associated with decline in perceived quality of life. Another study of randomized withdrawal demonstrated substantial improvement in cognitive function in those for whom medication was withdrawn (26).

PROGNOSIS OF UNTREATED EPILEPSY

Although some attribute a relatively favorable prognosis to early institution of antiepileptic medication therapy, evidence from studies from resource-poor countries with significant treatment gap suggests that many patients may enter spontaneous remission with no AED treatment. In northern Ecuador, 49% of 643 patients who had never received an AED were seizure free for at least 12 months (27). A study in rural Bolivia reported that 43.7% of untreated epilepsy cases were seizure free for more than 5 years when the cohort was revisited after 10 years (28). The findings from these studies suggest that most people with epilepsy have clinical symptoms of seizures for only a few years and can successfully discontinue medication.

PROGNOSIS OF INTRACTABLE EPILEPSY

The ILAE has defined drug resistant epilepsy as "a failure of adequate trials of 2 tolerated and appropriately chosen and used AED schedules" (13). This concept is not necessarily the equivalent of intractable epilepsy, which also would seem to incorporate a concept of seizure frequency or density. Only 5% to 10% of all incidence cases of epilepsy ultimately result in truly intractable disease. These cases probably account for half the prevalence cases of epilepsy.

Intractability of epilepsy is difficult to define as it is not simply the converse of seizure freedom. Moreover, the predictors of intractability may differ from those of seizure control or remission, and the definition of drug resistance will vary with the investigator's interest and available procedures. An identified etiology, younger age at onset (younger than age 1 year), high initial seizure frequency, and intellectual disability are predictors of intractability among children. The epilepsy syndrome, specifically cryptogenic or symptomatic generalized epilepsies, is a predictor of intractability in multivariate analyses. After adjustment for epilepsy syndrome, factors correlating with an increased risk of intractability include initial seizure frequency, focal EEG slowing, and a history of a previous episode of acute symptomatic or neonatal SE (29,30).

In one of the few prospective studies that followed a cohort of children with epilepsy from time of diagnosis, it was found that about 10% of the children meet criteria for intractability at any time but that this group was fluid with individuals shifting in and out of "intractability" as defined by seizure frequency (31).

Recent studies reported that approximately 3% to 5% of patients with intractable epilepsy per year, defined as at least one (or two) seizures monthly, become seizure free for at least 12 months. This seizure freedom is not necessarily associated with changes in the therapeutic regimen. This finding highlights the fact that, irrespective of the number of previous AEDs, there is still a small possibility of inducing meaningful seizure remission in this population (32). One retrospective cohort study of 187 patients with intractable epilepsy who had been followed for a mean of 3.8 years

reported a remission rate of 4% per year with 17 of the 20 who went into remission having undergone a medication change just prior to the onset of remission and 3 of the individuals experiencing remission for no obvious reason. Five of these 20 patients subsequently relapsed after 12 months of seizure freedom although they did not necessarily revert to the high seizure frequency (33).

While this is not the optimal comparison, one might use the above data of an annual remission rate of 3% as a comparator for expected control or remission in people treated with alternative therapies.

The prognosis of intractable epilepsy may be dramatically affected by epilepsy surgery. For some procedures (cortical resection, lesionectomy, hemispherectomy), the objective is a cure of the seizures. For other procedures (corpus callosotomy), the object is to eliminate the most disabling seizures. Two randomized trials have demonstrated superiority of surgical treatment over best medical treatment for people with intractable temporal lobe epilepsy, but outcome was reported at 1 or 2 years (17,34).

Reports of long-term follow-up are now available for persons with epilepsy who have had surgery as therapy for their seizures. These findings are discussed in Chapter 90. Results following vagus nerve stimulation are discussed in Chapter 71.

SUMMARY

The prognosis in persons with a single unprovoked seizure is excellent with only about 20% of people with no risk factors experiencing further seizures. About 70% of persons with epilepsy will become seizure free, generally early in the course of their illness. About 30% of persons with epilepsy will be considered “drug resistant” sustaining incomplete control of seizures despite adequate trials of antiepileptic medication. Of this number, about 10% will be truly intractable and be candidates for therapies other than medication.

CHAPTER 3 EXPERIMENTAL MODELS OF SEIZURES AND MECHANISMS OF STATUS EPILEPTICUS AND EPILEPTOGENESIS

TIMOTHY A. BENKE, MOLLY M. HUNTSMAN, AND AMY BROOKS-KAYAL

ANIMAL MODELS OF SEIZURES AND EPILEPSY: WHAT IS THE QUESTION?

One of the key issues in developing experimental models of seizures and epilepsy is "how close does your model need to be to the true human condition in order to reach valid, translational conclusions?" (1). In other words, is the best model for a cat actually a cat, preferably the same cat (2), or will a dog do because it also has fur? To some extent, the differences between the cat and dog are irrelevant, as our understanding of the mechanisms of brain processes from development to learning and memory in healthy and diseased states is still in its infancy.

The first step, undoubtedly, in developing a model is to define the pertinent questions. For the pediatric epilepsies, this step was approached in the "Models of Pediatric Epilepsies" workshop sponsored by NIH/NINDS, the American Epilepsy Society, and the International League Against Epilepsy (3). The pertinent questions advanced by this workshop were the following: (i) What are the long-term consequences of seizures? Can these be modified? (ii) What is the best antiseizure therapy? What is the best antiepileptogenic therapy? From these questions, the mechanisms of seizure initiation, prolongation, and termination can be addressed and their sequelae defined. Further, the mechanisms underlying the development of spontaneous repetitive seizures (SRS) (epileptogenesis) and associated cognitive dysfunction can begin to be addressed. The mechanisms by which modifiers such as genetic background, developmental stage, and other insults (hypoxia, trauma) may also be differentiated. From this, the committee proposed a table listing general strategies for model development (Table 3.1). In brief, models should be clinically relevant, developmentally appropriate, and generalized to a human condition (i.e., have validity).

Table 3.1 Strategies for Animal Model Development

1. Address a clinical need for better therapies
2. Address a key question or testable hypothesis
3. Address age specificities of developmental epilepsies, and exhibit age-specific manifestations
4. Address normal aspects of development as they relate to models of developmental epilepsies
5. Animal models of seizures and epilepsy should have EEG correlates; spontaneous seizures should be demonstrated in animal models of epilepsy
6. Investigate etiology and natural history of catastrophic/intractable epilepsies
7. Address role(s) of "multi-hit" mechanisms in epileptogenesis and epilepsies, i.e., trauma plus seizure or environment/diet plus genetic susceptibility
8. Address long-term role of seizures and other aspects of epileptic encephalopathies
9. Address model validity to clinical situation by comparisons with pharmacologic response, seizures phenotypes, outcomes, genetics, etc.
10. Allow cross-pollination from related fields: ischemia, sleep, trauma, synaptic plasticity, cancer/cell signaling, etc.

Modified from Stafstrom CE, Moshe SL, Swann JW, et al. Models of pediatric epilepsies: strategies and opportunities. *Epilepsia*. 2006;47(8):1407–1414.

While entire volumes have been devoted to the subject of model development in epilepsy (4,5), we will review the literature involving only a subset of the issues pertinent to a text on clinical epilepsy. Following an outline of techniques and the advantages and disadvantages of in vitro versus in vivo models, we will focus on the methods for invoking status epilepticus (SE) (a "prolonged" single seizure) via chemoconvulsants; single, repetitive, or prolonged seizures via hypoxia, temperature, kindling, or chemoconvulsants; and seizures induced by trauma or genetic alterations.

The process by which the initial insult (seizure, SE, or other) may lead to SRS (epilepsy) has been the subject of intense study, and multiple reviews have been put forth (6,7). Consensus regarding the relationship (cause or effect?) of hippocampal sclerosis and network reorganization to this process has not been forthcoming. Overall, the field has significantly shifted from a descriptive to a mechanistic focus involving key receptors, enzymes, and genetic regulation.

Seizures can be defined as paroxysms of abnormal, rhythmic, and synchronized discharges in the brain. Communication in the nervous system is a combination of electrical and chemical signaling with a balance between excitation and inhibition in each, primarily mediated between neurons. Glia modulate both types of communication primarily on a local basis, but frequently with distant consequences.

The resulting cascade (Fig. 3.1), beginning with receptor activation, followed by alterations in membrane polarization, potentially loops around, to result in alterations of the properties of the initial trigger of receptor activation. Consideration of this simplistic mechanism is important. Such a loop likely underlies normal plasticity associated with processes like learning and memory but perhaps becomes unstable with seizures and epileptogenesis, leading to aberrant plasticity that could result in both additional seizures and cognitive dysfunction.

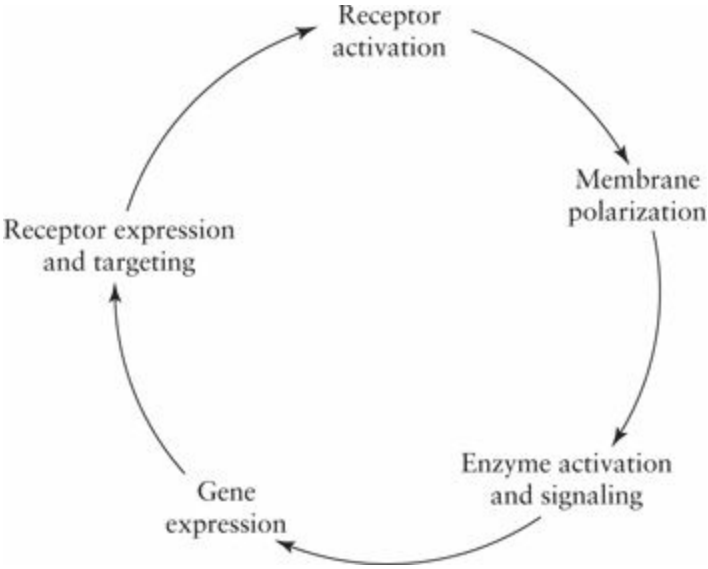

Figure 3.1. Proposed cascade of events following a seizure leading to potential adverse sequelae (medically resistant status epilepticus, epileptogenesis, learning impairment, etc.).

Review of Techniques

Experimental models can be divided into whole-animal (in vivo) versus in vitro studies (Table 3.2). Whole-animal models of acquired epilepsies typically involve single or multiple treatments to the animal that produce some form of injury or stimulation that results in later development of spontaneous seizures. Examples of these induced injuries include SE (chemoconvulsant and electrical), kindling, hypoxia, and head trauma. In genetic models, a spontaneous or induced genetic mutation or deletion results in seizures that happen spontaneously.

Table 3.2 Animal Model Summary

Model	Questions addressed
Pilocarpine and kainate	SE: consequences, treatment, role of development TLE and epileptogenesis: hippocampal networks, mechanisms, and therapies "Multi-hit" models
Pentylenetetrazol and flurothyl	Multiple brief seizure models: mechanisms of epileptogenesis Treatment of brief seizures Role of development on long-term consequences "Multi-hit" models
Temperature	Febrile seizures in children: mechanisms and therapies Role of development and long-term consequences Epileptogenesis "Multi-hit" models
HIE	True "multi-hit" model Role of development and long-term consequences Epileptogenesis: mechanisms and therapies Focal epilepsy and epileptogenesis: therapies
Toxins: tetrodotoxin and NMDA	Infantile spasms: mechanisms and therapies Role of development and long-term consequences Treatment Epileptic encephalopathies
Toxins: tetanus toxin	Focal epilepsy and epileptogenesis: therapies Role of development and long-term consequences
Trauma	True "multi-hit" model Role of development and long-term consequences Focal epilepsy and epileptogenesis: mechanisms and therapies
In vitro models	SE: consequences, treatment, role of development Role of development Synaptic and therapeutic mechanisms, especially when coupled with in vivo models
Genetic models	Catastrophic epilepsies: genesis, therapy, long-term consequences Linkage of human mutations with synaptic and electrical mechanisms in seizures and epilepsy "Multi-hit" models

Seizure "activity" must be carefully defined for several reasons. First, the definition of a seizure is often extremely variable, as in the clinical literature. Second, consciousness, routinely used as a modifier in describing clinical seizures, is arbitrarily defined in most animals used. Typically, rhythmic, stereotyped, altered behavior is observed and characterized as a seizure. As in the clinical literature, EEG has become the gold standard for correlating altered behavior with seizures, but its use is limited due to the time- and labor-intensive placement of electrodes, limitations of electrode stability over time, and the fact that electrographic seizures emanating from deeper structures can be missed when recording from the cortical surface.

In Vitro Versus In Vivo Models

In vitro models involve removal and subsequent manipulations of whole-brain structures, slices of brain structures, or isolation and culture of separated brain cells (neurons and glia). These studies allow detailed manipulations and measurements but are limited in multiple, key ways. While it is tempting to designate repetitive electrical discharges as a seizure in these models, seizures in the whole animal are associated with a change in behavior or sensation, which cannot be appreciated in these in vitro models. Therefore, to avoid confusion, the repetitive electrical discharges must be referred to as "seizure-like" events or an ictus. It is important to note that one researcher's abnormal ictal-induced phenomena may also be interpreted as another researcher's normal activity-dependent changes. In addition, certain seizures, and their sequelae, may involve the interplay of multiple brain structures and are thus difficult if not impossible to recreate in in vitro models. Finally, key processes such as development and epileptogenesis, which occur over a prolonged period of time, cannot be fully studied in in vitro models as they are limited by the length of time the in vitro preparation is viable (hours to weeks).

There are dozens of in vivo and in vitro models of seizures and epilepsy, and, as already mentioned, there is little consensus about which if any are the "optimal model." In reality, each model has its strengths and limitations, and the relative benefits depend on the specific question being asked. Below, we focus on the models that are in common use or emerging.

In Vivo Models

Pilocarpine and Kainate Models

The pilocarpine model and lithium–pilocarpine model [reviewed in (8)] involve the systemic administration of the muscarinic acetylcholine receptor agonist (pilocarpine) to induce a prolonged electrographic and behavioral seizure that requires cessation by benzodiazepines or barbiturates, typically after 1 to 2 hours, in order to prevent animal mortality. Clearly, from a clinical standpoint, muscarinic acetylcholine receptor agonism is very rarely the cause of SE in humans, with the exception of poisonings and chemical weapon exposures. Nevertheless, it is widely used because it results in severe SE, and animals eventually develop an epileptic phenotype with features very similar to those of human temporal lobe epilepsy (TLE) resulting in its widespread use for studying both of these conditions.

Kainate, a glutamate analogue that is not metabolized and can be injected either systemically or directly into the brain, results in seizures lasting several hours (9,10). Clinically, kainate originates as a shellfish poison, and human toxicity during outbreaks results in seizures and, in severe cases, hippocampal sclerosis (11). While this clinical situation is extremely rare, conditions involving glutamate overload that are known to be associated with seizures such as stroke, hypoxia (12,13), or infection may be mimicked to some degree by kainate administration. Similar to the pilocarpine model, kainate can induce an SE, and adult animals that survive kainate-induced SE may eventually develop an epileptic phenotype with features very similar to human TLE. In younger animals, kainate primarily activates the hippocampus, while in older animals, its effects are widespread (14).

Brief Seizure Models

Pentylenetetrazol and flurothyl are GABA-ergic antagonists that are administered systemically or inhaled, respectively (15). They both induce relatively short seizures, with flurothyl-induced seizures

being very brief and limited nearly to the length of exposure to the vapors. As a result, both agents are used to mimic conditions involving single or multiple brief, generalized seizures (16). The major limitations of these models are that the mechanism of seizure induction does not clearly parallel any human condition, and the animals never develop spontaneous seizures. Both agents are thought to act on all susceptible brain regions, including cortex and hippocampus (15).

Electrical kindling, whereby electrodes are implanted in order to stimulate select brain regions, can also be used to study how repeated, brief seizure-like activity can influence outcomes. Depending on the stimulation protocol, kindling can eventually lead to induced behavioral seizures. This model, however, is limited by the technicalities of long-term implantation in rodents and the fact that most kindling paradigms do not result in development of spontaneous seizures.

Clinical Models: Fever and Hypoxia/Ischemia

In models where seizures are induced in the setting of increased temperature (fever), hypoxia, and/or ischemia, the ability of these models to generalize to human pathologies is clearly evident. Hypoxia models can involve placing animals in an environment of reduced oxygen content until seizures are observed (17,18). Other methods involve single or multiple cerebral vessel occlusions, often in combination with exposure to an environment with reduced oxygen content. Methods involving vessel occlusion are often time-intensive. These methods are then limited by the elements of hypoxia and ischemia, as these may independently influence outcomes (19).

Temperature-induced seizures in developing animals (20,21) involve slowly heating the animal, typically with warmed air, until seizures are initiated. This model is gaining popularity as a model of febrile seizures but may be limited by the fact it is really a model of externally imposed hyperthermia rather than endogenous fever as occurs in the human condition. These models are particularly attractive as they may be used as preclinical models to evaluate therapies.

Toxin Models

Several models involve the direct infusion of toxins, compounds, or even genetic material into specific regions such as the hippocampus. These are each meant to model focal seizures or epileptogenesis, though the result can have distant effects. These include the tetanus toxin model [reviewed in (22)] and more recently the tetrodotoxin model (23), thought to be a model of epileptic spasms or West syndrome. The knockdown of AMPA receptor GluA2 subunit by injection of antisense probes results in acute seizures (24). Following withdrawal of direct injection of glutamate receptor antagonists, spontaneous seizures are provoked in immature animals, while systemic injection does not cause this to happen (25).

Trauma Models

Experimental models of trauma utilizing either direct impact methods (26) or surgical undercuts (27) are gaining popularity as models for studying the development of posttraumatic epileptogenesis and epilepsy. As head trauma is a common cause of acquired epilepsy in humans, these models seem very generalizable to human pathology. As a result, these models have been used to study the efficacy of antiepileptogenic compounds as well as the mechanisms underlying posttraumatic epileptogenesis.

In Vitro Models

In vitro methods involving brain slices or cultures use a variety of methods to induce seizure-like electrical events. These can involve perfusion of compounds that typically enhance or favor membrane excitability alone or in combination with electrical stimulation, akin to kindling. The resulting spontaneous neuronal-mediated discharges can then be recorded from groups of neurons or from individual neurons typically using electrophysiologic techniques. Imaging techniques using fluorescent dyes that are able to indicate changes in membrane voltage or secondary changes due to accumulations of specific ions, such as calcium, often complement electrophysiologic measurements as they are able to simultaneously record from populations of neurons that may be somewhat distant from each other. The pattern of these discharges is then interpreted in isolation, in groups or bursts, or when the bursts cluster together as an ictus. The transitions between these types of discharges are interpreted as indicative of ictal genesis and are thought to generalize to seizure genesis. When the ictus is prolonged, this event generalizes to SE. When the ability to generate an ictus becomes more facile, this situation is thought to generalize to epileptogenesis. Determining how excitation spreads through a slice of brain tissue is generalized to how it may spread in the intact preparation. Thus, application of anticonvulsants to an in vitro preparation has been used to determine their efficacy and precise mechanism(s) of action. In order to circumvent the issues of truly generalizable seizures, SE, or epileptogenesis in vitro, brain slices are often prepared at various time points after these phenomena have developed in vivo. Findings from hippocampal brain slices prepared from animals after experiencing an induced or spontaneous seizure in vivo allow examination of how overall synaptic transmission, plasticity, and seizure thresholds have become altered by these processes.

Preclinical Models and New Therapy Development: Neonatal Seizures

As an example of the use of preclinical models, the parameters for establishing an antiseizure medication as first-line treatment for neonatal seizures have recently been considered (28,29). These include utilizing relevant rodent model(s) of neonatal seizures, using EEG confirmation of seizures and drug efficacy, dose–response evaluation of efficacy, and acute and long-term aspects, including later epilepsy and behavioral consequences. Determining the relevant model is nontrivial; as noted, no model is ever perfect. These issues include face validity (similar endophenotype in humans and rodents, i.e., does the EEG and clinical picture look similar?), construct validity (similar biologic dysfunction in humans and rodents, i.e., are the triggering mechanisms similar?), and predictive ability (similar biologic response to treatments by humans and rodents, i.e., are acute and chronic aspects similar?).

We reviewed 32 studies that involved 62 separate treatment trials from 1992 to present in postnatal day (P)20 or younger rodents (Table 3.3). Most studies use pretreatment with an antiseizure medication resulting in a lack of construct validity since prophylaxis is not used clinically. Few studies validated their findings with EEG, which is important since some drugs may be proconvulsant (NMDA receptor antagonists) and because antiseizure medications are known to cause "electroclinical dissociation" in neonates, resulting in attenuation of behavioral manifestations without reduction in electrographic seizure activity. Unfortunately, no studies validated with EEG and dose response, because lower doses were sometimes found to be more effective (clinically) and earlier treatment was sometimes more effective (by EEG). Importantly, phenobarbital, the most

widely used therapy for neonatal seizures, has not been evaluated in the hypoxia model, the neonatal seizure model with likely the greatest construct validity. In the carotid artery occlusion model, phenobarbital had clinical efficacy when used as pretreatment. The efficacy of phenobarbital posttreatment has only been evaluated with EEG in the kainate model. The EEG efficacy of antidiuretic bumetanide, which is posited to overcome the depolarizing effect of GABA in the developing brain, has only been evaluated in the kainate model as pretreatment. Topiramate, levetiracetam, talampanel, and AMPA receptor antagonists have been evaluated for clinical efficacy (EEG data for levetiracetam) in the hypoxia model only when given as pretreatment.

Table 3.3 Evaluation of Preclinical Data for Anticonvulsant Efficacy for Neonatal Seizures

Rodent age	Convulsant	Anticonvulsant	Effect	Dose–response evaluation	Timing of anticonvulsant (B = before, A = after)	EEG confirmation	Ref.	Notes

Comparison of rodent ages, convulsants, anticonvulsants, and efficacy as reviewed.
ptz, pentylenetetrazol; ka, kainic acid; cao, carotid artery ligation; tet-tox, tetanus toxin; li–pilo, lithium–pilocarpine; PBS, phenobarbital; CBZ, carbamazepine; DZP, diazepam; VGB, vigabatrin; pos, positive; neg, negative.

While EEG evaluation for efficacy of antiseizure medications after onset of seizures may be the gold standard, it is important to recognize the experimental issues. Continuous video-EEG monitoring for nursing pups is technically challenging. Due to the growing skull, the recording duration is limited. The numbers and locations of electrodes are limited by the size of the skull and lack of accepted standardization. Further, details of background rhythms, seizure detection, and quantification lack widely accepted quantification and standardization.

Studies in immature rodent have demonstrated that, at relevant doses, phenobarbital, phenytoin, NMDA receptor antagonists, diazepam, valproate, and vigabatrin are proapoptotic. At higher doses, lamotrigine, carbamazepine, and topiramate are proapoptotic; in contrast, levetiracetam does not demonstrate apoptosis (59). Also, phenobarbital, phenytoin, and lamotrigine have negative behavioral consequences when administered to immature rodents (60).

In conclusion, preclinical rodent studies do not offer full evidence to recommend any antiseizure medication as efficacious for neonatal seizures as observed in clinical practice. Many drugs do affect seizure threshold, as demonstrated by those studies that administered the antiseizure medication prior to the seizure. Flupirtine shows best EEG evidence; however, phenobarbital does have efficacy. Further studies are needed that do not pretreat and that use EEG, evaluate the dose response, and fully consider short- and long-term outcomes.

MECHANISMS OF SE AND EPILEPTOGENESIS

Mechanisms of SE

Here, there are two basic questions: Why did the seizure not stop by itself, and why is SE more

difficult to stop with antiseizure medications than a single seizure? Was the underlying neuronal network susceptible to this happening, or did it become dynamically changed to allow its progression? Given that it has been found that the clinical situation is mimicked by the experimental in which benzodiazepines lose their potency as the seizure progresses (61), much effort has focused on the role of $GABA_A$ receptors and inhibitory synaptic transmission (62). These questions have been approached in a variety of ways, using in vitro brain slices or in vivo models employing pilocarpine, kainate, or kindling, sometimes in combination with in vitro brain slices prepared during or after the event. Recent studies suggest that during SE, $GABA_A$ receptors at inhibitory synapses onto granule cells of the dentate gyrus are removed from synaptic sites and moved to extrasynaptic sites and internal pools (63) in a subunit-specific manner (64). This likely minimizes their effectiveness in both self-termination of the seizure and the loss of effectiveness of benzodiazepines, in part mediated by loss of γ2 subunits, which modulate benzodiazepine sensitivity. These issues are complicated during development in the CA3 region of the hippocampus, where GABA-ergic synapses are depolarizing and thus contribute to the development of ictal activity (65,66); although recently the role of excitatory $GABA_A$ receptor-mediated currents has been questioned (67).

The alterations in $GABA_A$ receptors in the dentate gyrus are possibly mediated by NMDA receptor activation rather than by direct activation of $GABA_A$ receptors (63). It has been found that blocking NMDA receptors prevents the progression to drug-resistant SE (68). NMDARs then further contribute to the process as they are progressively recruited to synaptic sites as SE progresses (68). While in vitro studies suggest that NMDA receptors and AMPA receptors are involved in epileptogenesis (69–71), it is possible that their contribution to this process may be mediated by their effects on SE. Reductions in the AMPA receptor GluA2 subunit in CA1 and CA3 (72,73) 6 to 48 hours after SE, while implicated in cell death, may have also contribute to prolonging SE, perhaps through facilitated AMPA receptor function (74). Excess glutamate, which may occur with transporter dysfunction, has been shown to lead to NMDA receptor activation and seizures (75); however, this effect may be limited to developing animals in which glial regulation of extracellular glutamate by transporters is immature (76). Indeed, multiple genes, including those involved in transcription, are likely regulated following SE (77). Recent work has shown alterations in calcium-permeable AMPA receptors as a potential mechanism to prolong SE (78).

Mechanisms of Epileptogenesis

Epileptogenesis refers to the process by which a previously “normal” brain becomes capable of producing SRS. Animal models have typically employed prolonged SE to trigger this process; however, models of trauma and injections of toxins have also been used (see Review of Techniques). The nature and mechanisms of this process have been richly studied. Does this happen quickly or gradually, that is, what is the significance of the latent period between trigger and first SRS? This question is critical as it might represent a window of opportunity for intervention. What is the relationship of the sclerotic pathology, often seen in human TLE and animal models, to this process? How much of the process is due to network rewiring versus changes in neuronal and/or synaptic function? What are the signaling cascades mediating these processes and how can they be circumvented or reversed? Activation of group 1 metabotropic glutamate receptors, by themselves, has been shown to be epileptogenic (79,80), suggesting that the process might be less complicated.

The appearance of SRS has been taken to indicate the end of the latent period. Enhanced

excitability has been shown to gradually develop prior to the appearance of SRS (81), suggesting the end of the latent period is not a stepwise function into SRS and epilepsy. In support of this, an intensive video-EEG monitoring study has challenged the notion of the latent period by showing that the progression into SRS and epilepsy is a sigmoid function of time (82). In other words, after the first SRS, epilepsy continues to progress. Progression clearly represents a worst-case scenario, which may not always be present (83). Additional work is needed to determine where and if there is a window for interventions to prevent this progression.

Plasticity and Trafficking of $GABA_A$ Receptors in Epileptogenesis

During the process of epileptogenesis in animal models, there are alterations in the expression and membrane localization of several $GABA_A$ receptor subunits (α1, α4, γ2, and δ) in hippocampal dentate granule neurons (84–86). These alterations, which are associated with changes in phasic and tonic $GABA_A$ receptor-mediated inhibition, and in $GABA_A$ receptor modulation by benzodiazepines, neurosteroids, and zinc, begin soon after SE and continue as animals become epileptic (84–87). Several laboratories have documented similar changes in $GABA_A$ receptor subunit composition in human TLE and in animal models of TLE (84,86,88,89). Following pilocarpine-induced SE in adult rodents, $GABA_A$ receptor α1 subunit mRNA expression decreases and α4 subunit mRNA expression increases in dentate granule cells (DGCs) of the hippocampus, and animals uniformly go on to develop the recurrent spontaneous seizures that define epilepsy (84). The change in subunit expression correlates with a decreased sensitivity to zolpidem augmentation and increased sensitivity to zinc inhibition of $GABA_A$ receptor responses (84). Similar functional and subunit expression changes have been observed in DGCs isolated from surgically resected hippocampus from patients with intractable TLE (89). The changes in $GABA_A$ receptor subunit expression and function in DGCs of adult epileptic animals precede the development of epilepsy, and immature animals exposed to prolonged induced seizures show increased $GABA_A$ receptor α1 subunit expression and do not subsequently develop epilepsy (90), suggesting that $GABA_A$ receptor changes contribute to the epileptogenic process. Viral gene transfer studies demonstrating that the expression of higher α1 subunit levels inhibits development of epilepsy after SE provide further supporting evidence (91). Changes in $GABA_A$ receptor subunit expression associated with epileptogenesis vary by region and are distinct in CA1 compared to dentate gyrus (92). In addition, changes in surface expression (92) and membrane localization (93,94) of $GABA_A$ receptors related to altered receptor composition as well as loss of receptor anchoring proteins including gephyrin and GRIP (92) may play an important role in both genetic and acquired epileptogenesis.

Network Reorganization

Network reorganization in the hippocampus has been extensively studied as one of the presumed origins of SRS and because of similar findings in human TLE. Primarily, this has focused on the output of dentate granule cell neurons and has been thoroughly reviewed (8,95,96). Excitotoxic loss of mossy cells (97) in the dentate gyrus may lead to sprouting of dentate axons, known as mossy fibers (MF). The sprouted mossy fibers make aberrant excitatory connections locally in the dentate gyrus and distantly in CA3 creating an abnormal excitatory feedback circuit (98). These abnormal connections are dysfunctional, with a higher probability of activation, a larger NMDAR component

(99,100), and recruitment of kainate receptors (101). These disturbances, coupled with permanent alterations in $GABA_A$ receptors (see below), are thought to result in a circuit prone to trigger seizures in other regions, such as CA3 (95). Not without controversy, MF sprouting has not been proven to be either necessary or sufficient for development of TLE [reviewed in (7,102)]. Further aberrant circuits have also been described originating in CA3 (103) and CA1 (104–106). In trauma-induced epilepsy, aberrant connections are formed in the region of injury as well as the hippocampus [reviewed in (6,26,27)]. In the region of injury, discrete regions of apical dendrites have a selective overabundance of excitatory synaptic inputs and connectivity (107,108), which with alterations in membrane voltage-gated channel properties (109) may also contribute to the epileptic state.

Excitotoxic cell loss (which may occur following SE or other insults) throughout the hippocampus is thought to be mediated by glutamate toxicity via AMPA receptors (73,109) and NMDA receptors (110).

Secondary reactive gliosis may also contribute to synaptic dysfunction (111,112). Loss of hilar mossy cells and other neurons mediating inhibition is thought to be a critical potential contributor to the hyperexcitable steady state of the epileptic hippocampus. SE also has the paradoxical effect of inducing neurogenesis in the dentate gyrus (113). Some of the newly formed neurons may also participate in MF sprouting or other aberrant circuitry that leads to the epileptic hippocampus (114), although the exact role of newborn neurons in epileptogenesis continues to be studied.

The role of network alterations and other causative phenomena in epileptogenesis appears to be differentially regulated depending on when in development the process is initiated. Kainate-induced SE in adult animals causes, over time, SRS, CA3 cell loss, MFS into CA3 and dentate gyrus, sprouting into CA1 stratum pyramidale and stratum radiatum, and impaired learning in memory tasks (104,115,116). Similar results are found with the pilocarpine model (8,116,117). However, when animals younger than 14 days are treated with either kainate or pilocarpine, the animals do not develop spontaneous seizures (see below) (90,118,119). Single or repetitive episodes of SE in infancy caused by pilocarpine are not benign, however, and have been associated with long-term abnormalities of inhibitory neurotransmission (89). Further, single or multiple episodes of SE induced by pilocarpine at postnatal day 14 or later do result in SRS (120–122) as well as deficits in memory and learning that are inconsistently associated with cell loss and/or MFS (120,122–125). Studies in other models have not provided additional clarity regarding the association of cell loss and MF sprouting to the development of epilepsy after early-life seizures. Early-life focal administration of tetanus toxin results in a chronic epileptic state that includes memory impairment without cell loss (22) but does involve MF sprouting (126). In contrast, repetitive flurothyl seizures in early development result in MF sprouting, but they do not apparently result in SRS, only a reduced seizure threshold (127–129). Chronic perforant path kindling is associated with cell loss in the dentate gyrus (130). Similarly, in prolonged temperature-induced seizures, MF sprouting gradually develops; however, reduction in seizure thresholds is seen much earlier, and SRS have been reported only infrequently (131–133). Furthermore, MF sprouting appears in a model of early-life stress, apparently unrelated to seizures (134).

Seizure- or SE-Induced Alterations in Ion Channels

Early studies of in vitro brain slice models indicated that alterations in NMDA receptors with the successive prolongation of seizure-like discharges correlated with epileptogenesis (69–71). The mechanism of non–NMDA receptor-mediated calcium influx via calcium-permeable AMPA

receptors is also thought to underlie cell death in adult models of seizures (72,135–137) and hypoxia (18). AMPA receptor GluA1 subunit up-regulation has only been found in an adult model of electroconvulsive therapy (138). As noted previously, AMPA receptor GluA2 subunit "knockdown" studies have shown that down-regulation of this receptor subunit can lead to seizures and hippocampal injury (24). Clinical evidence from pathologic studies might support up-regulation of GluA1 expression (139–141). Seizures or SE in developing animals have found either no change (109,142) or a down-regulation of GluA2 (18,143) expression with no changes in GluA1 (144). Recurrent episodes of kainate-induced SE in developing animals are associated with a decrease in kainate binding (a reflection of AMPA receptors as well as KA receptors) in CA3 but not CA1 (119). Recurrent flurothyl seizures in developing animals have shown a long-term reduction in the expression of NMDA receptor subunits and the scaffolding protein PSD-95 (145). Transient alteration in the properties of synaptically activated AMPARs consistent with calcium-permeable AMPA receptors following hypoxic seizures in developing animals has been postulated to mediate the cascade resulting in later-life alterations in this model (146). These later-life alterations following the hypoxic-seizure cascade result from activation of the mammalian target of rapamycin (mTOR) pathway (58). Seizures induced by kainate in infant rats result in altered long-term potentiation, long-term depression, kindling, and learning associated with enhanced inhibition in the dentate gyrus (147) and mechanistically linked to reduced expression of the NMDA receptor GluN2A subunit, altered trafficking of AMPA receptor GluA1 subunit, and increased expression of PSD-95 (142). In contrast to hypoxia-induced seizures, early-life kainate seizures may not necessarily acutely involve the mTOR pathway; however, long-term consequences involve alterations in fragile X mental retardation protein–mediated signaling (148).

In adult epileptic animals induced by pilocarpine SE, GABA-ergic signaling is altered by specific reduction of $GABA_A$ receptor α1 subunits and an increase in α4 subunits in the dentate gyrus, resulting in a reduction in benzodiazepine sensitivity and enhanced inhibition by zinc (84). [This contrasts markedly to the developing hippocampus where pilocarpine SE does not result in epilepsy but results in an up-regulation of α1, overall receptor numbers and enhanced benzodiazepine sensitivity (90).] Changes in $GABA_A$ receptor subunit expression associated with epileptogenesis vary by region and are distinct in CA1 compared to dentate gyrus (92). In addition, changes in surface expression (92) and membrane localization (93,94) of $GABA_A$ receptors related to altered receptor composition as well as loss of receptor anchoring proteins including gephyrin and GRIP (92) may play an important role in both genetic and acquired epileptogenesis. Altered functions of voltage-gated sodium channels (149,150), T-type calcium channels (151,152), and potassium channels (153) have been described in epileptic animals and are thought to contribute to the epileptic state. In the hyperthermia model of febrile seizures, a single prolonged seizure results in permanent susceptibility to convulsants and enhanced in vitro kindling, mechanistically linked to enhancement of the voltage-gated potassium channel HCN (132,154,155).

The signaling pathways that regulate the plasticity in ion channel expression during epileptogenesis are just beginning to be elucidated. For example, recent studies have demonstrated that the mechanisms that regulate differential expression of $GABA_A$ receptor subunits in hippocampus after SE include the CREB/ICER, JAK/STAT, BDNF, and Egr3 signaling pathways (156,157). Targeting signaling pathways that alter the expression of genes involved in epileptogenesis may provide novel therapeutic approaches for preventing or inhibiting the development of epilepsy after a precipitating insult.

Sequelae Beyond Seizures

In adult models of epileptogenesis associated with cell loss and/or MF sprouting, uniformly, there is learning and memory impairment when assessed with the Morris Water Maze (MWM), a behavioral test used to assess spatial, long-term memory formation (158). Altered emotionality is also noted with fear conditioning (159). Mechanistically, this impairment is thought to be mediated by the anatomical damage, as similar deficits are observed in hippocampal lesion studies not associated with seizures or epileptogenesis (160). Similarly, in immature animals, abnormalities in the MWM are associated with histologic changes following repetitive SE (123–125), repetitive flurothyl seizures (129,161), tetanus toxin (22), and hypoxia/ischemia- (162) and hyperthermia- (132,154,155) induced seizures. In models where immature animals develop SRS, there is altered emotionality (121). Furthermore, kainate insult in infancy and again later in adulthood results in more prominent memory impairment than a single insult at either time (163). In immature animals following a kainate-induced seizure, there have not been any detectable problems with the MWM or histologic changes (116,164), including an absence of MF sprouting; similar findings have been reported for repeated episodes of kainate-induced SE in immature animals (119). As adults, these animals have only subtle abnormalities in the MWM (165), and in more difficult mazes, these animals have abnormalities most consistent with defective working memory (142,147,165,166); emotionality may be unaffected (165) [but see (166)]. Thus, permanent impairments in learning and memory are more severe in animal models when associated with significant histologic abnormalities. However, significant impairments can also exist without histologic abnormalities, which possibly reflect pathology limited to abnormal synaptic function isolated to the hippocampus.

Genetic Susceptibility

Advances in genetics have allowed for several human epilepsy syndromes associated with single gene defects to be further characterized [reviewed in (167)]. Following determination of the analogous gene in mice, similar defects can be introduced through cloning techniques in order to better understand how epilepsy develops in these syndromes as well as determine which treatments might be more efficacious. Often, the nature of the genetic defect, whether it represents a gain or loss of function, is not clear until the altered resulting protein is expressed in an intact, cloned animal model. In the animal model of Dravet syndrome, genetic knock-in of human mutations in voltage-gated sodium channels (NaV1.1) results in a phenotype very similar to that seen in humans (168,169). Importantly, these studies have highlighted how the balance between excitation and inhibition is a critical modifier in this disorder (170). However, this mechanism has recently been challenged (171). Similarly, genetic knock-in of human mutations in KCNQ2 and KCNQ3 has many similarities to the human phenotype of benign familial neonatal convulsions (172). Enhanced function of T-type calcium channels in thalamocortical circuits has been postulated to mediate childhood absence epilepsy. While specific mutations in T-type calcium channels have not been determined in the human condition, specific genetic targeting of enhanced expression of T-type calcium channels in this circuit has been found to mimic the human condition (173). However, genetic knock-in of human mutations in GABA receptors associated with generalized epilepsy syndromes has not uniformly resulted in phenotypes similar to the human conditions (174,175). Similarly, knock-in of human mutations in nicotinic acetylcholine receptors seen in autosomal dominant nocturnal frontal lobe epilepsy also does not reproduce features similar to the human syndromes (176). These negative results suggest not only the complexities of genetic technologies but also likely reflect basic underlying differences in

rodent and human physiology, especially susceptibility to seizures and epilepsy.

SUMMARY

Animal models, despite their limitations, have advanced our understanding of the mechanisms of seizures and epileptogenesis. Specifically, substantial gains have been made in understanding the ability of the hippocampus and cortex to rewire themselves following insults to result in circuits capable of spontaneous seizures. Developmental models have shown how significant physiologic and behavioral alterations can result without obvious histologic changes. Important questions remain to be answered in further understanding the signaling pathways, genetic programs, and subsequent synaptic modifications that underlie epileptogenesis as well as the behavioral consequences of seizures. These discoveries are crucial to determine safe and effective pharmacologic targets for stopping seizures and curing epilepsy and its consequences.

CHAPTER 4 GENETICS OF THE EPILEPSIES

JOCELYN F. BAUTISTA AND ANNE ANDERSON

The field of epilepsy genetics continues to grow with advances in genetic sequencing technology and knowledge about normal human genomic variation. Genetics plays a role not only in causation or susceptibility to disease but also in responsiveness to medications and adverse effects. This chapter provides an overview of the genetic contribution to human epilepsy in general, the genetics of specific epilepsy syndromes, and genetic testing principles in the epilepsies.

GENETIC CONTRIBUTION TO EPILEPSY

Although suspected for centuries, the genetic contribution to epilepsy was difficult to establish historically due to difficulties defining epilepsy, misdiagnosis of seizures, inaccurate family histories due to insufficient medical information, embarrassment and concealment of seizures among family members, as well as the presence of multiple causative factors aside from genetic risk. Epidemiologic studies eventually confirmed the importance of genetics by demonstrating an increased risk of epilepsy in family members of persons with epilepsy compared to the general population (1). Offspring of individuals with focal epilepsy were found to be just as likely to have epilepsy as offspring of individuals with generalized epilepsy, and both were three times more likely than were the general population (2). These population-based studies were further supported by twin studies, which showed higher concordance among monozygotic compared to dizygotic twins (3,4), as well as heritability studies (5), segregation analyses (6,7), and linkage studies (8,9). Animal genetic models of epilepsy have lent further support, but the strongest evidence has come from the finding of specific mutations in human epilepsy syndromes. Genetics plays a disease-causing role in the progressive myoclonic epilepsies (Chapter 19), as well as those associated with malformations of cortical development (Chapter 26), neurocutaneous syndromes (Chapter 30), inherited metabolic and mitochondrial disorders (Chapter 31), and chromosomal disorders. Aside from disease genes, there also appear to be genes that mediate responsiveness and the development of adverse events to antiepileptic medications (Chapter 49). Disease genes identified in idiopathic/presumed genetic epilepsy syndromes are the focus of this present chapter.

Much of this chapter focuses on genes identified in monogenic epilepsy syndromes, genes that are not as prevalent in the common epilepsies that are thought to display more complex inheritance patterns. Genome-wide association studies have been performed to determine the role of common single nucleotide polymorphisms (SNPs) in common epilepsy syndromes, investigating the “common disease, common variant” hypothesis. Despite some successes, findings have been associated with relatively minor increments in disease risk, explaining only a small proportion of known heritability. The alternative “common disease, rare variants” hypothesis is becoming more appealing with the increasing availability of improved sequencing technology that allows detection of low-frequency

rare variants with higher penetrance. Whole-exome sequencing allows identification of functional variants in the protein-coding sequence of the genome to identify genes that contain multiple rare variants across individuals with disease. As <2% of the genome codes for protein, whole-genome sequencing is another method of capturing additional genetic information. It is likely that both common and rare variants contribute to disease risk in common epilepsy syndromes; it is also likely that other genetic factors beyond point mutations, such as epigenetic effects and genomic structural variation such as copy number variants (CNVs), play an important role yet to be defined.

GENETICS OF EPILEPSY SYNDROMES

The majority of the currently known genetic mutations associated with presumed genetic epilepsy syndromes involve genes encoding ion channels or the regulatory molecules associated with them. More recently, mutations in several additional non-ion channel genes have been linked to presumed genetic epilepsy syndromes. Of note, however, is that while the first gene mutation associated with presumed genetic epilepsy was described in 1995 and a number of other genes have been identified since then, the genetic cause of the majority of presumed genetic epilepsy syndromes remains unclear. In the sections that follow, we present an overview of the major mutations identified to date and the functional consequences.

Ion channels are critical determinants of neuronal membrane excitability. While there are specific differences in the structure and function of the various ion channels for which mutations have been described, in general, these channels are composed of primary pore-forming subunit proteins that flux ions and a number of associated proteins that serve regulatory functions. Mutations in the genes encoding any one of these proteins may disrupt channel function. The expression of ion channels in the pre- and postsynaptic membranes is highly regulated and is a dynamic, activity-dependent process. Mutations in the proteins encoding these channels can affect the biophysical properties of the channels as well as their trafficking to and from the surface membrane. Thus, mutations in ion channel proteins can have dramatic effects on the intrinsic membrane properties of a neuron. Depending on the type of cells affected, there may be marked alterations in neuronal firing patterns and the network properties of the system, which may lead to seizures or a predisposition to them.

Ion Channel Gene Mutations

Mutations in nicotinic acetylcholine receptors (nAChRs), γ-aminobutyric acid (GABA), and glutamate receptors, and in voltage-dependent sodium, potassium, calcium, and chloride channels (ClCs) have been identified in some presumed genetic epilepsy syndromes. While these receptors and ion channels are functionally and molecularly distinct, they all flux ions in response to binding of a ligand to the extracellular domains of the pore-forming regions of the channels or in response to a change in membrane potential.

Nicotinic Acetylcholine Receptors

Background.

Neuronal nAChRs are ionotropic receptors formed by a pentamer of subunits that are arranged in the lipid bilayer of the surface membrane creating a pore that fluxes cations in response to ligand (acetylcholine) binding. There have been 17 different genes identified that encode for ACh receptor

subunits, which include α1–10, β1–4, δ, ε, and γ (10). In the forebrain, α and β subunits are the most abundant, and mutations in both these subgroups have been identified in epilepsy. Under physiologic conditions, binding of the endogenous agonist acetylcholine to the receptor induces permeability of the pore region to Na^+, Ca^{2+}, and K^+ ions (Na^+ and Ca^{2+} moving inward and K^+ outward). Nicotine is an exogenous agonist of the channel as the name implies. nAChRs are ubiquitously expressed in brain and localize to presynaptic and postsynaptic regions as well as nonsynaptic domains. Presynaptic nAChRs modulate neurotransmitter release in both inhibitory and excitatory neurons (GABA and glutaminergic, respectively), while postsynaptic receptors likely contribute to fast excitatory neurotransmission, and receptors localized nonsynaptically are thought to modulate neuronal excitability (11). Nicotinic AChRs are critical to a number of physiologic processes of the central nervous system (CNS) including arousal and sleep as well as cognitive functions.

Epilepsy Genetics and Syndromes.

Gene mutations in nAChRs subunits are associated with autosomal dominant nocturnal frontal lobe epilepsy (ADNFLE) and cases of sporadic nocturnal frontal lobe epilepsy (NFLE). In 1995, a mutation in CHRNA4, the gene encoding the α-4 nAChR subunit, was described in ADNFLE. This was the first gene mutation identified in association with an epilepsy syndrome. Subsequently, additional mutations have been described in CHRNA4; in the genes encoding the nAChR α-2 and β-2 subunits, CHRNA2 and CHRNB2, respectively; and in genes encoding other ion channels. The majority of the nAChRs mutations described so far involve the pore-forming region of the channel (12). At the molecular level, a number of effects have been described for the various mutations identified (13). One common effect appears to be an overall increased sensitivity of the receptor to acetylcholine, suggesting a gain of function mutation. Although several models have been proposed, exactly how the aberrant channel function leads to the clinical syndrome is unclear, particularly since the channels are ubiquitous but the disorder is of focal onset in the frontal lobes.

ADNFLE and sporadic cases of NFLE are characterized by brief motor seizures consisting of hyperkinetic limb movements with tonic or dystonic posturing of the extremities and onset in late childhood or early adolescence. However, there is significant variability in age of onset with some having onset in infancy. The seizures typically cluster during periods of nonrapid eye movement sleep and may be confused with nocturnal parasomnias. The incidence is unknown, but NFLE is thought to be underrecognized and easily misdiagnosed. In some cases, there are rare daytime seizures, including generalized tonic–clonic (GTC), generalized atonic, and complex partial seizures (CPS) (14). The ictal electroencephalogram (EEG) may demonstrate bifrontal slowing and epileptiform activity, but it also may be normal and is confounded by excessive movement artifact. ADNFLE has been associated with mutations in CHRNA4, CHRNB2, and CHRNA2 with incomplete penetrance of approximately 70% (approximately 30% of individuals who carry the mutation will never show clinical disease). Mutations in CHRNA4, CHRNB2, and CHRNA2 have been reported in about 10% to 20% of individuals with a positive family history, while these mutations are described in only about 5% of those with a negative family history of NFLE (15). Mutations in the corticotropin-releasing hormone (CRH) gene have been identified in ADNFLE (16,17). The majority of cases of ADNFLE/NFLE have seizures that respond well to antiepileptic medications, particularly to carbamazepine; however, resistance to antiepileptic drugs (AEDs) in roughly 30% of these patients is reported requiring trials of additional AEDs [for review, see (18)]. Indeed, those cases of sporadic NFLE that have been associated with mutations in CHRNA4 tend to be more refractory (19,20). The

neurologic exam and imaging studies were normal in individuals with ADNFLE/NFLE; however, neuropsychological assessment of patients with ADNFLE and mutations in the nAChR revealed impairments in cognitive function involving executive tasks and memory (21). Furthermore, there have been recent reports of autism associated with intellectual disability in a kindred with ADNFLE and CHRNA4 mutation (S252L) (22). ADNFLE and coexistent pervasive developmental disorder have been reported in an individual coexpressing a CHRNB2 mutation and also an SCN1A mutation (23).

$GABA_A$ Receptors

Background.

There are three classes of GABA receptors; however, thus far mutations associated with epilepsy have only been described in $GABA_A$ receptors, which are ionotropic receptors that flux chloride (Cl^-) in response to ligand binding. $GABA_A$ receptors underlie fast inhibition and regulate neuronal activity at a cellular and network level. The balance of inhibitory and excitatory neurotransmission is critical to physiologic functions of the CNS. There are 18 genes encoding a number of different $GABA_A$ receptor subunits (α1–6, β1–3, γ1–3, δ, ε1–3, θ, π). Various combinations of these subunits associate to compose the pentameric pore-forming functional $GABA_A$ channels in the CNS. Pentamers of two α, two β, and one γ or one δ subunit compose most $GABA_A$ receptors (24). The heterogeneity in the subunit composition of the receptor contributes to the pharmacologic profile and localization at a subcellular and regional level in the brain. These receptors are activated through ligand binding to the extracellular domains of the receptor. The endogenous ligand is GABA; however, the channels are well-known targets for a number of exogenous drugs, including benzodiazepines, barbiturates, and other sedative agents such as alcohol, which enhance inhibitory neurotransmission (25). Importantly, the pharmacology of these channels has been critical to the medical management of a number of neurologic disorders including epilepsy. Application of an antagonist of these receptors can evoke seizures, which is a phenomenon that has been exploited in basic science epilepsy laboratories.

Epilepsy Genetics and Syndromes.

Mutations in $GABA_A$ receptors have been associated with a variety of epilepsy syndromes, including childhood absence epilepsy (CAE), juvenile myoclonic epilepsy (JME), febrile seizures (FS), generalized/genetic epilepsy with febrile seizures plus (GEFS+), and severe myoclonic epilepsy of infancy (SMEI). Clinical descriptions of these syndromes can be found in Chapters 18, 19, and 34. Mutations in $GABA_A$ receptors include genes encoding: (i) the α1 and α6 subunits, GABRA1 and GABRA6, respectively; (ii) the β3 subunit, GABRB3; (iii) the γ2 subunit, GABRG2; and (iv) the δ subunit, GABRD.

GABRA1 mutations have been described in familial JME, with one family of 14 affected individuals over four generations, all with a similar phenotype of myoclonic and GTC seizures and generalized spike–wave complexes on EEG (26). Mutations in GABRA1 have also been described in a sporadic case of CAE. Out of 98 individuals with presumed genetic generalized epilepsy (GGE), one individual with clusters of daily absence seizures from 3 to 5 years of age was identified as

having a heterozygous mutation in GABRA1; there was no history of FS and no family history of seizures (27). A missense mutation in GABRA6 was described in a patient with CAE and atonic seizures (28). GABRB3 genetic abnormalities also have been associated with CAE. Twenty-eight of forty-five patients with CAE had polymorphisms in the promoter region of exon 1a of the GABRB3 subunit that reduced binding of transcriptional activators (29). Functionally, this mutation would lead to a reduction in GABRB3 subunit expression. A later report screening families of CAE probands revealed three missense mutations (at positions 11, 15, and 32) in GABRB3 associated with absence seizures and eyelid myoclonia, or grand mal seizures, or atonic seizures and vomiting, depending upon the mutation. However, incidental presence of the mutation at position 32 was found in two siblings of the proband who had generalized spike and wave activity with or without FS, and asymptomatic carriers were found in the relatives of the proband with a mutation at the 15 position.

GABRG2 mutations were identified by two independent groups in families with GEFS+ and CAE. Shortly thereafter, additional mutations in GABRG2 were described in families with GEFS+, SMEI or Dravet syndrome (DS), CAE, and FS. GEFS+ is a familial epilepsy syndrome, with at least two affected family members, encompassing a wide range of phenotypes from simple FS to FS persisting beyond 6 years of age (FS+), to afebrile GTC seizures, absence, myoclonic, or atonic seizures, and even focal seizures. While many patients have seizures that remit spontaneously, others may develop refractory epilepsy, including SMEI or DS. Separate mutations in GABRG2 also have been identified in several families with CAE and FS (30,31). In two other families, with isolated FS or FS with associated other seizure types, mutations in GABRG2 have been described (32,33). These families are arguably still within the spectrum of the GEFS+ phenotype.

GABRD is thought to be a susceptibility locus for GGE, and a mutation has been identified in one small family with GEFS+ (34). Clinical features of affected individuals in the families described above do not differ significantly from nonfamilial forms of GGE.

Functionally, the $GABA_A$ receptor mutations have been characterized in a number of laboratories, and a variety of functional effects have been identified including alterations in GABA sensitivity, reduced surface expression, alterations in the biophysical properties of the receptor, and dominant negative as well as loss of function effects. The net result of these alterations is a reduction in GABA-activated Cl^- currents and thereby alterations in inhibitory neurotransmission (12). As mentioned above, mutations in GABRD, the gene encoding the δ subunit, have been suggested as susceptibility alleles in GEFS+ and JME. The δ subunit is found in $GABA_A$ receptors localized exclusively to the extra- or perisynaptic regions, while those containing γ subunits are found both in the synaptic and extrasynaptic regions. These channels contribute to the tonic inhibitory current, and studies have shown that the mutations described in epilepsy reduce this current and the surface expression of the channels (12,35).

Sodium Channels

Background.

Voltage-gated sodium channels (Na_v) are composed of a complex formed by a large α subunit and smaller auxiliary β subunits. The Na_v α subunit consists of four internally repeated domains that each have six transmembrane spanning regions and a pore loop, which together form the ion-conducting pore that fluxes Na^+ ions. The β subunits associate with the α subunit complex and modify the channel

biophysical properties and interact with the cytoskeleton. Four of the nine genes encoding the Na_v channel α subunits are expressed in the mammalian CNS. These are SCN1A, SCN2A, SCN3A, and SCN8A, which encode $Na_v1.1$, $Na_v1.2$, $Na_v1.3$, and $Na_v1.6$, respectively. The $Na_v1.x$ channels are responsible for action potential initiation and propagation in neurons. The subcellular localization varies depending upon the subunit composition (36,37). These channels are critical to physiologic functions of the CNS, and the aberrant regulation or genetic mutation of the sodium channel α and β subunits has been associated with neuropathology, including epilepsy. Furthermore, these channels have been the target of therapeutics in epilepsy. The mechanism of action of some anticonvulsant drugs such as phenytoin, oxcarbamazepine, and lacosamide is thought to be in part through modulation of these channels.

Epilepsy Genetics and Syndromes.

Mutations in SCN1A, SCN2A, and SCN1B (encoding the β1 subunit) are well- described genetic causes of epilepsy. The first sodium channel mutation in epilepsy was described in 2000 in SCN1A (38) with two families with GEFS+. Subsequently, approximately 650 mutations have been described in this channel subunit in GEFS+ variants and SMEI or DS variants (35,39,40). Missense mutations are thought to account for the majority of SCN1A variants, while nonsense mutations and other genetic variants account for a relatively smaller proportion. Furthermore, the majority of known SCN1A mutations are de novo (88%). To date, over 20 mutations in SCN2A have been described in association with benign familial neonatal/infantile seizures (BFNIS), GEFS+, and SMEI/DS. More frequently, SCN2A missense mutations have been described in BFNIS, and nonsense or truncation mutations have been described in SMEI/DS. The mutations in SCN1A and SCN2A that led to more dramatic alteration in the protein product were associated with the more severe phenotype (DS). SCN1B mutations have been described in GEFS+, FS, early-onset absence epilepsy, and temporal lobe epilepsy (TLE) (12).

There is phenotypic variability with the sodium channel subunit mutations and complex genotype–phenotype relationships, suggesting that modifier genes play a role. As mentioned above, GEFS+ is a familial epilepsy syndrome with a highly variable phenotype, typically involving FS persisting beyond 6 years of age, followed by afebrile seizures. The afebrile seizures that follow FS can be either generalized or focal, including mesial TLE. Affected family members can have isolated FS, afebrile seizures, or both. Mutations in SCN1A, SCN2A, and SCN1B have been described in GEFS+. At the more severe end of the GEFS+ spectrum is SMEI or DS. While roughly 70% to 80% of Dravet patients will have SCN1A mutations (both missense and truncation), the etiology for the remaining affected individuals is unknown. De novo mutations in SCN1A have also been identified in cases of alleged pertussis vaccine–induced encephalopathy, which can resemble SMEI clinically (41). Furthermore, the diphtheria–tetanus–pertussis vaccine may be associated with earlier onset of SCN1A-associated DS (42). Mutations in SCN3A, SCN8A, and SCN9A (encoding Nav1.9) sodium channel α subunits also have been described in association with epilepsy and may be considered disease-modifying genes [for review, see (35)].

There is an increased incidence of sudden unexpected death in epilepsy (SUDEP) in DS compared to other chronic epilepsies (43). SCN1A mutations and SUDEP have been reported in some families, and recently, a frameshift duplication mutation in SCN1A was reported in association with SUDEP. While this channel has greatest expression in the brain, there are reports of SCN1A expression in the mammalian heart (44). Interestingly, mutation of the SCN5A channel, which has high

cardiac expression levels, causes Brugada syndrome. There is a report of SUDEP in an individual with epilepsy and long QT syndrome syndrome associated with a missense mutation in SCN5A (45).

Potassium Channels

Background.

Potassium channels are major determinants of the intrinsic membrane excitability of neurons and thus alterations in these channels will have profound effects on network behavior within the CNS. These channels are critical to physiologic functions of the CNS including development, plasticity, learning and memory, and many other functions. Mutations or aberrant regulation of a number of the K^+ channels expressed within the CNS has been described in neurologic disorders, including epilepsy. These channels are extremely diverse, and there are many different subunits described. The functional channel complexes flux K^+ ions outward. There are three major classes of K^+ channels that are defined by the number of transmembrane domains within each α subunit. Mutations in channels falling into two of these classes have been described in epilepsy. These include the voltage-dependent potassium (K_v) channel α subunits that are characterized by six transmembrane domains and the inward-rectifier K^+ (K_{ir}) channels that are characterized by two transmembrane domains. Each of these groups is characterized by subfamilies encoded by numerous genes. The functional channel is formed by multimerization of the α subunits and a host of associated or auxiliary subunits that influence the channel properties and trafficking (12,37).

Epilepsy Genetics/Syndromes.

KCNQ2 and KCNQ3 from the K_v family, which encode K_v7 α subunits, have been clearly linked to epilepsy. Channels composed of these subunits underlie the M-current, named so due to the observation that stimulation of muscarinic cholinergic receptors suppresses the current. M-channels contribute to a portion of the afterhyperpolarization (AHP), known as the medium AHP (mAHP). These channels are expressed early during development in the human brain. Recent reports indicate that over 50 mutations have been identified in KCNQ2 and KCNQ3 in families with benign familial seizures in the first year of life (35). The nomenclature for this disorder is based upon age of onset of seizures and includes benign familial neonatal convulsions/seizures (BFNC/BFNS) also known as benign familial neonatal convulsions or benign familial epilepsy type 1 occurring before day of life 5, benign familial neonatal/infantile convulsions/seizures (BFNIC/BFNIS) occurring between 2 days and 6 months of age, and benign familial infantile convulsions/seizures (BFIC/BFIS) occurring between 3 and 8 months of age. The seizures are focal with or without secondary generalization, with clustering of seizures at times. A small percentage of these individuals go on to have seizures later in life. The familial cases are autosomal dominant, but de novo mutations also have been identified. Compared to KCNQ2, relatively fewer mutations in KCNQ3 have been identified in families with this syndrome (46). The described mutations are predicted to result in truncation of the channel protein, and others are missense mutations. Evidence suggests that the net effect of these mutations is a loss of function. The decreased level of functional M-channels is predicted to lead to increased excitability within the CNS, particularly during the neonatal period. Indeed, under physiologic conditions, these likely play an important inhibitory role early postnatally when GABA neurotransmission is depolarizing and thereby excitatory. The epilepsy remission seen in affected

individuals is thought to be due to the developmental switch in GABA when it changes to become inhibitory (12). Myokymia later in life has been described in one family with KCNQ2 mutation and BFNS (47) . KCNQ2 mutations have recently emerged as a cause of neonatal epileptic encephalopathy with intractable tonic seizures evolving during the first week of life that eventually subside, but residual intellectual disability and motor impairment are present (48). The electroclinical features of the benign familial seizure subtypes are similar, and KCNQ2 mutations account for the majority of BFNS and BFNIS cases, although SCN2A mutations are another important cause of BFNIS, as already discussed. While KCNQ2 and KCNQ3 mutations are also seen in BFIS, mutations in the proline-rich transmembrane protein (PRRT2) gene are much more frequent, as discussed below. (49).

KCNA1 encodes the $K_v1.1$ α subunits. The K_v1 subfamily of K^+ channels is found throughout the brain and is localized to axonal regions where it contributes to repolarization and shaping of the action potential. Kv1.1 α subunits heteromultimerize with other K_v1 subunits, and the channels may be dramatically altered in their properties by inclusion of the $K_v\beta1.1$ auxiliary subunit in the supramolecular channel complex (37). Mutations in KCNA1 underlie autosomal dominant episodic ataxia type 1 (EA1), and some families with this disorder have epilepsy. The effect of this mutation on channel function is an overall loss of function with altered channel assembly, trafficking, and kinetics (12). KCNA1 mutations have been described in families with EA1, which is a rare disorder that is characterized by intermittent episodes of ataxia and myokymia as well as partial seizures in a few kindreds (50). Because not all families with this gene defect exhibit epilepsy as part of the phenotype, this gene locus is considered a susceptibility gene or risk factor for epilepsy.

KCNMA1 encodes the α subunit of the large-conductance voltage- and Ca^{2+}-activated K^+ channel, also called the BK channel (KCa1.1). The BK channel is distinct from other K^+ channels in that it can be activated by both intracellular Ca^{2+} and membrane depolarization. BK channels are highly conserved throughout evolution and are widely expressed in multiple mammalian cells including smooth muscle, inner ear hair cells, and neurons throughout the brain. The channels consist of a pore-forming α subunit (KCNMA1), which has at least nine splice variants in the human brain (51), and a regulatory β subunit, of which there are four isoforms (KCNMB1-4). A mutation in KCNMA1 has been identified in a family with generalized epilepsy and paroxysmal dyskinesia (GEPD) (52). Sixteen affected individuals developed epileptic seizures (n = 4), paroxysmal nonkinesigenic dyskinesia (n = 7), or both (n = 5). The mutation increases the sensitivity of the channel to calcium compared to the wild-type channel. This gain of function appears to cause more rapid action potential repolarization. The end result is that neurons fire at a higher sustained rate, likely due to a reduction of action potential width (53).

A mutation in KCND2, the gene encoding the $K_V4.2$ α subunit, has been described in an individual with medically intractable TLE. This same mutation was present in the father, suggesting that this gene may be considered a susceptibility locus (54). Missense variations in the gene encoding the K_{ir} 4.1 potassium channel (KCNJ10) have been associated with susceptibility to GGE syndromes of absence epilepsy and JME (34). Recently, mutations in the potassium channel tetramerization domain–containing protein 7 gene (KCTD7) have been described in association with progressive myoclonic epilepsy (35). The molecular function of the KCTD7 protein product is unclear; however, it is homologous to the tetramerization domain of voltage-gated potassium channels, and overexpression of this protein hyperpolarizes the cell and decreases excitability, suggesting a role for this molecule in dampening excitability.

Calcium Channels

Background.

Voltage-dependent calcium (Ca_v) channels flux calcium intracellularly in response to depolarization and thereby mediate a number of physiologic processes in the CNS including the activation of signaling pathways, gene transcription, and neurotransmitter release. Calcium channels consist of two families: high-voltage-activated (HVA) family and low-voltage-activated (LVA) family. The HVA family includes Ca_v1 (L-type) and Ca_v2 (P/Q-, N-, and R-type) channels, which are heterotrimers of subunits α, β, α_2-δ, and γ. The LVA family includes Ca_v3 (T-type) channels, which are monomers and are composed only of α subunits. HVA and LVA channels differ in function and electrophysiologic properties. Ca_v1 channels are typically localized postsynaptically in the somatodendritic regions and contribute to calcium signaling in response to action potential backpropagation, synaptic activity, and activity-dependent gene regulation. Ca_v2 channels are localized both pre- and postsynaptically with both axonal and somatodendritic expression. An important function for these channels is the regulation of presynaptic neurotransmitter release. Ca_v3 channels underlie a transient calcium current that activates at subthreshold potentials and is critical for the regulation of calcium flux at near resting membrane potential and also during action potentials. These channel subfamily members are fairly broadly distributed within the CNS (37). A number of AEDs mediate an anticonvulsant effect through altering the function of these channels (see Chapter 43).

Epilepsy Genetics.

Mutations in the genes encoding Ca_v channels and their auxiliary subunits were first described in mice; naturally occurring mutations in these channels were associated with generalized spike and wave activity (55). Subsequently, mutations in Ca_v channels associated with presumed genetic epilepsy in humans have been described. The most common mutations in Ca_v channels associated with epilepsy involve CACNA1H, which encodes the $Ca_v3.2$ channels, also known as T-type calcium channels. $Ca_v3.2$ channels are localized primarily in dendritic regions where they modulate neuronal excitability by promoting burst firing and boosting synaptic inputs. These channels contribute to the thalamocortical circuitry with expression both in neurons in cortical layer V and in reticular thalamic nuclei, and over 30 mutations have been described in families with GGE and CAE. T-type channels and low-threshold burst firing in the thalamocortical circuit are involved in the generation of thalamocortical oscillations during spike–wave discharges. A variety of different mutations have been described for CACNA1H in epilepsy. Some are associated with a gain of function, but others have effects on channel kinetics, trafficking, or decrease the underlying current. In addition, a number of sites for alternative splicing of $Ca_v3.2$ are present, and some of the identified mutations occur in these regions (12). Additional work is required to understand how these gene mutations contribute to the epilepsy phenotype.

The CACNA1A gene encodes the $Ca_v2.1$ α subunit, which underlies the P/Q-type calcium current, and is widely expressed in the CNS both in regions of the forebrain such as cortex and hippocampus and in the cerebellum (37). Subcellularly, these channels are localized presynaptically where they play a critical role in initiating neurotransmitter release. The channels are also localized in the somatodendritic regions where they modulate excitability of the postsynaptic membrane in neurons

(37). Mutations in CACNA1A have a strong link with familial hemiplegic migraine (FHM), episodic ataxia type 2, and spinocerebellar ataxia type 6 (56). Some families with mutations in this gene express a phenotype that also includes epilepsy. There are different mutations described, and functional characterization of some of them suggests that channel function is impaired in the mutant channel.

The CACNB4 gene encodes the Ca_v auxiliary β_4 subunit, a non–pore-forming modulatory subunit. Inactivation of the CACNB4 gene in the mutant "lethargic" mouse results in a neurologic phenotype resembling absence epilepsy with ataxia (57). Subsequently, mutations in CACNB4 were described in humans with GGE/JME and episodic ataxia (38).

In mouse models with mutations in HVA channel subunits, there is a compensatory increase in thalamic LVA (T-type channel) current, which is thought to contribute to the epilepsy phenotype (58). This is consistent with the finding of gain-of-function mutations in Cav3.2, an LVA channel subunit, in individuals with familial GGE.

Epilepsy Syndromes.

Susceptibility to GGE/CAE is associated with variants in the CACNA1H gene. In one study, missense mutations were identified in 12% of children of Chinese descent with CAE, with each child inheriting the missense mutation from one of his or her unaffected parents; there was no difference in clinical CAE phenotypes between individuals with and without mutations (59). Two possible explanations for the presence of missense mutations in unaffected parents are (i) the parents might have had CAE early in life that was undetected, and (ii) the missense mutations only increase susceptibility to CAE but alone are not sufficient to cause CAE. Variants in CACNA1H were also identified among 240 Caucasian individuals in Australia, from 167 unrelated GGE and GEFS+ families, with a wide variety of individual epilepsy syndromes including CAE, juvenile absence epilepsy (JAE), JME, myoclonic astatic epilepsy, GEFS+, FS, and TLE (60). All variants were also observed in some unaffected individuals, suggesting that the variants are susceptibility alleles. The types of variants identified in the studies above are population specific and present at low frequencies. Mutations in the CACNA1A gene have also been found to be associated with epilepsy. In one Swedish family of three mutation carriers, all had FHM and ataxia, and two had CPS (61). In a second family, five members had absence epilepsy with 3-Hz spike and wave activity and cerebellar ataxia (62). In a study of 48 individuals with SMEI or DS due to SCN1A mutations, the presence of CACNA1A variants appeared to modify the epileptic phenotype; those individuals with both SCN1A and CACNA1A mutations were more likely to have an earlier onset of seizures, absence seizures before 6 years of age, and more frequent prolonged seizures in the first year of life, compared to individuals who only had SCN1A mutations (63). Finally, coding variants in the CACNB4 gene were identified in two families with GGE and one family with episodic ataxia (38). Similar to CACNA1A variants, mutations in CACNB4 may be a genetic modifier in individuals with SCNA1 mutations and SMEI or DS (17).

Chloride Channels

Background.

This section is focused on voltage-gated ClCs, which contrasts an earlier section in this chapter covering ligand-gated chloride ($GABA_A$) receptors. There are a number of mammalian genes

encoding ClCs. This section focuses on the CLCN family of genes (CLCN1-7), which encode voltage-gated ClCs or chloride transporters; these channels flux chloride and serve a number of important functions throughout the organism. Voltage-gated ClCs have four subunits surrounding a pore, which fluxes Cl^- as well as other inorganic anions. The channels are composed of dimeric multisubunit proteins that are gated by multiple factors. For instance, channel opening to flux Cl^- out of the cell occurs in response to hyperpolarization and acidic extracellular pH (64). The channel is expressed in the CNS and has a critical role in GABA inhibition through maintaining a low intracellular concentration gradient (65,66).

Epilepsy Genetics and Syndromes.

Three mutations in the CLCN2 gene were identified in 3 of 46 unrelated families with GGE (67). In a reevaluation of two of the families reported, discrepancies were identified in family structure, phenotype, and genetic analysis (68), and as result, the paper was retracted. Other studies have reported CLCN2 mutations in individuals with epilepsy (69–72), but the evidence for their functional role is lacking (73–75). A study that used exome sequencing of 237 ion channel genes in 152 individuals with sporadic epilepsy of unknown origin found an excess of variation in CLCN1, which encodes the ClC-1 chloride channel, in those with epilepsy compared to controls (76). They also reported a CLCN1 truncation mutation in an individual with intractable generalized epilepsy and mild myotonic features, as well as demonstrated the presence of CLCN1 mRNA transcripts and ClC-1 protein in human brain autopsy specimens and in mouse brain, suggesting a role for CLCN1 in human epilepsy. While CLCN1 mutations have long been associated with autosomal dominant and autosomal recessive forms of myotonia congenita, ClC-1 protein previously was not believed to be expressed in the brain. This study also identified more missense variants in CLCN2, CLCN5, and CLCN7 in individuals with epilepsy compared to controls, but the significance of these findings remains to be seen.

Glutamate Receptors

Background.

The N-methyl-D-aspartate (NMDA) receptor is a glutamate-activated excitatory ion channel permeable to Na^+, K^+, and Ca^{2+}. NMDA receptors are composed of NMDA receptor 1 (NR1 or GRIN1) and NMDA receptor 2 subunits (NR2 or GRIN2). NMDA receptor antagonists have been investigated as potential anticonvulsant medications. Autoantibodies to NMDA receptors have been associated with limbic encephalitis, which is often characterized by seizures and status epilepticus.

Epilepsy Genetics and Syndromes.

Mutations in GRIN2A have been identified in patients with presumed genetic focal epilepsies with rolandic spikes and epilepsy-aphasia spectrum disorders. In a study of individuals with Landau–Kleffner syndrome, continuous spike and wave during slow-wave sleep (CSWS), and atypical rolandic epilepsy associated with speech disturbance, GRIN2A mutations were identified in about 20% of both familial and sporadic cases (77). Large 16p13.2 deletions that included GRIN2A were previously reported in individuals with severe cognitive impairment, dysmorphic features, and rolandic seizures (78). Mutations in GRIN2A were also identified in individuals with both familial

and sporadic childhood epilepsy associated with various degrees of cognitive impairment (79). In a separate study, GRIN2A mutations were identified in 4.9% of individuals with benign epilepsy with centrotemporal spikes and in 17.6% of individuals with CSWS (80). In another large study, screening individuals with epileptic encephalopathy of various causes, GRIN2A mutations were identified in 9% of individuals with epilepsy-aphasia spectrum disorders but not in other epileptic encephalopathies (81).

Na^+, K^+-ATPase Pump Gene (ATP1A2)

Background.

The Na^+, K^+-ATPase catalyzes the ATP-driven exchange of three intracellular Na^+ ions for two extracellular K^+ ions across the plasma membrane. The enzyme plays a crucial role in maintaining the transmembrane cation gradients that are dissipated in the propagation of action potentials. In addition, the Na^+ gradient produced by Na^+-K^+-ATPase is required for clearance of extracellular glutamate by astrocytes. ATP1A2 encodes the α-2 isoform of the major subunit of the Na^+, K^+-ATPase and is predominantly found in neural and muscle tissues. The ATP1A2 gene encodes a protein that is thought to play a role in calcium signaling during cardiac muscle contraction. In the CNS, ATP1A2 is expressed in neurons throughout the brain in the neonatal period, becoming more abundant in glia in adulthood. In the CNS, the α-2 isoform is thought to play a critical role in calcium signaling, although the exact mechanism of its pathogenesis is still unclear.

Epilepsy Genetics and Syndromes.

In a five-generation Dutch–Canadian family with FHM and BFIC/BFIS, a mutation was identified in the ATP1A2 gene, regardless of whether the affected family member had FHM, BFIC/BFIS, or both (82). In another study of 20 families with epilepsy and migraine, two families were found to have novel ATP1A2 mutations; six mutation carriers had both epilepsy and migraine, two had only epilepsy, and six had only migraine (83). While other similar families have been described, the most prominent phenotype is that of migraine or migraine and seizures with very few mutation carriers having epilepsy alone. In a case–control study of 152 German individuals with nonfamilial GGE and 111 healthy German controls, no significant association was found with seven polymorphisms of the ATP1A2 gene and GGE compared to controls, suggesting that ATP1A2 was not a major susceptibility gene in this particular epilepsy population (84). The ATP1A2 gene appears to play a more significant role in FHM.

Non-ion Channel Gene Mutations

Leucine-Rich, Glioma-Inactivated-1 (LGI1) Gene

Background.

The LGI1 gene was the first non-ion channel gene identified in human idiopathic/genetic epilepsy. LGI1 encodes a secreted protein with two distinct structural domains: the C-terminal region, which consists of seven copies of a 40-43-residue named EAR (epilepsy-associated repeat) or epitempin

(EPTP) domain, and the N-terminal region, which contains leucine-rich repeats (LRRs), surrounded by conserved cysteine-rich clusters. The function of the LGI1 gene product is not clear, but studies suggest a role in synaptic transmission (85–87), as well as in neuronal development (88,89). Other LRR-containing proteins are involved in signal transduction, cell growth regulation, adhesion, and migration.

Epilepsy Genetics.

The LGI1 gene product enhances AMPA receptor–mediated synaptic transmission in hippocampal slices. Mutations in LGI1 have been identified in individuals with autosomal dominant partial epilepsy with auditory features (ADPEAF) (90), also referred to as autosomal dominant lateral temporal lobe epilepsy (ADLTE). There is evidence for allelic heterogeneity, as 25 different mutations have been described in various families with ADPEAF or in sporadic individuals with lateral TLE. Most LGI1 mutations tested by cell transfection assay using HEK293 or 293T cell lines, regardless of whether they occur in the N-terminal LRR domain or the C-terminal EPTP domain, cause a significant reduction in protein secretion (91). CNV analysis identified a heterozygous 81-kb microdeletion of the LGI1 gene in affected members of an ADLTE family after exon sequencing failed to identify a point mutation (92). Beyond genetics, antibodies against LGI1 have been associated with limbic encephalitis.

Epilepsy Syndrome.

ADPEAF is characterized by focal seizures with auditory auras ranging from unformed sounds, such as humming or ringing, to distortions and volume changes, to more organized sounds, such as singing and music. Some affected individuals have seizures provoked by auditory stimuli. Age of onset can vary from 4 to 50 years, with mean age of onset in the late teens. Interictal EEG is often normal, as is magnetic resonance imaging (MRI). Seizures are generally well controlled with medications, but intractable epilepsy has also been reported (93). ADPEAF exhibits incomplete penetrance, estimated at 67%, regardless of the specific LGI1 mutation (94) . LGI1 mutations have been described in approximately 30% to 50% of the families tested, with no clear clinical distinction between those families with and without mutations (95,96). A subset of affected individuals with LGI1 mutations has GGE (95). De novo LGI1 mutations have been described in about 2% of sporadic partial epilepsy with auditory features (97,98). In an analysis of clinical and molecular information from the 36 published ADPEAF families with LGI1 mutations reported in the literature, disease-causing mutations were more likely to occur in the N-terminal LRR domain compared to the C-terminal EPTP domain, and auditory symptoms were less frequent in individuals with truncation mutations in the EPTP domain compared to mutations in other regions (99).

Myoclonin1/EFHC1 Gene

Background.

Myoclonin1/EFHC1 encodes a 640-amino acid protein, also called EFHC1, that consists of three DM10 domains of unknown function and a C-terminal region with a single calcium-binding EF hand motif. Mutations in Myoclonin1/EFHC1 occur in JME and JAE. There are several putative functions for the EFHC1 protein. In hippocampal neurons, EFHC1 overexpression induced apoptotic cell death, possibly through modulation of R-type calcium currents (100). More recent work suggests that

EFHC1 potentiates the activity of the transient receptor potential M2 channel TRPM2, a calcium-permeable channel that is linked to cell death (101). Another putative role is that of EFHC1 as a ciliary protein, as suggested by the presence of EFHC1 in cilia of ependymal cells lining the cerebral ventricles, and abnormal ciliary function in EFHC1-deficient mice (102–104). Intact ependymal ciliary function is required for normal CSF flow and the directional migration of neuroblasts, which depends on normal CSF flow. Yet another function attributed to EFHC1 is that of a microtubule-associated protein (MAP) involved in cell division and neuronal migration during development (105).

Epilepsy Genetics and Syndrome.

Heterozygous missense mutations in EFHC1 were first described in individuals with familial JME in 2004 (100). Numerous additional missense, nonsense, and deletion mutations have been described in various families as well as in sporadic cases of JME (106). Some mutation carriers without epilepsy were found to have epileptiform abnormalities on EEG, with an overall rate of 3% to 9% of JME patients seen in clinic having EFHC1 mutations (106). Mutations in the EFHC1 gene have also been identified in JAE and sporadic GGE (107). A homozygous mutation in EFHC1 was also discovered in a family with three of seven children presenting with intractable epilepsy beginning in the neonatal period (108).

Proline-Rich Transmembrane Protein 2 (PRRT2) Gene

Background.

The PRRT2 gene is located on chromosome 16; it consists of four exons encoding 340 amino acids, and the protein is predicted to have two transmembrane domains. In mice, high levels of PRRT2 mRNA are detected in the brain with lower levels in the spinal cord, with peak expression during postnatal development. The PRRT2 protein is poorly characterized, but it appears to interact with SNAP-25, a synaptosomal-associated protein involved in the release of neurotransmitters from synaptic vesicles at the presynaptic membrane.

Epilepsy Genetics and Syndromes.

PRRT2 mutations were first identified in families with paroxysmal kinesigenic dyskinesia (PKD) (109). Subsequently, different heterozygous truncating mutations in PRRT2 were found in families with PKD and infantile convulsions (110). Heterozygous PRRT2 mutations have also been reported in individuals with BFIC/BFIS, as well as additional families with the infantile convulsions and choreoathetosis (ICCA) syndrome or the co-occurrence of BFIC/BFIS and PKD (111). Although the ICCA syndrome was first linked to a region on chromosome 16 in 1997, the causative gene was not identified until 2011. In the 2 years following the original 2011 reports, over 50 mutations in over 300 individuals were identified, with the majority of families harboring the same recurrent frameshift mutation: PRRT2 c.649-650insC. Several de novo mutations were also reported. Most mutations led to protein truncation. Mutant truncated proteins showed loss of membrane targeting with the truncated proteins remaining in the cytoplasm. Mutations in PRRT2 appear to account for 40% to 80% of familial cases of BFIC/BFIS, PKD, or ICCA. The phenotypic variability, in which the same mutation can cause BFIC/BFIS, PKD, or both in different individuals in the same family, remains unexplained.

DEP Domain–Containing Protein 5 (DEPDC5) Gene

Background.

The Dishevelled, Egl-10 and Pleckstrin (DEP) domain–containing protein 5 (DEPDC5) gene is located on chromosome 22; there are several isoforms of approximately 1600 amino acids in length. In mice, expression occurs in neurons and GABAergic interneurons throughout brain development. The gene is strongly expressed in both the developing and adult human brain, and the encoded protein contains a DEP homology domain found in other proteins involved in G-protein signaling and membrane targeting, but the exact function of DEPDC5 is unknown.

Epilepsy Genetics and Syndromes.

Autosomal dominant familial focal epilepsy with variable foci (FFEVF) was first described in 1998 (112). FFEVF is characterized by marked intrafamilial variability in age of onset, ictal semiology and localization, seizure severity, cognitive function, and psychiatric comorbidity. Linkage studies mapped FFEVF to a region on chromosome 22q, but the causative gene was not identified until 2013. Mutations in DEPDC5 were identified in seven of eight large families with FFEVF, with an estimated penetrance of 66%; mutations were also identified in 10 of 82 (12%) small families with two or more individuals with nonlesional focal epilepsy (113). Most mutations introduced a premature stop codon leading to protein truncation (113). In another series of families with autosomal dominant focal epilepsies including FFEVF, ADNFLE, and familial TLE, DEPDC5 mutations were identified in 6 of 16 (37%) families, with most mutations causing premature protein truncation and loss of function (114).

GENETIC TESTING

Genetic testing is available for a number of the presumed genetic epilepsy syndromes described above (for information on currently available genetic tests, check www.genetests.org). Prior to ordering, it is important to differentiate genetic testing to establish a diagnosis in a patient with epilepsy or suspected epilepsy (diagnostic testing) from genetic testing in asymptomatic individuals to identify future risk of developing epilepsy (screening or predictive testing). It is also important to differentiate genetic testing in monogenic disorders (caused by a single “major” gene) versus genetic testing in complex genetic disorders, which may be caused by multiple genes and/or environmental factors. The ethical implications of genetic testing are complex and need to be addressed before testing is ordered, ideally with a geneticist or genetic counselor. Genetic testing has implications for the entire family, and yet each individual family member has the right to decide whether to participate in testing. The testing can involve the analysis of DNA, RNA, chromosomes, proteins, or metabolites. Genetic testing of symptomatic individuals (diagnostic testing) is most helpful when the test has high sensitivity and specificity, when the results will influence clinical management, when the disease is preventable or treatable, or when the results provide important information for other family members. Even without effective treatment, genetic testing can be valuable by establishing the diagnosis and excluding other possibilities, thus limiting further testing.

Complicating genetic testing in the epilepsies is incomplete penetrance and genetic heterogeneity. Many of the mutations identified to date have <100% penetrance; some individuals who carry the disease mutation will never have clinical disease. Most genetic epilepsy syndromes also display

genetic heterogeneity in that they can be caused by mutations in more than one gene; this clearly complicates the interpretation of a "negative" test of a single gene. Consider the case of a child diagnosed clinically with SMEI, whose parents request genetic testing to determine the risk to future offspring. Approximately 70% to 80% of patients with SMEI will have SCN1A mutations, with the vast majority occurring de novo. Mutations in GABRG2 have also been identified in SMEI patients, and SCN1A mutations have also been identified in patients with GEFS+, a typically more benign phenotype. If an SCN1A mutation is identified in the affected child, and not in the parents, the mutation is likely to have occurred de novo, and the risk to future offspring is low. However, it is difficult to exclude the possibility of gonadal mosaicism (the presence of the mutation in a subset of the gametes of one parent), in which case there would be increased risk to future offspring. If an SCN1A mutation is not identified in the affected child, one cannot rule out the possibility of a gene mutation in another gene, such as GABRG2. If an SCN1A mutation is identified in both the affected child and one parent, there is a 50% chance of transmitting that SCN1A mutation to future offspring, but the clinical phenotype would be difficult to predict, as SCN1A mutations have been identified in a wide range of phenotypes, from benign FS to severe intractable epilepsy.

As another example, consider the case of a 28-year-old woman with intractable NFLE. Her brother, father, paternal uncle, and paternal grandfather all have similar seizures at night. She plans to have children, and she wants to know the risk of epilepsy in her offspring. Based on her family history, her diagnosis is most likely ADNFLE, which has been associated with mutations in CHRNA4, CHRNB2, CHRNA2, as well as other genes. Mutations in CHRNA4 and CHRNB2 account for only a small percentage of all patients with ADNFLE, implying that other genes are involved. As with many autosomal dominant epilepsies, there is incomplete penetrance, estimated at 50% to 70%. If a CHRNA4 mutation is identified in this patient, there is a 50% chance of transmitting the mutation and a 25% to 35% chance of transmitting NFLE to her offspring. If a CHRNA4 mutation is not identified in this patient, she may still have a mutation in another gene, with a similar risk of transmitting the disease. In a patient with a clinical diagnosis of NFLE and a family history consistent with autosomal dominant inheritance, genetic testing would not necessarily change treatment or genetic counseling.

There are certain specific clinical scenarios in which genetic testing is playing an increasingly important role, such as in the evaluation of a child with an epileptic encephalopathy, with onset of medically refractory seizures in the first year of life associated with marked developmental delay. When neuroimaging for structural brain malformations, karyotyping for chromosomal abnormalities, and screening for inherited metabolic disorders are unrevealing, additional genetic testing can provide important information for diagnosis and treatment. Specific gene defects to consider are listed in Table 4.1, but the table is not meant to be exhaustive, particularly as new mutations continue to be identified at a rapid rate. In particular, in cases of Dravet syndrome, mutations have been described in SCN1A, SCN1B, SCN2A, PCDH19, and GABRG2. In children diagnosed with West syndrome characterized by infantile spasms and hypsarrhythmia, mutations have been identified in CDKL-5, ARX, STXBP-1, and PLCB1, as well as others. Ohtahara syndrome, an epileptic encephalopathy with onset in the first few days or weeks of life, characterized by burst suppression on EEG, has been associated with mutations in STXBP-1, ARX, SLC25A22, and SCN2A, as well as others. An epileptic encephalopathy similar to Ohtahara syndrome has been associated with KCNQ2 mutations, characterized by intractable tonic seizures in the first week of life associated with a burst suppression pattern on EEG and severe cognitive impairment, but, unlike Ohtahara syndrome, which often evolves to West syndrome, seizures resolve by 3 years of age. GLUT1 deficiency was first

described as a cause of epileptic encephalopathy, but the phenotypic spectrum has grown to include milder phenotypes including paroxysmal movement disorders and milder forms of epilepsy, including GGEs such as absence epilepsy. GLUT1 deficiency is caused by mutations in the solute carrier family 2 (facilitated glucose transporter) member 1 (SLC2A1) gene, and mutations in SLC2A1 have been identified in 10% of patients with early-onset absence epilepsy (115) and 1% of more common GGE syndromes including with JME, JAE, CAE, and epilepsy with GTC seizures (116). Diagnosing GLUT1 deficiency has important treatment implications, as the ketogenic diet is an effective therapy. Rare CNVs appear to play an important role in the epileptic encephalopathies (117). The role of CNV detection by SNP microarray or array comparative genomic hybridization (CGH) has become routine in the evaluation of nonsyndromic intellectual disability (children with global developmental delay) (118). Whole-exome sequencing is another powerful tool to detect genomic variation, but the results are complex and should be interpreted with the help of a genetic counselor or medical geneticist.

Table 4.1 Selected Inherited Human Epilepsy Syndromes

Epilepsy syndrome	Seizure types/clinical features	Chromosomal segment	Associated genes
Idiopathic/genetic focal			
Benign focal epilepsy of childhood; benign rolandic epilepsy; epilepsy-aphasia spectrum disorders	Focal and secondarily GTC seizures, nocturnal	15q14 16p13	Unknown *GRIN2A*
Benign familial infantile convulsions/seizures (BFIC/BFIS)	Onset between 3 and 8 mo of age. Focal and secondarily GTC seizures.	19q (BFIS1) 16p12-q12 (BFIS2) 2q23-q24 (BFIS3) 1p36-p35 (BFIS4) 20q13 8q24	Unknown *PRRT2* *SCN2A* Unknown *KCNQ2* *KCNQ3*
Benign familial neonatal-infantile convulsions/seizures (BFNIC/ BFNIS)	Onset between 2 d and 6 mo of age. Focal and secondarily GTC seizures.	2q24 20q13	*SCN2A* *KCNQ2*
Benign familial neonatal convulsions/seizures (BFNC/ BFNS)	Onset in the first few days of life. Tonic or secondarily GTC seizures. Spontaneous remission.	20q13.3 (BFNS1) 8q24 (BFNS2) inv(5)p15q11 (BFNS3)	*KCNQ2* *KCNQ3* Unknown
Autosomal dominant nocturnal frontal lobe epilepsy (ADNFLE)	Focal and secondarily GTC seizures, nocturnal	20q13.2-q13.3 (ENFL1) 15q24 (ENFL2) 1q21(ENFL3) 8p21 (ENFL4) 8q11-q13 22q11	*CHRNA4* Unknown *CHRNB2* *CHRNA2* *CRH* *DEPDC5*
Autosomal dominant partial epilepsy with auditory features (ADPEAF)	Focal seizures, often with auditory auras	10q24 (ETL1) 12q22-q23 (ETL2) 4q (ETL3) 9q21-q22 (ETL4) 8q13 (ETL5)	*LGI1* Unknown Unknown Unknown *CPA6*
Familial focal epilepsy with variable foci (FFEVF)	Focal seizures, arising from different foci within the same family	22q11	*DEPDC5*
Familial occipitotemporal lobe epilepsy and migraine with visual aura	Visual, cognitive, and autonomic auras; focal motor seizures, CPS, secondarily GTC; migraine with aura	9q21-q22 (ETL4)	Unknown
Familial temporal lobe epilepsy	Febrile seizures with childhood afebrile focal and GTC seizures, déjà vu aura; relatively benign course, normal MRI	12q22-q23 (ETL2) 4q13-q21 (ETL3) 8q13 (ETL5) 22q11	Unknown Unknown *CPA6* *DEPDC5*
Idiopathic/genetic generalized			
Childhood absence epilepsy (CAE)	Typical absence, GTC seizures	8q24 (ECA1) 5q31.1 (ECA2) 5q34 (ECA4) 15q11-q12 (ECA5) 16p13 (ECA6)	Unknown *GABRG2* *GABRA1* *GABRB3* *CACNA1H*
Juvenile myoclonic epilepsy (JME)	Myoclonic, absence, and GTC seizures	6p12-p11 (EJM1) 15q14 (EJM2) 6p21 (EJM3) 5q12-q14 (EJM4) 5q34 (EJM5) 2q23 (EJM6) 3q26 (EJM8)	*EFHC1* Unknown Unknown Unknown *GABRA1* *CACNB4* *CLCN2*
Genetic generalized epilepsy (IGE/GGE) comprised CAE, JAE, JME, epilepsy with grand mal seizures on awakening (EGMA)—*other potential susceptibility alleles have been reported that are not listed here*	Absence, myoclonic, GTC seizures	8q24 (IGE1/EIG1) 14q23 (IGE2/EIG2) 9q32-q33 (EIG3) 10q25-q26 (EIG4) 10p11 (EIG5) 16p13 (EIG6) 15q13 (EIG7) 3q13-3q21 (EIG8) 2q23 (EIG9) 1p36 (EIG10) 3q27 (EIG11) 1p34 (EIG12)	Unknown Unknown Unknown Unknown Unknown *CACNA1H* Unknown *CASR* *CACNB4* *GABRD* *CLCN2* *SLC2A1*

Epilepsy syndrome	Seizure types/clinical features	Chromosomal segment	Associated genes
Generalized/genetic epilepsy with febrile seizures plus (GEFS+)	Febrile seizures often beyond 6 y of age, followed by GTC, absence, myoclonic, atonic seizures	19q13 (GEFSP1) 2q24 (GEFSP2) 5q34 (GEFSP3) 2q24 1p36 (GEFSP5) 8p23-p21 (GEFSP6) 2q24 (GEFSP7)	*SCN1B* *SCN1A* *GABRG2* *SCN2A* *GABRD* Unknown *SCN9A*
Familial adult myoclonic epilepsy	GTC seizures, myoclonus	8q24 (FAME1) 2p11-q12 (FAME2) 3q26-q28 (FAME4) 1q32 (FAME5)	Unknown Unknown Unknown *CNTN2*
Familial infantile myoclonic epilepsy (FIME)	Febrile seizures, myoclonic and GTC seizures	16p13	*TBC1D24*
Other epilepsy syndromes			
Familial febrile seizures	GTC seizures with fever	8q13-q21 (FEB1) 19p (FEB2) 2q23-q24 (FEB3) 5q14-q15 (FEB4) 6q22-q24 (FEB5) 18p11.2 (FEB6) 21q22(FEB7) 5q34 (FEB8) 3p24-p23 (FEB9) 3q26 (FEB10) 8q13 (FEB11)	Unknown Unknown *SCN1A* *GPR98* Unknown Unknown Unknown *GABRG2* Unknown Unknown *CPA6*
Generalized Epilepsy with Paroxysmal Dyskinesia (GEPD)	Absence and GTC seizures, paroxysmal dyskinesia	10q22	*KCNMA1*
Infantile convulsions with choreoathetosis (ICCA)	Infantile convulsions, paroxysmal kinesigenic dyskinesia	16p11	*PRRT2*
BFIC and Familial Hemiplegic Migraine (FHM)	Infantile convulsions, migraine, or hemiplegic migraine	1q23	*ATP1A2*
Epileptic encephalopathies			
Dravet syndrome (Severe myoclonic epilepsy of infancy)	Onset in the first year of life. Febrile seizures followed by afebrile seizures later in life. Developmental delay.	2q24 (EIEE6) Xq22 (EIEE9)	*SCN1A* *PCDH19*
Early infantile epileptic encephalopathy (EIEE)		5q31 19q13 2q24 (EIEE11)	*GABRG2* *SCN1B* *SCN2A*
Ohtahara syndrome	Onset in the first few days or weeks of life. Tonic spasms but focal seizures can also be seen. Burst suppression pattern on EEG. With KCNQ2 mutations, seizures typically resolve by 3 y of age, but developmental delay persists.	Xp21 (EIEE1) Xp22 (EIEE2) 11p15 (EIEE3) 9q34 (EIEE4) 20q13 (EIEE7) 2q24 (EIEE11)	*ARX* *CDKL5* *SLC25A22* *STXBP1* *KCNQ2* *SCN2A*
West syndrome	Infantile spasms, severe global developmental delay. Hypsarrhythmia on EEG.	Xp21 (EIEE1) Xp22 (EIEE2) 9q34 (EIEE4) 20p12 (EIEE12) 9q34 (EIEE14) 1p34 (EIEE15)	*ARX* *CDKL5* *STXBP1* *PLCB1* *KCNT1* *ST3GAL3*
Epilepsy of infancy with migrating focal seizures	Refractory focal seizures, severe developmental delay, regression. Poor prognosis.	2q24 9q34 20p12	*SCN1A* *KCNT1* *PLCB1*
Myoclonic-astatic epilepsy	Onset between 2 and 5 y of age. Myoclonic, astatic/atonic, absence, and tonic–clonic seizures. Variable prognosis.	2q24 19q13 5q31 1p34	*SCN1A* *SCN1B* *GABRG2* *SLC2A1*
Epilepsy and mental retardation limited to females (EFMR)	Onset in the first year of life. Multiple focal and generalized seizure types, often associated with fever. Mental retardation. Poor language development, ataxia. Only seen in females.	Xq22.1 (EIEE9)	*PCDH19*
GLUT1 deficiency		1p34	*SLC2A1*

GTC, generalized tonic–clonic.

CONCLUSION

Genetics plays a role in virtually all epilepsy syndromes, through a diversity of mechanisms. The identification of specific mutations in ion channel subunits has contributed significantly to our knowledge of underlying pathogenic pathways leading to seizures and epilepsy, but clearly, non-ion channel genes are involved. Further work in the identification of gene defects and their functional characterization will continue to advance our understanding of basic mechanisms. Work toward improving phenotype–genotype correlations and delineating the functional significance of both common and rare polymorphisms in "epilepsy genes" will allow us to make better use of genetic testing in epilepsy.

The eventual hope is that understanding the genetics of human epilepsy will improve recognition, diagnosis, and treatment of individuals with epilepsy. In the search for new strategies to reduce the burden of disease, the discovery of epilepsy genetic risk factors offers a novel opportunity to identify individuals susceptible to epilepsy before it develops and to treat and prevent seizures and associated comorbidities in those individuals at risk.

CHAPTER 5 PICTORIAL ATLAS OF EPILEPSY SUBSTRATES

AJAY GUPTA AND RICHARD A. PRAYSON

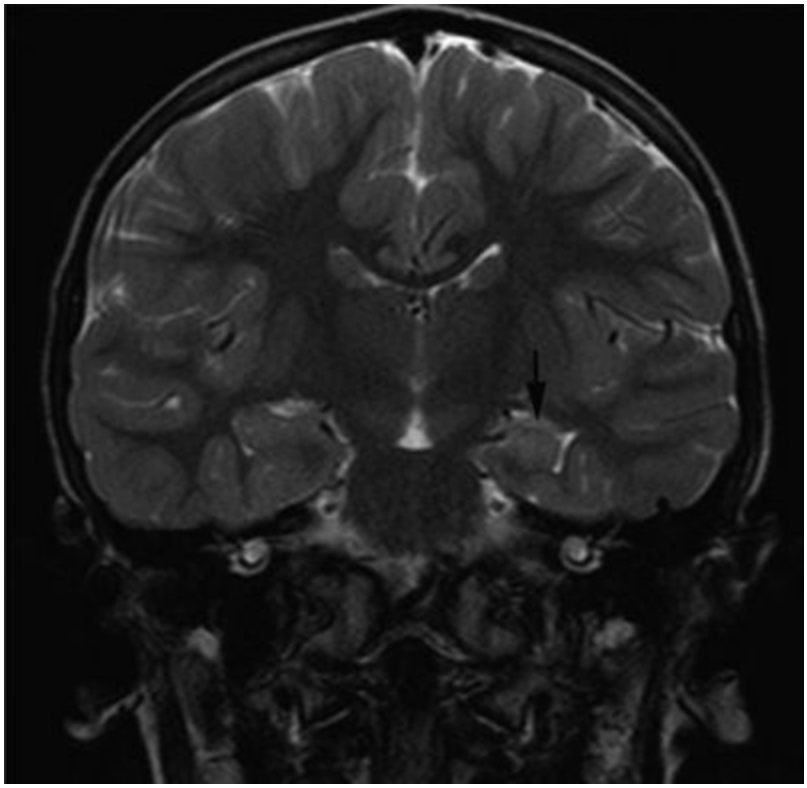

Figure 5.1. Mesial temporal sclerosis. Coronal T2-weighted image from MRI without gadolinium in a 7-year-old male with temporal lobe epilepsy shows increased signal intensity and decreased size of the left hippocampal formation (arrow).

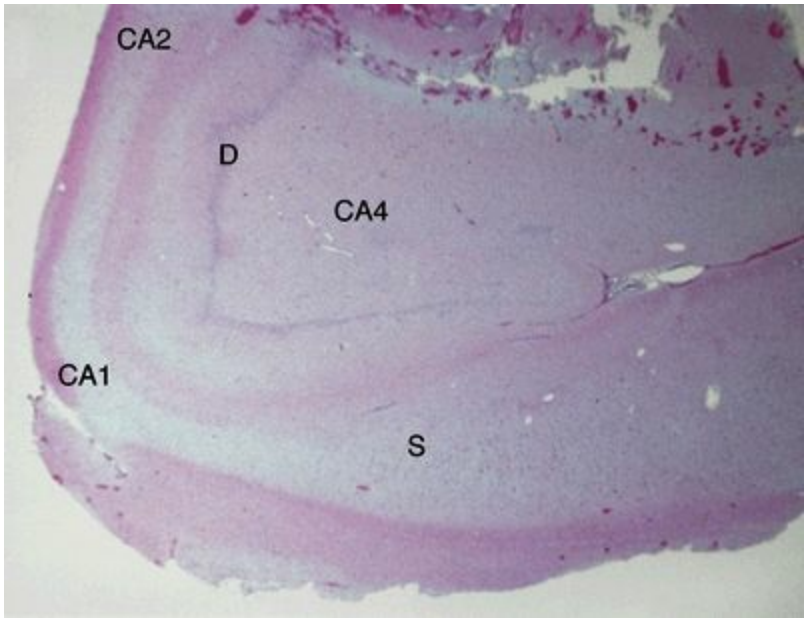

Figure 5.2. Low-magnification appearance of hippocampus in **hippocampal sclerosis** (HS). An adult patient who underwent anterior temporal lobectomy for treatment of intractable temporal lobe epilepsy. HS is the most common cause of intractable partial epilepsy in adults. HS is generally marked by preferential loss of neurons in the dentate (D), CA4 region, CA1 region, and subiculum (S). A lesser degree of neuronal loss may be observed in the CA3 and CA2 regions. Loss of neurons is accompanied by gliosis and, in severe cases, grossly evident atrophy.

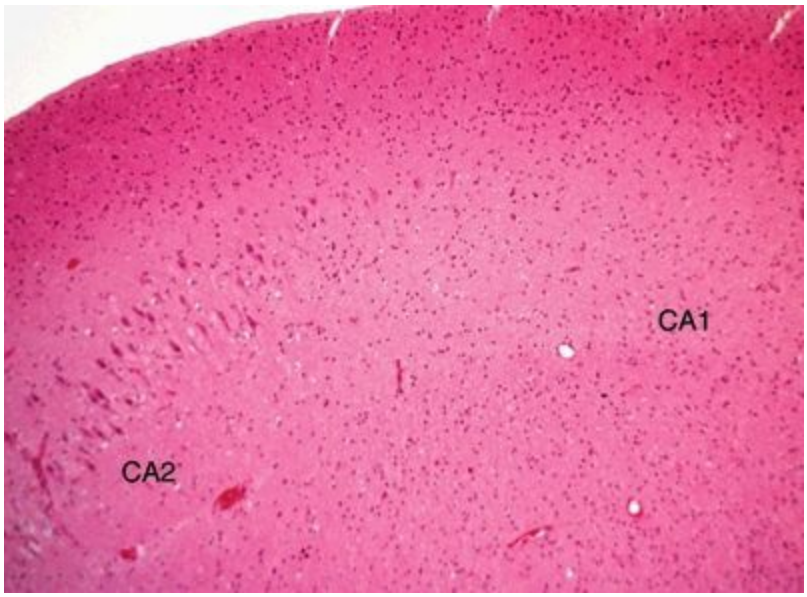

Figure 5.3. Higher-magnification appearance of the hippocampus in **hippocampal sclerosis** at the interface between CA2 and CA1 regions. There is a marked loss of neurons in the CA1 region with gliosis.

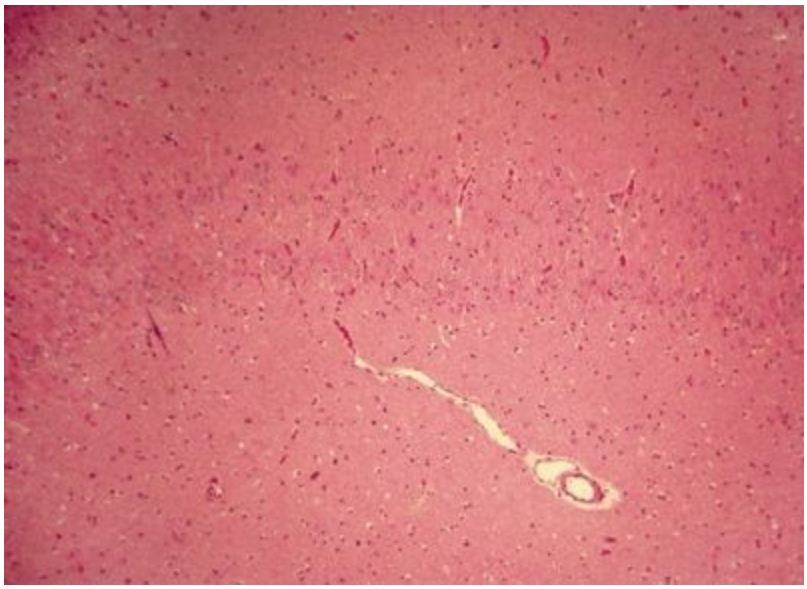

Figure 5.4. Histologic appearance of **double dentate** marked by two bands of neurons in the hippocampus. This represents a form a hippocampal dysplasia. Hippocampal dysplasia is an infrequent cause of temporal lobe epilepsy and may be seen as a dysmorphic hippocampal formation on a high-definition three-dimensional volume acquisition sequences on brain MRI.

Figure 5.5. Lissencephaly. Axial T2-weighted image from MRI without gadolinium in a newborn shows lack of normal sulcation (white arrows), parallel lateral ventricles, and absence of the corpus callosum (black arrow). Children with lissencephaly usually present with epileptic spasms, severe global developmental delay, microcephaly, and marked hypotonia during early infancy.

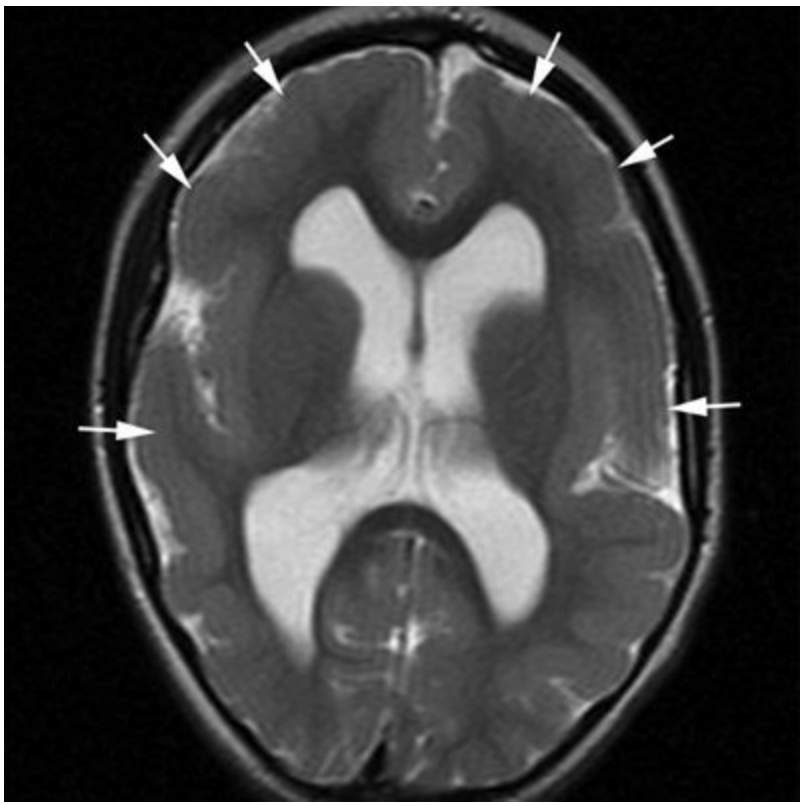

Figure 5.6. Pachygyria. Axial T2-weighted image from MRI without gadolinium in a 4-year-old with spastic quadriplegia and generalized seizures shows a paucity of sulcal markings and thickened cortex bilaterally (arrows).

Figure 5.7. The gross appearance of **lissencephaly (agyria)** characterized by a lack of gyral formation and a decreased number of sulci. Note enlargement of ventricles, suggesting parenchymal volume loss. The cortex is usually thickened on cross-section. Microscopically, there is an abnormally layered cortex, typically three to five layers.

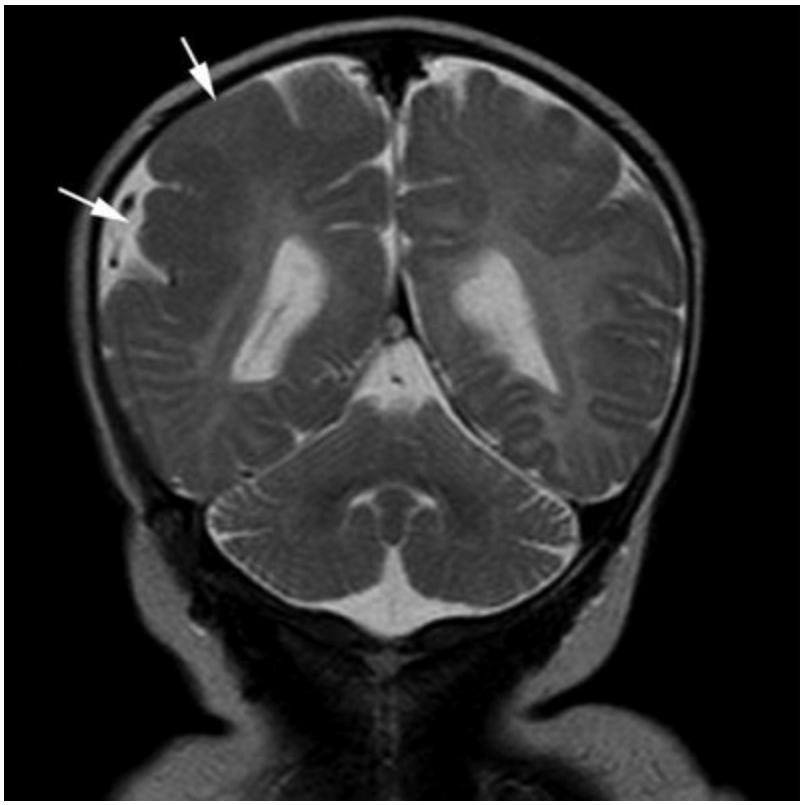

Figure 5.8. Polymicrogyria. Coronal T2-weighted image from MRI without gadolinium in a newborn with motor seizures shows generalized thickening of the cortex of the right parietal lobe characterized by multiple small gyri (arrows). Polymicrogyria are usually epileptogenic lesions, sporadic or familial in occurrence, and various brain MRI patterns have been recognized that help in making an accurate diagnosis.

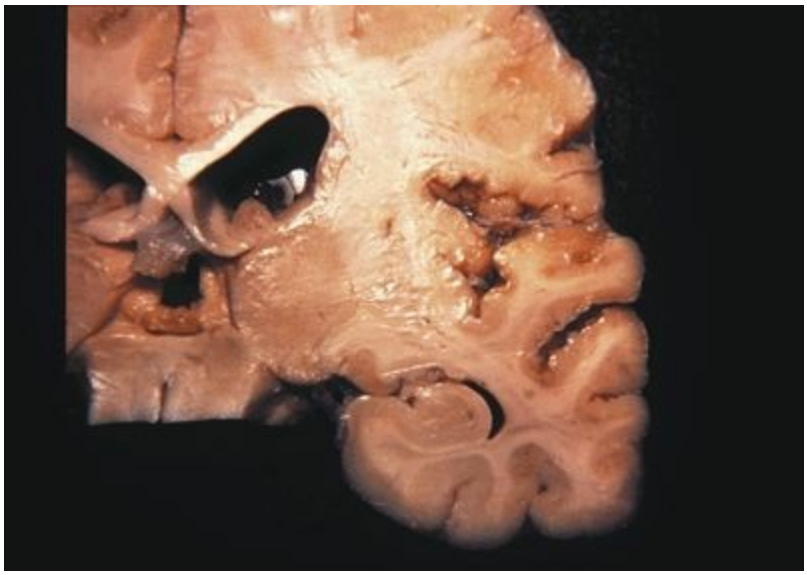

Figure 5.9. Gross appearance of **perisylvian polymicrogyria (micropolygyria)** marked by the focal presence of small, irregular gyri separated by shallow sulci. The cortex is often thinned and microscopically is composed of two- to four-layered cortex. The leptomeninges overlying polymicrogyria may be abnormally hypervascular due to a persistence of fetal leptomeningeal vascularization. Congenital bilateral perisylvian polymicrogyria (CBPP) usually presents with seizures during childhood. Other clinical findings in the patients with CBPP include pseudobulbar paresis, dysarthria, swallowing difficulties, and tongue paresis with inability to protrude tongue and to perform lateral tongue movements. (Photograph courtesy of Dr. Bette Kleinschmidt-DeMasters.)

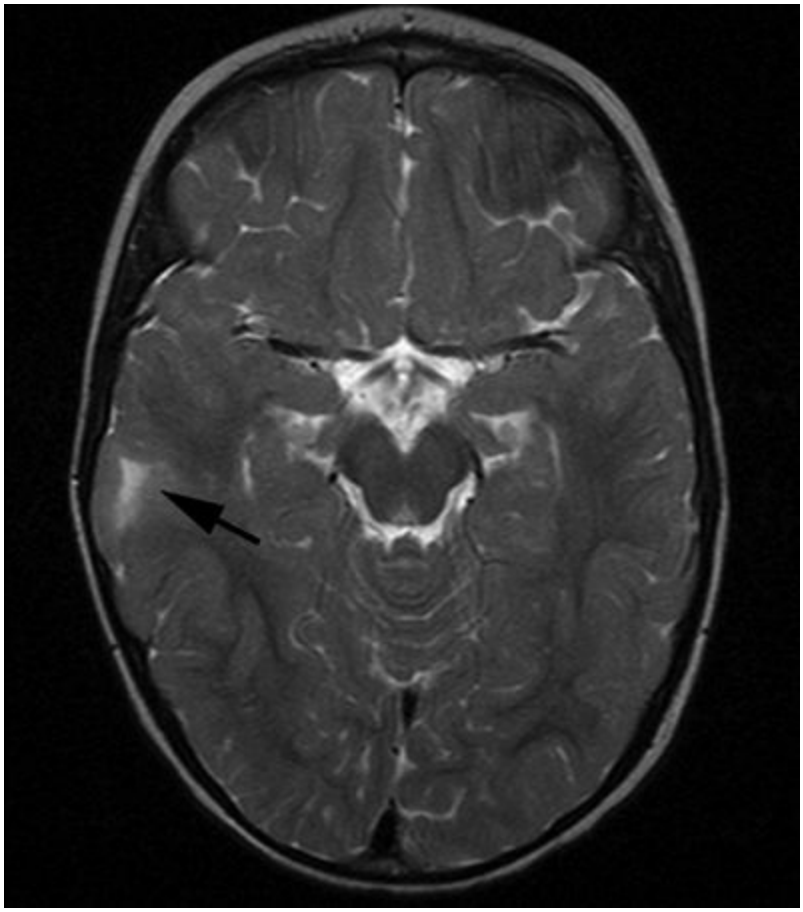

Figure 5.10. Balloon cell dysplasia. Axial T2-weighted image from MRI without gadolinium in an 18-month-old male with intractable seizures shows high signal in the right parietal subcortical white matter subtending a broad-based gyrus (arrow). Most focal cortical dysplasias are sporadic congenital malformations and, as a group, are one of the most important causes of intractable epilepsy that is surgically remediable.

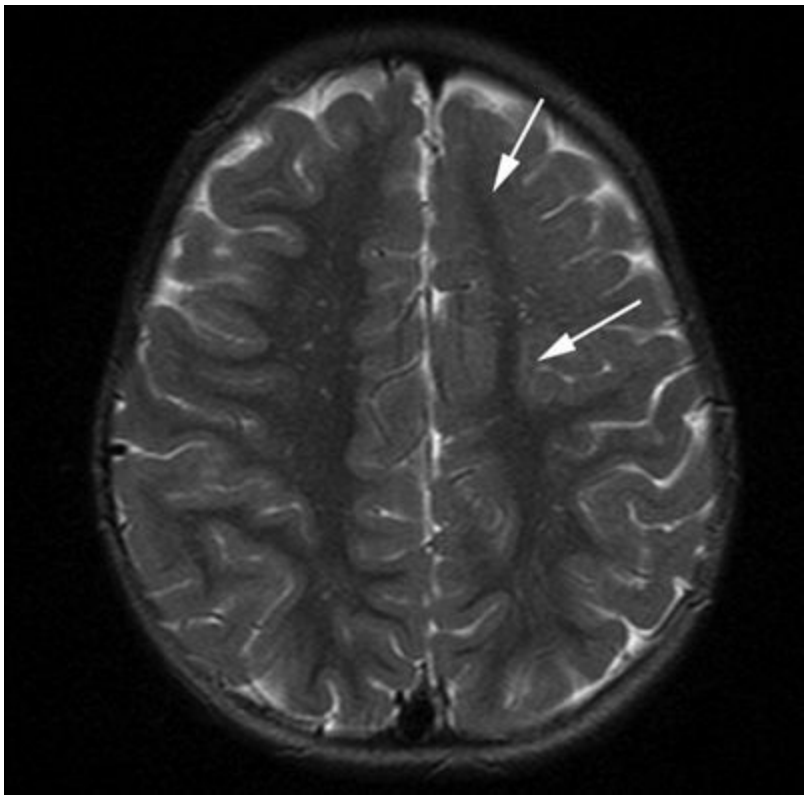

Figure 5.11. Lobar cortical dysplasia. Axial T2-weighted image from MRI without gadolinium in a 3-year-old with infantile spasms shows generalized blurring of the gray–white interface with lack of normal white matter arborization in the left frontal lobe (arrows).

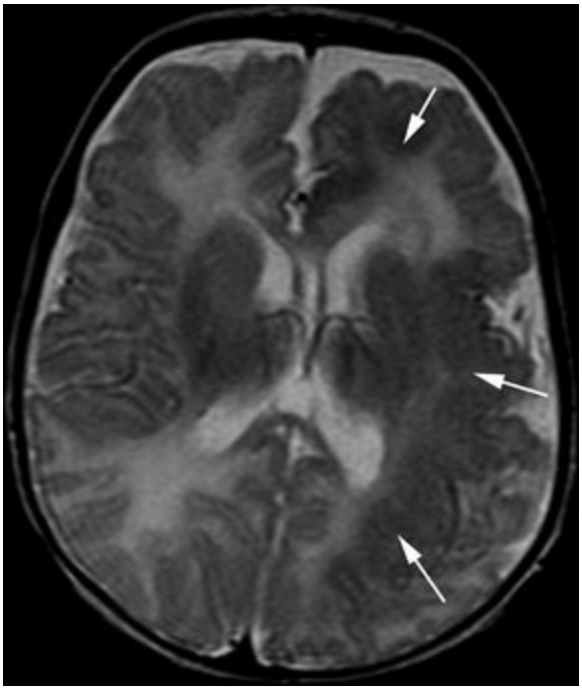

Figure 5.12. Hemispheric malformation of cortical development. Axial T2-weighted image from MRI without gadolinium in a 4-year-old boy with intractable infantile spasms since birth shows diffuse left hemispheric cortical thickening with lack of normal arborization of white matter (arrows).

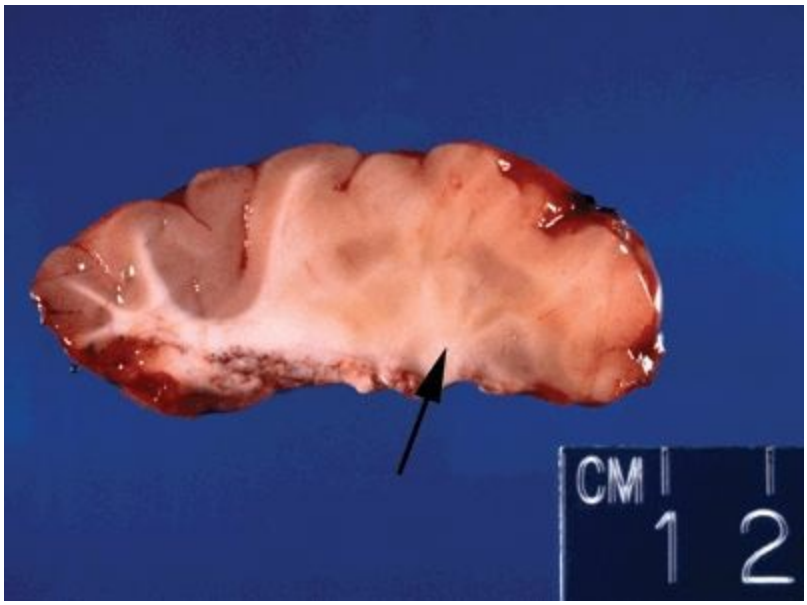

Figure 5.13. Gross appearance of **cortical dysplasia** marked by an indistinct gray/white interface (right portion of cross section —arrow) with evidence of gray matter tissue abnormally placed in white matter (**nodular heterotopia**).

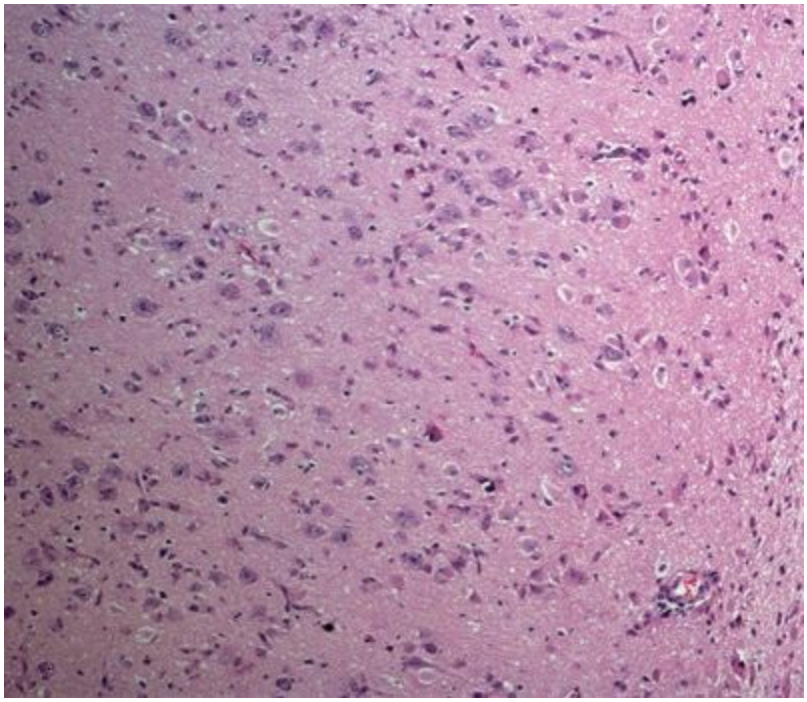

Figure 5.14. Histologic appearance of **cortical dysplasia** marked by a loss of normal cortical lamination, increased cellularity, and malpositioning of neurons within the cortex. Neurons normally have their apical dendrites oriented perpendicular with respect to the surface of the brain.

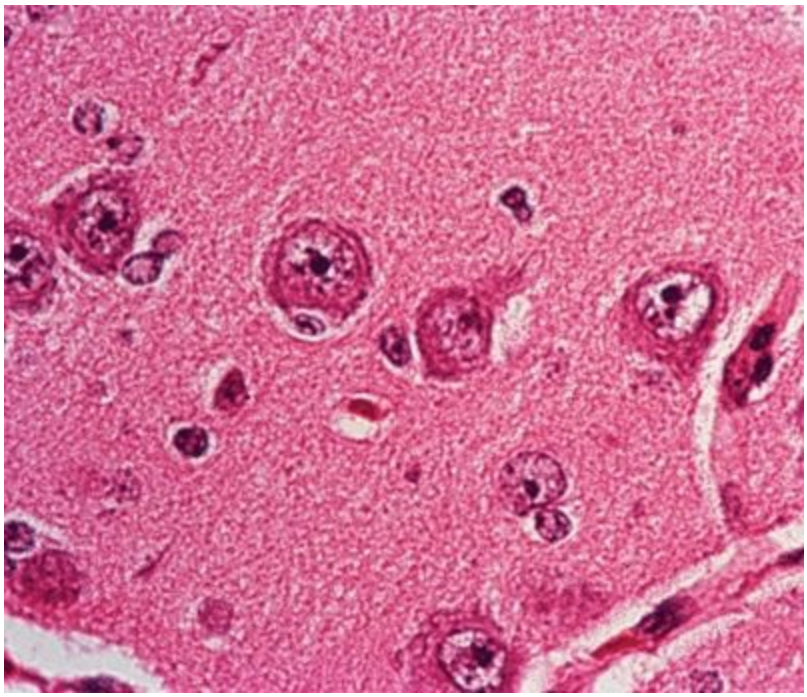

Figure 5.15. High-magnification appearance of neurons in cortical layer II of the parietal lobe in a patient with **cortical dysplasia**. The neurons are abnormally enlarged in size (**neuronal cytomegaly**) without any other evidence of dysmorphic features.

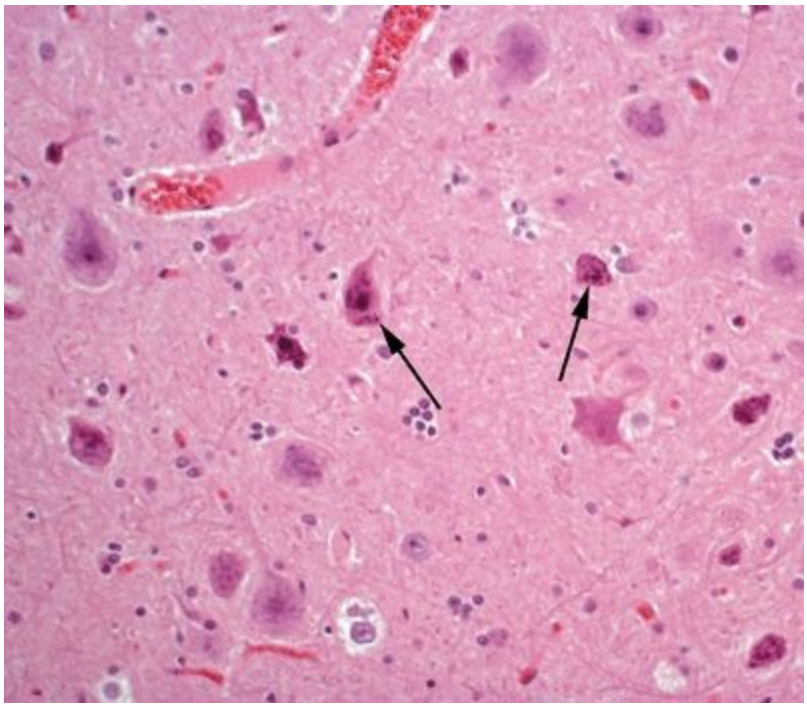

Figure 5.16. Histologic appearance of neurons in cortical layer III of the temporal lobe in a patient with **cortical dysplasia**. The neurons are marked by abnormal cytologic appearance (**dysmorphic neurons**) (arrows), including abnormal nuclear morphology and atypical distribution of Nissl substance. In addition, neurons are haphazardly arranged within the cortex.

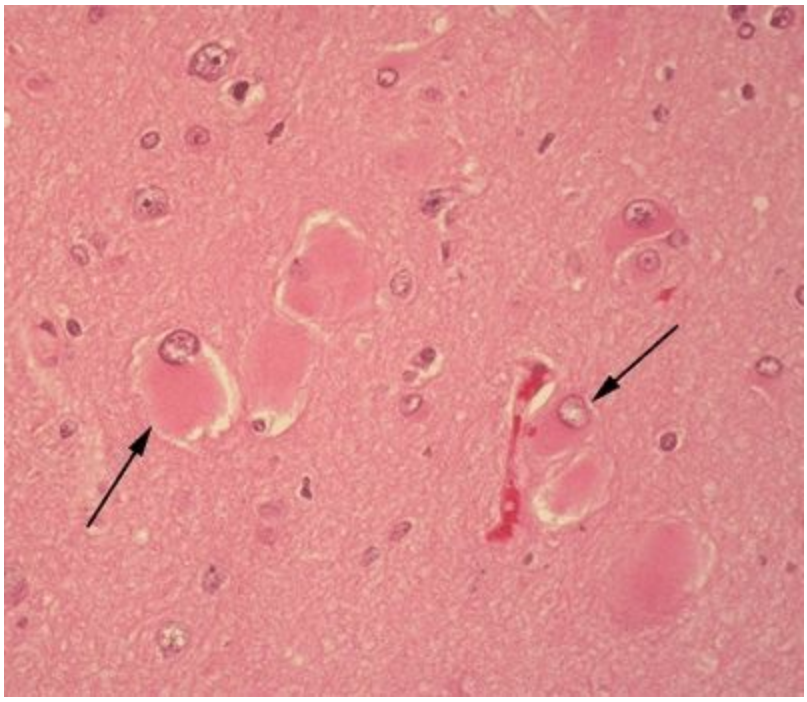

Figure 5.17. Histologic appearance of **balloon cells** (arrows) in the setting of **cortical dysplasia**. Balloon cells are marked histologically by the presence of abundant eosinophilic cytoplasm and eccentrically placed nuclei. Multinucleation may be observed. The derivation of these cells is still debated. A subset of balloon cells stain with markers of both glial differentiation (glial fibrillary acidic protein) and neural differentiation (neuron-specific enolase).

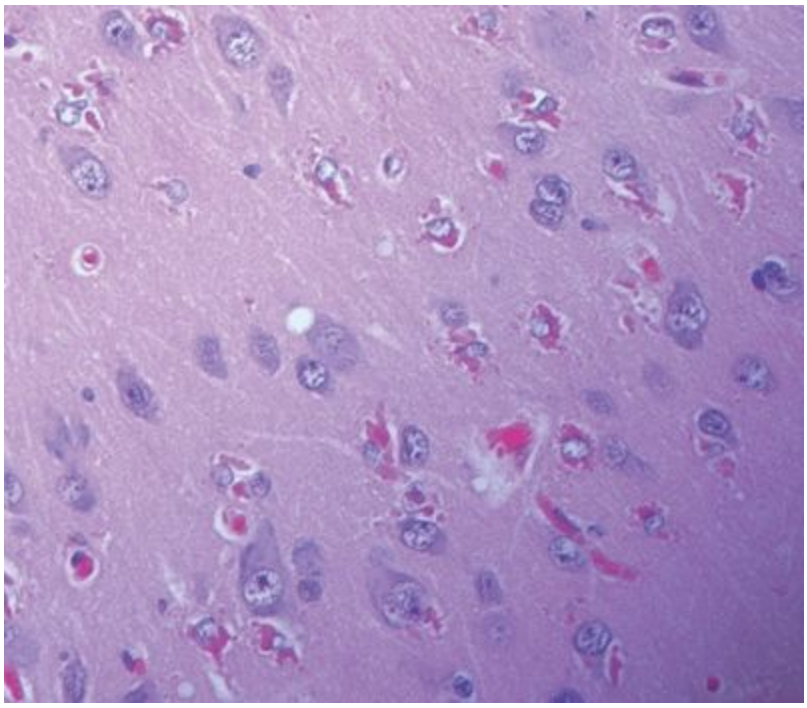

Figure 5.18. Hyaline protoplasmic astrocytopathy of the neocortex may be seen in cases of focal cortical dysplasia. This lesion is marked by eosinophilic inclusions in the cytoplasm of protoplasmic astrocytes in the neocortex, representing a filaminopathy.

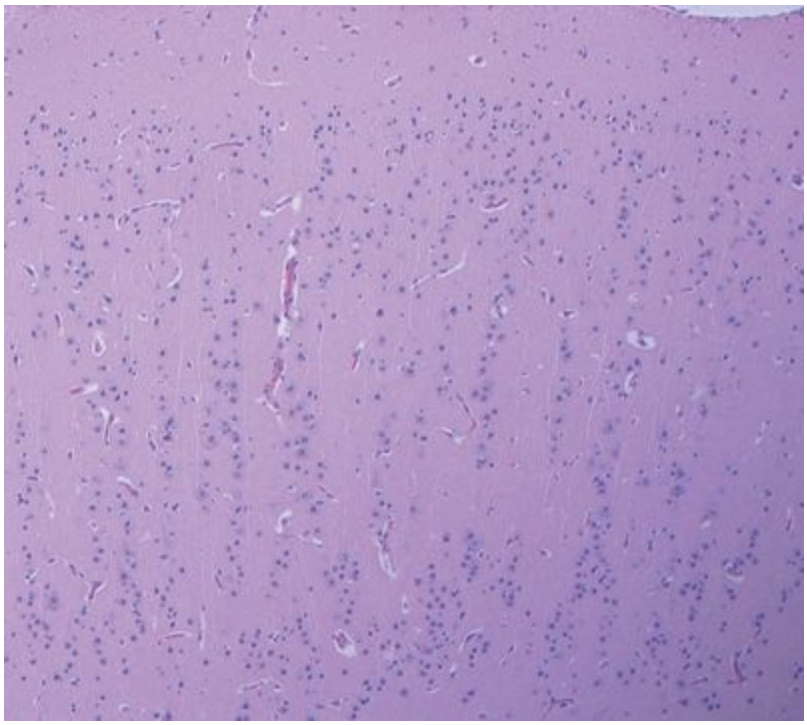

Figure 5.19. Focal cortical dysplasia marked by a linear array or columnar arrangement of cortical neurons. This pattern may rarely occur in isolation or more frequently occurs in conjunction with disorganization in the horizontal orientation in the cortical architecture.

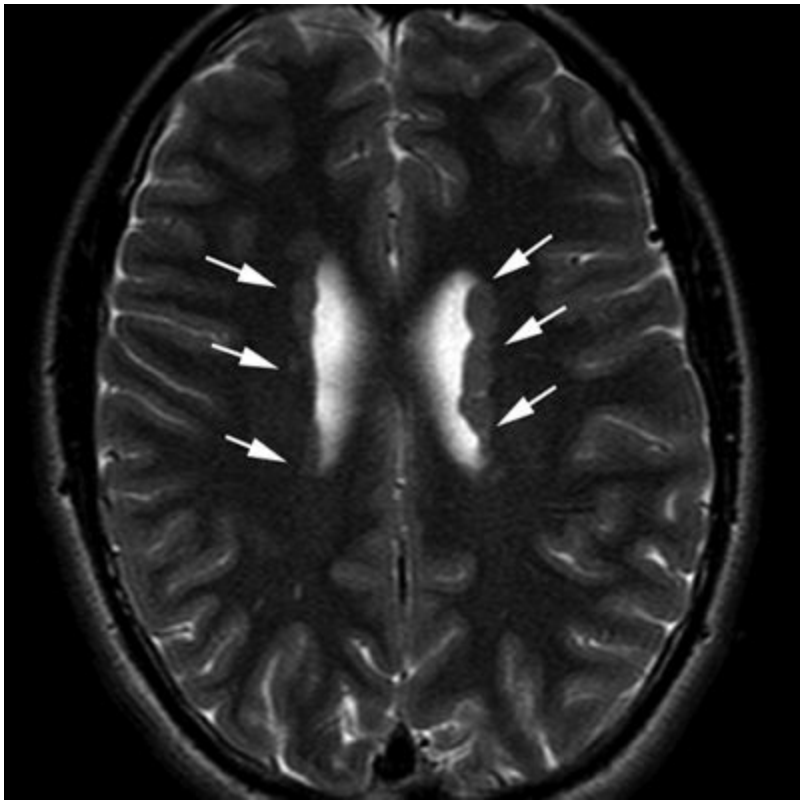

Figure 5.20. Subependymal (periventricular) heterotopia. Axial T2-weighted image from MRI without gadolinium in a 14-year-old female with history of ptosis and tremors shows gray matter nodularity lining the lateral ventricles bilaterally (arrows). Bilateral periventricular nodular heterotopica could be an X-linked dominant condition due to filamin A gene mutations.

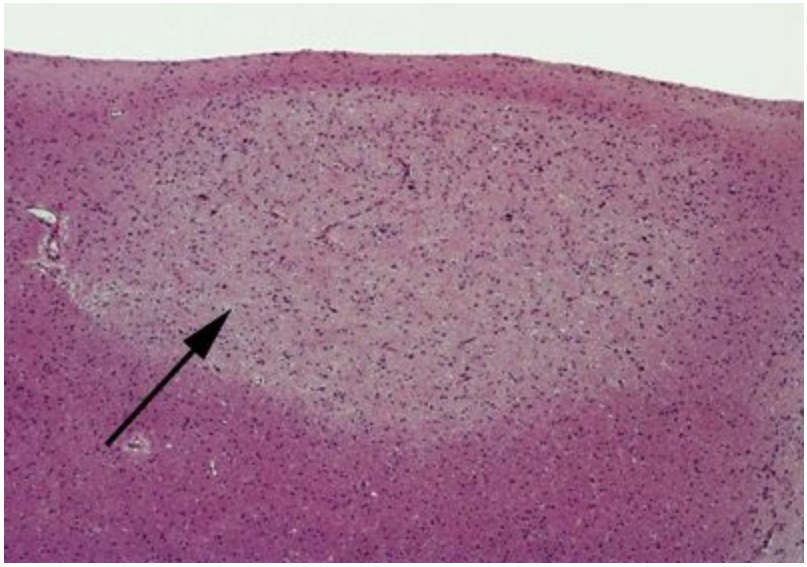

Figure 5.21. Microscopic appearance of a **subependymal (periventricular) nodular heterotopia** of gray matter (arrow). The nodule microscopically is marked by a mixture of neural and glial cells arranged in a disorganized fashion. Heterotopias are collections of mostly normal-appearing neurons in abnormal location presumably due to a disturbance in migration.

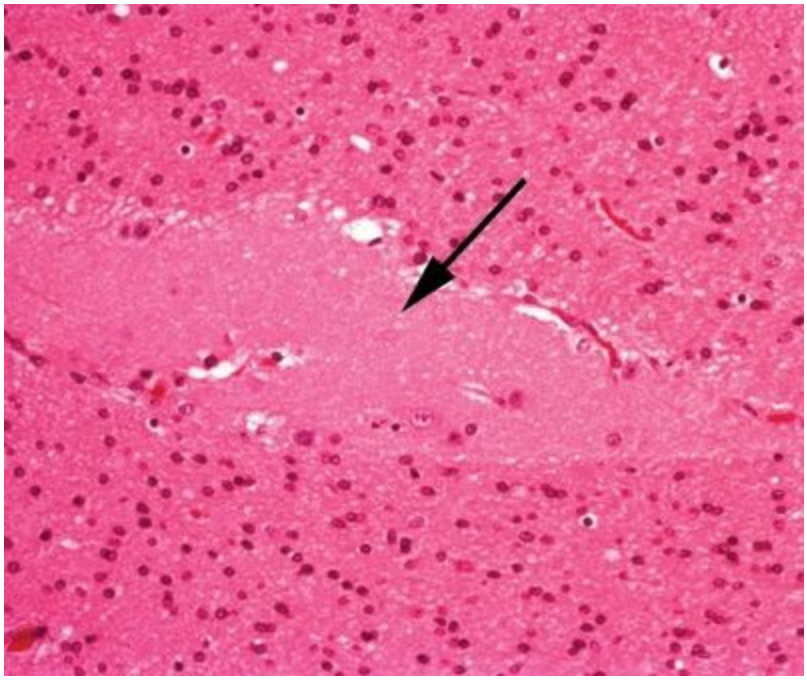

Figure 5.22. Small focus of the **heterotopic gray matter** situated in the deep white matter of the frontal lobe region (arrow).

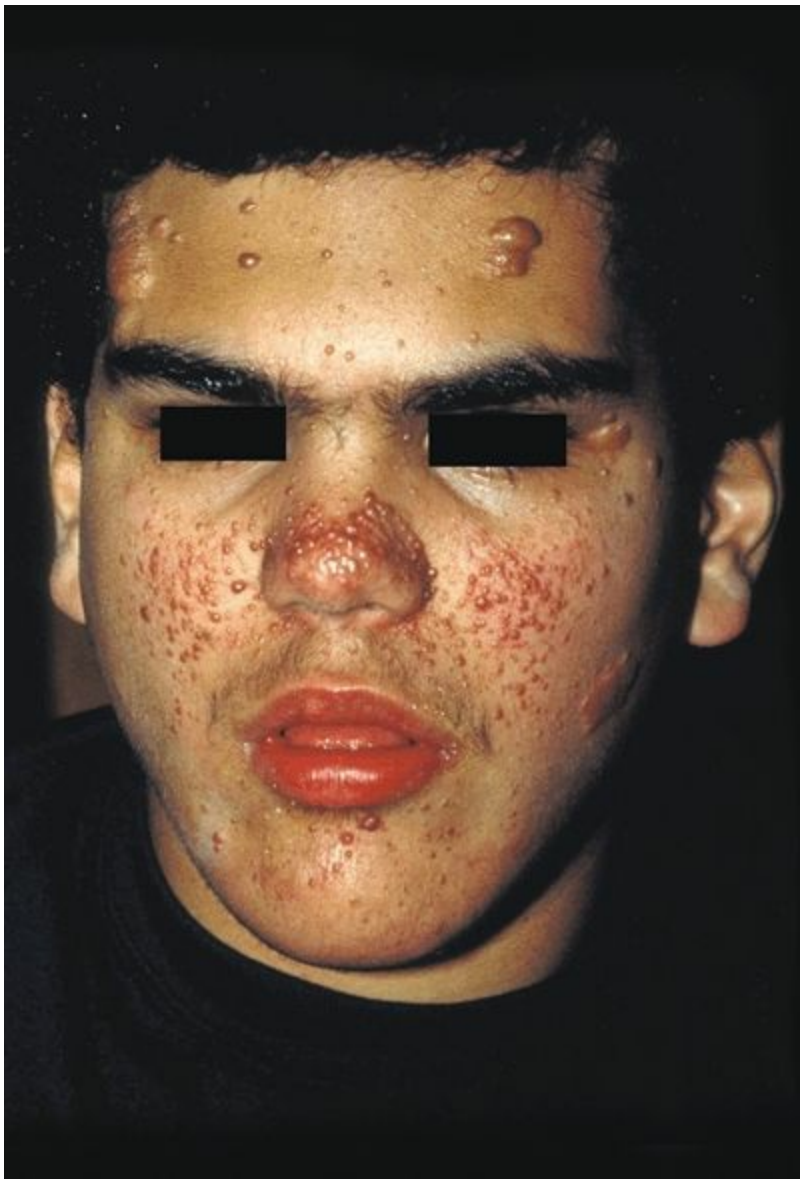

Figure 5.23. A patient with **facial adenoma sebaceum**, a diagnostic finding in tuberous sclerosis (TS). TS is an autosomal dominant condition that involves multiple organs and systems besides the central nervous system. Clinical spectrum is highly variable, and the diagnosis is usually made by looking for other findings like hypomelanotic skin patches, fibromatous skin plaques, dental pits, ungual fibromas, retinal hamartomas, cardiac rhabdomyomata, and renal cysts. TS is caused by mutations in the TSC 1 (hamartin) and 2 (tuberin) genes located on chromosomes 9 and 16, respectively. The phenotype due to TSC 1 and 2 mutations is generally difficult to distinguish clinically.

Figure 5.24. "Ash leaf macule" in a patient with **tuberous sclerosis**. Hypopigmented macules may only be visible under ultraviolet light in patients with fair skin color.

Figure 5.25. Ungual fibroma involving the little toe.

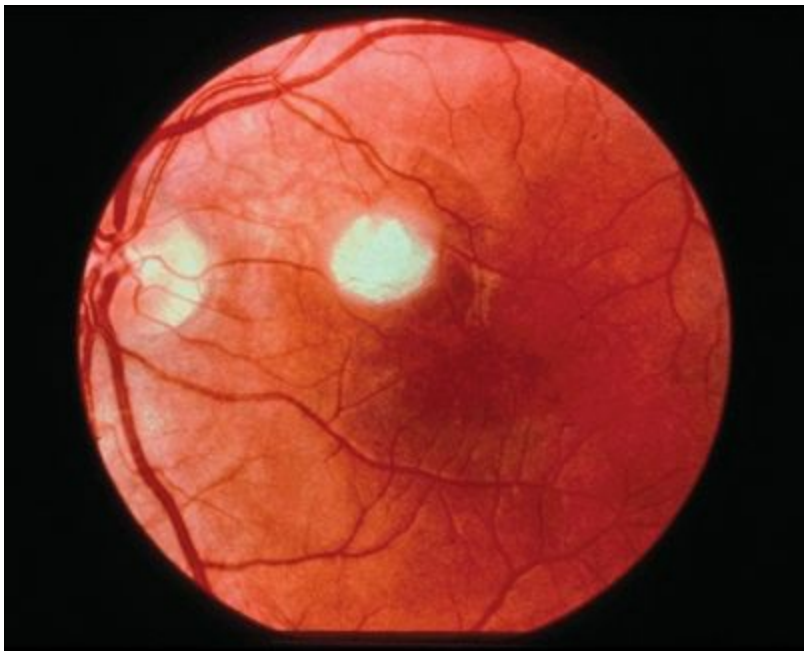

Figure 5.26. Retinal hamartoma seen on funduscopic examination.

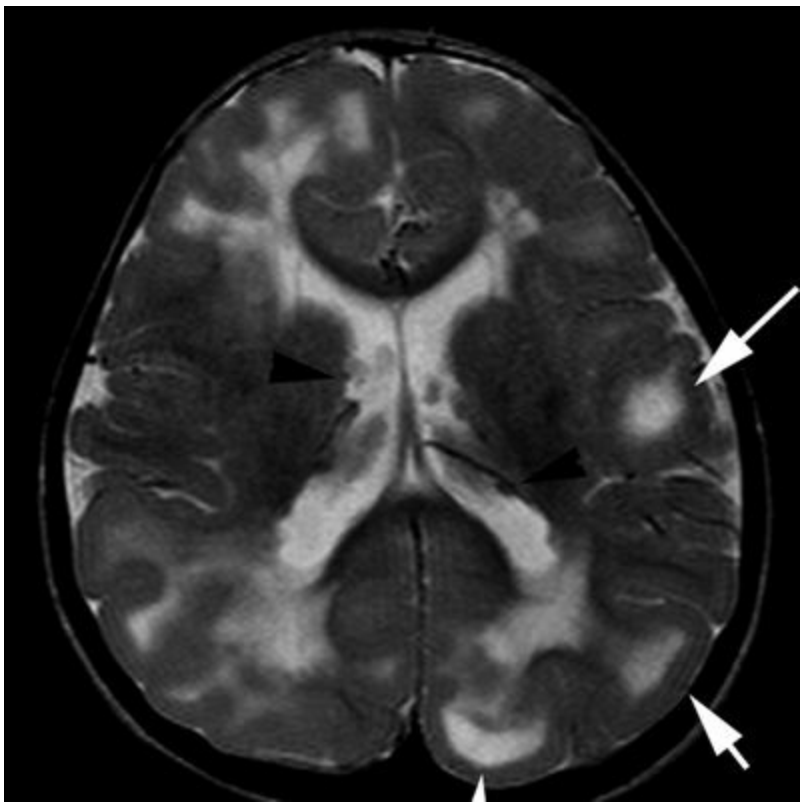

Figure 5.27. Tuberous sclerosis. Axial T2-weighted image from MRI without gadolinium in a 9-year-old male with over 20 seizures per day shows multiple subependymal low-signal-intensity nodules (black arrowheads) and multiple bilateral malformations of cortical development characterized by gyral broadening and subcortical white matter hyperintensity (white arrows).

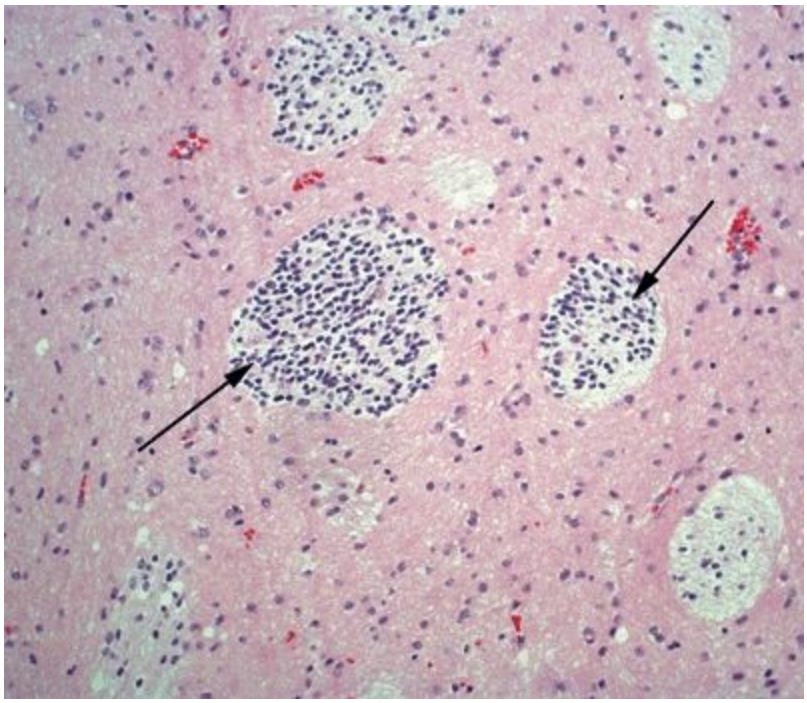

Figure 5.28. Histologic appearance of **hamartia** (arrows) characterized by an aggregation of small, immature-appearing neurons. This lesion most likely represents a form of cortical dysplasia and is seen in patients with tuberous sclerosis.

Figure 5.29. Gross appearance of a **cortical tuber** marked by obliteration of the gray/white interface (left most gyrus—arrow). Cortical tubers often have a firm consistency related to gliosis and microcalcifications. Other pathologic findings in the brain of tuberous sclerosis patients include subependymal nodules and giant cell astrocytomas typically located at the foramen of Monro, leading to obstructive hydrocephalus in some patients.

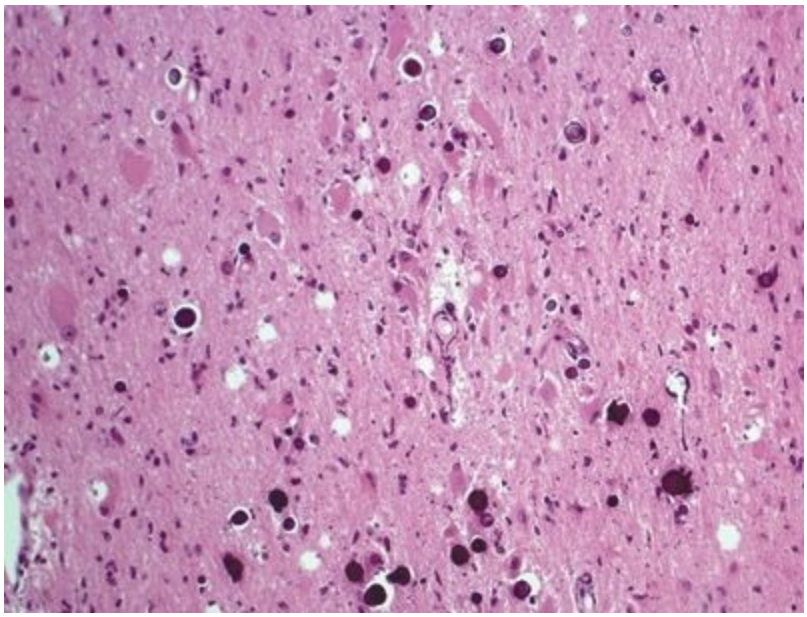

Figure 5.30. Histologic appearance of parenchyma from a **cortical tuber** of tuberous sclerosis. The histologic findings are generally that of a cortical dysplasia and are marked by abnormal cortical lamination, a malorientation of neurons within the cortex and dysmorphic neurons frequently accompanied by ballooned cells. Microcalcifications are also prominently noted in this particular microscopic field.

Figure 5.31. A child with **Sturge–Weber syndrome**. The presence of nevus flammeus in the distribution of the first division (ophthalmic) of the trigeminal nerve highly correlates with the central nervous system involvement.

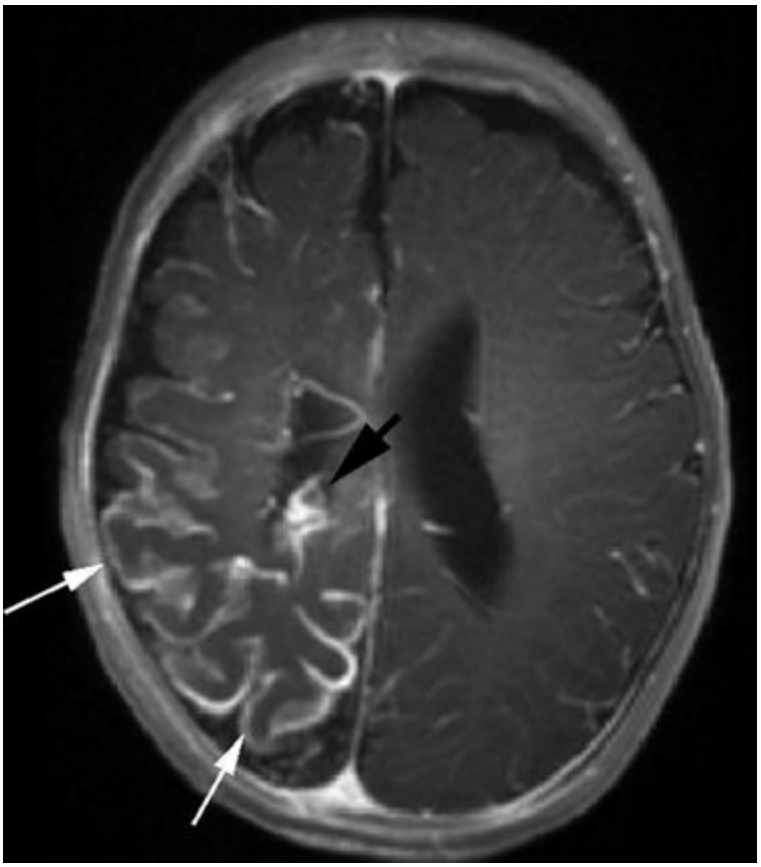

Figure 5.32. Sturge–Weber syndrome. Axial MPRAGE image from MRI with gadolinium in a 12-month-old girl with left tonic–clonic seizures shows diffuse gyriform enhancement (white arrows) with enlargement of the glomus of the right choroid plexus (black arrow).

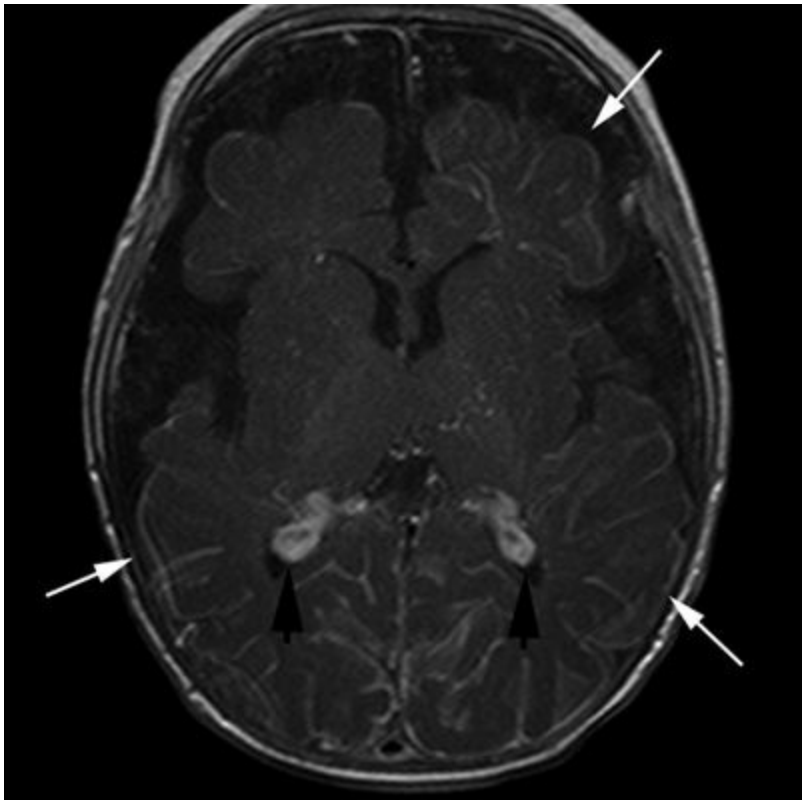

Figure 5.33. Sturge–Weber syndrome. Axial T1-weighted image from MRI with gadolinium in a 4-month-old girl with bilateral facial port-wine stains shows left frontal and bilateral parietooccipital gyriform enhancement (white arrows) with bilateral enlargement of the glomus of the choroid plexus (black arrows).

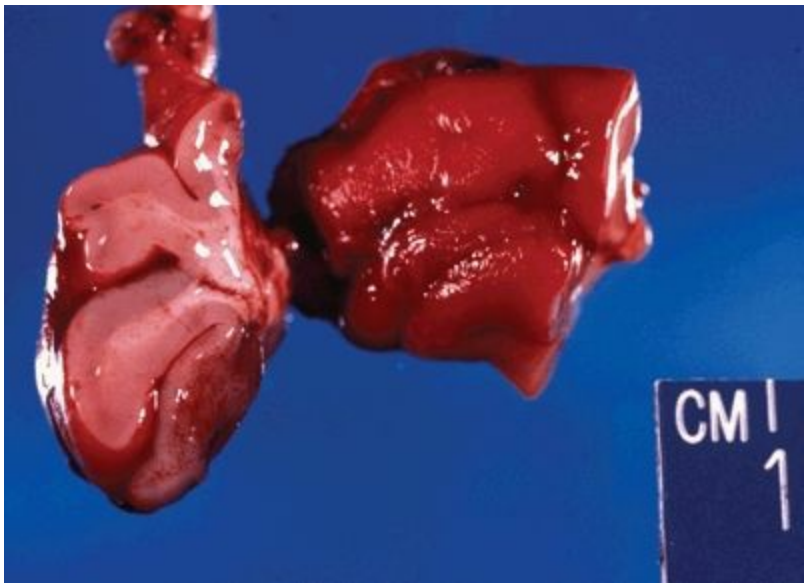

Figure 5.33. Cross-sectional **(left)** and external **(right)** views from a resection in a patient with **Sturge–Weber disease**. The leptomeninges appear hemorrhagic due to a proliferation of vessels.

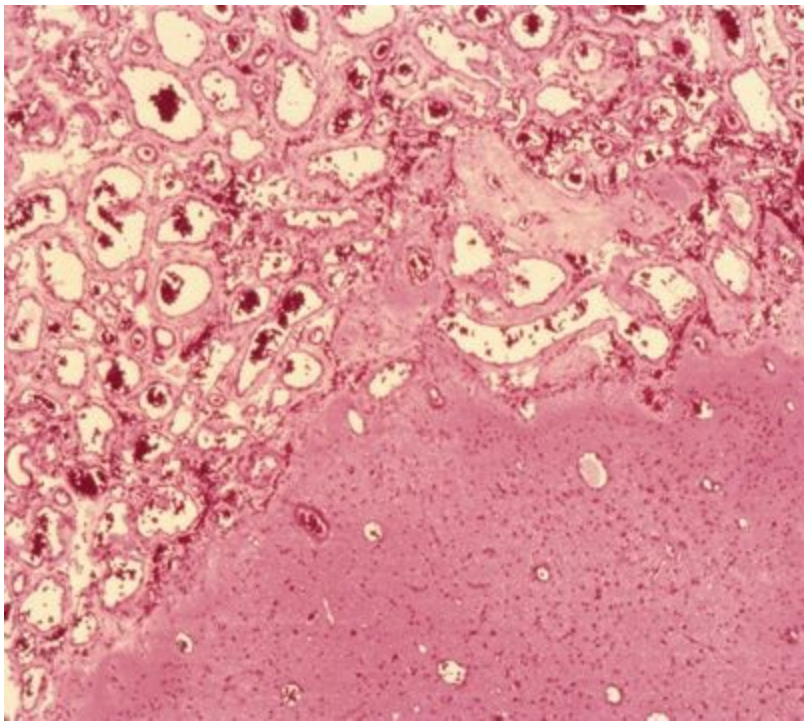

Figure 5.35. Histologic appearance of the leptomeninges in the setting of **Sturge-Weber disease**. The leptomeninges are marked by a proliferation of venous and capillary vessels arranged in a hemangiomatous configuration. There is no malignant potential to the lesion. The underlying cortex often demonstrates gliosis with prominent microcalcifications.

Figure 5.36. A child with a nevus on the cheek and left temple extending on to the scalp with loss of hair. She presented with partial seizures. Her brain MRI showed an extensive malformation of cortical development in the left temporoparietooccipital region. The constellations of findings suggest **epidermal nevus syndrome**, which is a sporadic condition. Epidermal nevus syndromes may be associated with hemimegalencephaly ipsilateral to the facial cutaneous findings.

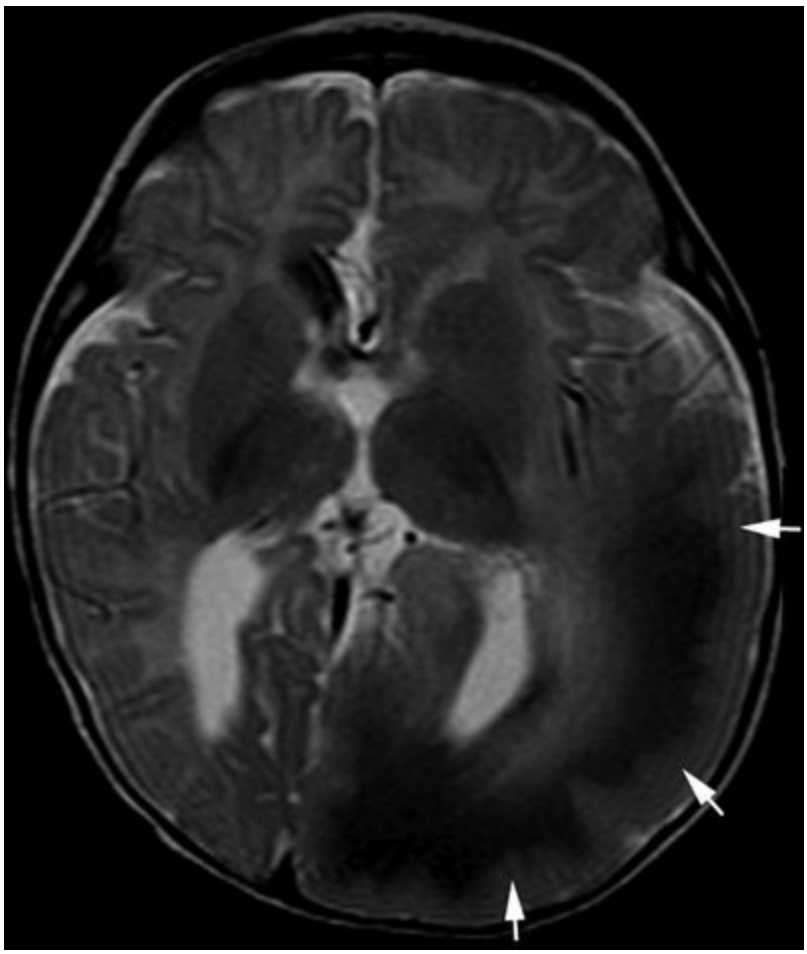

Figure 5.37. Epidermal nevus syndrome with hemimegencephaly. Axial T2-weighted image from MRI without gadolinium in a 6-month-old child with facial linear shows generalized enlargement of the left hemisphere with gyral thickening, decreased cortical signal, and blurring of the gray–white interface (arrows).

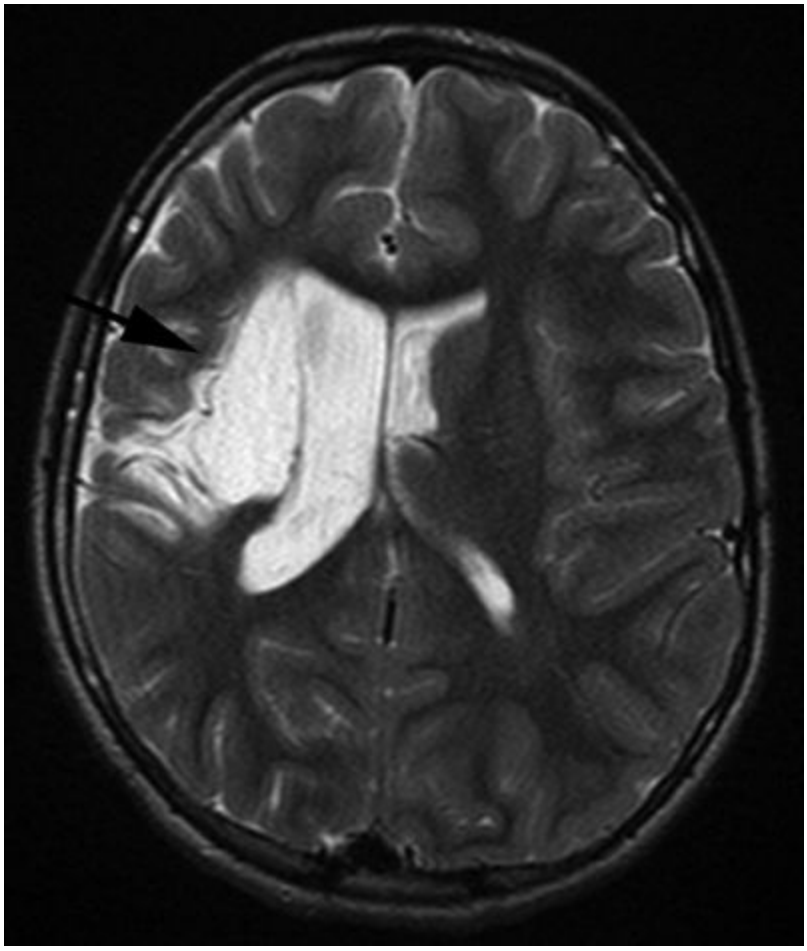

Figure 5.38. Remote infarction. Axial T2-weighted image from MRI without gadolinium in a 9-year-old boy with a history of posttraumatic occlusion of the right internal carotid artery as the infant shows cystic encephalomalacia in the right MCA territory (arrow).

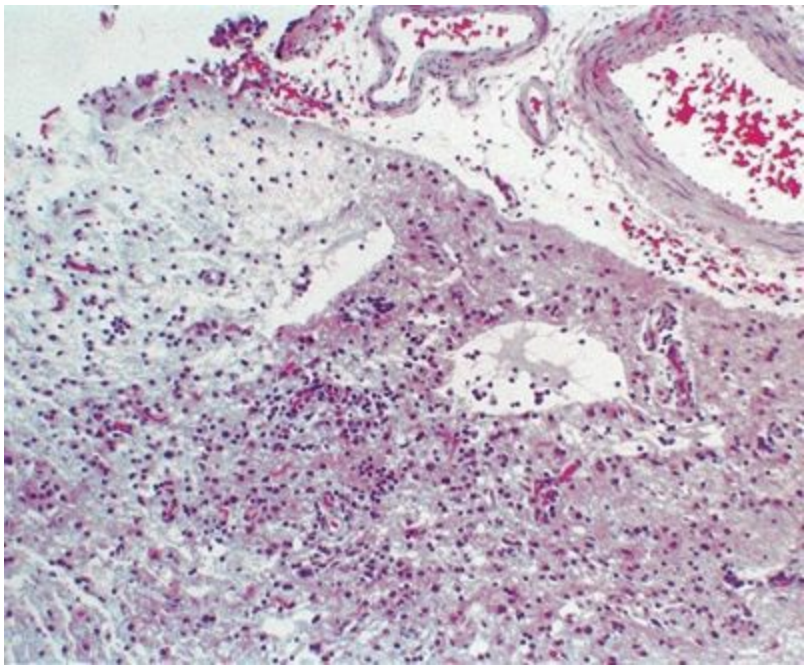

Figure 5.39. Histologic appearance of a **remote infarct** resulting in chronic epilepsy. The parenchyma is marked by cystic degeneration accompanied by macrophages and gliosis. Note the relative sparing of the molecular layer, which is more commonly observed with infarcts versus contusion.

Figure 5.40. Gross appearance of a circumscribed hemorrhagic-appearing lesion situated in the temporal lobe corresponding to a **cavernous angioma** (arrow).

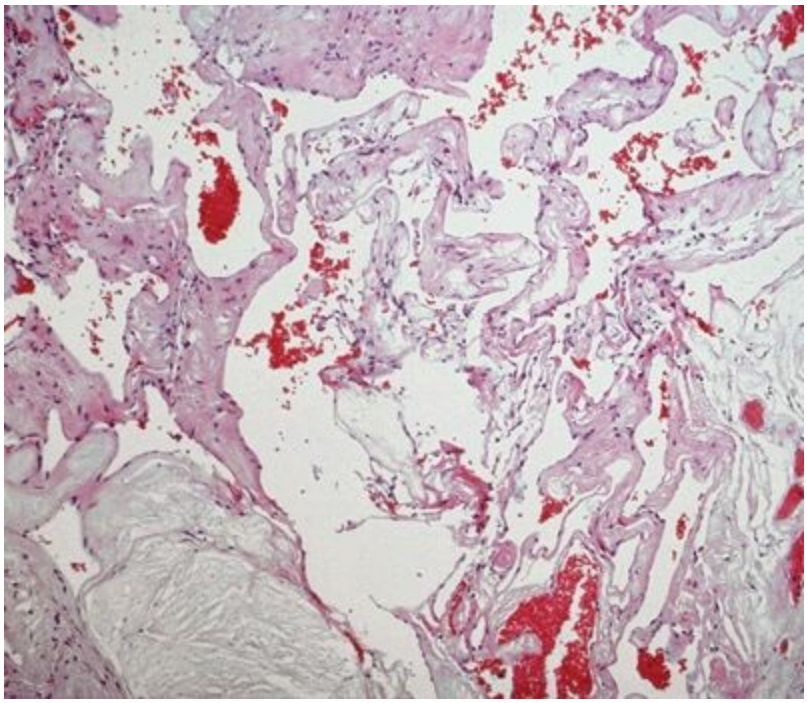

Figure 5.41. Microscopic appearance of the **cavernous angioma** in Figure 5.40. Cavernous angiomas are marked by a proliferation of dilated venous vessels, typically arranged in back-to-back fashion, without intervening neural parenchyma. Thickening of venous vessel walls may be observed. The lesions are often accompanied by adjacent gliosis and hemosiderin deposition.

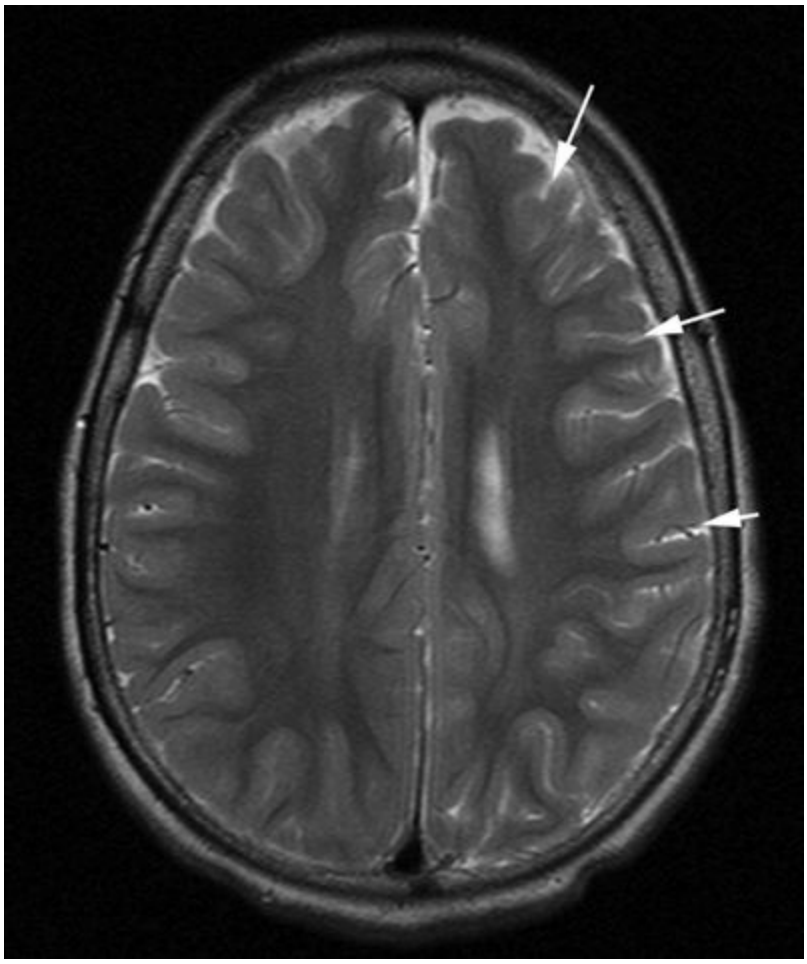

Figure 5.42. Rasmussen encephalitis. Axial T2-weighted image from MRI without gadolinium in a 3-year-old boy with a 1-year history of right tonic–clonic seizures progressive hemiparesis shows widening of the left frontal sulcal markings consistent with mild volume loss (arrows). Rasmussen encephalitis typically presents with intractable partial seizures (usually focal motor seizures and epilepsia partialis continua), progressive hemiparesis, cognitive decline, and unilateral cerebral atrophy with early and prominent involvement of the insular region.

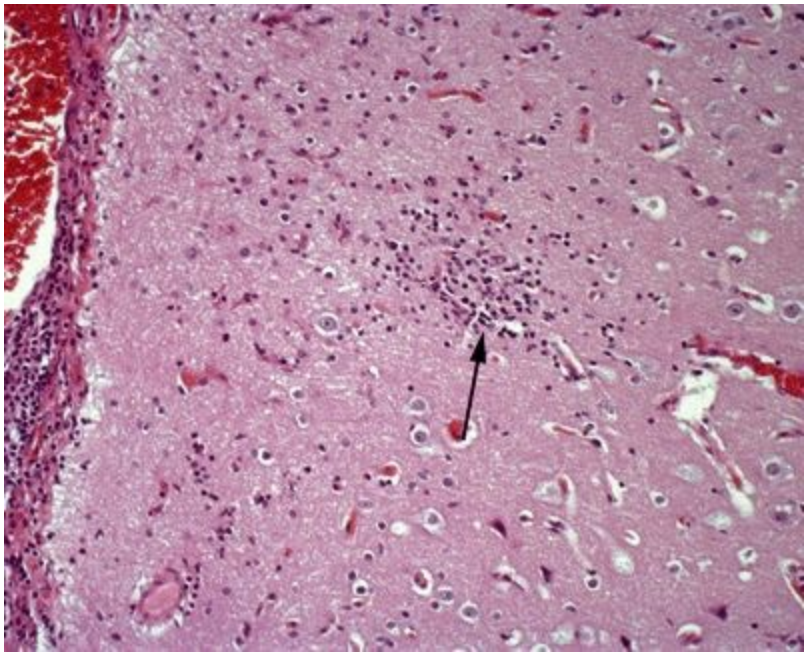

Figure 5.43. The histopathologic findings of **Rasmussen's encephalitis** often resemble those of viral encephalitis. These findings that are illustrated here include leptomeningeal chronic inflammation, perivascular parenchymal inflammation with microglial nodule formation (arrow), and gliosis.

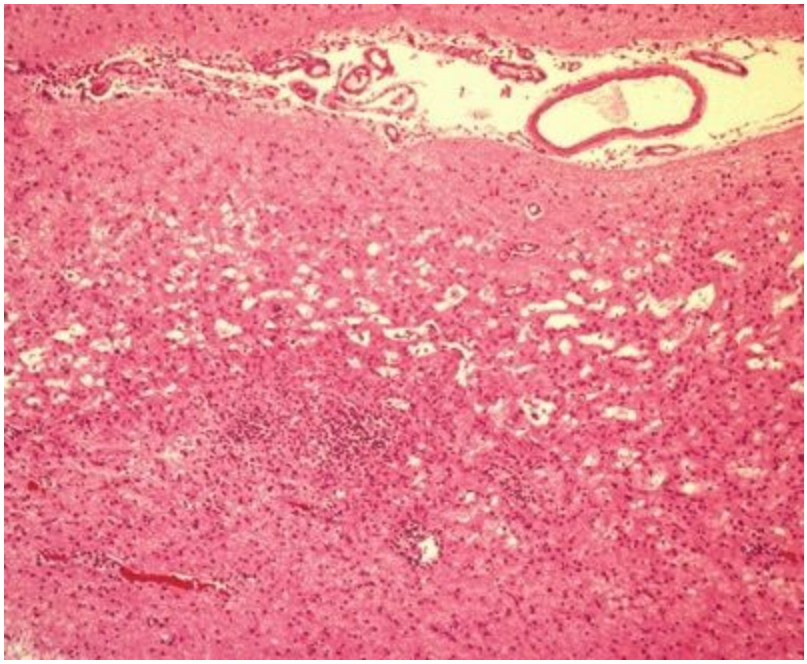

Figure 5.44. Many patients with **Rasmussen's encephalitis** demonstrate cortical atrophy, which microscopically is seen here and is marked by prominent gliosis, inflammation, and vacuolar degenerative changes in the cortex.

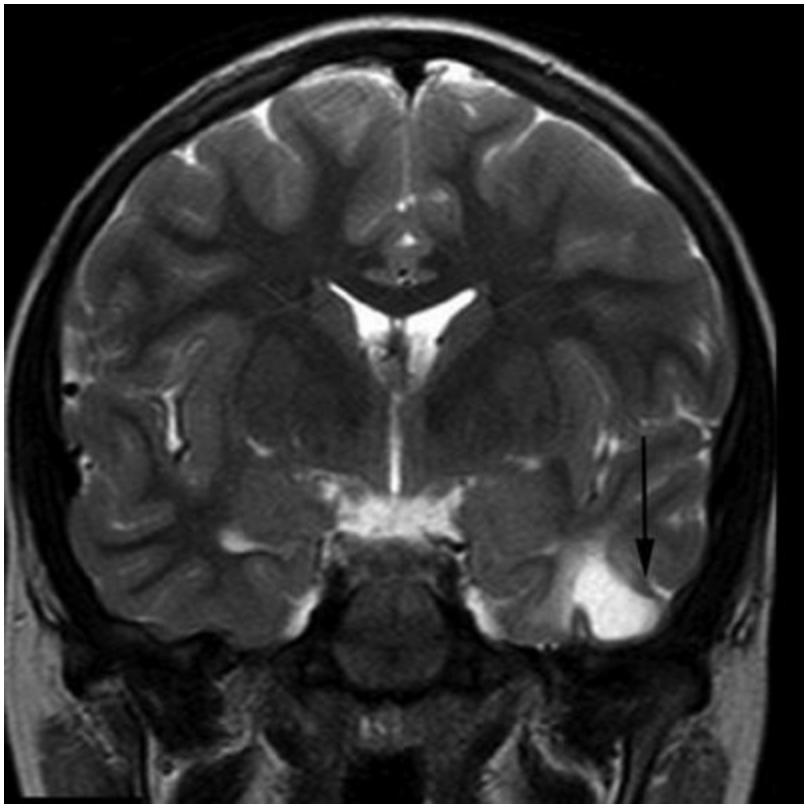

Figure 5.45. Ganglioglioma. Coronal T2-weighted image from MRI without gadolinium in a 9-year-old boy with a 6-year history of seizures consisting of staring spells shows a cystic cortical lesion of the left inferior temporal gyrus (arrow).

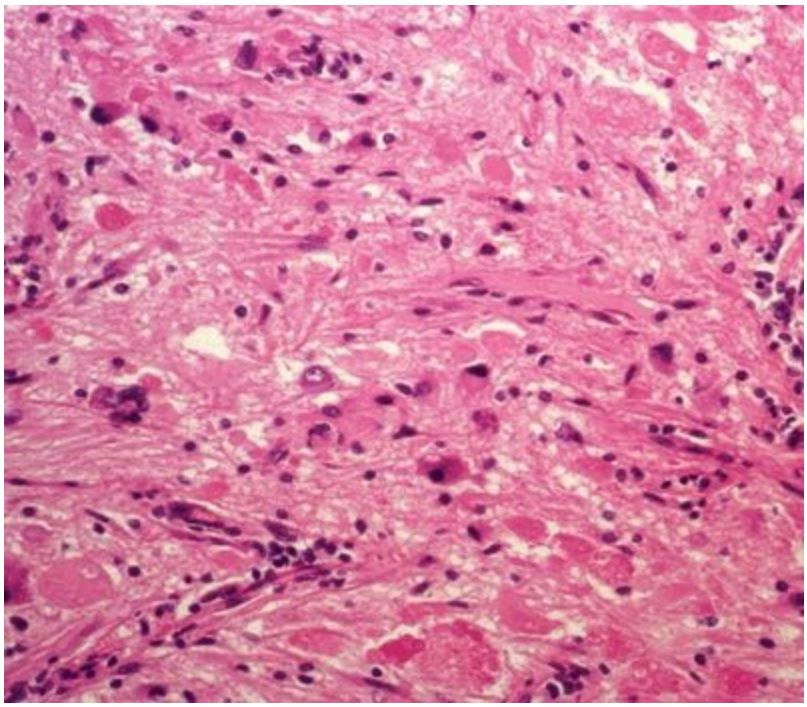

Figure 5.46. Histologic appearance of a **ganglioglioma**. The tumor represents a low-grade neoplasm (WHO grade I). It is marked by a proliferation of atypical ganglion cells intermixed with an atypical gliomatous component, most commonly resembling low-grade astrocytoma. Gangliogliomas most commonly arise in the temporal lobe, often in childhood, and are associated with cortical dysplasia. Perivascular chronic inflammation and eosinophilic granular bodies are also common features of this tumor type. This photomicrograph shows rare atypical large neuronal cells intermixed with a more spindle cell glioma component.

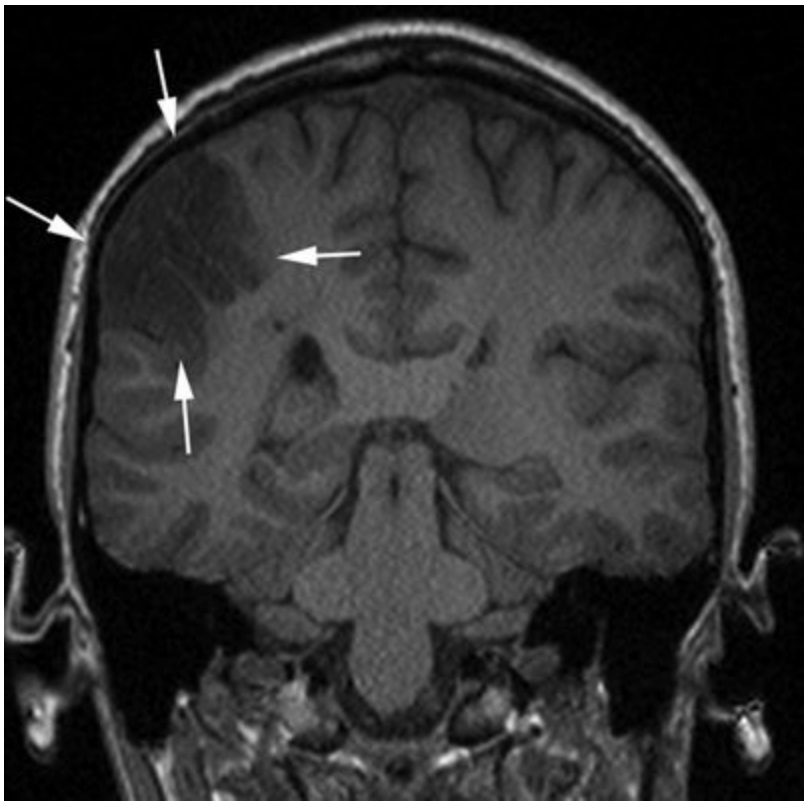

Figure 5.47. Dysembryoplastic neuroepithelial tumor. Coronal MPRAGE image from MRI without gadolinium in a 13-year-old girl with a 1-year history of left arm somatosensory progressing to dialeptic seizures shows a cortical lesion involving the right inferior parietal lobule characterized by multiple cystic structures, gyral broadening, and mild inner table scalloping (arrows).

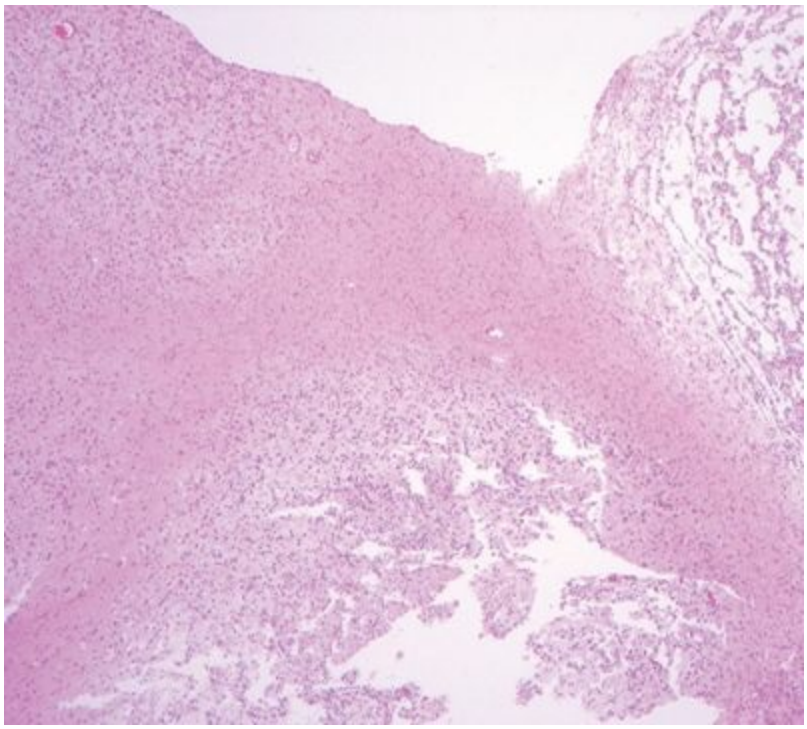

Figure 5.48. Low-magnification appearance of a temporal lobe **dysembryoplastic neuroepithelial tumor**. These WHO grade I lesions most commonly arise in the temporal lobe and are predominantly cortical based. Typically, they have multinodular architectural pattern and a microcystic appearance as seen in this photomicrograph.

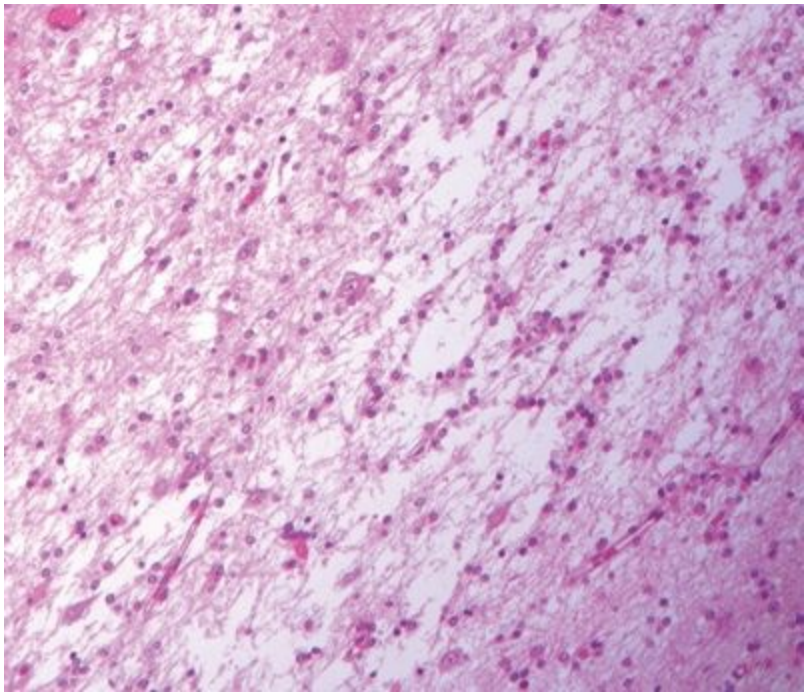

Figure 5.49. Higher-magnification appearance of a **dysembryoplastic neuroepithelial tumor** showing a proliferation of predominantly oligodendroglial-like rounded cells arranged against a mucoid background. Intermixed with these cells are smaller numbers of major appearing neuronal cells and astrocytic cells. Dysembryoplastic neuroepithelial tumors are also frequently accompanied by adjacent cortical dysplasia.

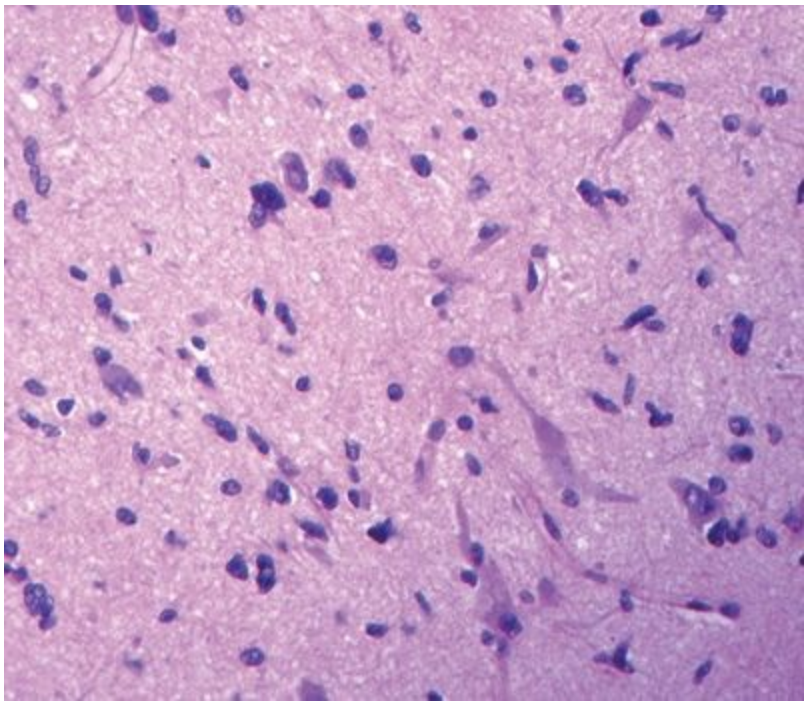

Figure 5.50. Histologic appearance of a **low-grade diffuse fibrillary astrocytoma** (WHO grade II). The tumor is marked by a mildly hypercellular parenchyma and cytologic atypia, as evidenced by nuclear enlargement and hyperchromasia and angularity to the nuclear contours. Areas of ganglioglioma may resemble low-grade astrocytoma, underscoring the importance of tissue sampling in order to identify the atypical ganglion cell component that helps define ganglioglioma. This tumor has the potential of degenerating into a higher- grade lesion over time (glioblastoma multiforme).

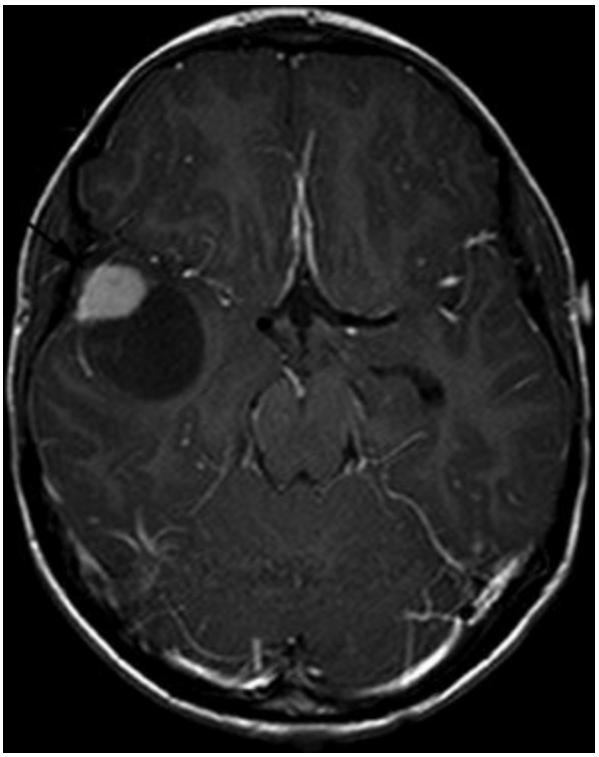

Figure 5.51. Pleomorphic xanthoastrocytoma. Axial T1-weighted image from MRI with gadolinium in a 10-year-old boy with a 1-year history of headache shows a lesion involving the cortex and subcortical white matter of the right temporal pole characterized by a large cyst with an enhancing mural nodule (arrow) without significant surrounding edema.

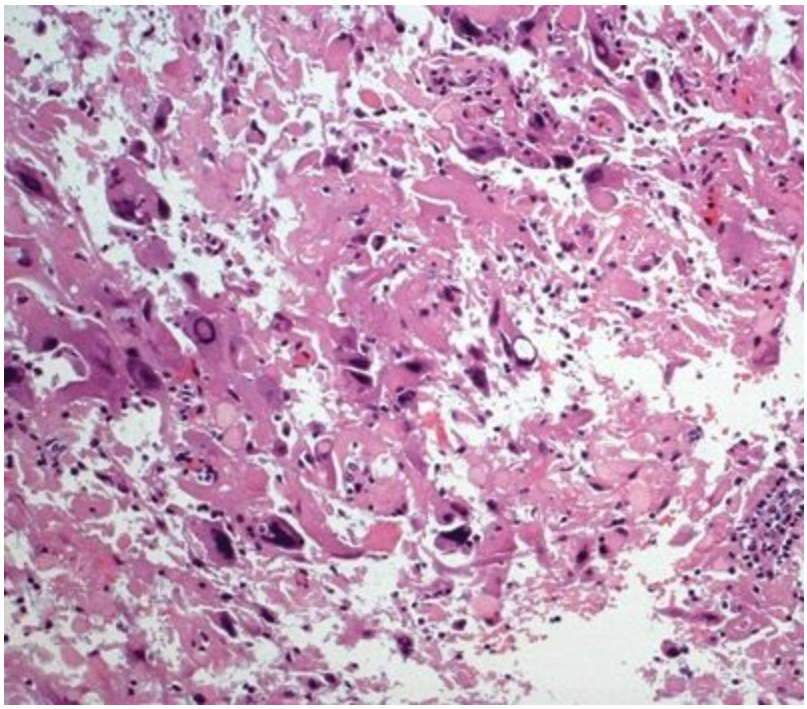

Figure 5.52. Pleomorphic xanthoastrocytomas are generally low-grade astrocytic tumors (WHO grade II) marked by prominent hypercellularity and nuclear pleomorphism, lipidized astrocytic cells, perivascular lymphocytes, and increased reticulin staining between individual tumor cells. In contrast to high-grade astrocytic tumors, most pleomorphic xanthoastrocytomas lack appreciable mitotic activity or necrosis. Most of these tumors arise either in the temporal or in the parietal lobe region in younger patients.

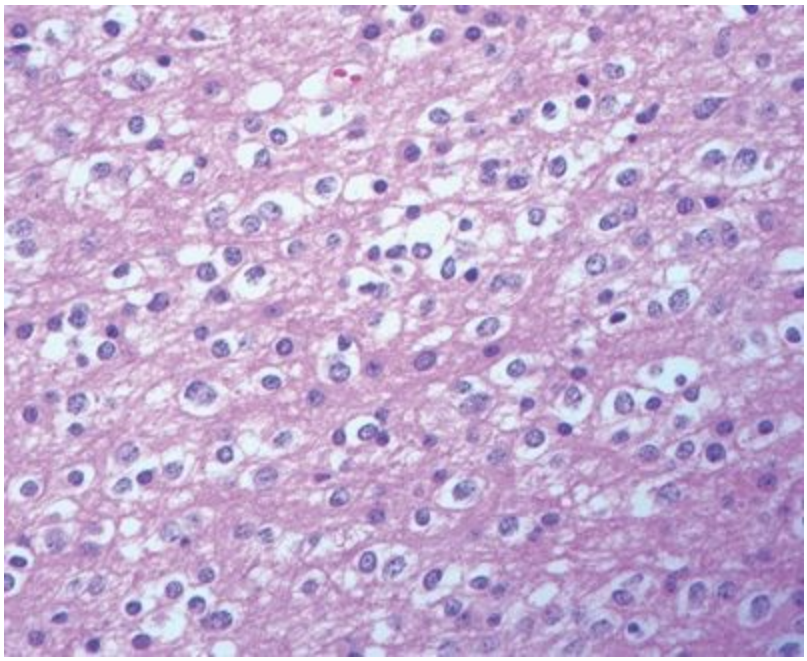

Figure 5.53. Low-grade oligodendroglioma: The histologic appearance of a low-grade oligodendroglioma (WHO grade II) arising in the temporal lobe is marked by a proliferation of cells with rounded nuclei, scant cytoplasm, and pericellular clearing ("fried egg" appearance). The pericellular clearing results from a delay in formalin fixation. These tumors, in contrast to dysembryoplastic neuroepithelial tumors, arise in the white matter and infiltrate into the overlying cortex. They are frequently calcified and have a prominent arcuate capillary vascular pattern. Many of these tumors demonstrate large deletions on chromosomes 1p and 19q and, like low-grade astrocytomas (WHO grade II), stain with IDH-1 antibody.

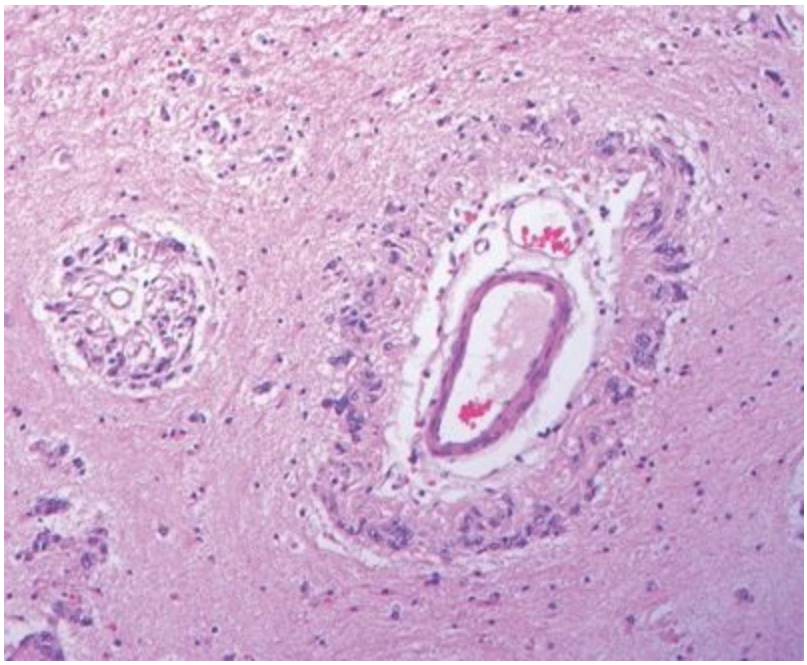

Figure 5.54. Angiocentric gliomas (WHO grade I) typically arise in young patients with chronic epilepsy in the temporal lobe. Microscopically, these tumors are marked by a striking perivascular pseudorosette-like pattern. The tumor frequently has an infiltrative margin.

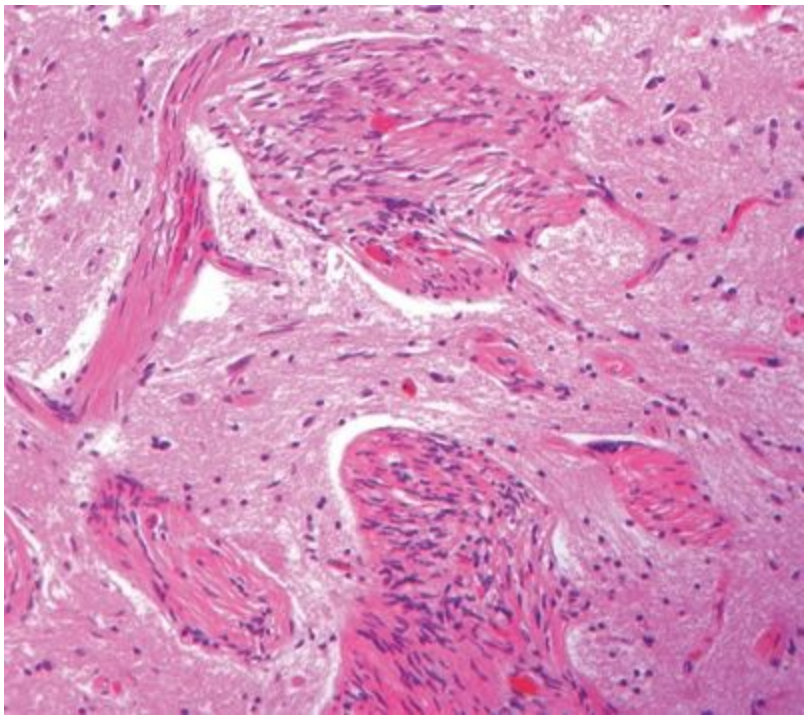

Figure 5.55. Meningioangiomatosis is a rare maldevelopmental lesion marked by a proliferation of blood vessels rimmed by a collar of spindled meningothelial cells. The lesion is usually primarily situated in the cortex but can extend to involve the underlying white matter. A subset of cases demonstrate an overlying meningioma. This lesion is associated with neurofibromatosis type II.

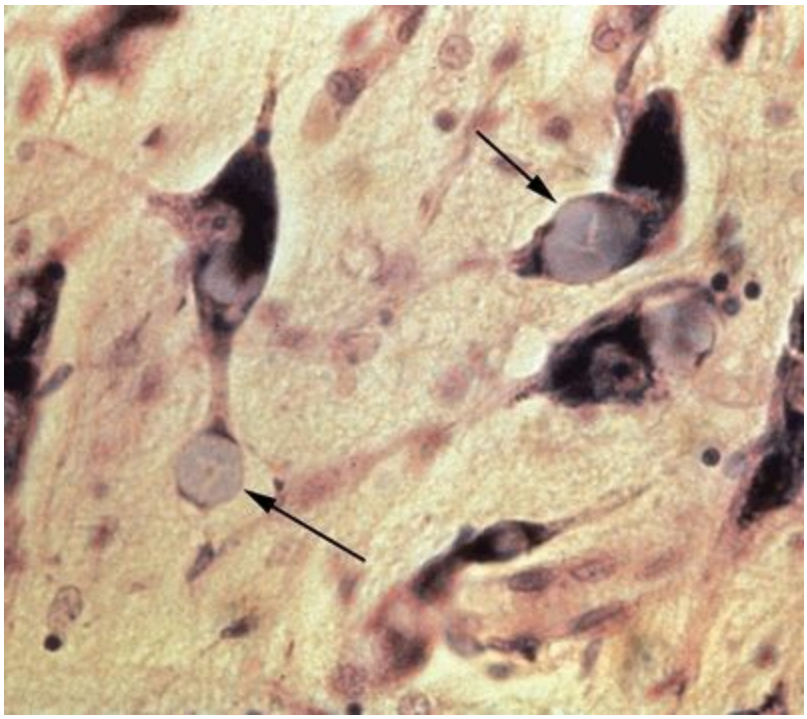

Figure 5.56. Lafora bodies (arrows) are intracytoplasmic neuronal polyglucosan structures that are seen in Lafora disease, which is an inherited progressive myoclonic epilepsy syndrome. It is an autosomal recessive disorder with onset in late childhood and adolescence. Characteristic seizures include myoclonic and occipital lobe seizures with visual hallucinations, scotomata, and photoconvulsions. The disease leads to an inexorable decline in the cognitive and neurologic functions, resulting in dementia and death usually within 10 years of onset.

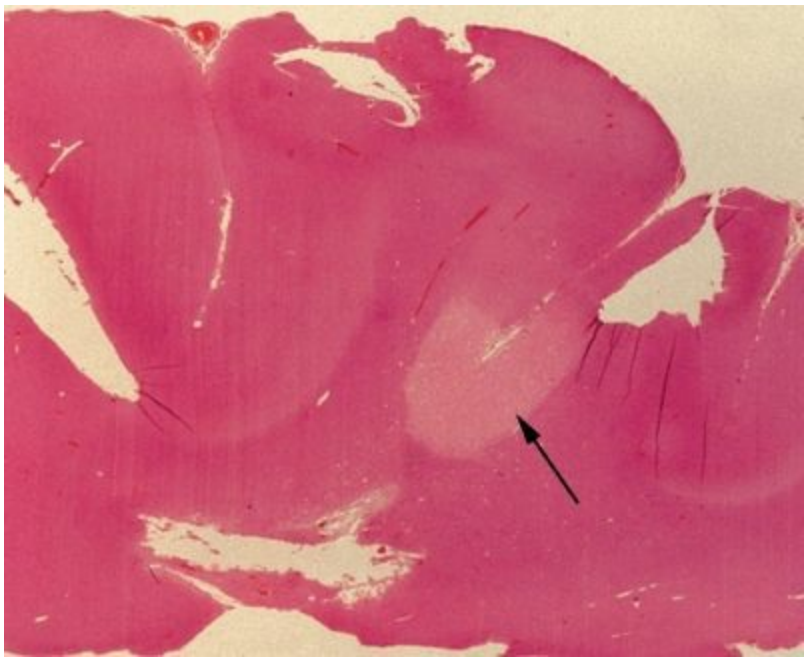

Figure 5.57. Invasive seizure monitoring with depth electrodes may occasionally result in infarcts associated with disruption of vessels. This low-magnification photomicrograph shows a pale zone of cortex (arrow) representing acute infarct due to placement of electrodes (**electrode-related infarct**).

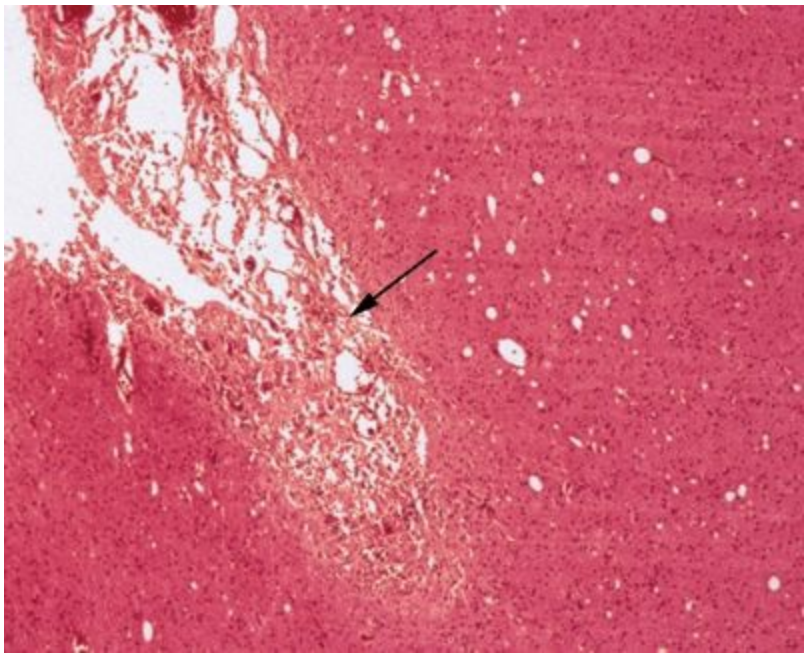

Figure 5.58. The tract along which a depth electrode was placed is observed. Evidence of **infarct/contusion along the electrode tract** as marked by vacuolated changes, surrounding gliosis, and a macrophage infiltrate (arrow).

PART II BASIC PRINCIPLES OF ELECTROENCEPHALOGRAPHY

ASSOCIATE EDITOR: HOWARD P. GOODKIN

CHAPTER 6 NEUROPHYSIOLOGIC BASIS OF THE ELECTROENCEPHALOGRAM

ERWIN-JOSEF SPECKMANN, CHRISTIAN E. ELGER, AND ULRICH ALTRUP*

Field potentials appear and are detectable in the space surrounding cellular elements of the nervous system. They comprise rapid waves and baseline shifts; the former correspond to the conventional electroencephalogram (EEG), and both phenomena are included in the so-called direct current (DC) potential. Field potentials are essential in the diagnosis and classification of epileptic seizures as well as in the control garnered by antiepileptic therapy. This chapter describes the elementary mechanisms underlying the generation of field potentials and the special functional situations leading to "epileptic" field potentials.

BIOELECTRICAL ACTIVITY OF NEURONAL AND GLIAL CELLS

The cells of the nervous system are generally differentiated into neurons and glial cells, whose processes intermingle and form a dense, highly complex matrix (Fig. 6.1). Because the actual interactions of these cellular elements are barely recognizable in spatiotemporal dimensions, principles of their structure and function inevitably are taken into account.

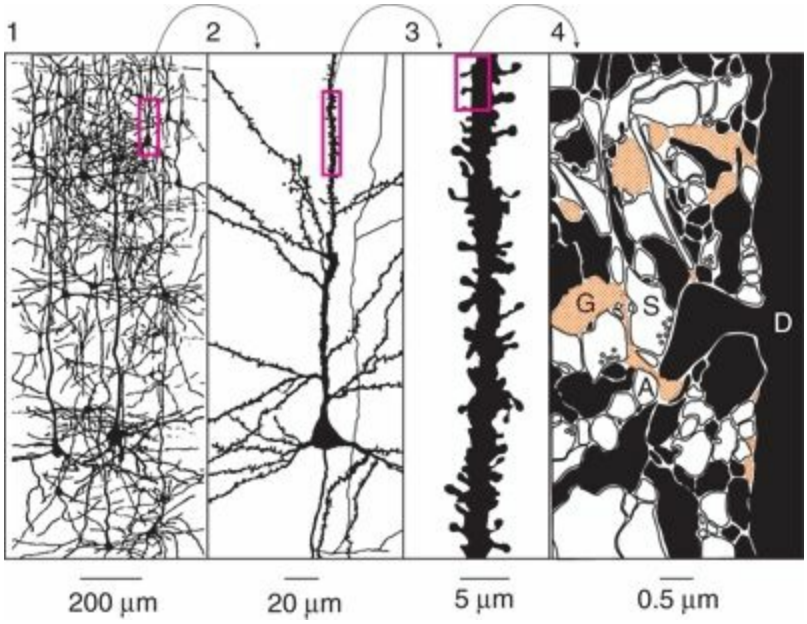

Figure 6.1. Morphology and histology of neuronal and glial elements in the neocortex. Rectangles and arrows indicate extended sections. In section 1, only a minor portion of the neurons is stained. A, axon; D, dendrite; G, glial cell; S, synapse. (Modified from Gaze RM. The Formation of Nerve Connections. New York: Academic Press; 1970; Purpura DP. Dendritic differentiation in human cerebral cortex: normal and aberrant developmental patterns. In: Kreutzberg GW, ed. Advances in Neurology. Vol. 12. New York: Raven Press; 1975:91–116; Valverde F. The organization of area 18 in the monkey: a golgi study. Anat Embryol. 1978;154:305–334;

Westrum LE, Blackstad TW. An electron microscopic study of the stratum radiatum of the rat hippocampus (regio superior, CA1) with particular emphasis on synaptology. J Comp Neurol. 1962;113:281–293, with permission.)

Neurons

A typical neuron consists of a soma (body, perikaryon) and fibers (dendrites and axons). In functional terms, with respect to information input, the relatively short and highly arborized dendrites can be considered extensions of the soma, as reflected in their being covered by thousands of synaptic endings. Axons are relatively long and, especially in their terminal regions, branch into collaterals. These neuronal output structures carry information into the terminal regions. Information is transferred to other neurons by way of synaptic endings (1–9).

Neuronal function is closely correlated with bioelectrical activity, which can be studied with intracellular microelectrode recordings. When a neuron is impaled by a microelectrode, a membrane potential of approximately 70 mV with negative polarity in the intracellular space becomes apparent. This resting membrane potential, existing in the soma and all its fibers, is based mainly on a potassium outward current through leakage channels. If the resting membrane potential is critically diminished, that is, if a threshold is surpassed, an action potential (AP) is triggered, which is based on sodium inward and potassium outward currents through voltage-dependent membrane channels. APs are conducted along the axons to the terminations, where they lead to a release of transmitter substances at the chemical synapse. These transmitters open another class of membrane channels in the postsynaptic neuron. Dependent on the ionic composition of the currents flowing through the transmitter (ligand)-operated channels, two types of membrane potential changes, commonly called postsynaptic potentials (PSPs), are induced in the postsynaptic neuron. When a sodium inward current prevails, depolarization of the postsynaptic neuron occurs. This synaptic depolarization is called an excitatory postsynaptic potential (EPSP) because it increases the probability that an AP will be triggered. When a potassium outward current or a chloride inward current prevails, hyperpolarization of the postsynaptic neuron occurs. Because hyperpolarization increases the distance between membrane potential and threshold, the synaptic hyperpolarization is called an inhibitory postsynaptic potential (IPSP) (10–12).

The EPSPs and IPSPs can interact with each other (Fig. 6.2). Electrical stimulation of an axon (ST1 in Fig. 6.2A) forming an excitatory synapse on a postsynaptic neuron can induce an AP at the site of stimulation. Conducted along the axon, the AP finally induces an EPSP in the postsynaptic neuron (ST1 in Fig. 6.2B). When only one synapse separates the site of stimulation from the site of EPSP generation, a monosynaptic EPSP appears. One way in which a summation of EPSP takes place is when the stimulation is repeated with an interstimulus interval shorter than the duration of the EPSP. With this temporal summation, the second EPSP can surpass the threshold and induce an AP (ST1 in Fig. 6.2B). A summation of EPSPs also can occur when monosynaptic EPSPs are evoked simultaneously at several locations on the postsynaptic neuron (spatial summation). Temporal and spatial summations are often combined with each other and are essential for information processing in the central nervous system, as when the AP reaches the target neuron by different ways. With stimulation at ST2 in Figure 6.2A, the triggered APs pass through varying numbers of relays before reaching their target. As APs are delayed with each synaptic transmission, they appear with temporal dispersion at the postsynaptic neuron and induce a long- lasting depolarization (ST2 in Fig. 6.2B). Because many synapses are involved, such a depolarization is called a polysynaptic EPSP. When a polysynaptic network is activated repeatedly, EPSPs of considerable amplitude and duration can appear, as demonstrated by the original recording in Figure 6.2C. As with EPSPs, IPSPs can be

induced both monosynaptically and polysynaptically and also are subject to temporal and spatial summation (ST3 and ST4 in Fig. 6.2A and B) (5,11,12).

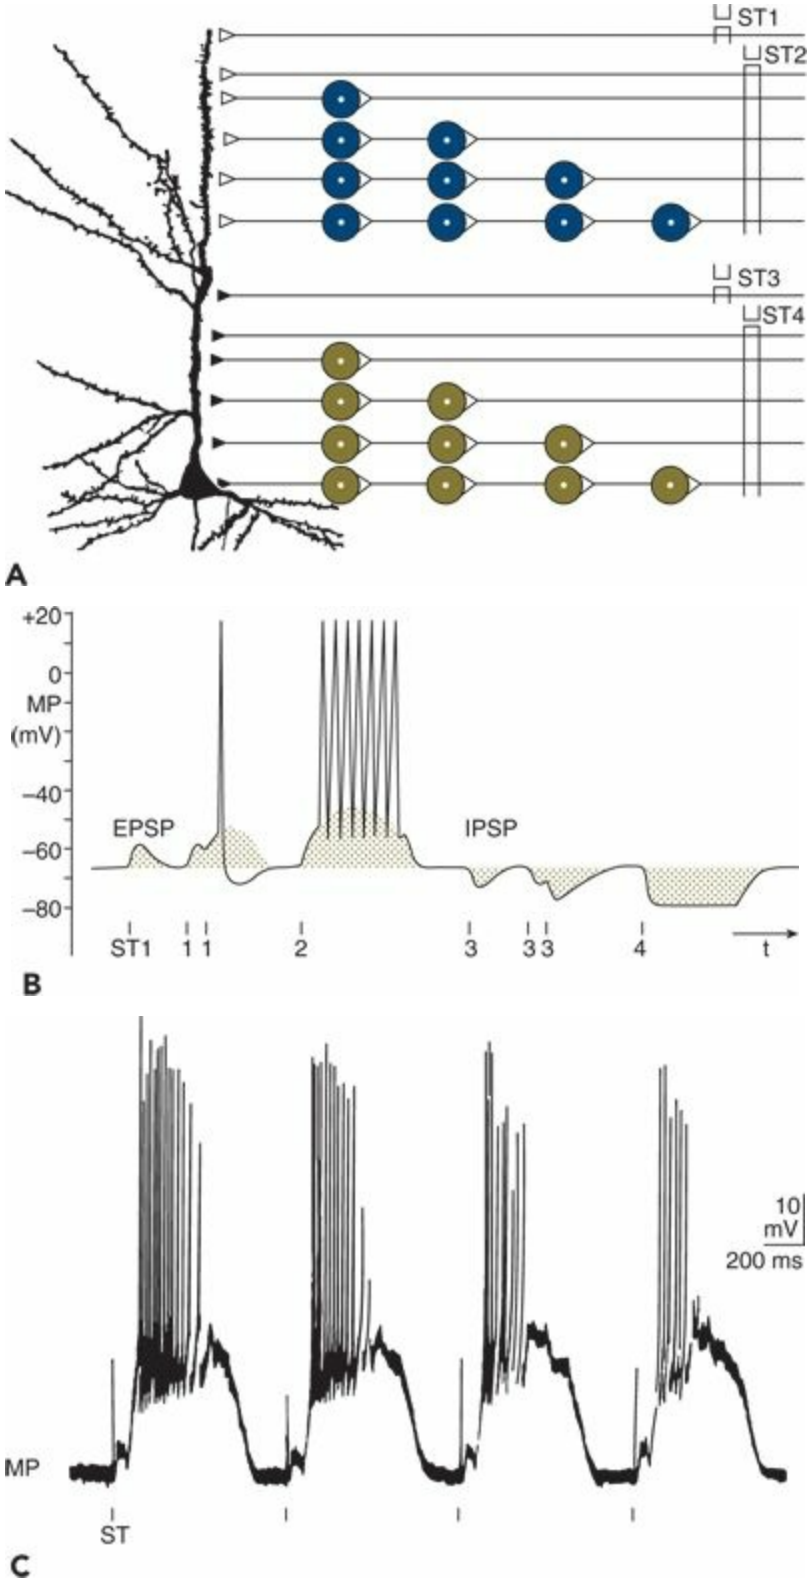

Figure 6.2. Bioelectrical activity of neuronal elements: membrane potential (MP), action potential (AP), excitatory postsynaptic potential (EPSP), and inhibitory postsynaptic potential (IPSP). **A:**Indicated are stimulation sites and the pyramidal neuron from which the recording was made. Open symbols represent excitatory synapses and filled symbols inhibitory synapses. Up to four interneurons are schematically drawn between stimulation sites (ST1 to ST4) and the neuron. **B:**Intracellular recording from the pyramidal neuron in **(A)** is shown. Single electrical stimuli applied at ST1 and ST3 evoked monosynaptic EPSP and IPSP, respectively. Paired stimulation at ST1 and ST3 led to a summation of the corresponding monosynaptic responses. After stimulation at ST2 and ST4, polysynaptic EPSP and IPSP, respectively, were elicited. **C:**Original tracing of synaptically mediated neuronal depolarizations in a spinal motoneuron of the cat is shown. Stimulation (ST) of pathways oligosynaptically and polysynaptically linked to the neuron led to early (oligosynaptic) and late (polysynaptic) potentials. (**A** and **B** adapted from Speckmann E-J. Experimentelle Epilepsieforschung. Darmstadt, Germany:

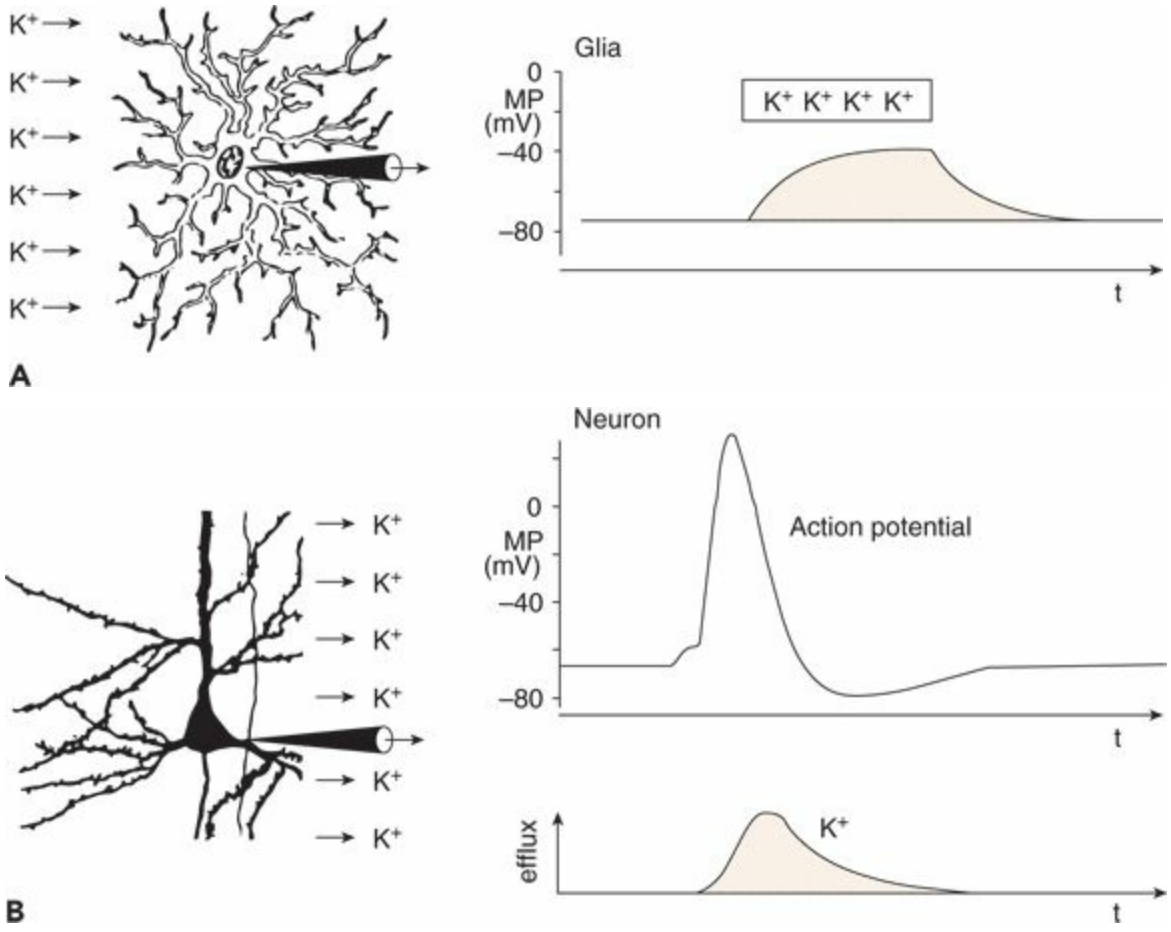
Wissenschaftliche Buchgesellschaft; 1986:13, with permission.)

In complex neuronal systems, EPSPs and IPSPs are often superimposed and induce long-lasting sequences of fluctuations of the membrane potential. These kinds of postsynaptic responses play a prominent role in the generation of extracellular potential fields, such as the EEG.

Glial Cells

Consisting of a soma and fibers, glial cells intermingle with the neuronal structures. Glial cell fibers are electrically coupled, building up an extended functional network (3,8,13).

Glial cells also show a membrane potential (Fig. 6.3A). Unlike neurons, glial cells do not generate APs and PSPs. Because their resting membrane potential is based exclusively on potassium outward current through leakage channels, its value is close to the potassium equilibrium potential. With an increase and a subsequent decrease in extracellular potassium concentration, glial cells depolarize and repolarize, respectively (Fig. 6.3A). Changes in the extracellular concentration of other cations have only small effects on the membrane potential of glial cells (14,15).



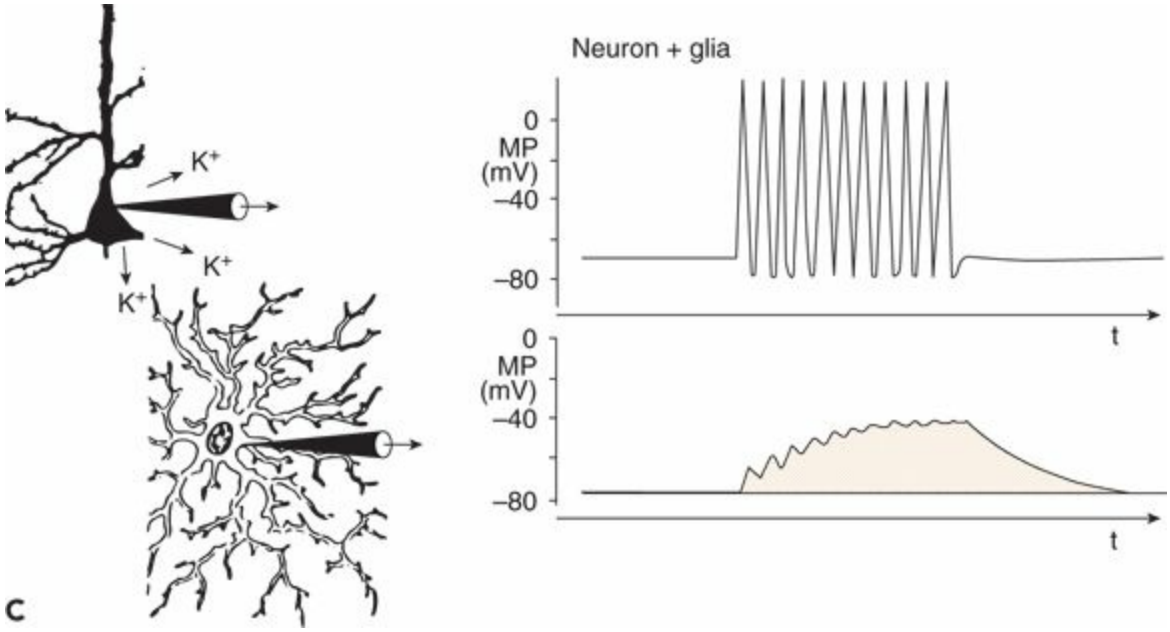


Figure 6.3. Changes in membrane potential (MP) of a glial cell induced by an increase in extracellular potassium concentration **(A)** and functional linkage between neuronal and glial activity **(B)** and **(C)**. **A:** The increased extracellular concentration of K^+ led to a sustained depolarization of the glial cell. **B:** During a neuronal action potential, an efflux of K^+ occurred. **C:** The K^+ concentration in the extracellular space close to the glial cell was raised during the repetitive firing of a neuron. This led to sustained depolarization of the neighboring glial cell. (**A** and **C** adapted from Zenker W. Feinstruktur des Nervengewebes. In: Zenker W, ed. Makroskopische und Mikroskopische Anatomie des Menschen. Vol. 3. Munich, Germany: Urban & Schwarzenberg; 1985:3–55, and **B** and **C** adapted from Valverde F. The organization of area 18 in the monkey: a golgi study. Anat Embryol. 1978;154:305–334.)

Glial cells and neurons are functionally linked by way of the extracellular potassium concentration (Fig. 6.3B and C). As mentioned, neuronal APs are associated with an outflow of potassium ions (see Fig. 6.3B). Thus, with an increase in the repetition rate of neuronal APs, the extracellular potassium concentration increases, resulting in depolarization of glial cells adjacent to the active neurons (see Fig. 6.3C) (11,14–16).

PRINCIPLES OF FIELD POTENTIAL GENERATION

Changes in membrane potential of neurons and glial cells are the basis of changes in extracellular field potential. The mechanisms involved can be described as follows: (i) primary transmembranous ion fluxes at a restricted membrane area of cells and consequent localized membrane potential changes; (ii) development of potential gradients between sites of primary events and the remaining areas of the membrane; and (iii) secondary ion currents because of the potential gradient along the cell membrane in the intracellular and extracellular spaces. The secondary current flowing through the extracellular space is directly responsible for the generation of field potentials (9,17). Because EPSPs and IPSPs are important in the generation of the EEG findings, the processes are explained in greater detail using the examples of an excitatory synaptic input (2,12,18,19).

A vertically oriented neuronal element, shown schematically in Figure 6.4, is impinged on by a single excitatory synapse whose afferent fiber can be stimulated. The resulting net influx of cations leads to depolarization of the membrane, that is, to an EPSP. Consequently, a potential gradient exists along the neuronal membrane and evokes an intracellular and extracellular current flow. As a result of the intracellular current, the EPSP spreads electrotonically; the extracellular current induces field potentials. The polarity depends on the site of recording. The electrode near the synapse "sees" the inflow of cations (a negativity), whereas the electrode distant from the synapse "sees" the outflow of

cations (a positivity). Between the two electrodes is the reversal point of the field potentials (12,20).

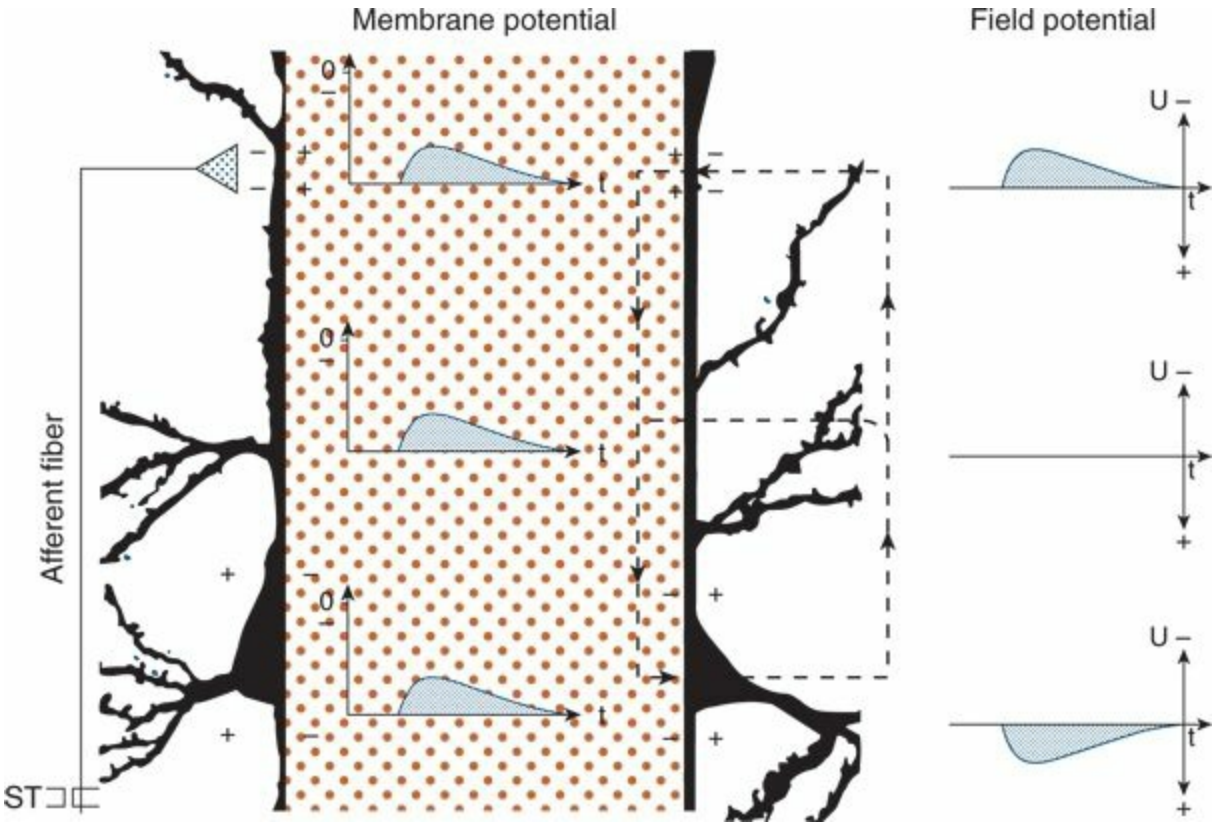

Figure 6.4. Principles of field potential generation in the neocortex. A perpendicular pyramidal neuron with an extended intracellular space (hatched area) is shown. An afferent fiber **(left)** formed an excitatory synaptic contact at the superficial aspect of the apical dendrite. Changes in membrane potential and in corresponding field potential are given in the intracellular and extracellular spaces, respectively. After stimulation of the afferent fiber (ST), an excitatory postsynaptic potential developed in the upper part of the dendrite and spread electrotonically to the lower parts. The local excitation (+ and −) led to tangential current flows (broken lines) and to the field potential changes in the extracellular space.

Corresponding effects occur with the generation of IPSPs. Activation of an inhibitory synapse induces an outflow of cations or an inflow of anions at the synaptic site. In this way, the membrane potential is increased at the synaptic site, and a potential gradient develops along the cell membrane, similar to that described for EPSPs. The potential gradient evokes a current flow from the synaptic site to the surrounding regions of the membrane. Compared with EPSPs, the extracellular current flow is inverted, as is the polarity of field potentials. Thus, the electrode near the synapse "sees" a positivity and the electrode distant from the synapse a negativity.

Field potentials are generated by extracellular currents, and their polarity depends on the direction of the current as well as on the positions of the extracellular electrodes. Figure 6.5 illustrates the generation and polarity of field potentials, as elicited by excitatory and inhibitory inputs to superficial and deep regions of vertical neuronal elements. Negative field potentials at the cortical surface may be based on superficial EPSPs as well as on deep IPSPs, and positive field potentials at the surface may be based on superficial IPSPs as well as on deep EPSPs (Fig. 6.6) (12,19,20).

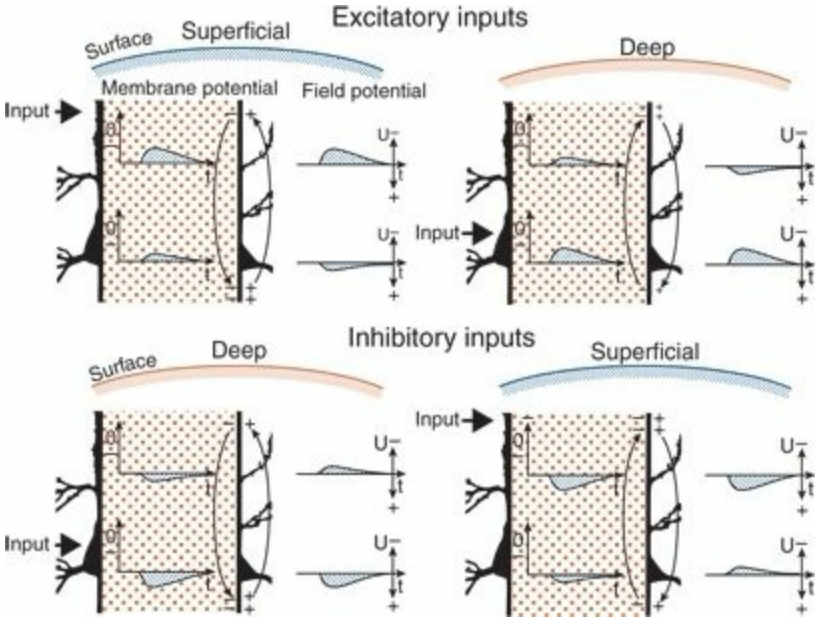

Figure 6.5. Generation of field potential in the neocortex by excitatory and inhibitory synaptic inputs reaching the superficial and deep parts of perpendicular pyramidal neurons. The intracellular space is extended (hatched areas). Changes in membrane potential and in the corresponding field potential are given in the intracellular and extracellular spaces, respectively. Locations of active inputs are indicated (heavy arrows). EPSP and IPSP, excitatory and inhibitory postsynaptic potentials, respectively. Excitatory inputs: With superficial excitation, an inward current generated an EPSP in upper and lower regions. Because of the direction of the extracellular current flow (light arrows), the field potential had negative polarity at the surface and positive polarity in the deep recording (cf. Fig. 6.4). With deep excitation, the current flow—and the field potentials—had inverse direction to that elicited by superficial excitation. Inhibitory inputs: With deep inhibition, an outward current generated an IPSP in lower and upper regions. Because of the direction of the extracellular current flow (arrows), the field potential had positive polarity in the deep recording and negative polarity at the surface. With superficial inhibition, the direction of current flow was inverse to that seen with deep inhibition; the field potentials were inverted as well. Differences in the shape of the various potentials were caused by the electrical properties of the tissue.

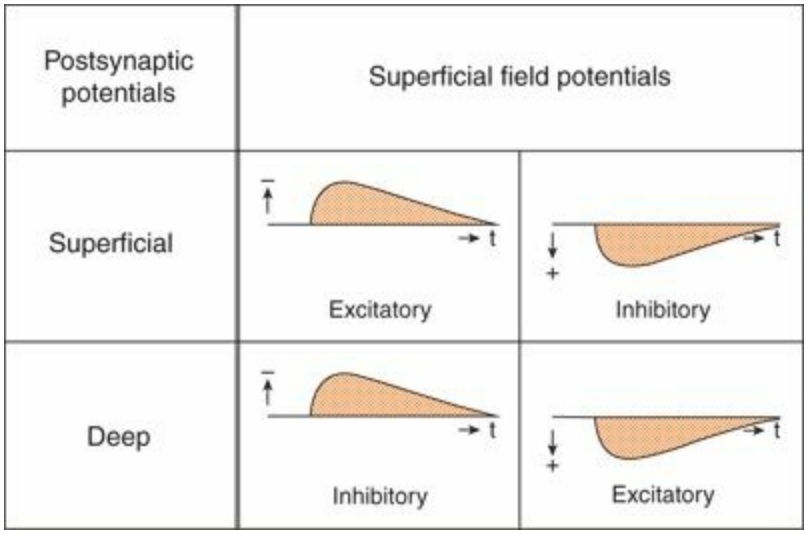

Figure 6.6. Synopsis of the synaptic processes underlying the generation of superficial field potentials in the cerebral cortex. Different mechanisms may lead to uniform superficial field potentials.

POTENTIAL FIELDS IN NEURONAL NETWORKS

Many neuronal elements contribute to the extracellular currents that generate field potentials recorded at the surface of central nervous system structures. The spatial arrangement of the neuronal elements and the positions of the recording electrodes play an essential role in establishing and detecting extracellular potential fields (2,12,21).

Two principal types of neuronal arrangements can be identified (Fig. 6.7). In the parallel type, the somata are in one layer and the dendrites are in opposite layers (see Fig. 6.7A). In the other type, the somata are in the center of a pool and the dendrites extend to its periphery (see Fig. 6.7B). The first arrangement is realized in the cortex and the second in brainstem nuclei.

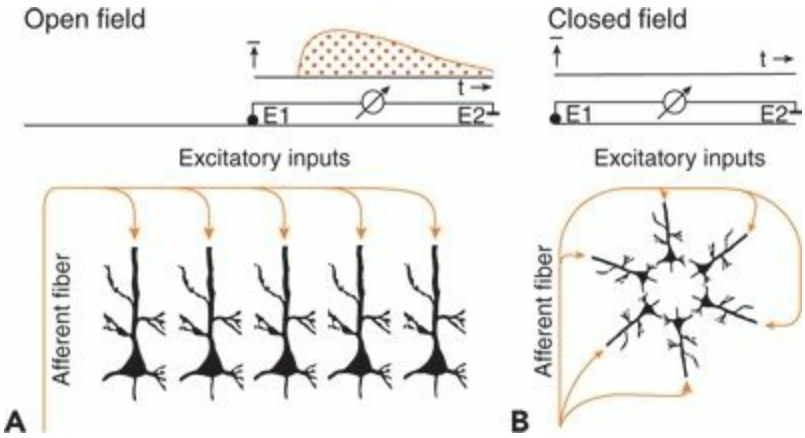

Figure 6.7. Neurons arranged to give open **(A)** and closed **(B)** fields. Field potentials are present **(A)** or missing **(B)** during excitatory inputs by way of afferent fibers. E1 and E2 indicate different and reference electrodes.

The two neuronal arrangements build up the so-called open and closed fields. In open fields, one electrode (E2 in Fig. 6.7A) largely integrates the potentials of the population (i.e., it is near the zero potential line), and the other electrode (E1 in Fig. 6.7A) sees only the positive or negative field, permitting the recording of a field potential. In closed fields, external electrodes do not see significant potential differences because the current flows within the pool compensate for each other (see Fig. 6.7B) (2,21).

TYPES OF FIELD POTENTIAL CHANGES

With respect to the time course, two types of field potentials can be differentiated, depending on the time constant of the amplifying recording device. The conventional EEG is recorded with a time constant of 1 second or less. Amplification with an infinite time constant, that is, by a DC amplifier, permits additional recording of baseline shifts and wavelike potentials (EEG/DC) (22–24).

Wave Generation (Conventional Electroencephalogram)

The generation of wavelike potentials is described in Figure 6.8, a representation of a column of neocortex. In its upper dendritic region, the neuron is activated by an afferent fiber by way of an excitatory synapse. The superficial EEG and the membrane potentials of the dendrite and afferent fiber are recorded. The afferent fiber shows grouped, followed by regular, discharges. With grouped discharges prominent, summated EPSPs occur in the dendrite; with sustained regular activity, a depolarizing shift of the membrane potential appears. The changes in membrane potential in the upper dendrite lead to field potentials. When amplifiers with a finite time constant are used, only fluctuations in field potential are recorded, corresponding to findings on conventional EEG. The shift of the membrane potential is not reflected (21,25).

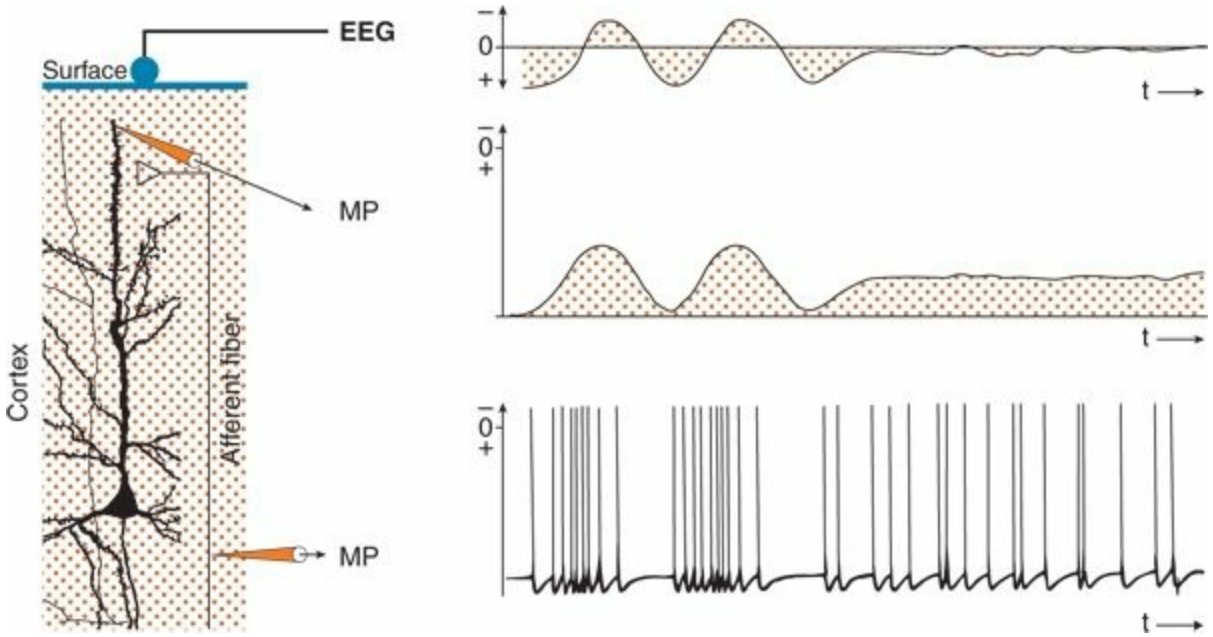

Figure 6.8. Wave generation in the electroencephalogram (EEG) at the surface of the cerebral cortex. A perpendicular pyramidal neuron is shown. An afferent fiber formed an excitatory synaptic contact at the superficial part of the apical dendrite. Simultaneous recordings of the membrane potentials (MPs) of the afferent fiber and the dendritic element, as well as of the EEG, are displayed. Groups of APs in the afferent fiber generate wavelike excitatory postsynaptic potentials (EPSPs) in the dendritic region and corresponding waves in the EEG recording. Tonic activity in the afferent fiber results in long-lasting EPSP with only small fluctuations. The long-lasting depolarization is not reflected on the conventional EEG recording.

Baseline Shifts (Electroencephalogram/Direct Current)

The generation of baseline shifts is described in Figures 6.9 and 6.10. In a column of the neocortex (see Fig. 6.9), a neuron is activated in its upper dendritic region by an afferent fiber by way of an excitatory synapse. In this case, the afferent fiber displays three levels of sustained activity. Medium regular activity is interrupted by periods of high repetition and silence. Consequently, owing to facilitation, the upper dendrite is depolarized during the high discharge in the afferent fiber and is hyperpolarized in the silent period because of disfacilitation. This results in corresponding field potential shifts. When amplifiers with an infinite time constant are used, these baseline shifts, which reflect sustained values of the membrane potential of neuronal elements, are recorded. With a sufficiently high upper frequency limit, the DC recording comprises conventional EEG waves as well as slow potential deviations (26–32).

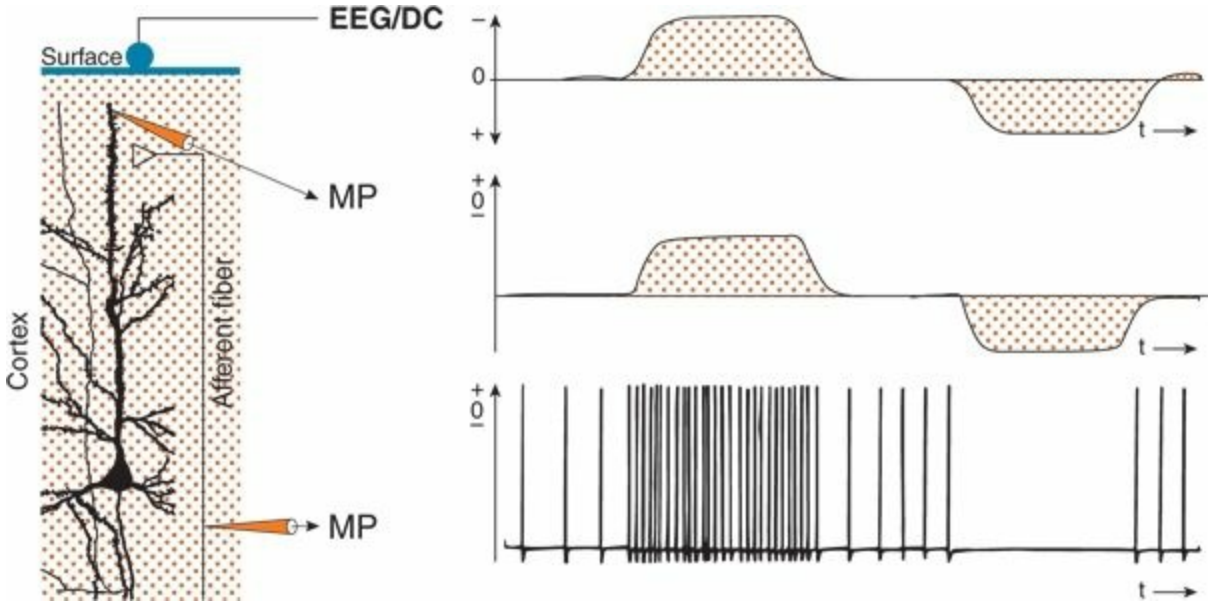

Figure 6.9. Sustained shifts in the electroencephalogram (EEG) at the surface of the cerebral cortex resulting from sustained neuronal activities. If recordings are performed with a direct current (DC) amplifier (EEG/DC), sustained potentials can also be recorded at the surface. In the perpendicular pyramidal neuron depicted, an afferent fiber formed an excitatory synaptic contact at the superficial part of the apical dendrite. The membrane potentials (MPs) of the afferent fiber and the dendritic element were recorded simultaneously, as was the EEG/DC. Increased and decreased sustained activity in the afferent fiber generated sustained depolarizations and hyperpolarizations of the dendritic region and corresponding negative and positive shifts of the EEG/DC recording.

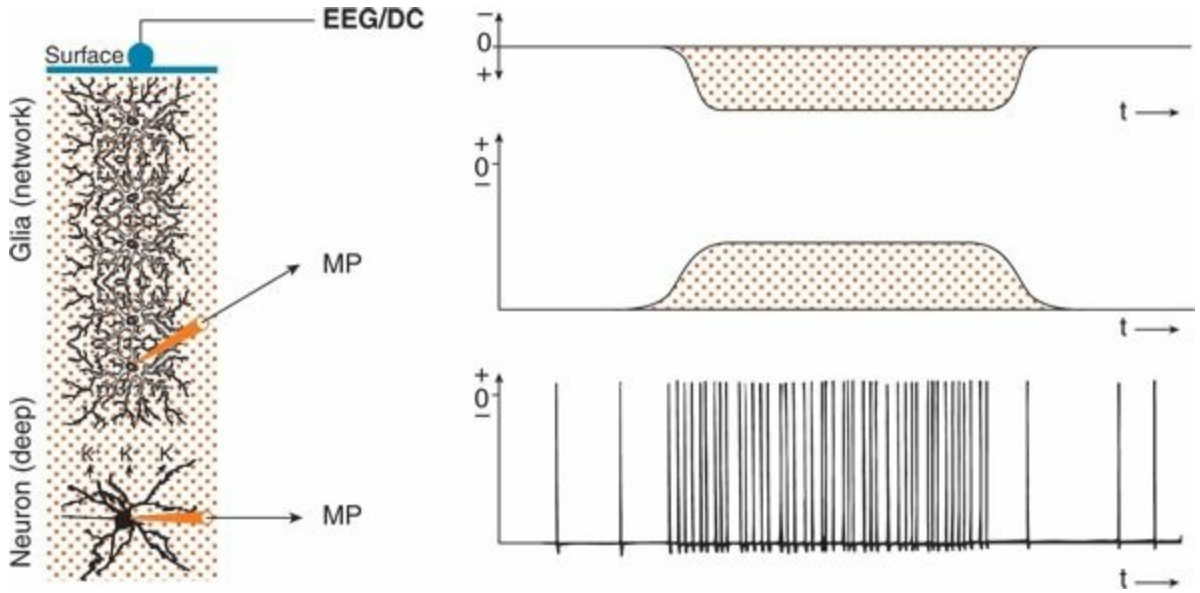

Figure 6.10. Sustained shifts in the electroencephalogram (EEG) performed with a direct current (DC) amplifier (EEG/DC) at the surface of the cerebral cortex generated by neuronal activity and mediated by a glial network. If recordings are performed with a DC amplifier, sustained potentials can also be recorded. A deep neuron functionally coupled to a perpendicularly oriented glial network is shown. The membrane potentials (MPs) of the deep neuron and of a glial cell as well as the EEG/DC were recorded simultaneously. Sustained increased activity of the deep neuron induced an increase in extracellular K^+ concentration and a corresponding depolarization of the glial cells. Because of the electrotonically coupled network of glial cells, a sustained positive potential was induced in the surface EEG/DC recording.

Glial cells also are involved in the generation of baseline shifts (Figs. 6.10 and 6.11). As noted, a functional coupling between neurons and glial cells exists (see Fig. 6.3). Figure 6.10 shows a neuron in deep cortical layers and a network of electrically coupled glial cells extending to the surface. The superficial EEG/DC and the membrane potentials of a glial cell and the neuron are recorded. With increased discharge frequency of the neuron, extracellular potassium concentration rises, evoking a

depolarization of the adjacent glial cell. The potassium- induced depolarization is conducted electrotonically within the glial network. A functional situation is present similar to that in a perpendicular neuron with a deep excitatory synaptic input (see Figs. 6.5 and 6.6). The superficial EEG/DC electrode sees a long-lasting positivity because of an outflow of cations from the glial cells in the upper layers. In other respects, this corresponds to the well-known spatial buffering of potassium. In principle, the aforementioned mechanism can make visible the activity of closed fields (see Fig. 6.7B) in baseline shifts of field potentials (31,33,34).

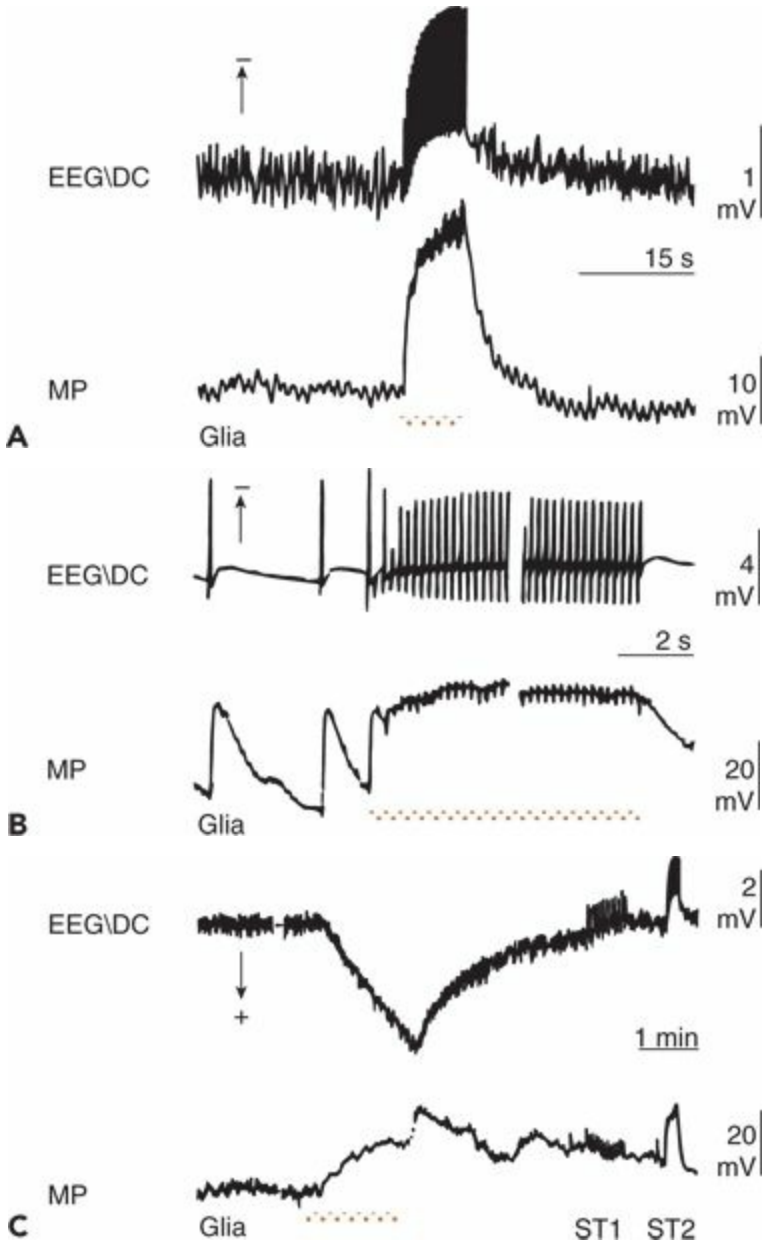

Figure 6.11. Simultaneous recordings of the electroencephalogram (EEG) potential performed with a direct current (DC) amplifier (EEG/DC) at the surface of the cerebral cortex and of the membrane potential (MP) of glial cells in an anesthetized and artificially ventilated rat. **A:**High-frequency electrical stimulation of the cortical surface (horizontal bar) is indicated. **B:**Focal epileptic activity induced by penicillin is indicated. Repetitive cortical stimulation (horizontal bar) increased the frequency of epileptic discharges (interruption, approximately 5 seconds). **C:**Increase of the local partial pressure of carbon dioxide (PCO_2) during apnea (horizontal bar) is shown. ST1 and ST2, low- and high-frequency electrical stimulation of the cerebral cortex, respectively. Depolarization of glial cells can be associated with both a positive **(C)** and a negative **(A** and **B)** shift in the EEG/DC. (**A** adapted from Caspers H, Speckmann E-J, Lehmenkühler A. DC potentials of the cerebral cortex. Seizure activity and changes in gas pressures. Rev Physiol Biochem Pharmacol. 1987;106:127–178; **B** adapted from Speckmann E-J. Experimentelle Epilepsieforschung. Darmstadt, Germany: Wissenschaftliche Buchgesellschaft; 1986; and **C** adapted from Caspers H, Speckmann E-J, Lehmenkühler A. Electrogenesis of slow potentials of the brain. In: Elbert T, Rockstroh B, Lutzenberger W, et al., eds. Self-regulation of the Brain and Behavior. New York :

Springer; 1984:26–41, with permission.)

Glial cells contribute to the generation of field potentials, although this mechanism is not dominant. Thus, the original recordings of cortical EEG/DC and membrane potentials of cortical glial cells demonstrate that glial depolarization occurs parallel to negative (see Fig. 6.11A and B) and positive (see Fig. 6.11C) baseline shifts of field potentials. On the whole, field potential changes can be thought to be generated primarily by neuronal structures (16,31).

BASICS OF EPILEPTIC FIELD POTENTIALS

As described, field potentials recorded during epileptic activity are based on changes in neuronal membrane potential. The amplitudes of field potentials exceed those of nonepileptic potentials because the underlying neuronal activity is highly synchronized. As a result of the synchronization, the activity of a single element represents that of the entire epileptic population. On that basis, changes in field potentials and neuronal membrane potential can clearly be related to one another (12,35–39).

Figure 6.12 shows typical recordings of epicortical EEG and of the membrane potential of a neuron in upper cortical layers. During the development of epileptic activity, flat depolarizations superimposed by APs appear first. These membrane potential changes evolve into typical paroxysmal depolarizations that consist of a steep depolarization triggering a burst of APs, a plateau-like diminution of the membrane potential, and a steep repolarization followed by an afterhyperpolarization or an afterdepolarization. With the appearance of the epileptic neuronal depolarizations, negative fluctuations of the local field potential develop. As Figure 6.12 shows, a close temporal relationship exists between development of the intracellularly recorded membrane potential and the extracellularly generated field potentials. Later, the duration and amplitude of the neuronal depolarizations and of the negative field potentials increase and reach a final level. The transition from epileptic to normal activity is also associated with a parallelism between field potentials and membrane potential changes. Thus, the epileptic negative field potentials represent the activity of an epileptic neuronal network (35–37,39).

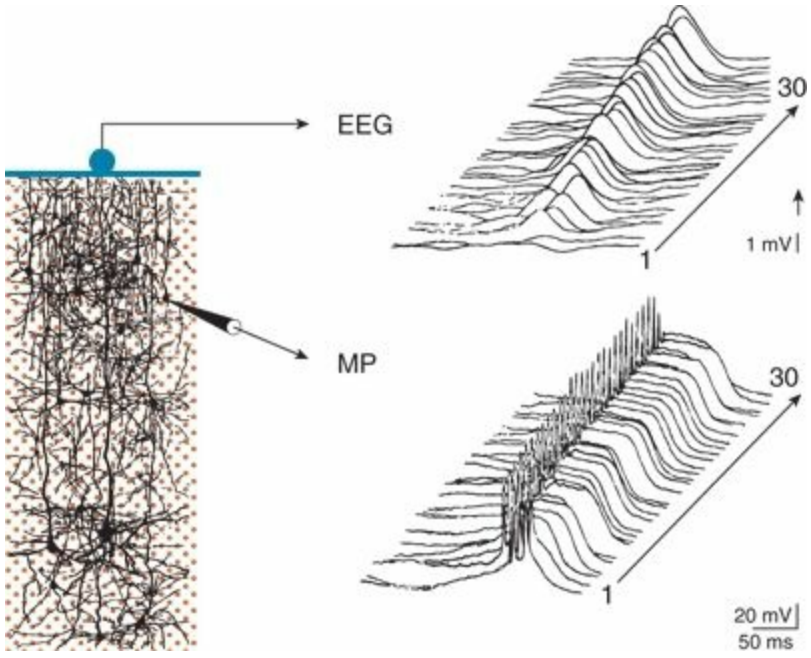

Figure 6.12. Simultaneous establishment of paroxysmal depolarizations of a neuron in superficial cortical layers and of sharp waves in the electroencephalogram at the cortical surface during development of an epileptic focus. Focal epileptic activity was induced by local

penicillin application. MP, membrane potential. Graphic superposition of 30 successive potentials with the commencement of focal epileptic activity is shown. (Adapted from Elger CE, Speckmann E-J. Vertical inhibition in motor cortical epileptic foci and its consequences for descending neuronal activity to the spinal cord. In: Speckmann E-J, Elger CE, eds. Epilepsy and Motor System. Baltimore, MD: Urban & Schwarzenberg; 1983:152–160, with permission.)

Epileptic foci can induce evoked potentials (EP) in nonepileptic areas (Fig. 6.13). In Figure 6.13A, two cortical columns generate epileptic activity, as indicated by the neuronal paroxysmal depolarizations and the concomitant negative spikes in the EEG. The epileptic activities at both sites are not necessarily synchronous. In Figure 6.13B, only one column is epileptically active. The epileptic discharges elicit synaptic potentials in the neighboring nonepileptic area. The synchronized burst discharges induced in the nonepileptic column then give rise to "epileptic evoked potentials."

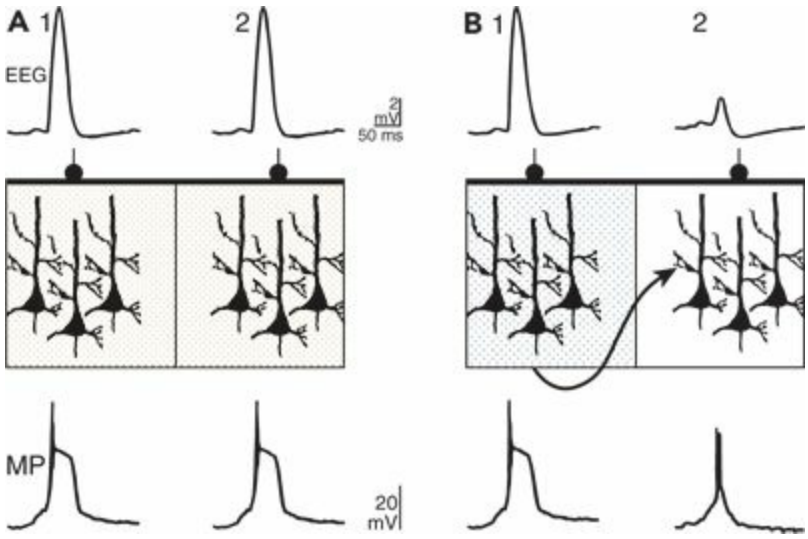

Figure 6.13. Electroencephalographic waves at the cortical surface representing locally generated **(A1** and **A2** and **B1)** and synaptically transmitted **(B2)** epileptiform neuronal discharges. Cortical columns with (hatched areas) and without (open area) locally generated epileptic activity are shown. Both **A1** and **A2** potentials represent directly epileptiform neuronal depolarizations. The potential in **B1** represents directly epileptiform neuronal discharges, and that in **B2** represents indirectly epileptiform discharges in the primary nonepileptic neighboring column, that is, a potential synaptically evoked by the epileptically active neurons (arrow). MP, membrane potential.

FIELD POTENTIALS WITH FOCAL EPILEPTIC ACTIVITY

For practical reasons, the description of field potential generation with focal epileptic activity takes into account the functional significance of an epileptic focus, especially motor phenomena (12,35,38,40,41).

The relationship between epileptic field potentials in motor cortical areas and their output to the spinal cord is detailed in Figure 6.14. In Figure 6.14A, the epicortical EEG spike is associated with a defined high-amplitude spinal field potential, indicating synchronized descending neuronal activity. These events result finally in muscular clonus. Superficial EEG potentials and spinal output are not always closely related, however. Each of these motor phenomena may be present without the other (see Fig. 6.14B and C) (42–47).

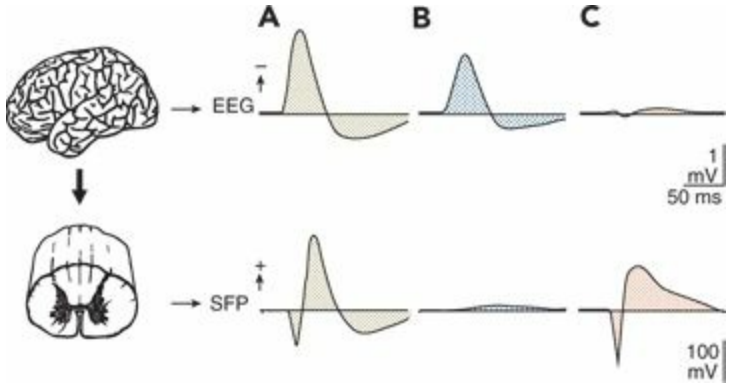

Figure 6.14. Dissociation in occurrence of epileptiform potentials on the surface EEG and of spinal field potentials (SFPs). Focal epileptiform activity was restricted to motor cortical layers. **A:**Simultaneous appearance of cortical and spinal activity is indicated. **B:**Presence of cortical activity and failure of spinal activity are shown. **C:**Failure of cortical activity and presence of spinal activity are shown. (Adapted from Elger CE, Speckmann E-J, Prohaska O, et al. Pattern of intracortical potential distribution during focal interictal epileptiform discharges (FIED) and its relation to spinal field potentials in the rat. Electroencephalogr Clin Neurophysiol. 1981;51:393–402, with permission.)

The aforementioned discrepancies between superficial EEG potentials and cortical output can be clarified by recording field potentials from within the cortex. In Figure 6.15, the superficial EEG was recorded simultaneously with intracortical field potentials at three depths, including layer V, and with spinal field potentials. With positive field potentials in layer V, spinal field potentials are missing (see Fig. 6.15A and B). Synchronized motor output appears only when the typical epileptic negative spike occurs in layer V (see Fig. 6.15C). In all these cases, the EEG spikes at the cortical surface are identical (42–44,46,47).

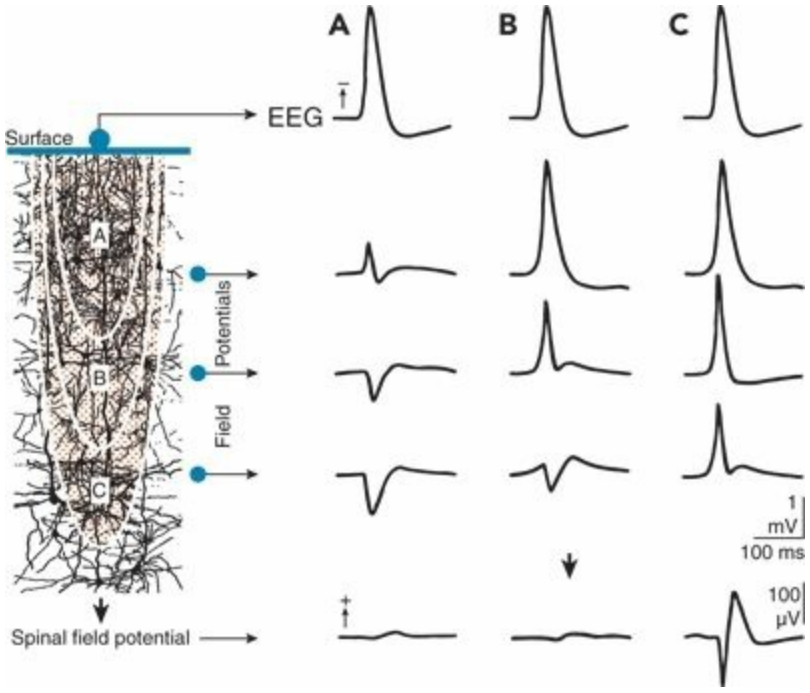

Figure 6.15. Epicortical (electroencephalogram), intracortical, and spinal field potentials during focal epileptiform activity. The actual vertical extension of the focus is indicated on the left and related to the tracings by letters. The occurrence of synchronized spinal field potentials is linked to the appearance of negative field potentials in lamina V **(A–C)**. (Adapted from Elger CE, Speckmann E-J, Caspers H, et al. Focal interictal epileptiform discharges in the cortex of the rat: laminar restriction and its consequences for activity descending to the spinal cord. In: Klee MR, Lux HD, Speckmann E-J, eds. Physiology and Pharmacology of Epileptogenic Phenomena. New York: Raven Press; 1982:13–20, with permission.)

The situations presented in Figure 6.15A and C are shown at the level of intracellular recordings in Figure 6.16. The positive field potentials in layer V parallel long-lasting and highly effective neuronal inhibitions, and the negative field potentials at the same site are based on typical neuronal paroxysmal depolarization shifts. Thus, the synchronized excitation of pyramidal neurons in layer V is a prerequisite for epileptic motor output. This excitation is not necessarily reflected in the superficial EEG, however (see Fig. 6.14C). Epileptic motor reactions based on a cortical focus may occur without appropriate signs on such a recording (43,44,46–48).

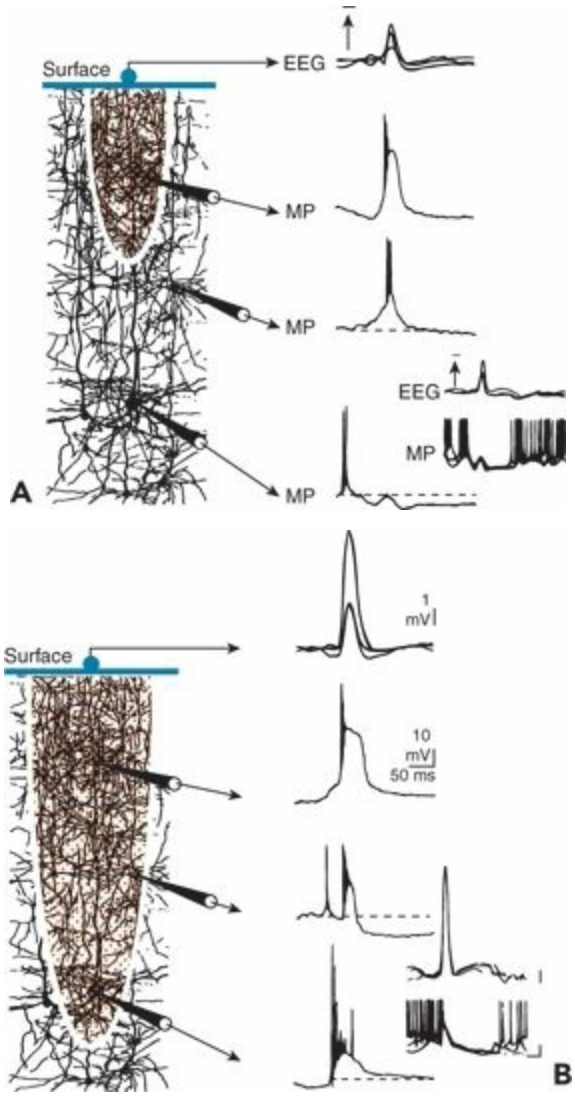

Figure 6.16. Membrane potential (MP) changes of single neurons in layers of the motor cortex during focal epileptic activity with different vertical extensions. Epileptic activity was recorded 5 **(A)** and 15 **(B)** minutes after local application of penicillin to the cortical surface. The drawings indicate vertical extension of the focus. The MP changes were recorded simultaneously with the electroencephalographic changes, which are superimposed to show the relationship of the curves to each other. **Insets:** Shown are three superimposed superficial electroencephalographic and deep MP recordings. (Adapted from Speckmann E-J. Experimentelle Epilepsieforschung. Darmstadt, Germany: Wissenschaftliche Buchgesellschaft; 1986:122, with permission.)

The difference between bioelectrical activity at the cortical surface and in deeper cortical layers becomes very clear when voltage-sensitive dyes are used instead of field potential recordings (49–51). With this technique, neuronal activity can be seen, although the requirements for the generation of field potentials are not fulfilled (cf. Fig. 6.7).

FIELD POTENTIALS WITH GENERALIZED

TONIC–CLONIC ACTIVITY

Observations made during tonic–clonic seizures in experimental animal studies are used to explain the generation of field potentials during generalized seizures. After repeated injections of pentylenetetrazol, typical tonic–clonic seizures appear (Fig. 6.17) accompanied by field potential changes consisting of baseline shifts and superimposed rapid waves. The latter allow the differentiation between the tonic and clonic phases (see Fig. 6.17C) (12,35–38,41).

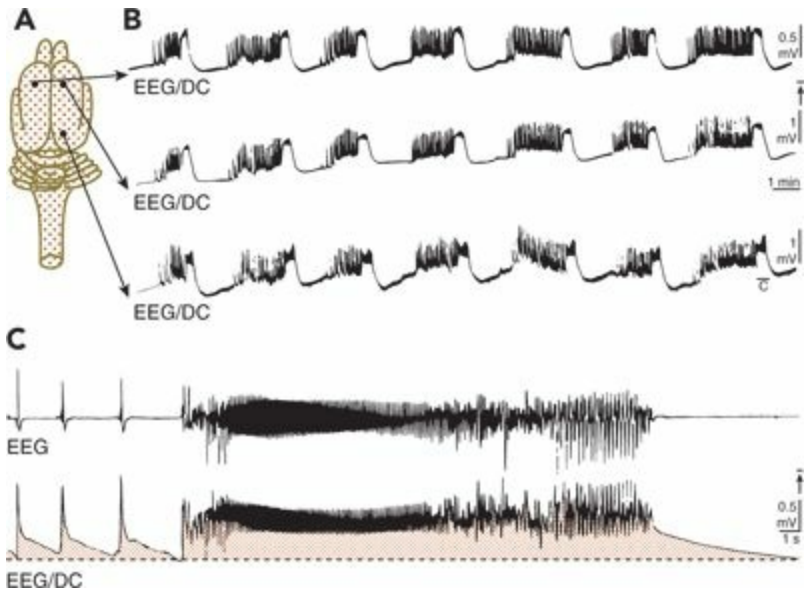

Figure 6.17. Experimental animal model of generalized tonic–clonic seizures elicited by repeated systemic administration of pentylenetetrazol. **A:** The recording arrangement is shown. **B:**Simultaneous recordings of the epicortical direct current (DC) potential from the motor regions of both hemispheres and from an occipital area are presented. **C:**Part **C** in **B** is displayed as a conventional electroencephalogram (EEG) and EEG/DC potential with an extended timescale. (Adapted from Speckmann E-J. Experimentelle Epilepsieforschung. Darmstadt, Germany: Wissenschaftliche Buchgesellschaft; 1986:69, with permission.)

Baseline Shifts (Electroencephalogram/Direct Current)

Figure 6.18 shows the relationship between baseline shifts of field potentials, from both surface and deep recordings, and membrane potential changes of pyramidal neurons in layer V. During tonic–clonic seizures, a series of paroxysmal depolarizations occurs in pyramidal tract neurons. This means that neuronal depolarization parallels a negative shift of the baseline of field potentials on superficial and deep recordings. The close temporal relationship can be discerned also on recordings with an extended timescale. Although the bioelectrical events are similar, discrepancies exist in the commencement of seizures and in the postictal phase. With seizure onset, a monophasic negative shift always occurs on deep recordings of field potentials. In contrast, the superficial EEG/DC findings can start with a monophasic negative or positive as well as a biphasic negative–positive fluctuation. In the postictal period, deep recordings always show a positive displacement of the baseline of field potentials and superficial recordings a negative displacement. Comparison of the different simultaneous recordings of field potentials and membrane potential reveals the following findings: The initial negative fluctuation and the postictal positive displacement of the field potential in deeper layers correspond, respectively, to the initial highly synchronized depolarization and to the postictal hyperpolarization of pyramidal tract neurons. This close correspondence is missing when superficially recorded EEG/DC shifts and neuronal membrane potential changes are compared. Thus, the mean neuronal activity is well represented in the baseline shift of deep field potentials. As far as

the superficial field potentials are concerned, additional generators, for example, glial networks, must be taken into account (14–16,18,52–54).

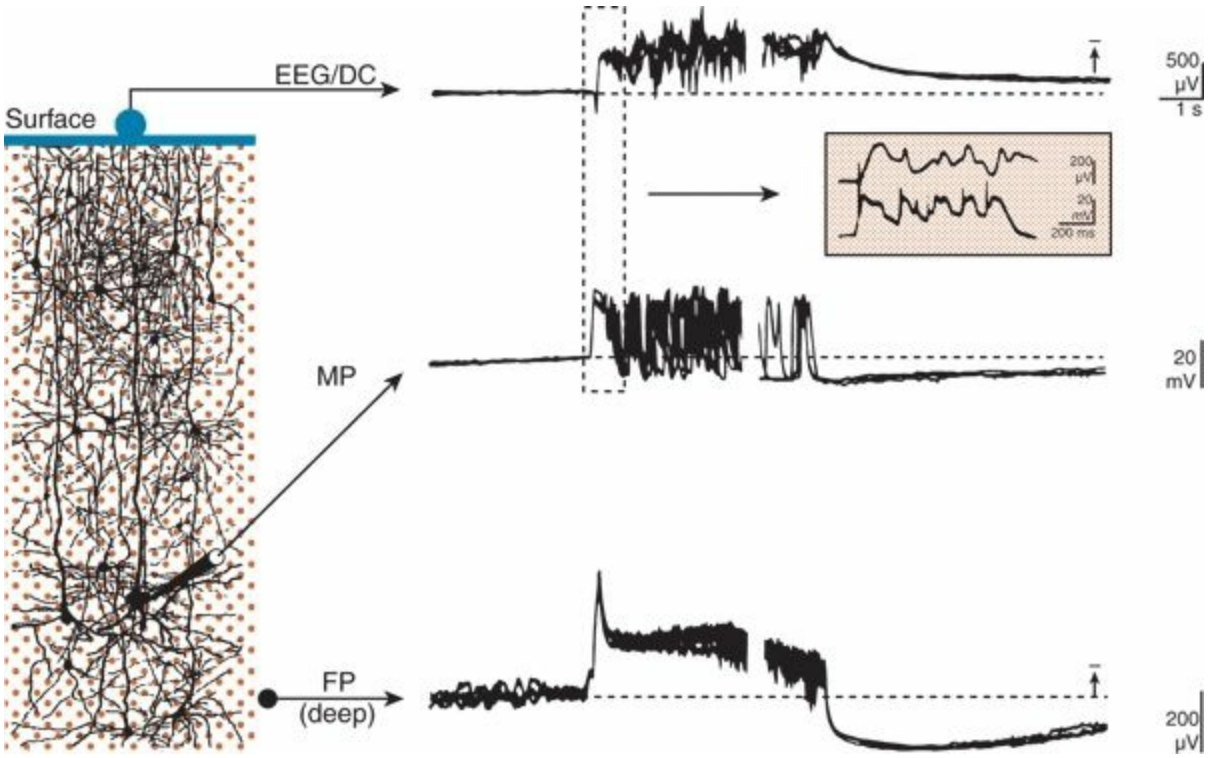

Figure 6.18. Relationship between shifts of the epicortical (electroencephalogram [EEG] performed with a direct current [DC] amplifier [EEG/DC]) and laminar field potentials (FPs) and changes in the membrane potential (MP) of a pyramidal tract cell during tonic–clonic seizures (inkwriter recordings with graphic superpositions). Epileptic activity was elicited by repeated systemic administrations of pentylenetetrazol. Interruptions were 30 to 60 seconds. **Inset:** Shown are parts of the EEG/DC and MP recordings displayed on an oscilloscope with an extended timescale.

Waves (Conventional Electroencephalogram)

The rapid waves superimposed on the baseline shifts of the EEG/DC can best be interpreted when the afferent impulse inflow to the upper cortical layers is evaluated. Figure 6.19 represents a cortical column with a perpendicularly oriented neuron. An afferent fiber forms an excitatory synapse in upper dendritic regions. The discharge frequency of the afferent fiber was recorded simultaneously with the surface EEG/DC. For further description, three types of waves were selected: monophasic negative (see Fig. 6.19A), monophasic positive (see Fig. 6.15C), and biphasic positive–negative (see Fig. 6.19B) waves. With the commencement of negative waves, the discharge rate increased from a low initial level (see Fig. 6.15A and B); during positive waves, the discharge rate decreased from a high level (see Fig. 6.19C). Thus, the generation of superficial waves can be explained as resulting from facilitation (negative waves) and disfacilitation (positive waves) of neuronal structures in upper cortical layers (20,22–24,40,46,47).

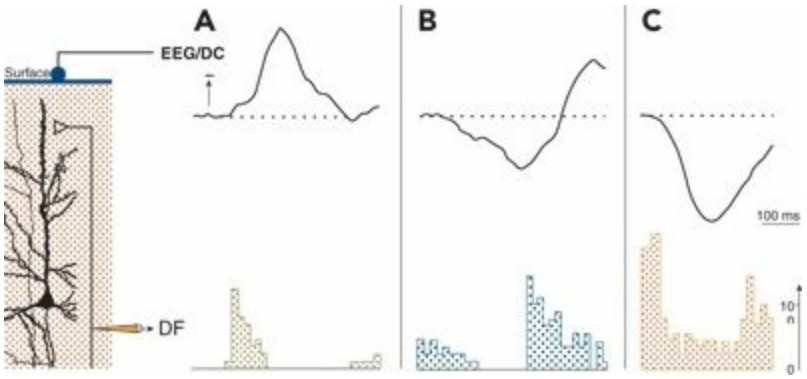

Figure 6.19. Relationship between different patterns of fluctuations of the epicortical field potential (electroencephalogram [EEG] performed with direct current [DC] amplifier [EEG/DC]) and changes in discharge frequency (DF) of neuronal elements in superficial cortical layers during tonic–clonic seizures. Epileptic activity was elicited by repeated systemic administrations of pentylenetetrazol. Up to 16 single events were averaged: monophasic negative **(A)** and positive **(C)**, as well as biphasic positive–negative **(B)**, fluctuations of EEG/DC. N, number of action potentials. CORRELATIONS OF MEMBRANE POTENTIAL CHANGES IN A NEURONAL POPULATION AND OF EEG SIGNALS

In addition to electroencephalography, there is a variety of other methods for detecting brain activity. Among these, single photon emission tomography, positron emission tomography, functional magnetic resonance imaging, and intrinsic optical imaging are based on metabolic changes associated with increases of local neuronal activity. Besides the latter "very indirect" methods, EEG including EP and magnetoencephalography represent "more direct ones" since they measure the field effects of the proper neuronal activity and therewith of the information processing brain activity. For the analysis of neuronal network functions, the immediate and simultaneous recording of membrane potentials of all neurons in a population by application of voltage-sensitive dyes is the "only direct" method available yet (49–51,55–57). Without doubt, all these methods have advantages and disadvantages. Thus, the functional imaging using voltage-sensitive dyes cannot be applied in patients for several reasons, for example, prerequisite of direct access to the brain structure to be investigated, photo toxicity, and pharmacologic side effects of the dyes. But this method is helpful to analyze the functional meaning of field potentials in living human brain slices in vitro, especially with spontaneously occurring epileptic discharges.

Principle and schematic example of recording neuronal membrane potentials using voltage-sensitive dyes are displayed in Figures 6.20 and 6.21. The living brain slices are stained with fluorescence (or absorption) dyes (A1 in Fig. 6.20). With depolarization and hyperpolarization, the fluorescence is decreased and increased, respectively (A2 and A3 in Fig. 6.20). The changes in fluorescence are measured via a microscope by an array of detectors and therewith the actual membrane potentials of the neurons are observed (B1 and B2 in Fig. 6.20).

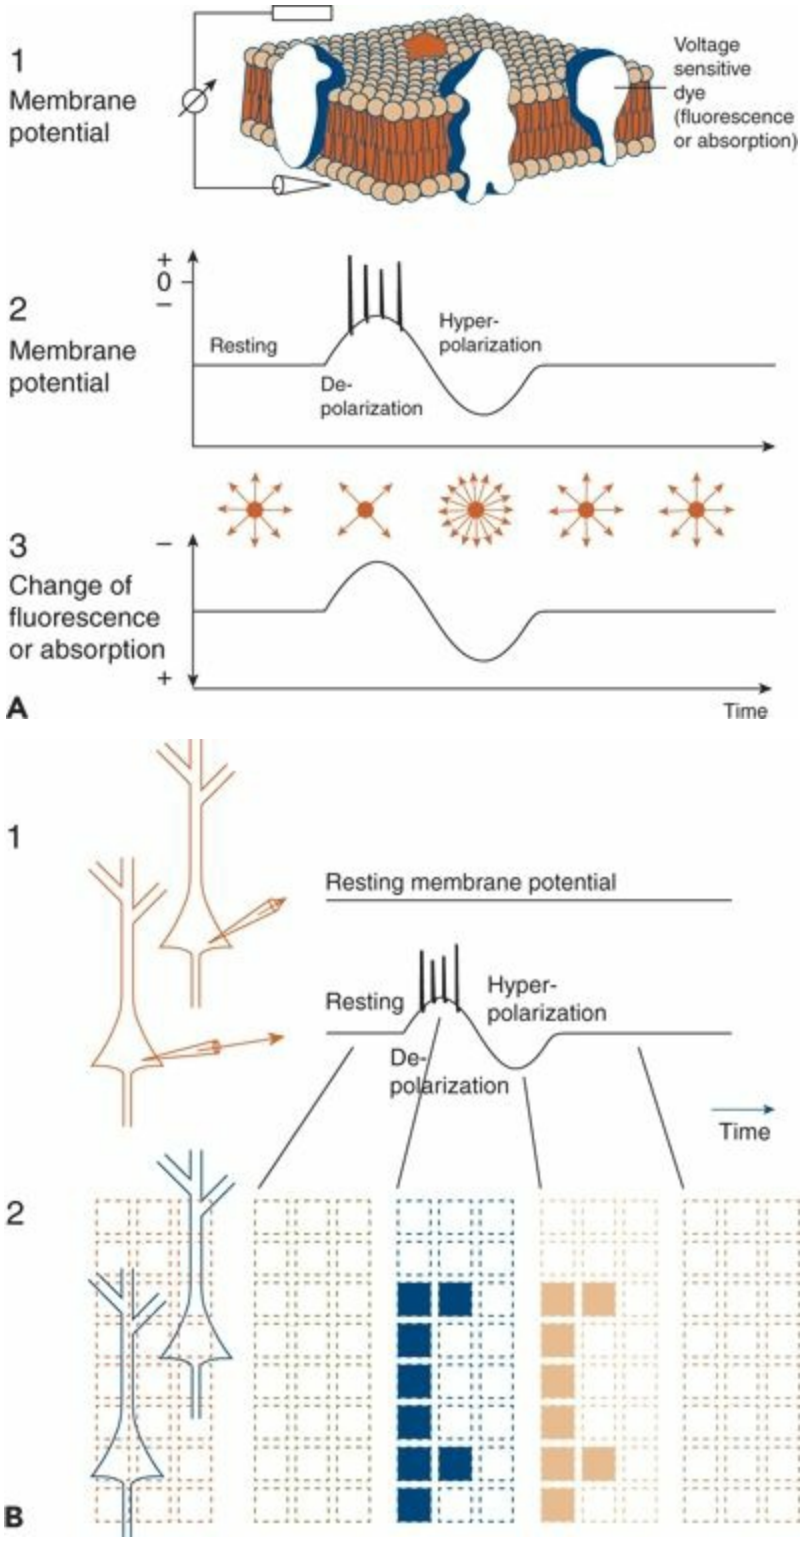

Figure 6.20. Recording of neuronal membrane potentials using voltage-sensitive dyes, principles and schematic example of application. **A:**(1) A dye is incorporated into the double lipid membrane of nerve cells and illuminated by light with dye-specific wavelength; simultaneously, the membrane potential is recorded with an intracellular microelectrode against a reference electrode in the extracellular space. (2) Changes of the membrane potential (MP) starting from the resting level passing a decrease (depolarization) with APs superimposed and a subsequent increase (hyperpolarization) and eventually returning to resting level. (3) In correspondence to the different MP levels, fluorescence and absorption of the dye changes. With fluorescent dyes, a depolarization is associated with decrease and a hyperpolarization with an increase of fluorescence (symbols). **B:**(1) Two neurons in a population; one stays in the resting state, the other changes its MP as in A (2). (2) By the aid of a microscope and a connected array of diodes (squares), the different MP changes of both neurons can be detected via the different optical behaviors. (Adapted from Speckmann E.-J. Das Gehirn meiner Kunst—Kreativität und das selbstbewusste Gehirn. Münster, Germany: Daedalus; 2012:176, with permission.)

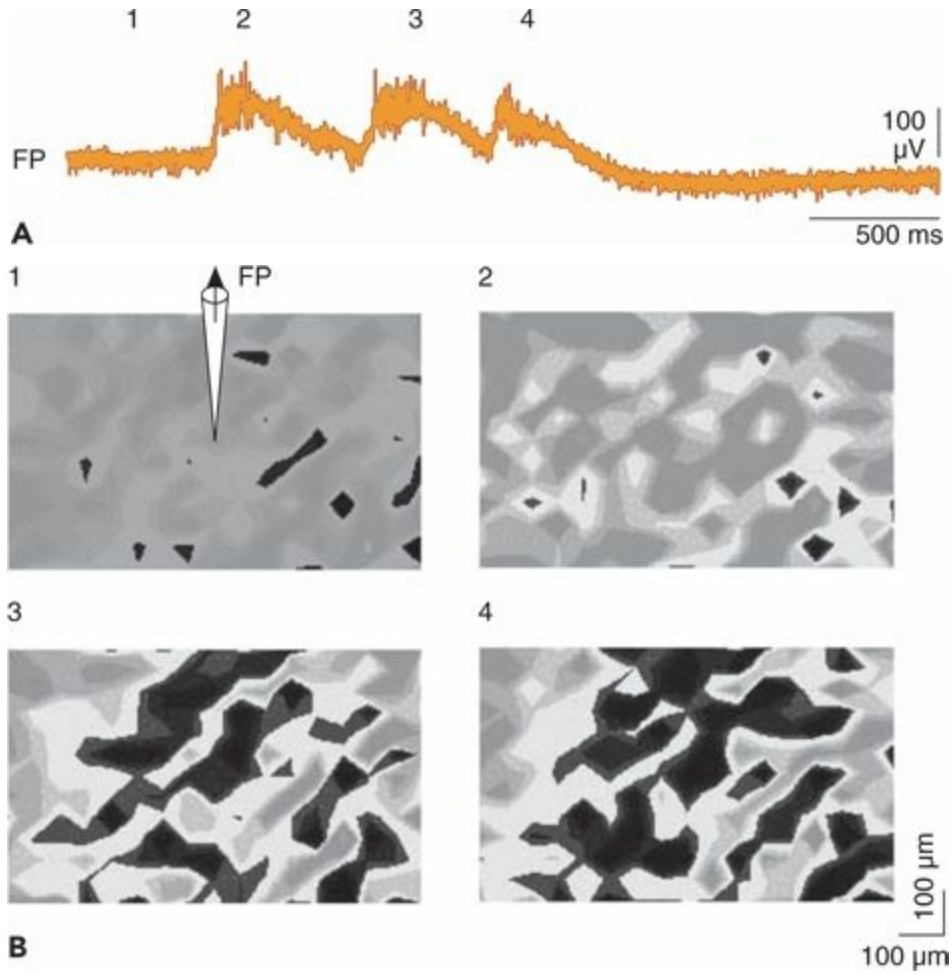

Figure 6.21. Simultaneous detection of membrane potentials (MP) of all neurons in a population (voltage- sensitive dye) and conventional recording of the local field potential (FP) at the same time. Living brain tissue (0.5 mm thick) from the temporal lobe of a patient who underwent epilepsy surgery. **A:**Recording of the local FP ("local EEG"). (1) Resting state, (2–4) epileptic discharges of different intensities. Epileptic discharges appeared spontaneously, that is, they were not induced experimentally. **B:**MP changes indicated by the intensity of fluorescence of the dye (black = decrease of the MP, depolarization). Similar epileptic potentials in the FP (2 and 3) are associated with different extents of neuronal depolarizations and similar extents of neuronal depolarizations with different epileptic potentials in the FP (3 and 4). (Adapted from Speckmann E.-J. Das Gehirn meiner Kunst—Kreativität und das selbstbewusste Gehirn. Münster, Germany: Daedalus; 2012: 176, with permission).

The method of simultaneous measurement of neuronal membrane potentials of all neurons in a population is successfully applied in living human brain slices (0.5 mm thick) in vitro obtained from neurosurgical interventions (tumor and epilepsy surgery) (49–51,58,59).

A comparison of the field potentials, that is, the local EEG, and of the neuronal membrane potentials detected by the aid of voltage-sensitive dyes is given in Figure 6.21. The tissue is a slice preparation from the temporal neocortex resected from a patient suffering from pharmacoresistent complex partial seizures. Most of these living human brain slices show spontaneous epileptic EEG potentials, that is, epileptic discharges not induced by experimental procedures. One can derive the following from the recordings:

1. During epileptic discharges, only a certain portion of the neurons in the population is active simultaneously, that is, a complete synchronization is missing (Fig. 6.21, numbers 2 through 4).
2. Similar epileptic potentials in the EEG (Fig. 6.21, numbers 2 and 3) are associated with different extents of neuronal depolarizations and similar extents of neuronal depolarizations with different epileptic potentials in the EEG (numbers 3 and 4).

CONCLUSION

Changes of neuronal activity associated with net current flows in the extracellular space produce field potentials. In clinical practice, a synchronization of the activity of neuronal elements is needed to recognize signals. As seen in superficial and deep potential fields, field potentials are generated in functionally different structures and may be based on different elementary mechanisms. Field potentials at the cortical surface, for example, can be interpreted in a variety of ways because they are not constantly related to neuronal activity in deep cortex.

CHAPTER 7 LOCALIZATION AND FIELD DETERMINATION IN ELECTROENCEPHALOGRAPHY

RICHARD C. BURGESS

LOCALIZATION AND MAPPING

The word "electroencephalogram" (EEG) is derived from Greek roots to create a term meaning an electrical picture of the brain. While interpreting an EEG, electroencephalographers maintain a three-dimensional picture of the brain/head in their minds. In principle, there are an infinite number of different source configurations of an electrical event within the head that may give rise to the same electrical field distribution at the scalp. Despite this theoretical constraint, one of the key functions of the electroencephalographer is to conceptualize the generators in relationship to this vision and to build an increasingly clear mental image of the foci of these generators. Methods for localization and field determination are tools to help the electroencephalographer infer the location, strength, and orientation of generator sources within the cortex, based on their manifestation at 21 or more EEG recording sites.

Scalp electrical activity arises from both physiologic and pathologic brain generators. Localization of epileptiform potentials from scalp EEG is critically important to pinpoint the epileptic focus and identify the region of brain pathology (1). Many electroencephalographers have taken a simplistic approach, assuming that the generator source must be close to the point where the maximum voltage is recorded. Attempts to systematize the localization of specific EEG activity date back to the early years of electroencephalography. In the mid-1930s, Adrian and Matthews (2) as well as Adrian and Yamagiwa (3) employed phase reversal techniques to localize normal rhythms, and Walter (4) used phase reversals for localization of abnormal EEG activity, as did Gibbs and Gibbs (5) in 1941 in their classic atlas. More recently, a variety of reviews have outlined general principles for the use of polarity, montages, and localization (5–11). It should be emphasized that phase reversals are not inherently an indicator of abnormality. Phase reversals occur as a result of both normal and abnormal activities. Phase reversals are most obvious for sharply contoured transient activity and therefore in the case of epileptiform abnormalities provide a dramatic visual clue.

Despite the critical importance of accuracy in localization, there has been an absence in the literature of descriptions of systematic methods for accomplishing this localization in a simple, manual fashion (12,13). Most textbooks emphasize the distribution that would occur as a result of an assumed generator (i.e., the "forward" problem). With the evolution of digital EEG (14), a variety of methods for computerized source localization have become available (15,16) at the push of a button within the EEG machine itself or as stand-alone software (17,18). These techniques are model based and have significant limitations; they have generally not been employed in routine clinical practice. A

practical guide for the step-by-step identification of the origin of epileptiform activity has been developed at the Cleveland Clinic Foundation (19) and is covered in some detail here.

The principles of source localization apply to any type of brain electrical activity; however, this review concentrates primarily on defining the electrophysiologic origin of epileptiform activity. While epileptologists generally rely heavily on the location of interictal discharges in the workup of patients leading up to epilepsy surgery (20,21), the relationship of the irritative zone (as manifest by interictal spikes) to the epileptogenic zone (identification of which is obviously crucial for surgical success) has been the subject of much debate (22,23). Nevertheless, the majority of the points covered in this review are illustrated using interictal spikes.

There are two steps in the interpretation of epileptiform discharges: surface field determination and source localization. Proper determination of the electrical field results from knowledge of the electrode positions and head shape and has only one answer. Accurate field determination is essential not only for accurate source localization but also for discrimination of epileptic activity from other nonepileptic transients. For source localization, on the other hand, no single unique solution exists. In order to arrive at a plausible solution for the source location, several assumptions are useful. In this chapter, practical neurophysiologic concepts that relate the generator to the surface electrical fields are described in the first section. Then, the next three sections describe important conventions used in visual interpretation of EEG regarding instrumentations, the field determination, and the source localization. Lastly, the application of computer-based techniques that aim to assist in the localization problem is briefly discussed.

PRACTICAL CONCEPTS OF ELECTRICAL FIELDS APPLIED TO BRAIN GENERATORS

Sources

The electrical activity recorded during an EEG is a scalp representation of the current dipoles generated by the underlying intracranial local field potentials (24–28). These intracranial sources, either focal dipoles or sheets of dipoles, represent the postsynaptic potentials originating from vertically oriented neurons. A unit current dipole is created by the intercellular laminar currents in the apical dendrites arising from the pyramidal cells in the outer layer of the cerebral cortex. Specifically, superficial excitatory postsynaptic potentials and deep inhibitory postsynaptic potentials generate almost all spontaneous EEG activities (29), particularly the epileptogenic abnormalities. When populations of neurons are more or less synchronously activated for relatively long durations, the activity can be macroscopically recorded from a certain distance as a linear summation of the unit dipoles (26–28). This summated activity may also be represented as a dipole or sheet of dipoles along the cortex. Thus, the generator of epileptic activity can be explained by a single or multiple equivalent current dipoles (8,13,30,31). The surface potential can be thought of as a two-dimensional projection or shadow of a complex three-dimensional electrical object residing inside the head.

Fundamental to scalp localization is the concept of the “inverse” problem, which entails an estimate, based on surface data, of the magnitude, location, and distribution of electrical fields throughout the brain. Whereas the forward problem is solvable with unique solutions, the inverse problem is not. The mathematical representation of the biophysics underlying volume conduction is covered by Nunez (9).

The forward problem can be stated as follows: Given known charge distributions and volume conductor geometries and properties, predict the resulting surface potential distribution. The solution involves applying numerical or analytical methods for any known set of geometries and boundary conditions (9,32) to solve the linear Poisson equation:

$$\nabla^2\Phi = -\frac{\rho}{\varepsilon}$$

where ∇^2 is the second spatial gradient operator, Φ is the scalar potential in volts, ρ is the free charge density, and ε is the permittivity of the mass of tissue. Multiple sources can be shown to combine linearly, so that a combination of sources results in the arithmetic sum of the potential distributions that each would produce individually.

The corresponding inverse problem can be stated as follows: Given a surface potential distribution and the volume conductor geometries and properties, determine the underlying charge distribution. Unfortunately, a given surface map can be produced by any of an infinite number of possible source distributions. EEG records at a distance from the sources and employs only a limited number of sensors—typically 20 to 30 in a routine scalp EEG. Therefore, this problem generally has no unique solution (33). Nevertheless, simplifying assumptions are usually made: (i) The source dipole is near the surface; (ii) the source dipole is perpendicular to the surface; (iii) the head is a uniform, homogeneous volume conductor; (iv) at least one recording electrode is essentially over the source; and (v) the reference is not contained in the active region.

On the basis of these assumptions, one generally looks for a single predominating potential maximum on the surface, with the source lying directly below it; however, a variety of nondipolar source configurations could produce the same observation. For example, a simple monopolar charge buildup, a curved dipole sheet, or a finite-thickness dipole "pancake" would all produce a single well-defined maximum. In addition, signals originating from confined but deep-seated generators will be broadly distributed when recorded from the surface (34,35), and these cannot be reliably distinguished from more superficial but widespread epileptic regions.

In addition to these "equivalent" source possibilities, others are physiologically similar but generate very different surface maps. Through variations in orientation and shape, dipole sheets can produce charge reorientation and cancellation. The resultant range of possible scalp distributions serves as a reminder that observed scalp maxima do not necessarily lie directly above maximal brain activity. Jayakar et al. (36) have pointed out the difficulties in localizing epileptic foci on the basis of simple models, owing to effects from dipolar orientation, anatomic variations, and inhomogeneities, among other factors.

Volume Conduction

In a volume conductor, the electrical field spreads instantaneously over an infinite number of pathways between the positive and negative ends of the dipole. Outside the neuron, the circuit is completed by the current flowing through the extracellular fluid in a direction opposite to the intracellular current. Through the process of volume conduction, electrical activity originates from a local field generator and spreads through a conductive medium to be picked up by a distant recording electrode. Volume conduction is passive—that is, it does not involve active regeneration of the signal by intervening neurons or synaptic relays—and occurs as easily through saline as through brain parenchyma. Potentials recorded by way of volume conduction are picked up synchronously and at

the speed of light at all recording electrodes. Although attenuated with distance by the medium, volume-conducted components preserve their original polarity and morphology.

The attenuation factor is defined by the inverse square law: That is, the recorded electrical potential falls off in direct proportion to the square of the distance from the generator (37,38). For example, a 100-μV potential seen at the electrode directly overlying a cortical generator (assume a distance of 1 cm away) will be reflected as a 4-μV potential at an electrode that is 5 cm away and as only a 1-μV potential at 10 cm away. The rapidity of this falloff is a function of the depth of the generator, with more superficial generators falling off much more rapidly. Distant generators have a "flat" falloff, one of the hallmarks of a "far-field" potential (Fig. 7.1).

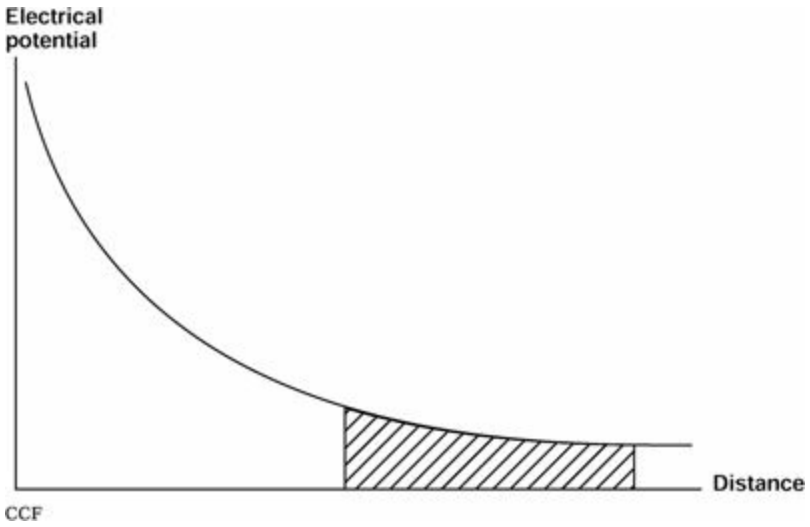

Figure 7.1. The electrical potential recorded by an electrode decreases in a parabolic fashion the farther away from the source it is. The difference recorded between two electrodes close to the source (near-field potentials) will be greater than the differential recordings from the tail of the curve. These far-field potentials (in the shaded region) are also lower in absolute amplitude.

The medium through which current travels to reach the recording electrode is not homogeneous but rather exhibits a variety of conductivities (39). As the current attempts to complete its circuit by following the path of least resistance, these differences in conductivities, especially differences among cerebrospinal fluid (CSF), skull, and scalp, and their associated boundaries, affect the electrical potential recorded on the scalp. The signal is not only altered in amplitude but is also stretched out during its passage to the surface because of the spatial summation and shunting effects of the intervening layers. In the skull, the conductivity in a tangential direction is higher than in a direction perpendicular to the surface. This produces a "smearing effect" on the surface potential distribution (40). Although the current tends to flow along the path of least resistance, there is still some flow throughout the volume conductor, thereby permitting recording of the electrical potential at all sites on the volume conductor, albeit with the amplitude inversely related to the square of the distance from the source (see Fig. 7.1).

The head also contains normal or abnormal openings that present low-resistance paths to conducted currents. The current tends to flow toward skull defects, whether physiologic (such as foramina) or acquired through trauma or surgery, and around cavities (such as the ventricles), markedly distorting the field in the region of the defect. The resistivity of scalp or brain tissue is many times smaller than that of bone (41–43). As a result, surface potentials near these openings will be unusually high, and the largest potentials can be seen at the location of the defect even when the source is several centimeters away from the defect (40,44,45).

Surface Electrical Manifestations

A variety of real-world considerations complicate the interpretation of surface recordings. Because the dipoles measured at the scalp ordinarily are oriented radially, scalp electrodes see primarily the positive or the negative pole—but usually not both. Although generators located at the apex of a gyrus lie perpendicular to the scalp (i.e., vertical dipoles), any generator within a cortical fissure will present a dipole at an angle to the scalp. Nearly 70% of the cortical surface lies within the sulcal depths (46). In addition, many brain areas—most notably the mesial frontal, parietal, occipital, and basal temporal cortex—are diversely oriented and lie at varying distances from surface electrodes. Hence, it is not sufficient to assume that the generator must be close to the point where the maximum potential is recorded (7). Finally, the choice of reference affects the form of the EEG measurements.

When a generator dipole is oblique or parallel to the scalp, the resulting surface potentials can lead to false localization of the potential maximum. The typical bell-shaped distribution of the electrical field is replaced by one shaped like a sideways "S" in this circumstance. Because both the positive and the negative ends of the dipole may be recorded at the scalp, the surface potential can exhibit two "maxima" of opposite polarity. Between the two ends will be a zero isopotential boundary where the generator will not be picked up at all (Fig. 7.2).

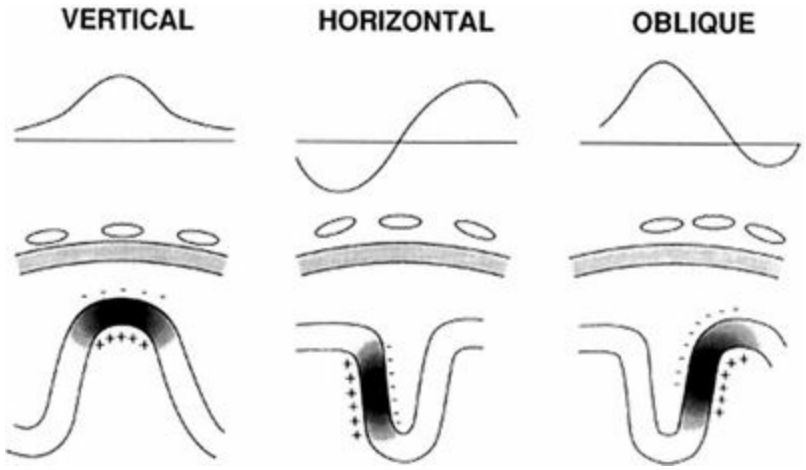

Figure 7.2. There are unusual sources wherein both the negative and the positive poles are recorded on the surface. The bottom row of figures shows a patch of cortex containing gyri and sulci. The darker areas represent the cortical mantle that is activated by an epileptic discharge, with negative and positive poles highlighted. In the middle row of illustrations, the positions of the electrodes on the scalp, relative to the discharging cortex, are shown. The top row illustrates the voltage that would be recorded on the EEG as a function of the distance along the scalp right below it.

It is important to distinguish true horizontal dipoles, such as those arising at a sulcus or the interhemispheric fissure, from field distributions resulting from widely separated activity but giving rise to distinct negative and positive maxima. For example, bisynchronous temporal spikes differing slightly in phase, such that the negative component on the left aligns with the positive component on the right, may appear to represent huge transverse dipoles (36); however, careful evaluation with an alternative reference (or the demonstration that the spikes also occur asynchronously) can prove that the fields represent not the source and sink of a single dipole but rather two generators (47) linked by corticocortical propagation.

When a source lies deeper in the brain, two changes occur: The surface potential becomes smaller and the field becomes more widespread relative to the surface maximum (34,35,48). Although the shape of the electrical field gradient can indicate the type of field and the distance of the

generator, identifying the source on the basis of the potential difference between any scalp electrodes becomes increasingly difficult. When the potential field gradient is relatively flat, as is the case in the far-field potential from a deep-seated source, a bipolar montage will display the waveform at relatively smaller amplitude (see Fig. 7.1). Diffuse discharges may be better appreciated on referential montages, assuming that the reference is not involved. An adequate "vantage point" may be impossible with surface electrodes when the focus is deep. It may be impossible to find a scalp electrode reference that is not electrically involved in the active region, and some cases can only be resolved by invasive electrode placements that can monitor more limited areas (see Chapter 82) (32,49–52).

The combination of multiple sources can produce a variety of results. A superficial source can overshadow a deep one, distorting or even hiding it. Because the amplitude of a measured potential is inversely proportional to the square of the distance from the recording electrode, nearby sources can appear significantly higher at the recording electrodes. A given electrode thus has a "view" of the nearby generators, such that dipoles that combine to reinforce each other will have a large net effect, whereas those that cancel will produce a smaller or null potential (53).

Complicating this problem is the fact that the equivalent dipole is an abstraction. In reality, only sources that extend over multiple layers of several square centimeters of cortical tissue have sufficient energy to generate detectable scalp discharges (48,54). An epileptogenic zone almost always consists of a continuum of dipoles, resulting in a sheet or "patch" (55) dipole. Such a source may cover an extended brain region, with the constituent areas lying at various depths and orientations. Since each surface electrode has a three-dimensional cone of pick-up, both reinforcement and cancellation are possible to produce a variety of surface potential distributions. Overall, the conduction phenomena leading to surface potentials follow the "solid-angle" rule (56), that is, the net surface potential is proportional to the solid angle of the cone subtended by the recording electrode, that is, $V_{electrode} = V_{source}\ (\Omega/4\pi)$. Unless a dipole sheet parallels the surface, the maximum surface potential may be elsewhere than directly over the affected area, as illustrated in Figure 7.3. The solid angle theorem helps to explain the results of multiple synchronously discharging pyramidal neurons arrayed over a cortical region containing both sulci and gyri.

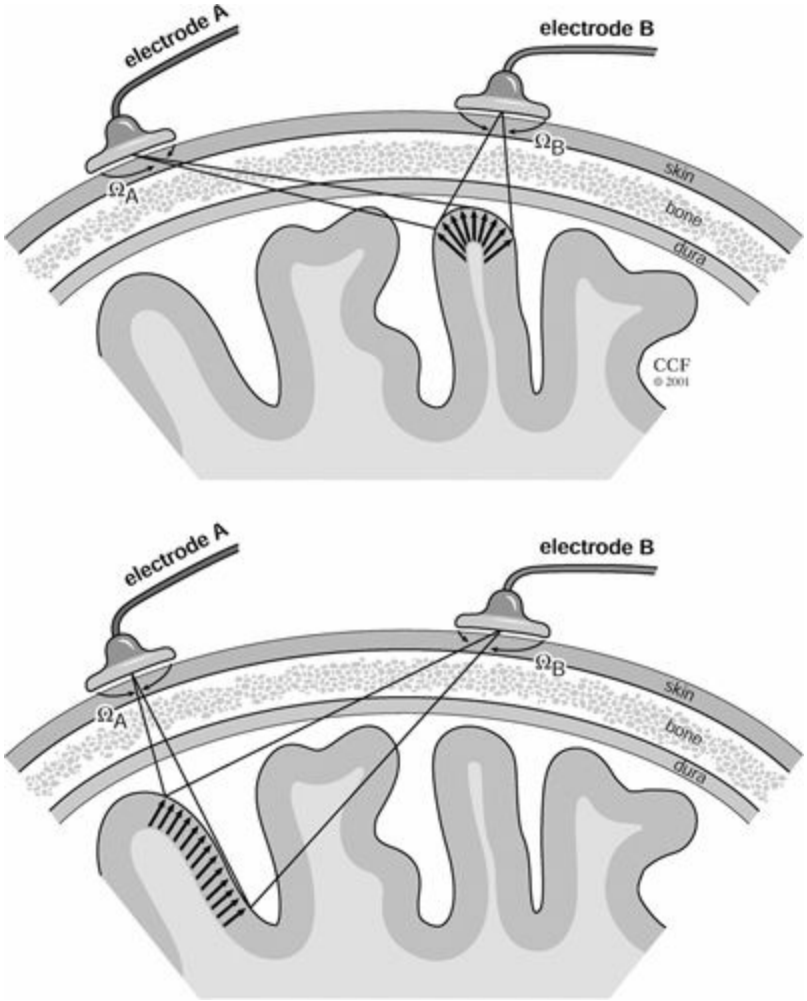

Figure 7.3. Use of the solid-angle rule to ascertain the signal measured on the scalp surface relative to the orientation of the dipole. **Top:**Surface electrode B sees a large electrical potential because of the orientation and proximity of the dipole layer, as borne out by the solid angle Ω_B. **Bottom:**: In this case, the potential seen by electrode A is actually lower than that measured by the more distant electrode B because of the arrangement of the dipoles in the discharging region. The smaller solid angle, Ω_A, is proportional to the voltage measured on the scalp.

In the same way that opposing dipoles can cancel each other relative to a distant electrode, a sheet of nonparallel dipoles can produce a "closed" field (57) whose potential contributions will cancel, resulting in a negligible potential at the surface (58). These generators, usually not visible on scalp EEG, are observed primarily on invasive recordings (53). Even when not a completely closed field, multipolar source–sink configurations tend to produce more cancellation than dipolar generators and to attenuate more quickly as a function of distance (9). This irregular structure is particularly likely in the basal and mesial areas of the temporal cortex and the hippocampus, where cortical infolding is so prevalent (59).

The head consists of a series of roughly concentric layers that separate the brain from the scalp surface. Each of these layers—CSF, meninges, bone, and skin—presents different electrical characteristics to the currents that conduct the EEG to the surface. These layers occasion considerable current spreading, which causes the potential from localized foci to appear in a much broader scalp area (9,60). Spreading in itself would not be an insurmountable problem, because it is theoretically possible to recover deep dipole sources based on observed surface potentials, using appropriate mathematical transformations. Such recovery, however, is guaranteed only in a perfectly spherical concentric conductor, onto which electrodes can be placed in any location. The head is not a perfect globe, however, and significant constraints disqualify the face or neck, which may be preferred for

certain sources, as electrode sites.

Electrode Placement as Spatial Sampling

Placement of scalp electrodes should be considered an exercise in spatial sampling. Electrode density must be generous enough to capture the available information but not so closely spaced as to overwhelm with redundant data. Inability to precisely locate a cortical generator may be the result of spatial undersampling ("aliasing"). The assumption that a potential will decrease monotonically as distance increases from the involved electrode is based not only on an uncomplicated electrical field, that is, a monopole (61), but also on an electrode placement sufficiently dense to accurately represent the spatial contours of the field. Cooper et al. (54) suggested that at least 6 cm^2 of cortex discharging simultaneously is required to reflect a visible potential on the scalp surface, and more recently, it has been suggested that the required area for surface detectability is even larger, based on simultaneous intracranial and scalp EEG recordings (22,62). Because most epileptogenic potentials seen on the scalp are visible at multiple electrodes, a considerably larger cortical area must be synchronously discharging to produce these potentials (24).

Especially controversial is the detectability of spikes generated in the mesial temporal lobe. Some authors believe that scalp EEG recording of deep sources is possible (63), while others have found it impossible to record spikes from the mesial temporal structures (64,65). Sphenoidal electrodes provide a significantly better view of the mesial area, as shown in Figure 7.4, and are frequently employed in epilepsy monitoring units.

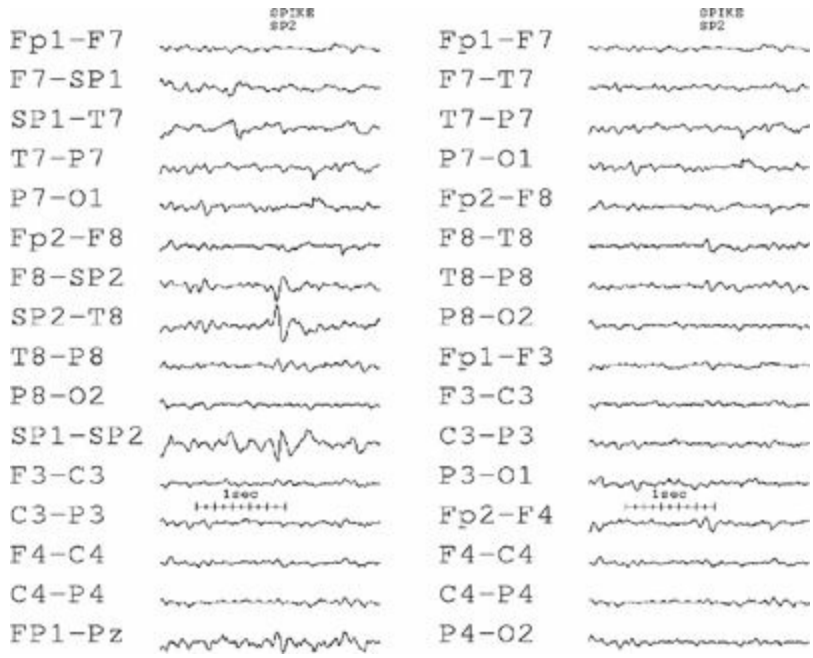

Figure 7.4. This EEG shows an example of a spike that is highly focal in the right sphenoidal electrode. Note that in the conventional double-banana longitudinal montage without the sphenoidals, this discharge is almost invisible.

The widely accepted International 10–20 Electrode Placement System (66), although relatively easy to apply reproducibly, has some inherent limitations in terms of the accuracy of localization (67). When more precise localization is indicated to avoid spatial aliasing, scalp electrodes should be placed at least once every 2.5 cm (68). The maximum spacing can be determined theoretically (24) as well as experimentally, and as many as 128 electrodes (spaced approximately 2 cm apart) may sometimes be necessary (69).

Boundary Problems

Regardless of the fineness of the scalp electrode grid, boundary effects will occur at the edges of the array. The maximum potential must be well within the scope of the recording electrodes to ascertain that a physiologic gradient exists away from the electrode. For example, epileptic sharp waves arising from mesial temporal structures are frequently localized outside the area covered by the 10–20 placement (70–73). It is impossible to determine the complete extent of the maximum fields unless the area is surrounded by regions of lesser activity. Recordings in which the activity is large all the way to the boundary of the region defined by the montage must be "remontaged" to include, if possible, all the relevant electrodes, or further recording must be carried out with additional electrodes. This may be especially complicated when it is difficult to position electrodes inferior to the customary borders of scalp coverage.

A significant portion of the head cannot be practically surveyed, and important brain areas such as the basomesial temporal cortex and other deep sources are only indirectly accessible with standard scalp electrodes. Additional electrodes inferior to the 10–20 system (66) must be employed to provide a better view. In certain circumstances, the information obtained from a combination of closely spaced scalp electrodes such as the international 10–10 system (74–76) and sphenoidal electrodes can obviate the need for more invasive recordings (77).

EEG INSTRUMENTATION CONSIDERATIONS RELATED TO LOCALIZATION

Differential Amplifiers

Amplifiers used in clinical neurophysiology measure the difference between two potentials at the inputs to the amplifier and provide an amplified version of this difference at the output. These devices, called differential amplifiers, eliminate unwanted signals that are identical at both inputs, called common-mode signals. The two terminals at the input to a differential amplifier are sometimes labeled G1 and G2, recalling when a screened "grid" within the vacuum tube amplifier controlled the flow of electrons from cathode to plate. Modern opamp-based differential amplifiers employ complex integrated circuits, and the terms "input 1" and "input 2" are used throughout this chapter.

The amplifier itself has no concept of polarity; it simply does the subtraction and the gain multiplication and then provides an output voltage that is a linear function of the input voltages, according to the following equation:

$$V_{output}(t) = G \times \left[V_{input1}(t) - V_{input2}(t) \right]$$

where $V_{output}(t)$ and $V_{inputN}(t)$ are the output and input voltages, and G is the gain of the amplifier. Only during interpretation of the EEG waveform in the context of the underlying generators does the concept of polarity have any meaning. Inexperienced electroencephalographers often mistakenly ascribe a polarity at the input to a specific waveform deviation at the output (12). It should be remembered that there are no positive deflections and no negative deflections. There are only upward and downward deflections (12). Figure 7.5 illustrates four different input conditions that give rise to exactly the same deflection.

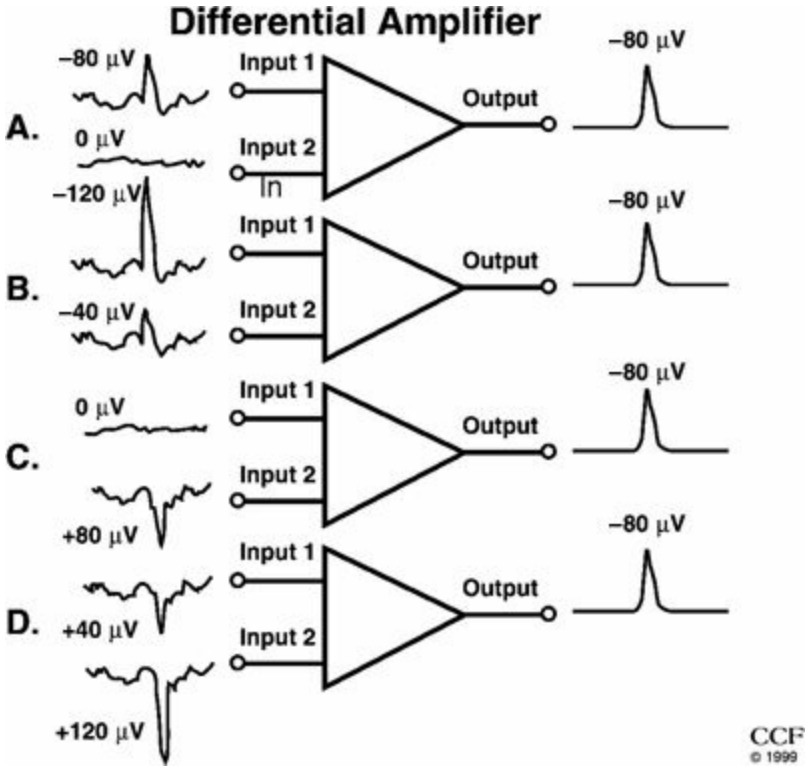

Figure 7.5. A and **B:**Illustrate a surface-negative spike. Input 1 is more negative than input 2. Because a differential amplifier responds only to the difference between the two inputs (input 1 – input 2), the spikes illustrated will yield identical output voltages; (−80) – (0) is the same as (−120) – (−40). The background electroencephalogram activity, because it is more widespread than the spikes and therefore almost the same at both inputs, is largely canceled out. In **(C)** and **(D)**, the spike is surface positive, that is, input 2 is more positive than input 1. The calculations (0) – (+80) and (+40) – (+120) both result in an answer of −80, and the background is still canceled out. All four circumstances yield identical outputs despite the differing amplitudes and polarities.

Polarity Conventions

Deflection refers to the vertical direction on the page or display screen in which the waveform component under study appears to go, and it is a function only of the display instrumentation. By EEG convention, upward deflections are caused by input 1 being more negative than input 2. Downward deflections are caused by input 1 being more positive than input 2 (78). These relationships imply nothing about the underlying polarity of the signals at inputs 1 and 2—only the polarity of their differences. When the name of electrode connected to input 1 is written above the deflection and the name of input 2 below, the deflection will point to the electrode with the “relative” negativity as has been done in Figure 7.6.

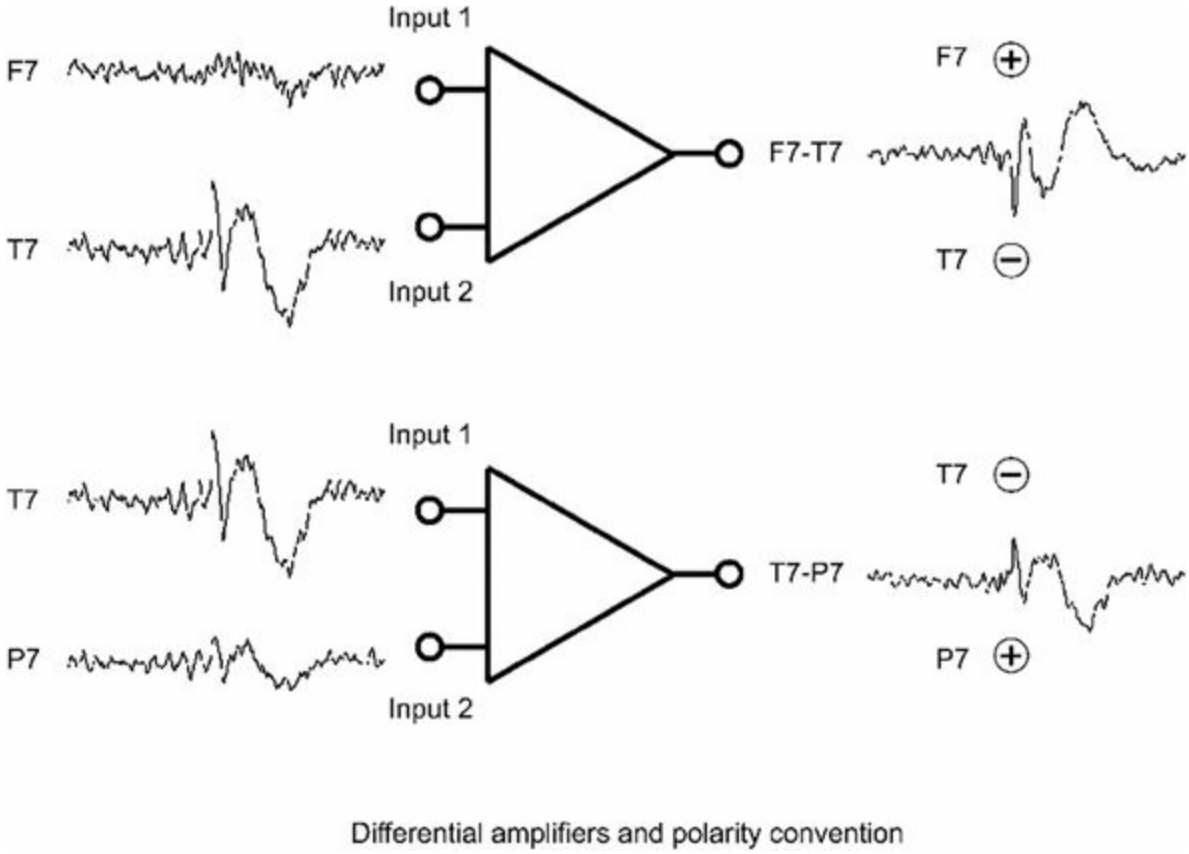

Figure 7.6. Differential amplifier and polarity conventions. The differential amplifier is designed to amplify only the difference between the signals at the two inputs. An upward deflection appearing at the output is caused by input 1 being more negative than input 2. A downward deflection results from input 1 being more positive than input 2. This convention is common to all clinical EEG machines. When the name of the electrode (i.e., its "derivation") connected to input 1 is written above the waveform and that connected to input 2 is written below as in this figure, the deflection always points to the electrode of higher "relative" negativity.

If the difference between the two signals at the input is 0, no deflection will occur. When two electrodes (no matter how close to the source of the sharp wave or spike) that lie along the same isopotential line (typically at the same distance from the generator) are input to a differential amplifier, the output will reflect no activity, even though both electrodes may be measuring high amplitudes in an absolute sense. Some amplifiers used in basic neurophysiology research and in clinical evoked potentials employ another convention, designed to display positive input 1 as an upward deflection.

Derivations and Montages

A derivation describes the connections of the electrodes to the amplifier inputs. A montage is a combination of derivations arranged down the EEG page to display many amplifier channels simultaneously in a way that aids in the identification and localization of abnormalities (79). Each amplifier could be connected to any pair of electrodes available. Likewise, these amplifier outputs could be arranged in any fashion on the screen; the arrangement in chains assists our visual localization capabilities.

The arrangement of derivations into a montage determines whether it is called bipolar or referential. Derivations in bipolar montages are established between neighboring electrodes to emphasize focal activity. They take advantage of the subtractive nature of differential amplifiers to effect a high degree of cancellation. Any montage can be analyzed to locate the maximum of a sharp wave or spike, provided that the montage has a logical order (6,80,81). It is convenient to link the

electrodes in a systematic "chain" of bipolar derivations. Because input 1 of each succeeding channel in the montage is the same as input 2 of the preceding channel, the electrodes are all electrically linked in a structured way and—more importantly—algebraically.

Bipolar montages are of maximum advantage when attempting to pick out localized potentials, as they help to cancel out more widespread activity. Bipolar montages are most logically arranged in a longitudinal or transverse direction. In a referential montage, the same electrode is connected to input 2 of every channel, while each channel has a different electrode connected to input 1. In contrast to bipolar montages, referential montages do a better job (as long as the reference is judiciously chosen) of picking up activity that has a more widespread distribution.

ELECTRICAL FIELD DETERMINATION ON THE SCALP

Identification of Peaks; Measurement of the Amplitude

Interictal epileptiform abnormalities are recognized by their morphology—an impression of "standing out" from the background—and by their electrical field distribution, which must demonstrate a realistic relationship between the electrical potentials at topographically associated electrode positions. In choosing an abnormality to localize, the peak selected must be representative of the patient's population of spikes, and the sample must be as clean as possible.

It is assumed that an activity starts from "zero" and reaches its maximum after a certain time. The amplitude of the activity is measured between the zero and the maximum peak. However, it is often difficult to identify the level of the "zero" in each EEG channel correctly, because the activity is superimposed on the background, arises from the noise level, or continues from the preceding activity. Sometimes sharp activity can be separated from a slower background, if the frequency of the epileptic activity is clearly different, by using filtering.

Practically, the amplitude is measured as peak to peak or baseline to peak. Identification of the baseline and peak may be particularly troublesome in the case of polyphasic discharges, in which each phase is brief and difficult to line up temporally. When analyzing a peak, the maximum value in each EEG channel should be identified at exactly the same time point. During visual analysis of a waveform, the montage selected will influence identification of the peak, resulting in different, or sometimes erroneous, field determinations. Multiple peaks or phase reversals with small time shifts reflect sequential change in the location of the maximum. In the EEG tracings shown in Figure 7.7, note that the peaks of several of the channels were reached on different phases of the waveform, giving the erroneous appearance of a phase reversal. Computerized source localization techniques are especially sensitive to the selection of the appropriate time frame. Errors in identifying the peaks that are to be mapped can cause extraordinary displacements in the apparent localization of the sources (82,83).

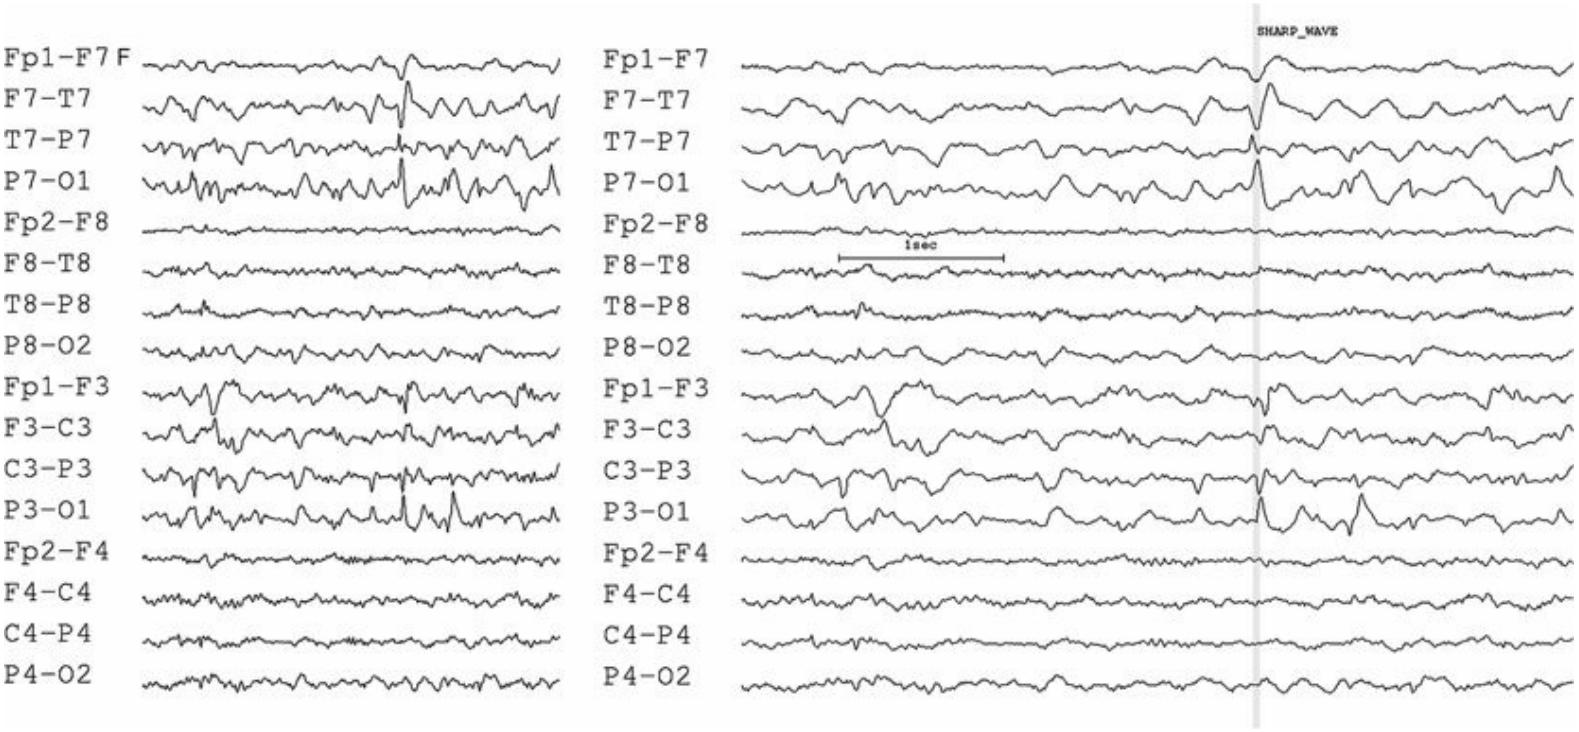

Figure 7.7. Phase reversals—choosing the same component. Be certain to select the proper phase of the discharge. The EEG on the left appears to show a confusing distribution, at first glance, with phase reversals at multiple sites. On the right, the timescale of the same epoch has been doubled. The vertical marker reveals that the discharge actually consists of three phases, with each peak at a slightly different time. The phase reversal at T_7–P_7 occurs prior to the phase reversal at P_3.

The peak of the sharp wave (i.e., the negative extrema) generally has the highest amplitude at the electrode closest to the involved cortical epileptogenic neurons (7). The main component of an epileptic discharge may be preceded by a smaller deflection of the opposite polarity. Early components show a more localized field than later ones (84,85), and they are more synchronous than the slow wave that frequently follows a spike. Thus, the initial deflection probably contains more localizing information (36), and employing the lower- frequency waves for localization may not always represent the epileptogenic region.

Mapping the Electrical Field

The two-dimensional display of the scalp regions involved in epileptiform or other activity is called mapping. Isopotential lines are drawn on a representation of the scalp to specify the topography of equivalent electrical potentials, similar to the isocontour lines drawn by a surveyor on a land map. From the area where the activity is maximum, succeeding regions that are further away will show a lower amplitude and can be divided into convenient isopotential contours. Because EEG amplitude is always measured with respect to a reference, the absolute amplitude will be dependent on the reference. But as shown in Figure 7.8, the shape of the contour distribution does not change with the reference.

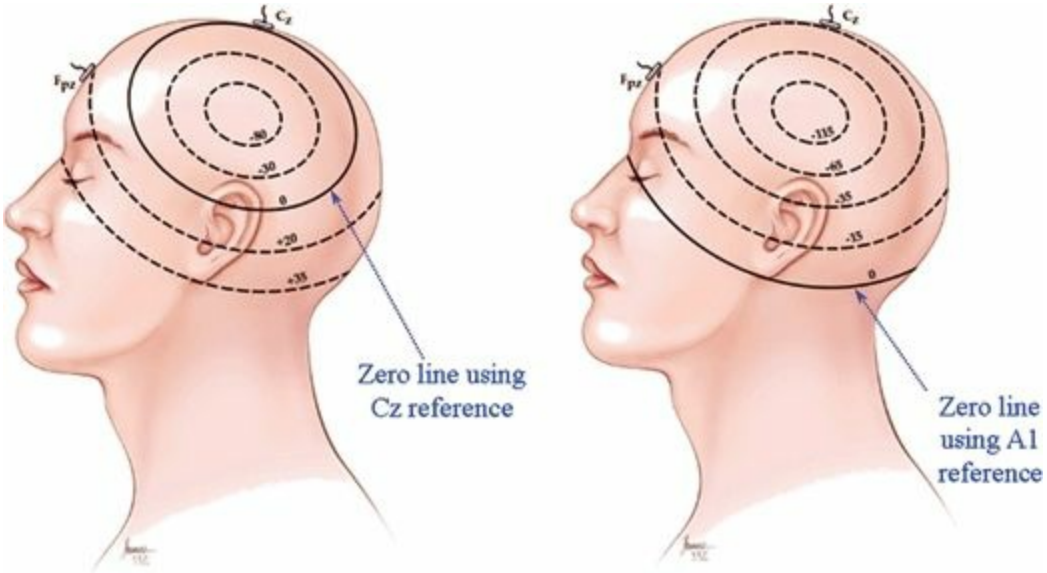

Figure 7.8. Topographical distribution of electrical potentials (in microvolts). EEG amplitudes are always measured relative to another reference. Note that the specific choice of reference electrode does not affect the shape of the isocontours of this left temporal discharge.

The potential fields of spikes and sharp waves can be mapped even without electronic assistance by tracking the relationships of the electrical potential level between electrodes. As the initial step, a longitudinal or transverse chain of the electrodes is used to map the one-dimensional relationship of voltage level to electrode position, as illustrated in Figure 7.9, top. Then, two chains are connected to each other through a common electrode to obtain the two-dimensional relationship. To create an isopotential contour map, a 100% value is assigned to the maximum and a 0% value is assigned to the minimum. However, as discussed later, the polarity of the maximum depends on an assumption about the generator. The "maximum" may be the highest negative point or the highest positive point. Similarly, the "minimum" may be negative or positive or may have a mid-curve value when two maxima of opposite polarity are assumed, for example, a horizontal dipole generator. Depending on the polarity of the maximum, that is, the point given a 100% value, at least two different isocontour maps can be obtained, as shown in Figure 7.10. To make the correct choice, some assumptions must be introduced, as described later.

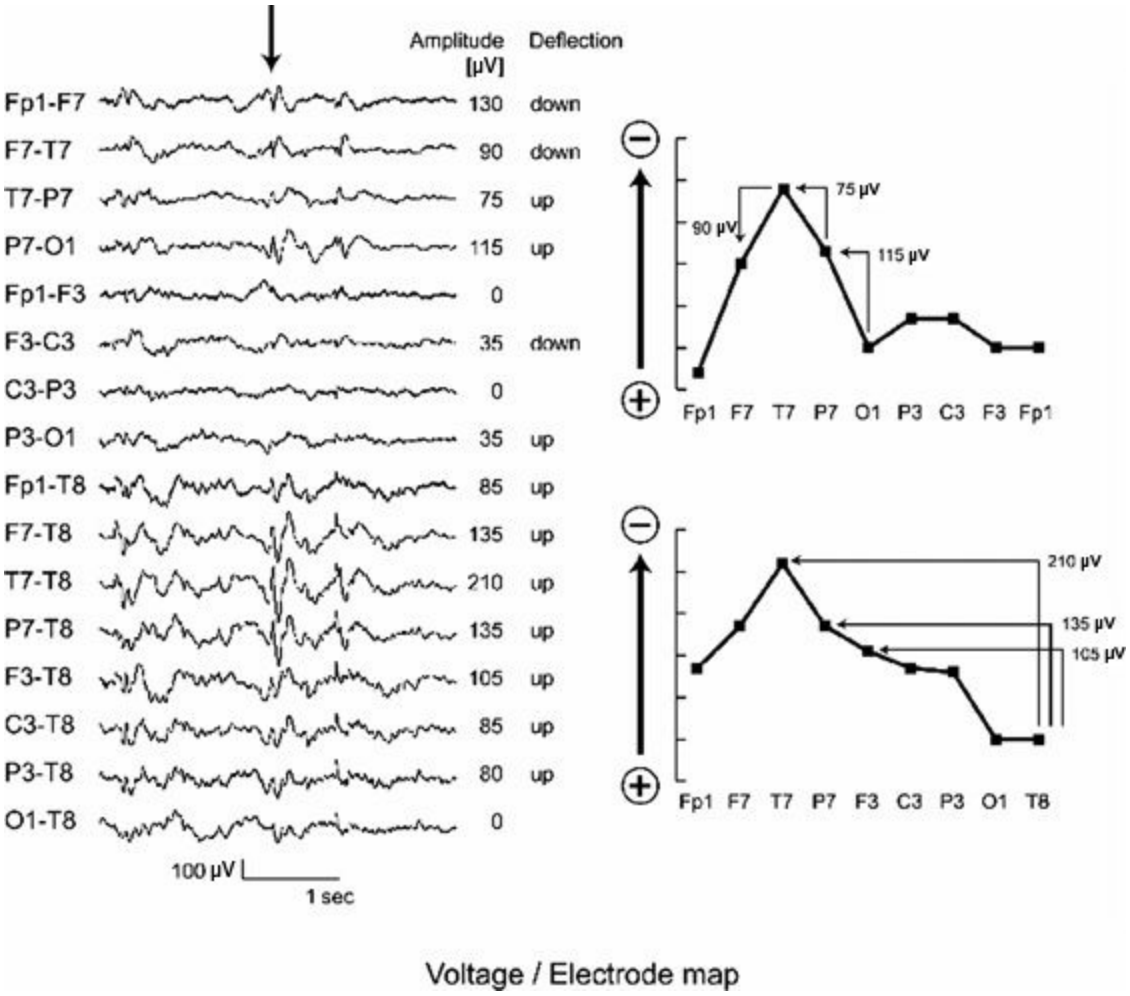

Figure 7.9. Voltage/electrode map. The EEG shows the same activity in two different montages: A bipolar montage in the top eight traces and a referential montage in the bottom eight. Two voltage/electrode maps for the spike indicated by the arrow are reconstructed manually from the two montages, respectively. In the bipolar montage, the difference of the potential level (amplitude) and relative polarity (deflection) between neighboring electrodes is sequentially tracked along the "chain" of the montage. Here, the potential mapping was started from a common electrode O_1 with a value of 0 μV assumed. Employing the algebraic relationships between the electrode derivations, the calculated amplitudes at each individual electrode are graphed. The resulting voltage level at Fp_1 differed slightly between the two bipolar chains, owing to minor differences in manual measurement of the amplitudes. For the referential montage, the measured amplitudes are written down directly, as no calculations are necessary. If all the deflections are in the same direction and the referential electrode (input 2) is located at the minimum, as seen in this example, then the amplitude of the deflection simply reflects the voltage level of the electrode. No matter which montage is used, the field determination should be same in terms of location of the maximum. The voltage/electrode maps may differ in detail, however, reflecting a varying degree of visibility of the spike between montages.

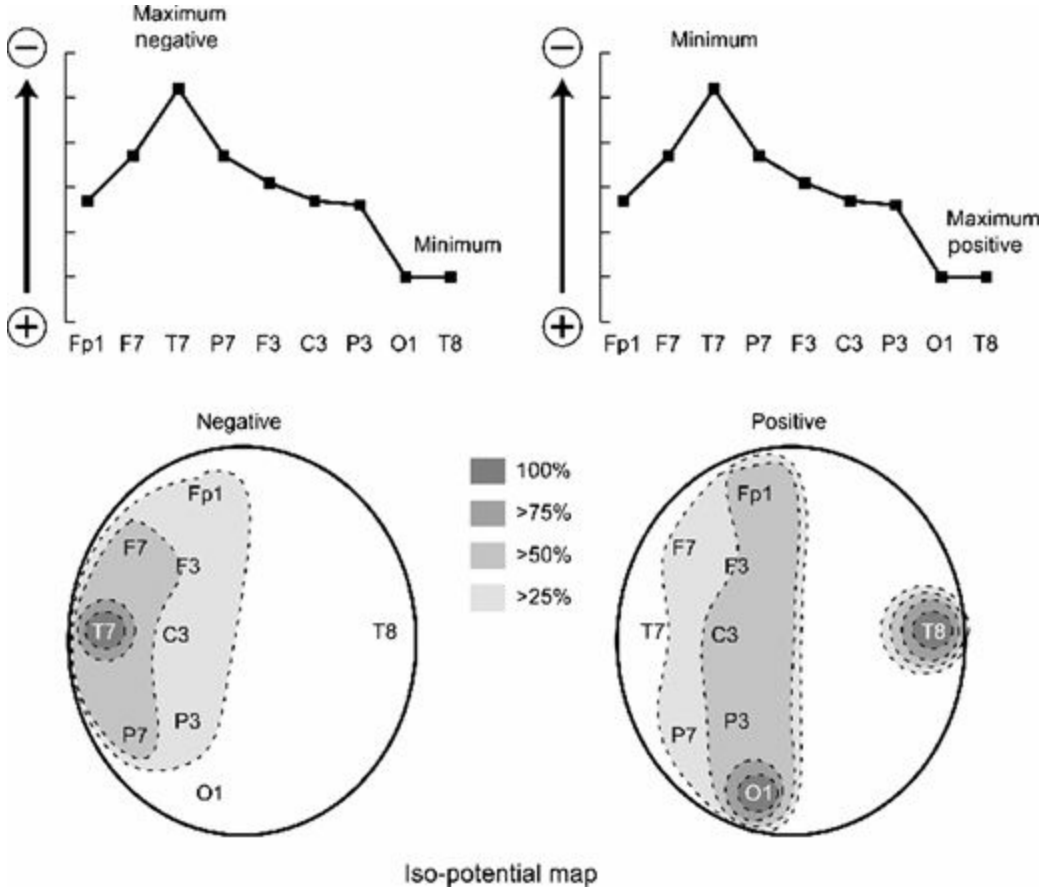

Figure 7.10. Isopotential map. As in Figure 7.9, the vertical axis of the top figures represents electrical potential, and the horizontal axis shows electrode location. A 100% value is assigned to the maximum, and a 0% value is assigned to the minimum. Depending on the polarity of the maximum, at least two different maps can be obtained, illustrated on the bottom row. In the map on the left side, the maximum is assumed to be negative, and the falloff of potential with distance is physiologic. On the right, the opposite assumption was made, that is, the maximum is a positive potential, resulting in a very unphysiologic distribution. Thus, it was deduced that this spike has maximum negativity from the left temporal area.

The ideal situation in referential recording occurs when the reference electrode is totally inactive or picks up activity of negligible amplitude. In this situation, those channels showing some activity will deflect in one direction only, as illustrated in Figure 7.9, bottom. The electrode closest to the generator will show the largest waveform deflection, and the amplitude of the deflection in all the other channels will be directly proportional to the magnitude of the activity recorded from each of those electrodes. This situation makes it especially easy to find the maximum and to assess the extent of the field distribution (see Fig. 7.9). To achieve this ideal situation, a contaminated reference must be recognized and a "distribution montage" constructed instead, typically with a reference electrode from the other hemisphere (Fig. 7.11).

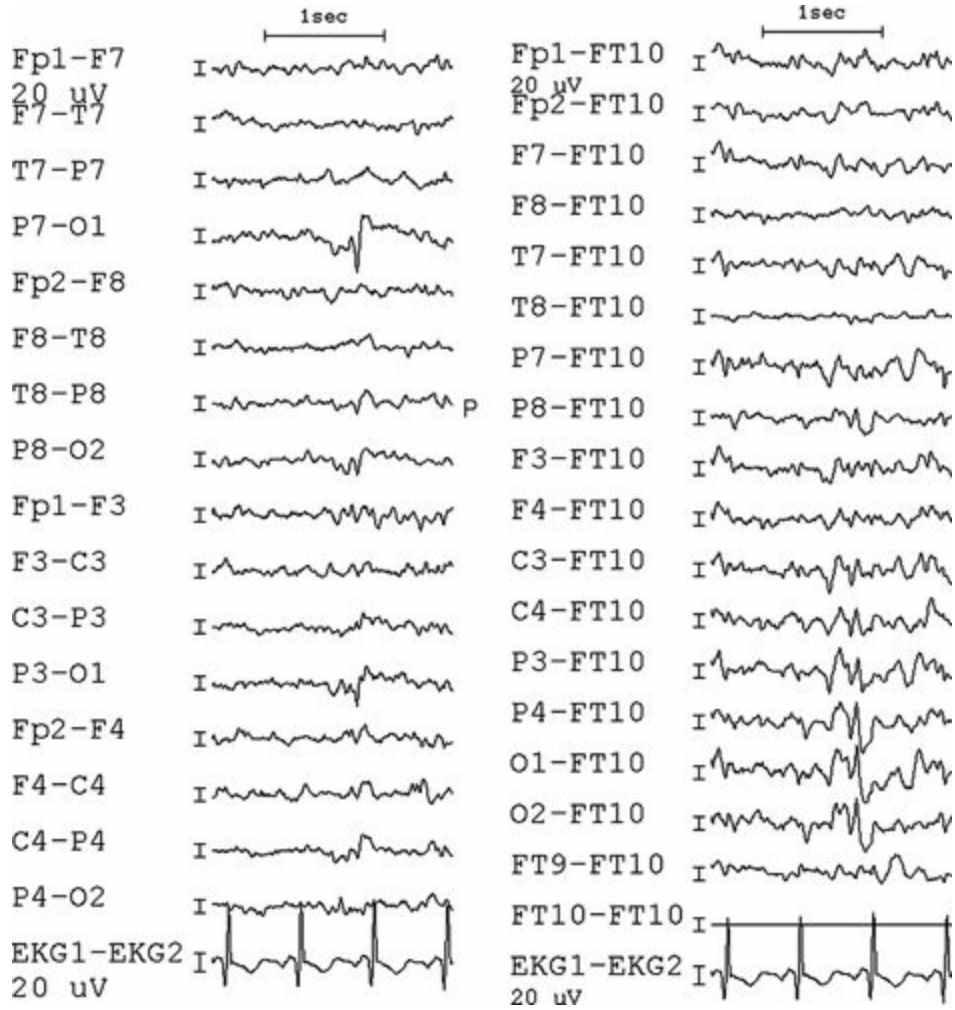

Figure 7.11. On the left, a bipolar montage with no phase reversal suggests that the activity is either at the beginning or at the end of the chain. The same time period is shown on the right, and the distribution montage to an uninvolved contralateral electrode confirms the left posterior maximum of this surface-negative discharge.

In mapping potentials measured from a bipolar recording, the bipolar measurements first must be converted to voltages relative to a selected "reference" electrode. The wisest choice usually is to select the least involved electrode at the beginning or end of the chains, taking advantage of the fact that certain electrodes are common to more than one chain. For instance, in the "double-banana" longitudinal montage, the frontal polar and occipital electrodes occur in both ipsilateral chains. These common electrodes provide an electrical connection between chains and allow an algebraic determination of the potential gradient of the electrical field over the entire area covered by the two chains. Because all the electrodes in both chains are related to each other by a sequence of subtractions, one can determine the relative amplitude at any electrode to the reference electrode. Of course, the exact amplitude (in absolute terms) at any scalp electrode is unknown. However, electrodes relatively distant from the site of maximum activity "see" a negligible potential, hence the assumption that the potential of the particular transient under study at these uninvolved electrodes is zero. The fact that the potential at this uninvolved electrode may not be exactly zero is unimportant because the relative differences between electrodes will be appropriately preserved.

Although it is possible to localize a spike or sharp wave from a single montage if electrical connections between the chains (or appropriate assumptions) exist, recording from multiple montages, especially "crisscrossing" montages, will help to confirm the topography of the discharge and can better define the topographic distribution. When the amplitudes of the potential distribution do not match exactly between chains or montages, the discrepancies most likely arise from errors in

visual measurement, erroneous assumptions of zero potential, or difficulty recognizing the same waveform in different montages. Generally, referential montages with uninvolved references will be better able to map the distribution of the activity.

The procedure for mapping the potential field, illustrated in Figures 7.9 and 7.10, can be summarized as follows:

1. Measure the amplitude of the component of interest in each channel.
2. Select an electrode that appears to be uninvolved. Assume a value of 0 for that electrode.
3. Calculate the amplitude of all the electrodes relative to the selected electrode, based on the algebraic relationship established by the montage.
4. Follow this procedure for all the chains connected by common electrodes.
5. Assume another zero electrode to calculate the distribution in chains not connected by a common electrode.
6. If the resulting distribution has potentials both above and below zero, start with another "zero" electrode.
7. Draw isopotential contours around the resulting distribution.
8. If the topographic distribution is unphysiologic, assume the opposite polarity for the waveform.

These principles can be applied most profitably when electrode montages are simple and systematic, as recommended by the American Clinical Neurophysiology Society (79).

Rules for Field Identification

A practical set of rules for identification of the electrical fields seen on the EEG is outlined in Table 7.1. The following sections provide more detailed instructions for the application of these rules.

Table 7.1 Rules for Potential Distribution

Montage type	Phase reversal	Conclusion
Bipolar	No	Maximum or minimum is located at the end of the chain
Bipolar	Yes	Maximum or minimum is located at the electrode of the phase reversal
Referential	No	Referential electrode is either maximum or minimum
Referential	Yes	Referential electrode is neither maximum nor minimum

Bipolar Montage

Derivations in a bipolar montage are customarily arranged in chains (6,79,80); that is, the electrode connected to input 2 of one channel is also connected to input 1 of the next channel. Electrode chains

are usually parallel, along transverse or sagittal axes, and contain no single electrode common to all channels.

When the deflections of two channels move simultaneously in opposite directions, this defines a "phase reversal." The presence or absence of phase reversals provides useful and immediate clues to localize maxima and minima. Whether the montage is bipolar or referential radically alters the meaning of the phase reversal (Table 7.1). In bipolar montages, there are two types of phase reversals: negative phase reversals (wherein the deflections point toward each other) and positive phase reversals (wherein they point away from each other).

If there is a phase reversal, the electrode where it occurs is either the minimum or the maximum of the electrical field. (The term "maximum" denotes absolute value, not necessarily maximum negativity.) The location of the maximum depends on the assumed polarity of the generator. Phase reversals involving surface-negative activity generate a negative phase reversal, in which the deflections "point" toward each other. However, the same picture theoretically could result from a positive electrical field that is minimum at the site of the phase reversal and larger at the ends of the chain. Conversely, a positive potential maximum at an electrode in the middle of a bipolar chain will cause the deflections to point away from each other, that is, a positive phase reversal.

If there is no phase reversal, then the electrical field maximum must be located under either the first or the last electrode of the chain (Fig. 7.12). The potential field minimum must then be at the opposite end of the chain. Because the potential gradient for each pair of electrodes in the chain is in the same direction, the potential decreases progressively from the electrode with the highest potential to the one with the lowest potential.

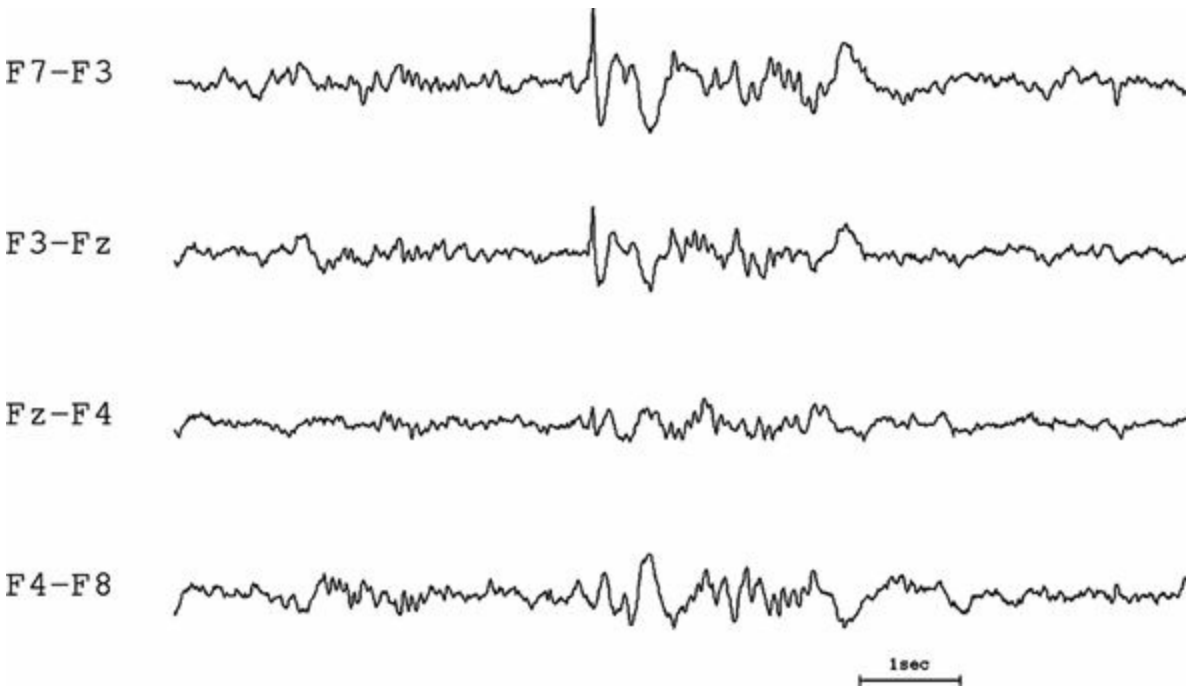

Figure 7.12. Bipolar montage with no phase reversal. Electroencephalographers are used to looking for phase reversals in a bipolar montage. In this tracing, there is no phase reversal; therefore, the discharge must be coming from either the beginning or the end of the chain. If the sharp wave is negative, implying that the activity is at the beginning of the chain (F_7), the distribution has a much more realistic falloff (i.e., it has a single peak with a monotonic decline). If the sharp wave is assumed to be positive, then the maximum would have to be at the end of the chain (F_8) with an oddly flat distribution on the right and a rapid falloff on the left.

In a bipolar montage, the amplitude may be misleading because it indicates differences in electrical potential and not the electrode of maximal involvement (Fig. 7.13). Because the gradients

tend to be steeper in regions of highest activity, the electroencephalographer may habitually but unwisely determine the maximum on the basis of amplitude. Inexperienced electroencephalographers will often (erroneously) localize by a cursory impression of the "maximum field." It is very important, however, to keep in mind that recordings made between a pair of electrodes (a derivation) are actually measuring the electrical gradient.

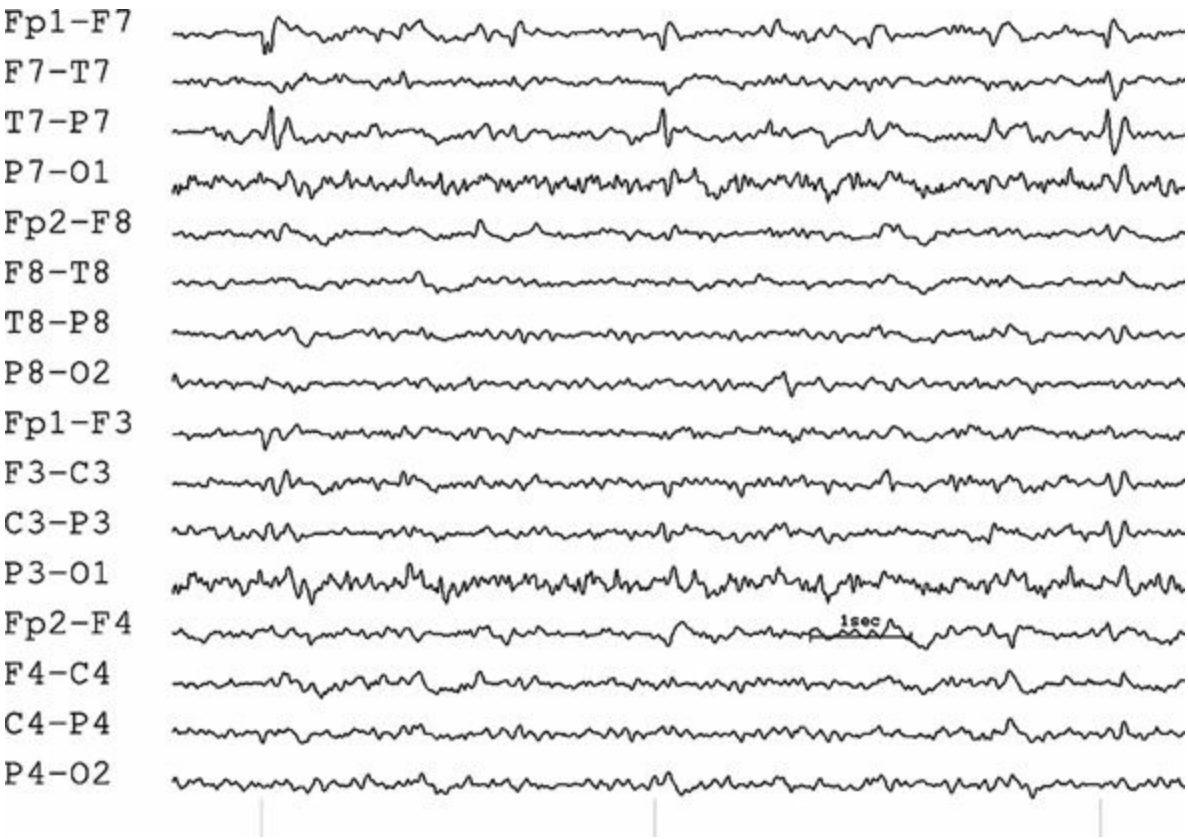

Figure 7.13. Bipolar montage with phase reversal. The amplitudes of the differences between the voltages at input 1 and input 2 do not indicate the maximum of the electrical field. In this circumstance, the amplitude of the sharp wave is actually maximum at F_7 and T_7, but approximately equal in those two adjacent electrodes, so the discharge is localized to both electrodes.

Referential Montage

All derivations in a referential montage connect the same electrode (or electrode combination) to input 2. If some derivations within a given montage use one reference electrode (e.g., the left ear) whereas others use a different reference (e.g., the right ear), only those sets of channels with a common reference should be analyzed together.

If there is no phase reversal (as shown in Fig. 7.14), the reference electrode (i.e., the one connected to input 2) is either the minimum or the maximum of the electrical field. If the reference electrode is the minimum of the electrical field, the maximum will be at the electrode with the largest amplitude. This situation is the easiest to analyze, because the amplitude of the deflection in each channel directly reflects the level of activity in input 1 of the channel.

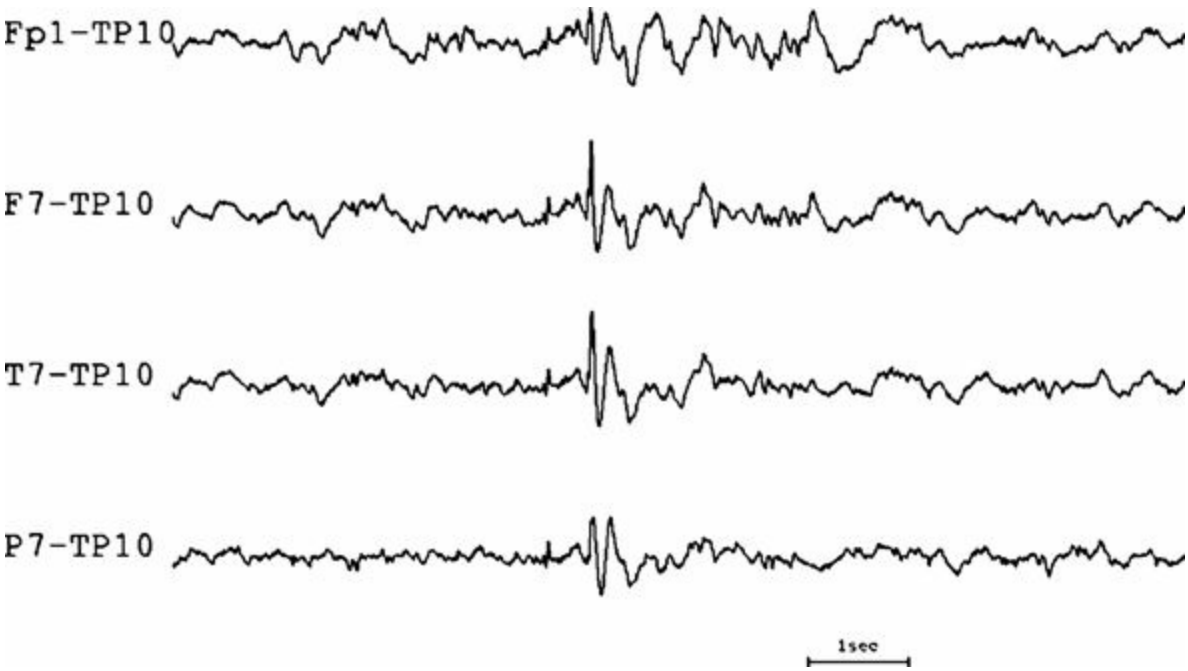

Figure 7.14. Referential montage with no phase reversal. This montage, which employs a contralateral reference chosen because it appeared to be uninvolved in the discharge, helps to clarify the location of a spike widely distributed across the left temporal region.

If the reference is maximum, the electrode at input 1 of the largest amplitude channel is at the minimum of the electrical field. If the reference is maximum and some channels show no deflection, the electrodes connected to input 1 of those channels are also maximum.

If there is a phase reversal, then the reference electrode is neither the minimum nor the maximum of the electrical field (Fig. 7.15). Hence, the reference is "involved," that is, at some intermediate potential. This indicates that some electrodes connected to input 1 have a greater potential and some a lower potential than the reference. If, for instance, the polarity of the discharge is negative, those electrodes connected to input 1 that have a higher potential than the reference will point upward, whereas those less negative than the reference will point downward. The channels that show no activity (isopotential with the reference) measure a negativity at input 1 equal to that at the reference. If the recorded potential has two maxima of opposite polarity, such as seen in tangential dipole sources, then referential montages will show phase reversals even if the reference is the minimum.

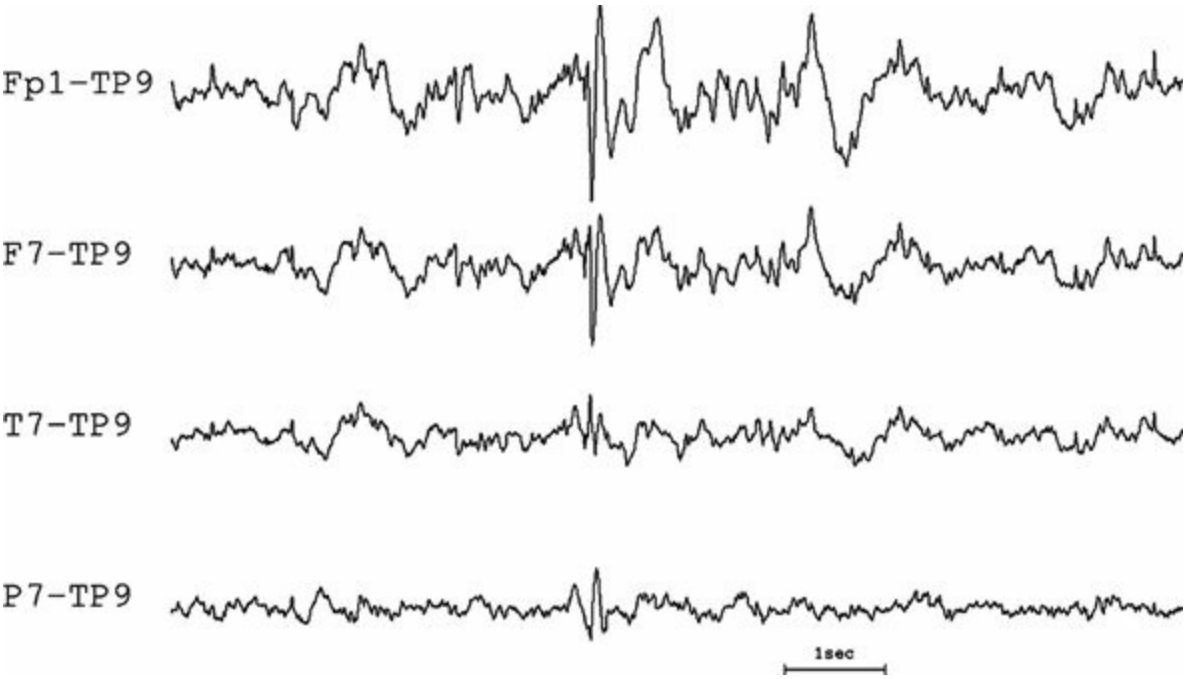

Figure 7.15. Referential montage with phase reversal. Since there is a phase reversal between channels 2 and 3, the reference is neither minimum nor maximum, that is, it must be "involved." This tracing is actually of the same discharge as shown in Figure 7.14, employing a less wisely chosen reference.

Choice of a Reference

In a referential montage, any electrode may be the reference, but a reference that is one uninvolved in the electrical field will best suit the electroencephalographer's purpose. The voltage difference between any pair of electrodes is entirely unrelated to the choice of reference (86,87); subtracting the voltage measured referentially at electrode B from that measured referentially at electrode A will produce exactly the voltage measured bipolarly from the A–B derivation, regardless of the reference chosen. This is true for a single electrode or a mathematically calculated one such as the average reference (88–90) and is the principle of computer-aided montage reformatting.

The amplifiers in a reference montage perform their differential function exactly as in a bipolar montage. Referential recordings measure not the absolute potential under the various scalp electrodes but the potential difference, as do bipolar recordings. Specifically, however, they measure the difference between each electrode and a chosen common reference. Instead of chains of electrodes, with each succeeding amplifier sharing one input from the previous amplifier, all the amplifiers share a common input 2. What the amplifier "sees" depends on the electrical relationship between the reference and the field of the waveform. The reference may be completely uninvolved in the field (a minimum), may be in an area that picks up a higher value of the waveform than any of the other electrodes (a maximum), or may lie somewhere in between (neither a maximum nor a minimum).

When mapping the distribution of a particular wave, the choice of reference electrode will affect the appearance of the traces as well as the electroencephalographer's ability to localize. For evaluating epileptic foci, the reference is normally chosen to be completely uninvolved in the electrical field distribution of the spike or sharp wave (all deflections should point in the same direction). Typically, the electrode most distant from the activity of interest will be the least involved reference. "Standard" referential montages occasionally include the reference in the field distribution (some deflections pointing upward, some downward). An electrode at the vertex (C_z) is an excellent reference for displaying temporal spikes but may be a poor choice during sleep when it is very

active. In the linked-ears reference (91) (frequently used to decrease electrocardiographic artifact), the reference electrode (A_1 connected to A_2) connects the two brain regions. This electrical shunt changes the field generated (92), decreasing, for example, asymmetries between the temporal regions (9) and producing other distortions (93). The "weighting" applied to activity from each side will depend entirely on the electrode impedances, with the ear having the lower impedance predominating. When temporal lobe epileptiform activity spreads to the ipsilateral ear, the linked-ear reference will inappropriately reveal spikes in both hemispheres.

A common average reference has been advocated (89) to avoid the problem of an "active reference." Using passive summing networks, active amplifier configurations, or combinatorial software, it is possible to devise a reference that combines all the electrodes applied to the head, the so-called common average reference (88,89). The disadvantages of this system are threefold: (i) The common average reference is, by definition, contaminated because the abnormal potential will influence all of the channels (94); (ii) depending on the number of electrodes included in the average, the potential under study will be reduced by a small proportion; and (iii) large-amplitude focal pathologic activities will be reflected proportionally in all the inactive channels as well, albeit with apparently opposite polarity.

A variety of calculated references and transformations are available, but these must be used with caution. The "source derivation" provides useful "deblurring" by arithmetically estimating the cortical sources that generate a scalp distribution; however, this method gives increasing weight to distant electrodes and can produce erroneous results when these sites are active (36,38,95,96). Because there is no ideal reference for all cases, it is usually best to distribute the electrical field potentials by manual selection of an uninvolved and quiet electrode as a reference.

SOURCE LOCALIZATION

Assumptions

After determination of the electrical field, the sources responsible for the production of the field can be localized with the aid of a number of simplifications. The procedure for determining the polarity and location of the generator is based on the following four specific assumptions:

1. Epileptogenic sources are simple dipoles or sheets of dipoles obeying a simple principle of superposition (48).
2. Dipoles are fundamentally oriented perpendicularly, with only one pole generally detectable on the scalp (78) and therefore can be treated as if they were monopoles. When both the positive and the negative poles are recorded from the surface, the localization system outlined below will not apply.
3. Epileptiform discharges are chiefly surface-negative phenomena. In the absence of a skull defect, a transverse- lying dipole (as in benign focal epileptiform discharges of childhood), or other evidence of an unusual discharge, the assumption of surface negativity will usually result in the proper distribution.
4. The head is essentially a uniform, homogeneous volume conductor.

Choosing Between Two Possibilities

The application of the rules above will yield two possible hypotheses in each case. In a bipolar chain, for example, a downward deflection with no phase reversals may be generated by either a negativity maximum at the last electrode of the chain (Fig. 7.16) or a positivity maximum at the first electrode of the chain. To choose between the two possibilities in any given case, one must guess about the polarity of the source generator or the relative likelihood of one of the two electrodes being the more active.

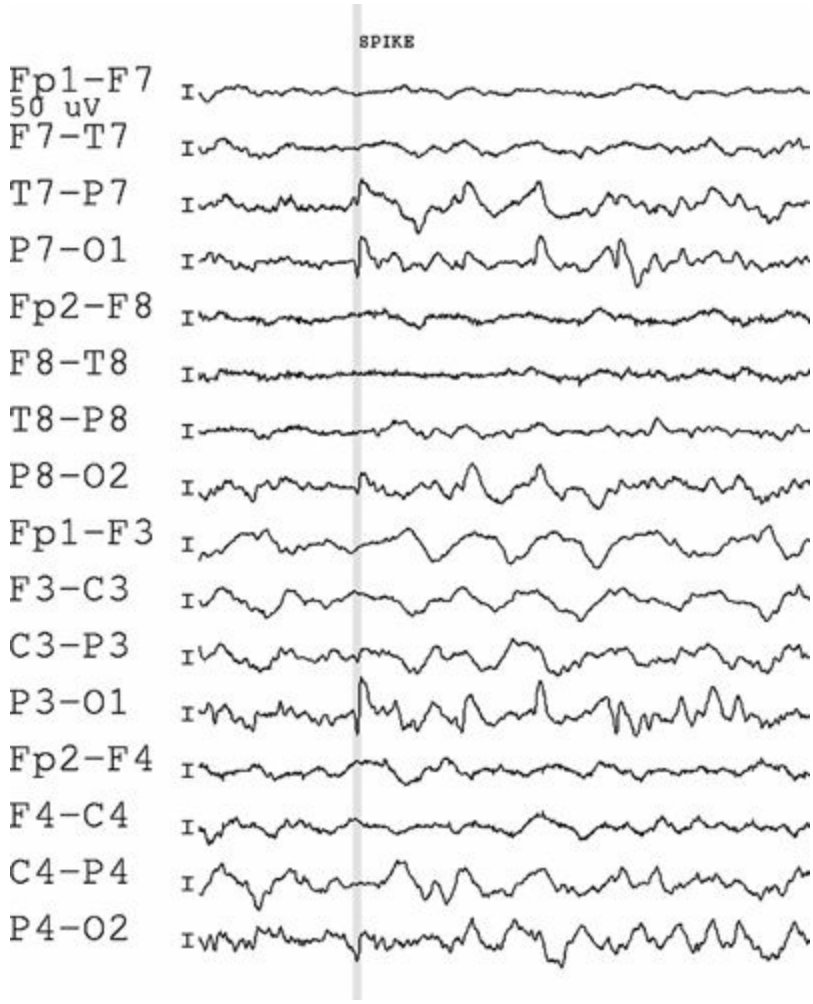

Figure 7.16. Bipolar montage with maximum negativity at the end of the chain. The marker brackets the downgoing negative component.

Because the localization of a transient will depend on a correct assumption about its polarity, all possible clues must be used to make an educated guess about polarity. For example, if the transient appears to be epileptiform, it is most likely to be surface negative, whereas if morphology and location suggest a positive occipital sharp transient (POST), it can be expected to be surface positive (Fig. 7.17). The best strategy is to see if the distribution based on the assumed polarity makes physiologic sense; if not, the opposite polarity will have to be tried. In Figure 7.10, the isopotential map based on an assumption that the polarity of the maximum is negative displays a more logical potential falloff for focal activity than the opposite assumption. Therefore, it is most likely that this activity has negative polarity with a maximum at electrode T_7.

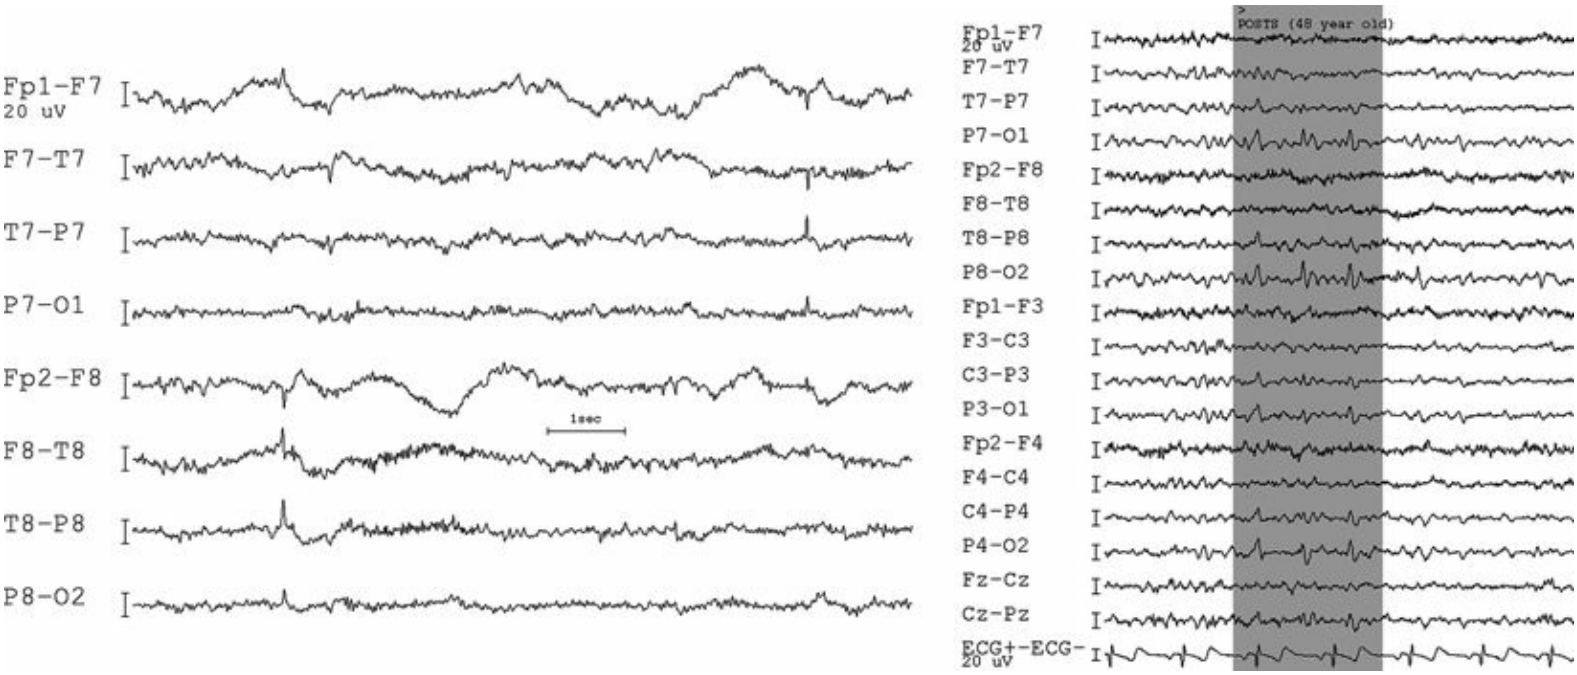

Figure 7.17. Clues to identifying the origin of sharply contoured waveforms. **Left:**Although these discharges stand out dramatically from the background, their presence during sleep and their very brief duration suggest that the transients here are "benign epileptiform transients of sleep (BETS)." BETS are often multiphasic, but the predominant component is negative, as in this example. **Right:** The electrical field distribution of these sharply contoured waves is consistent with POSTS (positive occipital sharp transients), that is, a positivity at the end of the chain. If the electroencephalographer assumed instead that they were negative, suggesting epileptiform discharges, their distribution across the entire head would have been more difficult to explain physiologically.

Determination of the electrical field of a discharge may help to differentiate artifacts or extracortical physiologic activity from abnormal brain activity (Fig. 7.18). Because the electrical gradient is steepest at the electrodes closest to the source, the electrical potential difference between inputs 1 and 2 becomes smaller as one moves farther away from the generator source (97). For this reason, the steepest potential gradient, and the largest deflection, will most often appear in the channels nearest the source.

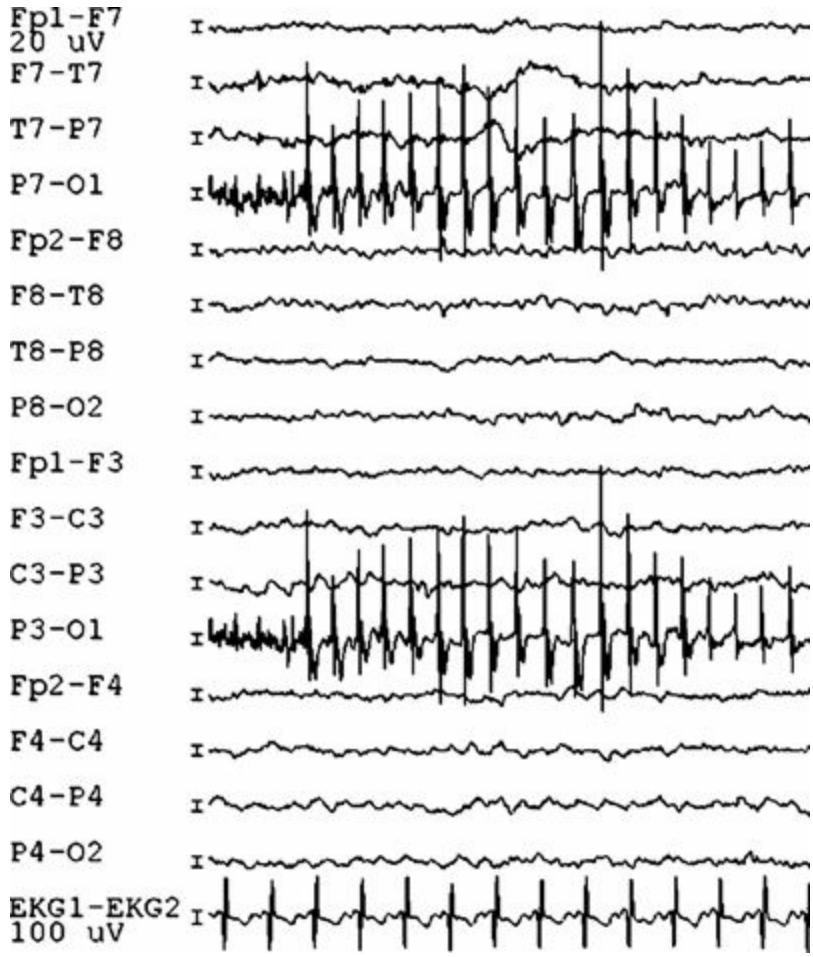

Figure 7.18. Artifacts. The sharply contoured discharges emanating from the left posterior region cannot be dismissed as artifacts on the basis of morphology alone nor do they match up with the EKG artifact. However, since they appear only in channels 4 and 12, they must be arising solely from electrode O_1. If these large-amplitude occipital "spikes" were epileptogenic, electrical field theory would dictate a much more gradual falloff. Because the field shows a precipitous, and therefore impossible, distribution, these discharges must be artifacts.

When dealing with an invariant spike, seen in various chains and montages, analyses based on any of the multiple electrode chains or montages should all reach the same conclusion (see Figs. 7.9 and 7.19). Corroborating a potential localized on a longitudinal montage by using a transverse montage (i.e., montages that are at right angles to each other), for example, can be helpful. If different conclusions result from the analysis of different montages, the assumptions about polarity or location were probably incorrect on one of the montages. Nevertheless, consistent conclusions across montages do not prove that the assumptions were correct, as the same error about polarity or location may have been made throughout the analysis.

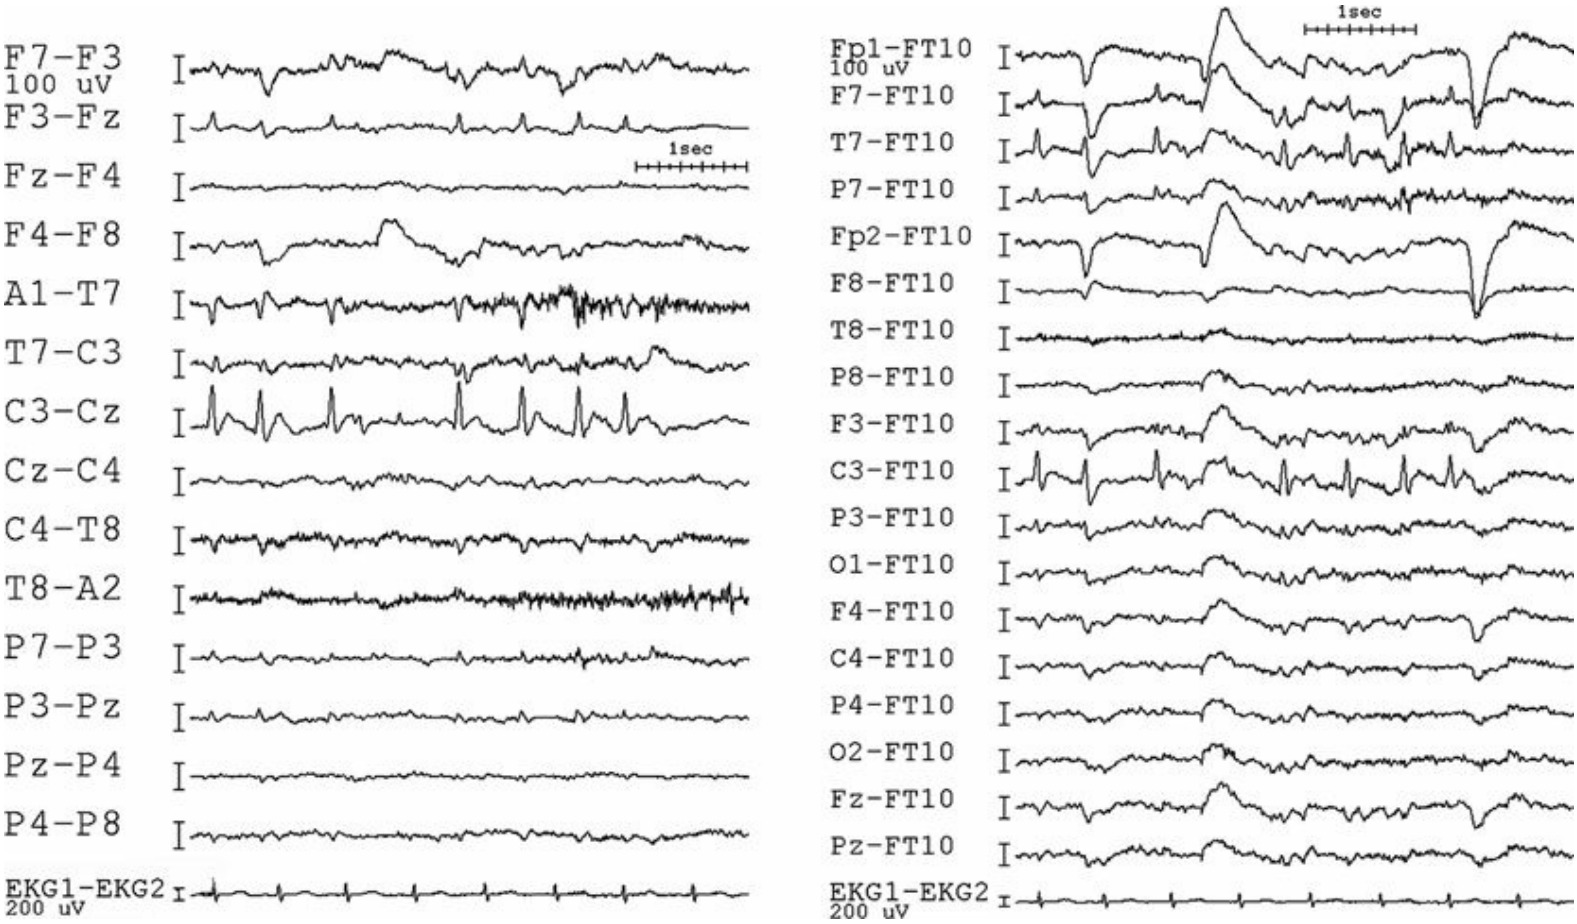

Figure 7.19. The phase reversals in the transverse montage shown on the left suggest the possibility of benign rolandic spikes. On the right, an ad hoc distribution montage employing a contralateral electrode clearly shows a typical centrotemporal distribution. It is also easier to distinguish the eye movement artifacts from the sharp waves in this montage.

Localization Rules: Cautions and Limitations

While the majority of this explanation has focused on the distribution of isolated transients, typically epileptiform activity, the same rules apply to the distribution of more prolonged or rhythmic activities, such as the wicket rhythm in Figure 7.20. Regardless of which component is chosen for analysis, the same principles can be applied. The simple rules and procedures for manual localization of electrical activity on the basis of bipolar or referential montages, outlined above, are valid only for single sources; that is, they presuppose a single monopolar generator. Regional abnormalities such as those encountered in focal epilepsy quite frequently satisfy this assumption as an approximation. Some EEG patterns, however, are produced by two or more generators of the same or different polarity acting simultaneously. When multiple sources or horizontal dipoles are involved, even highly sophisticated mathematical source localization techniques may not enable us to identify the exact composition of such generators.

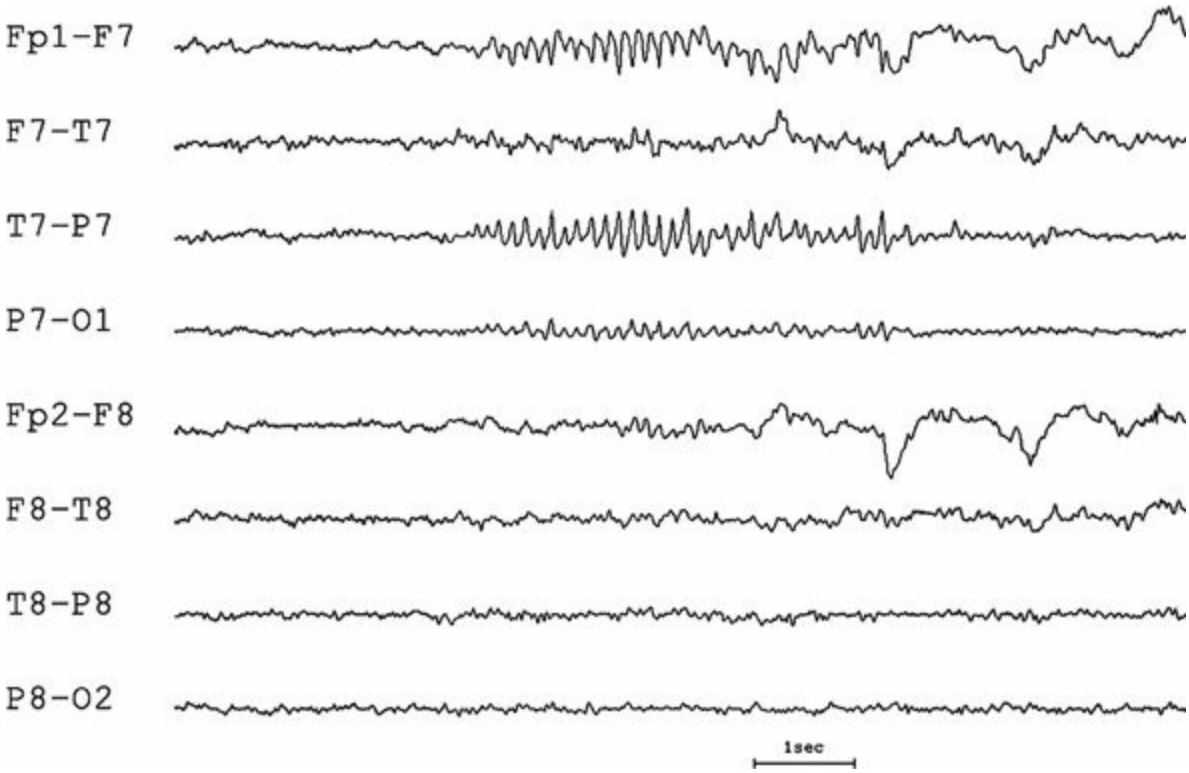

Figure 7.20. Bipolar montage with phase reversal. Phase reversals need not always occur in adjacent channels. This EEG shows the phenomenon for some normal activity rather than the abnormal discharges seen in Figure 7.13. The phase reversal of this arciform activity spans the isoelectric temporal channels, consistent with the broad distribution of a wicket rhythm.

Although both poles of the dipolar generator must be present by definition, one of them is oriented deep within the head, allowing assumption of a monopole. On occasion, however, both poles may be represented on the scalp surface, precluding the use of these rules. This occurs, for example, in the case of an epileptogenic focus originating from the superior mesial portion of the motor strip (98). Cortical regions involving the interhemispheric fissure, such as the foot area or the calcarine cortex, are especially likely to produce these horizontal dipoles. Specifically, the end of the dipole traditionally at the surface will be buried within the fissure with its maximum seen on the contralateral scalp, and the ordinarily deep end of the dipole may be close to the scalp surface on the ipsilateral side. Because of their location, horizontal dipoles also can be seen in benign focal epileptiform discharges of childhood (99).

The electrical fields resulting from these transverse dipoles are characterized by a simultaneous surface-negative and surface-positive potential seen at different electrodes on the scalp or by a double-phase reversal (13,100). Note that when double-phase reversals or other factors indicate, for example, a huge anteroposterior dipole or a transverse dipole extending from one hemisphere to the other (47), the physiologic meaning of such an unusual field must be questioned. A horizontal dipole should not be the first thought when the electroencephalographer confronts deflections pointing in opposite directions. An involved reference, the most common cause for this phenomenon, must be excluded.

As noted, in a bipolar montage, the channels of highest amplitude must not be confused with the area of greatest activity. This mistake is most likely to occur when the chain has no phase reversals, indicating that the maximum of the discharge originates from either the beginning or the end of the chain or when the maximum is broadly distributed across several channels (Fig. 7.20). A greater amplitude seen in one or more channels is solely a manifestation of a greater potential difference.

Obviously, determining whether a phase reversal is present is a key aspect of the localization

procedure. Multiple fast components may be confusingly mixed when viewed from a bipolar montage and are more accurately represented in a referential montage to identify the individual components that are phase reversing across channels. A discharge with an extremely broad field can result in rather tiny differences between adjacent electrodes.

Because the brain, skull, and scalp do not have homogeneous conductivity, current pathways from active epileptogenic areas can vary dramatically among the recording sites. This variability may lead to a site of maximal scalp activity considerably distant from the fundamental generator (101).

Although general physiologic and physical principles can explain the phenomena involved, clinical interpretation of a particular set of measurements often will have to be based on experience and information that is not easily derivable from first principles. Nevertheless, by remaining aware of alternative possibilities, the electroencephalographer can avoid misinterpreting unusual recordings.

COMPUTER-AIDED METHODOLOGY FOR LOCATING EEG SOURCES

Topographic Mapping of Voltage and Other Parameters

Topographic EEG mapping is the generation of a pictorial representation based on measurements obtained from multichannel EEG analysis—usually simultaneous, instantaneous amplitudes of some parameter. Computer-aided mapping can accurately summarize the field distribution and may help to highlight locally originating activity (102). Computed topographic maps can be used (i) to describe an already known localization (perhaps for communication with nonneurophysiologists), (ii) to confirm a conventionally determined localization, (iii) to identify changes not detected in the original interpretation, and (iv) to display statistical differences between patient populations (so-called Z scores) (103). These maps should always be used in conjunction with the raw EEG data (104,105).

Automated mapping may be used to represent the topographic distribution of any variable, whether derived from complex calculations or simply displaying electrical field distributions as shown in Figure 7.21, depending on the application. In the evaluation of epileptic patients, the topographic distribution of sharp waves may present a valuable display, once their characteristics have been reduced to a metric (106). It is important to remember that a computerized system is unlikely to perform the measurement in every case as it would have been done manually, so that visual inspection of the waveform is essential for each map (104).

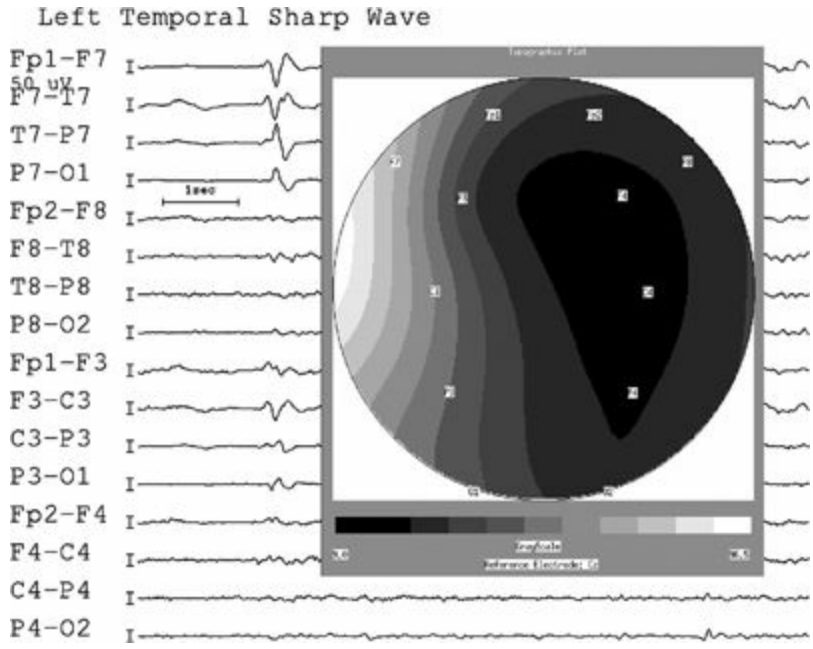

Figure 7.21. Topographic mapping. Digitization of the electroencephalogram offers the opportunity for interactive postprocessing that may help to convey location in an easy to understand way. In this figure, the electrical field of the sharp wave seen phase reversing at T_7 in the EEG has been automatically mapped onto a top view of a spherical model of the head. Using baseline-to-peak amplitude measurements from a C_Z reference, interpolating the amplitudes at every scalp location between electrodes, dividing into 10 isocontours, the amplitude map has been plotted as a gray-scale intensity. Koszer et al. (113) have demonstrated relatively good congruence between the manual process carried out by electroencephalographers described in the text and computerized topographic mapping methods.

When used to map the amplitude of the EEG or evoked potential at a specific point in time, interpolation between the voltages measured at the electrodes must be carried out to present a smooth contour on the map. The most practical interpolation method is the one based on spherical splines (107). Unlike magnetic resonance imaging and computed tomography, in which the intensity of every pixel is based on a measurement, topographic maps are derived from measurements at only 16 to 32 points, with the balance obtained via interpolation, creating the illusion of a higher resolution than actually exists.

Once the computer has associated the amplitude information with its topographic location, mathematical techniques even more powerful than electrical field mapping can be brought to bear. As a result of volume conduction, potentials generated within a small brain region will be seen over a wide area of scalp. The spreading of the field to the scalp can be mathematically reduced by current source derivation methods (102,108). These spatial deblurring techniques such as the Laplacian operator (109) can narrow the apparent distribution of the electrical field, thereby emphasizing discrete foci (94). The Laplacian operator supplies information about the locally occurring activity in a "reference-free" manner (81), taking into account the direction of the field along the scalp to define the differences between adjacent electrodes.

Commercial instrumentation for topographic mapping is relatively easy to use. Many EEG machines produce in real-time a topographic display, synchronized with the cursor positioned and continuously updated. Although much attention has been paid to the algorithms for generating and presenting these displays, there is a danger that the relatively complex calculations that go into generating these maps will lead to gross misinterpretation as a result of the wide range of variables (101,105,110,111). There are a number of pitfalls and caveats associated with topographic mapping (111,112) that have prevented widespread acceptance of this technique for most clinical applications

(101). Jayakar et al. (36) have described several limitations of these methods.

Computer-aided topographic mapping actually is not well suited to display epileptiform EEG elements owing to their rapid time course. Because not all the channels may be at their peak simultaneously, the maps may show an unexpected result, that is, the maps may demonstrate spike progression but will not necessarily reflect the manually determined localization (113). Moreover, computer topographic mapping of the amplitude of the EEG signal (or of evoked potentials, spectral measurements, or statistical analysis) provides no new information and cannot be used to make classifications not apparent in the raw data. Topographic mapping techniques, even with sophisticated enhancements such as the Laplacian operator or spatial deblurring, do not provide any conclusive three-dimensional information about the source of scalp-recorded signals (114). Nevertheless, they can make it easier to grasp the special relationships existing between electrodes in various neighborhoods of the scalp or to chart the progress of an epileptic discharge across the scalp as shown in Figure 7.22. To decrease errors, several restrictions imposed by the interpolation methods and the boundary value problem dictate the use of more electrodes than are conventionally placed. Indeed, adding closely spaced electrodes alone may reveal new information.

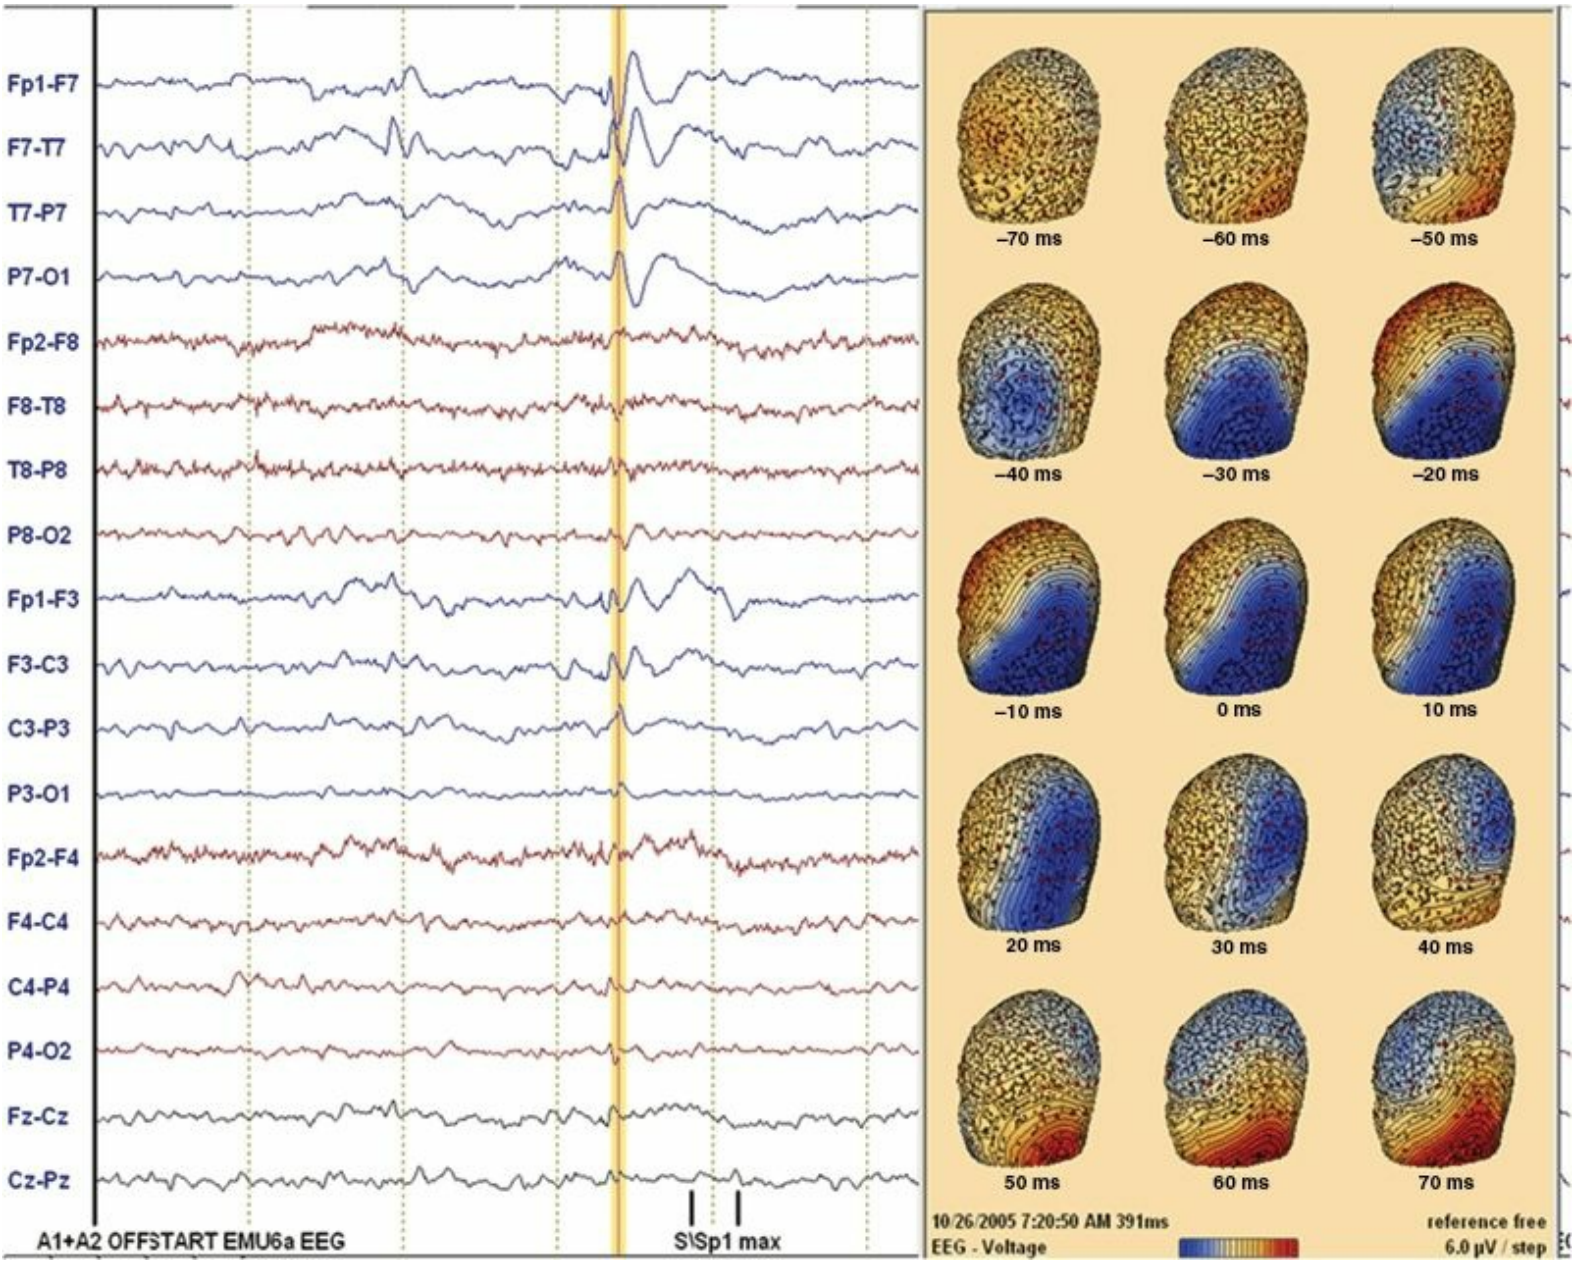

Figure 7.22. A sequence of topographic maps can show the evolution and subsequent dissipation of the electrical field of a spike.

Each of the snapshots illustrates the extent of the electrical field of this left temporal discharge in 10 msec time increments, spanning the 140-msec epoch swept out in yellow. On a computer screen, this can even be presented as a slow-motion cine loop.

Dipole Modeling and Source Localization

Visual inspection, aided by simple enhancements such as distribution montages and the rules outlined above, is the time-honored method to identify the location from which epileptic EEG activity arises. There are, however, difficulties in identifying the source of a scalp potential that derive, in part, from the fact that the amplitude seen on the scalp is a function of not only its distance from the generator but also the orientation of the dipolar generator. Not only do the generators of the EEG dipoles possess an orientation but also they are complex sheets of dipoles arranged on a convoluted surface, following the contours of the cortex. The other problem that distorts the relationship between scalp potentials and the underlying cortical generators is the nonhomogeneity of the cerebral tissue, scalp, and skull.

There are computerized methods for EEG source localization that attempt to address some of these difficulties. These packages (such as BESA) (15) and CURRY (115,116) were initially developed in the realm of research, and they provide myriad tools to calculate and extract quantities from electrophysiologic data (117–121). Computerized source analysis is an attempt to identify the origin of electrical potentials seen on the scalp by solving the "inverse problem." Source analysis is most commonly carried out by postulating a single or multiple spatiotemporal dipole models chosen to account for the surface signals and their timing relationships (122–124). Although the sources of electrical activity recorded by the EEG are actually folded sheets of dipolar pyramidal neurons, the traditional computer model typically uses only a single dipole with no spatial extent. In order to explain a widespread scalp distribution, the computer model tends to locate these dipoles deep to the actual cortical location. Solutions to the inverse problem involve simplifications and approximations and, even when well-defined dipoles using implanted sources in the human brain are employed, often produce errors of a few centimeters (63,125). Although it is not possible to uniquely identify the positions of the electrical sources in the brain from the scalp electrodes (126), appropriate assumptions can yield useful information in some cases (16,127). An illustration of the practical use of the equivalent current source dipole method to localize three epileptic discharge is shown in Figure 7.23.

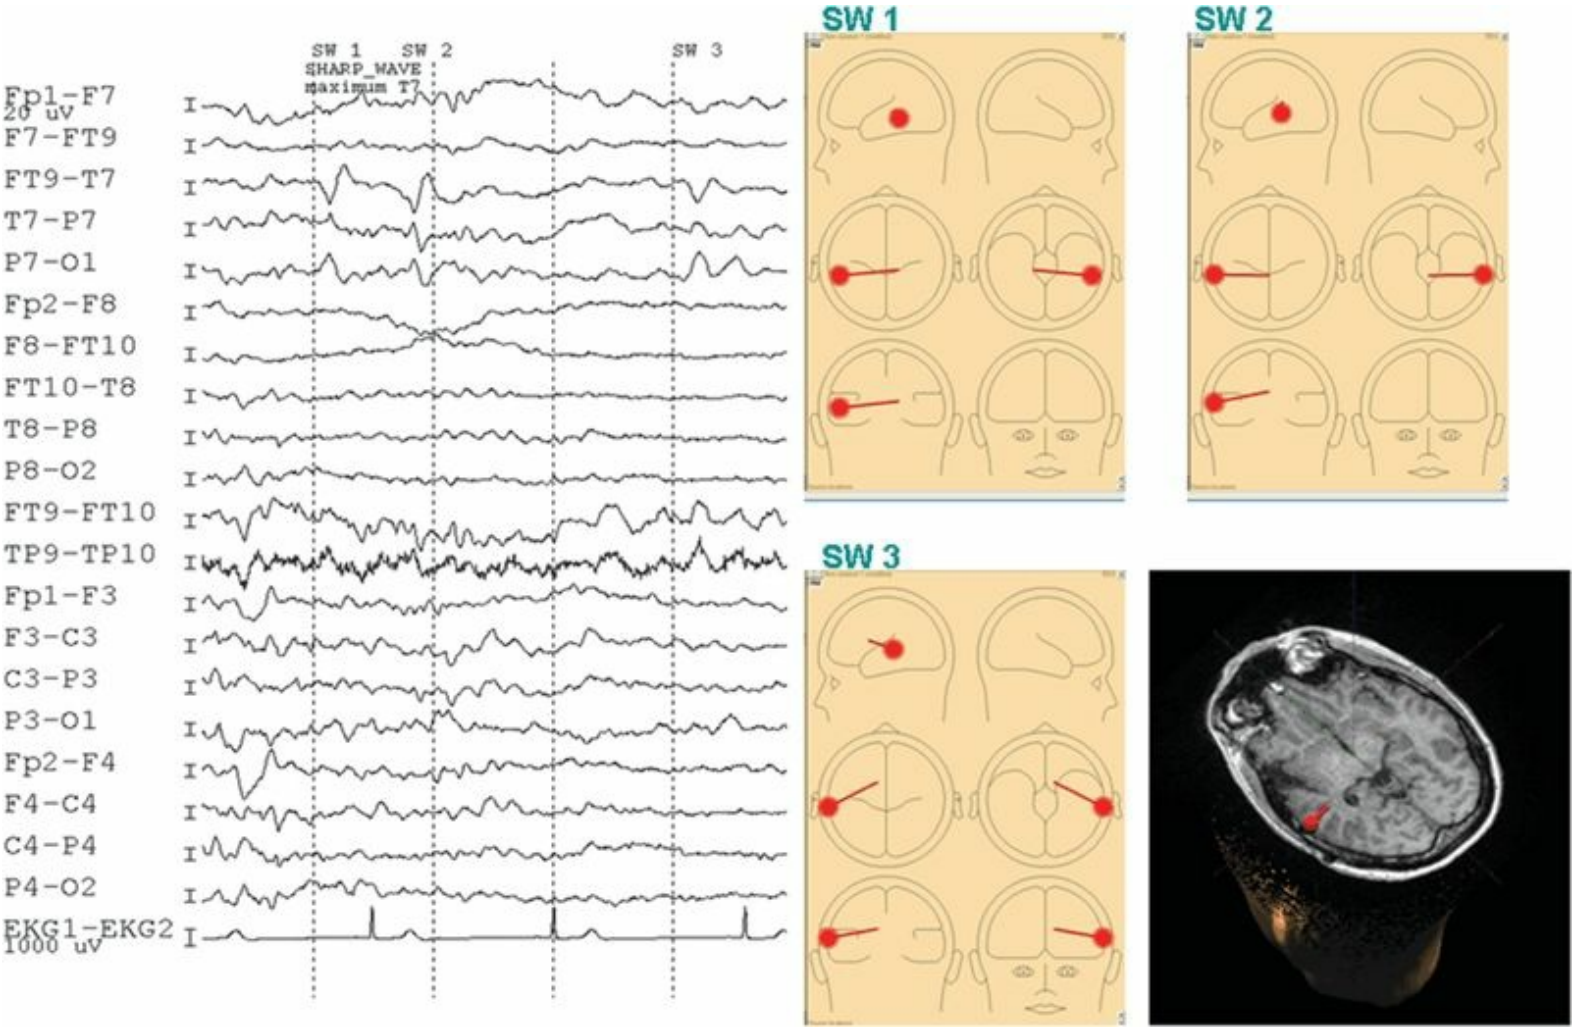

Figure 7.23. Source analysis of three broad, left temporal sharp waves using a single equivalent dipole. The location of sharp wave 3 is shown coregistered with the MRI.

Localization using dipole source analysis has been the subject of many validation (128) and comparison studies (129). In recent years, purveyors of these packages have enhanced their offerings to be of more use in clinical medicine. Several journals have dedicated special issues to the various aspects of this methodology (130), and there have even been some large prospective studies evaluating its value in presurgical epilepsy evaluation (131). Although computerized "source analysis" was applied beginning in the mid-1980s to identify single or multiple foci (122,123) and has been continuously developed for more than 25 years, the extra time and effort required have discouraged use of these techniques in EEG on a routine basis. This software methodology is sometimes limited, because in clinical use only the simplest of models of the source (e.g., equivalent current dipole) and the head (e.g., concentric spheres) are employed. While other source models exist that are perhaps more visually pleasing and can illustrate the activity of more broadly distributed activity (as illustrated by the min-norm example shown in Figure 7.24), they are still subject to the inherent limitations of the head model for EEG. The temporal dynamics of the source and the intracranial anatomic pathology associated with epilepsy often make these models inexact, and the results may be misleading (132). Even when artificial dipoles with known locations are localized, the errors in location range from 13 to 22 mm (133).

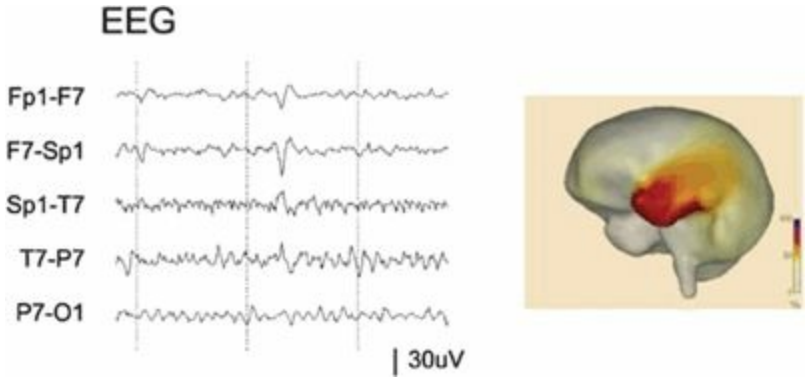

Figure 7.24. Distributed source modeling attempts to overcome the "point source" assumption of the single equivalent dipole model. A common method is the minimum-norm estimate, which postulates a large number (typically 5000 to 15,000) of fixed dipole sources arrayed throughout the active portions of the brain. The strength of each dipole is estimated and displayed as a color-coded intensity, as in this example of a left temporal sharp wave.

The source localization procedure attempts to account for all of the activity recorded by the electrodes. Therefore, activity that is unrelated to the waveform under study will have to be explained by the model as well, such activity as normal background (alpha rhythm, vertex waves, spindles), noncerebral signals (EKG, EMG), and artifacts (instrumentation, external machinery, electrodes). The effects of these other activities are difficult to recognize in the source localization results. Accuracy hinges on assumptions, and depending on the models and the procedure, there are multiple opportunities for errors (134,135):

1. Inadequate head model shape—nonspherical head, irregularity of concentric layers
2. Insufficient compartments in the head model—neglecting the skull in the spherical model
3. Anatomic layer conductivity and thickness measurement errors—especially the bone
4. Inhomogeneity of brain regions—such as ventricles, cystic, or resected areas
5. Measurement location error—differences between the actual locations and assumed locations of electrodes, fiducials, sources
6. Source modeling errors—differences between the actual source and the source model in shape and extent

It has been shown that even the conductivity anisotropy of brain tissue causes field distortions, for example, in the vicinity of large fiber tracts (136). It is important to remember that the results of source localization are, in the signal processing chain, considerably distant from the raw data. For this reason, it is important to apply these computerized methods with caution and to always display and review with the raw EEG. Despite the automated nature of computerized source localization, the electroencephalographer's expert judgment about a priori constraints and which sources to reject as possible solutions is of critical importance.

The different tissues that the EEG signal has to traverse on its way to the scalp have very different conductivities, thereby influencing the representation on the surface and consequently the accuracy of computerized source localization. These differences in conductivity between the brain, CSF, bone, and scalp have a negligible effect on the magnetic field. The modeling required for source localization of magnetoencephalography (MEG) signals—which arise from the same neuronal activity that generates EEG signals—is therefore much simpler, providing a generally more accurate computerized solution to this sophisticated inverse problem. The volume conductor model that represents the physical properties of the medium between the sources and the sensors is especially

complex for the electroencephalography of patients with highly distorted head anatomy. MEG, on the other hand, is unaffected by the tissue variations inherent in scalp, skull, CSF, dura, and brain parenchyma. The use of MEG for evaluation of epileptic patients is covered in detail in Chapter 76.

While new imaging techniques have decreased the importance of EEG for many neurologic disorders, EEG is still the sine qua non for the diagnosis of epilepsy. If the seizure semiology, ictal scalp EEG features, and the neuroimaging fail to produce a consensus regarding the focus localization, then further studies—usually including even more EEG from intracranial recordings—will be required in order to outline a target for surgical resection.

CHAPTER 8
ELECTROENCEPHALOGRAPHIC ATLAS OF EPILEPTIFORM ABNORMALITIES

SOHEYL NOACHTAR AND ELAINE WYLLIE

Electroencephalography (EEG) is generally considered the single most important laboratory tool in the evaluation of patients with epilepsy. This atlas of material from patients seen at the Cleveland Clinic Foundation and the University of Munich illustrates some of the EEG findings discussed throughout this book. Additional EEG atlases and textbooks are listed in the bibliography at the end of this chapter.

METHODS

These tracings were made following American Electroencephalographic Society guidelines (1), with electrodes placed according to the International 10-20 Electrode Placement System (2). Additional closely spaced electrodes according to the 10-10 system (Fig. 8.1) were used in some cases to better define a focal epileptogenic zone. The combinatorial electrode nomenclature used here is that recently proposed by the American Electroencephalographic Society (3) and the International Federation of Clinical Neurophysiology (2). The EEG terminology used in this chapter follows the recommendation of the International Federation of Clinical Neurophysiology (4).

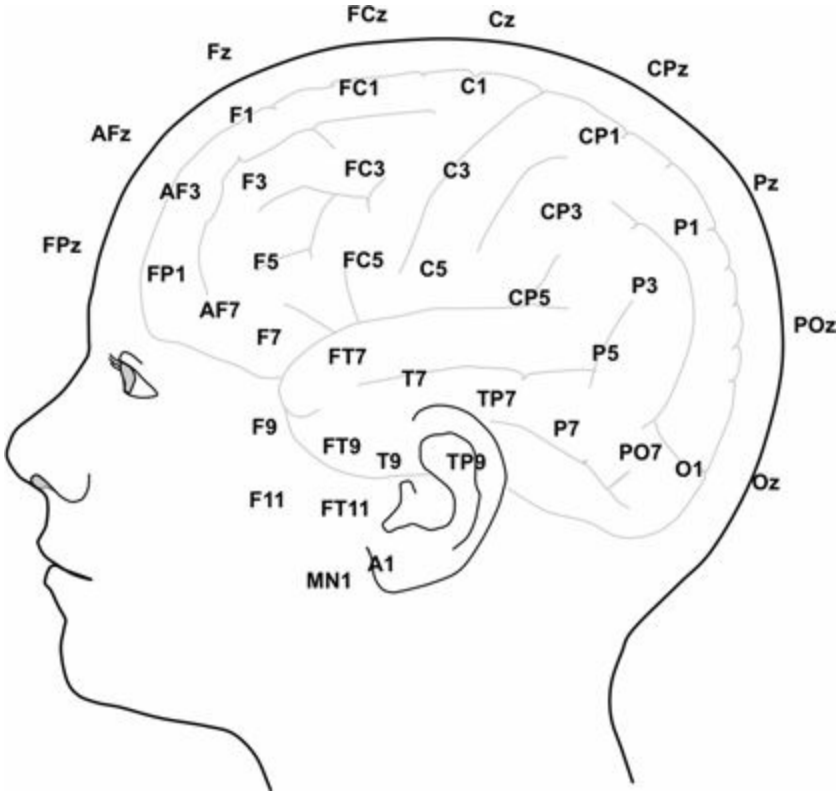

Figure 8.1. Electrode positions and nomenclature of the combinatorial 10-10 system proposed by the American Electroencephalographic Society (1) and the International Federation of Clinical Neurophysiology (2).

For consistency and ease of interpretation, we displayed most tracings with the same longitudinal bipolar montage (Fig. 8.2). Occasionally, the activity was best shown with a transverse bipolar montage (Fig. 8.3), a longitudinal bipolar montage with anterior temporal or sphenoidal electrodes (see Fig. 8.2), or a referential montage (Fig. 8.4).

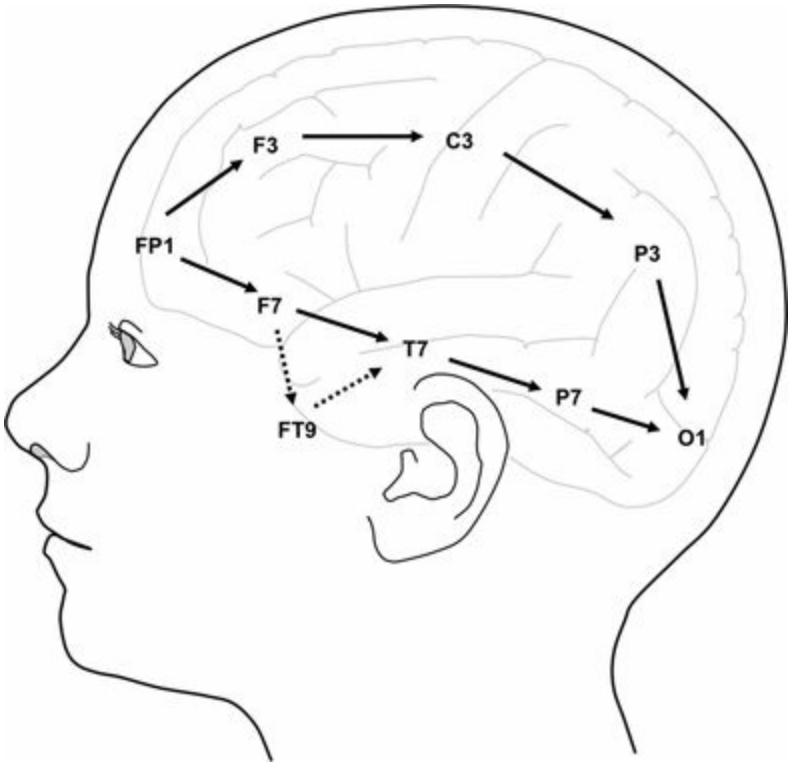

Figure 8.2. Longitudinal bipolar montage, left-sided electrodes. The "double-banana" montage used for almost all the tracings in this atlas includes the channels shown with filled arrows, ordered as follows: right temporal chain, left temporal chain, right parasagittal chain, and left parasagittal chain. The "anterior temporal" montage used in some of the tracings is modified to include the channels

shown with broken arrows to reflect anterior, basal, or mesial temporal discharges with anterior temporal (FT9, FT10) or sphenoidal (SP1, SP2) electrodes.

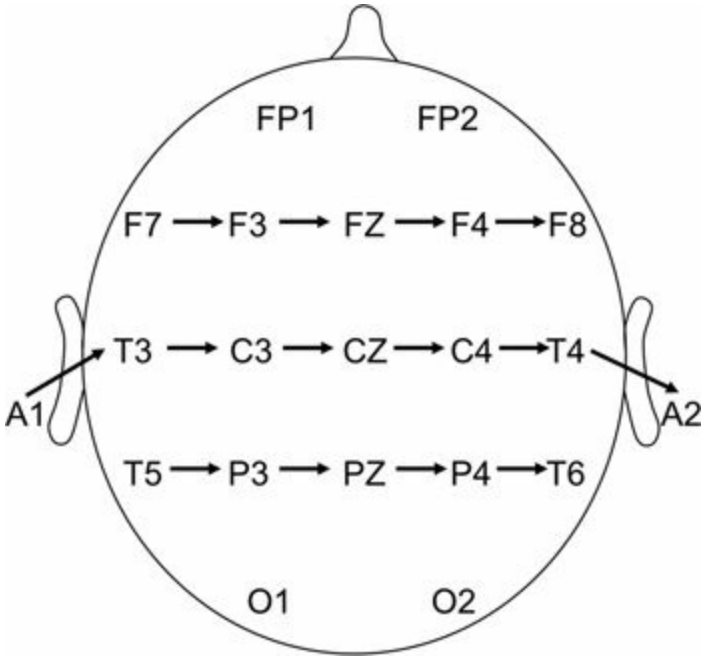

Figure 8.3. Transverse bipolar montage, vertex view. Channels are arrayed in order, as follows: frontal chain, temporocentral chain, and parietal chain.

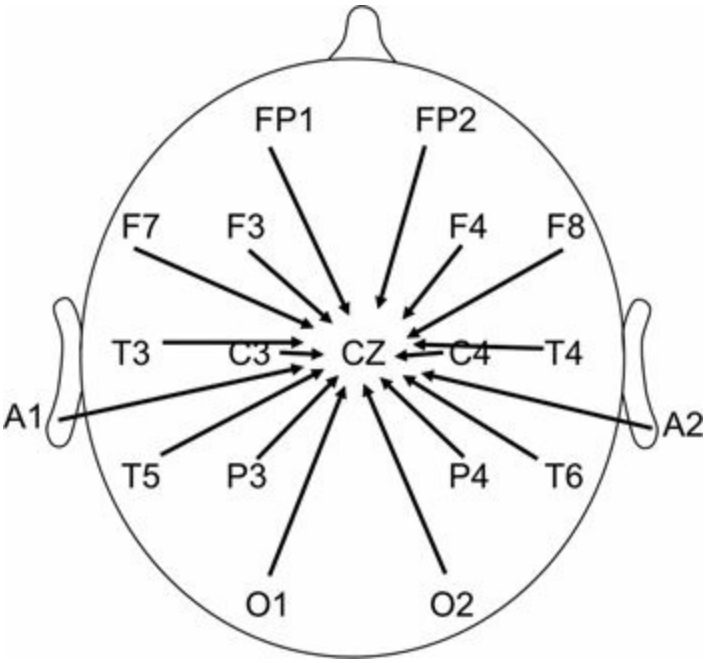

Figure 8.4. Reference montage to vertex.

PART I: NORMAL ELECTROENCEPHALOGRAPHIC PATTERNS AND VARIANTS SOMETIMES CONFUSED WITH EPILEPTIFORM ACTIVITY

For epileptologists to fulfill the basic obligation to "do no harm," they must avoid "overreading" normal variants on EEG (5,6). This section includes several normal patterns that may be easily mistaken for epileptiform discharges, resulting in an incorrect diagnosis of epilepsy and inappropriate recommendations for antiepileptic medication.

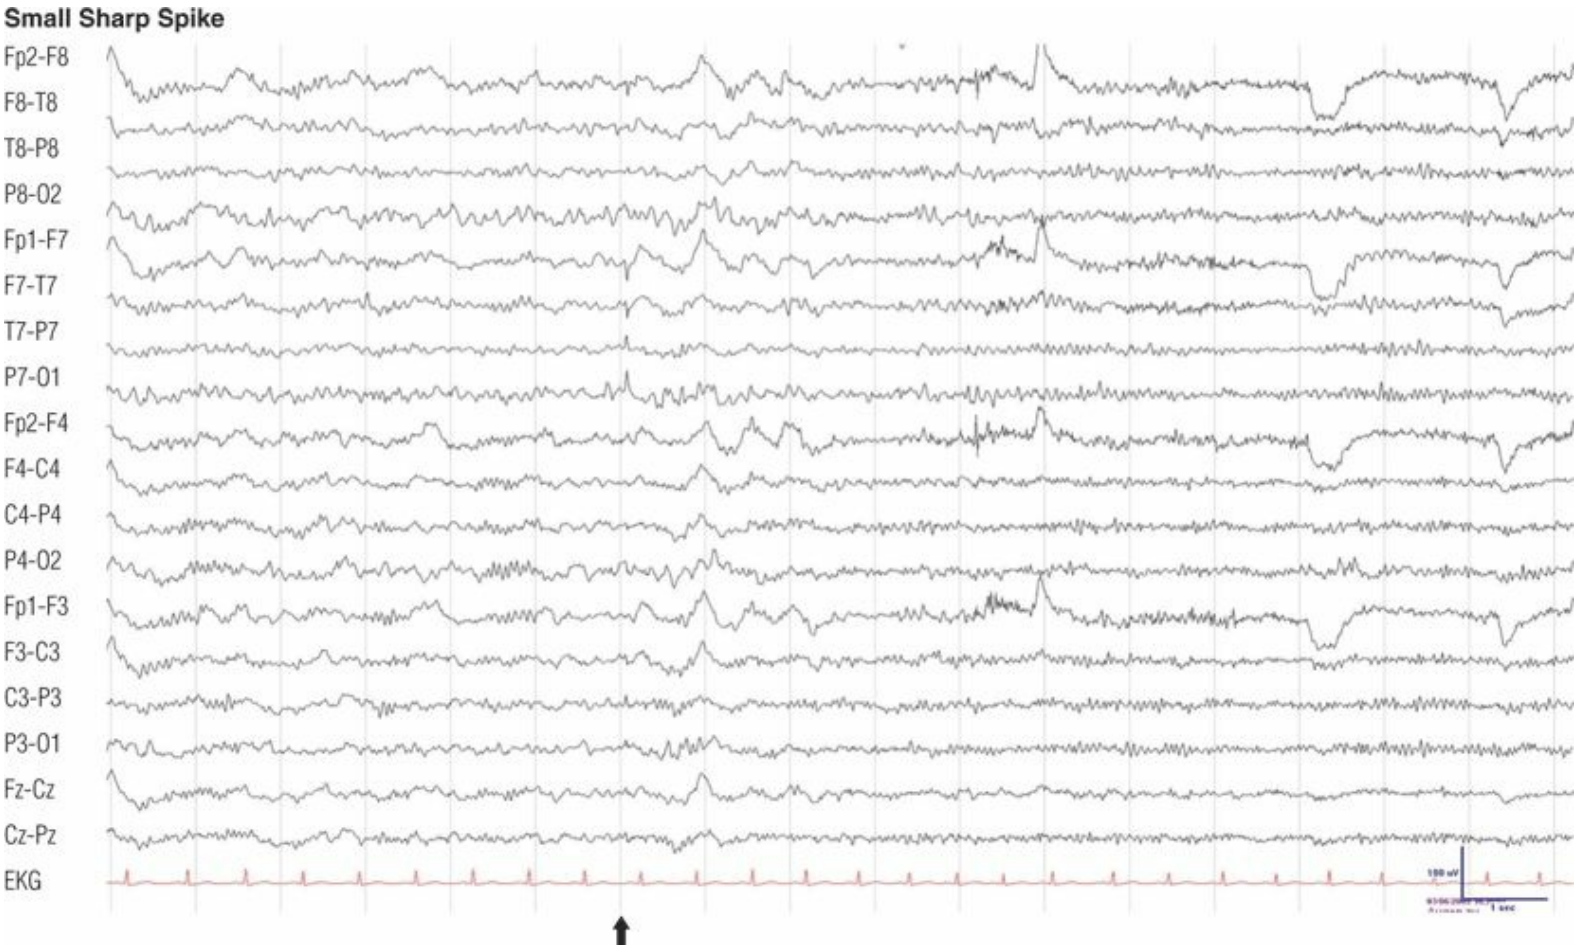

Figure 8.5. Forty-two–year-old man, otherwise normal, with chronic tension headache. Note the low-amplitude monophasic sharp transient (arrow) followed by a minimal slow wave, maximum negativity in the left posterior temporal region (electrode P7), undisturbed background rhythms, during light sleep. During the second half of the EEG, the patient is awake. Small, sharp spikes have also been called benign epileptiform transients of sleep (7).

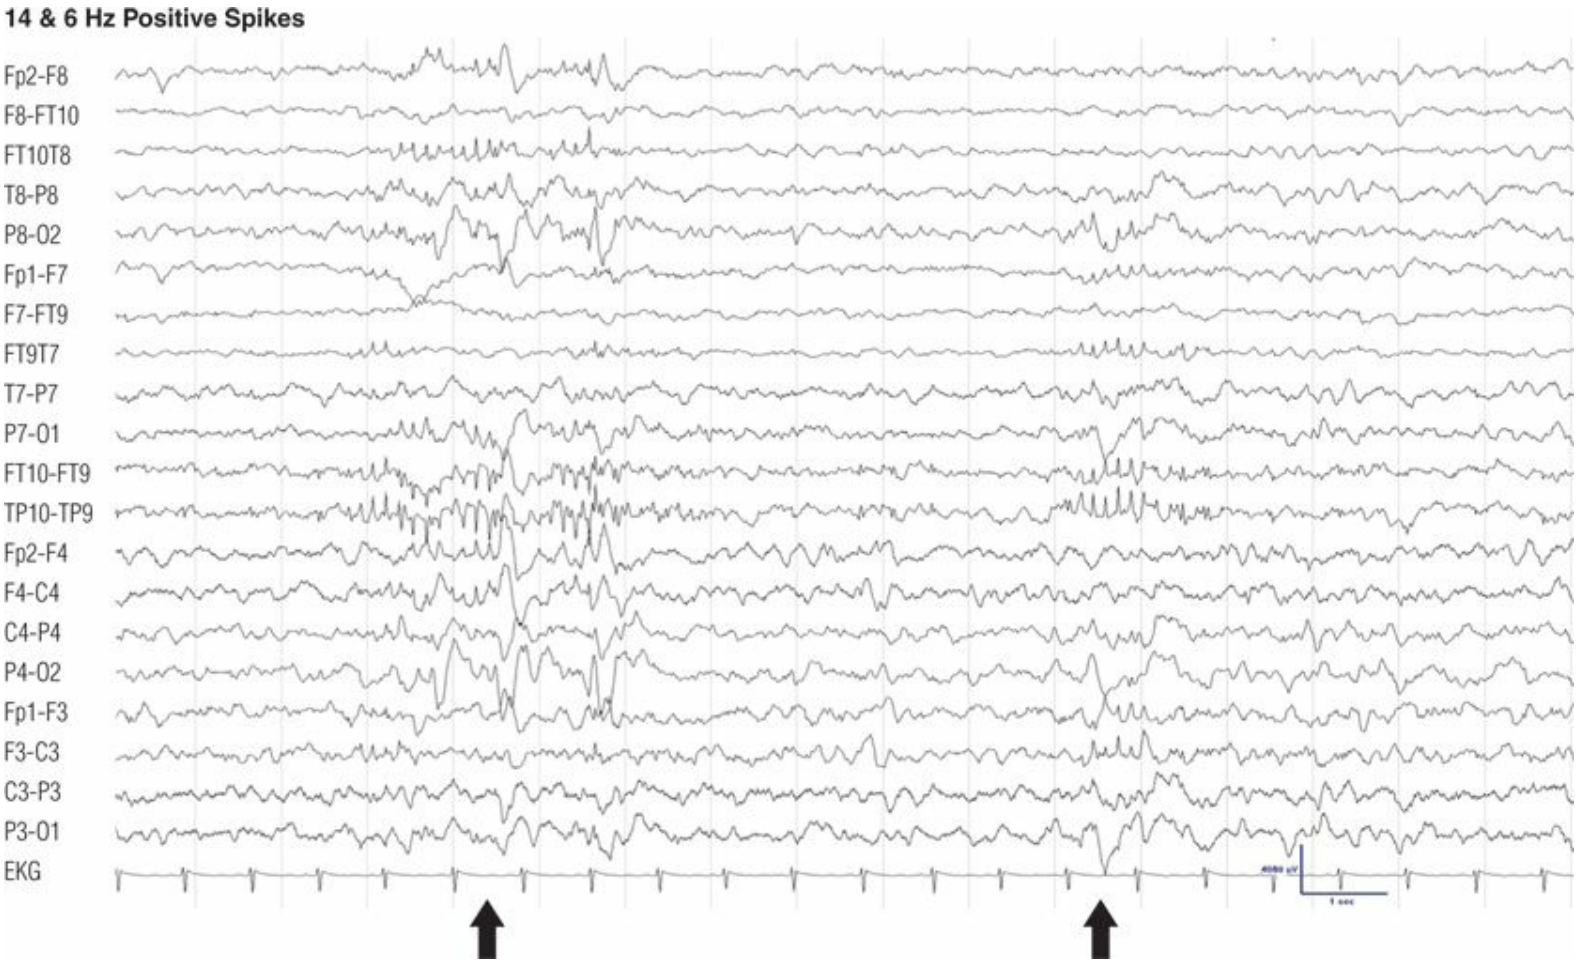

Figure 8.6. Thirteen-year-old girl, otherwise normal, with vasovagal syncope. Note the burst of sharply contoured 14- and 6-Hz activity with maximum positivity in the left and right posterior temporal regions, occurring in light sleep (8). The transhemispheric montage TP10-TP9 depicts the highest amplitude of the positive spikes. Positive spikes of 14 and 6Hz have also been called ctenoids.

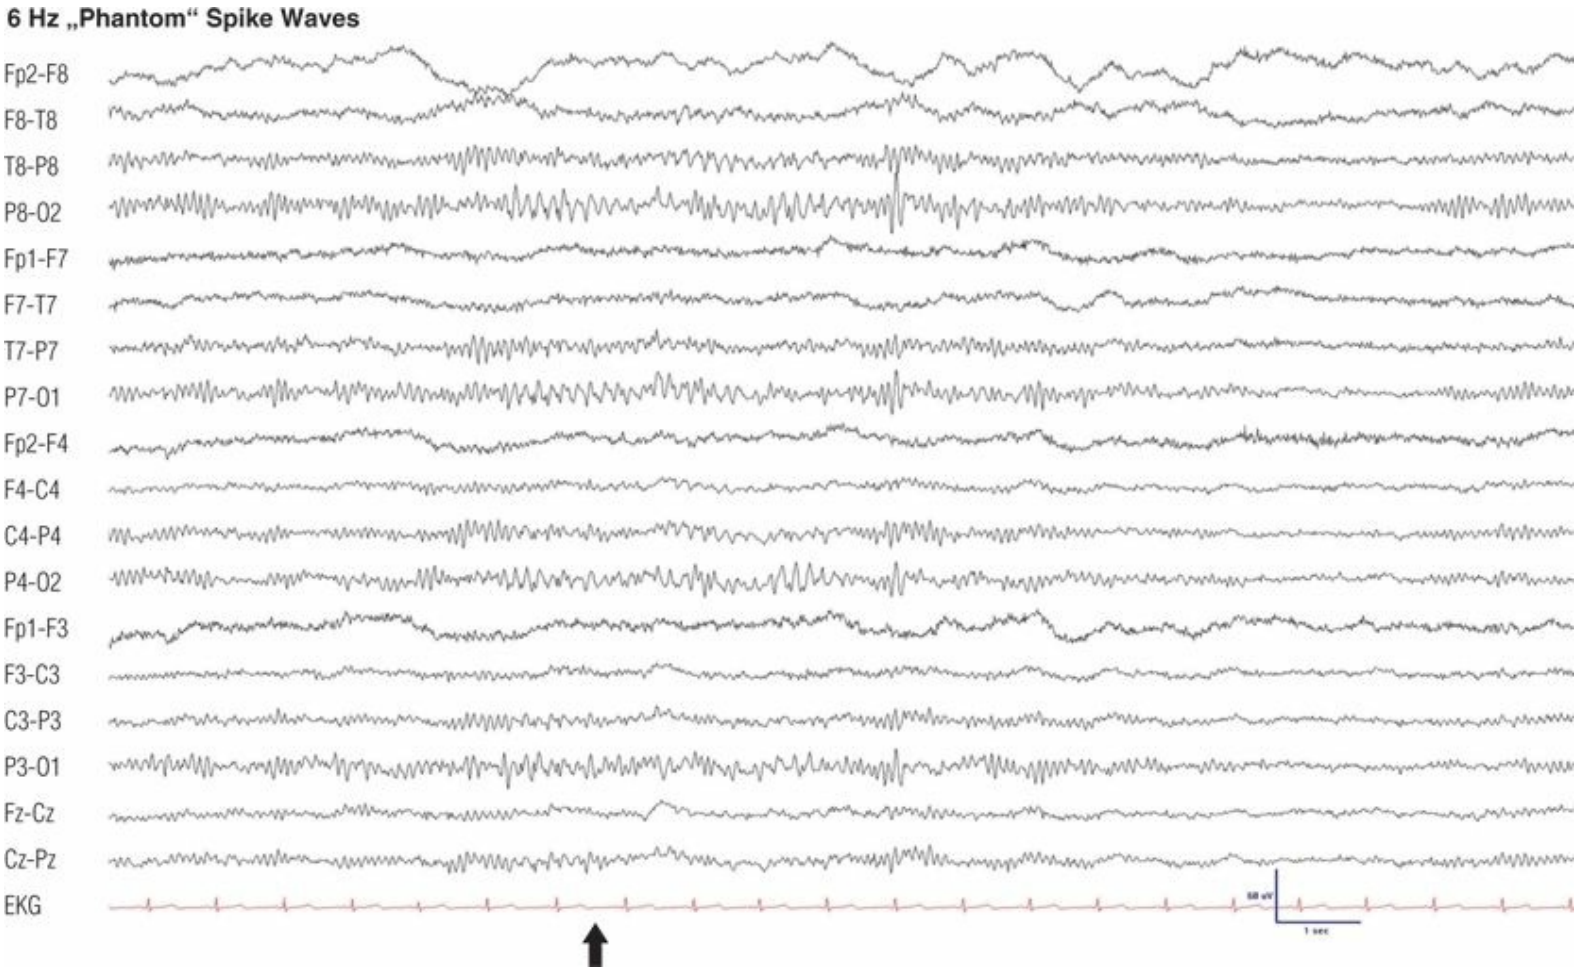

Figure 8.7. Twenty-two–year-old woman with vasovagal syncope. Note the generalized burst of 6-Hz low-amplitude spikes with 6-Hz slow waves occurring during drowsiness in the posterior regions (6).

Figure 8.8. Fifty-four–year-old woman with migraine. Note the 7-Hz, rhythmic, sharply contoured waves with maximum negativity in midtemporal regions, occurrence during drowsiness, and undisturbed background rhythms. The typical frequency of wicket spikes is 6 to 11 Hz (9).

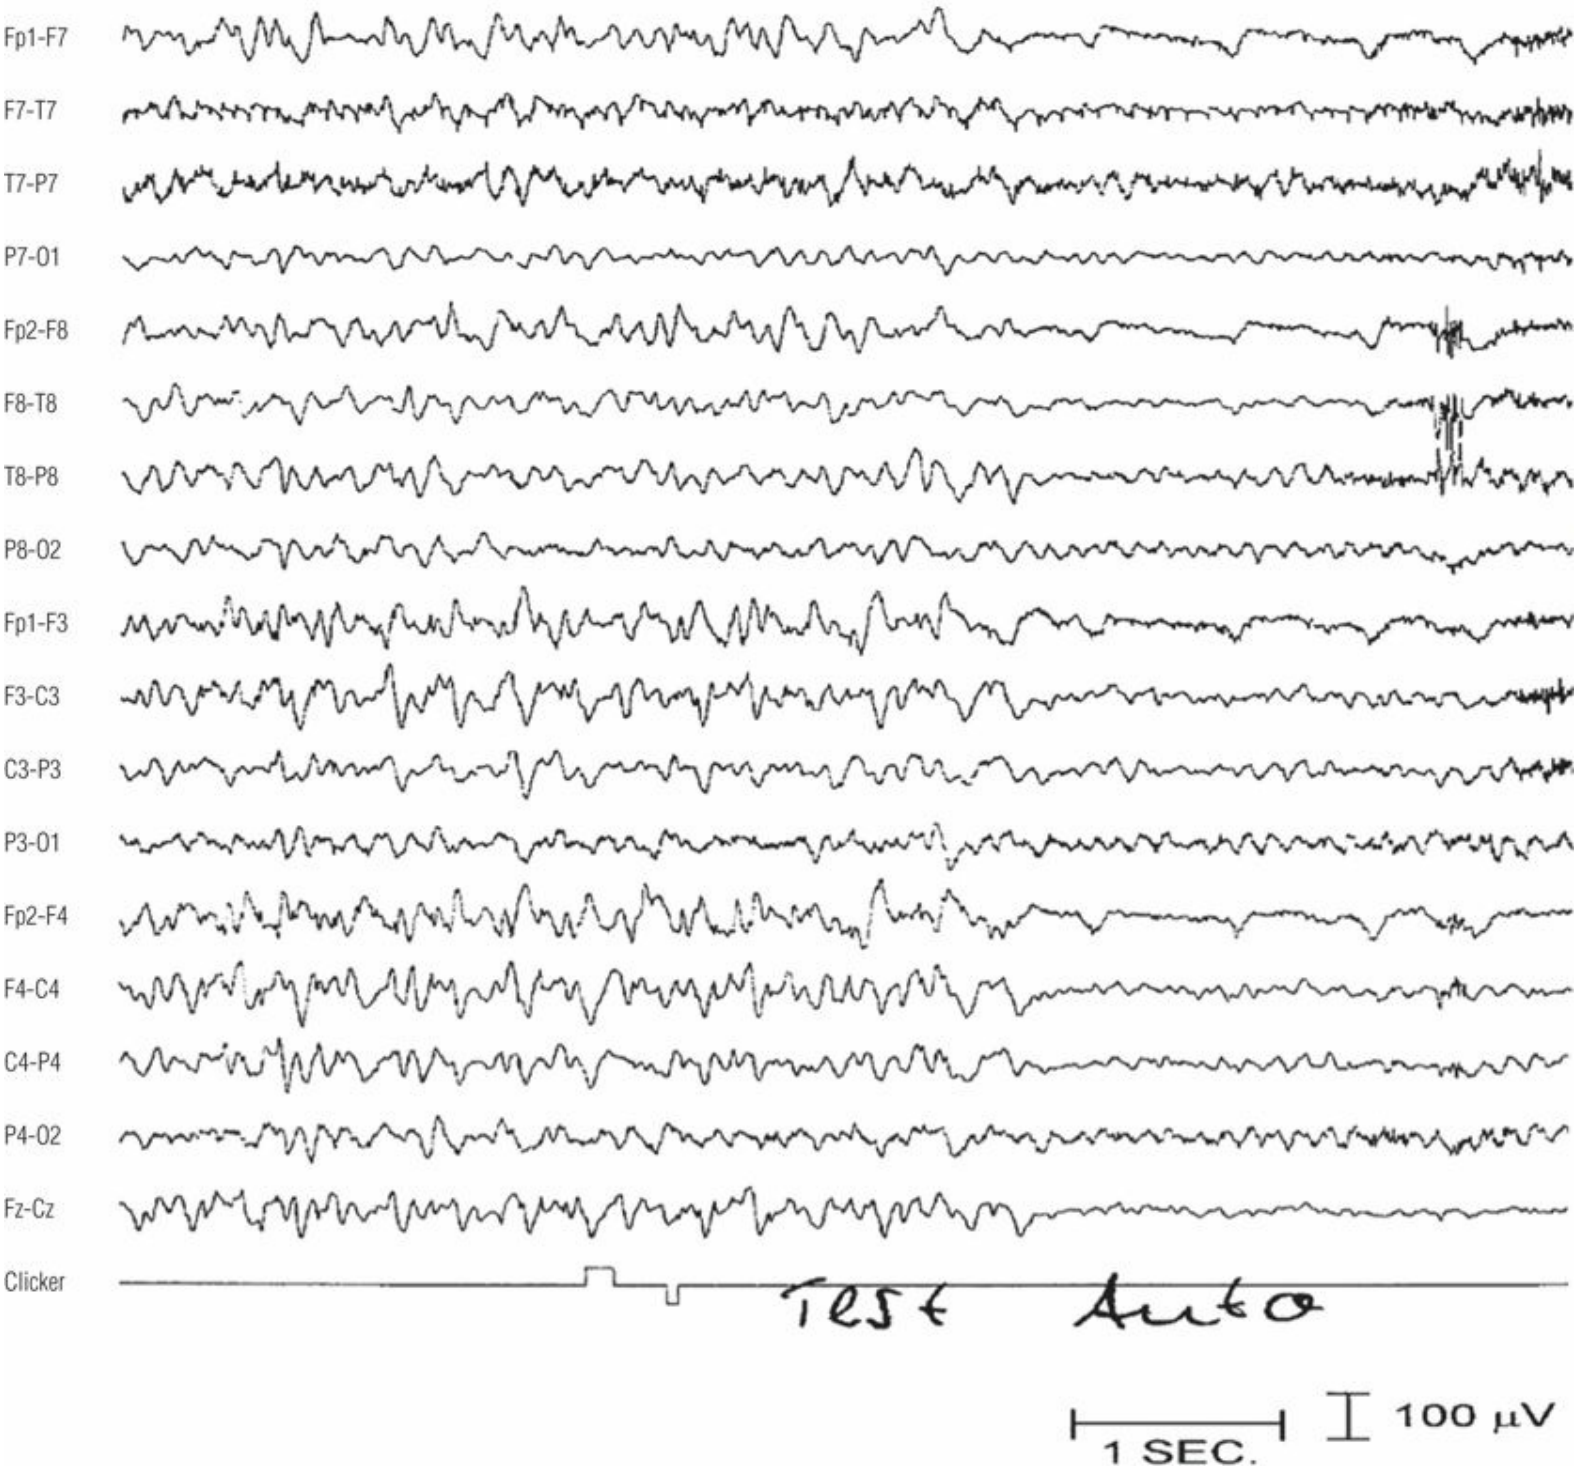

Figure 8.9. Sixty-one–year-old woman with depression. Note the diffuse frontal-maximum, rhythmic, sharply contoured theta and delta activity (10) that ended after 34 seconds and was immediately followed by a normal posterior dominant alpha rhythm. During the rhythmic activity, the patient responded appropriately to an auditory stimulus (clicker). In the last channel, the upward deflection was from the technician's sound stimulus, and the subsequent downward deflection was from the button pressed by the patient in response. The patient remained awake and responsive throughout the recording and afterward recalled the test word ("auto").

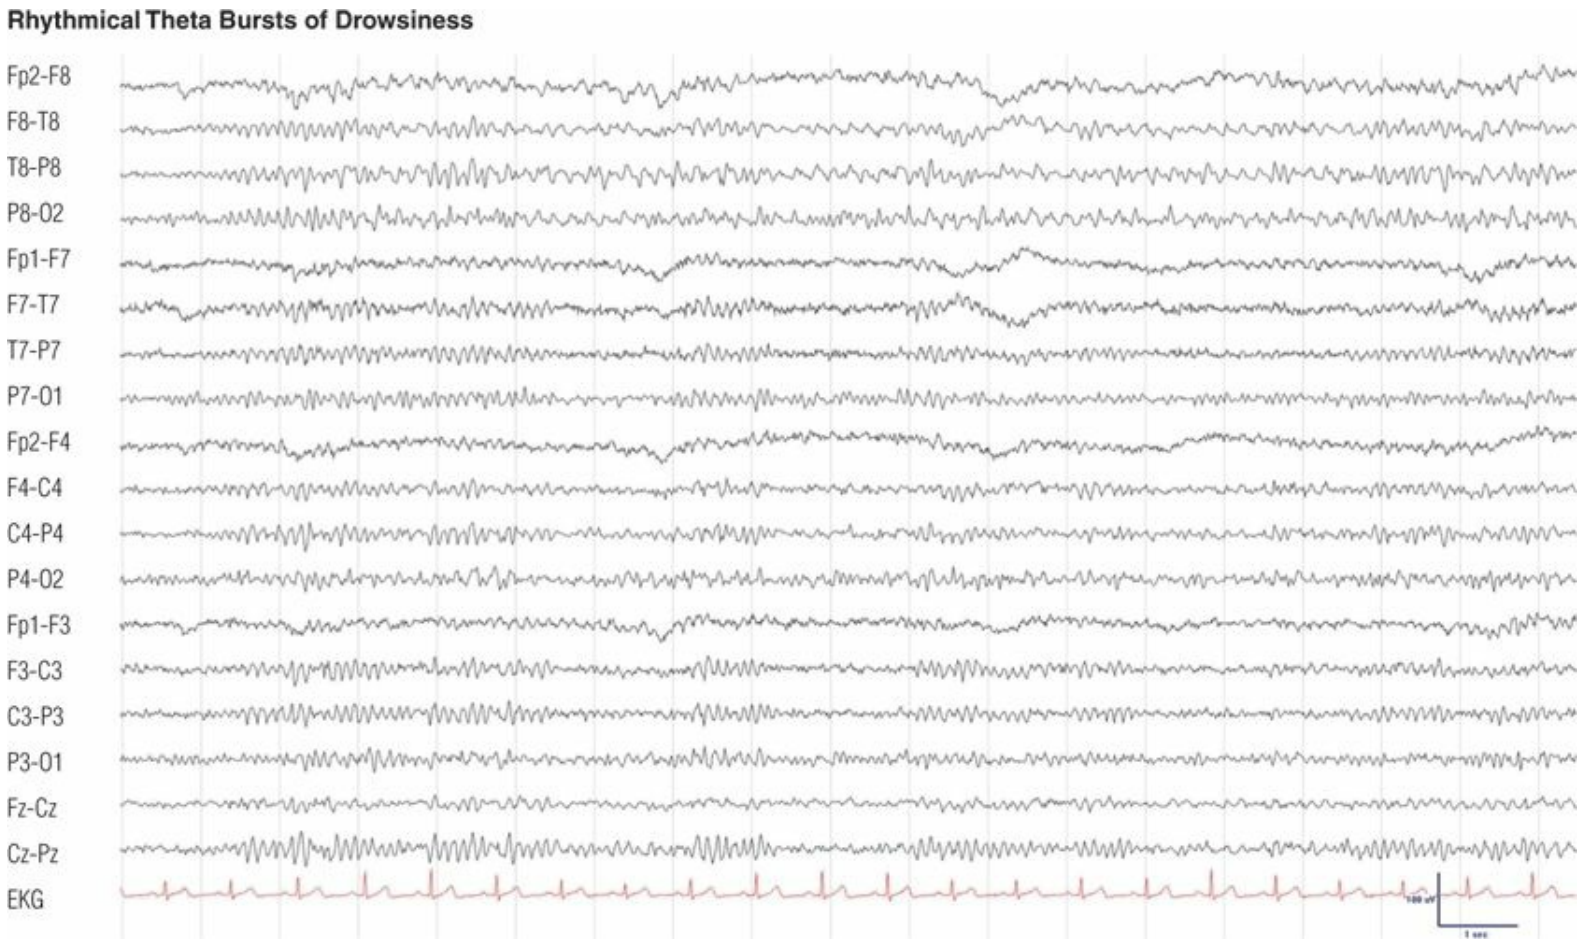

Figure 8.10. Thirty-three–year-old woman with depression. This rhythmic theta activity during drowsiness, with sharply contoured waves maximal in the left midtemporal region, has also been called psychomotor variant (6,11).

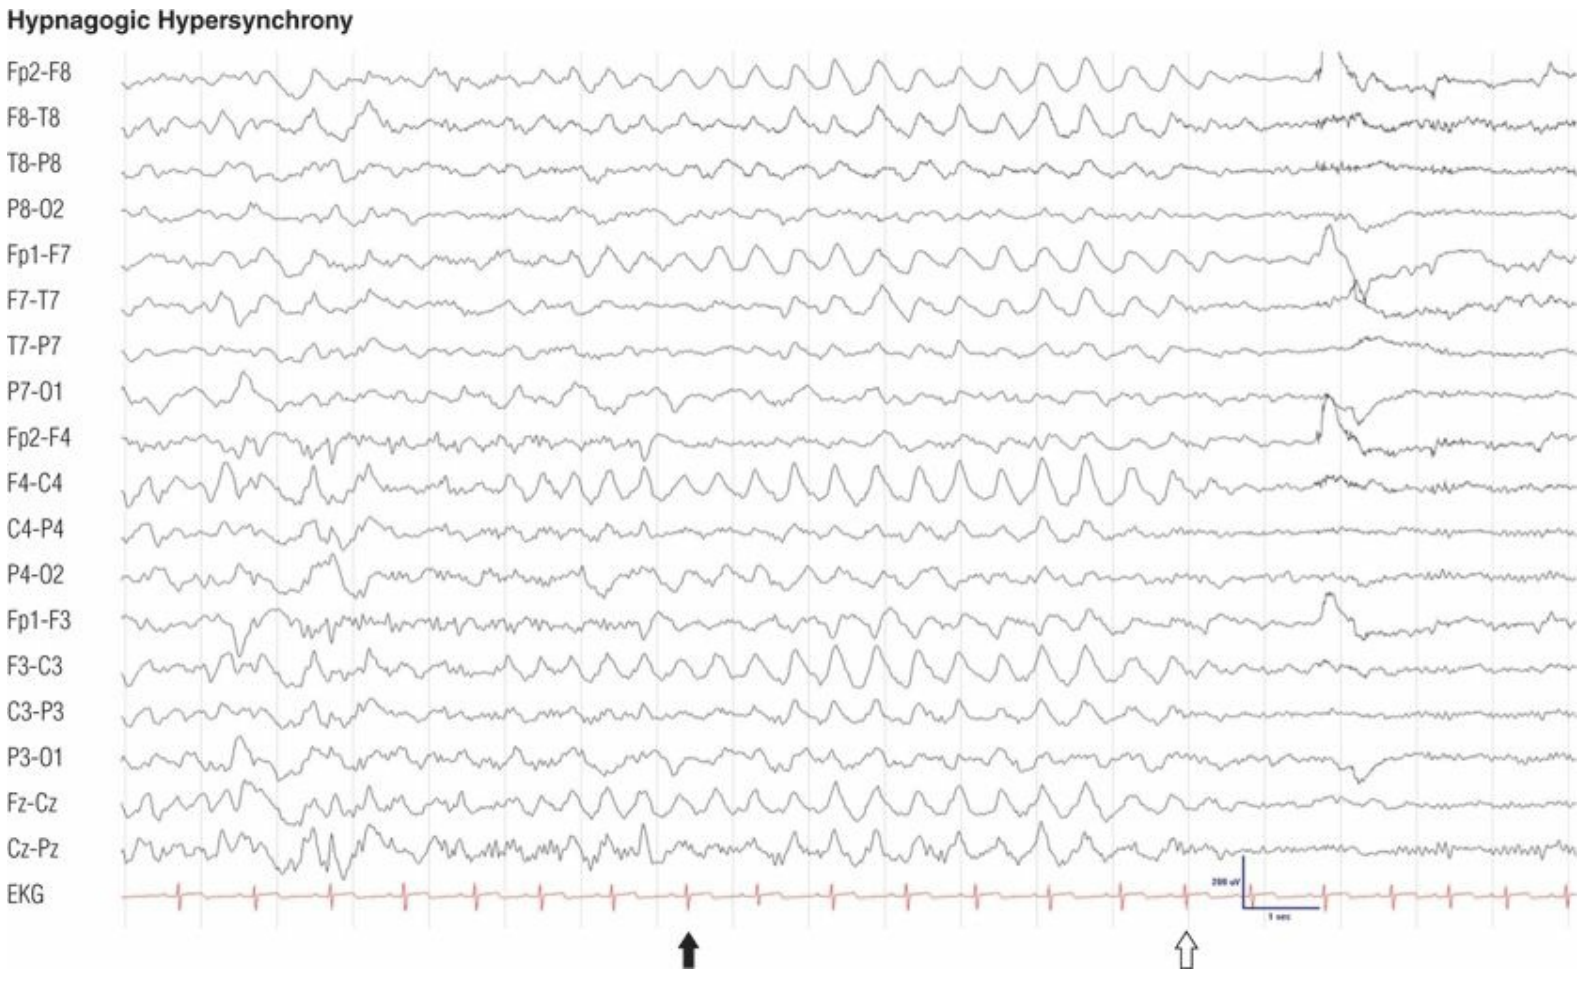

Figure 8.11. Eleven-year-old normal boy. Note the generalized, rhythmic, high-amplitude delta waves during drowsiness (black arrow), which cease with arousal (open arrow).

Figure 8.12. Sixteen-year-old girl with vasovagal syncope. Note the central vertex waves (black arrow) and runs of positive occipital sharp transients of sleep (POSTS) (open arrows) (channels 4, 8, 12, and 16), both normal features of stage I or II non–rapid eye movement (non-REM) sleep.

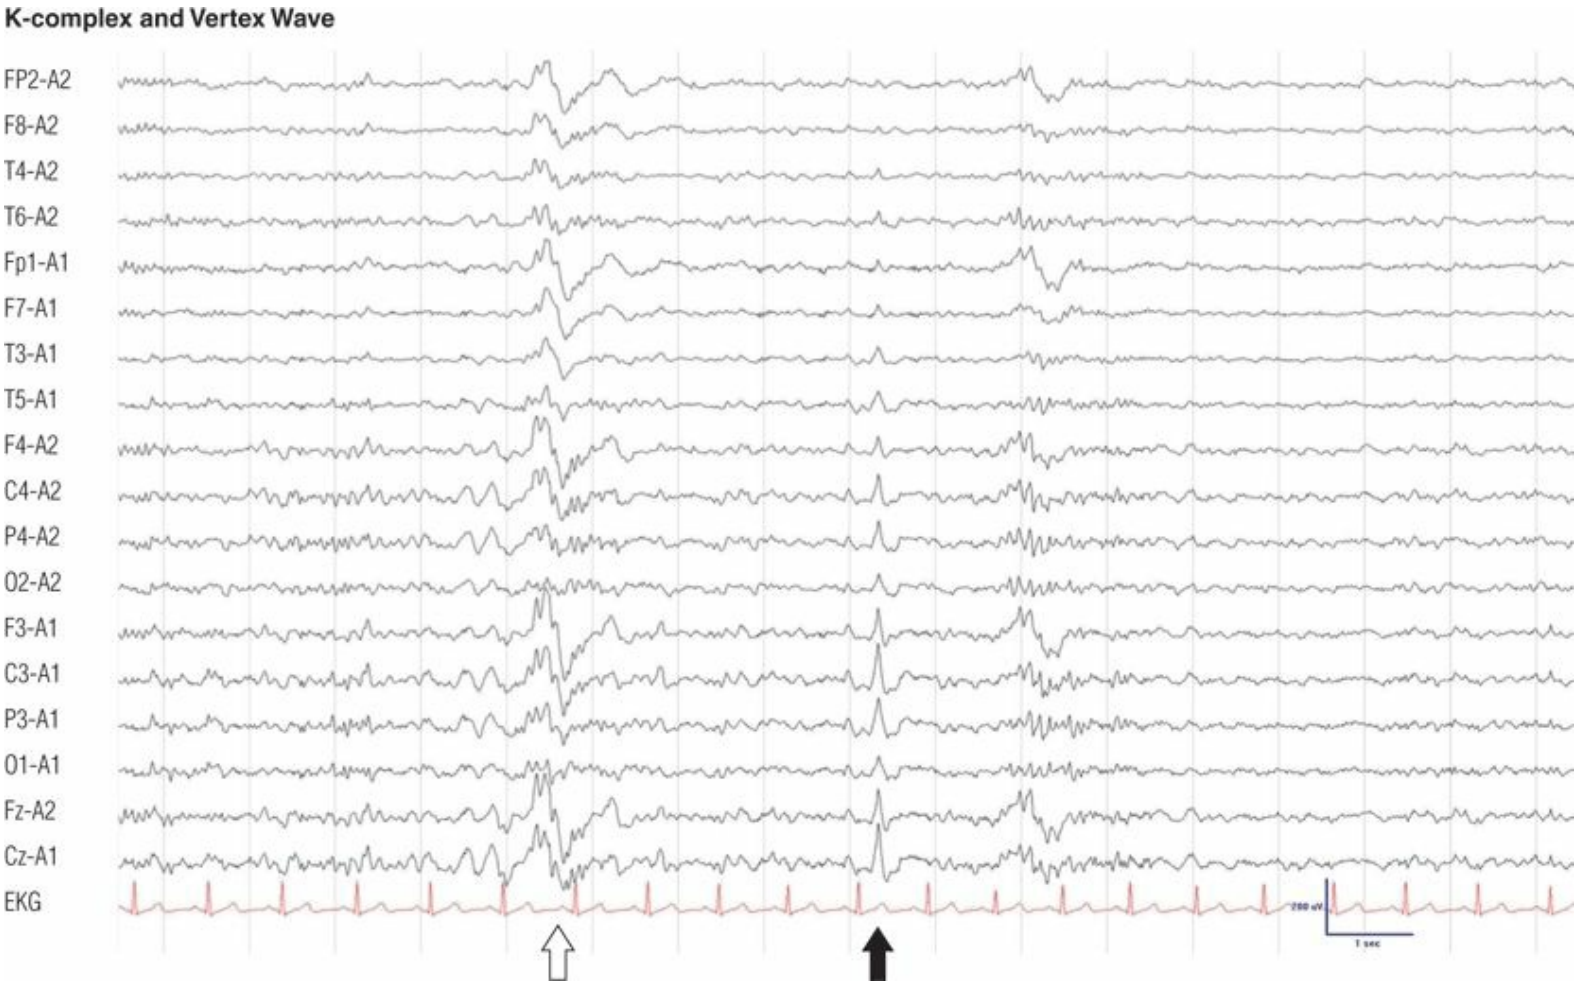

Figure 8.13. Twenty-four–year-old man. K-complexes (open arrow) and vertex wave (solid arrow). Note the sleep spindle, which is associated with the K-complex during stage II non-REM sleep.

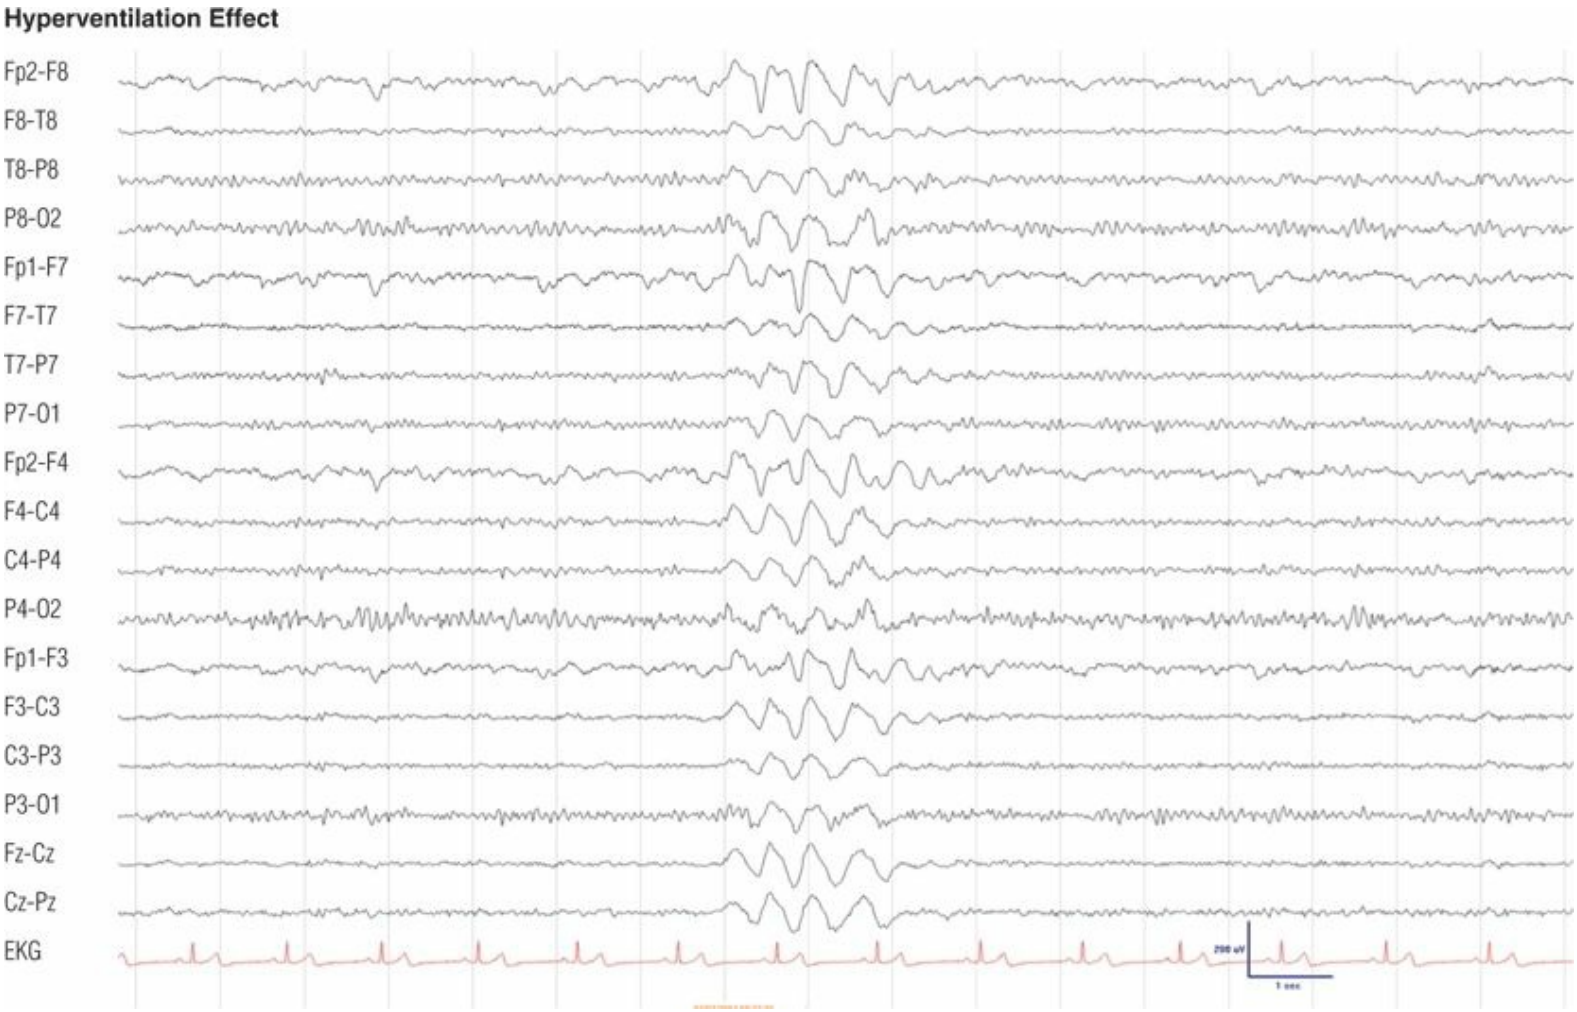

Figure 8.14. Eighteen-year-old girl with school tension headache. Hyperventilation-induced high-amplitude rhythmic delta slowing is a normal response. The girl was alert and responsive during this tracing, which was obtained after 1 minute of hyperventilation.

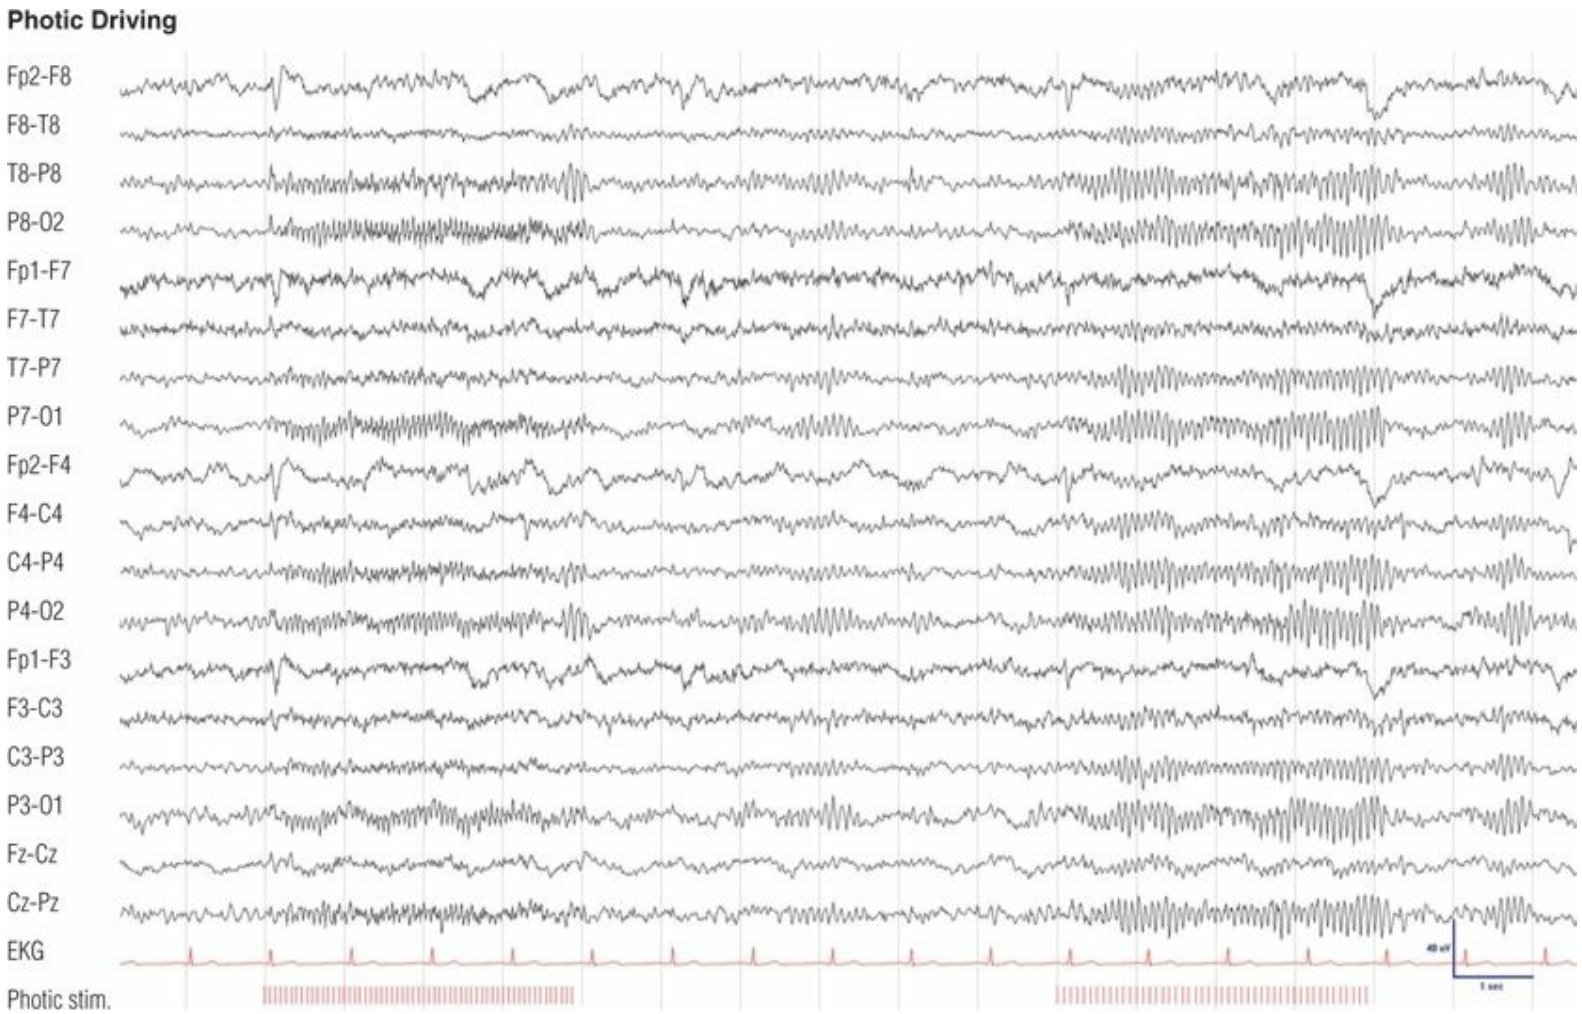

Figure 8.15. Sixteen-year-old boy with childhood absence epilepsy since 7 years of age, seizure free on medication for the last 3 years. Note the time-locked, unsustained, bioccipital response to 8- and 4-Hz photic stimulation, separated by normal posterior background activity. Photic driving represents a normal response to photic stimulation and is not related to the epilepsy of the patient.

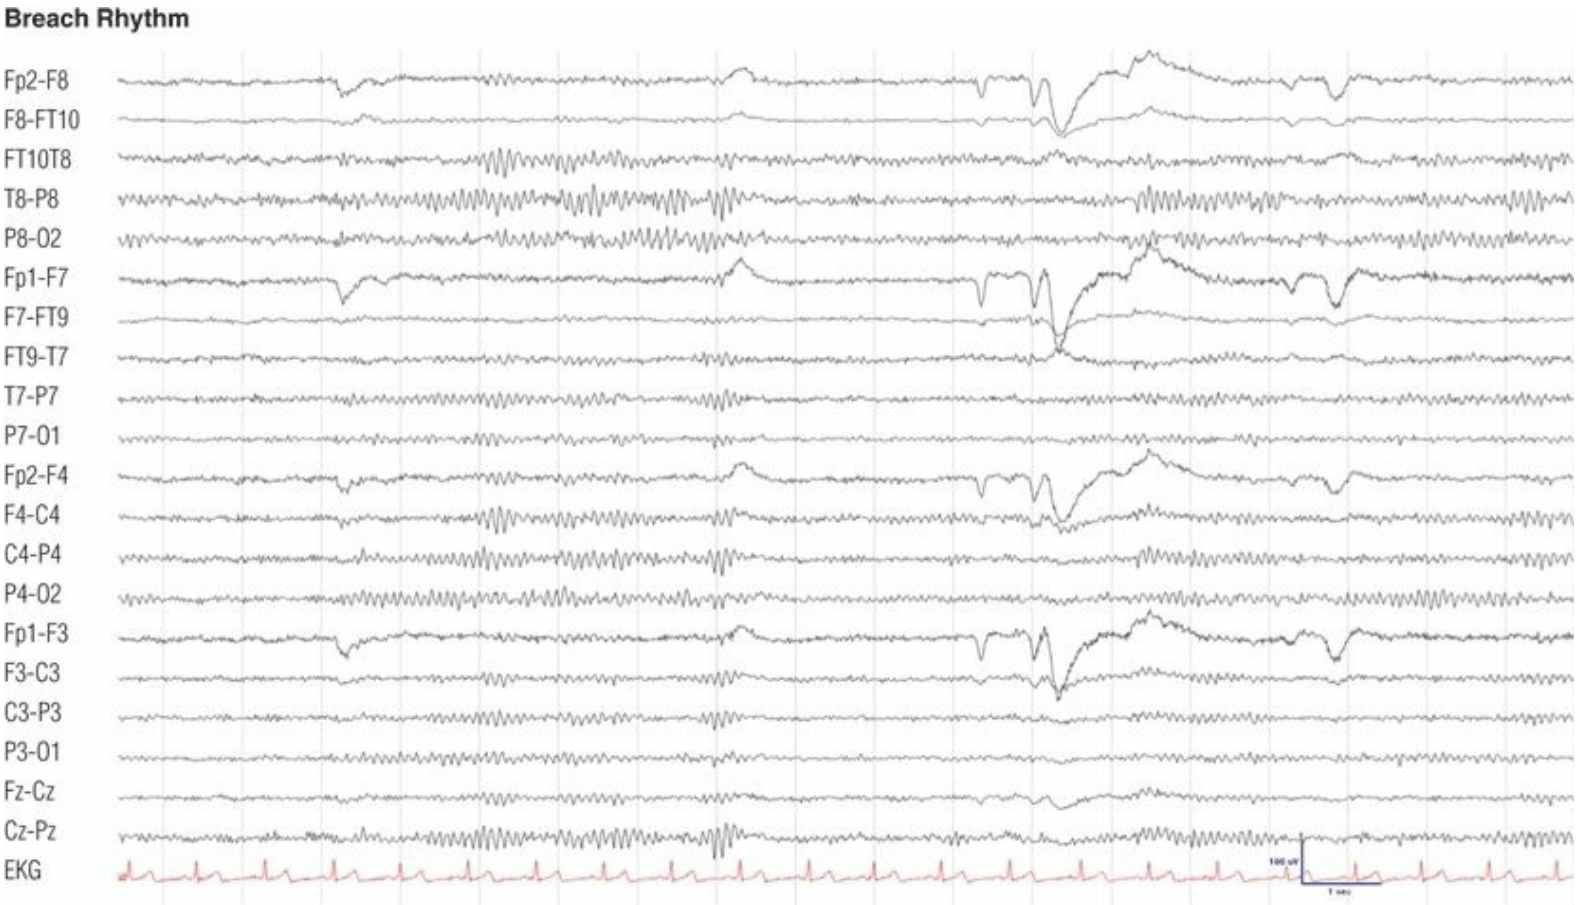

Figure 8.16. Fifty-one–year-old woman with trigeminal neuralgia, status after right parietotemporal craniotomy for vascular decompression. Note the asymmetry of background rhythms owing to the skull defect (12), maximum at the right temporal (T8, P8) electrodes.

PART II: ELECTROENCEPHALOGRAPHIC ABNORMALITIES OF THE GENERALIZED EPILEPSIES

Childhood Absence Epilepsy

Generalized spike–wave complexes	Figure 8.17

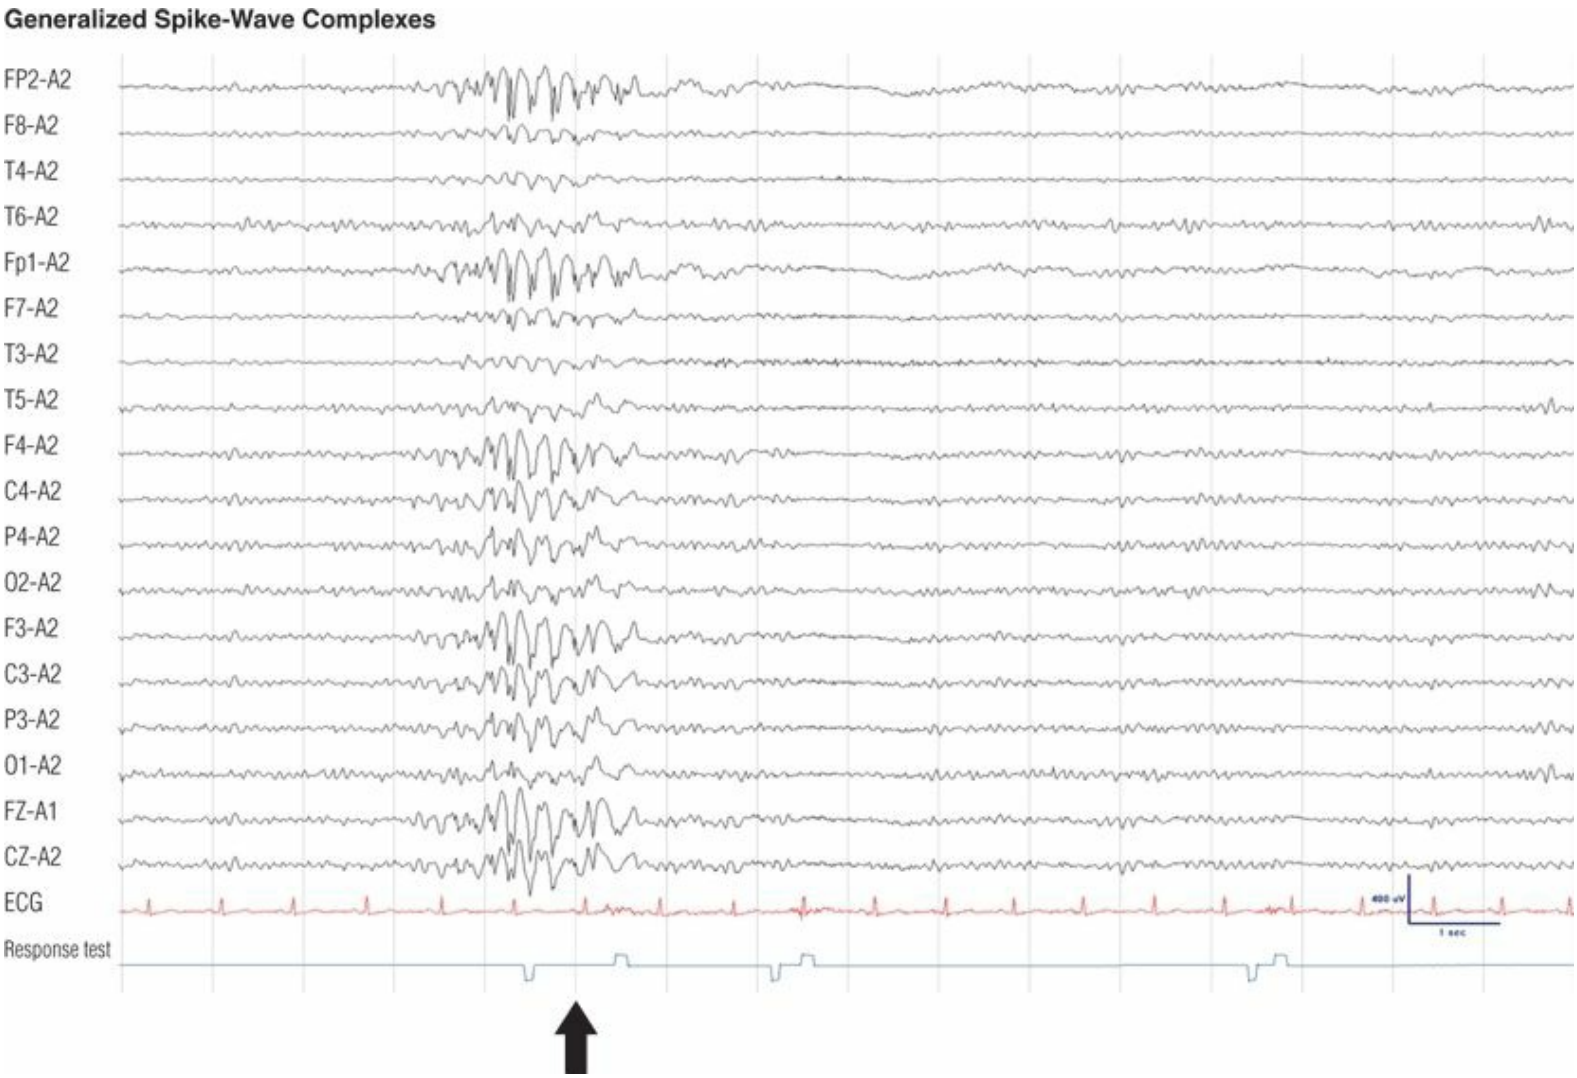

Figure 8.17. Twelve-year-old boy, otherwise normal, with recent onset of absence seizures. These irregular generalized spike-and-wave complexes were precipitated by hyperventilation and lasted for almost 2 seconds. Note that the patient failed to press a button (black arrow) as a response to an auditory stimulus (clicker test) given to him during the SWC, but he responded to a second stimulus at the end of the discharge. These episodes would go unnoticed if not tested.

Juvenile Absence Epilepsy

Absence status epilepticus	Figures 8.18 and 8.19

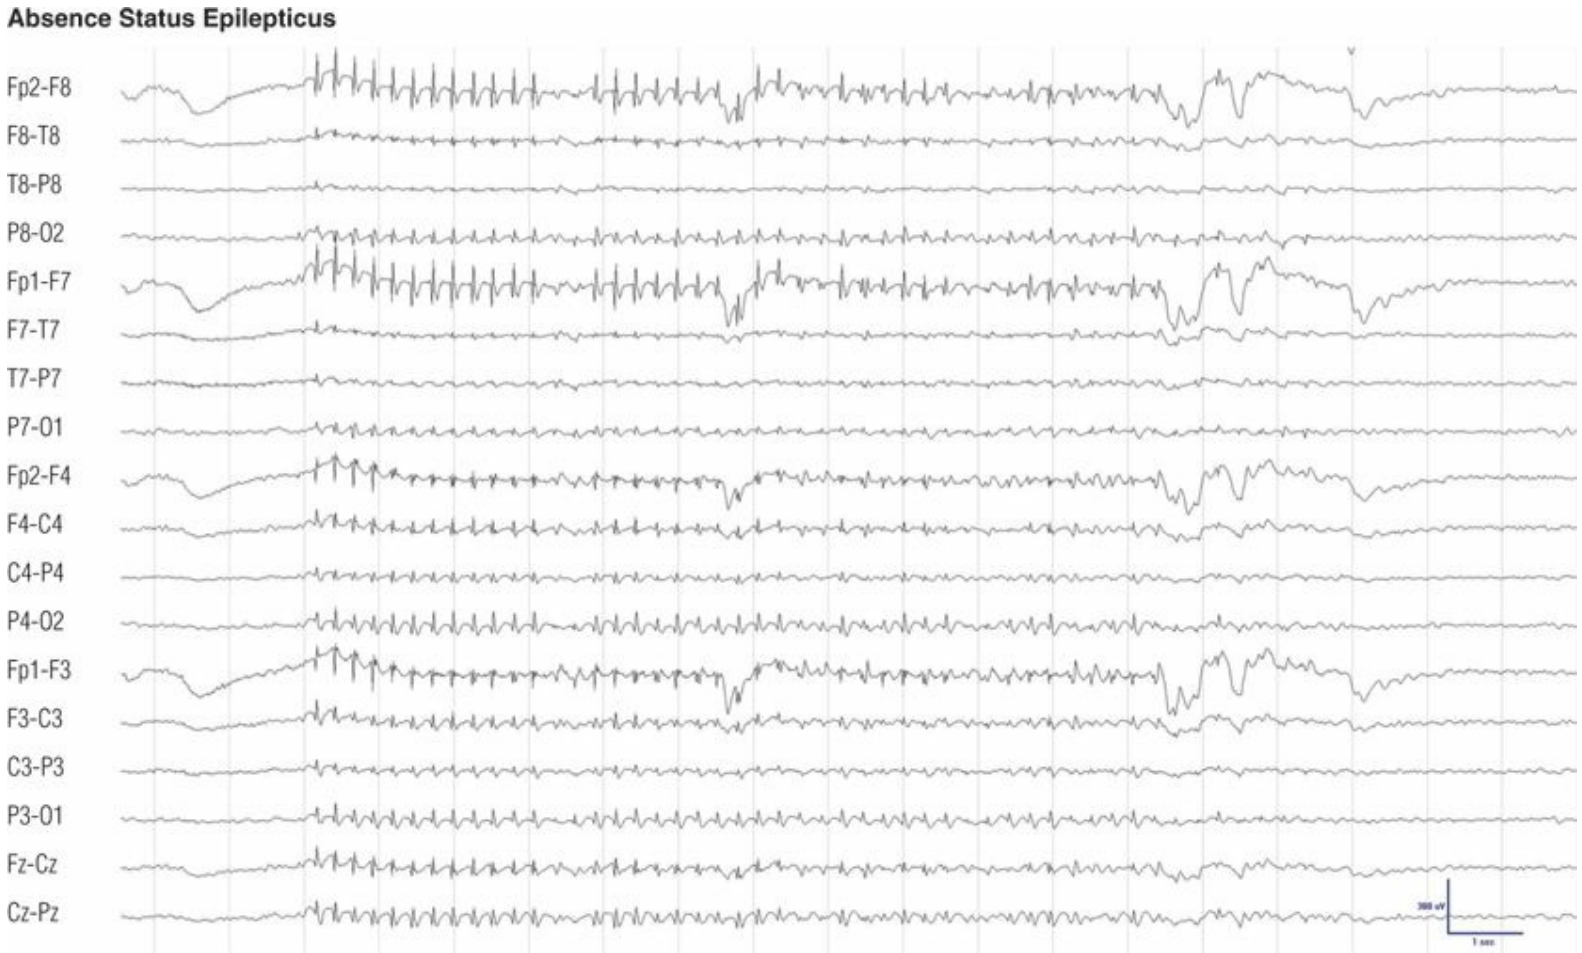

Figure 8.18. Thirty-six–year-old woman with absence seizures during childhood. She was seizure free throughout adulthood off medication until recently absence status epilepticus began during drug treatment with imipramine for depression. During this episode, with generalized spike-and-wave complexes, she was unresponsive. Electroencephalographic findings and behavior returned to normal after intravenous injection of lorazepam.

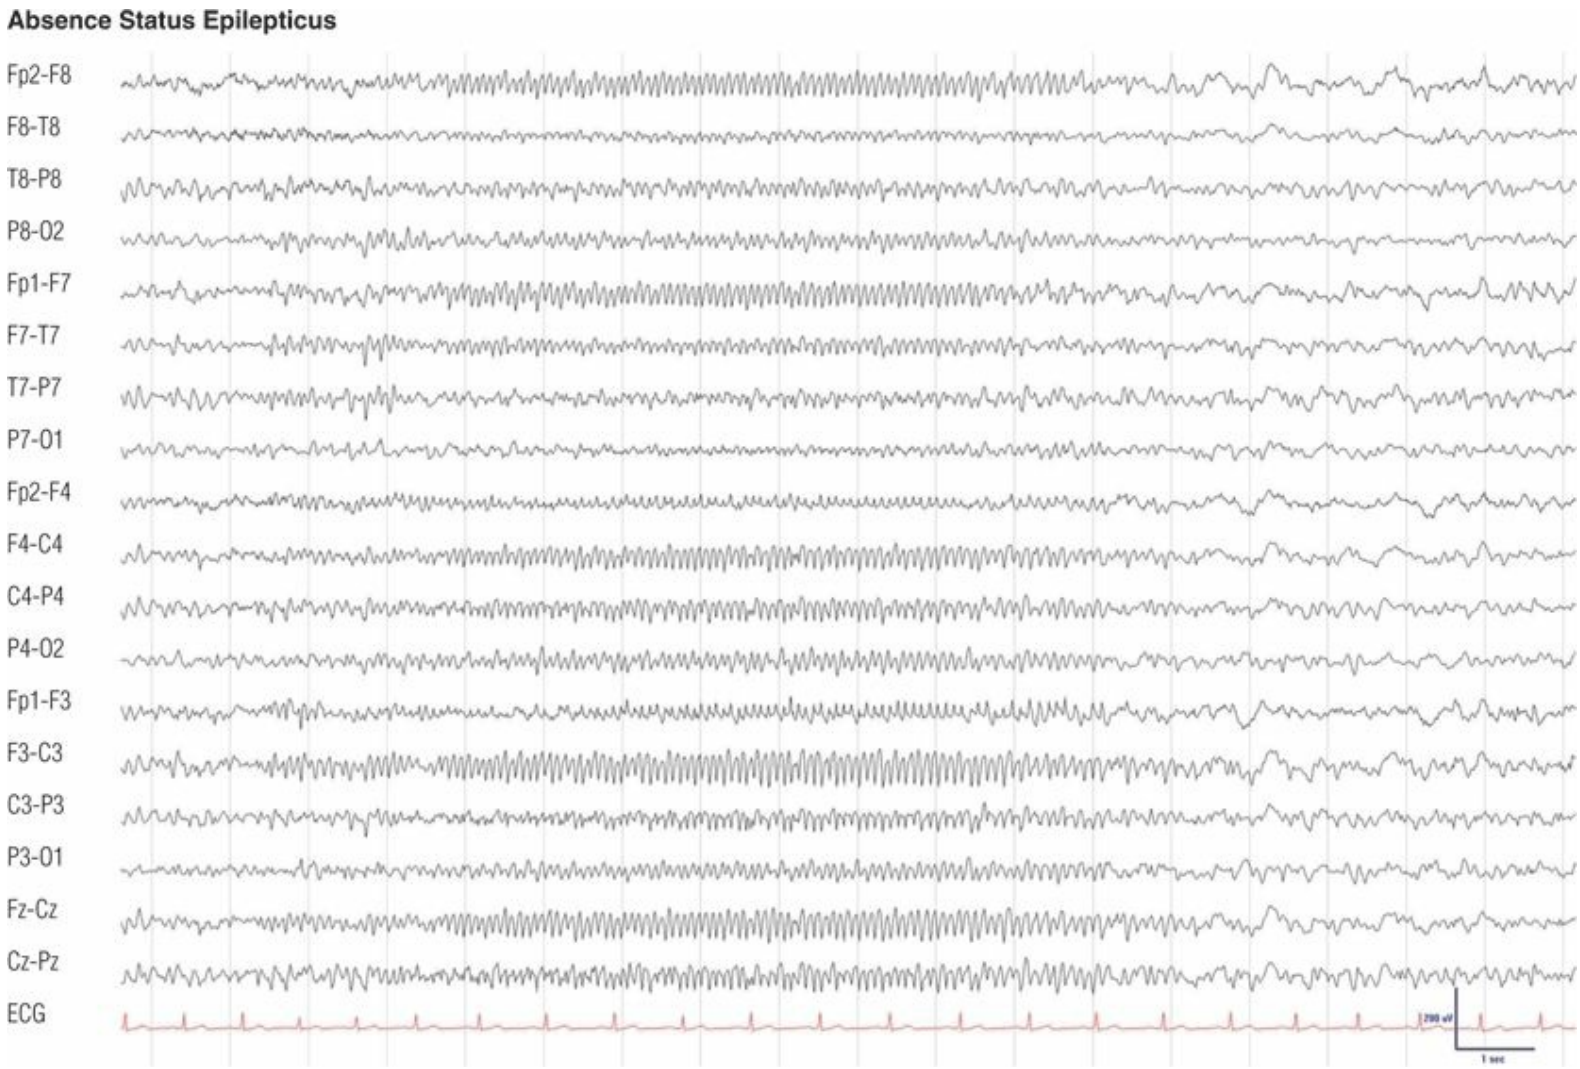

Figure 8.19. Fifty-eight–year-old man with juvenile absence epilepsy with a 2-day history of confusion and agitation prior to this electroencephalogram (EEG). He was switched to topiramate and stopped valproic acid erroneously. EEG findings and behavior returned to normal after intravenous injection of clonazepam.

Myoclonic Epilepsy

Photoparoxysmal response in juvenile myoclonic epilepsy	Figure 8.20
Generalized myoclonic seizure	Figure 8.21

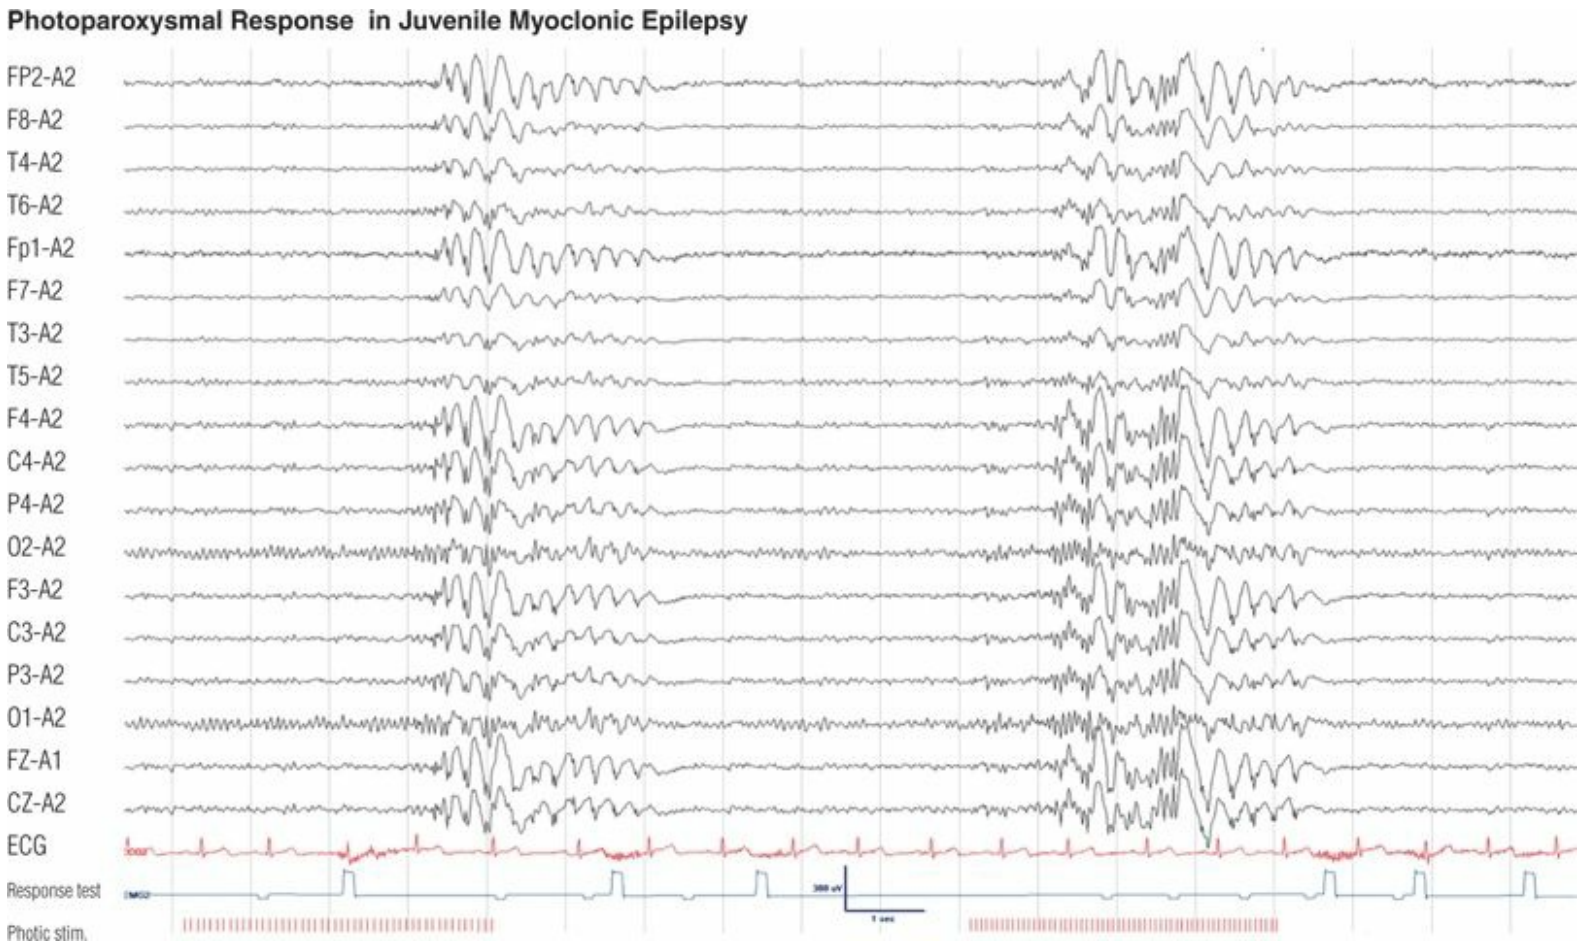

Figure 8.20. Sixteen-year-old boy with a 4-year history of myoclonic jerks of the upper extremities and a few generalized tonic–clonic seizures in the morning after awakening. Photic stimulation elicited generalized polyspikes and spike–wave complexes at 12 and 15 Hz. His responses to auditory stimuli during these discharges were either absent or delayed (absence seizure) (see clicker test).

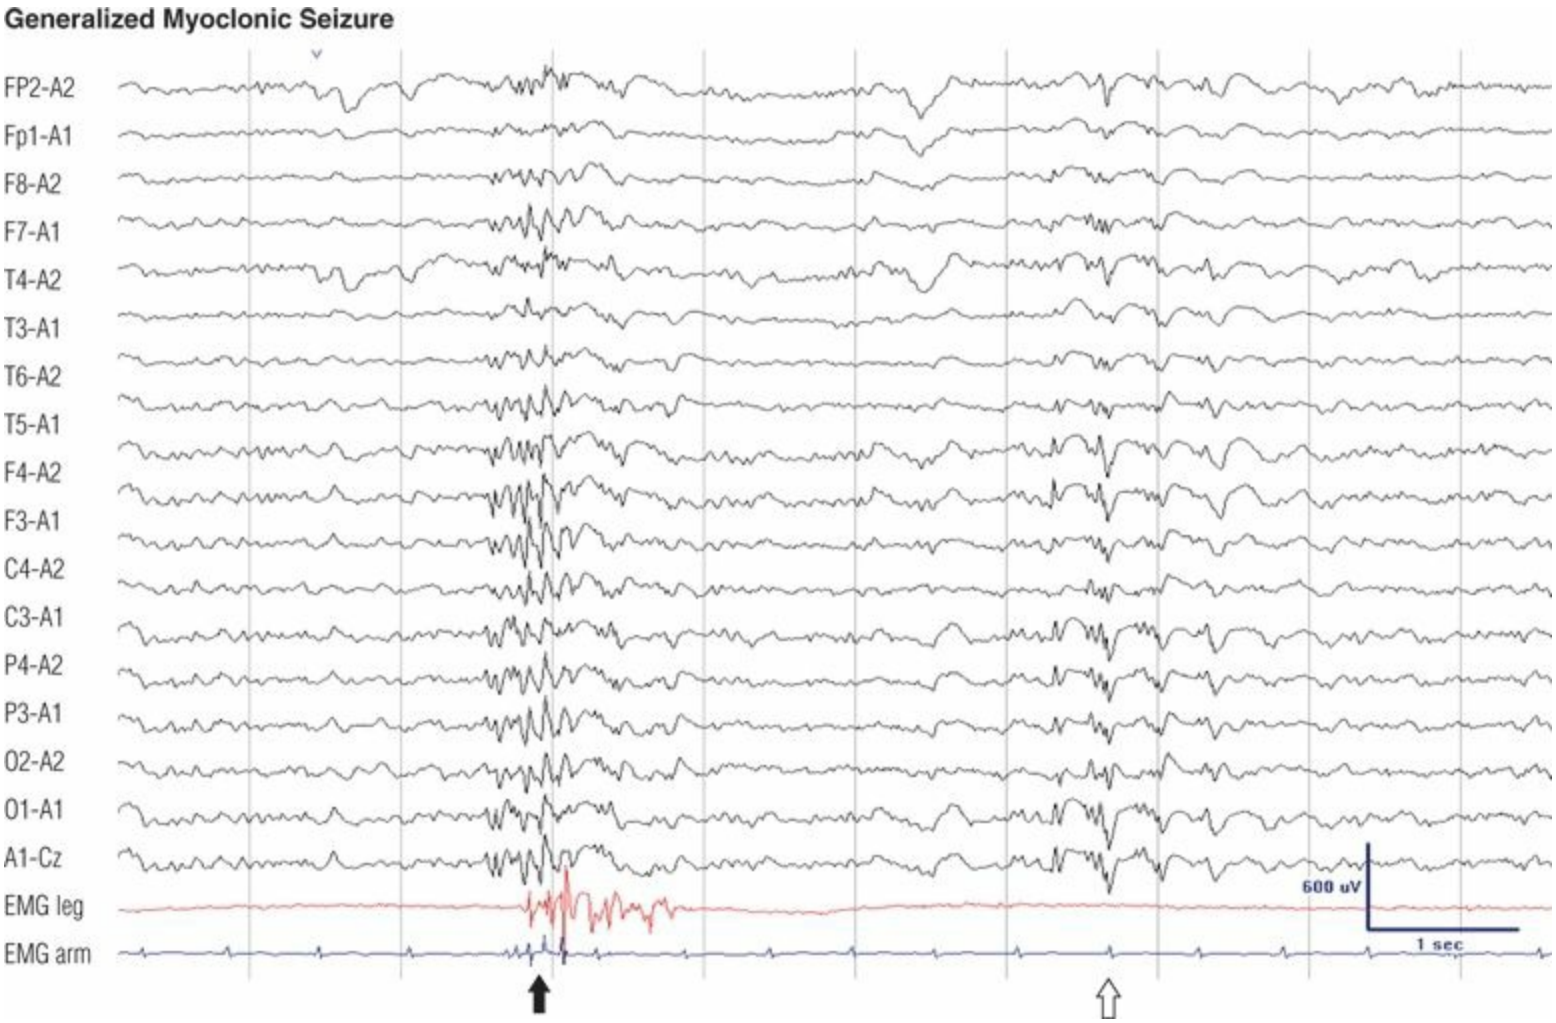

Figure 8.21. Twenty-two–year-old man, otherwise normal, with generalized myoclonic and generalized tonic–clonic seizures on awakening since adolescence. His generalized myoclonic seizures consisted of jerks of the arms. EEG during drowsiness. Note the dense generalized polyspikes were associated with jerks (solid arrow), whereas the other discharges (open arrow) were not.

Infantile Spasms

Hypsarrhythmia	Figure 8.22
West syndrome: infantile spasm	Figure 8.23

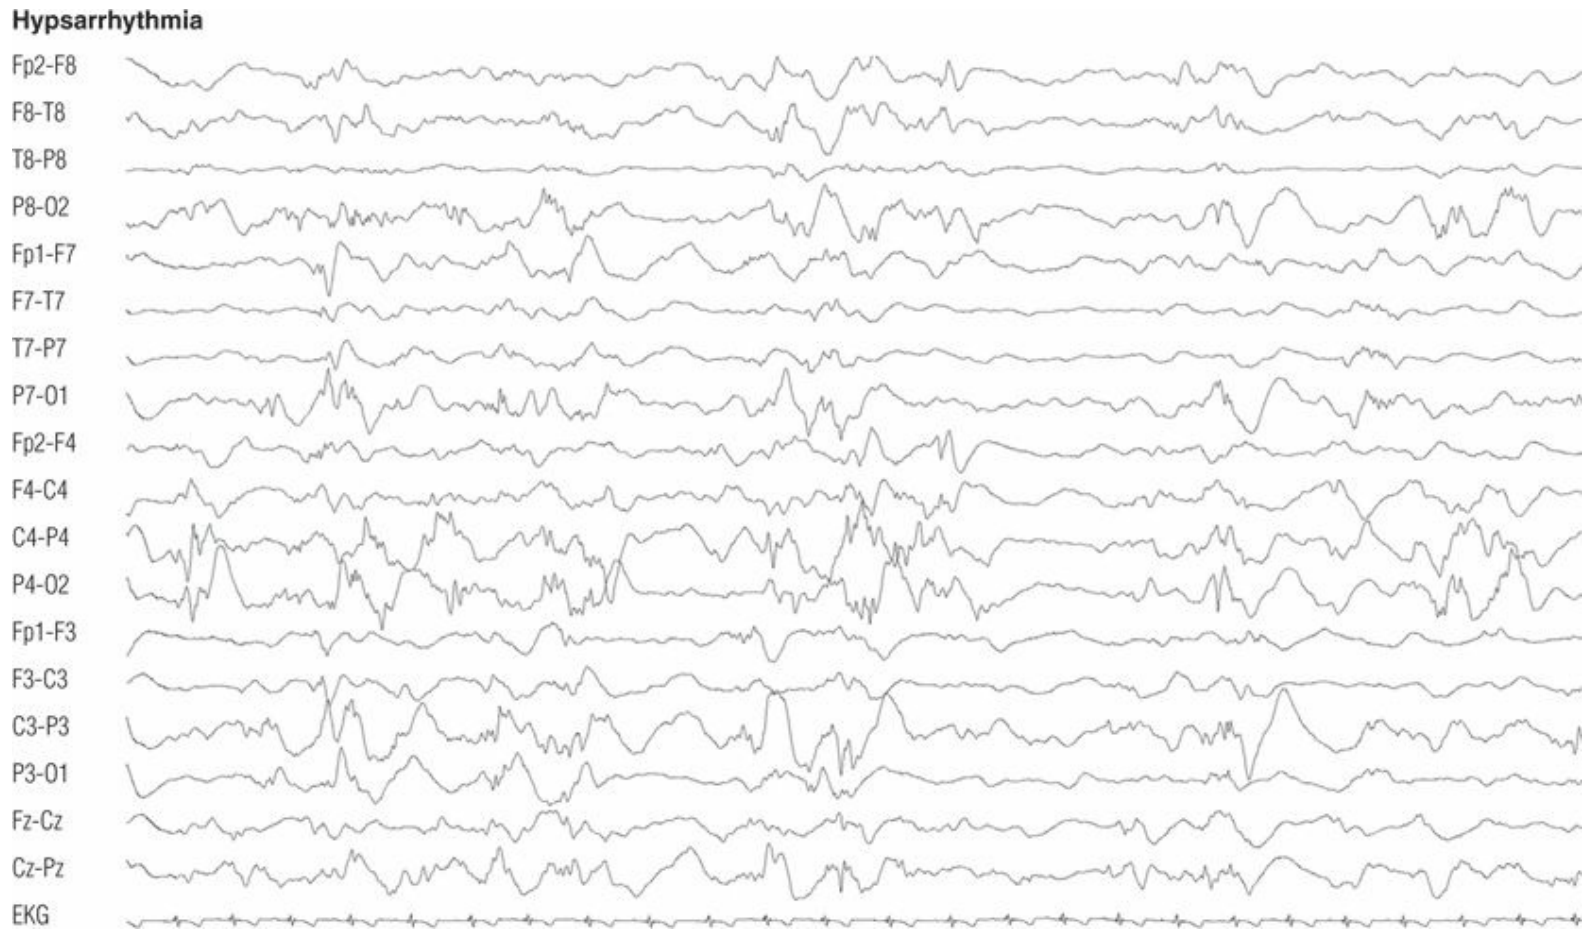

Figure 8.22. Ten-month-old boy with infantile spasms and developmental delay. Awake electroencephalographic record showed disorganized background rhythms dominated by multifocal spikes and high-amplitude slowing.

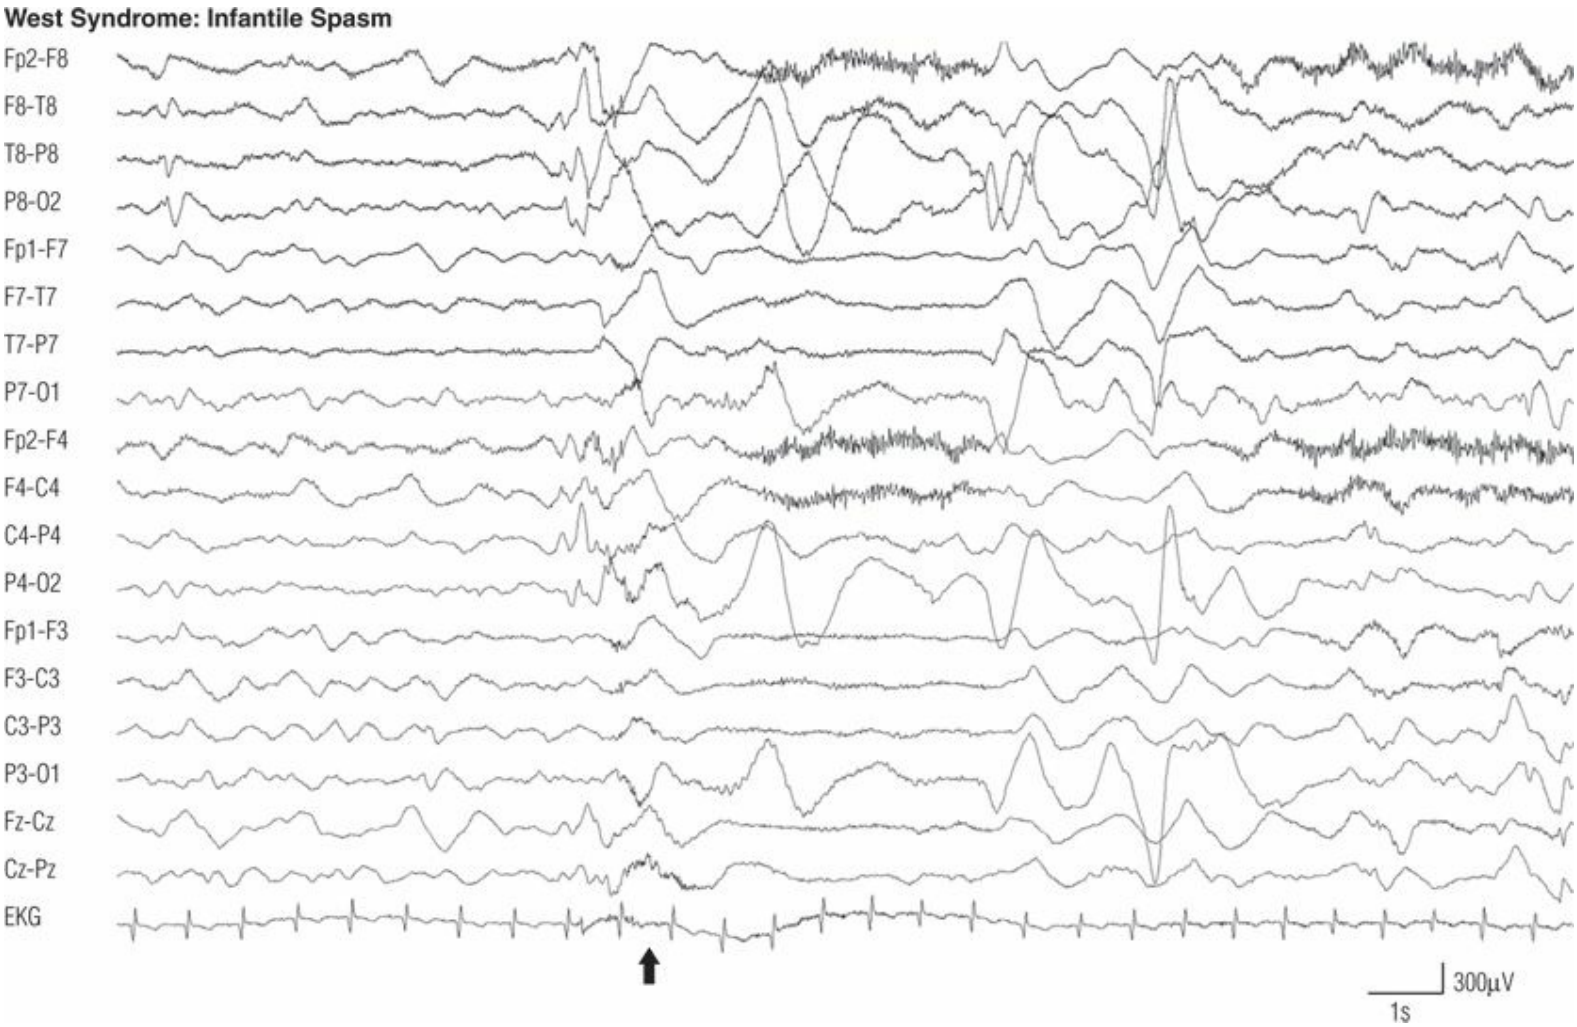

Figure 8.23. EEG during a spasm (arrow), from the same infant as in Figure 8.22. Note the generalized electrodecremental pattern for 3 seconds. The spasm involved tonic abduction and extension of both arms with flexion of the trunk and neck.

Lennox–Gastaut Syndrome

Generalized slow spike–wave complexes	Figure 8.24
Generalized paroxysmal fast and polyspikes in sleep	Figures 8.25 and 8.26
Atonic seizures	Figure 8.27

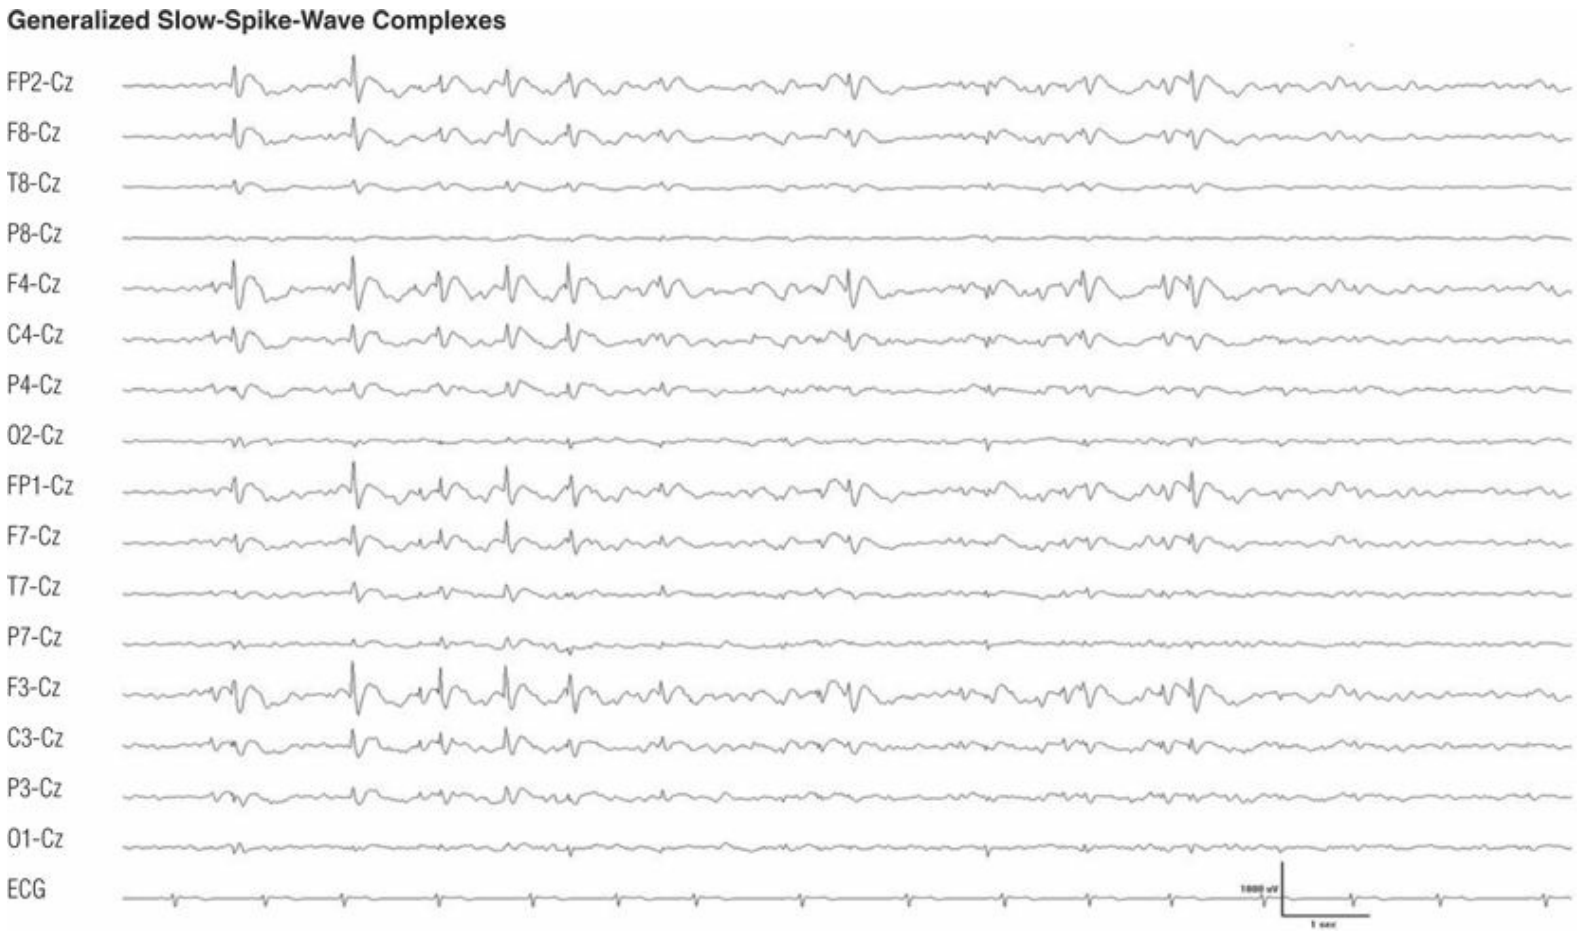

Figure 8.24. Seven-year-old boy with developmental delay and intractable generalized tonic, atonic, myoclonic, tonic–clonic, and atypical absence seizures since age 3 years. Note the bifrontal maximum of the generalized sharp– and slow–wave complexes (5), also called slow spike-and-wave complexes.

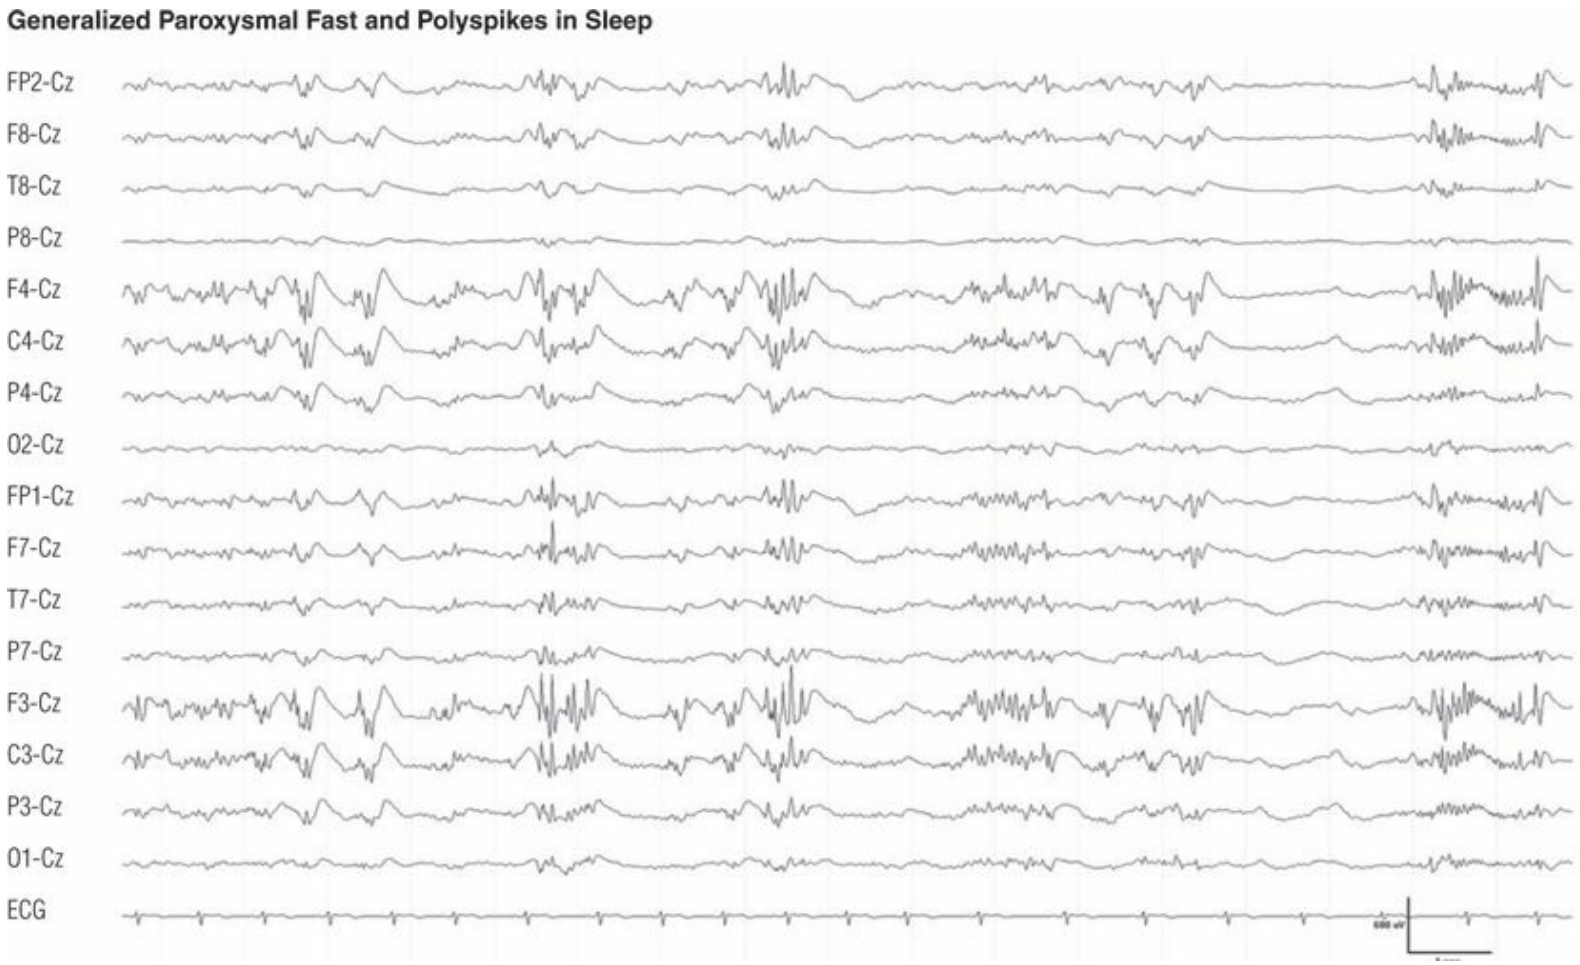

Figure 8.25. Same patient as in Figure 8.24. Generalized polyspikes and paroxysmal fast during drowsiness.

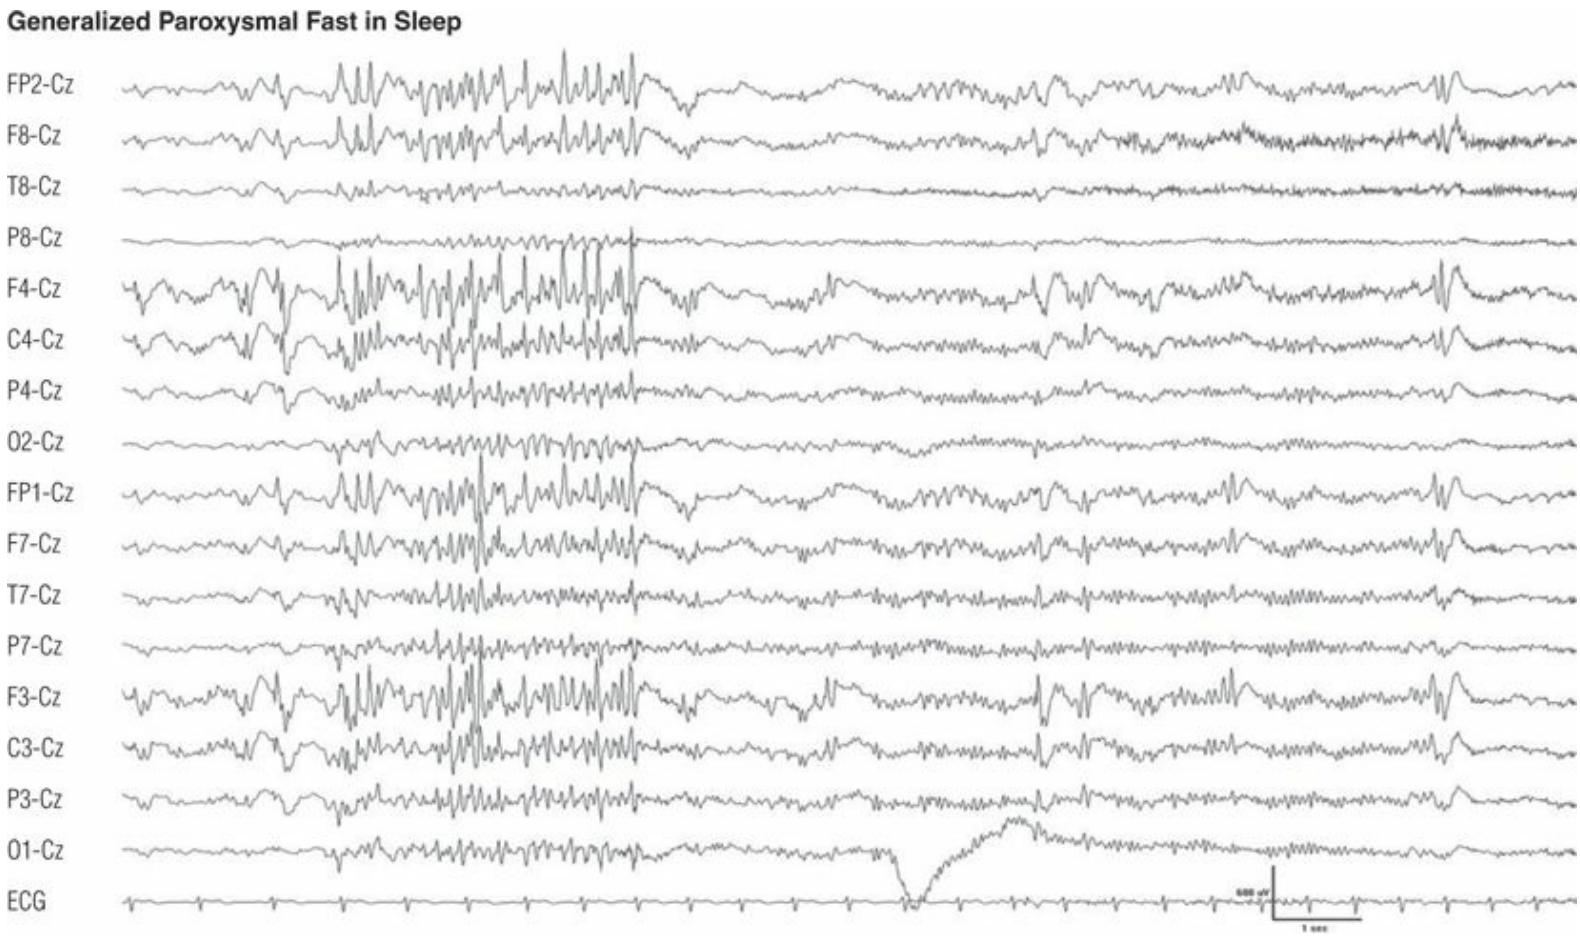

Figure 8.26. Same patient as in Figures 8.24 and 8.25. During drowsiness, generalized paroxysmal fast occurred. When the

paroxysmal fast lasted longer than 5 to 6 seconds, generalized tonic seizure was observed.

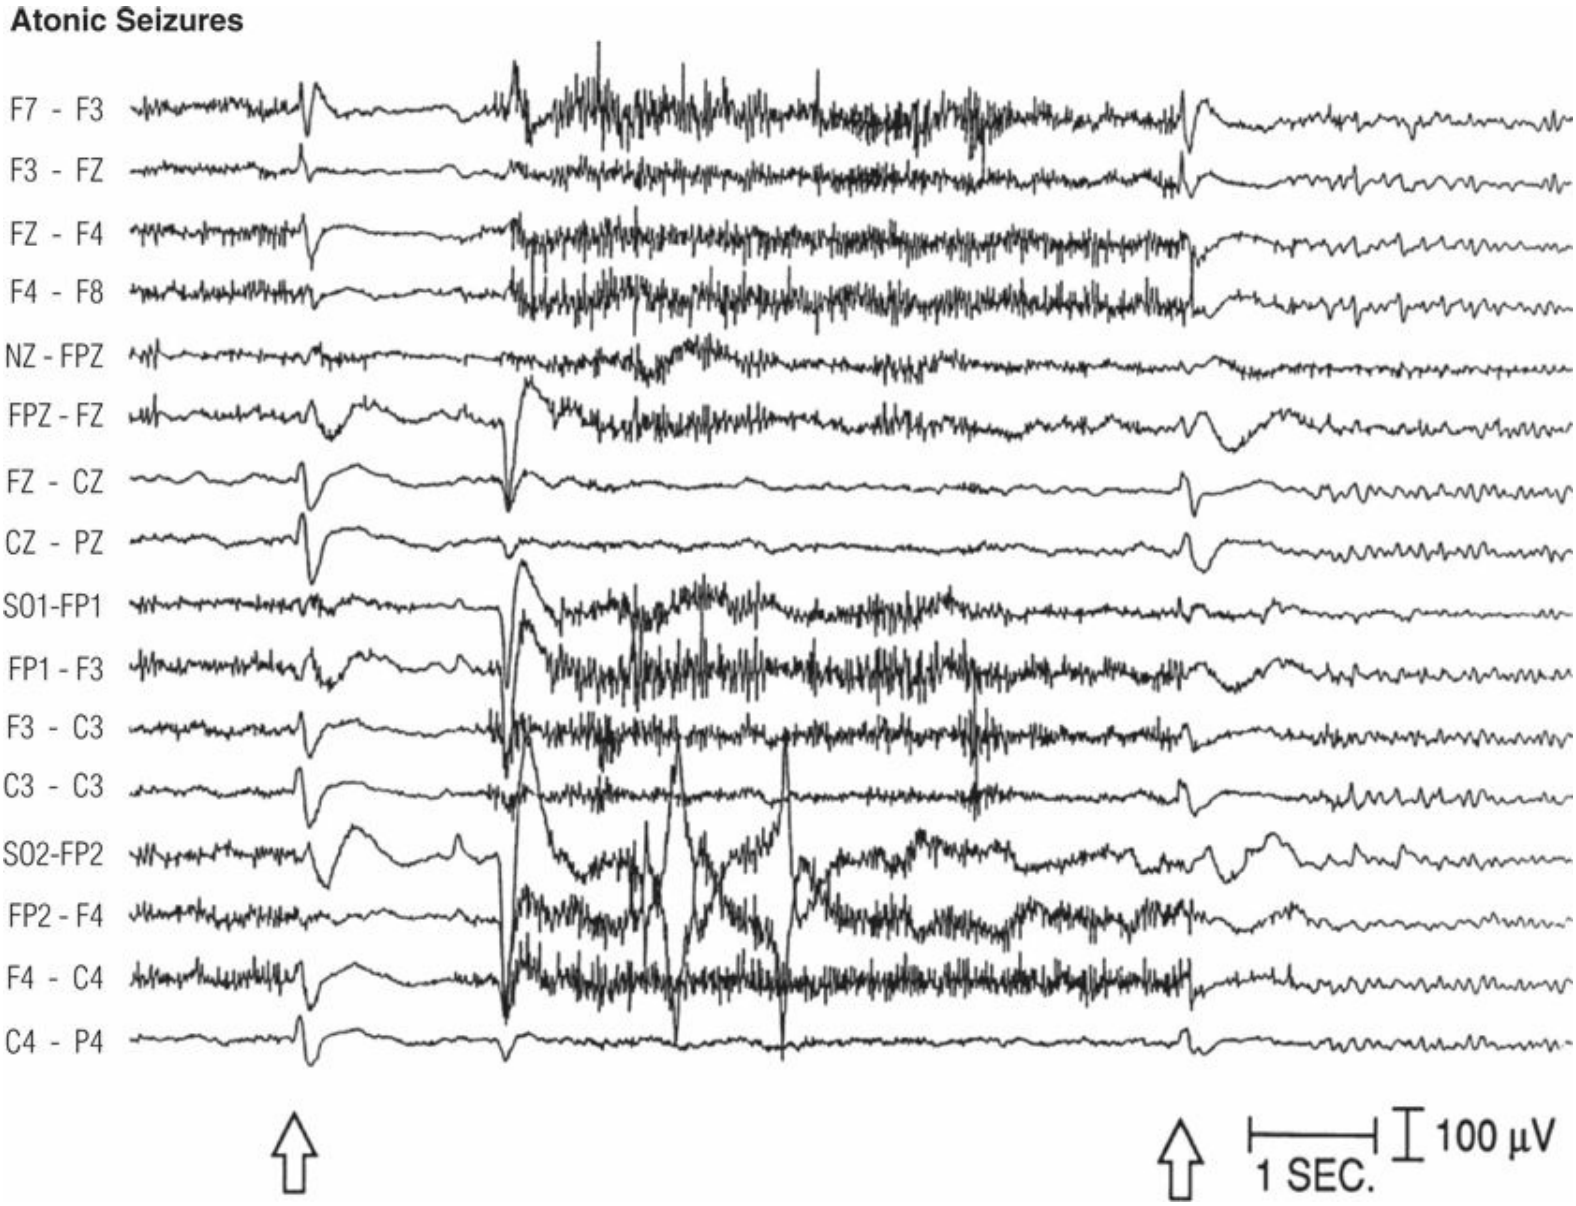

Figure 8.27. Forty-one–year-old man with borderline intelligence and intractable generalized tonic, atonic, generalized tonic–clonic, and atypical absence seizures since age 3 years. Interictal electroencephalogram showed generalized sharp– and slow–wave complexes. Two seizures are recorded here, with limp head nodding plus tonic stiffening and elevation of both arms. Each seizure began with a generalized sharp wave (open arrows) followed by attenuation of electroencephalograph activity and cessation of muscle artifact.

Intractable Epilepsy with Multifocal Spikes

Intractable epilepsy with multifocal spikes	Figure 8.28

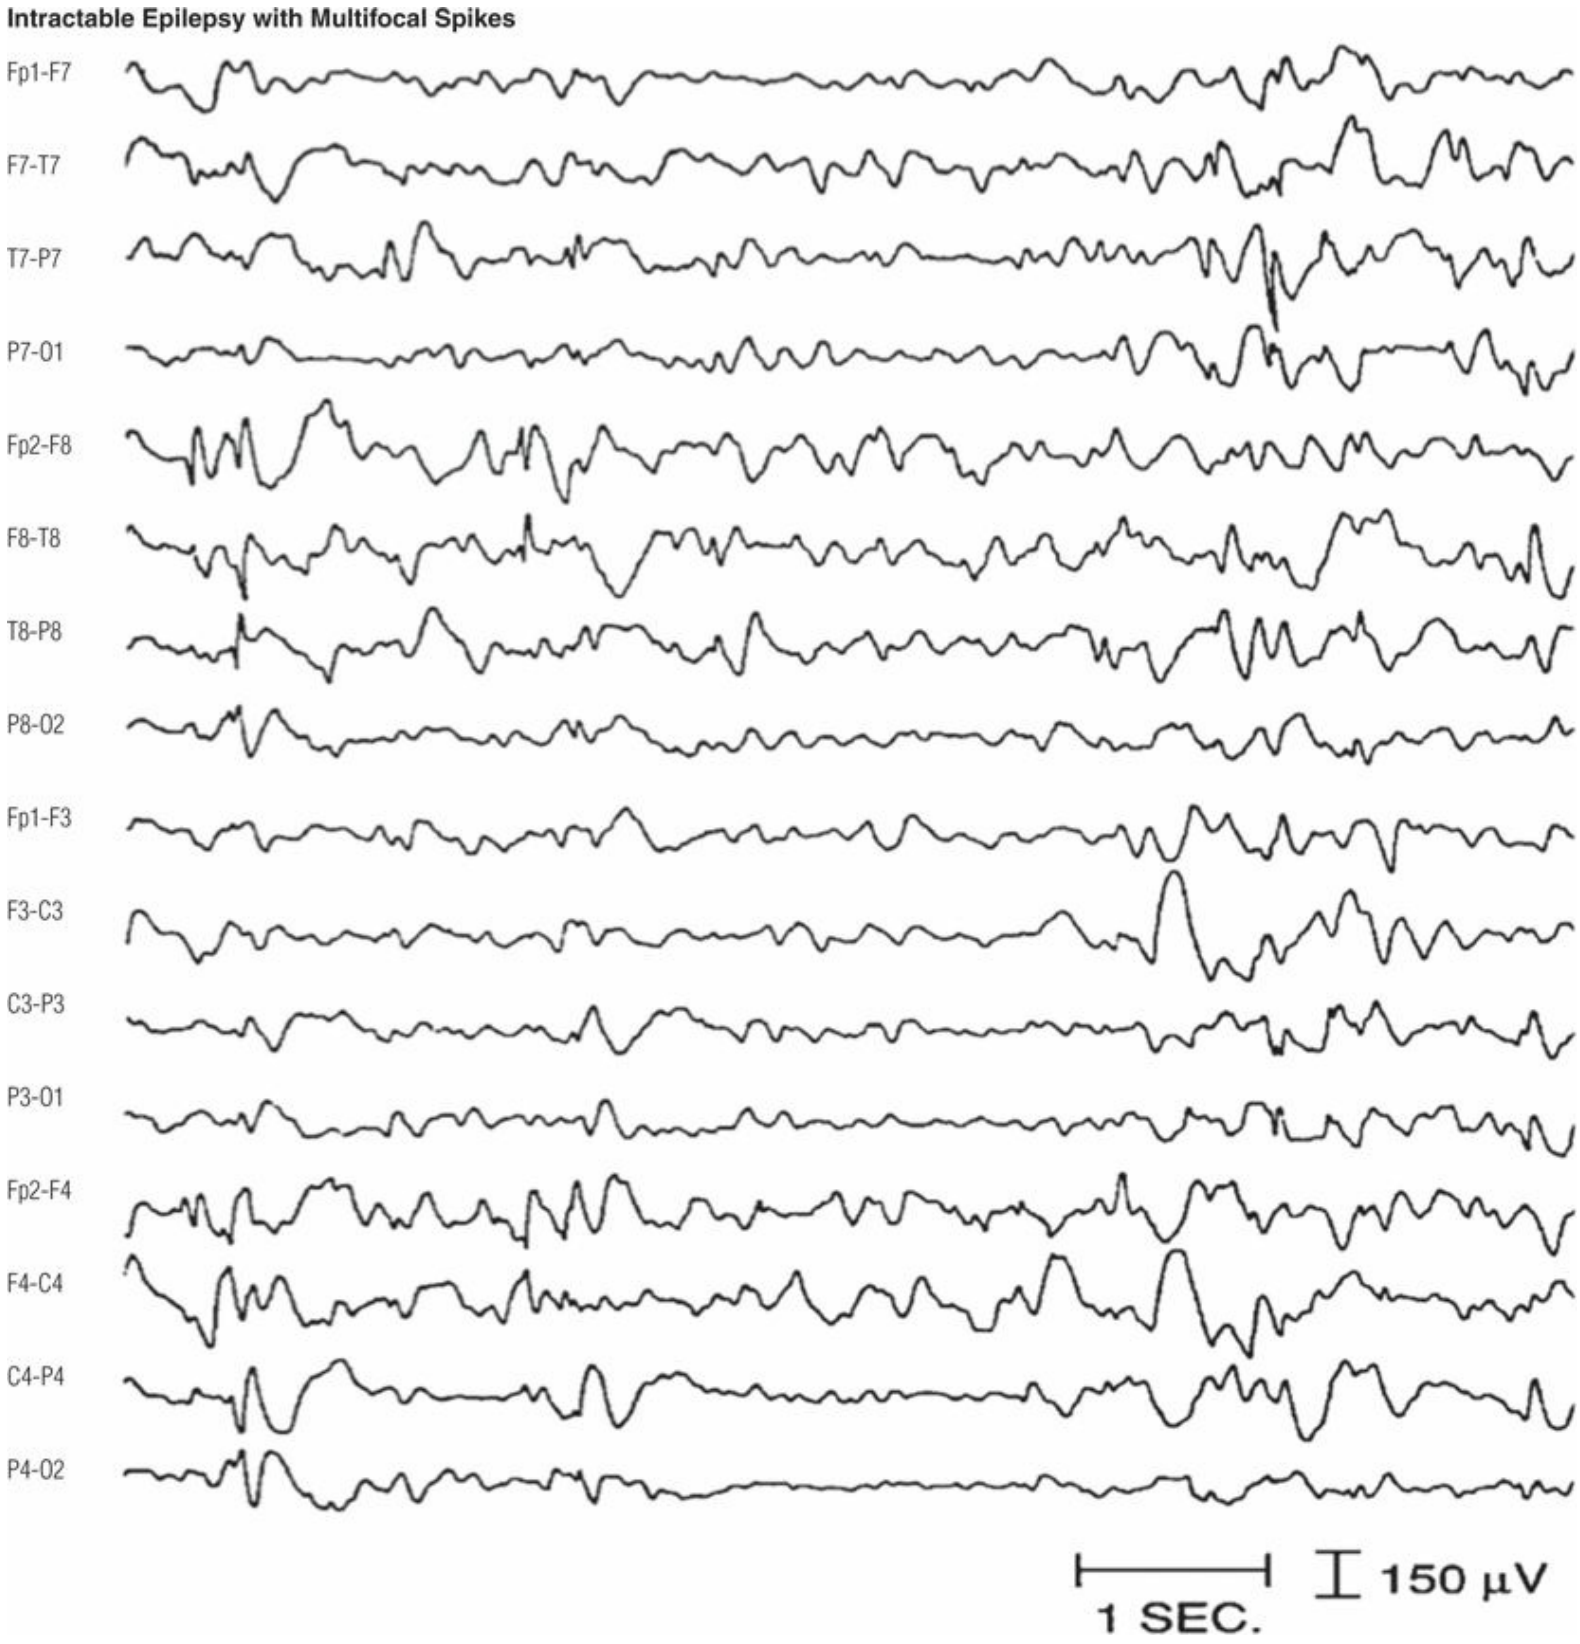

Figure 8.28. Three-year-old boy with developmental delay and intractable clusters of generalized tonic, myoclonic, and atypical absence seizures. This electroencephalographic pattern is not uncommon in children with clinical features similar to those of Lennox–Gastaut syndrome (13).

Stimulation-Related Epilepsy

Cognitive (Soduko)-induced spikes	Figures 8.29 and 8.30

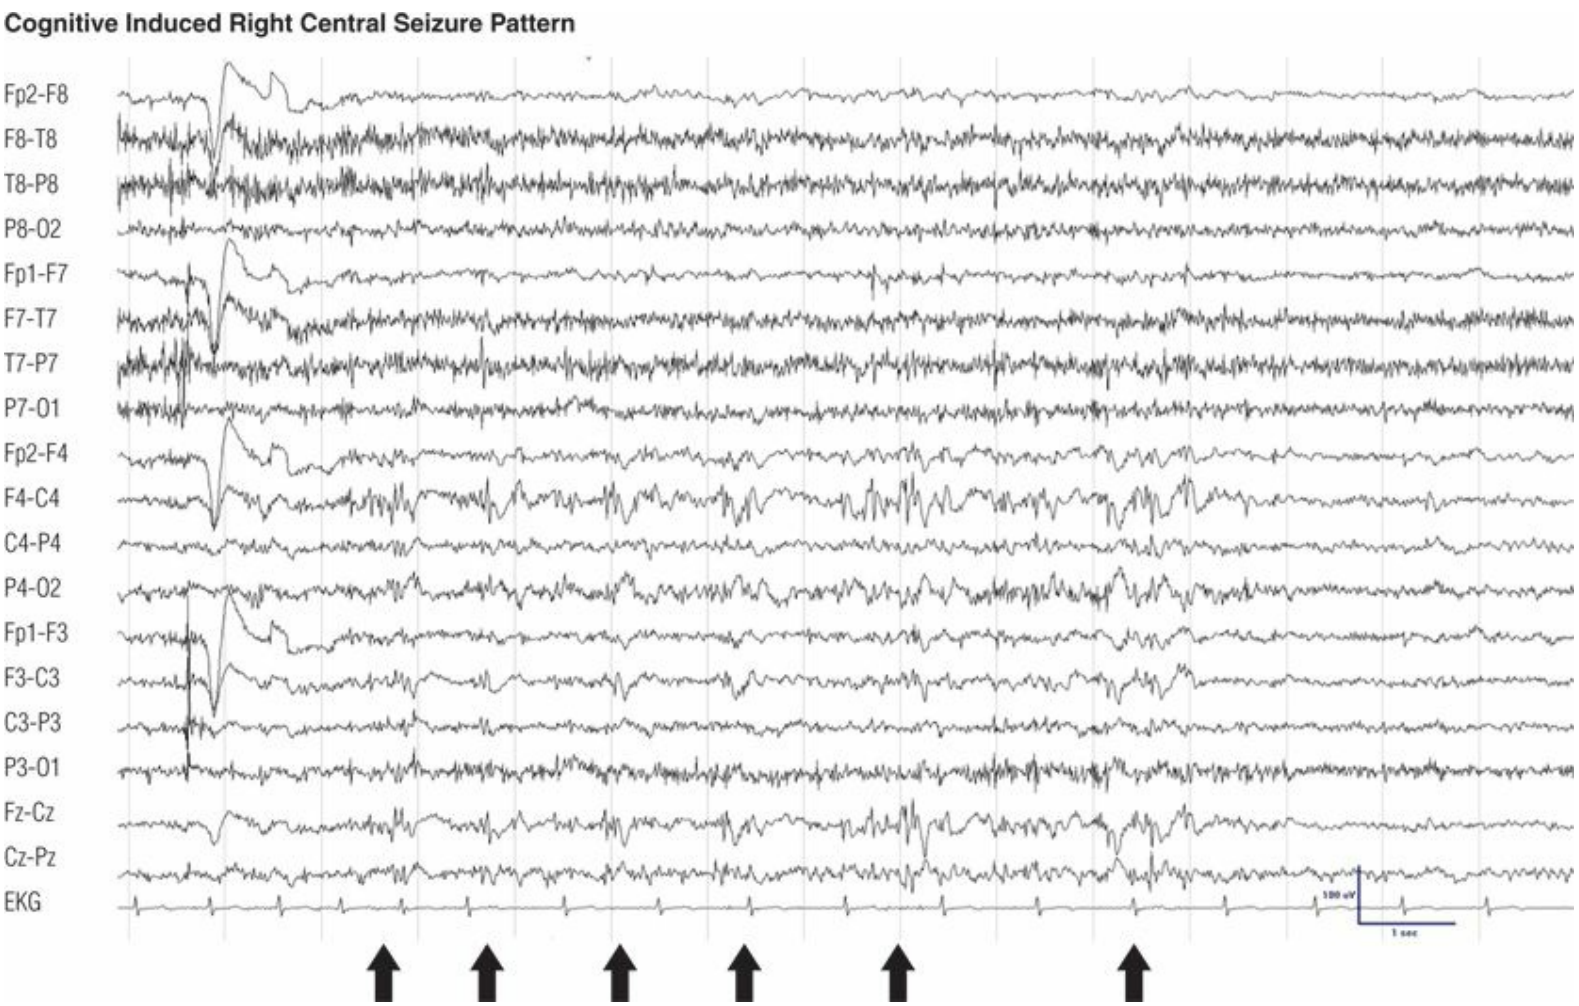

Figure 8.29. Twenty-five–year-old right-handed man with focal clonic seizure induced by cognitive tasks. He developed Lance–Adams syndrome after he was buried by an avalanche resulting in 15 minutes of hypoxia. When the patient was trying to solve Sudoku puzzles, he developed clonic seizures of the left arm (14). These evolved into GTCS in case he continued with the riddle. The unilateral clonic seizures stopped immediately when the sudoku was discontinued. During this EEG, the patient was solving a sudoku; note the initial eye movement artifact that is followed by repetitive right central polyspike bursts.

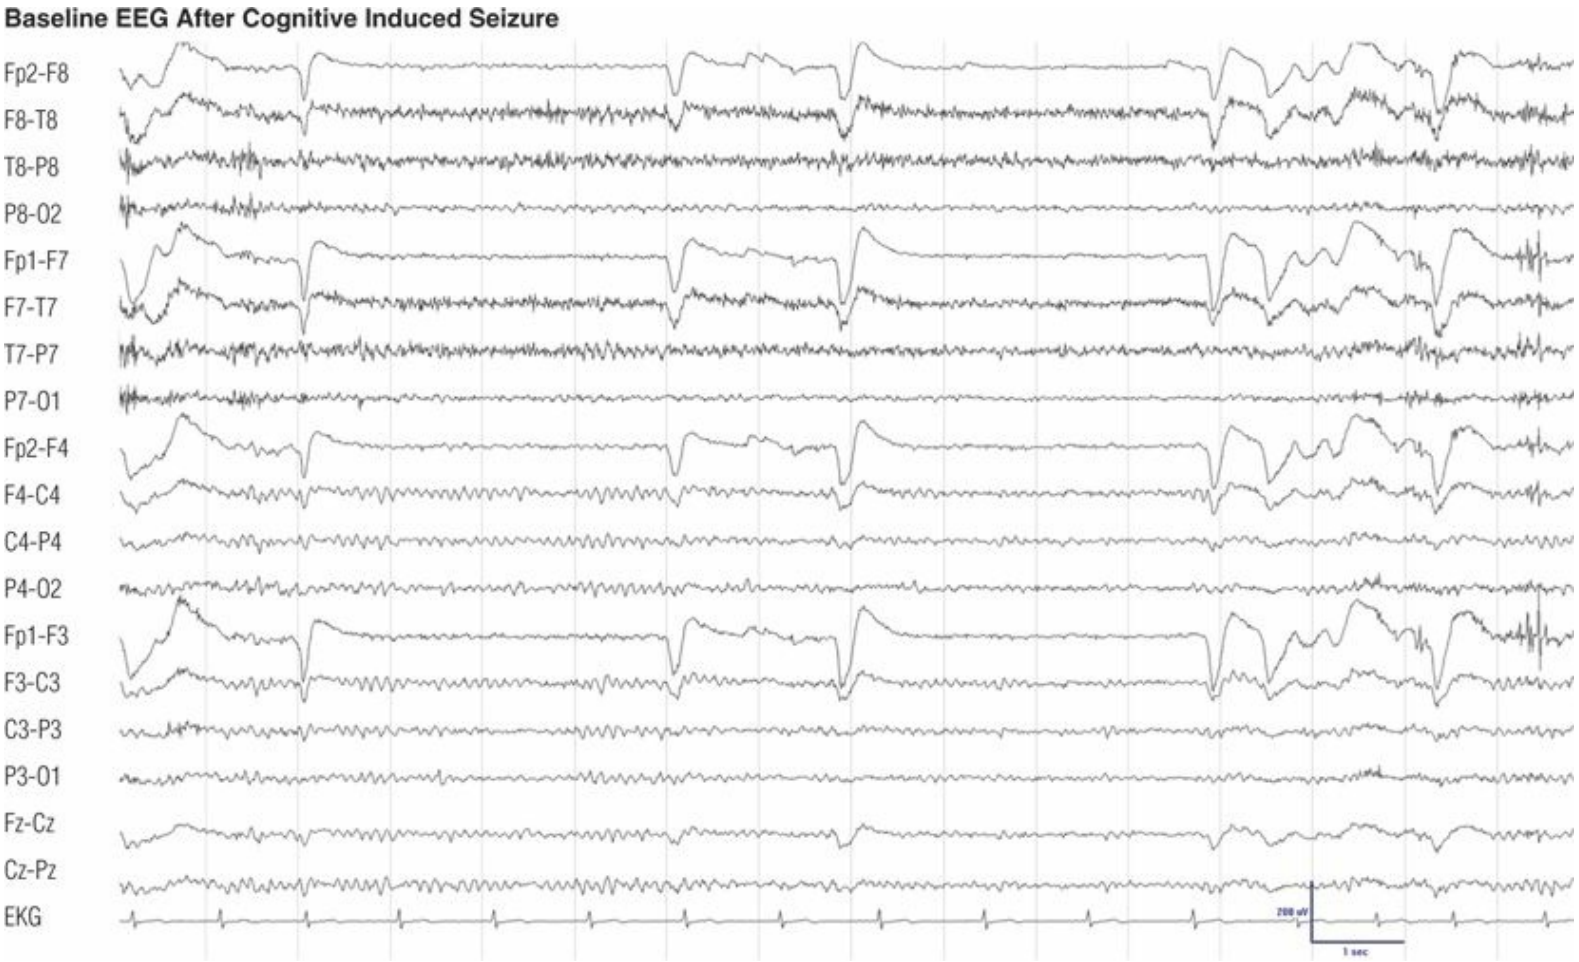

Figure 8.30. Same patient as in Figure 8.29. The EEG normalized and the left arm clonic seizure ceased immediately after cessation of the sudoku.

PART III: ELECTROENCEPHALOGRAPHIC ABNORMALITIES OF THE FOCAL EPILEPSIES

Localization-related (partial, focal, or local) epilepsies (15) involve seizures arising from a cortical region within one hemisphere. The first several illustrations are from children who had benign epileptiform discharges of childhood on EEG, with or without clinical seizures. The rest of the figures are from patients with symptomatic epilepsy and focal seizures arising from specific cortical regions, grouped by location of the epileptogenic zone. For most of the titles and legends, we use terminology from the most recent seizure and epilepsy classification systems of the International League Against Epilepsy (16). Some additional terms are also used here, such as "aura" instead of "simple partial seizure with special sensory symptoms" and "focal clonic seizure" instead of "simple partial seizure with focal motor signs." Some newer terms were also included (17); these are discussed further in Chapter 9.

Benign Focal Epileptiform Discharges of Childhood

Centrotemporal sharp waves	Figure 8.31

Bilateral secondary synchrony	Figure 8.44
Bilateral tonic seizure from sleep	Figure 8.45
Unilateral negative myoclonic seizure	Figure 8.46

Figure 8.31. Nine-year-old boy with benign focal epilepsy of childhood. Awake electroencephalogram showed normal findings, but recording during drowsiness and light sleep showed left centrotemporal sharp waves (benign focal epileptiform discharges of childhood) (18). Many children with benign focal epileptiform discharges of childhood do not have seizures (19), and the finding may be incidental.

Centrotemporal Sharp Waves – Dipole potential

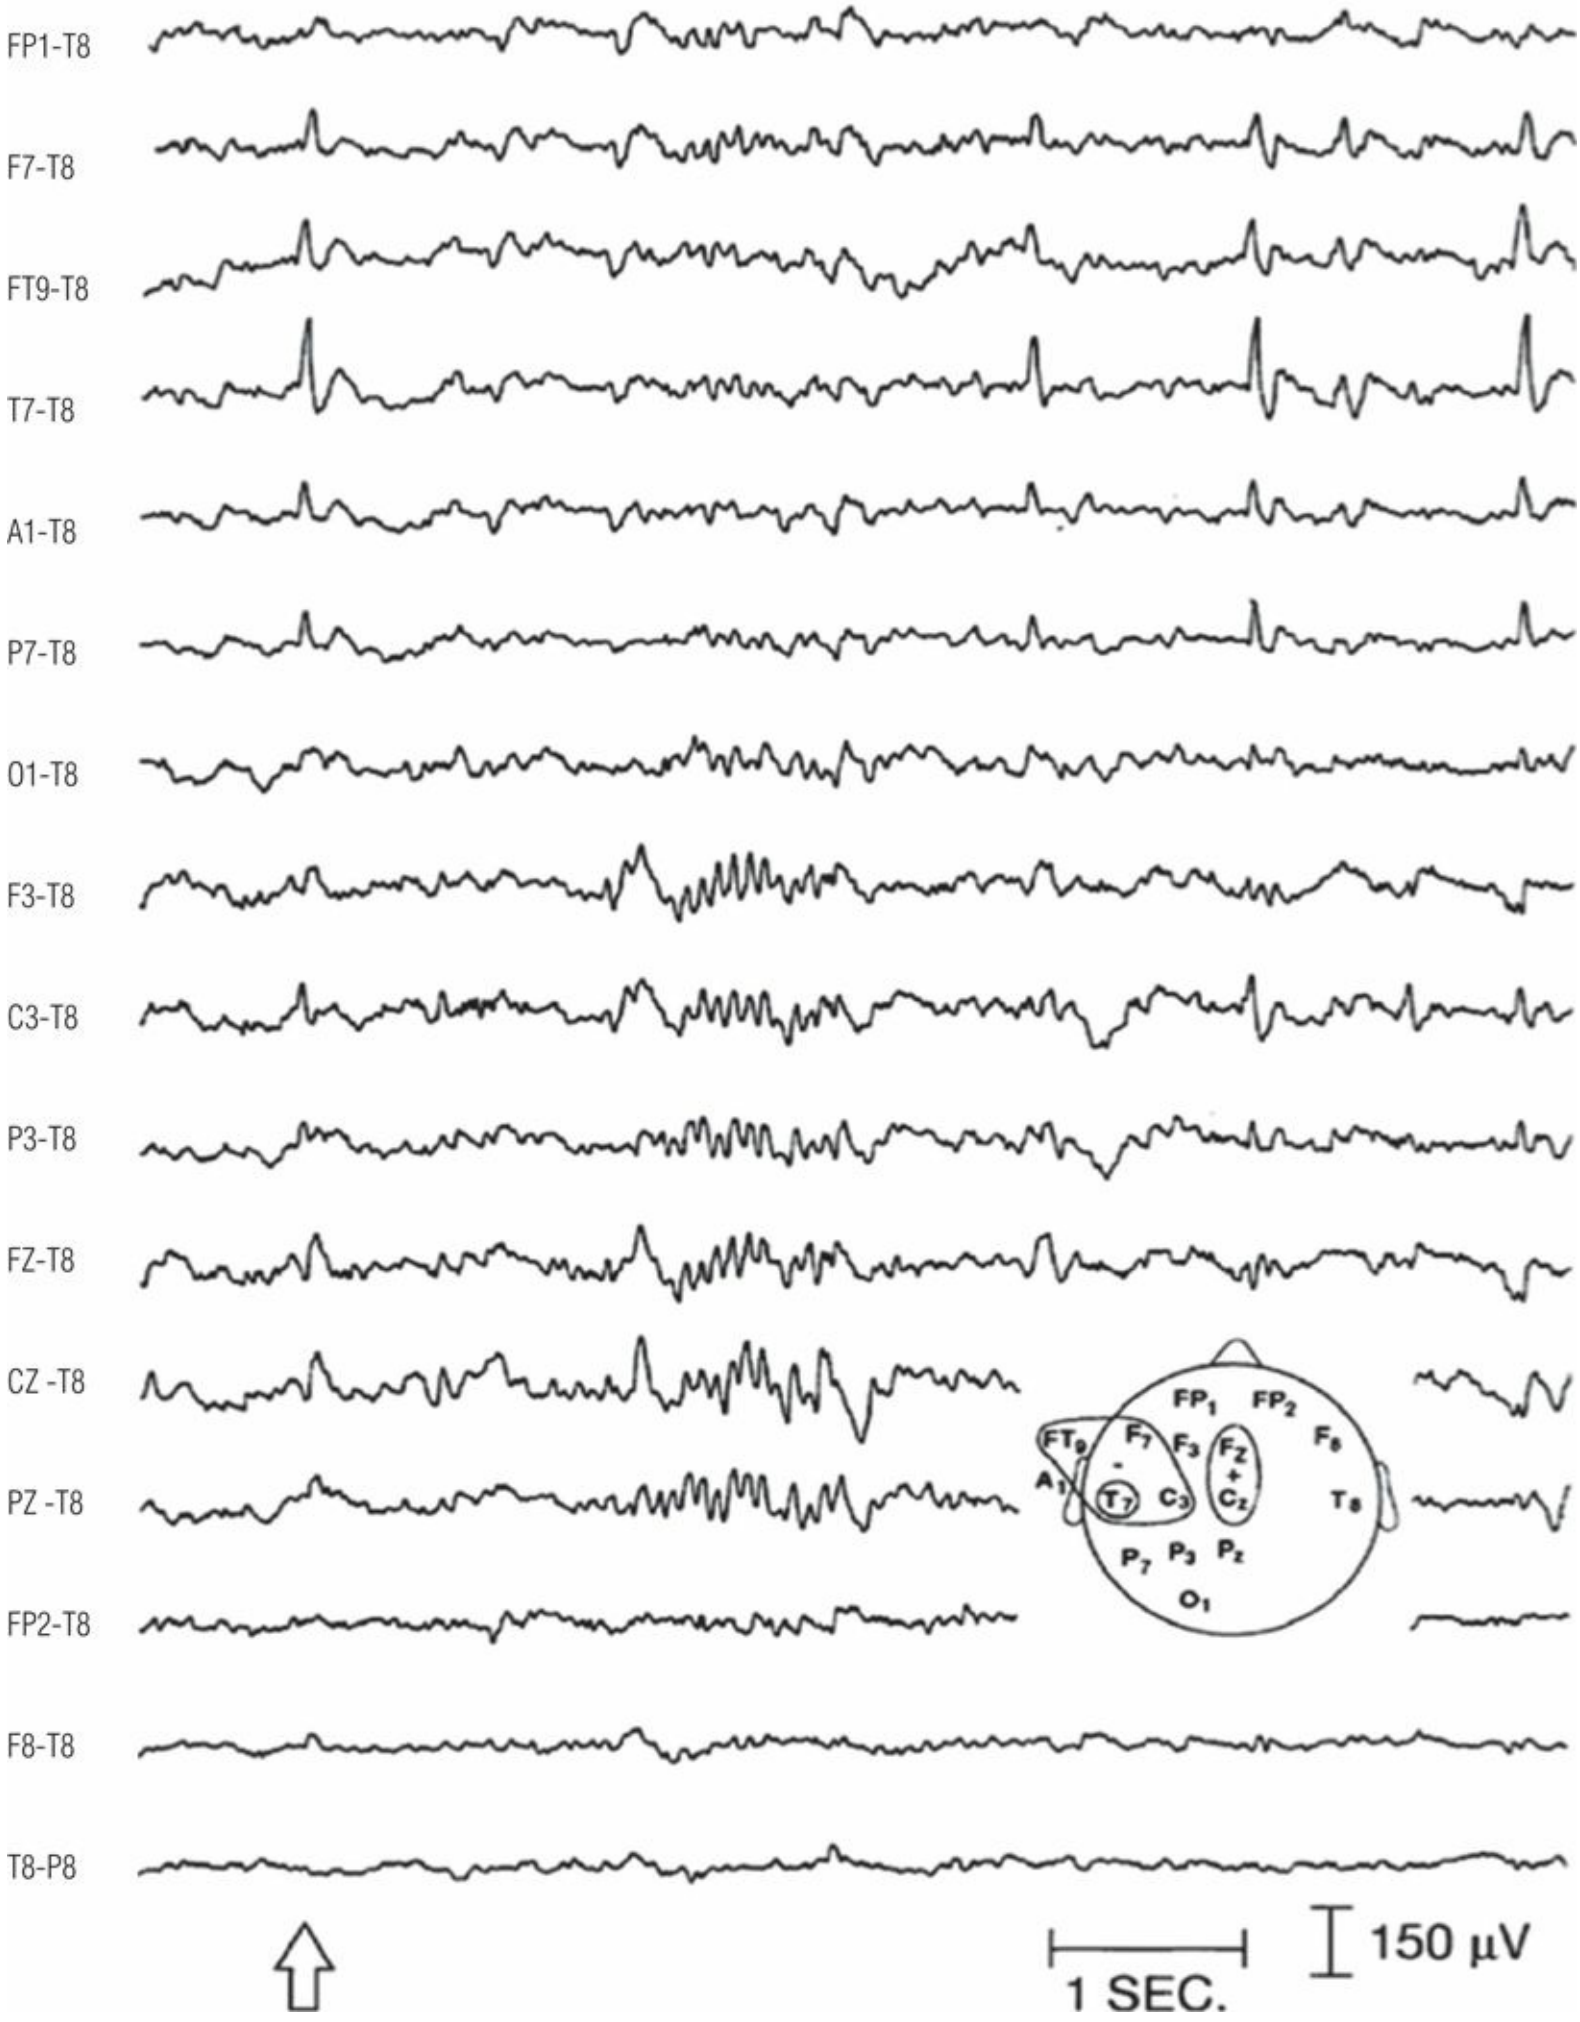

Figure 8.32. Referential electroencephalogram from a 8-year-old patient with attention deficit hyperactivity disorder and no history of seizures. Note that the sharp waves were reflected at the scalp as dipoles, with maximum negativity over the left centrotemporal region and maximum positivity over the vertex. Dipole potentials are typical of benign focal epileptiform discharges of childhood, possibly as a result of horizontal orientation along banks of the sylvian or rolandic fissures (18).

Figure 8.33. Ten-year-old boy with migraine and no history of seizures. The right occipital sharp waves with typical morphology of benign focal epileptiform discharges of childhood (18) were abundant in light sleep but rare during wakefulness.

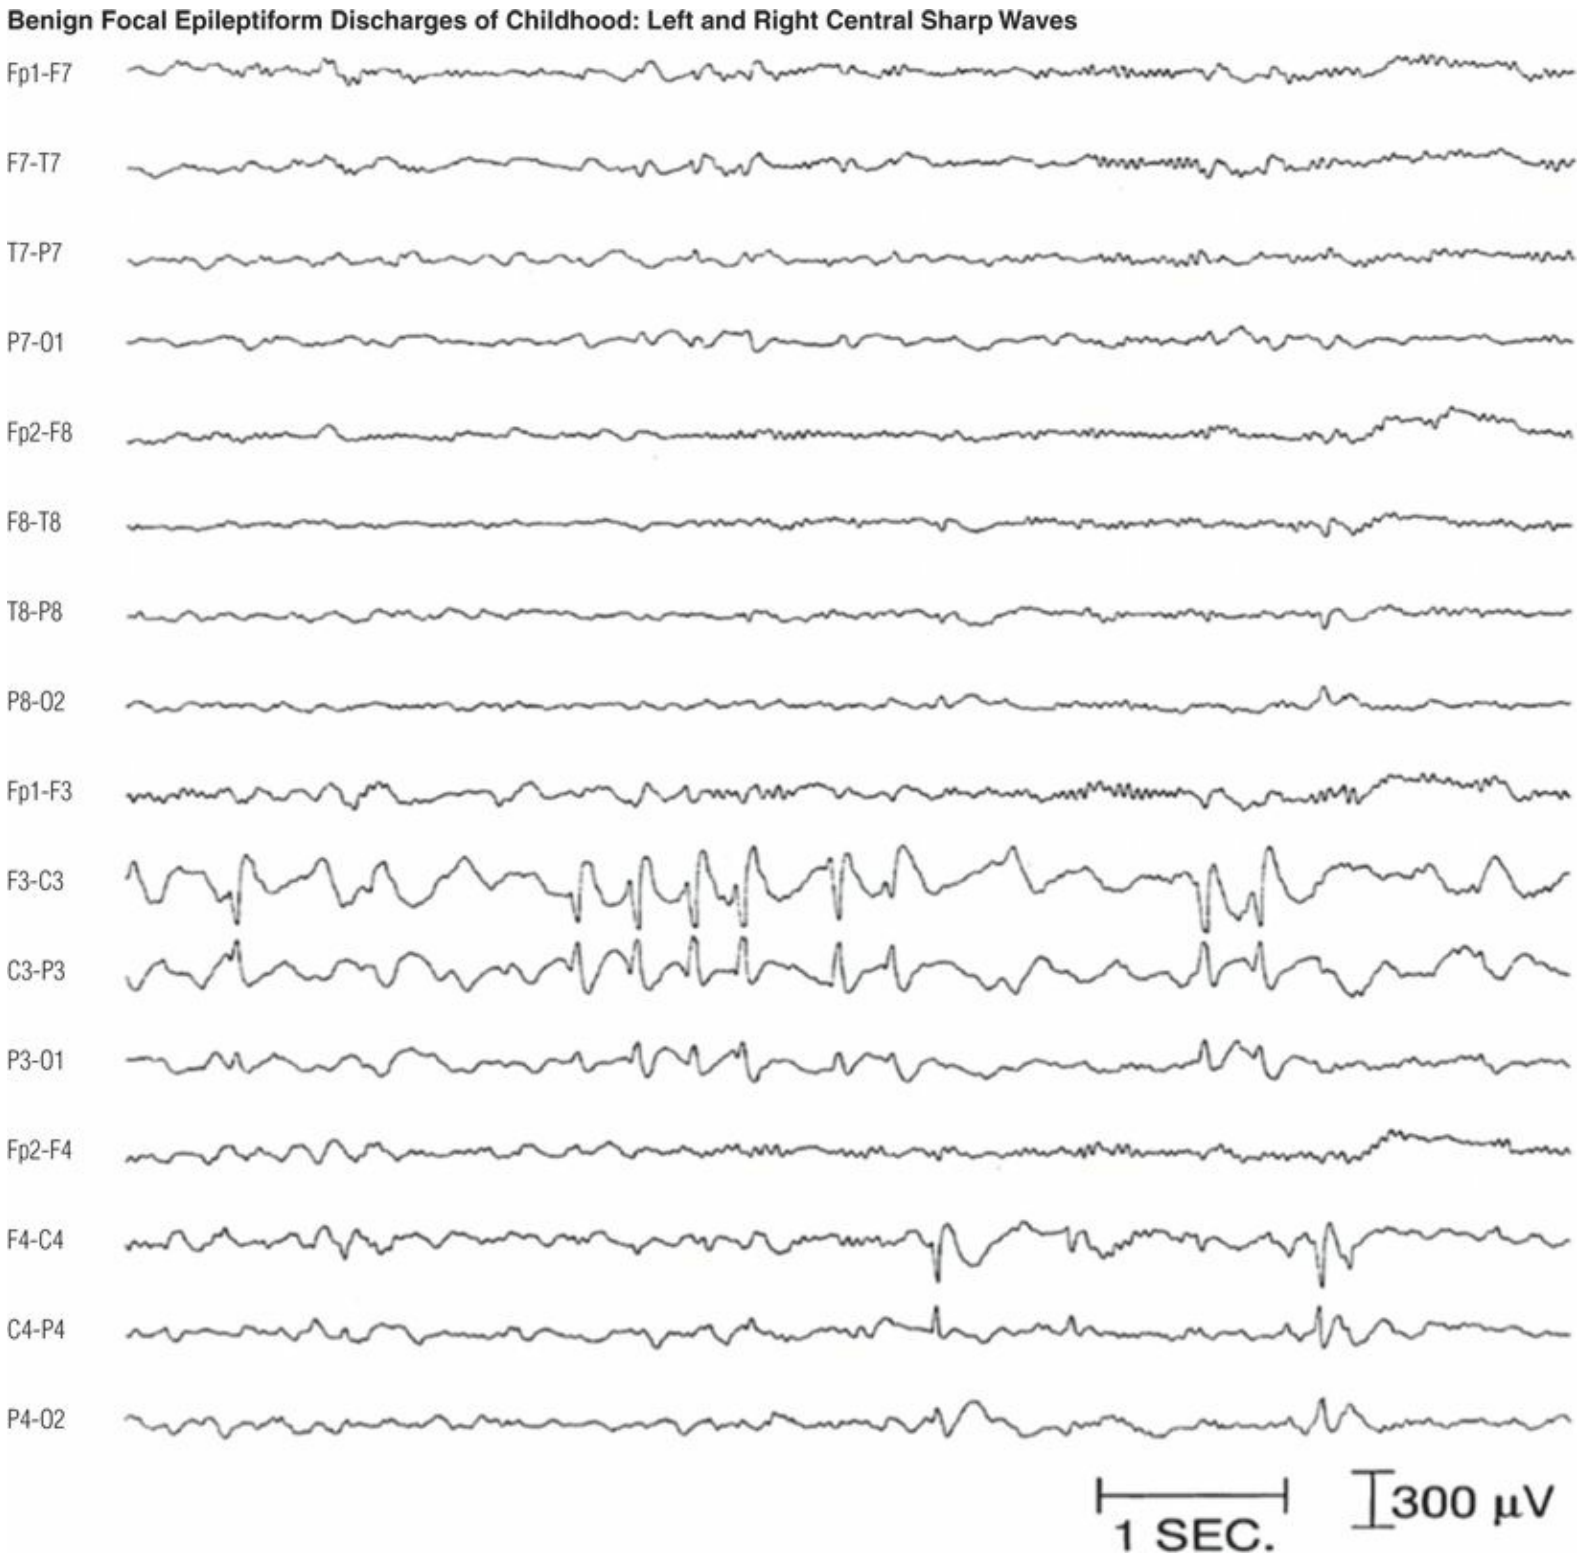

Figure 8.34. Eight-year-old boy, otherwise normal, with rare nocturnal generalized tonic–clonic convulsions since age 4 years. Benign focal epileptiform discharges of childhood are commonly bifocal or multifocal, often from homologous areas of both hemispheres (18).

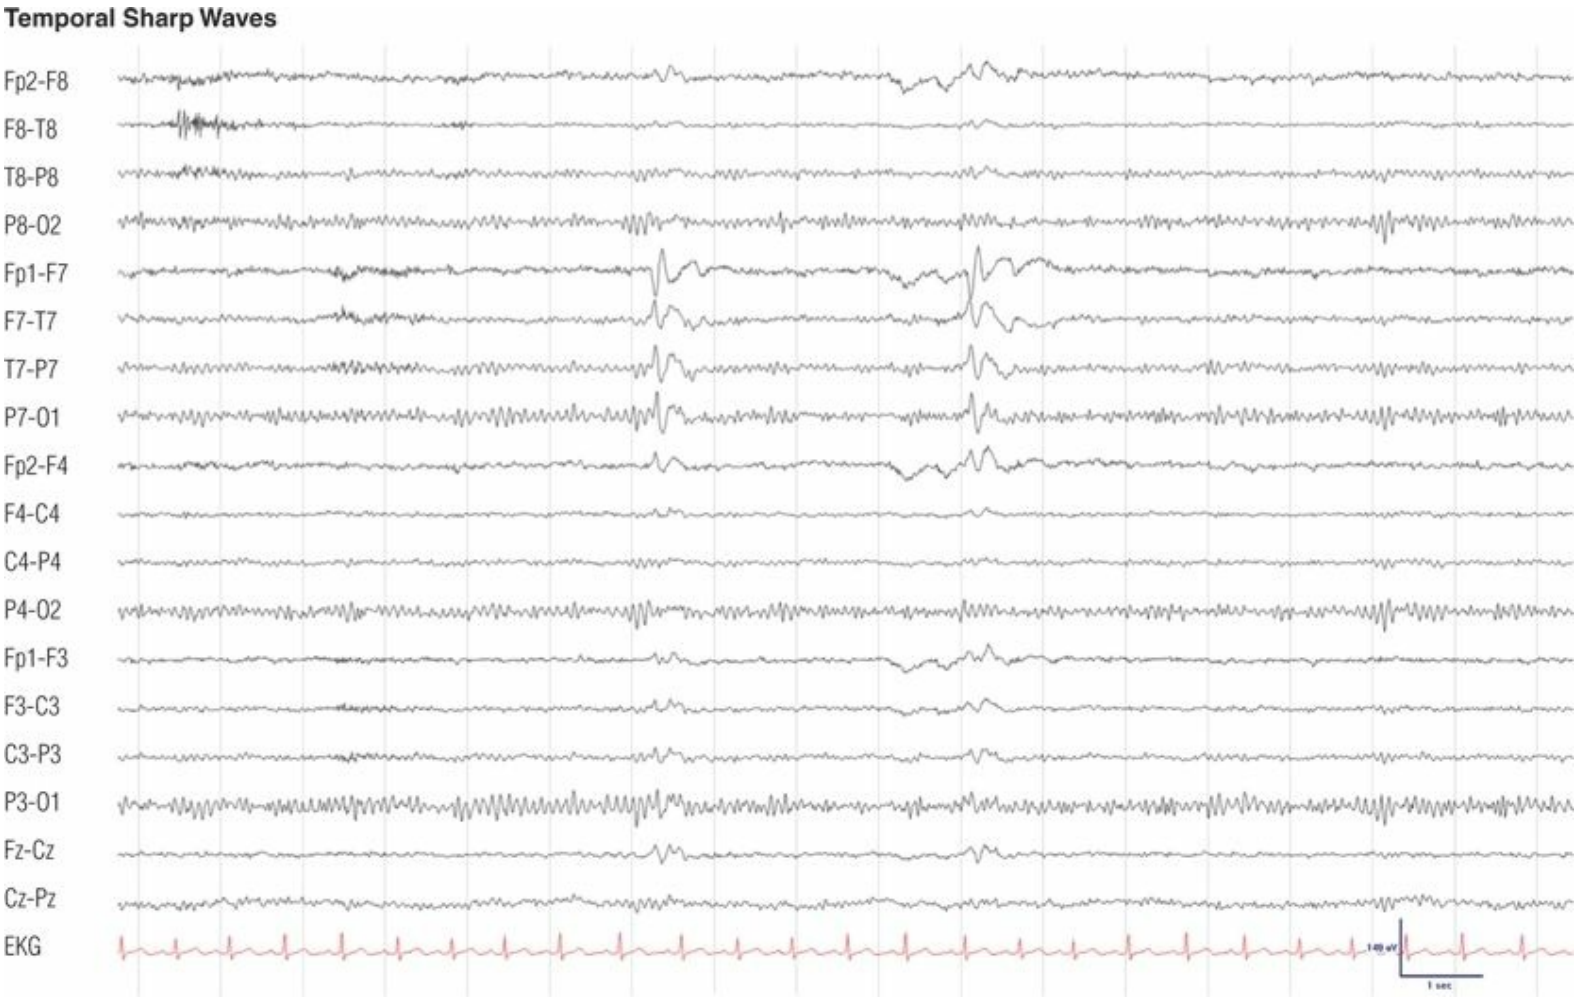

Figure 8.35. Thirty-seven–year-old woman with complex partial seizures with automatisms since age 8 years. Interictal electroencephalogram showed sharp waves from the left anterior temporal region, with maximum amplitude at electrode F7.

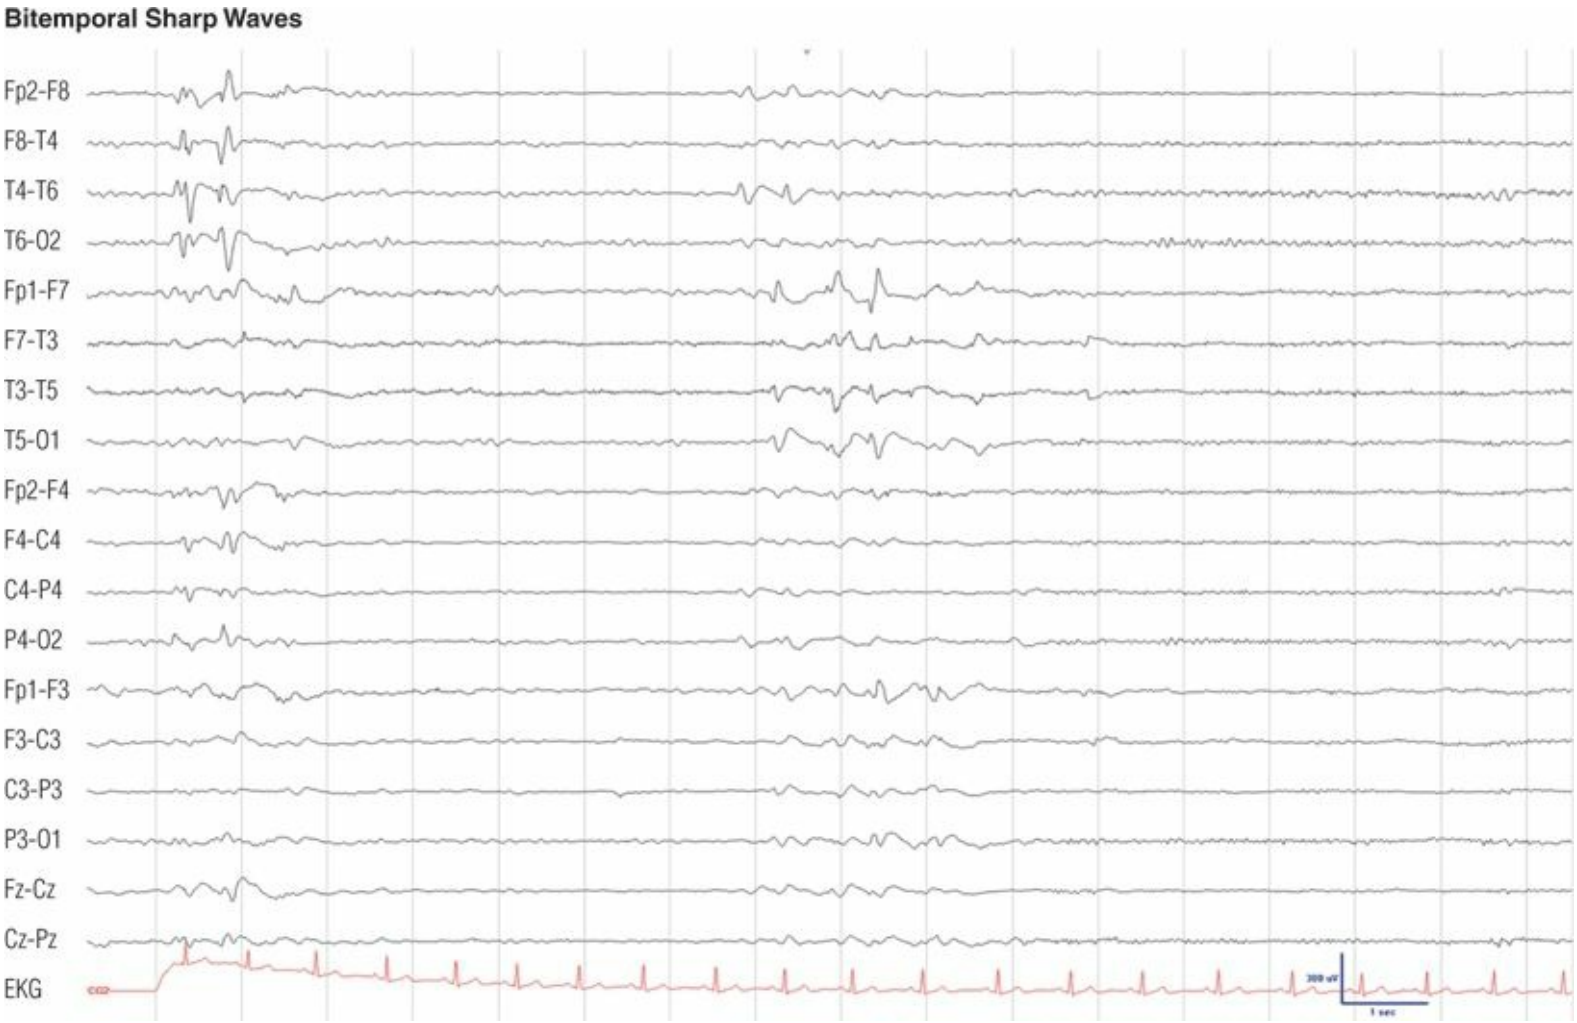

Figure 8.36. Thirty-four–year-old man with onset of complex partial seizures with automatisms at age 4. Interictally, sharp waves were recorded over the right and left temporal region, but all recorded seizures arose from the right temporal lobe.

Figure 8.37. Twenty-five–year-old man with complex partial seizures with automatisms since age 5 years due to bilateral perisylvian dysplasia (20). Note the frequent left temporal polyspike bursts and right temporal spikes and slowing.

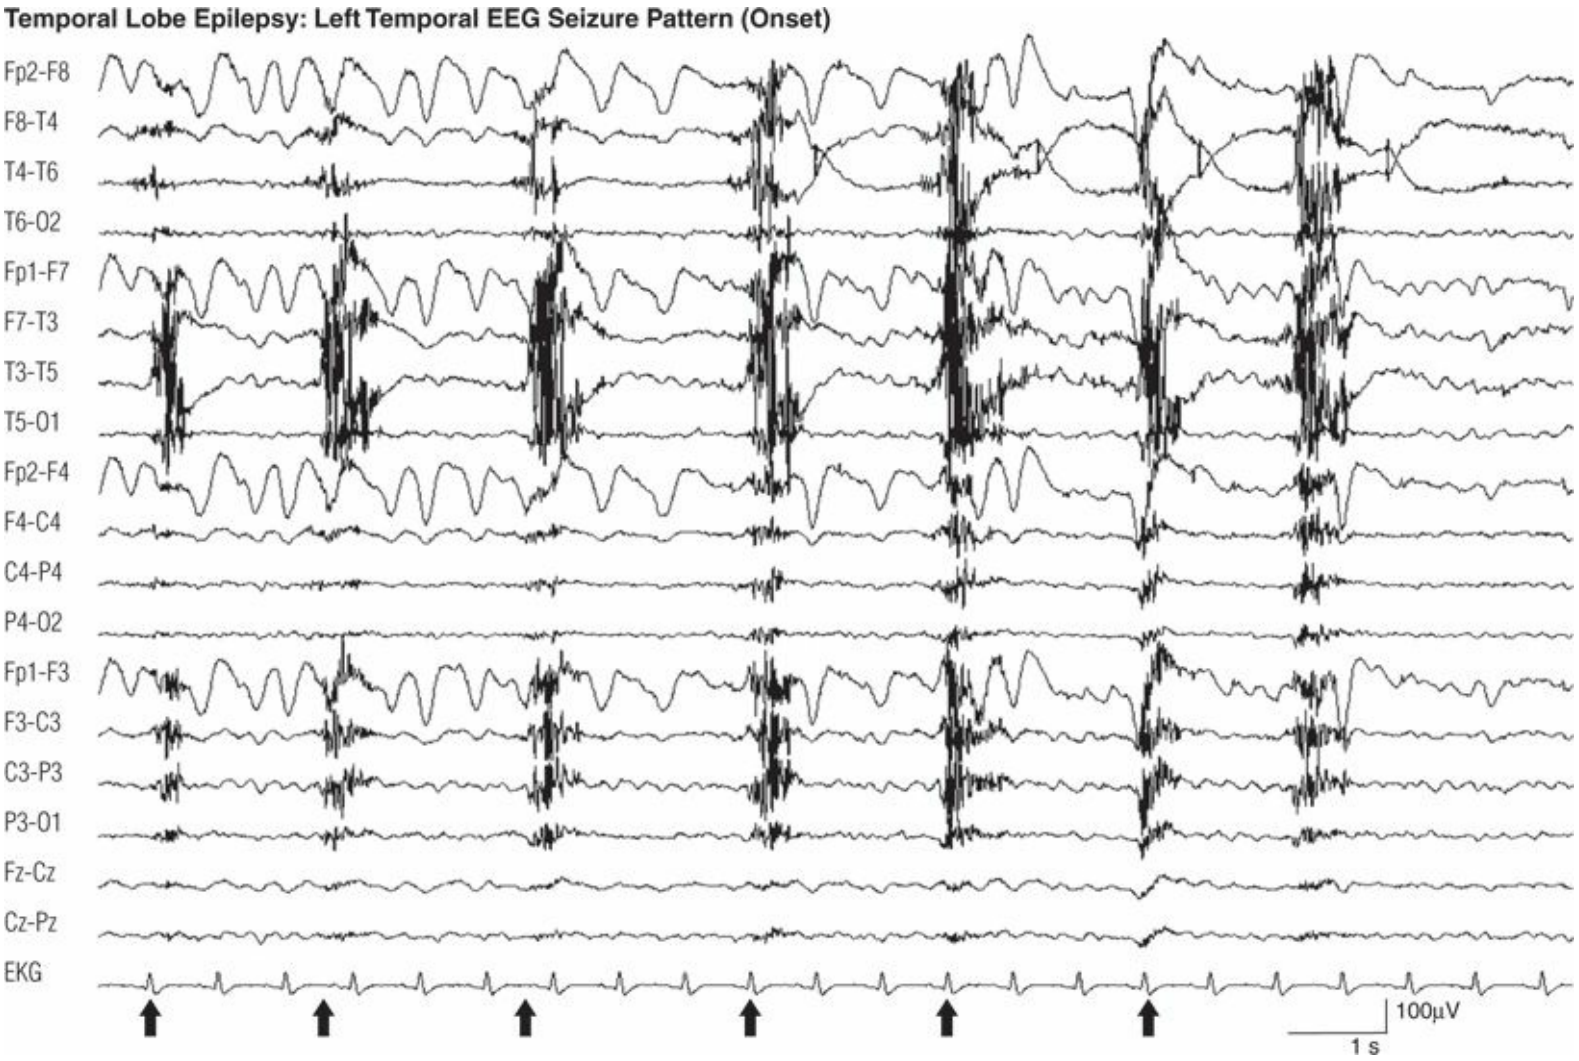

Figure 8.38. Forty-two–year-old man with left temporal lobe epilepsy due to mesial temporal sclerosis. Note the rhythmical left temporal theta waves indicating the EEG onset of a seizure characterized by oral automatisms. The EMG artifacts reflect the chewing movements (arrows).

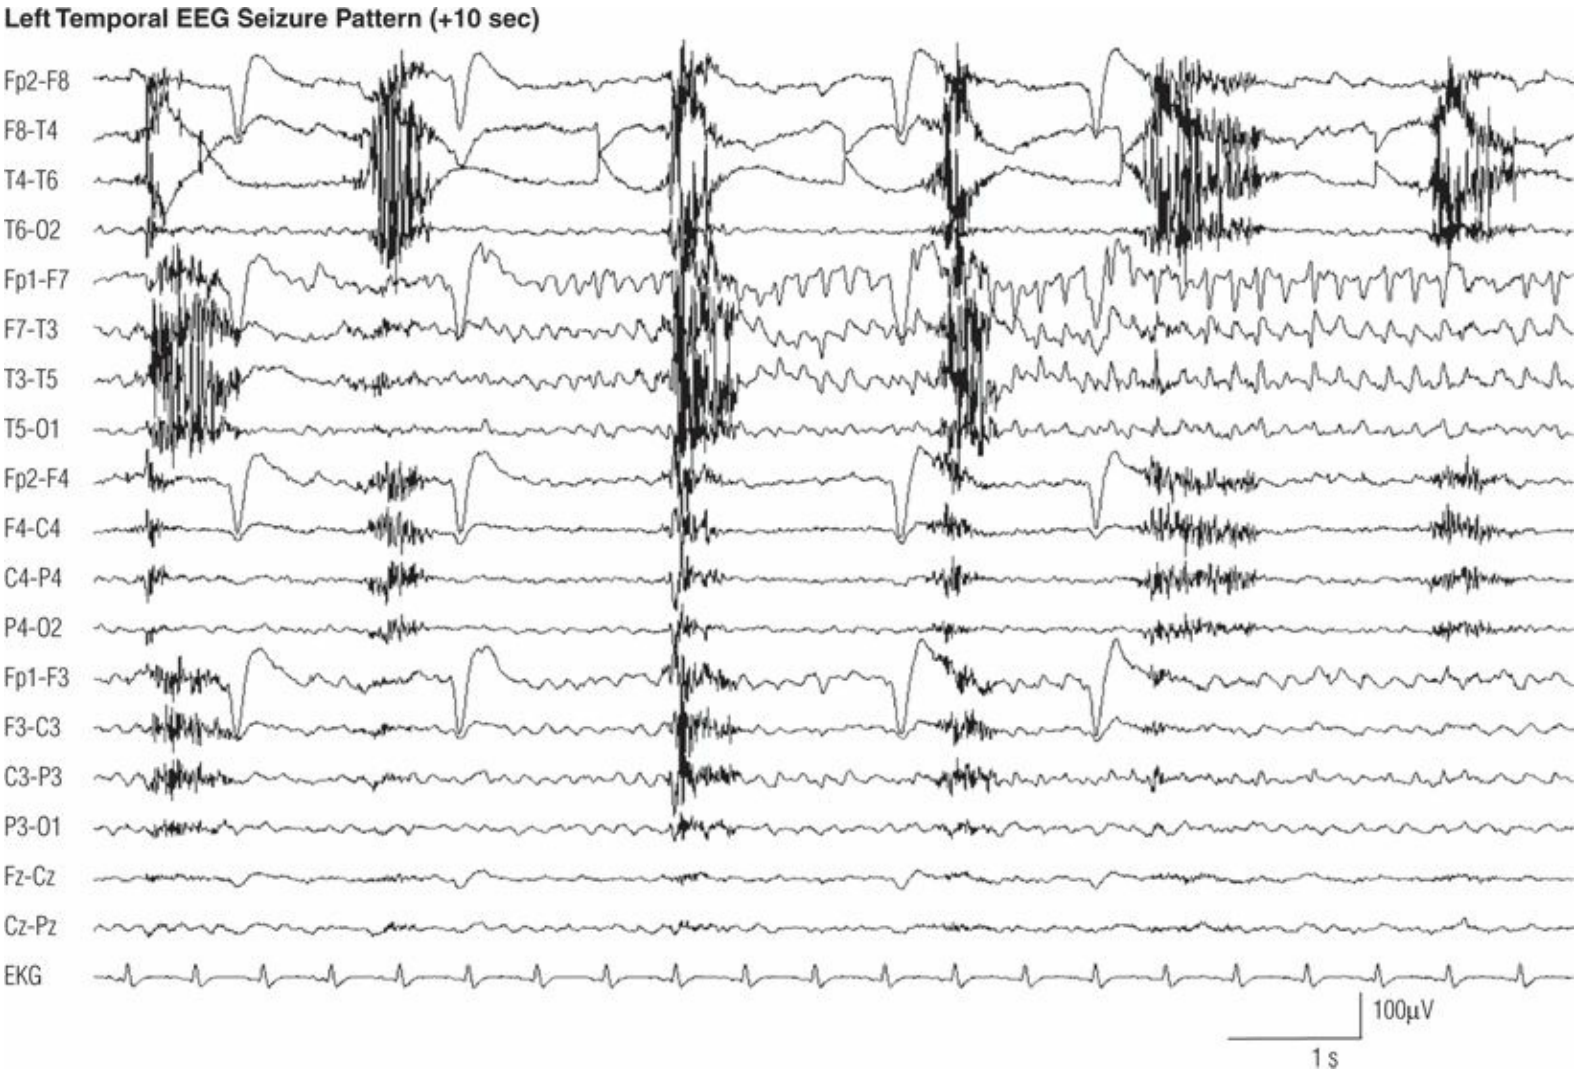

Figure 8.39. Continuation of the seizure shown in Figure 8.38. The rhythmical left temporal theta waves slow down and evolve into repetitive spikes. Clinical features included staring, unresponsiveness, and oral automatisms. The patient is seizure free following left anterior and mesial temporal resection.

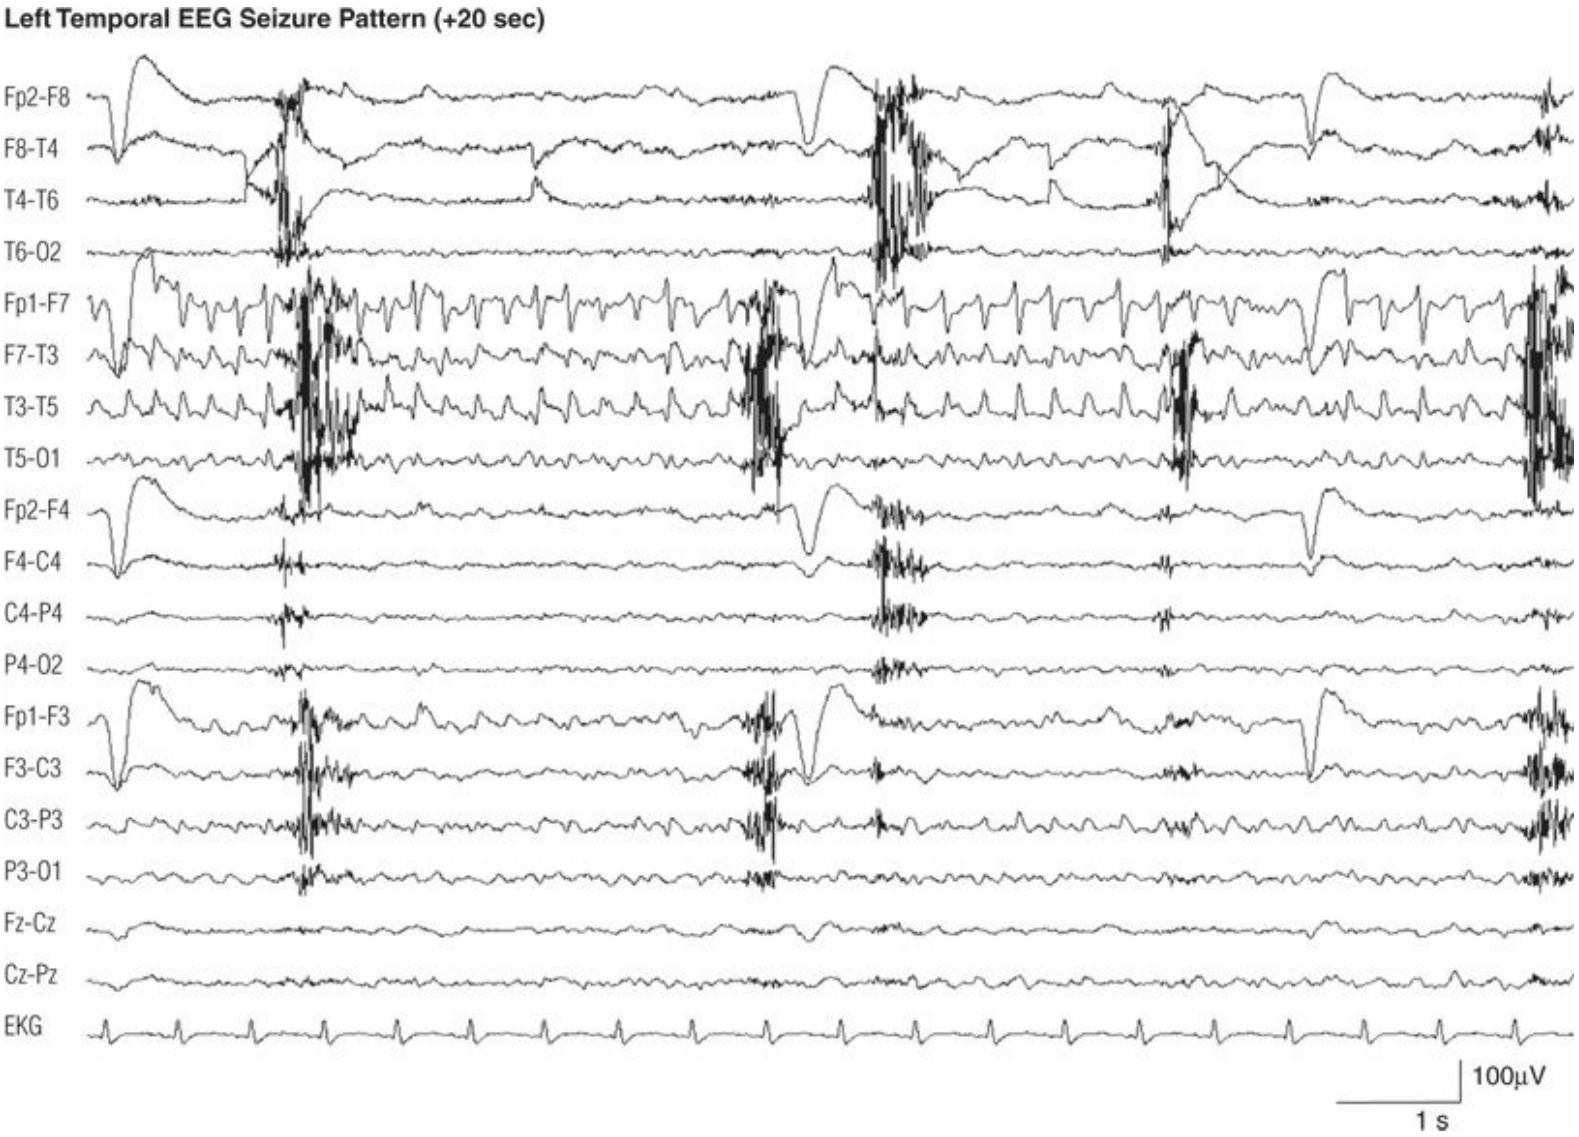

Figure 8.40. Continuation of the seizure shown in Figure 8.39.

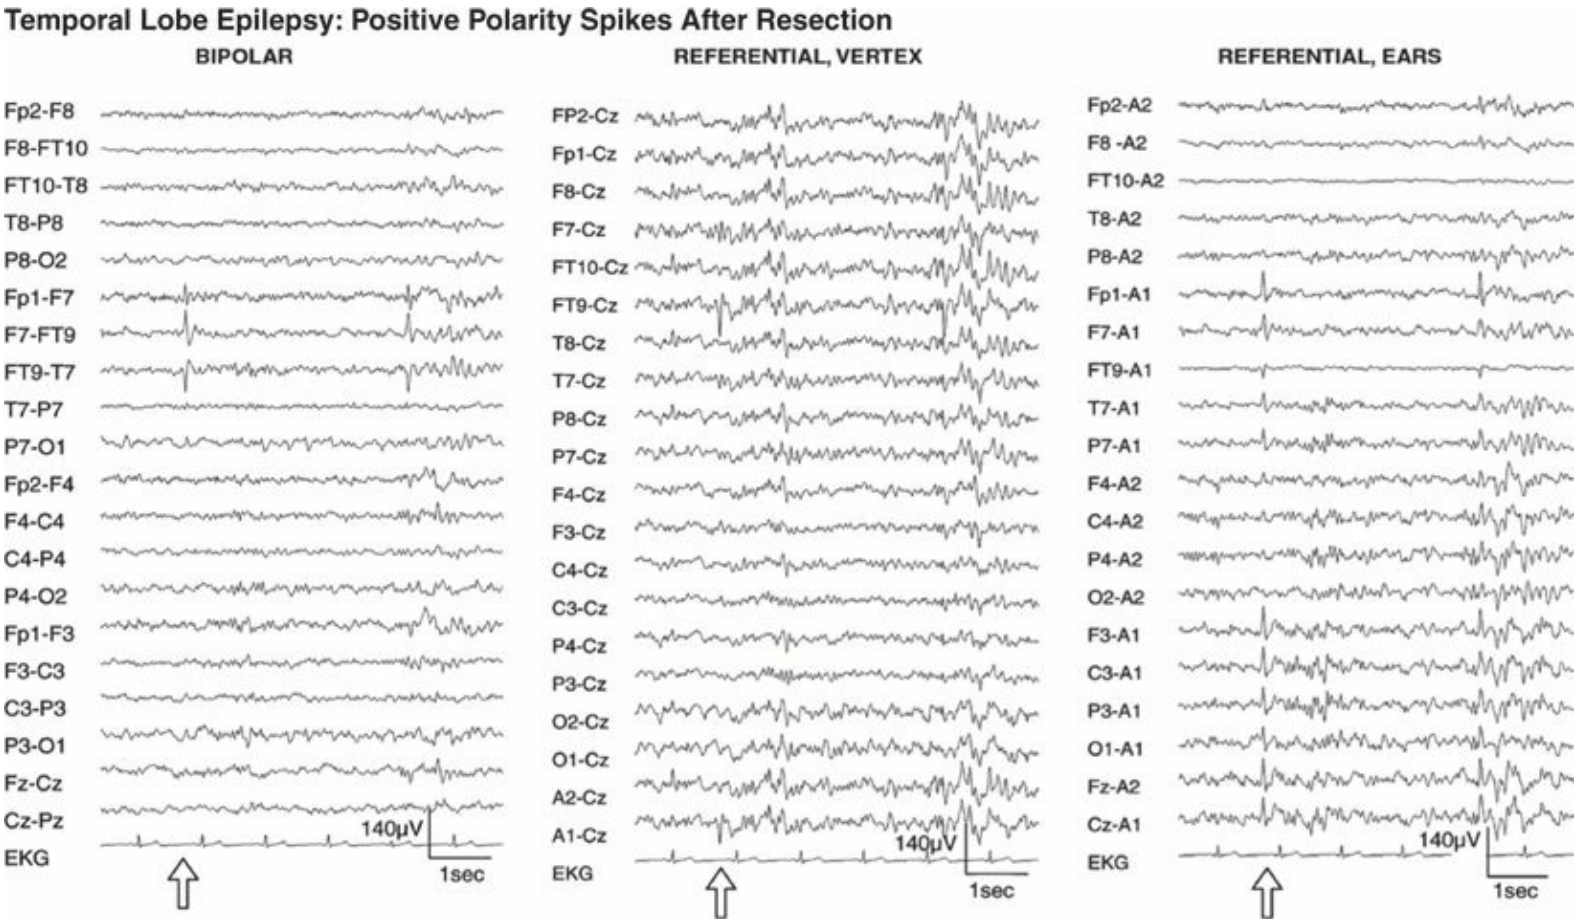

Figure 8.41. Bipolar and referential montages of the same spike (arrows) of a patient who underwent left anterior temporal lobe resection for medically intractable temporal lobe epilepsy. Note that the left anterior spike (electrode FT9) has a positive polarity. This is a rare finding in patients following temporal resections. The downward deflection in the vertex reference (Cz) in the electrodes FT9 and A1 reflects the positivity. The ear reference montage shows that the electrode FT9 shows the maximum positivity (downward deflection), whereas the other left-sided electrodes are relatively negative with regard to left ear electrode (A1) and, therefore, point upward. This may give rise to the false impression of a negative spike in the left frontal region in the ipsilateral ear reference montage.

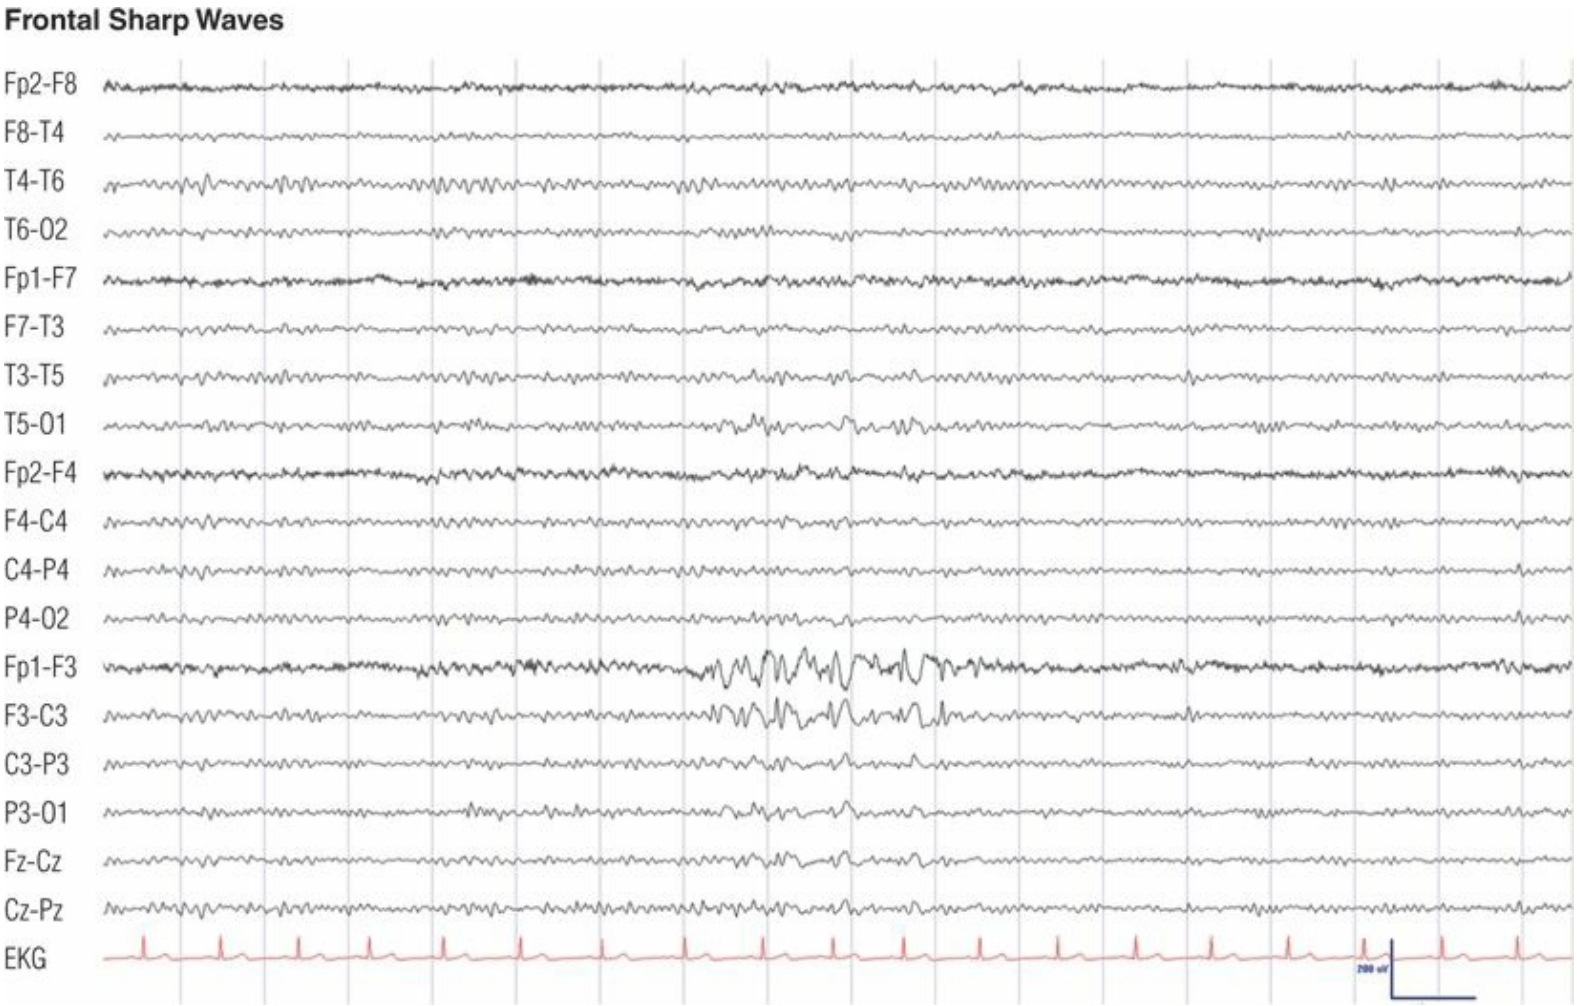

Figure 8.42. Thirty-year-old man with intractable right versive and generalized tonic–clonic seizures due to left frontal cortical malformation. Interictal sharp waves were maximum in the left frontal region at electrode F3.

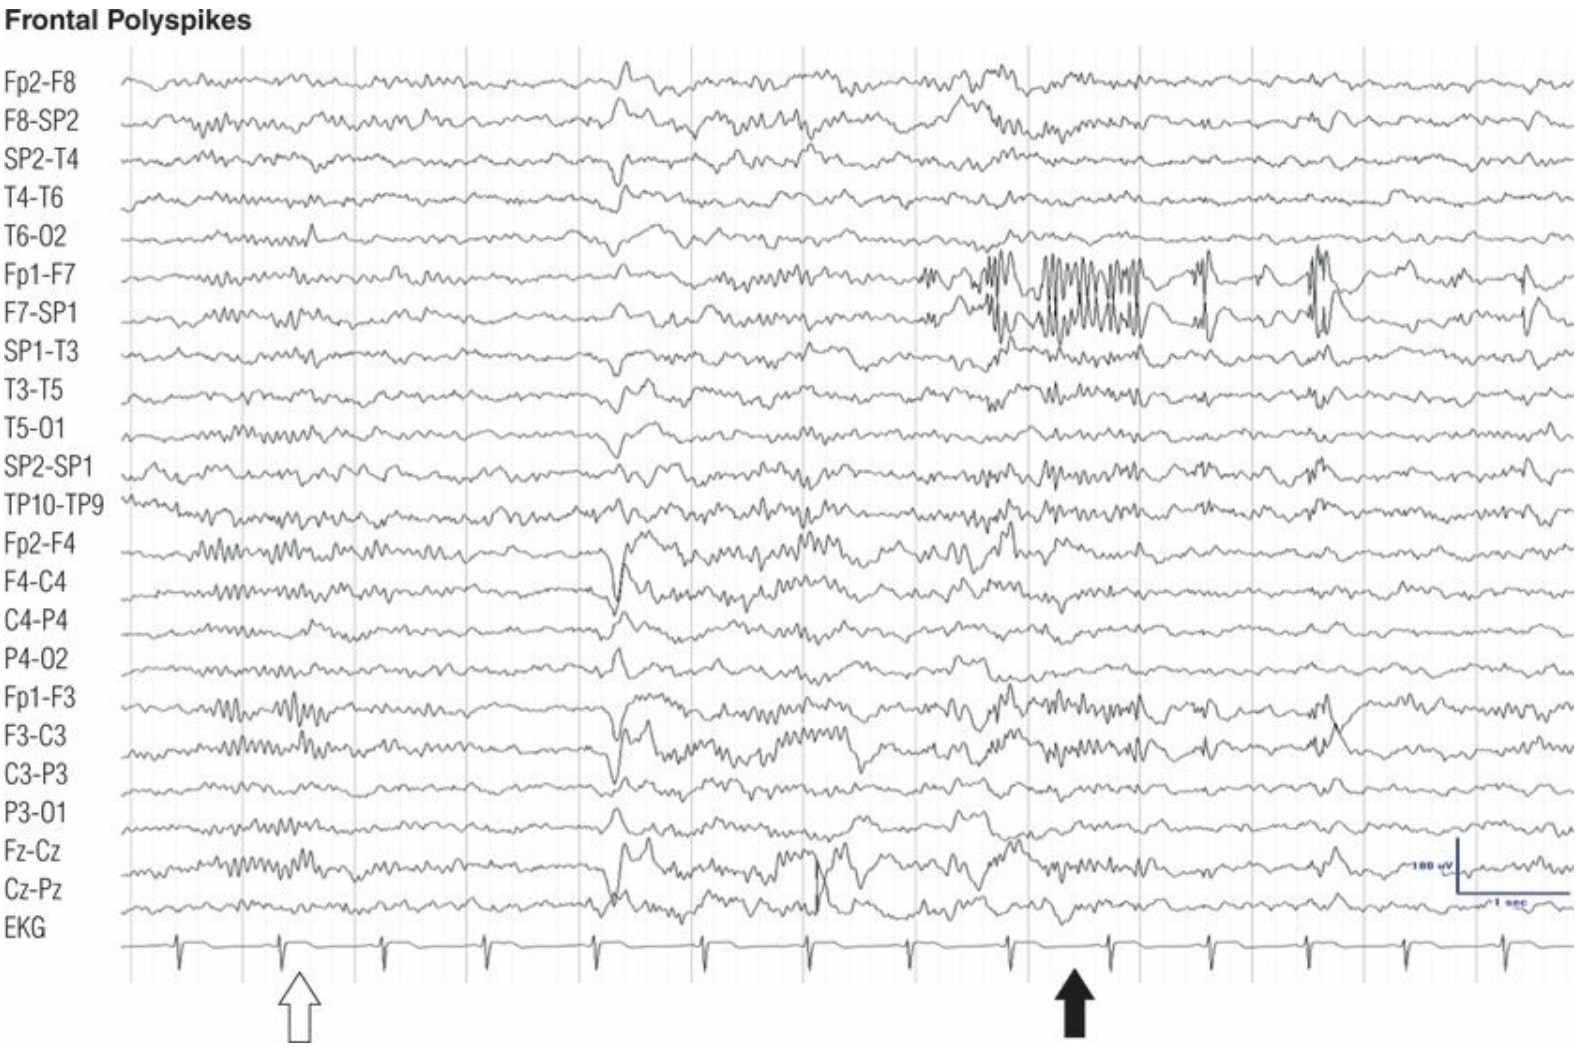

Figure 8.43. Twelve-year-old boy with bilateral asymmetric tonic seizures evolving into the right arm clonic seizures due to left fontal cortical malformation. Note the polyspikes with maximum at electrode F7 (solid arrow) (20) during light sleep characterized by sleep spindles and vertex wave (open arrow).

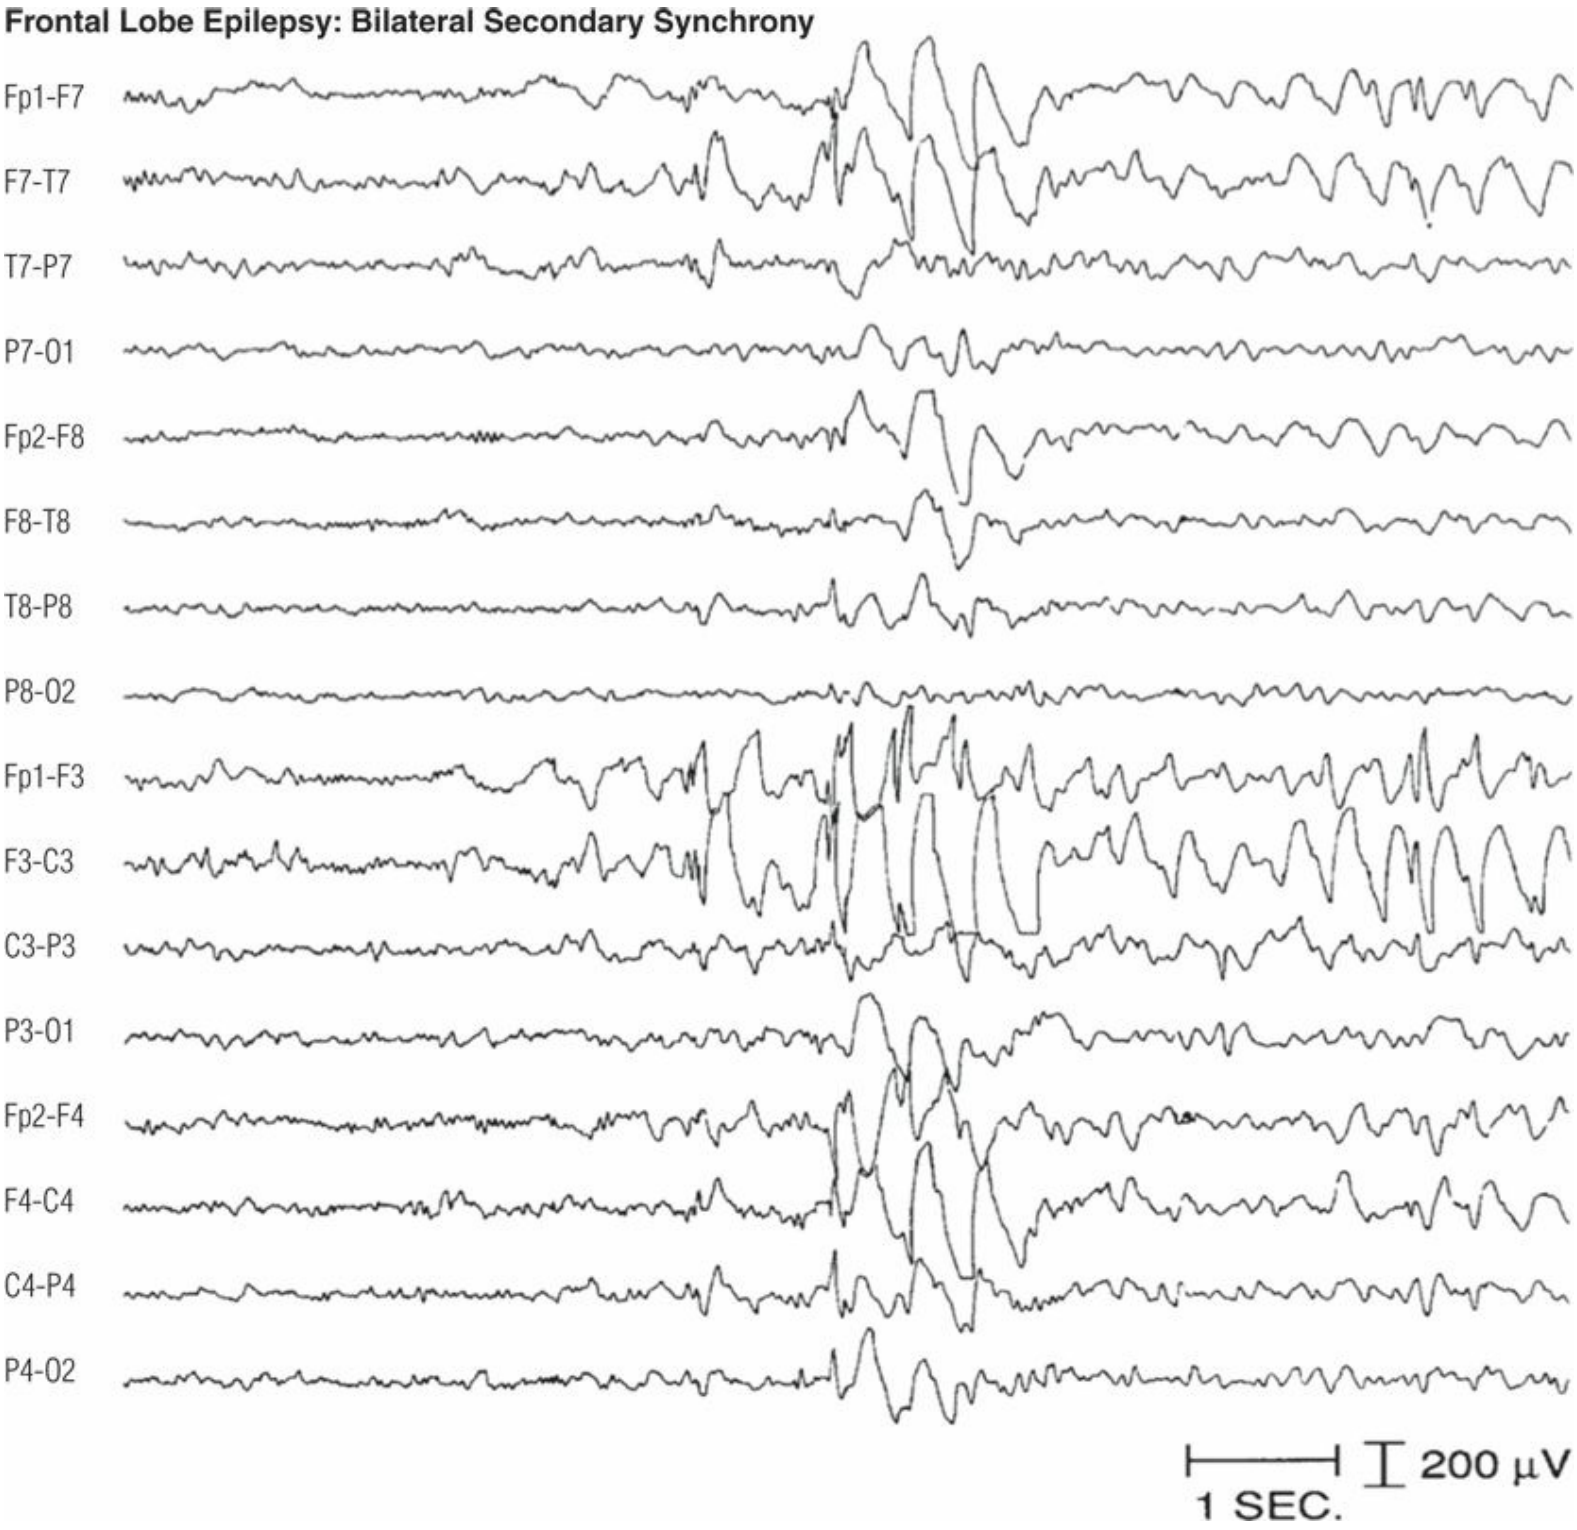

Figure 8.44. Seventeen-year-old boy with intractable frontal lobe epilepsy due to encephalomalacia of the left frontal lobe as a result of head trauma at age 13 years. Interictal sharp waves were maximum in the left frontal region but frequently showed secondary bilateral synchrony with generalization.

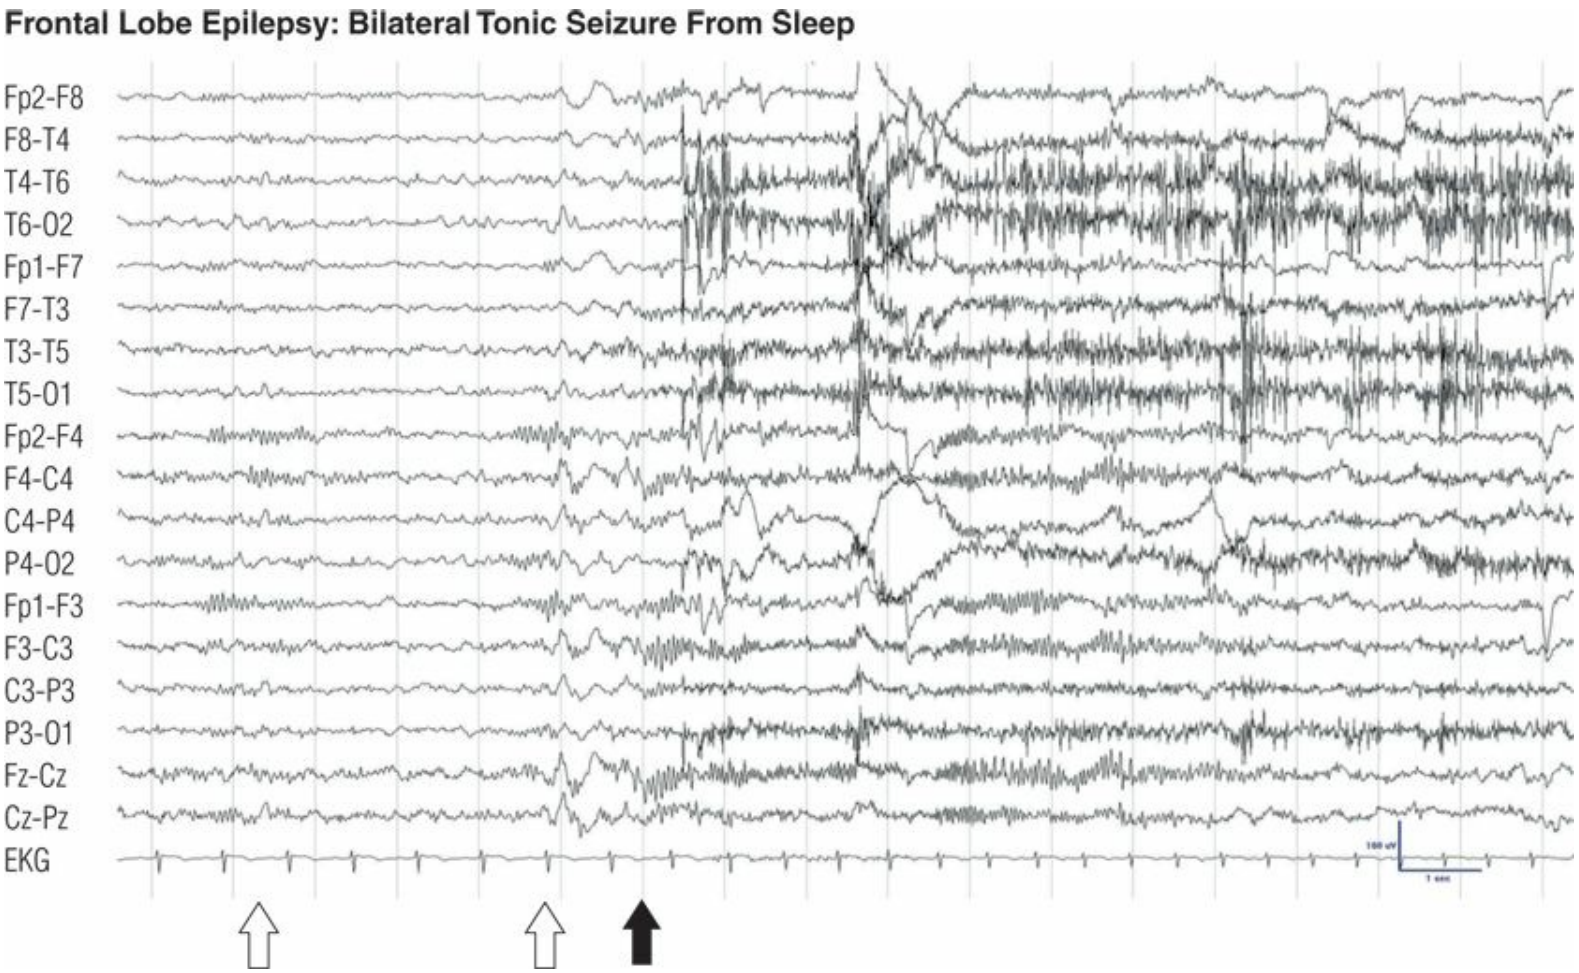

Figure 8.45. Twenty-four–year-old man with MRI–negative focal epilepsy. Note the high-frequency discharge in the left mesial frontal region (electrodes F3 and Fz) (solid arrow) arising out of light non-REM sleep characterized by sleep spindles (open arrows). Abundant EMG artifacts are caused by a bilateral asymmetric tonic seizure.

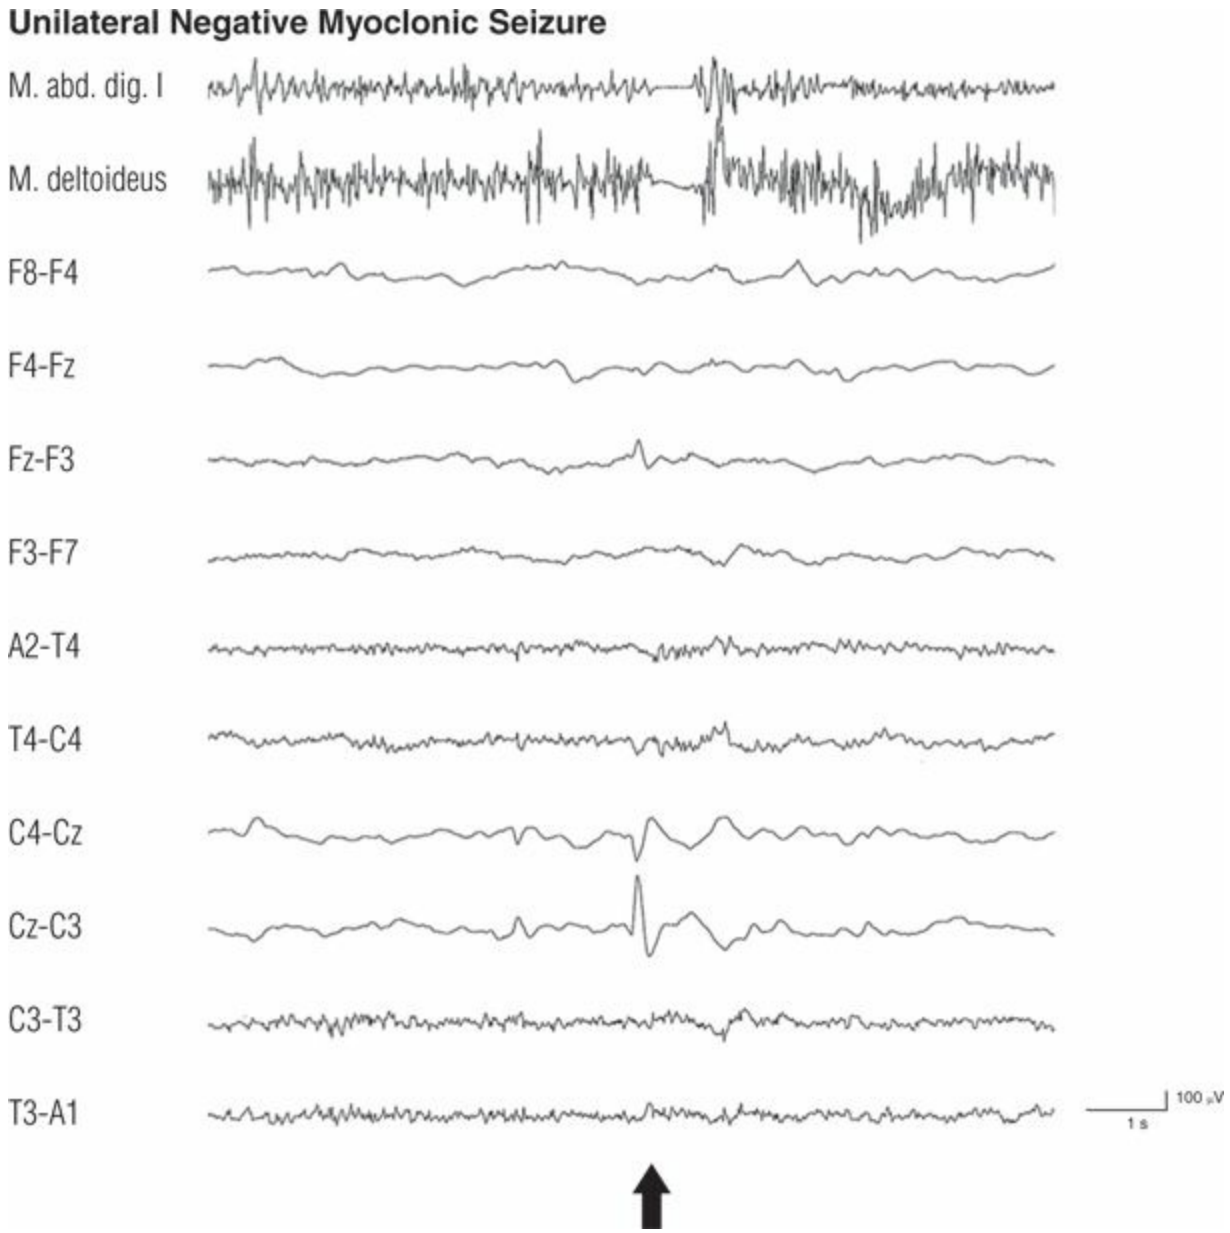

Figure 8.46. Nineteen-year-old man with a perinatal left frontotemporal encephalomalacia. Since the age of 3 years, he has had bilateral asymmetric tonic seizures that evolved into generalized tonic–clonic seizures. Later, negative myoclonic seizures occurred. Note the EMG silent period in the right hand (m. abd. dig I) and right shoulder (m. deltoid) associated with the right central sharp wave (arrow). Negative myoclonus occurs only during tonic muscle contraction. This EEG reflects a so-called paradoxical lateralization since the sharp wave shows maximum negativity ipsilateral to the negative myoclonus of the arm (21). Paradoxical lateralization in this case is most likely due to a left mesial frontal generator (21).

Mesial Frontal Lobe Epilepsy

Sharp waves at vertex	Figure 8.47
Bilateral tonic seizure	Figure 8.48

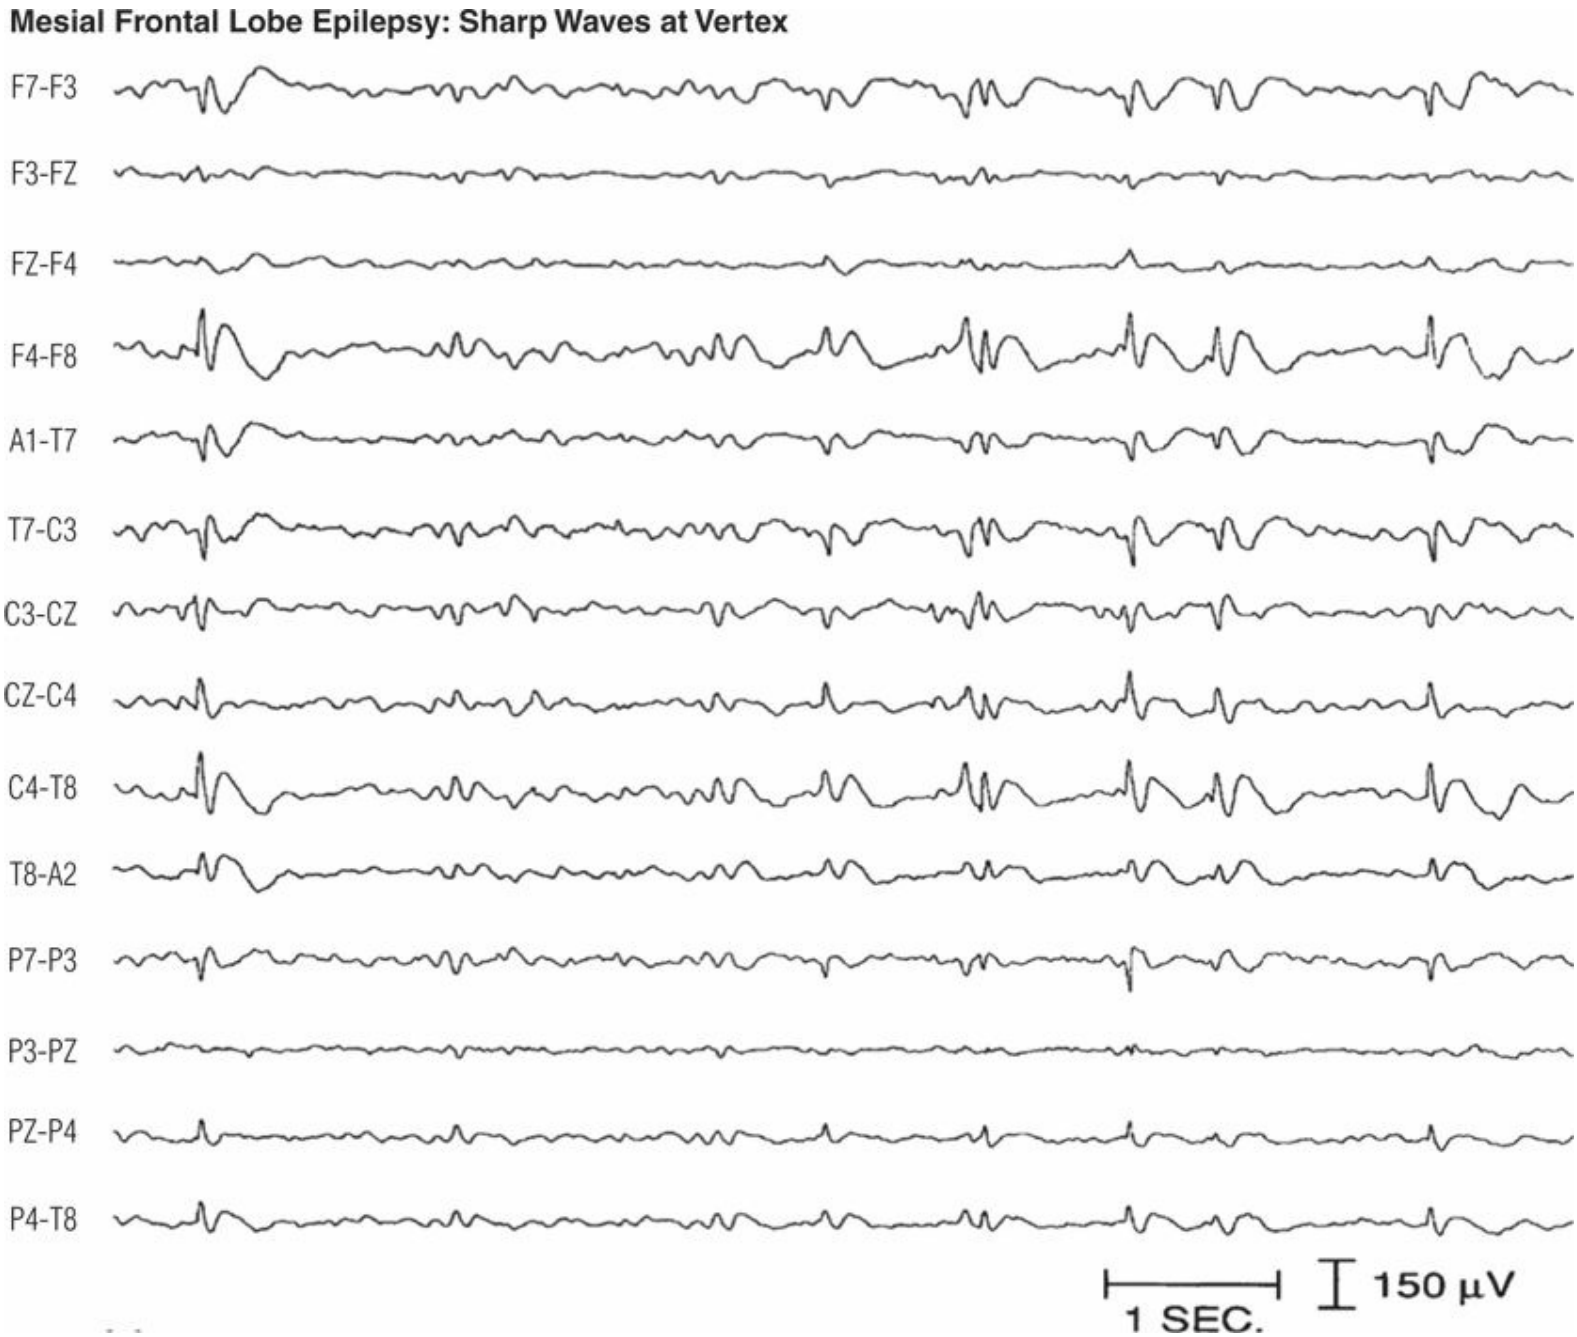

Figure 8.47. Seventeen-year-old woman with a low-grade astrocytoma in the left mesial frontal lobe (paracentral lobule). Intractable seizures involved brief tonic abduction of both arms, version of head and eyes to the right, and falling backward without loss of consciousness. Note the frequent sharp waves at the vertex.

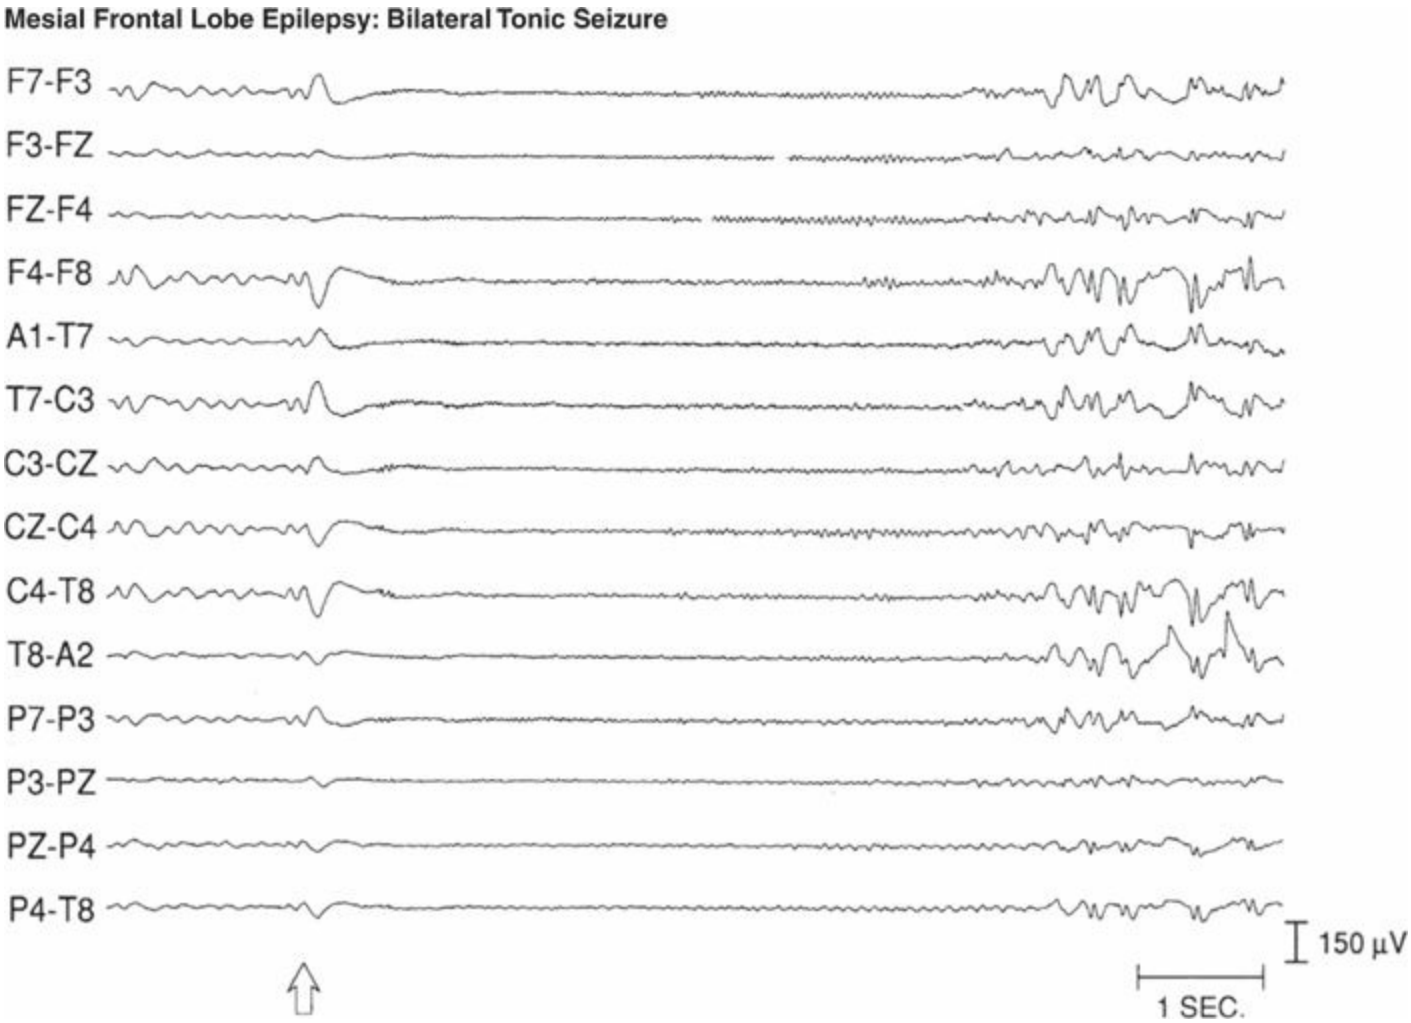

Figure 8.48. Electroencephalogram during a typical seizure from the patient described in Figure 8.47. At clinical onset (arrow), a vertex slow transient and then a generalized electrodecremental pattern with paroxysmal fast activity were recorded, followed by paroxysmal vertex sharp waves.

Paracentral Epilepsy

Focal clonic seizure	Figures 8.49 and 8.50
Frontocentral sharp waves	Figure 8.51
Epilepsia partialis continua	Figure 8.52

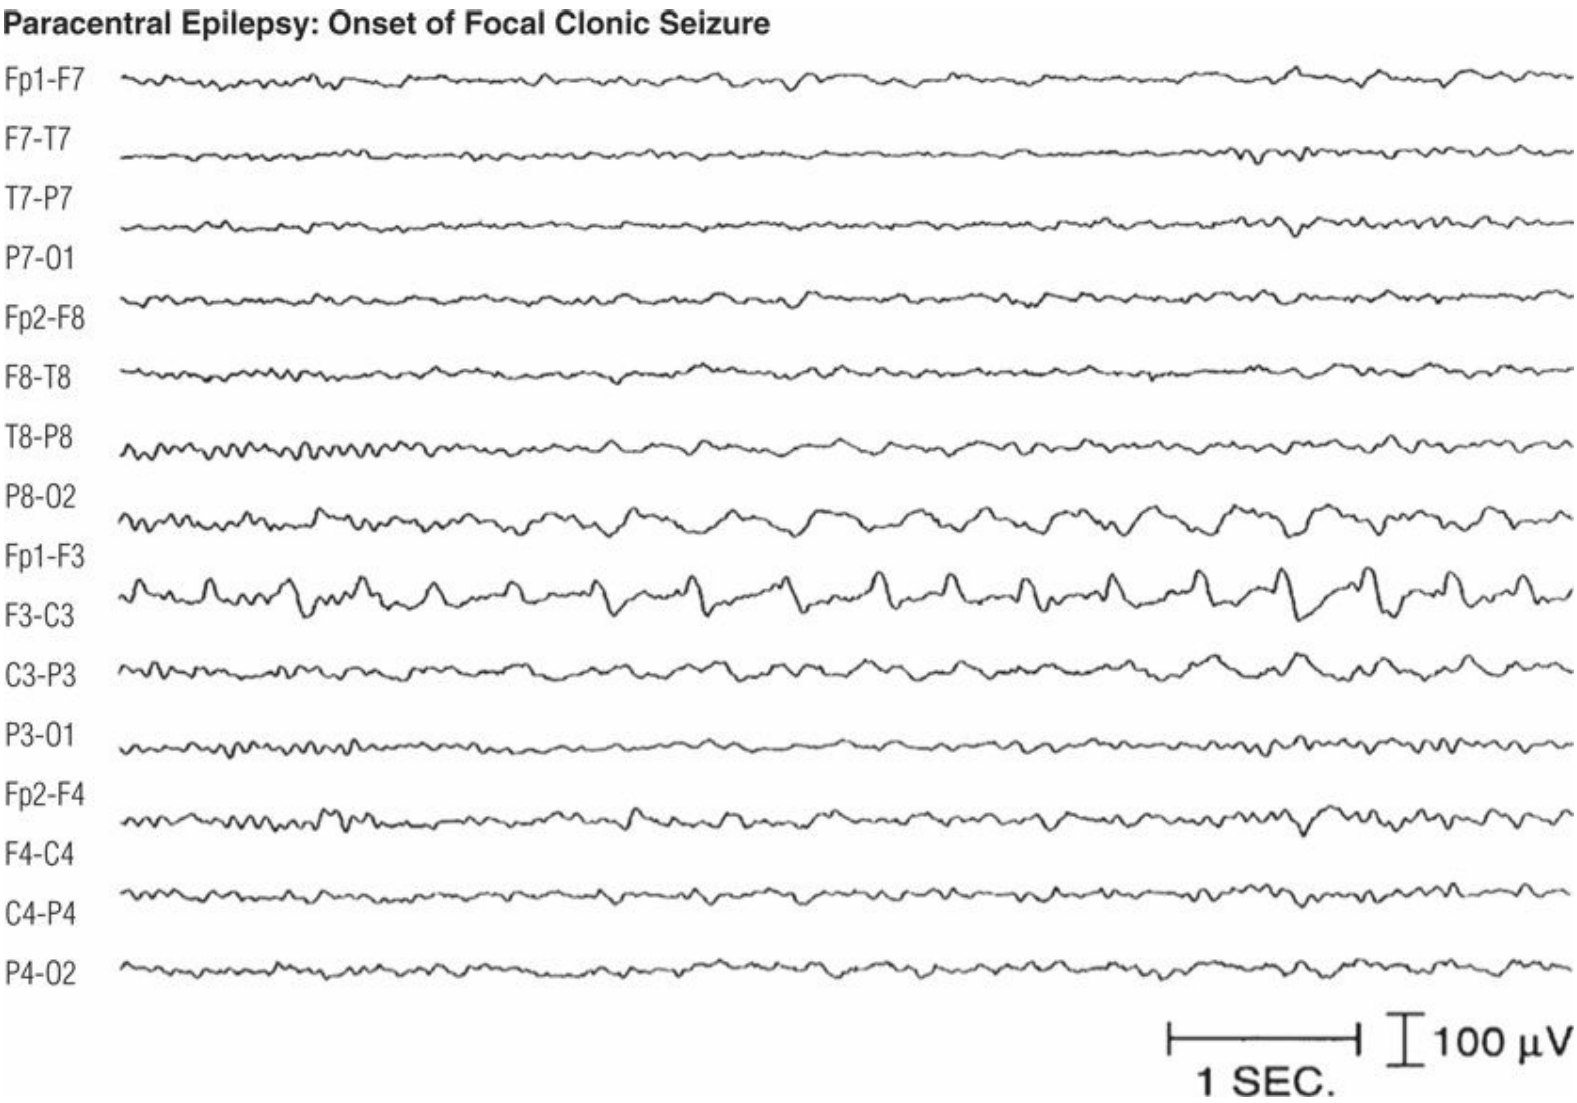

Figure 8.49. Four-year-old girl with frequent nocturnal focal clonic seizures with Jacksonian spread. Seizures began with twitching of the right shoulder and thoracic wall, followed by version of the head to the right and clonic jerking of the right arm and leg without loss of consciousness. Seizure pattern on electroencephalogram was maximum at the left central region.

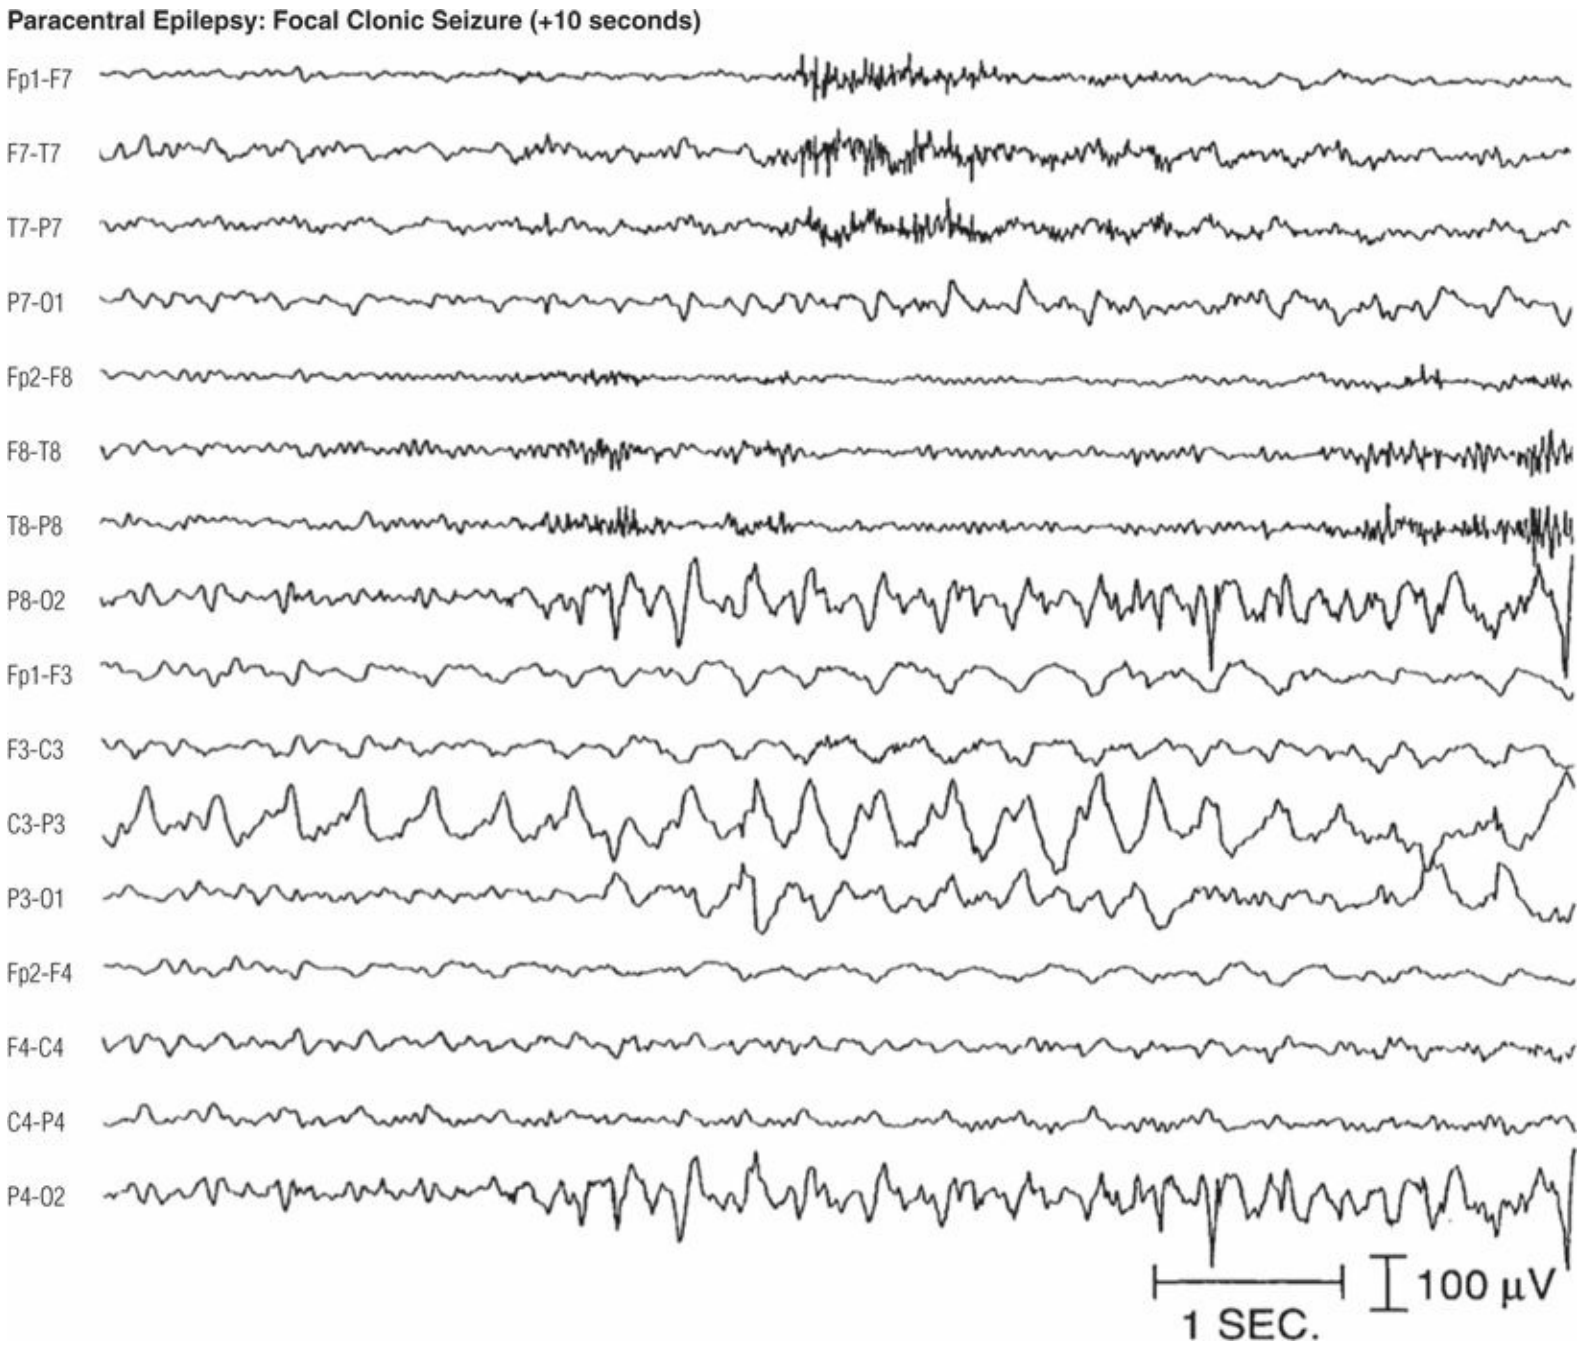

Figure 8.50. Evolution of the seizure in Figure 8.48, with spread of the ictal discharge into left parietal and occipital regions.

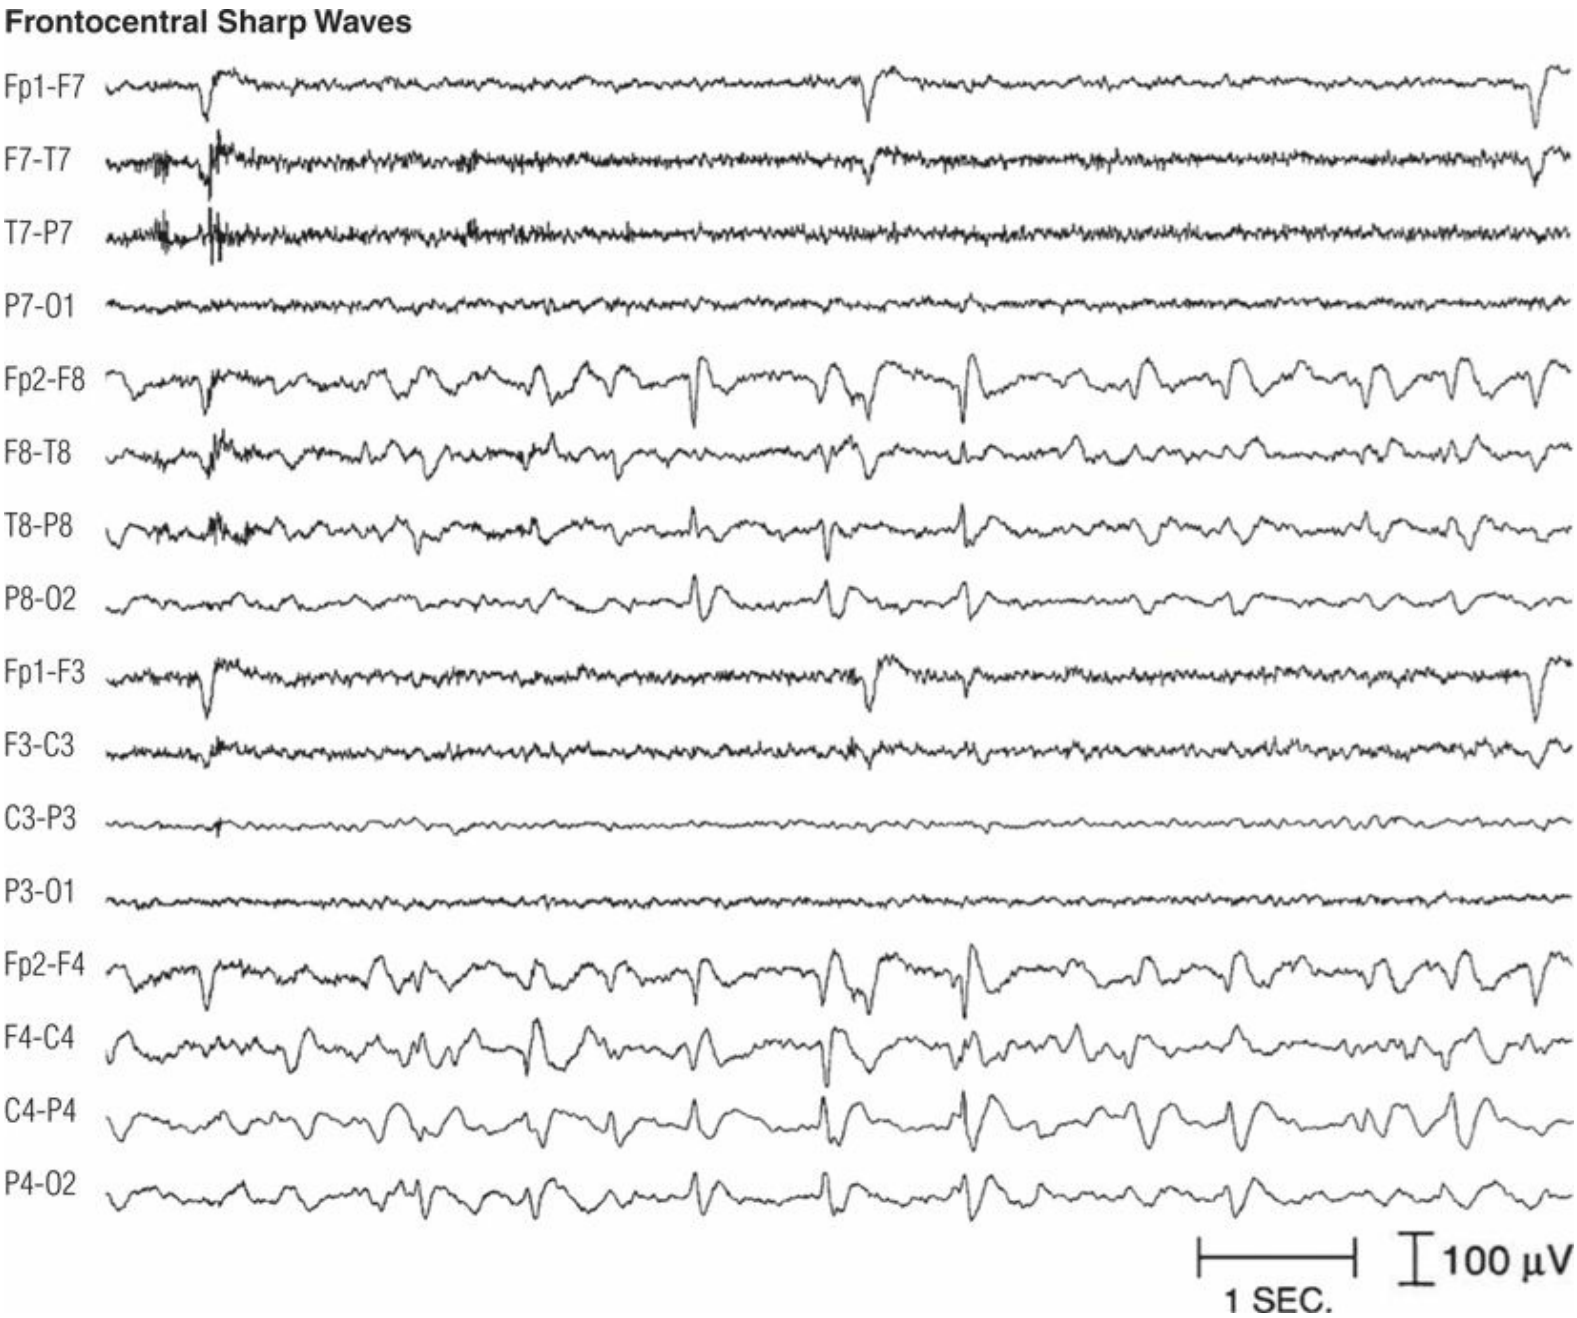

Figure 8.51. Eight-year-old boy with left hemiparesis and posttraumatic encephalomalacia in the right frontocentral white matter as a result of a motor vehicle accident at age 3 months. Interictal electroencephalogram showed right hemisphere slowing with sharp waves over the right frontocentral region (maximum at the C4 electrode).

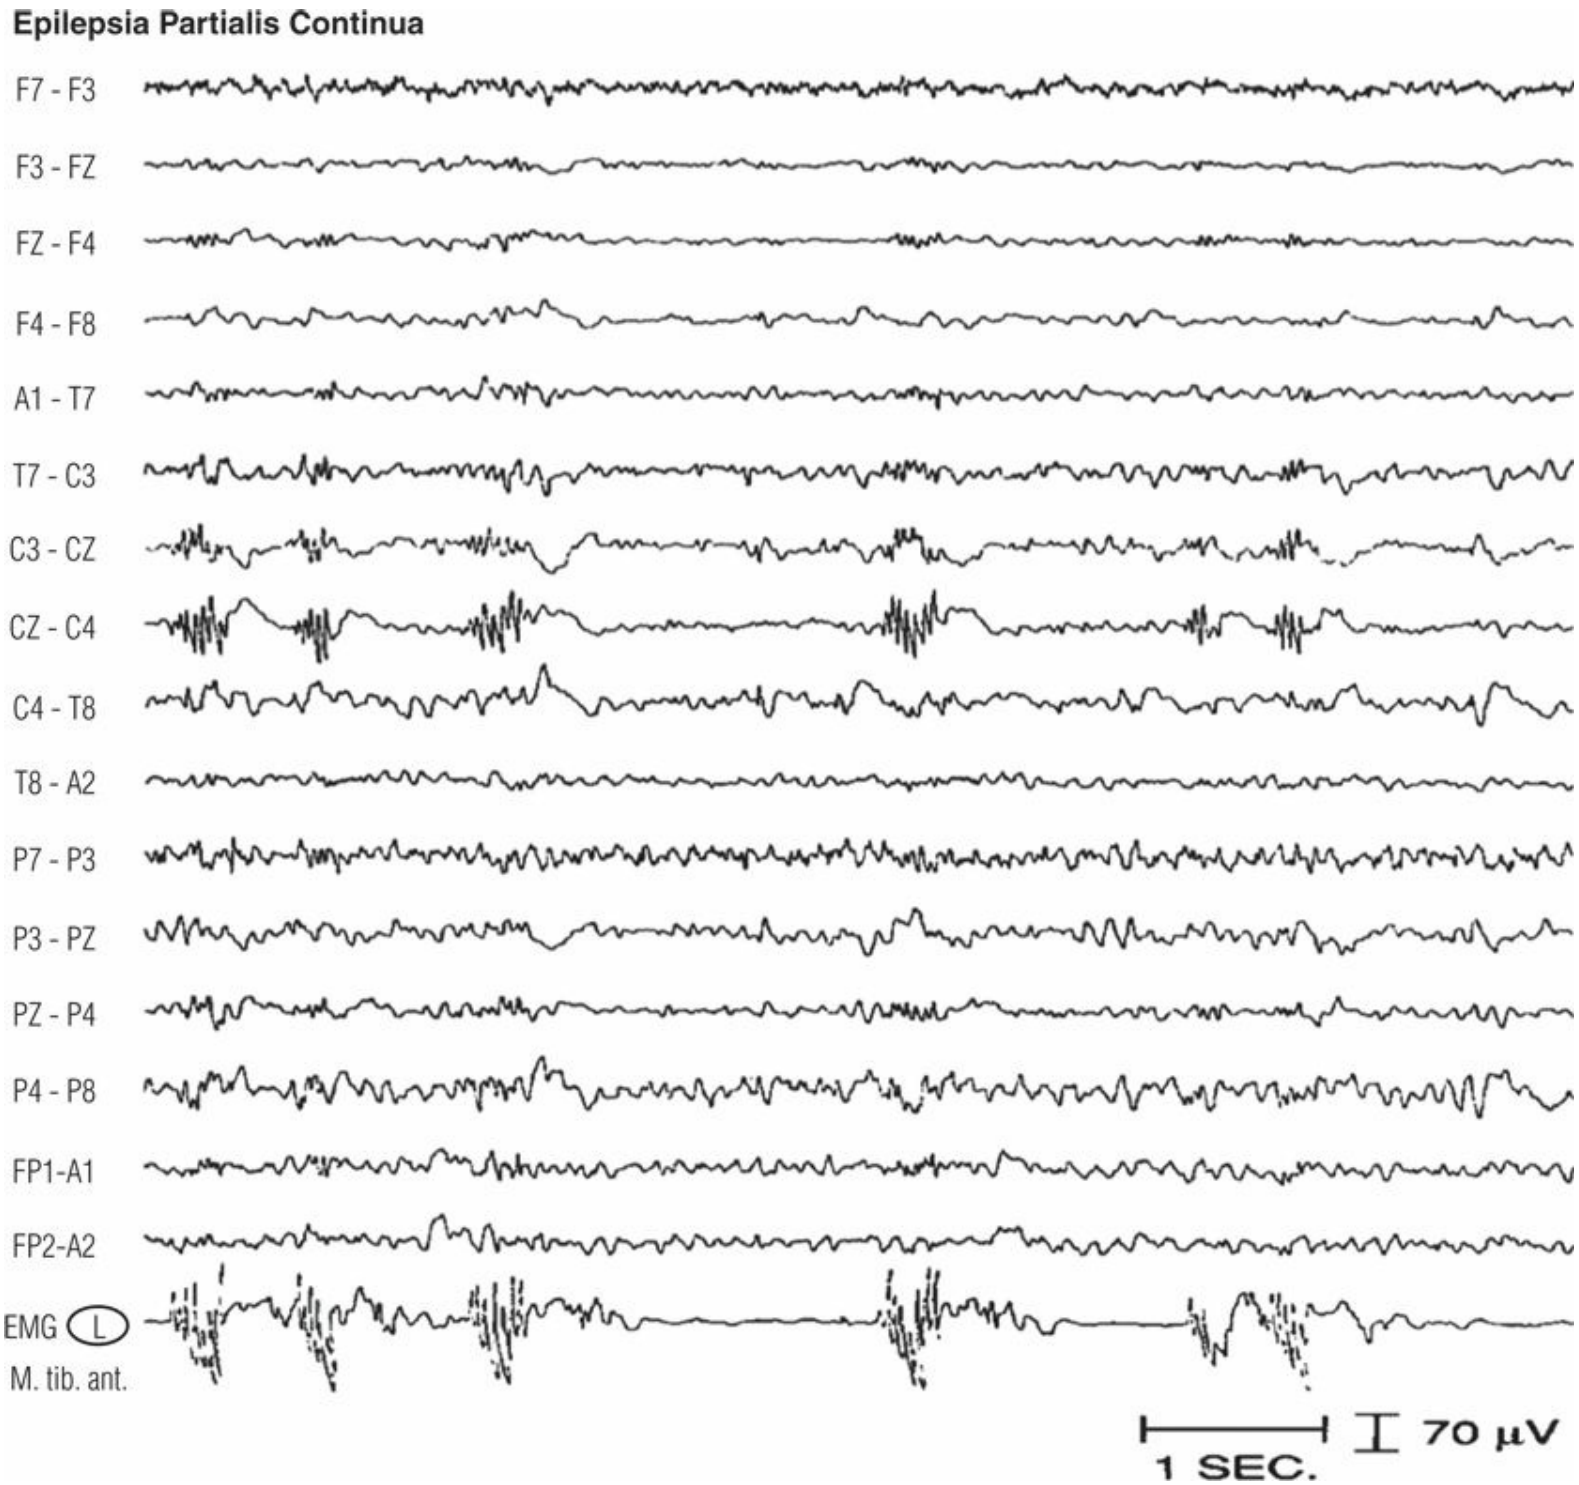

Figure 8.52. Sixty-nine–year-old man with continual jerking of the left foot and leg for 6 weeks, without loss of consciousness. Electromyography from the left tibialis anterior muscle showed that jerks occurred synchronously with each burst of polyspikes on electroencephalogram. Polyspikes were maximum at left vertex electrodes, presumably as a result of paradoxical lateralization of the discharge from the right interhemispheric region (21).

Occipital Lobe Epilepsy

Occipitotemporal spikes	Figure 8.53
Visual aura and left versive seizure	Figure 8.54

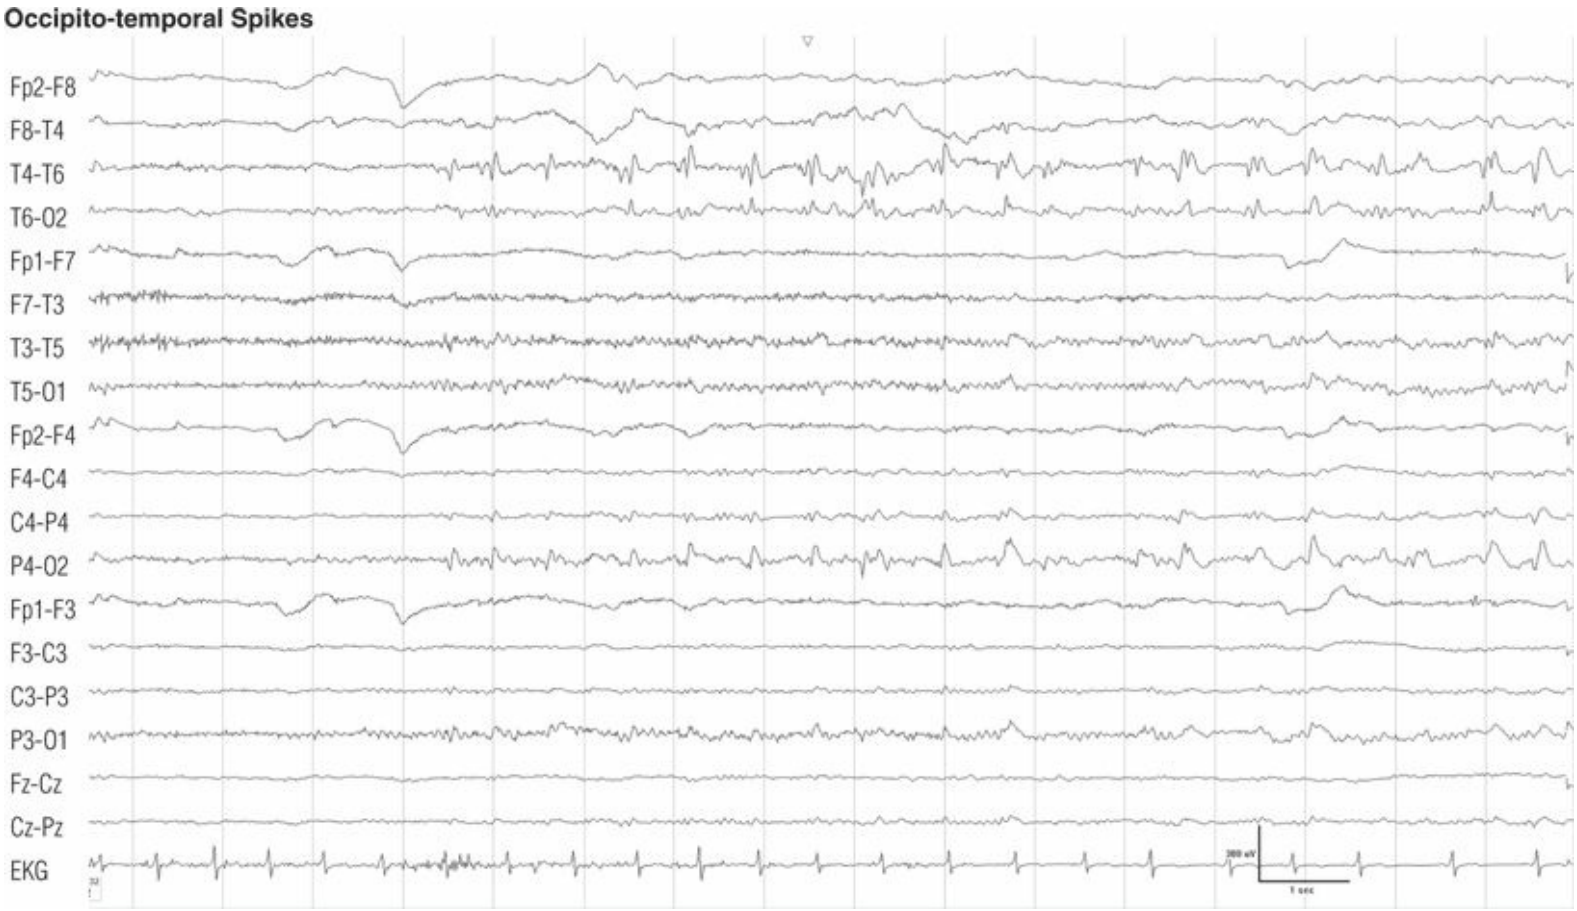

Figure 8.53. Seventeen-year-old boy with right occipital lobe epilepsy due to cortical malformation. Note the frequent spikes and polyspikes in the right occipital region maximum at electrodes O_2 and P8 (20).

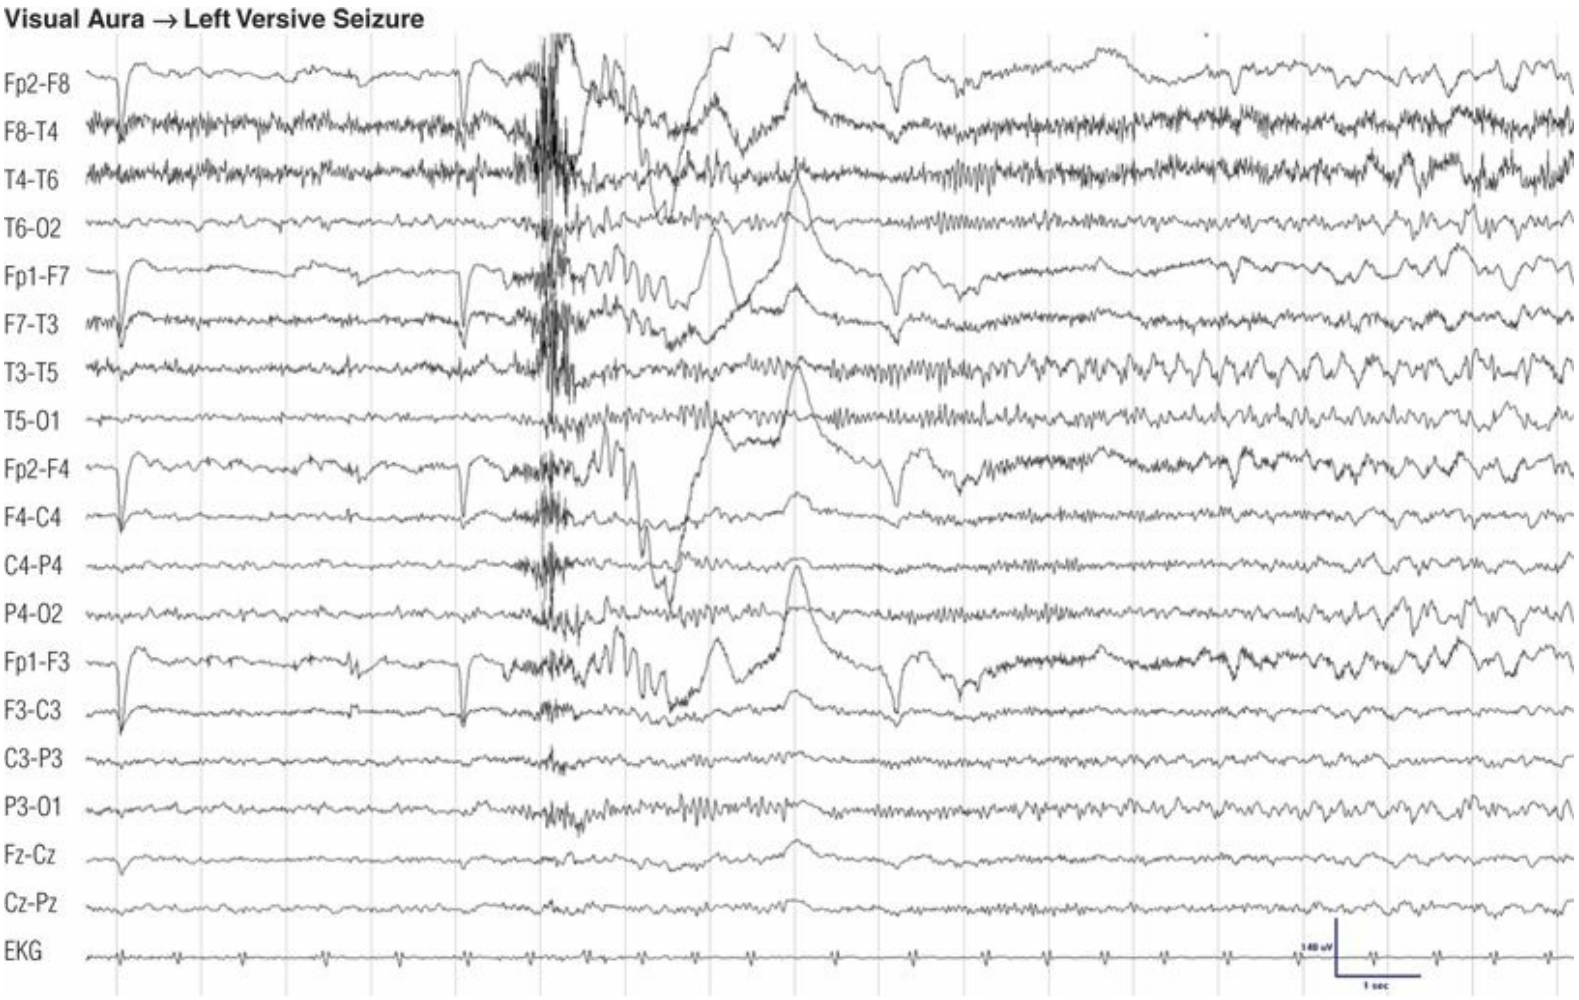

Figure 8.54. Recording of a left visual aura that evolved into a left versive seizure in the same patient as in Figure 8.54. Note the high-frequency discharge in the occipital regions at seizure onset (arrow), which can hardly be lateralized overlapping with a burst of EMG artifact.

PART IV: ELECTROENCEPHALOGRAPHIC FINDINGS IN NONEPILEPTIC PAROXYSMAL DISORDERS

The differential diagnosis of epilepsy includes a wide variety of paroxysmal disorders (see Chapter 40 and 41). During a clinical episode, the EEG recording may be crucial to clarifying the exact nature of the spells. In most of these disorders, the ictal electroencephalogram is normal. Three nonepileptic paroxysmal disorders with abnormal EEG findings are syncope, breath-holding spells, and sleep attacks caused by narcolepsy.

Pallid infantile syncope	Figures 8.55 and 8.56
Cyanotic breath-holding spell	Figures 8.57 and 8.58
Narcolepsy	Figure 8.59

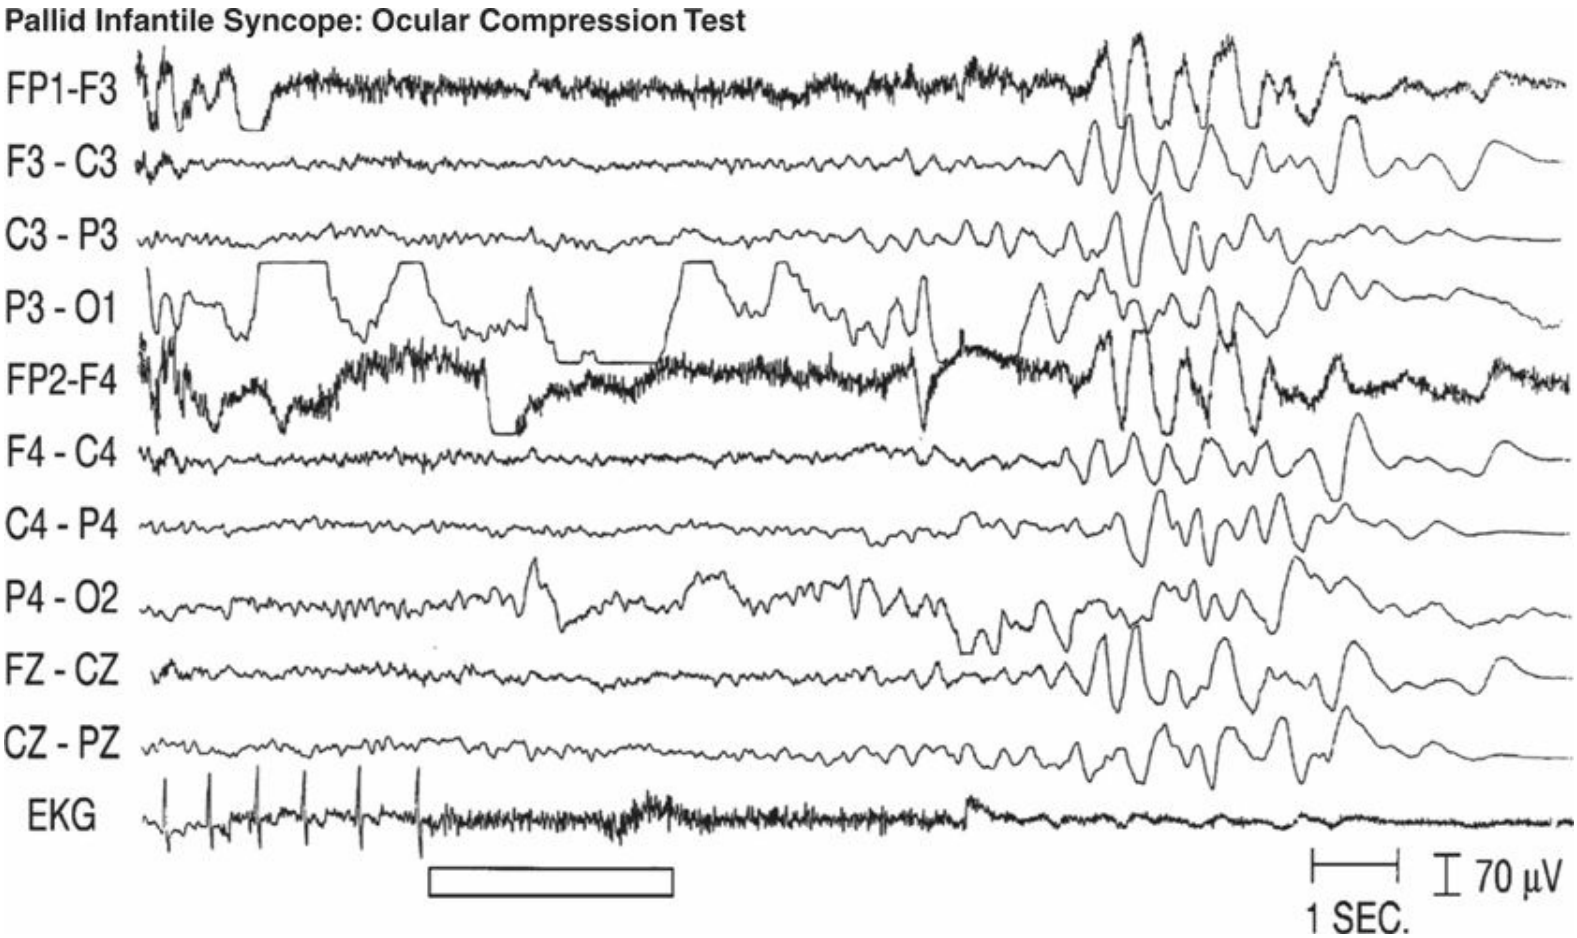

Figure 8.55. Two-year-old boy with pallid infantile syncope. Ocular compression (22,23) (bar), a controversial provocative maneuver, resulted in syncope with cardiac asystole for 12.5 seconds. Electroencephalography showed diffuse high-amplitude slowing followed by cerebral suppression as a result of global cerebral ischemia.

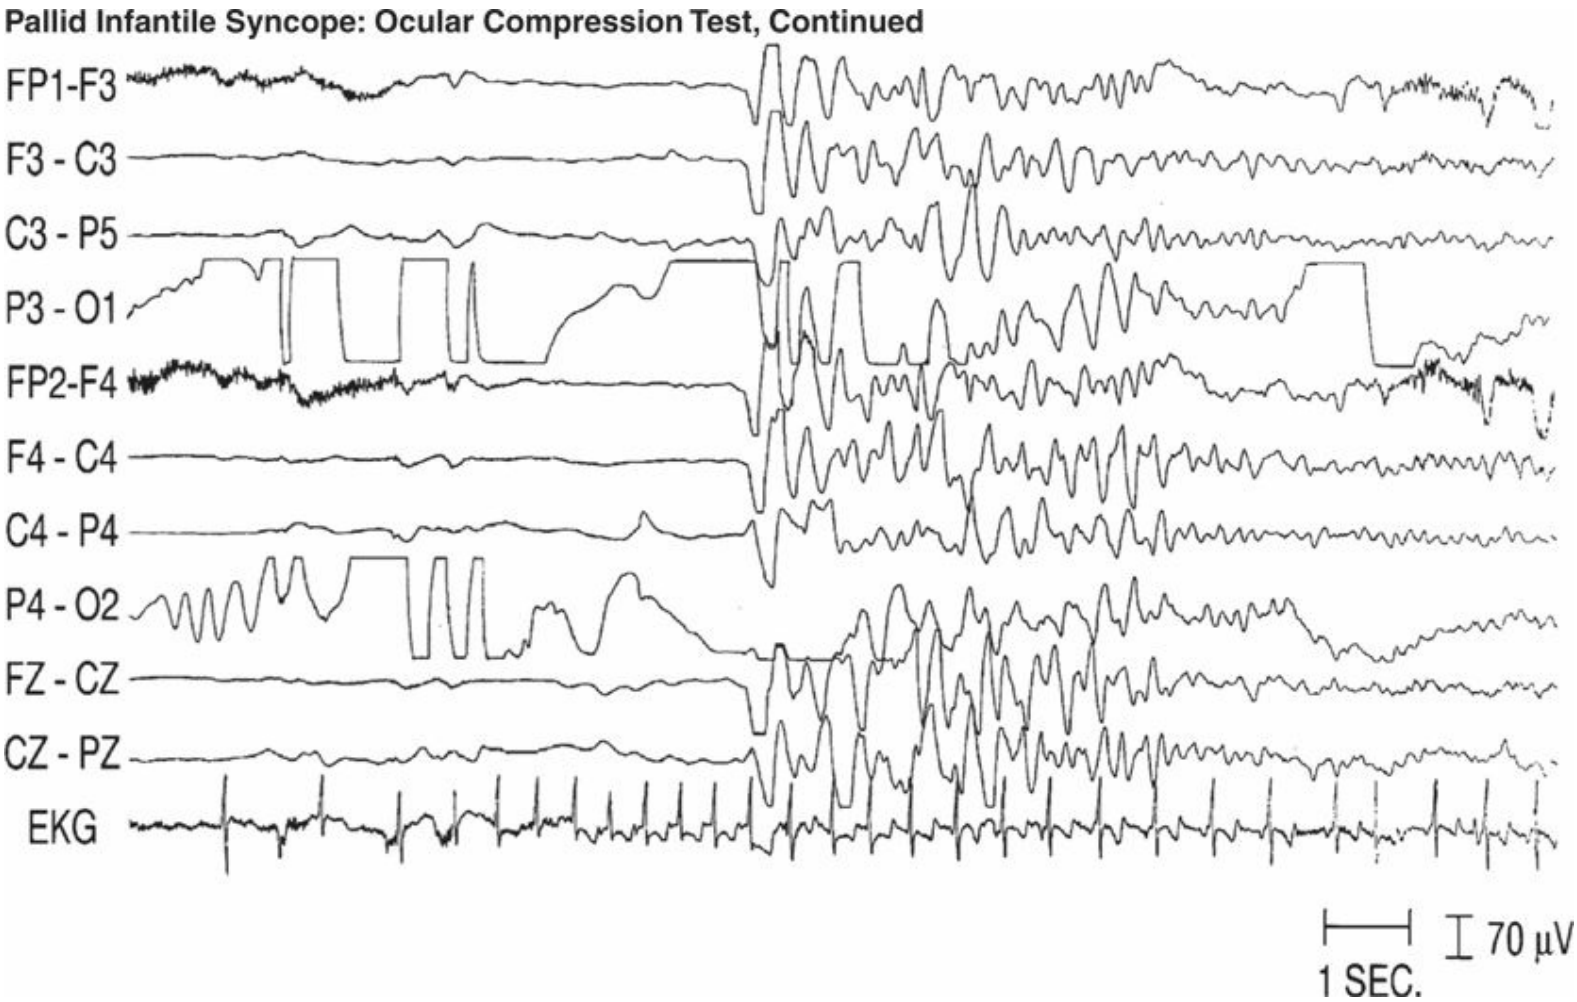

Figure 8.56. With recovery of the patient shown in Figure 8.56, electroencephalogram showed high-amplitude slowing followed by normal rhythms. Asystole with ocular compression may be caused by activation of the oculocardiac reflex (trigeminal afferent, vagal efferent pathways) (22,23).

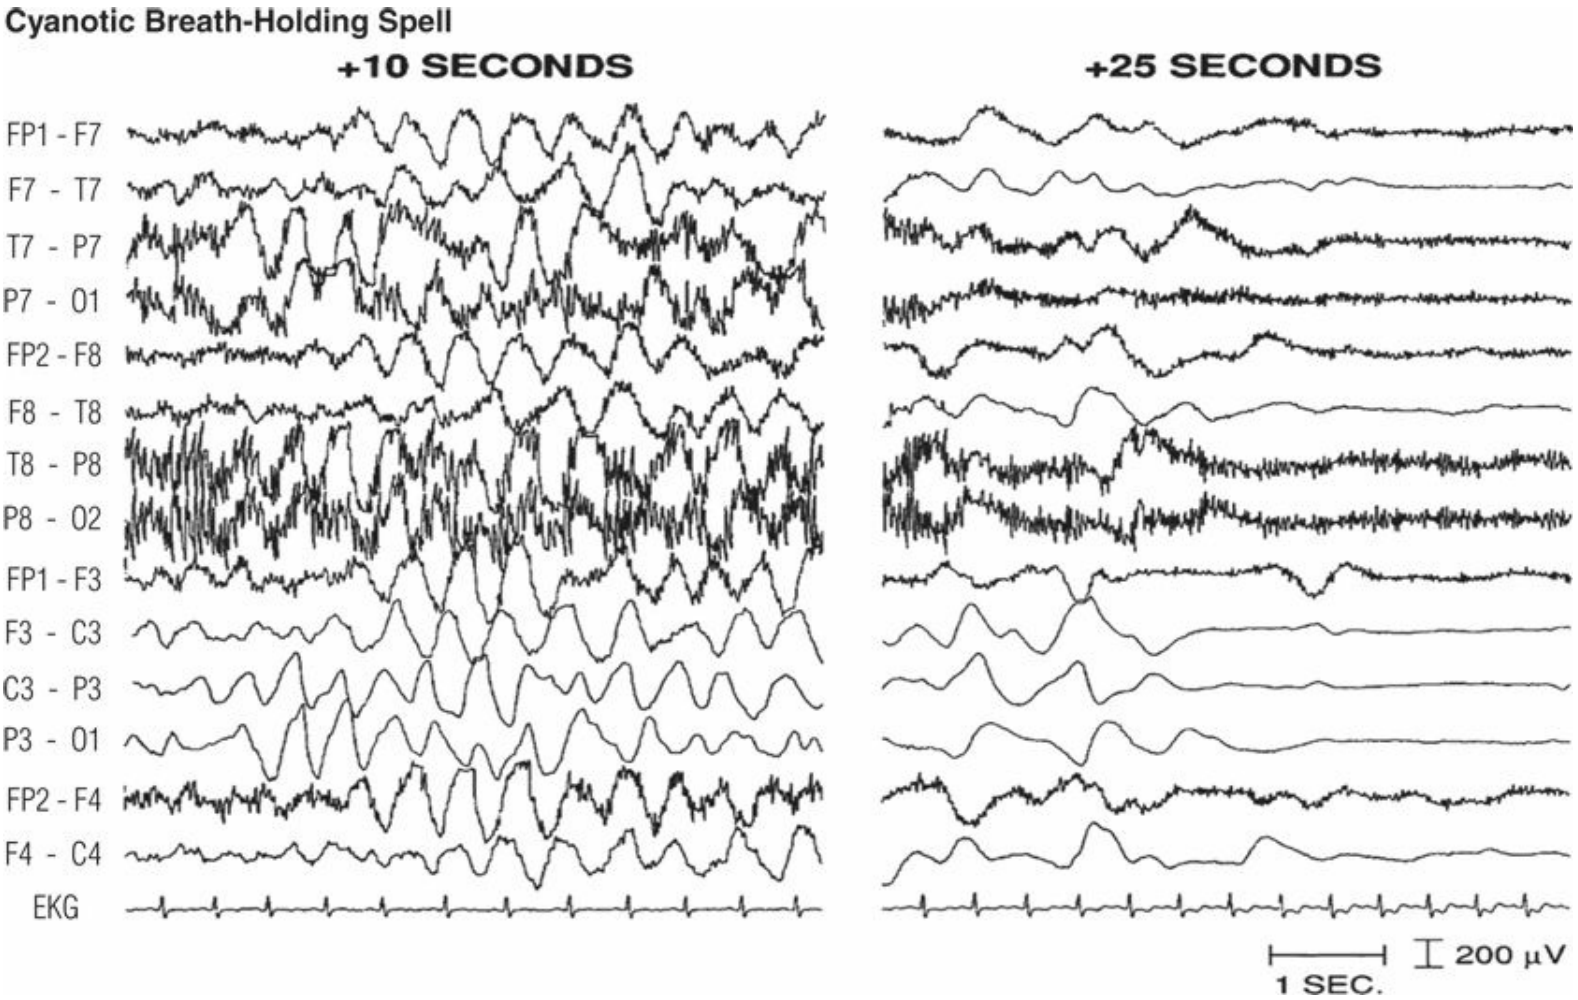

Figure 8.57. Two-year-old boy with cyanotic breath-holding spells sometimes followed by generalized tonic–clonic seizures. This episode occurred during crying and involved cessation of respiration for 40 seconds, oxygen desaturation to 73%, cyanosis, loss of consciousness, opisthotonic posturing, and urinary incontinence.

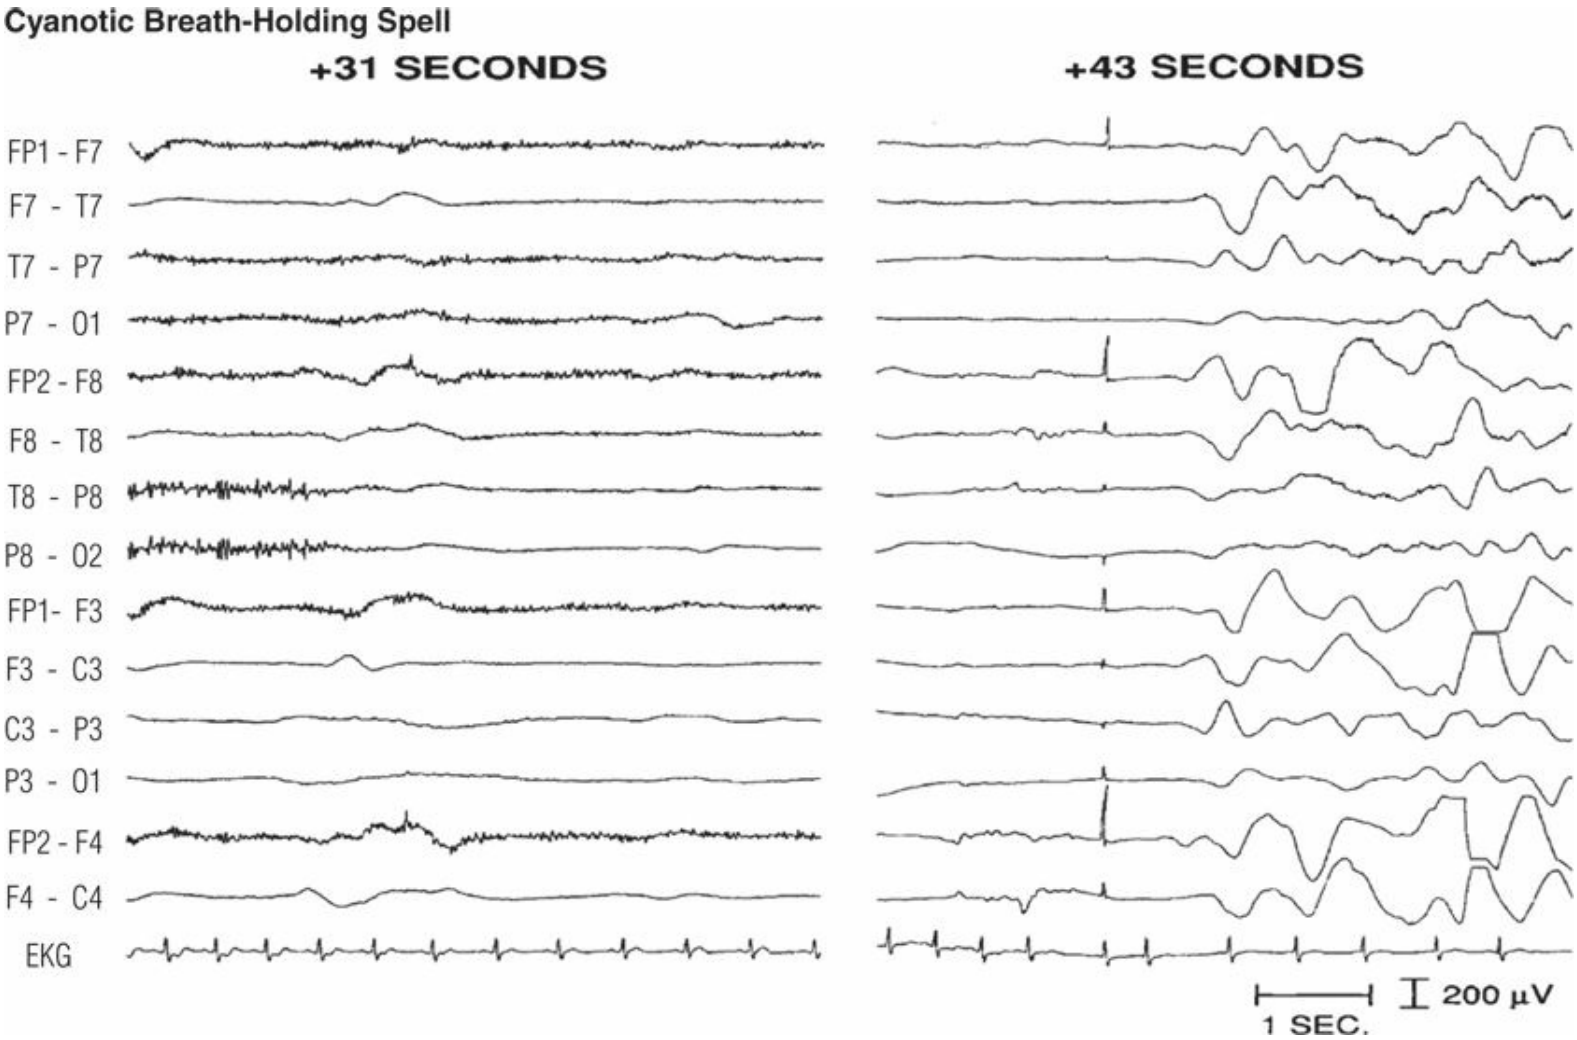

Figure 8.58. As the episode continued in the patient shown in Figure 8.58, electroencephalographic activity was similar to that during the syncopal attack in Figures 8.56 and 8.57, but the electroencephalogram showed tachycardia instead of asystole.

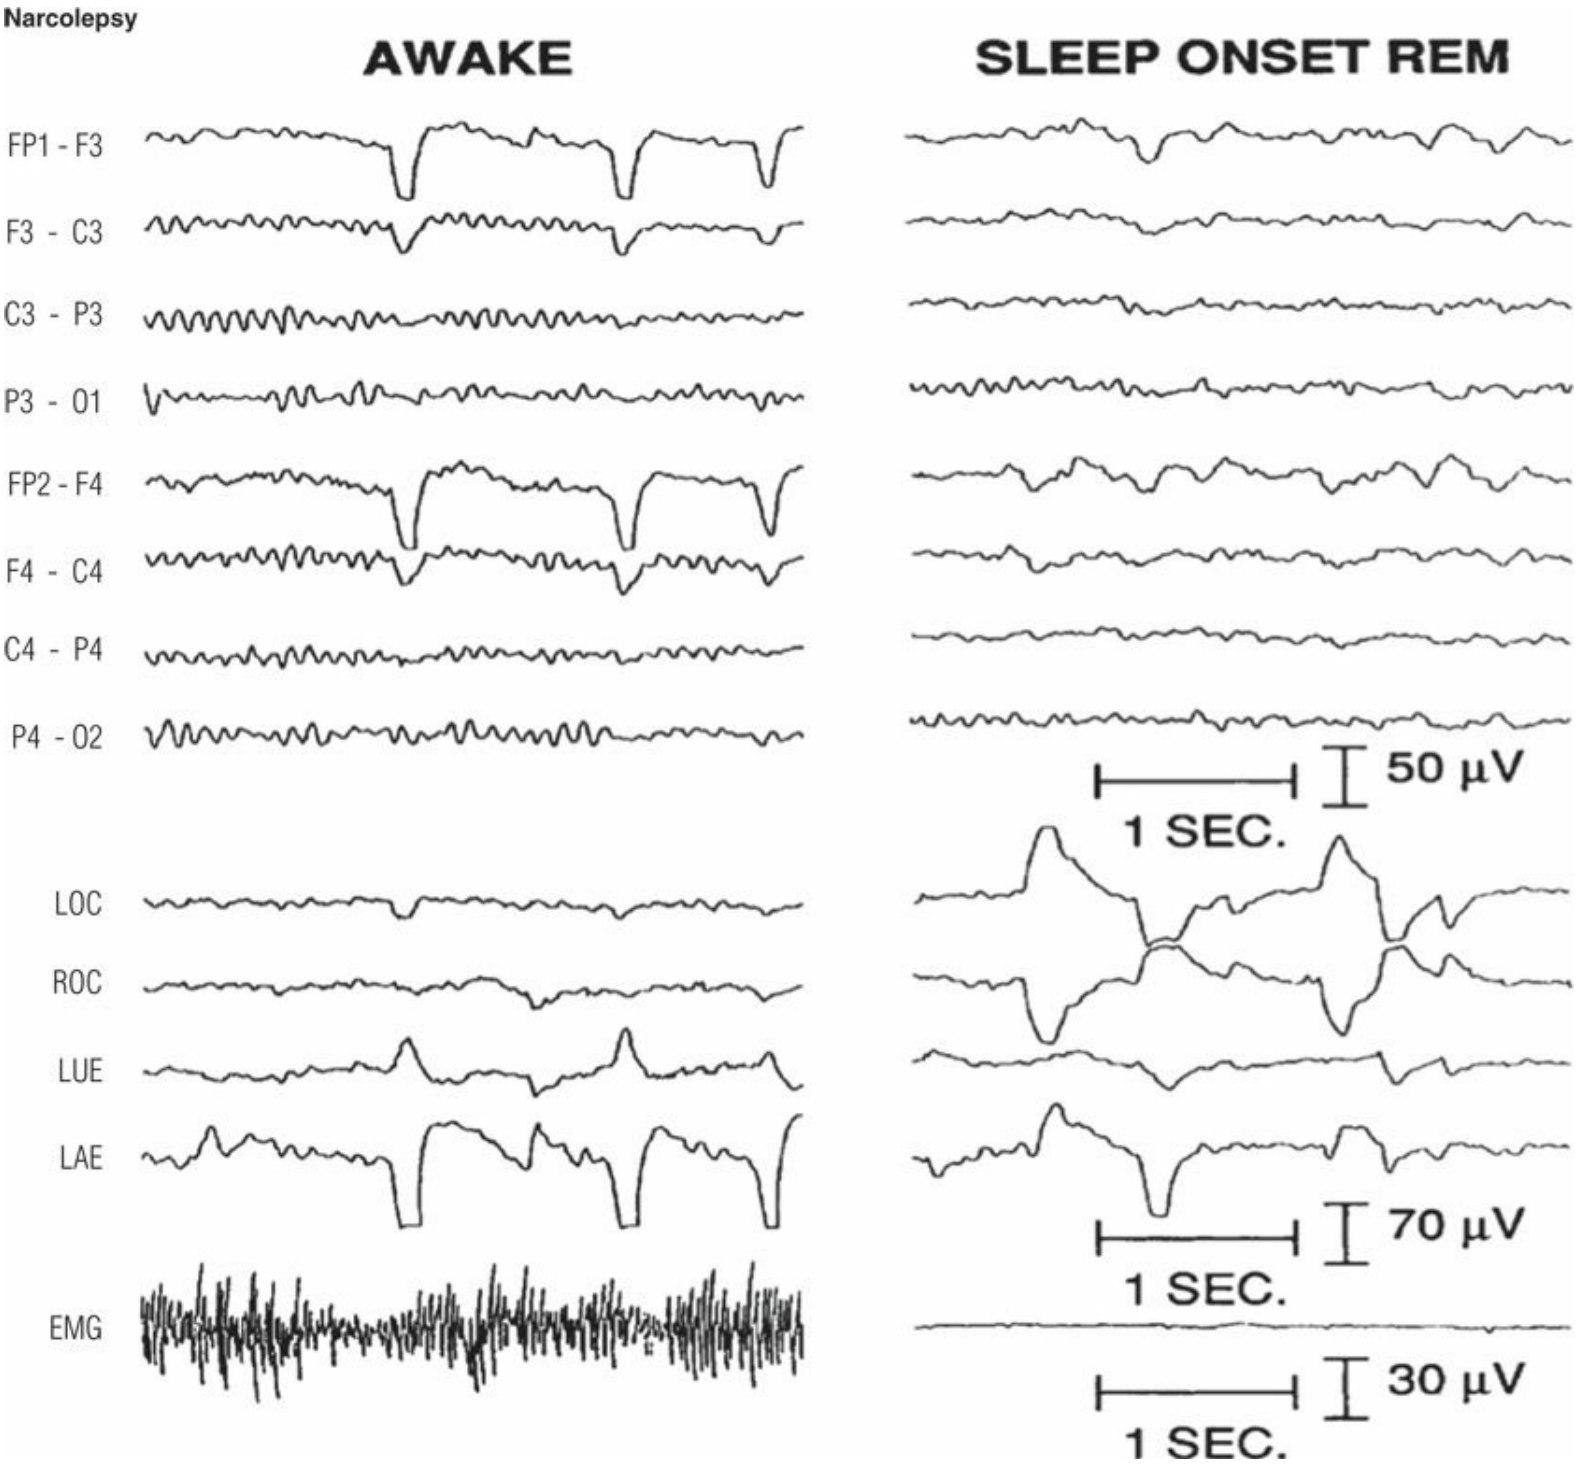

Figure 8.59. Fifty-six–year-old man with episodes of loss of consciousness (sleep attacks) and automatic behavior (minisleeps). Multiple sleep latency test gave evidence of narcolepsy with short sleep latency (2 minutes) and sleep-onset rapid eye movement periods (REM latency, 1 minute). Typical features during rapid eye movement sleep included rapid eye movements, absent muscle artifact, and drowsy electroencephalographic pattern. LOC and ROC, left and right outer canthus; LUE and LAE, under and above left eye. Ocular electrodes were referential to A1/A2. EMG is at the chin.

CHAPTER 9 TERMINOLOGY FOR SEIZURES AND EPILEPSIES

TOBIAS LODDENKEMPER AND ANNE T.BERG

INTRODUCTION

The international efforts to provide common terms and concepts for classifying seizures and epilepsy were first formalized in the late 1960s in the reports of Merlis (1) and Gastaut (2). Over time, these were revised culminating in the most widely used system for classification of epilepsies that was proposed in 1989 by the Commission on Classification and Terminology of the International League Against Epilepsy (ILAE) (3). This epilepsy classification remains in place despite ongoing discussions and proposals and is appended to this chapter. ILAE's 1981 seizure classification (4) and its 1985 and 1989 classifications of the epilepsies (3,5) have given physicians around the world a common language. These ILAE classifications rested on earlier classification approaches in 1969 and 1970 (1,2) and reflected concepts and understandings dating back to the late 1800s. These classifications were mainly based on two features: (a) the distinction between generalized and focal features and (b) etiologic considerations, although this latter was largely aligned with neurodisability as it greatly predated modern genetics. To bring terminology and concepts up to date and reflect advances in the neurosciences such as imaging and genetics and the advances in understanding of brain function, new approaches have been suggested (2010 report). An overview of the timeline of different proposals and classifications is given in Table 9.1.

2010: Commission report—Terminology and organization
2014: Pending update

TERMINOLOGY AND DEFINITIONS

It is critical to differentiate between epilepsy, epilepsy syndrome, and seizure types and acknowledge that these are different entities.

Seizure: Hughlings Jackson was among the first to outline the distinction between seizures and epilepsy. According to Jackson, "A convulsion is but a symptom, and implies only that there is an occasional, an excessive, and a disorderly discharge of nerve tissue on muscles. This discharge occurs in all degrees; it occurs with all conditions of ill health, at all ages, and under innumerable circumstances" (6). This definition has not changed in the last 150 years. According to the ILAE, an epileptic seizure "is a transient occurrence of signs and/or symptoms due to abnormal excessive or synchronous neuronal activity in the brain." Defining features include "mode of onset and termination, clinical manifestations, and abnormal enhanced synchrony" (7).

Epilepsy: The term epilepsy initially characterized both the disease and its attacks (8). An operational definition was provided 20 years ago by the ILAE: "A condition characterized by recurrent (two or more) epileptic seizures, unprovoked by any immediate identified cause. Multiple seizures occurring in a 24-h period are considered a single event. An episode of status epilepticus is considered a single event. Individuals who have had only febrile seizures or only neonatal seizures as herein defined are excluded from this category" (9). In 2005, the ILAE attempted to provide a conceptual definition although the report may have overstated this summary in referring to this as an operational definition: "epilepsy is a disorder of the brain characterized by an enduring predisposition to generate epileptic seizures and by the neurobiologic, cognitive, psychological, and social consequences of this condition. The definition of epilepsy requires the occurrence of at least one epileptic seizure. Elements in the definition of epilepsy include history of at least one seizure, enduring alteration in the brain that increases the likelihood of future seizures, and associated neurobiologic, cognitive, psychological, and social disturbances" (7). Most recently in 2014, the epilepsy definition was revised and now includes "(1) At least two unprovoked (or reflex) seizures occurring >24 h apart; (2) one unprovoked (or reflex) seizure and a probability of further seizures similar to the general recurrence risk (at least 60%) after two unprovoked seizures, occurring over the next 10 years; (3) diagnosis of an epilepsy syndrome" (10).

Epilepsy Syndrome: The concept of epilepsy syndromes was introduced over many years and was firmly ensconced in the ILAE report of 1989. An epilepsy syndrome is defined as "a complex of signs and symptoms that define a unique epileptic condition. This must involve more than just a seizure type: thus frontal lobe seizures per se, for instance, do not constitute a syndrome" (11). The ILAE furthermore distinguishes epileptic diseases, which are defined as "a pathologic condition with a single, specific, well-defined etiology. Thus progressive myoclonic epilepsy is a syndrome, but Unverricht-Lundborg is a disease" (11).

EARLY ILAE CLASSIFICATIONS

The first ILAE classification in 1969/1970 (1,2) distinguished primary or secondary epilepsy (based on identification of causes but largely in association with neurodisability) and partial or generalized (based on seizure manifestations). If the cause was not known, the term "primary" was used, whereas "secondary" alluded to a known cause. "Partial" indicated onset from a focal area in the brain, either based on semiologic features or based on clinical evaluation, and generalized included epilepsy with no clear single area of onset in the brain.

The 1981 seizure classification (4) further distinguished seizures into partial or generalized and took into account more than two types of features for a given partial or generalized seizure.

Specifically, the classification outlined partial and generalized seizures. Among partial seizures, simple partial, complex partial, and secondary generalized seizures were recognized. Among generalized seizures, absence, myoclonic, atonic, tonic, and tonic–clonic seizures were included.

Partial seizures could be "simple" and "complex" depending on the preservation or loss of consciousness during the events. Secondarily generalized was used, when a partial seizure spreads and involves the whole brain (and both sides of the body simultaneously with loss of consciousness). Generalized epilepsies were characterized by specific seizures in the form of absence (i.e., staring spells), myoclonic (muscle jerks), loss of tone (atonic), increased tone (tonic), and tonic plus clonic movements. Notably, epileptic spasms were excluded from this classification.

A revised epilepsy classification was published in 1985 (5). Because the term secondary generalized epilepsy was sometimes confused with the different concept of "secondary" or "secondarily" generalized tonic–clonic seizures, it was abandoned in the subsequent revision. The terms primary and secondary were replaced with idiopathic (there is no cause except a possible genetic predisposition), symptomatic (the epilepsy is secondary to an underlying disorder of the brain), and cryptogenic (the cause is not known but presumed to be symptomatic). Both terms were applied to partial and generalized epilepsies. Furthermore, the recognition of "benign" rolandic epilepsy necessitated a category of "primary partial" epilepsies. Furthermore, this publication introduced the new concept of epilepsy syndromes as "Epileptic disorder characterized by a cluster of signs and symptoms customarily occurring together."

THE 1989 ILAE CLASSIFICATION

The 1989 ILAE epilepsy classification is used worldwide and is reproduced in the appendix to this chapter. It was revised from proposals made in 1970 (1,2) and 1985 (5) and, like the 1981 ILAE seizure classification (4), is based primarily on the definition of electroclinical syndromes. In 1969, Henri Gastaut proposed the first classification of epilepsies (2), which was used as the basis of the first ILAE epilepsy classification system that was proposed one year later (1). This classification provided the major division between "partial" (focal) and generalized epilepsies. Each seizure type was grouped according to this dichotomy and associated with interictal and ictal electroencephalographic (EEG) findings, etiology and pathologic findings, and age of manifestation.

About 15 years later, a revision introduced the concept of epilepsy syndromes "defined as an epileptic disorder characterized by a cluster of signs and symptoms customarily occurring together. The signs and symptoms may be clinical (e.g., case history, seizure type, modes of seizure recurrence, and neurologic and psychological findings) or as a result of findings detected by ancillary studies (e.g., EEG, x-ray, CT [computed tomography], and NMR [nuclear magnetic resonance])" (5). This revision divided many specific epilepsy syndromes under the major dichotomy of generalized and "localization-related" (focal) epilepsies and associated them with clinical and EEG findings, etiologies, and disease severity.

The primary dichotomy of these classification systems was set between localization-related (focal) epilepsies, "in which seizure semiology or findings at investigation disclose a localized origin of the seizures" (3), and generalized epilepsies, characterized by "seizures in which the first clinical changes indicate initial involvement of both hemispheres… [and] the ictal encephalographic patterns initially are bilateral" (3). EEG findings are the laboratory results that carry the most weight for defining a focal epilepsy syndrome.

In addition to localizing information, previous epilepsy classifications also contained etiologic

information. The 1970 epilepsy classification (1) further divided the generalized epilepsies into primary, those occurring in the setting of normal neurologic status, with seizures that begin in childhood or adolescence and lack any clear cause, and secondary, those involving abnormal neurologic or psychological findings and diffuse or multifocal brain lesions. Because the term secondary generalized epilepsy was sometimes confused with the different concept of "secondary" or "secondarily" generalized tonic–clonic seizures, it was abandoned in the 1985 (5) and 1989 (3) revisions. Primary and secondary were replaced with idiopathic and symptomatic. The 1970 classification (1) applied the etiologic dichotomy only to generalized epilepsies because all focal epilepsies were assumed to be associated with some type of brain lesion. This did not include the idiopathic syndrome of benign epilepsy of childhood with centrotemporal spikes, and therefore, the 1985 (5) and 1989 (3) revisions applied idiopathic and symptomatic to the focal epilepsies as well. The term cryptogenic was added in the 1989 (3) classification to describe epilepsy syndromes that are presumed to be symptomatic but are of unknown cause in specific patients.

In spite of its widespread use, the 1989 proposal has been criticized because of its separation between "partial" and "generalized" epilepsies, and therefore, it does reflect our growing appreciation for the complex manifestations of epilepsy in the brain or how that can change over time, especially in the developing brain. Furthermore, the terms "idiopathic," "cryptogenic," and "symptomatic" are based on assumption and lack of knowledge rather than actual evidence. Now that the ability to collect the necessary evidence has developed, those assumptions are being called into question. Additionally, the system accommodates didactic grouping purposes but has limitation when used in clinical practice during the process of data acquisition: A working diagnosis is usually assigned first, and subsequently, etiologies are explored. A final diagnosis and classification is frequently not possible before workup was completed. Furthermore, the systems description of seizure semiology is limited and is thought to mingle seizure semiology and epilepsy type or syndrome and only allows a strict one-to-one relationship between seizure type and epilepsy. In all, the 1989 classification rests on concepts developed over the past century and does not readily incorporate our rapidly expanding knowledge about the causes and manifestations of epilepsy afforded to us by advances in neuroimaging, molecular cell genetics, neuroimmunology, and other fields.

SEMIOLOGIC SEIZURE CLASSIFICATION

A seizure classification based only on clinical semiology, so-called semiologic seizure classification, was proposed by Hans Lüders et al. in the late 1990s (12,13). This considered the following clinical seizure features:

1. Auras: Ictal manifestations having sensory, psychosensory, and experiential symptoms.
2. Autonomic seizures: The main ictal manifestations are objectively documented autonomic alterations.
3. "Dialeptic" seizures: Their main ictal manifestation is an alteration of consciousness independent of ictal EEG manifestations. The term "dialeptic" seizure has been introduced to distinguish this concept from absence seizures (as dialeptic seizures with a generalized ictal EEG) and complex partial seizures (as dialeptic seizures with a focal ictal EEG).
4. Motor seizures: Motor symptoms and are subclassified as simple or complex. Simple motor seizures are characterized by simple, unnatural movements that can be triggered by

electrical stimulation of the primary and supplementary motor area (such as myoclonic, tonic, clonic and tonic–clonic, versive seizures). Complex motor seizures are characterized by complex motor movements resembling natural movements but occurring in an inappropriate setting (definition of "automatisms").

5. Special seizures: Seizures characterized by "negative" features (so named atonic, astatic, hypomotor, akinetic, and aphasic seizures). The semiologic seizure classification identifies in detail the somatotopic distribution of ictal semiology and seizure evolution and paved the way for an ILAE glossary of seizure semiology.

GLOSSARY OF SEIZURE SEMIOLOGY

Terms from the semiologic seizure classification were incorporated in an ILAE glossary of seizure semiology terms in 2001 (11). This glossary delineates descriptive terms that provide additional details on clinical seizure presentation. The glossary contained terms for reference to semiology, as well as terms for indicating seizure timing and duration, severity, prodromes, and postictal phenomena. According to this glossary, seizures can be termed "motor" when they involve musculature in any form. The motor event could consist of an increase (positive) or decrease (negative) in muscle contraction to produce a movement. Seizures can be called "tonic" when consist in a sustained increase in muscle contraction lasting a few seconds to minutes; "atonic" when appearing as a sudden loss or diminution of muscle tone without apparent preceding myoclonic or tonic event lasting 1 to 2 seconds, involving the head, trunk, jaw, or limb musculature; or "myoclonic" if they present with a sudden, brief (usually <100 milliseconds) involuntary single (or multiple) contraction of muscles or muscle groups of variable topography. The term "clonic" was used to refer to myoclonus that is regularly repetitive, involves the same muscle groups at a frequency of about 2 to 3 Hz, and is prolonged. "Tonic–clonic" refers to a sequence consisting of a tonic followed by a clonic phase (14). The glossary also contains details on automatisms and associated features of semiology. The term "automatism" is recommended for a more or less coordinated, repetitive, motor activity mostly occurring when cognition is impaired. Automatisms often resemble a voluntary movement and may consist of an inappropriate continuation of ongoing preictal motor activity. Lip smacking, lip pursing, chewing, licking, teeth grinding, and swallowing are termed "oroalimentary" (14). The term "dyscognitive" refers to events in which [1] disturbance of cognition is the predominant feature, and [2a] two or more of the components of cognition are involved, or [2b] involvement of such components is undetermined. Components of cognition were defined as follows:

1. Perception: symbolic conception of sensory information
2. Attention: appropriate selection of a principal perception or task
3. Emotion: appropriate affective significance of a perception
4. Memory: ability to store and retrieve percepts or concepts
5. Executive function: anticipation, selection, monitoring of consequences, and initiation of motor activity including praxis and/or speech

2001 ILAE PROPOSAL: A SYNDROME-ORIENTED

CLASSIFICATION

To resolve these existing controversies surrounding the 1989 epilepsy classification, the ILAE's Commission on Classification and Terminology published a common terminology for ictal semiology (14) and a revised five-axis classification scheme of epilepsies (11). This proposal (11) was also based on epilepsy syndromes that appeared in previous classifications. The authors defined an epileptic syndrome as "[a] complex of signs and symptoms that define a unique epilepsy condition" (11). However, due to ongoing discussions, this proposal was again revised and another progress report was issued 5 years later (15).

Axes of the 2001 ILAE Proposal

The different axes in the 2001 ILAE proposal included seizure description (axis 1), seizure type (axis 2), epilepsy syndrome (axis 3), etiology (axis 4), and impairment (axis 5).

Axis 1 described ictal seizure semiology through a standardized glossary of descriptive ictal terminology (14). This terminology was independent of pathophysiologic mechanisms, epilepsy focus, or seizure etiology.

Axis 2 was based on a list of accepted epileptic seizure types constructed by the task force. These seizure types were closely related to diagnostic epilepsy entities or indicated underlying mechanisms, pathophysiology, or etiology or implicated related prognosis and therapy.

Axis 3 identified the epilepsy syndrome diagnosis and separated epilepsy syndromes from entities with epileptic seizures. Epilepsy syndromes were divided into "syndromes in development" and fully characterized syndromes (16).

Axis 4 delineated the etiology of epilepsies, which included pathologic and genetic causes as well as diseases frequently associated with epilepsy, and this list was a work in progress at the time of publication.

Axis 5 was incomplete at the time of publication and was intended to include an optional classification of the degree of disability and impairment caused by the epilepsy.

Compared with the 1989 version of epilepsy classification, the diagnostic scheme of the 2001 proposal attempted to overcome shortcomings among EEG features, clinical seizure semiology, and syndromic classification efforts. By dividing the seizure classification into several axes, the ILAE responded to the criticism that a strict one-to-one relationship is lacking between epilepsy syndromes and seizure types. The introduction of a multiaxial diagnostic scheme reflected the recognition of epilepsy as a clinical symptom that can manifest with different semiologic seizure types and be intertwined with different etiologies. It also tried to respond to criticism that seizure semiology was not sufficiently emphasized in previous classifications. Furthermore, it tried to address the more and more confluent borders between generalized and focal epilepsies. The term partial was replaced by focal. Additionally, it attempted to model epilepsy syndromes more flexible by defining "accepted syndromes" versus "syndromes in development." However, critics highlighted an incomplete and preliminary presentation, lack of inclusion criteria for "accepted" syndromes, redundancy among classification axes, lack of information on age of onset, and inability to use this classification in all patients and lack of applicability (17–20). Due to ongoing discussions, the ILAE core group on classification revised this approach and provided an update in 2006 (15).

THE 2006 REPORT OF THE ILAE CLASSIFICATION

CORE GROUP

This proposal aimed to outline "scientifically rigorous criteria for identification of specific epileptic seizure types and specific epilepsy syndromes as unique diagnostic entities" (15). Criteria included epileptic seizure types, age of onset, progressive nature, interictal EEG, associated interictal signs and symptoms, pathophysiologic mechanisms, anatomical substrate, and etiologic categories, as well as genetic basis. Subsequently, the group scored epilepsy syndromes listed in the 2001 proposal on a scale from 1 to 3, with 3 being the most clearly and reproducibly defined. The proposal mentioned that this was a very preliminary method and intended to ignite further research and category suggestions or possible cluster analysis of signs and symptoms (15). Based on this proposal, epilepsy syndromes could be assigned in up to 70% of cases in a first comparison (21). However, persistent inter- and intra-axial discordance was noted necessitating further revision in 2010.

THE 2010 REVISED TERMINOLOGY AND CONCEPTS FOR ORGANIZATION OF SEIZURES AND EPILEPSIES

This additional update is an "interim organization" and tries to address ongoing criticisms to concepts and terminology (22). Classification is not treated as a rigid doctrine but a guide to summarize our current understanding about seizures and epilepsies in a useful manner. This revision includes the concept of electroclinical syndromes and essentially leaves the suggested syndrome list from 2006 unchanged although it incorporated additional, well-documented syndromes (22). It also addresses the variable degrees of precision of diagnosis and attempts to include the natural evolution. Epilepsies are now organized by specificity into three major divisions of electroclinical syndromes, nonsyndromic epilepsies with structural–metabolic causes, and epilepsies of unknown cause. This organization allows further description within divisions by dimensions as previously suggested (17). These may include cause, seizure types, age at onset, and others. Furthermore, it emphasizes the descriptive seizure terminology from 2001 (14) within these dimensions, specifically for focal epilepsies. Seizures are now recognized as "occurring in and rapidly engaging bilaterally distributed networks (generalized) and within networks limited to one hemisphere and either discretely localized or more widely distributed (focal)" and terms such as complex partial and simple partial have been abandoned. It also rekindles the terminology "focal" and differentiates from "generalized" seizures, while recognizing that generalized epileptic seizures do not necessarily include the entire cortex. Suggested etiologic concepts within the causal dimension include genetic, structural–metabolic, and unknown replacing idiopathic, symptomatic, and cryptogenic. Further changes in terminology and classification remain work in progress.

DO NOT CLASSIFY—DIAGNOSE!

While the ILAE efforts still continue to revise this epilepsy classification, clinicians continue to take care of epilepsy patients and make clinical epilepsy diagnoses, largely unaffected by the Ivory Tower, theoretical discussions, and deliberations on epilepsy classification. Like any other neurologic condition, the general neurologic diagnostic approach to diagnosis of characterizing the clinical presentation (namely, the seizures), followed by localization in the CNS, and investigating

underlying etiologies and comorbidities can also be applied to epilepsy. The diagnostic approach to seizures and epilepsy involves five independent steps:

1. How old is the patient?
2. Is it epilepsy?
3. What is the clinical presentation? (What are the seizure symptoms/the neurologic exam findings/cognitive or developmental status?)
4. What are the results of investigational tests?
5. Can you localize the source of the seizures, can you identify one or several epilepsy causes, or can you identify an epilepsy syndrome? (Is there a functional or structural lesion and if so, where is it? Is there a genetic factor? A vascular, infectious, toxic, autoimmune, metabolic, idiopathic/unknown, neoplastic, congenital, degenerative, and endocrine component (mnemonic: VITAMIN CDE)? This process requires comparison of all collected evidence in the setting of previously described findings and literature categories. Interpretation of above collected clinical findings and test results may allow localization or syndrome diagnosis. Also, are there other related features that may assist with diagnosis making or fit with known syndromes? Ongoing synopses of independent investigational techniques include synthesis and integration of all results into a working and ultimately final diagnosis during the process of collection of a detailed history and clinical course, seizure semiology analysis either by history or video review, physical examination, electrophysiologic studies, structural neuroimaging and functional and metabolic neuroimaging, and laboratory testing including genetic and histopathologic studies, and these studies aid in answering the questions outlined above.

1. How Old Is the Patient?

Perhaps the single most important overriding factor in the diagnosis of a patient with epilepsy is the age at onset. This is because different types of epilepsies, seizures, and causes of epilepsy manifest at different ages. If one begins with age, the field of diagnostic possibilities rapidly simplifies and one can focus on a relatively restricted range of possibilities. That said, there are fundamental principles to guide diagnosis at any age.

2. Is It Epilepsy?

Any given patient may present with nonepileptic seizures. Therefore, it is always crucial to consider the option that events may be nonepileptic. The differentiation between epileptic and nonepileptic events is often challenging. Video–EEG monitoring can help capture clinical semiology and an EEG correlate—or lack thereof. In infants and children, overdiagnosis of epilepsy is often seen in the context of breath-holding spells, gastroesophageal reflex, excessive startling, or parasomnias among others. In older adolescents and adults, a phenomenon known as nonepileptic (sometimes psychogenic) seizures is seen. This is a conversion disorder and ideally should result in the involvement of a psychiatrist.

Diagnosis is recognized as an ongoing interactive and iterative process. Once further evidence and results become available, patients can be diagnosed with an increasing degree of precision or

results may inform further, more targeted testing. If it is uncertain whether the patient has epilepsy or nonepileptic seizures, we prefer the term paroxysmal event. As further information becomes available through the steps outlined previously (e.g., an electroencephalogram [EEG] demonstrating left mesial temporal sharp waves, left temporal EEG seizures, and an MRI showing left hippocampal atrophy), the diagnosis becomes more precise (left mesial temporal lobe epilepsy). Therefore, it is helpful to document progress in diagnostic workup and diagnosis as well as a revised diagnostic hypothesis with every patient encounter. Additional details on localizing and lateralizing evidence of clinical seizures as well as diagnostic syndromic features are also outlined in several other chapters in this book.

3. What Is the Clinical Presentation?

A detailed account of the episodes in question is crucial. Specific questions may focus on who witnessed the event, when and where events occur, whether they are triggered by external stimuli, how they begin, how they evolve, and how they end, which are essential to determining the type of seizure.

The seizure setting includes a reliable witness who can provide a detailed account of the event in question. Alternatively, a video recording of the event may also be extremely helpful, especially in circumstances if the patient cannot recall the event or parts of the event. Emphasis should also be placed on the immediate period prior to the seizure, as a detailed account of that time period may reveal potential seizure triggers or prodrome. Examples may include the patient's baseline activity, changes in the setting or patient behavior immediately before the event (i.e., occurrence out of sleep), or clinical symptoms that the patient experienced prior to seizure onset, such as a headache or fever.

Onset: Detailed reconstruction of the seizure onset may divulge further information about potential auras, although auras do not necessarily need to be present. However, the first clinical symptom often provides most information regarding the ictal onset zone and epileptogenic zone as the initial symptomatogenic zone is usually closest to the actual seizure onset (23).

Evolution: Further clinical seizure features and evolution may present with a variety of different presentations, including motor, language, automatisms, autonomic manifestations, and alteration of consciousness among others. The clinical signs and symptoms are the most important pieces of information for localizing a lesion in the central nervous system (23). Seizures and seizure semiology are the clinical manifestation of epilepsy. The ILAE epilepsy terminology from 2001 (14), based on clinical seizure descriptions (12,13,24–29), provides a helpful framework for this description. This glossary uses only the clinical semiology and does not require any additional diagnostic techniques other than analysis of an observed or videotaped seizure. Of note, data from other investigational techniques, such as EEG, MEG, MRI, or nuclear imaging, are not necessary to utilize the glossary.

Postictal: Events that happen after the seizure may also provide additional information. Lateralizing signs, such as postictal hemiparesis (Todd palsy) or postictal nose wiping, may continue to provide additional clinical information.

In between and after seizures, the physical examination can add information regarding etiology, type of epilepsy, and epilepsy syndrome (i.e., a hemiparesis may point toward a large hemispheric lesion; progressive hemiparesis over time may implicate a tumor or Rasmussen encephalitis in the appropriate clinical setting) (23).

Frequency, patterns, and seizure clusters: It may also be crucial to inquire about seizure frequency; seizure patterns, such as predominant occurrence at night; or seizure occurrence in

clusters, as seen during epileptic spasms.

4. What Are the Results of Investigational Tests?

An EEG helps in the evaluation of seizure type and localization and possible diagnosis of an epilepsy syndrome and aids in the estimation of seizure recurrence risk. Activation procedures (hyperventilation, photic stimulation, sleep/sleep deprivation) can be performed to provoke epileptiform abnormalities (23).

Neuroimaging, including MRI, can investigate a possible cause of seizures, such as the identification of a structural abnormality. In general, as a practical guideline, persistent postictal focal deficits and the lack of return to baseline within a few hours after a seizure should suggest the need of neuroimaging to rule out additional neurologic structural lesions.

Further investigations to determine the etiology of seizures including genetic testing through laboratory blood tests may also be considered if clinically indicated.

5. Do the Presentation and Investigational Findings Fit with a Specific Epilepsy Localization, Known Genetic Cause, or Well-Described Epilepsy Syndrome?

Seizures are caused by the co-occurrence of multiple triggering factors. On the basis of investigational methods used to determine the cause of the epilepsy (e.g., histopathology, metabolic testing, MRI imaging, genetic testing) or localization to a certain area in the brain, factors responsible for the generation of seizures can be found simultaneously at different diagnostic levels. To account for multiple coexisting etiologic factors, the etiology dimension permits the classification of several factors in one patient. Other diagnostic techniques, such as genetics, have led to the identification of other coexisting causes and, with the results from further research in newer fields, will gain in importance in the future. A large proportion of children with epilepsy and a smaller proportion of adults have epilepsies that may fit criteria for specific electroclinical syndromic diagnoses. Such diagnoses are not independent of any of the other features discussed above, but they do provide a clinical gestalt that allows some confidence regarding the preferred treatments, likely neurologic consequences, and long-term outcomes for the patient. These syndromes are addressed in several different chapters in this text.

CONCLUSION

The classification of epilepsies is an ongoing process. While the terminology of the 1989 ILAE proposal (3) is in widespread use (and is reproduced here as an Appendix), it does not reflect the current approach, terminology, and concepts used in the contemporary diagnosis and treatment of patients with epilepsy. Newer proposals attempt to provide adjust for scientific progress and implement language that directly applies the advances from neuroimaging, genetics, and other areas of neuroscience to the patient and—in doing so—provide a transparent translation of discoveries to patient care. While the classification of epilepsy continues to be revised, we urge the readers not to waste time with classification, but to diagnose their patients, to be able to provide the most appropriate treatment. The general neurologic approach of seizure description, localization and etiology, and comorbidity confirmation works also well in epilepsy, in particular when approaching

and diagnosing a new epilepsy patient.

CHAPTER 9 APPENDIX PROPOSAL FOR REVISED CLASSIFICATION OF EPILEPSIES AND EPILEPTIC SYNDROMES

(COMMISSION ON CLASSIFICATION AND TERMINOLOGY OF THE INTERNATIONAL LEAGUE AGAINST EPILEPSY 1989). REPRODUCED WITH PERMISSION FROM EPILEPSIA. 1989;30:389–399.

PART I: INTERNATIONAL CLASSIFICATION OF EPILEPSIES AND EPILEPTIC SYNDROMES

1. Localization-related (focal, local, partial) epilepsies and syndromes
   1.1 Idiopathic (with age-related onset)At present, the following syndromes are established, but more may be identified in the future:

- Benign childhood epilepsy with centrotemporal spike
- Childhood epilepsy with occipital paroxysms
- Primary reading epilepsy

1.2 Symptomatic (Part III)

- Chronic progressive epilepsia partialis continua of childhood (Kojewnikow syndrome)
- Syndromes characterized by seizures with specific modes of precipitation (see Part IV)

Apart from these rare conditions, the symptomatic category comprises syndromes of great individual variability, which are based mainly on seizure types and other clinical features, as well as anatomic localization and etiology—as far as these are known.

The seizure types refer to the International Classification of Epileptic Seizures. Inferences regarding anatomic localization must be drawn carefully. The scalp EEG (both interictal and ictal) may be misleading, and even local morphologic findings detected by neuroimaging techniques are not necessarily identical with an epileptogenic lesion. Seizure symptomatology and, sometimes, additional clinical features often provide important clues. The first sign or symptom of a seizure is often the most important indicator of the site of origin of seizure discharge, whereas the following sequence of ictal events can reflect its further propagation through the brain. This sequence, however, can still be of high localizing importance. One must bear in mind that a seizure may start in a clinically silent region, so that the first clinical event occurs only after spread to a site more or less distant from the locus of initial discharge. The following tentative descriptions of syndromes related to anatomic localizations are based on data that include findings in studies with depth electrodes.

Temporal Lobe Epilepsies

Temporal lobe syndromes are characterized by simple partial seizures, complex partial seizures, secondarily generalized seizures, or combinations of these. Frequently, there is a history of febrile seizures, and a family history of seizures is common. Memory deficits may occur. On metabolic imaging studies, hypometabolism is frequently observed [e.g., positron emission tomography (PET)]. Unilateral or bilateral temporal lobe spikes are common on EEG. Onset is frequently in childhood or young adulthood. Seizures occur in clusters at intervals or randomly.

General Characteristics

Features strongly suggestive of the diagnosis when present include:

1. Simple partial seizures typically characterized by autonomic and/or psychic symptoms and certain sensory phenomena such as olfactory and auditory (including illusions). Most common is an epigastric, often rising, sensation.
2. Complex partial seizures often but not always beginning with motor arrest typically followed by oroalimentary automatism. Other automatisms frequently follow. The duration is typically >1 minute. Postictal confusion usually occurs. The attacks are followed by amnesia. Recovery is gradual.

Electroencephalographic Characteristics

In temporal lobe epilepsies, the interictal scalp EEG may show the following:

1. No abnormality.
2. Slight or marked asymmetry of the background activity.
3. Teporal spikes, sharp waves and/or slow waves, unilateral or bilateral, synchronous but also asynchronous. These findings are not always confined to the temporal region.
4. In addition to scalp EEG findings, intracranial recordings may allow better definition of the intracranial distribution of the interictal abnormalities.

In temporal lobe epilepsies, various EEG patterns may accompany the initial clinical ictal symptomatology, including (a) a unilateral or bilateral interruption of background activity and (b) temporal or multilobar low-amplitude fast activity, rhythmic spikes, or rhythmic slow waves. The onset of the EEG may not correlate with the clinical onset depending on methodology. Intracranial recordings may provide additional information regarding the chronologic and spatial evolution of the discharges.

Amygdalohippocampal (Mesiobasal Limbic or Rhinencephalic) Seizures

Hippocampal seizures are the most common form; the symptoms are those described in the previous paragraphs except that auditory symptoms may not occur. The interictal scalp EEG may be normal, may show interictal unilateral temporal sharp or slow waves, and may show bilateral sharp or slow waves, synchronous or asynchronous. The intracranial interictal EEG may show mesial anterior temporal spikes or sharp waves. Seizures are characterized by rising epigastric discomfort, nausea, marked autonomic signs, and other symptoms, including borborygmi, belching, pallor, fullness of the face, flushing of the face, arrest of respiration, pupillary dilatation, fear, panic, and olfactory–gustatory hallucinations.

Lateral Temporal Seizures

Simple seizures characterized by auditory hallucinations or illusions or dreamy states, visual misperceptions, or language disorders in case of language dominant hemisphere focus. These may progress to complex partial seizures if propagation to mesial temporal or extratemporal structures occurs. The scalp EEG shows unilateral or bilateral midtemporal or posterior temporal spikes, which are most prominent in the lateral derivations.

Frontal Lobe Epilepsies

Frontal lobe epilepsies are characterized by simple partial, complex partial, secondarily generalized seizures, or combinations of these. Seizures often occur several times a day and frequently occur during sleep. Frontal lobe partial seizures are sometimes mistaken for psychogenic seizures. Status epilepticus is a frequent complication.

General Characteristics

Features strongly suggestive of the diagnosis include

1. Generally short seizures
2. Complex partial seizures arising from the frontal lobe, often with minimal or no postictal confusion
3. Rapid secondary generalization (more common in seizures of frontal than of temporal lobe epilepsy)
4. Prominent motor manifestations, which are tonic or postural
5. Complex gestural automatisms frequent at onset
6. Frequent falling when the discharge is bilateral

A number of seizure types are described below; however, multiple frontal areas may be involved rapidly, and specific seizure types may not be discernible.

Supplementary Motor Seizures

In supplementary motor seizures, the seizure patterns are postural, focal tonic, with vocalization, speech arrest, and fencing postures.

Cingulate

Cingulate seizure patterns are complex partial with complex motor gestural automatisms at onset. Autonomic signs are common, as are changes in mood and affect.

Anterior Frontopolar Region

Anterior frontopolar seizure patterns include forced thinking or initial loss of contact and adversive movements of the head and eyes, with possible evolution including contraversive movements and axial clonic jerks and falls and autonomic signs.

Orbitofrontal

The orbitofrontal seizure pattern is one of complex partial seizures with initial motor and gestural automatisms, olfactory hallucinations and illusions, and autonomic signs.

Dorsolateral

Dorsolateral seizure patterns may be tonic or, less commonly, clonic with versive eye and head

movements and speech arrest.

Opercular

Opercular seizure characteristics include mastication, salivation, swallowing, laryngeal symptoms, speech arrest, epigastric aura, fear, and autonomic phenomena. Simple partial seizures, particularly partial clonic facial seizures, are common and may be ipsilateral. If secondary sensory changes occur, numbness may be a symptom, particularly in the hands. Gustatory hallucinations are particularly common in this area.

Motor Cortex

Motor cortex epilepsies are mainly characterized by simple partial seizures, and their localization depends on the side and topography of the area involved. In cases of the lower prerolandic area, there may be speech arrest, vocalization or dysphasia, tonic–clonic movements of the face on the contralateral side, or swallowing. Generalization of the seizure frequently occurs. In the rolandic area, partial motor seizures without march or jacksonian seizures occur, particularly beginning in the contralateral upper extremities. In the case of seizures involving the paracentral lobule, tonic movements of the ipsilateral foot may occur, as well as the expected contralateral leg movements. Postictal or Todd paralysis is frequent.

Kojewnikow Syndrome

Two types of Kojewnikow syndrome are recognized, one of which is also known as Rasmussen syndrome and is included among the epileptic syndromes of childhood noted under symptomatic seizures. The other type represents a particular form of rolandic partial epilepsy in both adults and children and is related to a variable lesion of the motor cortex. Its principal features are (a) motor partial seizures, always well localized; (b) often late appearance of myoclonus in the same site where somatomotor seizures occur; (c) an EEG with normal background activity and a focal paroxysmal abnormality (spikes and slow waves); (d) occurrence at any age in childhood and adulthood; (e) frequently demonstrable etiology (tumor, vascular); and (f) no progressive evolution of the syndrome (clinical, EEG, or psychological, except in relation to the evolution of the causal lesion). This condition may result from mitochondrial encephalopathy (MELAS). NOTE: anatomical origins of some epilepsies are difficult to assign to specific lobes. Such epilepsies include those with pre- and postcentral symptomatology (perirolandic seizures). Such overlap to adjacent anatomic regions also occurs in opercular epilepsy.

In frontal lobe epilepsies, the interictal scalp recordings may show (a) no abnormality; (b) sometimes background asymmetry, frontal spikes, or sharp waves; or (c) sharp waves or slow waves (either unilateral or frequently bilateral or unilateral multilobar). Intracranial recordings can sometimes distinguish unilateral from bilateral involvement.

In frontal lobe seizures, various EEG patterns can accompany the initial clinical symptomatology. Uncommonly, the EEG abnormality precedes the seizure onset and then provides important localizing information, such as (a) frontal or multilobar, often bilateral, low-amplitude fast activity, mixed spikes, rhythmic spikes, rhythmic spike waves, or rhythmic slow waves or (b) bilateral high-amplitude single sharp waves followed by diffuse flattening.

Depending on the methodology, intracranial recordings may provide additional information

regarding the chronologic and spatial evolution of the discharges; localization may be difficult.

Parietal Lobe Epilepsies

Parietal lobe epilepsy syndromes are usually characterized by simple partial and secondarily generalized seizures. Most seizures arising in the parietal lobe remain as simple partial seizures, but complex partial seizures may arise out of simple partial seizures and occur with spread beyond the parietal lobe. Seizures arising from the parietal lobe have the following features: Seizures are predominantly sensory with many characteristics. Positive phenomena consist of tingling and a feeling of electricity, which may be confined or may spread in a jacksonian manner. There may be a desire to move a body part or a sensation as if a part were being moved. Muscle tone may be lost. The parts most frequently involved are those with the largest cortical representation (e.g., the hand, arm, and face). There may be tongue sensations of crawling, stiffness, or coldness, and facial sensory phenomena may occur bilaterally. Occasionally, an intraabdominal sensation of sinking, choking, or nausea may occur, particularly in cases of inferior and lateral parietal lobe involvement. Rarely, there may be pain, which may take the form of a superficial burning dysesthesia or a vague, very severe, painful sensation. Parietal lobe visual phenomena may occur as hallucinations of a formed variety. Metamorphopsia with distortions, foreshortenings, and elongations may occur and are more frequently observed in cases of nondominant hemisphere discharges. Negative phenomena include numbness, a feeling that a body part is absent, and a loss of awareness of a part or a half of the body, known as asomatognosia. This is particularly the case with nondominant hemisphere involvement. Severe vertigo or disorientation in space may be indicative of inferior parietal lobe seizures. Seizures in the dominant parietal lobe result in a variety of receptive or conductive language disturbances. Some well-lateralized genital sensations may occur with paracentral involvement. Some rotatory or postural motor phenomena may occur. Seizures of the paracentral lobule have a tendency to become secondarily generalized.

Occipital Lobe Epilepsies

Occipital lobe epilepsy syndromes are usually characterized by simple partial and secondarily generalized seizures. Complex partial seizures may occur with spread beyond the occipital lobe. The frequent association of occipital lobe seizures and migraine is complicated and controversial. The clinical seizure manifestations usually, but not always, include visual manifestations. Elementary visual seizures are characterized by fleeting visual manifestations that may be either negative (scotoma, hemianopsia, amaurosis) or, more commonly, positive (sparks or flashes, phosphenes). Such sensations appear in the visual field contralateral to the discharge in the specific visual cortex, but can spread to the entire visual field. Perceptive illusions, in which the objects appear to be distorted, may occur. The following varieties can be distinguished: a change in size (macropsia or micropsia) or a change in distance, an inclination of objects in a given plane of space, and distortion of objects or a sudden change of shape (metamorphopsia). Visual hallucinatory seizures are occasionally characterized by complex visual perceptions (e.g., colorful scenes of varying complexity). In some cases, the scene is distorted or made smaller, and in rare instances, the subject sees the subject's own image (heautoscopy). Such illusional and hallucinatory visual seizures involve epileptic discharge in the temporoparietooccipital junction. The initial signs may also include tonic and/or clonic contraversion of eyes and head or eyes only (oculoclonic or oculogyric deviation),

palpebral jerks, and forced closure of eyelids. Sensation of ocular oscillation or of the whole body may occur. The discharge may spread to the temporal lobe, producing seizure manifestations of either lateral posterior temporal or hippocampoamygdala seizures. When the primary focus is located in the supracalcarine area, the discharge can spread forward to the suprasylvian convexity or the mesial surface, mimicking those of parietal or frontal lobe seizures. Spread to contralateral occipital lobe may be rapid. Occasionally, the seizure tends to become secondarily generalized.

1.3 CryptogenicCryptogenic epilepsies are presumed to be symptomatic, and the etiology is unknown. Thus, this category differs from the previous one by the lack of etiologic evidence (see definitions).

2. Generalized epilepsies and syndromes

2.1 Idiopathic (with age-related onset—listed in order of age)

- Benign neonatal familial convulsions
- Benign neonatal convulsions
- Benign myoclonic epilepsy in infancy
- Childhood absence epilepsy (pyknolepsy)
- Juvenile absence epilepsy
- Juvenile myoclonic epilepsy (impulsive petit mal)
- Epilepsy with grand mal (GTCS) seizures on awakening
- Other generalized idiopathic epilepsies not defined above
- Epilepsies with seizures precipitated by specific modes of activation

2.2 Cryptogenic or symptomatic (in order of age)

- West syndrome (infantile spasms, Blitz–Nick– Salaam–Krämpfe)
- Lennox–Gastaut syndrome
- Epilepsy with myoclonic astatic seizures
- Epilepsy with myoclonic absences

2.3 Symptomatic

2.3.1 Nonspecific etiology

- Early myoclonic encephalopathy
- Early infantile epileptic encephalopathy with suppression burst
- Other symptomatic generalized epilepsies not defined above

2.3.2 Specific syndromes

- Epileptic seizures may complicate many disease states. Under this heading are included diseases in which seizures are a presenting or predominant feature.

3. Epilepsies and syndromes undetermined whether focal or generalized

3.1 With both generalized and focal seizures

- Neonatal seizures
- Severe myoclonic epilepsy in infancy

- Epilepsy with continuous spike waves during slow-wave sleep
- Acquired epileptic aphasia (Landau–Kleffner syndrome)
- Other undetermined epilepsies not defined above

3.2 Without unequivocal generalized or focal features. All cases with generalized tonic–clonic seizures in which clinical and EEG findings do not permit classification as clearly generalized or localization related, such as in many cases of sleep grand mal (GTCS), are considered not to have unequivocal generalized or focal features.

4. Special syndromes

4.1 Situation-related seizures (Gelegenheitsanfälle)

- Febrile convulsions
- Isolated seizures or isolated status epilepticus
- Seizures occurring only when there is an acute metabolic or toxic event due to factors such as alcohol, drugs, eclampsia, and nonketotic hyperglycemia

PART II: DEFINITIONS

Localization-Related (Focal, Local, Partial) Epilepsies and Syndromes

Localization-related epilepsies and syndromes are epileptic disorders in which seizure semiology or findings at investigation disclose a localized origin of the seizures. This includes not only patients with small circumscribed constant epileptogenic lesions (anatomic or functional), i.e., true focal epilepsies, but also patients with less well-defined lesions, whose seizures may originate from variable loci. In most symptomatic localization-related epilepsies, the epileptogenic lesions can be traced to one part of one cerebral hemisphere, but in idiopathic age-related epilepsies with focal seizures, corresponding regions of both hemispheres may be functionally involved.

Generalized Epilepsies and Syndromes

According to the International Classification of Epilepsies and Epileptic Syndromes, generalized epilepsies and syndromes are epileptic disorders with generalized seizures, i.e., "seizures in which the first clinical changes indicate initial involvement of both hemispheres.... The ictal encephalographic patterns initially are bilateral."

Epilepsies and Syndromes Undetermined as to Whether They Are Focal or Generalized

There may be two reasons why a determination of whether seizures are focal or generalized cannot be made: (a) the patient has both focal and generalized seizures together or in succession (e.g., partial seizures plus absences) and has both focal and generalized EEG seizure discharges (e.g., temporal spike focus plus independent bilateral spike-and-wave discharges), and (b) there are no positive signs of either focal or generalized seizure onset. The most common reasons for this are the seizures occur during sleep, the patient recalls no aura, and ancillary investigations, including EEG, are not revealing.

Idiopathic Localization-Related Epilepsies

Idiopathic localization-related epilepsies are childhood epilepsies with partial seizures and focal EEG abnormalities. They are age related, without demonstrable anatomic lesions, and are subject to spontaneous remission. Clinically, patients have neither neurologic and intellectual deficit nor a history of antecedent illness, but frequently have a family history of benign epilepsy. The seizures are usually brief and rare, but may be frequent early in the course of the disorder. The seizure patterns may vary from case to case, but usually remain constant in the same child. The EEG is characterized by normal background activity and localized high-voltage repetitive spikes, which are sometimes independently multifocal. Brief bursts of generalized spike waves can occur. Focal abnormalities are increased by sleep and are without change in morphology.

Benign Childhood Epilepsy with Centrotemporal Spikes

Benign childhood epilepsy with centrotemporal spikes is a syndrome of brief, simple, partial, hemifacial motor seizures, frequently having associated somatosensory symptoms that have a tendency to evolve into GTCS. Both seizure types are often related to sleep. Onset occurs between the ages of 3 and 13 years (peak, 9 to 10 years), and recovery occurs before the age of 15 to 16 years. Genetic predisposition is frequent, and there is male predominance. The EEG has blunt high-voltage centrotemporal spikes, often followed by slow waves that are activated by sleep and tend to spread or shift from side to side.

Childhood Epilepsy with Occipital Paroxysms

The syndrome of childhood epilepsy with occipital paroxysms is, in general respects, similar to that of benign childhood epilepsy with centrotemporal spikes. The seizures start with visual symptoms (amaurosis, phosphenes, illusions, or hallucinations) and are often followed by a hemiclonic seizure or automatisms. In 25% of cases, the seizures are immediately followed by migrainous headache. The EEG has paroxysms of high-amplitude spike waves or sharp waves recurring rhythmically on the occipital and posterior temporal areas of one or both hemispheres, but only when the eyes are closed. During seizures, the occipital discharge may spread to the central or temporal region. At present, no definite statement on prognosis is possible.

Idiopathic Generalized Epilepsies (Age Related)

Idiopathic generalized epilepsies are forms of generalized epilepsies in which all seizures are initially generalized, with an EEG expression that is a generalized, bilateral, synchronous, symmetrical discharge (such as is described in the seizure classification of the corresponding type). The patient usually has a normal interictal state, without neurologic or neuroradiologic signs. In general, interictal EEGs show normal background activity and generalized discharges, such as spikes, polyspike, spike wave, and polyspike waves ≥3 Hz. The discharges are increased by slow sleep. The various syndromes of idiopathic generalized epilepsies differ mainly in age of onset.

Benign Neonatal Familial Convulsions

Benign neonatal familial convulsions are rare, dominantly inherited disorders manifesting mostly on the 2nd and 3rd days of life, with clonic or apneic seizures and no specific EEG criteria. History and investigations reveal no etiologic factors. About 14% of these patients later develop epilepsy.

Benign Neonatal Convulsions

Benign neonatal convulsions are very frequently repeated clonic or apneic seizures occurring at about the 5th day of life, without known etiology or concomitant metabolic disturbance. Interictal EEG often shows alternating sharp theta waves. There is no recurrence of seizures, and the psychomotor development is not affected.

Benign Myoclonic Epilepsy in Infancy

Benign myoclonic epilepsy in infancy is characterized by brief bursts of generalized myoclonus that occur during the first or second year of life in otherwise normal children who often have a family

history of convulsions or epilepsy. EEG recording shows generalized spike waves occurring in brief bursts during the early stages of sleep. These attacks are easily controlled by appropriate treatment. They are not accompanied by any other type of seizure, although GTCS may occur during adolescence. The epilepsy may be accompanied by a relative delay of intellectual development and minor personality disorders.

Childhood Absence Epilepsy (Pyknolepsy)

Pyknolepsy occurs in children of school age (peak manifestation, ages 6 to 7 years), with a strong genetic predisposition in otherwise normal children. It appears more frequently in girls than in boys. It is characterized by very frequent (several to many per day) absences. The EEG reveals bilateral, synchronous symmetrical spike waves, usually 3 Hz, on a normal background activity. During adolescence, GTCS often develop. Otherwise, absences may remit or, more rarely, persist as the only seizure type.

Juvenile Absence Epilepsy

The absences of juvenile absence epilepsy are the same as in pyknolepsy, but absences with retropulsive movements are less common. Manifestation occurs around puberty. Seizure frequency is lower than in pyknolepsy, with absences occurring less frequently than every day, mostly sporadically. Association with GTCS is frequent, and GTCS precede the absence manifestations more often than in childhood absence epilepsy, often occurring on awakening. Not infrequently, the patients also have myoclonic seizures. Sex distribution is equal. The spike waves are often >3 Hz. Response to therapy is excellent.

Juvenile Myoclonic Epilepsy (Impulsive Petit Mal)

Impulsive petit mal appears around puberty and is characterized by seizures with bilateral, single, or repetitive, arrhythmic, irregular myoclonic jerks, predominantly in the arms. Jerks may cause some patients to fall suddenly. No disturbance of consciousness is noticeable. The disorder may be inherited, and sex distribution is equal. Often, there are GTCS and, less often, infrequent absences. The seizures usually occur shortly after awakening and are often precipitated by sleep deprivation. Interictal and ictal EEG have rapid, generalized, often irregular spike waves and polyspike waves; there is no close phase correlation between EEG spikes and jerks. Frequently, the patients are photosensitive. Response to appropriate drugs is good.

Epilepsy with GTCS on Awakening

Epilepsy with GTCS on awakening is a syndrome with onset occurring mostly in the second decade of life. The GTCS occur exclusively or predominantly (>90% of the time) shortly after awakening regardless of the time of day or in a second seizure peak in the evening period of relaxation. If other seizures occur, they are mostly absence or myoclonic, as in juvenile myoclonic epilepsy. Seizures may be precipitated by sleep deprivation and other external factors. Genetic predisposition is relatively frequent. The EEG shows one of the patterns of idiopathic generalized epilepsy. There is a significant correlation with photosensitivity.

Generalized Cryptogenic or Symptomatic Epilepsies (Age Related)

West Syndrome (Infantile Spasms, Blitz–Nick–Salaam–Krämpfe)

Usually, West syndrome consists of a characteristic triad: infantile spasms, arrest of psychomotor development, and hypsarrhythmia, although one element may be missing. Spasms may be flexor, extensor, lightning, or nods, but most commonly they are mixed. Onset peaks between the ages of 4 and 7 months and always occurs before the age of 1 year. Boys are more commonly affected. The prognosis is generally poor. West syndrome may be separated into two groups. The symptomatic group is characterized by previous existence of brain damage signs (psychomotor retardation, neurologic signs, radiologic signs, or other types of seizures) or by a known etiology. The smaller, cryptogenic group is characterized by a lack of previous signs of brain damage and of known etiology. The prognosis appears to be partly based on early therapy with adrenocorticotropic hormone (ACTH) or oral steroids.

Lennox–Gastaut Syndrome

Lennox–Gastaut syndrome manifests itself in children ages 1 to 8 years, but appears mainly in preschool-aged children. The most common seizure types are tonic axial, atonic, and absence seizures, but other types such as myoclonic, GTCS, or partial are frequently associated with this syndrome. Seizure frequency is high, and status epilepticus is frequent (stuporous states with myoclonias, tonic, and atonic seizures). The EEG usually has abnormal background activity, slow spike waves <3 Hz, and, often, multifocal abnormalities. During sleep, bursts of fast rhythms (approximately 10 Hz) appear. In general, there is mental retardation. Seizures are difficult to control, and the development is mostly unfavorable. In 60% of cases, the syndrome occurs in children suffering from a previous encephalopathy but is primary in other cases.

Epilepsy with Myoclonic Astatic Seizures

Manifestations of myoclonic astatic seizures begin between the ages of 7 months and 6 years (mostly between the ages of 2 and 5 years), with (except if seizures begin in the first year) twice as many boys affected. There is frequently hereditary predisposition and usually a normal developmental background. The seizures are myoclonic, astatic, myoclonic astatic, absence with clonic and tonic components, and tonic–clonic. Status frequently occurs. Tonic seizures develop late in the course of unfavorable cases. The EEG, initially often normal except for 4- to 7-Hz rhythms, may have irregular fast spike wave or polyspike wave. Course and outcome are variable.

Epilepsy with Myoclonic Absences

The syndrome of epilepsy with myoclonic absences is clinically characterized by absences accompanied by severe bilateral rhythmical clonic jerks, often associated with a tonic contraction. On the EEG, these clinical features are always accompanied by bilateral, synchronous, and symmetrical discharge of rhythmical spike waves at 3 Hz, similar to childhood absence. Seizures occur many times a day. Awareness of the jerks may be maintained. Associated seizures are rare. Age of onset is approximately 7 years, and there is a male preponderance. Prognosis is less favorable than in pyknolepsy owing to resistance to therapy of the seizures, mental deterioration, and possible

evolution to other types of epilepsy such as Lennox–Gastaut syndrome.

Symptomatic Generalized Epilepsies and Syndromes

Symptomatic generalized epilepsies, most often occurring in infancy and childhood, are characterized by generalized seizures with clinical and EEG features different from those of idiopathic generalized epilepsies. There may be only one type, but more often there are several types, including myoclonic jerks, tonic seizures, atonic seizures, and atypical absences. EEG expression is bilateral but less rhythmical than in idiopathic generalized epilepsies and is more or less asymmetrical. Interictal EEG abnormalities differ from idiopathic generalized epilepsies, appearing as suppression bursts, hypsarrhythmia, slow spike waves, or generalized fast rhythms. Focal abnormalities may be associated with any of the above. There are clinical, neuropsychological, and neuroradiologic signs of a usually diffuse, specific, or nonspecific encephalopathy.

Generalized Symptomatic Epilepsies of Nonspecific Etiology (Age Related)

Early Myoclonic Encephalopathy

The principal features of early myoclonic encephalopathy are onset occurring before age 3 months, initially fragmentary myoclonus, and then erratic partial seizures, massive myoclonias, or tonic spasms. The EEG is characterized by suppression burst activity, which may evolve into hypsarrhythmia. The course is severe, psychomotor development is arrested, and death may occur in the first year. Familial cases are frequent and suggest the influence of one or several congenital metabolic errors, but there is no constant genetic pattern.

Early Infantile Epileptic Encephalopathy with Suppression Burst

This syndrome is defined by very early onset, within the first few months of life, frequent tonic spasms, and suppression burst EEG pattern in both waking and sleeping states. Partial seizures may occur. Myoclonic seizures are rare. Etiology and underlying pathology are obscure. The prognosis is serious with severe psychomotor retardation and seizure intractability; often, there is evolution to the West syndrome at age 4 to 6 months.

Epilepsies and Syndromes Undetermined as to Whether They Are Focal or Generalized

Neonatal Seizures

Neonatal seizures differ from those of older children and adults. The most frequent neonatal seizures are described as subtle because the clinical manifestations are frequently overlooked. These include tonic, horizontal deviation of the eyes with or without jerking, eyelid blinking or fluttering, sucking, smacking, or other buccal–lingual–oral movements, swimming or pedaling movements, and, occasionally, apneic spells. Other neonatal seizures occur as tonic extension of the limbs, mimicking

decerebrate or decorticate posturing. These occur particularly in premature infants. Multifocal clonic seizures characterized by clonic movements of a limb, which may migrate to other body parts or other limbs, or focal clonic seizures, which are much more localized, may occur. In the latter, the infant is usually not unconscious. Rarely, myoclonic seizures may occur, and the EEG pattern is frequently that of suppression burst activity. The tonic seizures have a poor prognosis, because they frequently accompany intraventricular hemorrhage. The myoclonic seizures also have a poor prognosis, because they are frequently a part of the early myoclonic encephalopathy syndrome.

Severe Myoclonic Epilepsy in Infancy

Severe myoclonic epilepsy in infancy is a recently defined syndrome. The characteristics include a family history of epilepsy or febrile convulsions, normal development before onset, seizures beginning during the first year of life in the form of generalized or unilateral febrile clonic seizures, secondary appearance of myoclonic jerks, and often partial seizures. EEGs show generalized spike waves and polyspike waves, early photosensitivity, and focal abnormalities. Psychomotor development is retarded from the 2nd year of life, and ataxia, pyramidal signs, and interictal myoclonus appear. This type of epilepsy is very resistant to all forms of treatment.

Epilepsy with Continuous Spike Waves During Slow-Wave Sleep

Epilepsy with continuous spike waves during slow-wave sleep results from the association of various seizure types, partial or generalized, occurring during sleep, and atypical absences when awake. Tonic seizures do not occur. The characteristic EEG pattern consists of continuous diffuse spike waves during slow-wave sleep, which is noted after onset of seizures. Duration varies from months to years. Despite the usually benign evolution of seizures, prognosis is guarded because of the appearance of neuropsychological disorders.

Acquired Epileptic Aphasia (Landau–Kleffner Syndrome)

The Landau–Kleffner syndrome is a childhood disorder in which an acquired aphasia, multifocal spike, and spike-and-wave discharges are associated. Epileptic seizures and behavioral and psychomotor disturbances occur in two-thirds of the patients. There is verbal auditory agnosia and rapid reduction of spontaneous speech. The seizures, usually GTCS or partial motor, are rare and remit before the age of 15 years, as do the EEG abnormalities.

Special Syndromes

Febrile Convulsions

Febrile convulsions are an age-related disorder almost always characterized by generalized seizures occurring during an acute febrile illness. Most febrile convulsions are brief and uncomplicated, but some may be more prolonged and followed by transient or permanent neurologic sequelae, such as the hemiplegia–hemiatrophy–epilepsy (HHE) syndrome. Febrile convulsions tend to recur in about one-third of affected patients. Controversy about the risks of developing epilepsy later has largely been resolved by some recent large studies; the overall risk is probably not more than 4%. The indications for prolonged drug prophylaxis against recurrence of febrile convulsions are now more

clearly defined, and most individuals do not require prophylaxis. Essentially, this condition is a relatively benign disorder of early childhood.

PART III: SYMPTOMATIC GENERALIZED EPILEPSIES OF SPECIFIC ETIOLOGIES

Only diseases in which epileptic seizures are the presenting or a prominent feature are classified. These diseases often have epileptic pictures that resemble symptomatic generalized epilepsies without specific etiology, appearing at similar ages.

Malformations

Aicardi syndrome occurs in females and is noted for retinal lacunae and absence of the corpus callosum; infantile spasms with early onset; and often asymmetric, diffuse EEG abnormalities generally asynchronous with suppression burst and/or atypical hypsarrhythmia.

Lissencephaly–pachygyria is characterized by facial abnormalities and specific CT scan features, axial hypotonia, and infantile spasms. The EEG shows fast activity of high-voltage "alpha-like" patterns without change during wakefulness and sleep.

The individual phacomatoses have no typical electroclinical pattern. We emphasize that West syndrome is frequent in tuberous sclerosis and that generalized and partial seizures may follow the otherwise typical course of infantile spasms. Sturge–Weber syndrome is a frequent cause of simple partial seizures followed by hemiparesis.

Hypothalamic hamartomas may present with gelastic seizures, precocious puberty, and retardation.

Proven or Suspected Inborn Errors of Metabolism

Neonate

Metabolism errors in the neonate include nonketotic hyperglycinemia and D-glyceric acidemia, showing early myoclonic encephalopathy with erratic myoclonus, partial seizures, and suppression burst EEG patterns.

Infant

The classical phenylketonuria can express itself as a West syndrome. A variant of phenylketonuria with biopterin deficiency causes seizures starting in the second 6 months of life in infants who have been hypotonic since birth. The seizures are generalized motor seizures associated with erratic myoclonic jerks and oculogyric seizures.

Tay–Sachs and Sandhoff disease present with acoustic startle or myoclonus in the first months of life, without EEG manifestations. In the 2nd year, myoclonic jerks and erratic partial seizures occur, along with marked slowing of the background rhythms.

Another type of metabolic error is early infantile type of ceroid lipofuscinosis (Santavuori–Haltia–Hagberg disease). Massive myoclonus begins between the ages of 5 and 18 months, with a highly suggestive EEG pattern of vanishing EEG.

Pyridoxine dependency is manifested by seizures that have no suggestive characteristics, but this condition must always be suspected since therapeutic intervention is possible.

Child

Late infantile ceroid lipofuscinosis (Jansky–Bielschowsky disease) is characterized by onset between the ages of 2 and 4 years of massive myoclonic jerks, atonic, or astatic seizures. The EEG shows slow background rhythms, multifocal spikes, and a characteristic response to intermittent photic stimulation at a slow rate.

An infantile type of Huntington disease appears after age 3 years, with a slowing of mental development, followed by dystonia, GTCS, atypical absence seizures, and myoclonic seizures. The EEG shows discharges of generalized spike waves and polyspike waves, with the usual photic stimulation rate.

Child and Adolescent

A juvenile form of Gaucher disease is marked by onset at approximately 6 to 8 years of age, with epileptic seizures of various types, most commonly GTCS or partial motor. The EEG shows progressive deterioration of background activity, abnormal photic response, diffuse paroxysmal abnormalities, and multifocal abnormalities with a clear posterior predominance.

The juvenile form of ceroid lipofuscinosis (Spielmeyer–Vogt–Sjögren disease) is characterized by onset between the ages of 6 and 8 years, a decrease in visual acuity, slowing of psychomotor development, and appearance of cerebellar and extrapyramidal signs. After 1 to 4 years, GTCS and fragmentary, segmental, and massive myoclonus occur. The EEG shows bursts of slow waves and slow spikes and waves.

Onset of Lafora disease occurs between the ages of 6 and 19 years (mean 11.5 years) and is characterized by generalized clonic and GTCS, with a frequent association of partial seizures with visual symptomatology, constant myoclonic jerks (fragmentary, segmental, and massive myoclonus), and rapidly progressive mental deterioration. The EEG shows discharges of fast spike waves and polyspike waves, photosensitivity, deterioration of background activity, and the appearance of multifocal abnormalities, particularly posteriorly. On the average, death occurs 5.5 years after onset.

The so-called degenerative progressive myoclonic epilepsy (Lundborg type) also falls into this category. The only significant well-individualized group is the Finnish type, described by Koskiniemi et al. Onset occurs between the ages of 8 and 13 years, with myoclonus (segmental, fragmentary, and massive) and GTCS, associated cerebellar ataxia, and slowly progressive although generally mild mental deterioration. The EEG shows slow abnormalities (theta rhythms and later, delta rhythms), with generalized spike waves predominantly in the frontal area and photosensitivity. Patients survive ≥15 years.

Dyssynergia cerebellaris myoclonica (DCM) with epilepsy (Ramsay Hunt syndrome) appears between the ages of 6 and 20 years (mean 11 years) with myoclonias or GTCS. Above all, the myoclonic syndrome is characterized by action and intention myoclonus. The GTCS are rare and sensitive to therapy. Mental deterioration, when present, is slow. Most of the neurologic manifestations are limited to cerebellar signs. In the EEG, the background activity remains normal, with generalized paroxysmal abnormalities (spikes, spike waves, and polyspike waves) and photosensitivity. During REM sleep, rapid polyspikes appear, localized in the central and vertex regions.

The clinical picture for the cherry-red spot myoclonus syndrome (sialidosis with isolated deficit in neuraminidase) is very similar to that of the Ramsay Hunt syndrome, with myoclonus, photosensitivity, and cerebellar syndrome. Other characteristics include the nearly constant existence

of amblyopia and presence of a cherry-red spot on funduscopic examination. The EEG is similar to that of DCM with the following specific features: the polyspike-wave discharges always correspond to a massive myoclonus, and there is no photosensitivity.

A Ramsay Hunt–like syndrome can also be associated with a mitochondrial myopathy, with abnormalities of lactate and pyruvate metabolism (7).

Adult

Kufs disease (adult ceroid lipofuscinosis) is a relatively slow, progressive storage disease with frequent generalized seizures that may be very intractable. Unlike juvenile storage disease, the optic fundi may be normal. The main characteristic is an extreme photic sensitivity on slow photic stimulation.

A large number of epilepsy-related diseases in childhood, adulthood, and old age are not enumerated here because the seizures are not distinctively different from other seizure types and are not critical for diagnosis.

PART IV

Precipitated seizures are those in which environmental or internal factors consistently precede the attacks and are differentiated from spontaneous epileptic attacks in which precipitating factors cannot be identified. Certain nonspecific factors (e.g., sleeplessness, alcohol or drug withdrawal, or hyperventilation) are common precipitators and are not specific modes of seizure precipitation. In certain epileptic syndromes, the seizures clearly may be somewhat more susceptible to nonspecific factors, but this is only occasionally useful in classifying epileptic syndromes. An epilepsy characterized by specific modes of seizure precipitation, however, is one in which a consistent relationship can be recognized between the occurrence of one or more definable nonictal events and subsequent occurrence of a specific stereotyped seizure. Some epilepsies have seizures precipitated by specific sensation or perception (the reflex epilepsies) in which seizures occur in response to discrete or specific stimuli. These stimuli are usually limited in individual patients to a single specific stimulus or a limited number of closely related stimuli. Although the epilepsies that result are usually generalized and of idiopathic nature, certain partial seizures may also occur following acquired lesions, usually involving tactile or proprioceptive stimuli.

Epileptic seizures may also be precipitated by sudden arousal (startle epilepsy); the stimulus is unexpected in nature. The seizures are usually generalized tonic but may be partial and are usually symptomatic.

Seizures precipitated by integration of higher cerebral function such as memory or pattern recognition are most often associated with complex partial epilepsies but are occasionally observed in generalized epilepsies (such as reading epilepsy). Seizures also occur spontaneously in most such patients.

Primary Reading Epilepsy

All or almost all seizures in this syndrome are precipitated by reading (especially aloud) and are independent of the content of the text. They are simple partial motor-involving masticatory muscles, or visual, and if the stimulus is not interrupted, GTCS may occur. The syndrome may be inherited. Onset is typically in late puberty, and the course is benign with little tendency to spontaneous seizures. Physical examination and imaging studies are normal, but EEG shows spikes or spike waves in the dominant parietotemporal region. Generalized spike and wave may also occur.

CHAPTER 10 EPILEPTIC AURAS

NORMAN K. SO

The word "aura" (from Greek for air, Latin for breeze) was first applied to epilepsy by Galen's teacher, Pelops (1), who interpreted reports of altered sensations ascending to the head from an extremity as support for a humoral mechanism in which a vapor passed up the blood vessels and, therefore, a peripheral origin of epileptic seizures.

The aura, of course, is a seizure, not the cause, as Erastus pointed out around 1580. Jackson's systematic study of auras ushered in a new era when he correlated the sensations with functional localization in the brain (2). The 1981 International Classification of Epileptic Seizures (3) defined the aura as "that portion of the seizure which occurs before consciousness is lost and for which memory is retained afterwards." Furthermore, an aura in isolation constitutes a sensory seizure (4). Conventional usage limits the aura to the initial sensations of a seizure that the patient is aware of in the absence of observable signs. This definition specifically separates an aura from other focal seizures and is the definition used in this chapter. For example, with autonomic phenomena, when cold shivering is experienced at seizure onset, the sensation of shivering would be an aura; but if accompanied by observable signs like piloerection, the observable sign would exclude classifying this focal seizure as an aura.

The aura usually only lasts seconds to minutes. On occasion, auras can be longer lasting, continuous, or recurrent with short interval breaks. Intracranial electroencephalographic (EEG) studies have shown that prolonged auras (aura continua) can represent continuous or recurrent seizures, a form of focal status epilepticus (5).

Auras should be separated from prodromal symptoms that can last for hours or days before a seizure. The symptoms are typically different, comprising symptoms such as nervousness, anxiety, dizziness, and headache, which do not have the same potential localizing significance as auras. Sometimes, the patient may not be conscious of anything untoward, but family members or friends may describe irritability or other personality change. Such prodromes resemble those recounted by some patients before a migraine attack. Gowers' speculation (1) that the prodrome is "indicative of slight disturbance of the nerve centers" has not been improved on.

Some patients with generalized epilepsy experience stereotyped sensations before or during a generalized seizure. Like an aura, these premonitory symptoms can be varied but usually lack the character that suggests activation of a circumscribed area of the cortex. Sensations include dizziness, warmth, cold, generalized tingling, anxiety, and a "spaced-out" or confused feeling. Some of the sensations likely correspond to a buildup of absence (dizziness, light-headedness, and confusion) or myoclonic seizures (anxiety, restlessness, jumpiness, and jerking) before loss of consciousness or convulsive activity. However, elementary visual hallucinations and abdominal sensations indistinguishable from those in focal epilepsy have been reported preceding seizures in several genetic (idiopathic) generalized epilepsies (6,7).

An early onset of epilepsy, lower intelligence quotient, male gender, and right temporal lobe focus have been associated with a higher incidence of "simple primitive" auras, whereas complex

"intellectual" auras with illusions or hallucinations accompanied male gender and a verbal intelligence quotient of >100 (8). Aura content may relate to the patient's individual psychological makeup. Stimulation of various mesial limbic structures elicited auras with features that were intimately related to ongoing psychopathologic processes (9). Emotional responses and hallucinations produced by electrical stimulation were reported to depend on the background affective state (10). Patients who experienced anxiety or fear during temporal lobe electrical stimulation scored higher on the "psychasthenia" scale of the Minnesota Multiphasic Personality Inventory, whereas those experiencing dreamlike or memory-like hallucinations scored higher on the "schizophrenia" scale (11).

PRESENCE AND ABSENCE OF AURAS

The incidence of auras in large populations is imprecise. In the 32-year epidemiologic study from Rochester, Minnesota (12), epilepsy with focal sensory seizures was seen in 3.7% of all patients. A further 26.4% were classified to have temporal lobe epilepsy, but the incidence of aura in this group was not separately reported. In the two large series of clinic- and office-based epileptic patients studied by Gowers (1) and by Lennox and Cobb (13) (Table 10.1), an aura was present in 56% of patients. Although notable discrepancies exist between the two series in relative frequencies of unilateral somatosensory auras, bilateral general sensations, and visual auras, other categories are remarkably consistent. Differences are most likely explained on the basis of definitions of aura type. The incidence of auras ranged from 46% to 77% in patients who either underwent presurgical evaluation by long-term monitoring with scalp or intracranial EEG electrodes (14–16) or had temporal lobe surgery (17).

Table 10.1 Incidence of Aura in Two Series of Clinic- and Office-Based Epileptic Patients

Aura	Gowers (1) %[a] (n = 2013)	Lennox and Cobb (13) % (n = 1359)
Present	1145 (57%)	764 (56%)
Somatosensory[b]	18.0	8.5
Bilateral sensations	4.5	38.0
Visceral/epigastric	18.0	14.5
Vertiginous	19.0	12.0
Cephalic	8.0	5.5
Psychic	8.0	11.0
Visual[c]	16.0	6.5
Auditory	6.0	2.0
Olfactory	1.0	1.0
Gustatory	1.5	0.1

[a]Percentages apply to patients with aura.
[b]Includes motor phenomena at onset.
[c]Includes illusions and hallucinations.
From Gowers WR. *Epilepsy and Other Chronic Convulsive Diseases: Their Causes, Symptoms & Treatment*. 2nd ed. London, UK: J & A Churchill; 1901; Lennox WG, Cobb S. Aura in epilepsy: a statistical review of 1,359 cases. *Arch Neurol Psychiatry*. 1933;30:374–387.

Lennox and Cobb (13) reported that a long disease duration correlated with an increase in the incidence of auras and wrote that "It is more accurate to speak of the recollection of aura(s) rather than of their presence." Young children may lack the verbal capacity to describe the sensations that herald a seizure, even though their actions indicate some awareness of the impending event. Similarly, adults who deny any warning, nevertheless, may press the seizure alarm button during video–EEG monitoring but have no recollection of having done so. Some patients without auras might have had them earlier in the illness. Anecdotal experience suggests that auras may disappear as the disease progresses. The seizure either induces an amnesia so immediate that there is no memory of a warning or causes retrograde amnesia. This is supported by a study that showed that amnesia for auras depended on the severity of the seizure (18). An isolated aura is nearly always recollected when there is a unilateral EEG ictal discharge. The aura is more likely to be forgotten if the seizure becomes secondarily generalized or involves a bilateral EEG ictal discharge.

Isolated auras can persist after epilepsy surgery despite the complete cessation of complex partial (focal seizures with dyscognitive features) or secondarily generalized seizures. Isolated postoperative auras occurred in 15% to 35% (19–21) of patients after surgery for temporal lobe epilepsy and in 22% of a series after focal resective surgery unselected for location (22). Persistent auras after temporal lobe surgery may relate to incomplete removal of epileptogenic tissue in residual temporal lobe structures or neighboring areas of the operculum and insula. When epigastric auras persist after functional hemispherectomy, the insula is again implicated as it is the only cortical structure still connected on the side of surgery. Although isolated postoperative auras are often regarded as of little significance, and classified among the "seizure-free" outcomes, they may portend a reduced chance of complete seizure control (23) even if published studies do not all agree on this point, and a reduced quality of life on self-assessment (22). A small number of patients may lose their aura after temporal lobectomy even as they continue to have postoperative seizures leaving them with no warning; yet others may experience a different aura (19).

CLINICAL LOCALIZATION

An aura provides evidence of focal seizure onset and can help to localize the epileptogenic zone, provided the symptoms share a certain stereotypy and consistency even if they may vary from time to time in the same patient. Caution though is advised when interpreting the report of preceding sensation in the evaluation of a first seizure owing to the limited reliability of a single observation (24).

Patients with psychogenic nonepileptic seizures (PNES) can report a range of sensations, sometimes difficult to distinguish from that of an epileptic aura with alterations in smell, taste, vision, or tingling; but more often, the symptoms are long lasting and nonspecific, with headache, pain, and confusion prominent. Rarely, a PNES starts with an epileptic aura (25) in a patient whose epileptic seizures are well controlled. The PNES that follows an epileptic aura can be interpreted to represent a learned response or an example of psychogenic elaboration.

Current concepts on the localizing value of auras rely heavily on the pioneering studies of Penfield and Jasper (26) who correlated sensations and signs obtained through electrical stimulation of the awake patient with those of the patient's spontaneous seizures. Subsequent studies with long-term intracranial electrodes for the recording of spontaneous seizures and extraoperative electrical brain stimulation have extended early observations (27–29).

Although an aura may help to localize the epileptogenic zone, an important point must be kept in

mind. The initial sensation of an aura is related to the first functional brain area affected by the seizure that has access to consciousness, but this may not be the site of seizure origin. A seizure starting in the posterior parietal region may be initially asymptomatic until ictal activity spreads to adjacent functional areas. Spread to the postcentral gyrus may elicit a somatosensory sensation as the first warning; propagation to parietooccipital association cortex may give rise to initial visual illusions or hallucinations. Furthermore, it remains unclear whether experience of an aura is contingent on direct ictal activation of the cortical areas subserving those functions or whether an aura sensation may also be evoked by remote excitation or decoupling of inputs within a larger functional network. A sensory jacksonian march cannot be explained by other than ictal spread along the somatosensory cortex. The sometimes indistinguishable auras found in patients with hippocampal sclerosis and temporal neocortical pathology support the role of a distributed network that functionally links the limbic and neocortical structures in the temporal lobe. Cortical stimulation in extratemporal epilepsy also showed that sites at which an aura is reproduced can extend well beyond the expected functional map for those sensations (29).

The localizing value of auras has been studied in a number of ways. Penfield and Kristiansen (30) recorded the initial seizure phenomenon in 222 patients with focal epilepsy and commented on the likely localization of different auras. Auras reported in patients with well-defined epileptogenic foci in different brain regions can be compared from different series (Table 10.2) or, better yet, prospectively (35) (Table 10.3). Data from patients (31,32) who become seizure free after localized brain resections are particularly important. Making comparisons from different series in the literature is hampered by several problems: Terminology of aura type is not uniform, auras can be grouped together in dissimilar ways, and classification rules are unclear when multiple sensations occur in the same aura. In spite of the different approaches, retrospective and prospective series yielded a similar conclusion: Auras have localizing significance. Patients with temporal lobe epilepsy have the highest incidence of epigastric, emotional, and psychic auras (31,35,36). Frontal lobe epilepsy is distinguished by frequent reports of no aura (32,35). When an aura is present in frontal lobe epilepsy, cephalic, somatosensory, and general body sensations predominate. Perirolandic epilepsy with centroparietal foci and parietal lobe epilepsy are most likely to experience somatosensory aura (33,37). Not surprisingly, occipital lobe epilepsy has the highest incidence of visual aura (34,38). No single aura sensation is necessarily restricted to a single lobe, however.

Adapted from Palmini A, Gloor P. The localizing value of auras in partial seizures: a prospective and retrospective study. *Neurology*. 1992;42:801–808.

While most auras cannot lateralize the side of seizure onset, there are exceptions. Unilateral somatosensory aura in an extremity and lateralized visual aura are contralateral to the side of seizure onset. A lateralized auditory aura (sound in one ear) may also refer to the contralateral hemisphere. Pilomotor seizures, if unilateral, however, point to the ipsilateral hemisphere. Ictal headaches, if lateralized, are likewise ipsilateral to the site of seizure onset.

FUNCTIONAL CORRELATIONS

The EEG signature of auras depends on the recording technique. An isolated aura is a focal seizure of restricted extent and may not be apparent in scalp EEGs. In a study of temporal lobe epilepsy (39) studied by a combination of surface and depth electrodes, only 19% of auras confirmed by depth recordings had a surface ictal EEG correlate. In the same study, 10% of depth electrode recorded subclinical EEG seizures, and 86% of clinical seizures were accompanied by surface changes. An EEG that incorporates sphenoidal electrodes may have a better chance (28%) of detecting an

electrographic change during auras in patients with temporal lobe epilepsy (15). The surface EEG ictal pattern is often subtle as compared with that of a complex partial seizure and may appear as low-frequency rhythmic sharp waves, sudden attenuation of the ongoing background, or abrupt cessation of ongoing interictal spikes sometimes followed by rhythmic slow waves.

Depth electrodes targeted directly at mesial limbic structures (where the majority of temporal lobe seizures originate) have been more successful in demonstrating EEG ictal activity in temporal lobe auras than were simultaneous recordings from subdural electrodes over the lateral temporal convexity (40,41). Nevertheless, even in patients with clinical seizure onset in one temporal lobe localized by depth electrodes, only about half of isolated auras showed an ictal EEG correlate (16,42). In the same patient, some auras may be associated with ictal EEG changes, whereas others show no change (43). This suggests that seizures may arise dynamically from different discrete areas within a larger epileptic zone. In neurophysiologic terms, these observations support the belief that only a very small portion of the brain is activated to produce aura sensations. On the basis of firing patterns of limbic neurons recorded by microelectrode techniques in patients with temporal lobe epilepsy, only 14% of neurons at the epileptogenic zone are estimated to increase their firing rate in an aura. The corresponding estimate for a subclinical seizure is 7% and for a clinical complex partial seizure 36% (43). In agreement, an ictal–interictal subtraction single photon emission computed tomography study of isolated auras showed no clear dominant or reproducible areas of hyperperfusion in most cases (44).

Although an aura reflects activation of functional cortex by a circumscribed seizure discharge, the seizure discharge frequently spreads. A seizure that spreads along a single functional area as the postcentral gyrus produces the sensory equivalent of a jacksonian march. An aura can also spread across different functional regions. A seizure that starts in the primary visual area of the occipital lobe and spreads to the temporal limbic structures may present with initial transient blindness followed by other sensations referable to the temporal lobe.

Multiple sensations can occur even when seizure activity is relatively confined to one region, as at the start of temporal lobe seizures. Anxiety, epigastric, and “indescribable” sensations commonly precede the more complex phenomena of déjà vu and other illusions of vision or sound (45). When multiple auras can be dissected out along a sequence, they likely correlate with propagation of the ictal discharge within the temporal lobe, as recorded in a subdural EEG study (46). In other cases, a time series cannot be discerned, and the multiple sensations seem to occur simultaneously or vary in order from one seizure to another in the same patient. An alternative explanation for multiple auras could be that they are secondary to activation of a distributed network of several functional areas (47). The temporal limbic system, with extensive connections to the septum, hypothalamus, temporal neocortex, insula, and parieto-occipital association cortex, is precisely such a system. In support of this hypothesis, electrical stimulation of temporal limbic structures by depth electrodes can produce different sets of sensations at different times, despite stimulation of the same contacts (11).

SOMATOSENSORY AURAS

Tingling, numbness, and an electrical feeling are common, whereas absence of sensation or a sensation of movement is less. A sensation that starts focally in an extremity or shows a sensory march, such as an ascent from the hand up the arm to the face, points to a seizure discharge in the primary somatosensory area of the contralateral postcentral gyrus (26). A clinically identical seizure may have started more posteriorly in “silent” parietal cortex and caused symptoms only after it

spread to the postcentral gyrus. A primary somatosensory aura can be interrupted by clonic jerking of the affected part and reflects spread from the postcentral to the precentral gyrus. A seizure starting in the primary motor area of the precentral gyrus can also cause a somatosensory aura, rapidly accompanied by clonic motor phenomena. Indeed, the precentral gyrus accounted for 25% of the sites producing a somatic sensation during intraoperative stimulation of the rolandic cortex (26).

Somatic sensations with a wide segmental (whole limb or side of body) or bilateral distribution indicate seizure activity outside the primary somatosensory area. Seizures arising from or involving the second sensory area, situated in the superior bank of the sylvian fissure and parietal operculum (26,48), evoke somatic sensations of the contralateral or ipsilateral sides of the body or both. The sensation can be rudimentary, but second sensory auras include pain, coldness, and a desire for movement (26).

Seizures arising from the supplementary motor area were preceded by an aura in nearly half the patients in one study (49). Penfield and Jasper (26) elicited somatic sensations from the supplementary sensory area, a part of the mesial cortex in the interhemispheric fissure, posterior to the supplementary motor area. Extraoperative stimulation using chronically implanted subdural electrodes not only confirmed the existence of supplementary sensory areas but also showed that they intermingle and overlap with the supplementary motor area, so that the two regions can best be regarded as a single functional entity (50,51). Auras from the supplementary motor and sensory areas include nonspecific tingling, desire for or sensation of movement, and feelings of stiffness, pulling, pulsation, and heaviness. These sensations usually involve extensive areas of a contralateral extremity or side of the body or bilateral body parts. They may be perceived as a generalized body sensation as well. Penfield and Jasper (26) also elicited epigastric sensations on stimulation of the supplementary motor area.

Chronic recordings and stimulation studies of depth electrodes implanted into the posterior insular cortex revealed a fourth brain region that can give rise to contralateral somatosensory sensations (52,53). The sensations include those of tingling, electrical shock, heat, and sometimes pain. They can involve more localized or more extensive regions on the contralateral side of the body. Somatosensory auras occur in a small percentage of patients with temporal lobe epilepsy (17) (Table 10.2). Since the temporal lobe is devoid of representation for somatic sensation, these auras are thought to occur secondarily to propagation of the ictal discharge into the second sensory area, the insula, or postcentral gyrus.

As an aura, a general body sensation, including diffuse warm and cold thermal sensations, has little value in cortical localization, having been reported as seizure aura from all regions of the brain. Besides the supplementary motor area, the mesial temporal structures (54) have responded to stimulation with such diffuse sensations.

Ictal pain as aura can be classified according to the affected parts: cephalic, abdominal, and somatosensory. Ictal headache will be discussed with other cephalic auras and abdominal pain with epigastric aura. Painful body sensations may represent the initial aura or occur as a component of an aura or seizure. The pain may be sharp, burning, electric, cold, or cramp-like and may be focally to diffusely distributed. Pain as an isolated symptom is much less common than as an association of paresthesias and other somatic sensations (55,56). Some patients experience cramp-like pain with tonic muscle spasm of an affected part. Well-localized and unilateral ictal pain generally occurs contralateral to an epileptic focus in the postcentral gyrus or neighboring parietal lobe (55–59). Electrical stimulation of the postcentral gyrus can elicit contralateral pain (57,60). Resection of the parietal cortex with the epileptic focus has successfully abolished painful seizures (56,57). Other

areas reported to produce painful somesthetic auras are the second sensory area (26,61) and insular cortex (53). The localization of heat, cold, warmth, and flushing is variable or poorly understood. When these sensations are focal and unilateral, the same cortical regions described above are presumed responsible. When they are felt over wide segmental areas, on both sides of the body or in a generalized distribution, they lack reliable localizing or lateralizing value.

There are further somatic sensory alterations, which are distinctive with possible localizing value. Pharyngeal dysesthesias of tingling and burning or laryngeal discomfort to the point of a choking sensation are uncommon auras, sometimes reported in patients with seizures arising from the insula (53) or spreading from the temporal lobe to the insula. Aura sensations of body deformation, when a limb or part of the body is felt altered in size, twisted, or absent, suggest ictal alteration of sensory integration, a parietal lobe phenomenon (33).

VISUAL AURAS

Spots, stars, blobs, bars, or circles of light, monochromatic or variously colored, implicate seizure activity in the visual areas of the occipital lobes and occur in a majority of seizure arising there (26,34,38). These stationary or moving images may be lateralized to the visual field contralateral to the involved lobe but also may appear directly ahead. When they are lateralized and move across the field of vision, the patient's head may turn to follow them. Some patients describe darkness proceeding to blindness, which can also occur as a postictal phenomenon in those with visual auras. Such ictal blindness or amaurosis occurs in up to 30% of occipital seizures. An occipital seizure may propagate to the temporal lobe or the parietal cortex. In the former instance, a visual aura may be followed by psychic experiences, epigastric aura, or emotional feelings, whereas a somatosensory aura may follow in the latter case. Auras with formed visual hallucinations are discussed under psychic auras, as are visual illusions such as macropsia and micropsia.

AUDITORY AURAS

The auditory cortex lies in the transverse gyrus of Heschl in the superior bank of the superior temporal gyrus or temporal operculum. Electrical stimulation there and in the adjacent superior temporal gyrus produces simple sounds variously described as ringing, booming, buzzing, chirping, or machinelike (26). Similar elementary auditory phenomena are described with auditory auras. At other times, partial deafness may occur, with impairment of auditory comprehension if the language dominant hemisphere is involved. Auras with such characteristics suggest seizure activity in the superior temporal neocortex, Heschl gyrus, or temporal operculum (26,62) and are usually noted in patients with lateral neocortical temporal lobe epilepsy rather than mesial temporal lobe epilepsy. Auditory aura is a defining feature in patients with autosomal dominant partial epilepsy with auditory features associated with LGI1 gene mutation (63). If the sounds in an aura are lateralized to one ear, the focus is usually in the contralateral hemisphere. Because seizures can spread to other portions of the temporal lobe, auditory auras are frequently accompanied by other temporal lobe phenomena. Other auditory illusions and formed hallucinations are discussed later on in this chapter.

VERTIGINOUS AURAS

Stimulation of the posterior extent of the superior temporal gyrus can elicit feelings of displacement

or movement, including rotatory sensations (26). True vertiginous auras are probably uncommon but may be localized to the posterior part of the superior temporal neocortex (62) and experienced as one of several aura sensations that may arise together or in succession. True vertigo must be distinguished from nonspecific dizziness, which, on questioning, may resolve to cephalic sensations, light-headedness, or sense of impending loss of awareness, none of which has reliable localizing value. Early reports of patients with so-called vertiginous seizures probably included a large number with such nonspecific dizziness (64).

OLFACTORY AURAS

Jackson and Beevor (65) reported a "case of tumor of the right temporosphenoidal lobe bearing on the localization of the sense of smell and on the interpretation of a particular variety of epilepsy." The patient experienced a "very horrible smell which she could not describe." The term "uncinate fits" has been used to describe seizures with this aura because pathologic lesions are frequently found in the medial temporal lobe. The smell of an olfactory aura is often unpleasant or disagreeable (26,66) with odors akin to burning rubber, sulfur, or organic solvents. However, the smell can be neutral or even pleasant (67). The incidence of olfactory aura is low at about 1% (see Table 10.1). Whether patients with this symptom are disproportionately likely to have temporal lobe tumor is open to debate (66,68), as nonneoplastic lesions such as mesial temporal sclerosis can also be found responsible (67,69).

Other than the medial temporal lobe, the olfactory bulb is the only structure that can produce an olfactory sensation on electrical stimulation, and rarely, seizures starting in the orbitofrontal cortex can produce an olfactory aura (27). Olfactory aura rarely occurs in isolation; gustatory or other sensations referable to the temporal lobe frequently occur together or follow.

GUSTATORY AURAS

Usually disagreeable, the taste experienced may be described as sharp, bitter, acid, or sickly sweet. The incidence is low (see Table 10.1). Penfield and Jasper (26) ascribed the representation of taste deep in the sylvian fissure adjacent to and above the insular cortex. Hausser-Hauw and Bancaud (70) localized gustatory hallucinations to the parietal or rolandic operculum. They also recorded spontaneous and electrically induced seizures from the temporal limbic structures that were associated with gustatory phenomena but believed that the aura resulted from seizure propagation to the opercular region. Temporal lobectomies failed to abolish the gustatory hallucinations in three of their patients. The course of seizures with gustatory aura depends on the site of the epileptogenic zone. Suprasylvian seizures are likely to involve salivation, second sensory area sensations, and clonic facial contractions. Seizures of temporal origin may have epigastric aura in addition and develop automatisms.

EPIGASTRIC OR ABDOMINAL AURAS

Under this heading are various sensations localized to the abdomen or lower chest that may move to the throat and head but rarely descend in the opposite direction. "Visceral" and "viscerosensory" are other terms to describe this aura. Commonly characterized as a feeling of nausea, epigastric aura may also be reported as butterflies in the stomach, emptiness, queasiness as "going over a hill," tightness,

and churning; occasionally, it may be painful (58,71). This aura is frequently associated with or preceded or followed by other sensory, psychic, emotional, or autonomic phenomena (72). The sensation cannot be considered secondary to altered gastroesophageal function, as direct intraesophageal and intragastric pressure recording showed its occurrence with and without peristalsis (72,73). Although an abdominal aura is most common in temporal lobe epilepsy, it has been associated with epilepsies from all lobes of the brain (see Tables 10.2 and 10.3). Epigastric sensations can be elicited in epileptic and nonepileptic individuals by electrical stimulation of the amygdala, hippocampus, anteromedial temporal region, sylvian fissure, insula, supplementary motor area, pallidum, and centrum medianum of the thalamus (14,72).

CEPHALIC AURAS AND ICTAL HEADACHES

Cephalic aura includes a range of sensations felt in the head that includes dizziness, electrical shock, tingling, fullness, pressure, or other ill-defined sensations. It should not be confused with a somatosensory aura arising from the different cortical sensory areas. Moreover, electrical stimulation studies have provided no clear localization, and cephalic sensations have been reported as auras in focal seizures arising from all brain regions but may be more common in frontal lobe epilepsy (see Tables 10.2 and 10.3).

The relationship of headache to seizures is complex and is still the subject of considerable debate. Most common are postictal headaches, which can be diffuse or lateralized. Headaches can occur as an epileptic prodrome. Some patients with both migraine and epilepsy report that their seizures seem to be triggered by a headache. A headache of abrupt onset at the beginning of a seizure can be considered an aura or an ictal headache. An ictal headache can be pounding like a migraine but also sharp and steady. The pain may build gradually, but several patients studied with scalp or intracranial recording showed abrupt pain onset and offset synchronous with EEG seizure activity (74,75). Ictal headache is not well localized to any specific region and has been described also in generalized epilepsy. A lateralized headache is likely to be ipsilateral to the side of the epileptogenic focus (56,71,74,76). Many well-studied patients had temporal lobe epilepsy, possibly reflecting the increased likelihood of intensive presurgical EEG monitoring in this group. Patients with occipital lobe epilepsy represent the other major population with ictal headache, and when associated with a visual aura need to be differentiated from classic migraine. Ictal or postictal headache is often a striking symptom in benign epilepsy of childhood with occipital paroxysms (77) and in occipital seizures of patients with Lafora disease (78) and other progressive myoclonus epilepsies. It is possible that ictal headaches are not auras in the sense of a perception linked to localized neuronal activation, but the result of “an alteration in intracranial circulation either preceding the attack or coincidental with its onset” (26), akin to what occurs during migraine aura.

EMOTIONAL AURAS

Ictal fear describes pronounced anxiety or intense terror that is out of proportion to, and separable from, the understandable apprehension that can accompany any seizure. In some patients, the fear resembles a real-life experience, such as suddenly finding a stranger standing close behind, or is associated with an unpleasant psychic hallucination of past events. Others seemingly localize the sensation to the chest or stomach in association with an epigastric aura (79). Ictal fear may be accompanied by symptoms and signs of autonomic activation, such as mydriasis, tachycardia, and

hyperventilation, and behavioral manifestations of screaming, calling for help, and agitated movements. An aura of fear has been linked to temporal lobe epilepsy (80) and can be elicited on stimulation of the mesial temporal structures (28,81). An aura of fear can be difficult to separate from a panic attack when it occurs in isolation, and correct identification relies on the associated ictal clinical and EEG findings.

Elation and pleasure are infrequent auras. The preictal happiness and ecstasy reported by Dostoyevski are cited as an example. Electrical stimulation of the left amygdala appeared able to produce either pleasant or unpleasant emotions, while right amygdala stimulation induced mainly negative emotions of fear and sadness (82). But in general, pleasurable sensations are rarely elicited by electrical stimulation. Depression as an aura or ictal phenomenon is debatable. In the largest series, reported by Williams (79), many of the patients had depression that lasted for hours to days, making it likely that this state constituted a prodromal mood change rather than an aura.

PSYCHIC AURAS

In 1880, Hughlings Jackson (2) described "certain psychical states during the onset of epileptic seizures" that included "intellectual aurae…reminiscence…dreamy feelings…dreams mixing up with present thoughts…double consciousness…'as if I went back to all that occurred in my childhood'… These are all voluminous mental states and yet of different kinds." Both Gowers (1) and Penfield and Jasper (26) included emotional auras under the heading of psychic auras. Others used the term "experiential" phenomena for these events (28,81).

An illusion results from faulty interpretation of present experience in relation to the environment. Aware of the error in perception, the patient has "mental diplopia" in the jacksonian sense. A hallucination is a lifelike experience unrelated to present reality. Psychic hallucinations include dreamlike events or memory flashbacks that are complex and "formed," in contrast to the elementary "unformed" hallucinations that characterize excitation of the primary sensory areas. Nevertheless, epileptic patients invariably sense that the hallucinations are not real.

The nature of psychic auras is as varied as their complexity. Many attempts at classification have been made (Table 10.4), but it may be fruitless to adhere to an overly rigid categorization of these rich phenomena that offer glimpses into the workings of human consciousness. For example, déjà vu can be considered an illusion of familiar memory; the converse, when what should have been a familiar visual experience becomes unfamiliar, is called jamais vu. The corresponding auditory illusions are déjà entendu and jamais entendu. Despite reports that psychic auras can occur with focal seizures from elsewhere in the brain, the consensus ascribes them to epileptic activation of the temporal lobe. Penfield and Perot (83) found that the sites eliciting psychic phenomena during acute intraoperative stimulation were nearly all in the lateral temporal neocortex, particularly along its superior border, and only occasionally in basal or mesial temporal regions. In contrast, later studies (28,84,85) identified both mesial temporal limbic (amygdala, hippocampus, entorhinal cortex) and temporal neocortex structures as capable of producing psychic phenomena, even in the absence of an electrical afterdischarge. To reconcile these differences, Gloor (47) proposed a hypothesis based on the model of a neuronal network with reciprocal connections—in this case, between the limbic structures and the temporal neocortex. Psychic phenomena arising "from the activation of matrices in distributed neuronal networks" could presumably be elicited from different locations within the temporal lobe, including temporal isocortex and various limbic structures. Signal analysis during déjà vu upon stimulation of the entorhinal cortex in epileptic patients found increased EEG signal

correlations between medial temporal structures (86).

Table 10.4 Psychic Auras

	Illusion	Hallucination
Memory	Déjà vu, jamais vu, déjà entendu, jamais entendu, strangeness	Memory flashbacks, dreams of past
Vision	Macropsia, micropsia, objects nearer or farther, clearer or blurred	Objects, faces, scenes
Sound	Advancing or receding, louder or softer, clearer or fainter	Voices, music
Self-image	Mental diplopia, depersonalization, derealization, remoteness	Autoscopy
Time	Standstill, rushing, or slowing	—
Others	Increased awareness, decreased awareness	—

Forced thinking refers to an awareness of intrusive stereotyped thoughts, fixation on, or crowding of thoughts. Penfield and Jasper (26) separated it from psychic auras and localized it to the frontal lobe. Autoscopy, a hallucination of self-image, is seeing oneself as a "double," or as an external entity observed from a distance after the mind is felt to have left the body (87,88), and has been associated with localization of the ictal focus in the temporal lobe or right parietal lobe.

AUTONOMIC AURAS

There is no consensus on the range of phenomena to be included in this category. Epigastric sensations are considered an autonomic aura by some, although there is insufficient evidence for implication of autonomic afferent or efferent pathways. One of the commonest autonomic sensations is that of palpitations with an accompanying tachycardia. It is often associated with auras of fear, anxiety, or epigastric sensation. These are frequent symptoms in temporal lobe epilepsy. When palpitation occurs alone as aura and is the dominant symptom, it would be appropriate to classify it as an aura. However, tachycardia occurs not just with the aura, but even more frequently during the clinical seizure, and it would be redundant and misleading to call it an autonomic seizure.

Respiratory symptoms experienced as an aura include such sensations as not being able to breathe, a need to breathe more deeply, and of a breath filling the chest that would not expire. Alterations in respiratory rhythms have been reported on stimulation of temporal limbic structures and in seizures of insular origin (53).

Cold shivering and associated piloerection as auras can be experienced over diffuse or extended areas or localized and lateralized to one part of the body. This aura is probably not unique to a single cortical area, but seems most common in temporal lobe epilepsy (89–91). When unilateral, the side of piloerection is more likely ipsilateral to the side of the epileptic focus.

Urinary urgency has been reported both at seizure onset and afterward. It is uncommon as an aura and may be more common postictally. The localization of these sensations implicates the nondominant frontal lobe in the vicinity of the cingulate gyrus or the nondominant temporal lobe (92,93).

SEXUAL AURAS

These uncommon erotic feelings may or may not be accompanied by genital sensations or symptoms or signs of sexual arousal. They are distinguished from the sometimes unpleasant superficial genital sensations without sexual content that arise from stimulation of the primary somatosensory area at the parasagittal convexity or interhemispheric fissure and possibly the perisylvian region. Sexual auras seem to arise from the temporal lobe (94) with other cases reported from the parasagittal area implicating the sensory cortex. The cases reported thus far have shown a female preponderance. Of those patients whose sexual aura resulted in orgasm, a right hemisphere lateralization has been found in one review (95).

CONCLUSION

Epileptic auras are rich in symptomatology. As the earliest or only symptom of an epileptic discharge, it can convey information on possible sites of seizure onset. A familiarity of different aura symptoms and their anatomico-functional relationships will reward the clinician and neurophysiologist.

CHAPTER 11 FOCAL MOTOR SEIZURES

ANDREAS V. ALEXOPOULOS AND STEPHEN E. JONES

In memoriam: Dudley S. Dinner, MD (1947–2007)
"One who is the giver of knowledge is the giver of life."

HISTORY

Focal motor seizures have been recognized since the time of Hippocrates, who first observed seizures affecting the body contralateral to the side of head injury (1). Hughlings Jackson was the first to theorize that focal seizures are caused by "a sudden and excessive discharge of gray matter in some part of the brain" and that the clinical manifestations of the seizure depend on the "seat of the discharging lesion" (2,3).

During the second half of the 19th century, Fritsch and Hitzig (4) pioneered stimulation of the brain in animals. They discovered that electrical stimulation of the exposed cerebral cortex produced contralateral motor responses in dogs (5,6). Experimental faradic stimulation of the human cerebral cortex was first performed by Bartholow in 1874 (7). In 1909, Cushing (8) reported that faradic stimulation of the postcentral gyrus could be used to determine the anatomic relationship of the sensory strip to an adjacent tumor. Motor responses elicited by electrical stimulation in humans were first described by Krause in the beginning of the 20th century (9) and by Foerster more than 70 years ago (2). These early observations led to the fundamental work of Penfield and Brodley (10), who used electrical stimulation to elucidate the motor and sensory representation of the human cerebral cortex and pioneered the techniques for the functional localization of the sensorimotor cortex during surgery.

FUNCTIONAL ANATOMY OF THE MOTOR CORTEX

Strictly speaking, the motor cortex (Fig. 11.1) consists of three motor areas: the primary motor area (PMA or M1) in the precentral gyrus, which houses a complete representation of body movements; the supplementary sensorimotor area (SSMA or SMA) on the mesial surface rostral to the PMA, also containing a complete motor representation (hence the term supplementary); and a more loosely defined premotor cortex (PreMC) on the lateral convexity (11).

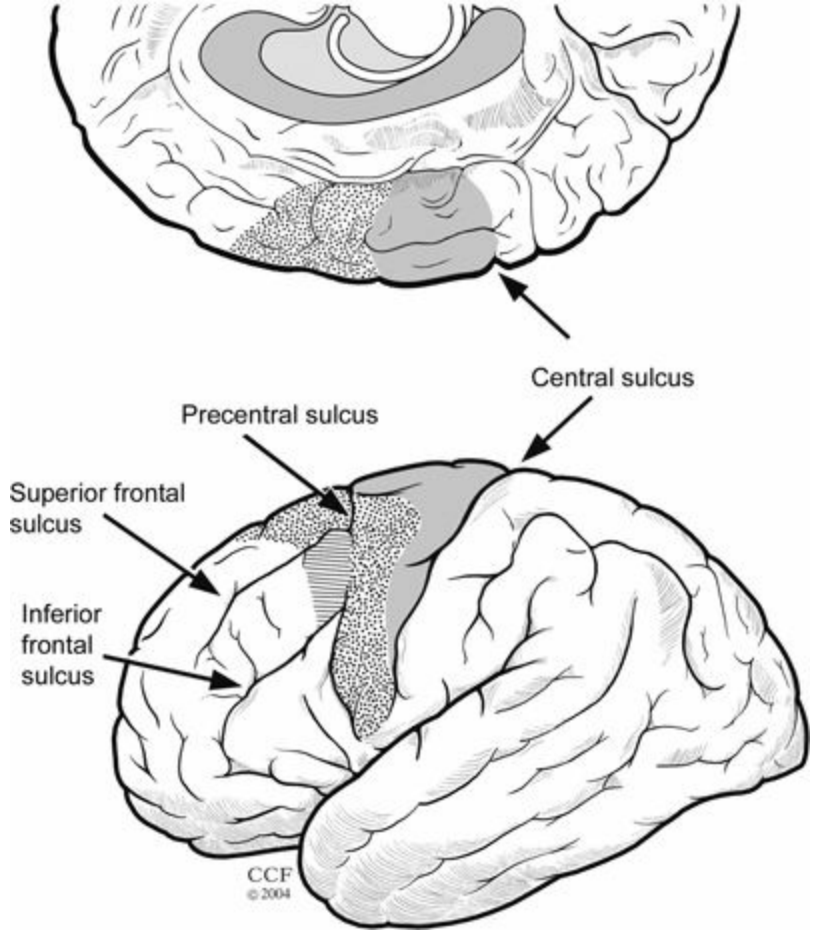

Figure 11.1. Mesial and lateral aspects of the left hemisphere: schematic representation of the three motor areas and their approximate relationship to the surface hemispheric anatomy. The shaded area corresponds to the primary motor cortex (Brodmann area 4). The stippled area illustrates the supplementary sensorimotor cortex on the mesial aspect. On the lateral view, the stippled area represents the premotor cortex. Also note the approximate location of the frontal eye field (hatched area).

The prefrontal and orbitofrontal cortices, as well as the dorsolateral and mesial frontal cortices anterior to the SSMA, are not considered part of the motor cortex. The term prefrontal cortex is used to define the extensive part of the frontal lobe that lies anterior to the motor and premotor zones (12). Modern anatomic and physiologic studies in humans and primates challenge the traditional division of motor areas (13). For example, part of the cingulate cortex, which was previously linked to the limbic system, is now considered as a fourth main motor area, the so-called cingulate motor area (14,15).

Activation studies using positron emission tomography (PET) or functional magnetic resonance imaging (fMRI) allude to the complex organization of the motor system. The breadth of cortical and subcortical areas activated with even the simplest movements attests to the wide distribution and extent of interconnected neural networks underlying motor control (14). Observed movements presuppose a series of parallel or sequential processes involving the selection, planning, preparation, and initiation of action (14,16).

Efferent and Afferent Connections

The familiar hierarchical model of motor control is based on the four levels of spinal cord, brainstem, PMA, and PreMC SSMA. This concept has influenced our understanding of the various motor manifestations of seizures (17). Motor commands are organized hierarchically from the most automatic (e.g., deep tendon reflexes) to the least (e.g., skilled and precise voluntary movements). Each level of motor control retains a somatotopic organization and receives peripheral sensory

information that is used to modify the motor output at that level (18). The cerebral cortex exerts its motor control by way of the corticospinal and corticobulbar pathways. The cortex also modulates the action of motor neurons in the brainstem and spinal cord indirectly through its influence on the brain's various descending systems.

To this day, limited direct information exists about specific neuronal connections between functional brain regions of the human cortex (19). Our knowledge of detailed connectivities is derived from invasive tracer studies in primates. Recent imaging advances are now permitting noninvasive studies of neuronal connections in humans, using the techniques of diffusion tensor imaging (DTI) and functional connectivity MRI (fcMRI)—the latter technique aims to identify highly correlative BOLD signal changes present in different regions of the cortex during the resting state or during specific tasks (20). Importantly, cortical regions identified by fcMRI may reside at a considerable distance from each other. Optogenetic techniques now also allow further in vivo mapping of interactions of motor and premotor areas in animal models (21).

Brainstem Motor Efferents

The brainstem gives rise to several descending motor pathways, which are divided into ventromedial and dorsolateral groups (22,23). The ventromedial system sends fibers through the ventral columns of the spinal cord and terminates predominantly in the medial part of the ventral horn, which contains the motor nuclei controlling proximal limb and axial muscle groups. In contrast, the dorsolateral system descends in the lateral part of the spinal cord and terminates on the lateral motor cell complex, which innervates more distal limb muscles (24). Thus, the dorsolateral motor system places its emphasis on muscles devoted to fine motor control.

Motor Cortex Efferents

The axons that project from layer V of the cortex to the spinal cord run together in the corticospinal tract (a massive bundle of fibers containing approximately 1 million axons). About one-third of corticospinal and corticobulbar fibers arise from the PMA. Another third originate from the SSMA and PreMC, and the rest have their origin in the parietal lobe (arising mainly from the somatosensory cortex of the postcentral gyrus) (25). The corticospinal fibers together with the corticobulbar fibers run through the posterior limb of the internal capsule to reach the ventral portion of the brainstem and send collaterals to the striatum, thalamus, red nucleus, and other brainstem nuclei (26). Many of these relationships can now be visualized noninvasively using combined fMRI and DTI techniques (Fig. 11.2). In the brainstem, the corticobulbar fibers terminate bilaterally in cranial nerve motor nuclei (either directly via a monosynaptic route or indirectly), with the exception of motor neurons innervating the lower face, which receive mostly contralateral corticobulbar input. About three-fourths of the corticospinal fibers cross the midline in the pyramidal decussation at the junction of the medulla and spinal cord and descend in the spinal cord as the lateral corticospinal tract (19). Uncrossed fibers descend as the ventral corticospinal tract. The lateral and ventral divisions of the corticospinal tract terminate in approximately the same regions of spinal gray matter along with corresponding brainstem-originating pathways. The majority of corticospinal tract terminals project on spinal interneurons. An estimated 5% of the fibers synapse directly on (both alpha and gamma) motor neurons (27).

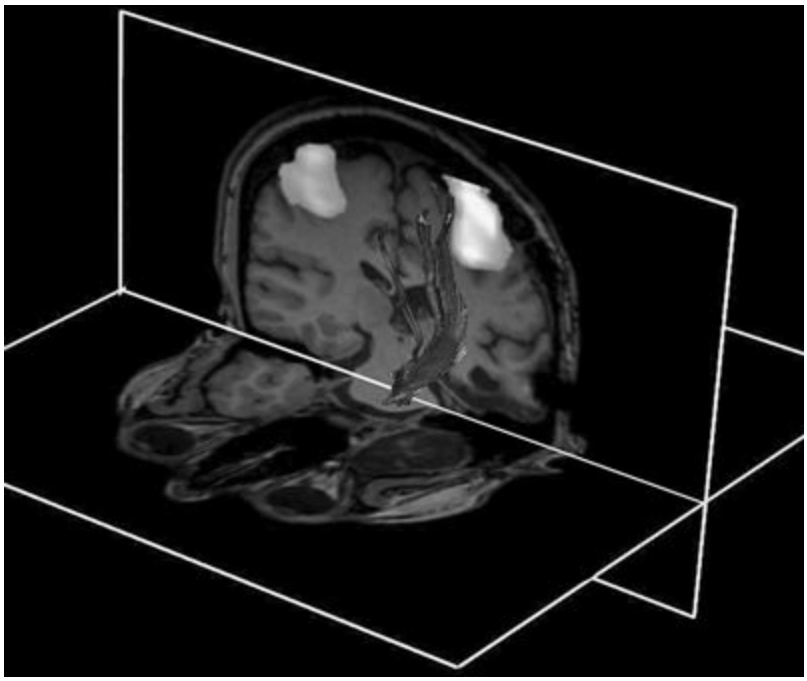

Figure 11.2. Combination of DTI, fMRI, and anatomic imaging demonstrating relationship of the left corticospinal tract to the motor regions using a finger-tapping paradigm. The fMRI and anatomic images are displayed as cut planes, with 3D superimposition of a surface representation of DTI tracks. A seed region for deterministic tracking is placed in the central pons—from this structure, the tracks ascend superiorly through the internal capsule and corona radiata to terminate in pericentral cortex. Note the expected close approximation of central tracks to the hand area.

These anatomic arrangements of descending tracts underlie the contralateral and/or bilateral motor manifestations of focal seizures arising from the motor cortex (17).

Motor Cortex Afferents

The major cortical inputs to the motor areas of cortex are from the prefrontal and parietal association areas (18). These are focused mainly on the PreMC and the SSMA, whereas the PMA receives a large input from the primary somatosensory cortex (28). In addition, the PMA receives direct and indirect inputs from the PreMC and the SSMA. In particular, the SSMA projects bilaterally to the primary motor cortex in a somatotopically organized manner. Other corticocortical inputs arrive from the opposite hemisphere through the corpus callosum (Fig. 11.3), which interconnects heterotopic as well as homologous areas of the two hemispheres (29,30). The major subcortical input to the motor cortical areas comes from the thalamus, where separate nuclei convey modulating inputs from the basal ganglia and the cerebellum (28).

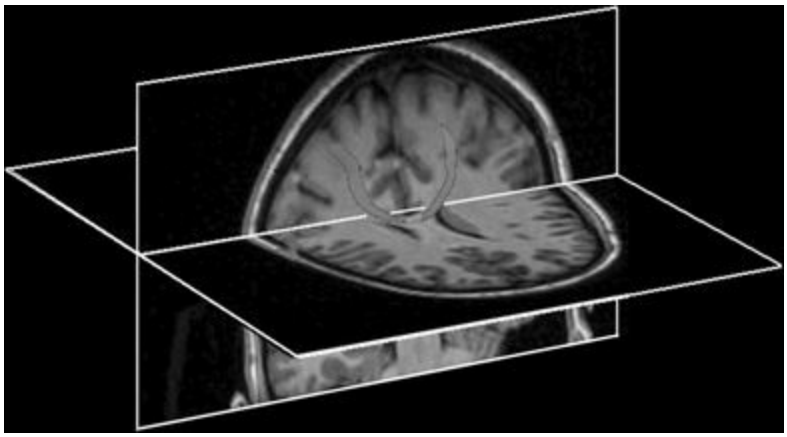

Figure 11.3. Example of corticocortical connectivity using probabilistic tractography from high-resolution DTI images. One seed region is placed in one motor area, and the target region is placed in the contralateral motor area. Computed tracts course across the corpus callosum as expected. The tracts are displayed as a red 3D overlay on black and white anatomic cut planes.

Stimulation Studies

In clinical practice, insights into the functional anatomy of the motor cortex and other eloquent brain cortical areas are afforded by direct cortical stimulation. At the same time, electrical stimulation of the human cortex provides an experimental model that can be used to reproduce the effects of cortical activation after an ictal discharge (31). Several groups use cortical stimulation to trigger habitual auras and/or seizures in an attempt to better delineate the ictal onset zone before epilepsy surgery.

In general, the observed clinical response is assumed to arise from cortex below the stimulated electrode or from the region between two closely spaced electrodes, given that the current density drops off rapidly with increasing distance from the tissue underlying the stimulated electrode (32,33). Electrical stimulation can elicit "positive" responses (such as localized movements resulting from activation of the PMA or SSMA cortex) or "negative" responses (such as inhibition of motor activity). The latter becomes apparent only if the patient engages in specific tasks during stimulation. In areas such as the supplementary motor cortex, both positive responses in the form of bilateral motor movements and negative responses such as speech arrest can be demonstrated. The area of stimulation gives rise to distinctive patterns of motor activation of the PMA, SSMA, or premotor regions. Overlapping clinical manifestations are commonly observed as a result of the highly developed interconnectivity between these regions (34).

Negative motor responses interfere with a person's ability to perform a voluntary movement or sustain a voluntary contraction when cortical stimulation is applied (35). The patient is unaware of the effects of stimulation unless asked to perform the specific function integrated by the stimulated cortical region. In a systematic review of 42 patients who had subdural electrodes over the perirolandic area, the Cleveland Clinic group observed negative motor responses over both hemispheres, when stimulating the agranular cortex immediately in front of the primary and supplementary face areas (35). To distinguish the two negative motor areas, investigators proposed the terms primary negative motor area (PNMA, in regard to the region of the inferior frontal gyrus immediately in front of the face PMA) and supplementary negative motor area (SNMA, in reference to the mesial portion of the superior frontal gyrus immediately in front of the face SSMA). Other investigators have been able to confirm and extend these observations using similar techniques of direct cortical stimulation with subdural electrodes, and have concluded that negative motor areas are in fact widely distributed throughout the perirolandic region and within the PreMC (36). These areas are considered a part of the cortical inhibitory motor system, the epileptic activation of which may give rise to **focal inhibitory motor seizures** (also referred to by some authors as "akinetic" seizures). Such seizures can be easily overlooked because patients may remain unaware of their weakness and/or inability to execute specific movements, unless they are carefully examined.

The effects of functional localization and effects of electrical stimulation in the three broad motor areas are briefly discussed below.

Primary Motor Area

The PMA resides in the anterior wall of the central sulcus (see Fig. 11.1) and corresponds to Brodmann area 4. On the basis of cytoarchitectonic criteria, area 4 is recognized primarily by the

presence of Betz cells (giant pyramidal cells) in cortical layer V and the absence of a granular layer IV (37). The central sulcus marks the border between the agranular motor cortex and the granular somatosensory cortex (38).

Radiographically, the central sulcus appears as a prominent, almost always continuous, sulcus, which extends from the mesial aspect (near the brain's apex) along an oblique coronal trajectory toward (and near to) the sylvian fissure. The superior and inferior aspects of the central sulcus are terminated by the paracentral lobule and subcentral gyrus, respectively, which effectively appear as a joining of the pre- and postcentral gyri. The radiographic identification of the central sulcus is often critical to the interpretation of imaging studies and planning surgical procedures, as it provides a central landmark from which other topologies can be located. There are several characteristic features identifying the central sulcus, three of which are shown in the cartoon of Figure 11.4 and on the T1-weighted MRI images of Figure 11.5. Most easily identified is the so-called hand knob, which assumes the form of an upside-down omega ("Ω") on axial images (39). Formed by a relative gyral hypertrophy corresponding to the PMA of the hand, the "hand knob" appears to project posteriorly from the precentral gyrus into the contour of the central sulcus. Due to anatomic variation, this feature sometimes assumes the shape of a horizontal epsilon ("ε"), rather than the inverted omega (39). Another confirmatory feature of the "hand knob" on the sagittal plane is that it appears as if forming a backward "hook" (see Fig. 11.5), but this appearance is less reliable than is the characteristic axial morphology. A second helpful landmark is the topology of the superior central gyrus, which is easily seen running along an anterior–posterior direction along the medial frontal lobe and whose posterior margin is the precentral gyrus. Identification of the precentral gyrus is further aided by demarcation of the pre- and postcentral sulci. Lastly, axial images nicely portray the pars marginalis, which is the ascending ramus arising from the posterior cingulate sulcus. The left and right ascending rami appear on axial images as bilaterally paired paramedian features that together form the shape of a "bracket" or "smile" (40). This characteristic appearance is often preserved over multiple axial slices and can be used to identify the central sulcus and differentiate it from the adjacent postcentral sulcus.

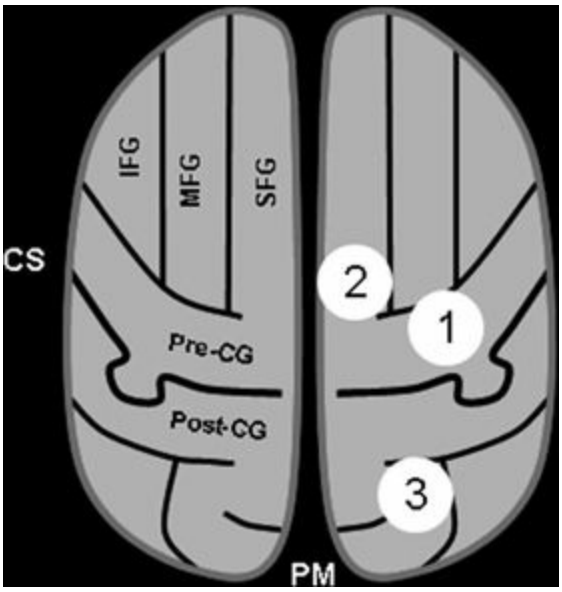

Figure 11.4. Key features for identifying the sensorimotor cortex. The essential step is identification of the central sulcus (CS), which separates the precentral gyrus anteriorly (motor cortex) from the postcentral gyrus posteriorly (sensory cortex). This schematic of an axial section illustrates three classic features that aid in the identification of the CS. (1) the "hand knob" is a posterior protuberance of the precentral gyrus, which corresponds to relative "hypertrophy" of the primary hand motor area. The shape of the sulcus in this area is often described as that of an upside-down omega ("Ω"). (2) The anterior–posterior orientation of the superior frontal gyrus is often easily identified, as it aligns along a paramedian plane. While the anterior margin of the SFG extends to the frontal poles, the posterior

margin merges with the precentral gyrus, such that the most posterior margin often appears as the central sulcus. (3) Posterior to the medial aspect of the central sulcus is the pars marginalis, which often has a slight concavity—when pairing together, the left and right pars marginalis assume the characteristic appearance that resembles a "smile" or "bracket," which can be seen on multiple axial sections, making identification easy. (IFG, inferior frontal gyrus; MFG, middle frontal gyrus; SFG, superior frontal gyrus; Pre-CG, precentral gyrus; post-CG, postcentral gyrus; CS, central sulcus; PM, pars marginalis.)

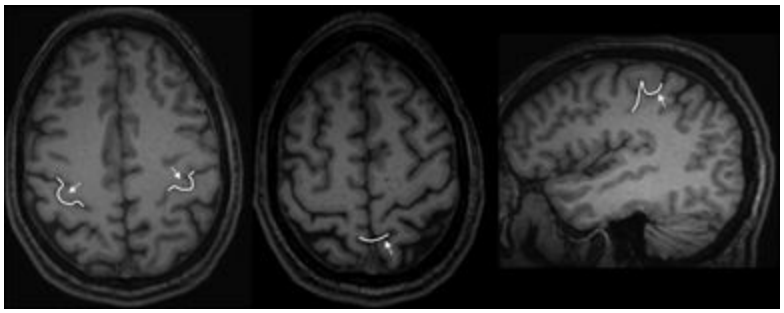

Figure 11.5. MRI examples of the landmark features described in Figure 11.4, which help locate the central sulcus. Shown as overlaid white line segments are the "omega" of the hand knob (**left** image) and the pars marginalis "smile" (**middle image**). The **middle** image also demonstrates the architecture of the superior frontal gyrus terminating posteriorly in the precentral gyrus. The **right** image displays the backward "hook" as described in the text—this feature is appreciated on sagittal images passing through the hand knob.

The somatotopic organization of the PMA was elucidated by the pioneering work of Krause (9), Penfield, Jasper, and Rasmussen (41,42), and others (Fig. 11.6). In this region of the PMA, simple movements were elicited with the lowest intensity of electrical stimulation (43). The resulting motor maps show an orderly arrangement with the tongue and lips near the sylvian fissure and the thumb, digits, arm, and trunk represented successively along the central sulcus, ending with the leg, foot, and toes on the mesial surface. The somatotopic organization of the motor cortex is not fixed and can be altered during motor learning or after injury (44). The layout of the motor homunculus is topographically similar to that of the somatosensory homunculus, which resides immediately behind the PMA. Contemporary noninvasive methods, such as BOLD imaging fMRI, nicely confirm and recapitulate the classic homunculus (see Fig. 11.6). Output of the PMA is directed to the corticospinal and corticobulbar tracts, as well as to the SSMA and homologous areas in the opposite hemisphere via the corpus callosum (45).

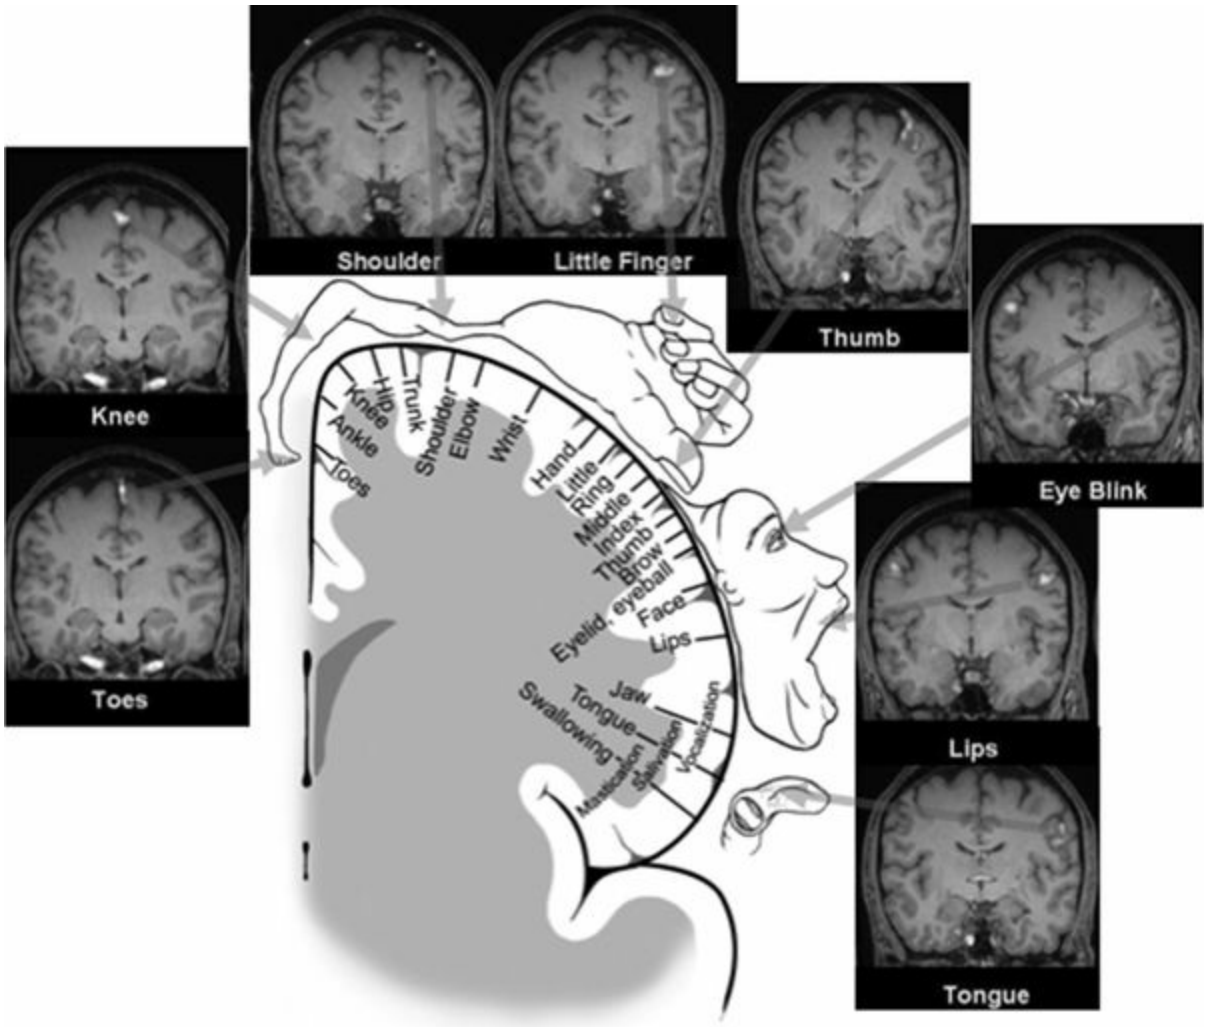

Figure 11.6. The motor homunculus after Penfield and Rasmussen depicting the somatotopic arrangement of the primary motor cortex (PMA) (with the tongue and lips near the sylvian fissure and the thumb, fingers, arm, and trunk represented successively along the precentral gyrus ending with the leg, foot, and toes on the mesial surface) occupies the center of this figure. Muscle groups involved in fine movements feature a disproportionately large representation. Surrounding this schematic representation of the motor homunculus are corresponding images of fMRI activation of the primary motor cortex obtained with eight different motor tasks—the fMRI images nicely recapitulate the classic motor homunculus. Images are provided in coronal oblique reformatted planes that are roughly parallel to the motor strip. Significant activity is shown as color overlay. The toe, knee, shoulder, and finger tasks employed flexion/extension or tapping at a rate of about 2 per second, using the right-sided limb only. The eye blink, lip (pursing), and tongue (pressing against palate) tasks were bilateral motions performed at a similar rate. Right lower extremity movements are clearly localized along the left superomedial cortical surfaces, with right upper extremity movements localized along left superolateral cortical surfaces. Note bilateral motions from the eyes, lips, and tongue show corresponding bilateral activation. (Adapted from Penfield W, Rasmussen T. The Cerebral Cortex of Man—A Clinical Study of Localization of Function. New York : The MacMillan Company; 1950, with permission.)

Stimulation Studies

In the PMA, single stimuli typically elicit single clonic movements of the contralateral somatic muscles represented by the area of the motor homunculus being stimulated. High-frequency (50 to 60 Hz) stimulus series result in slower, tonic contralateral motor responses (46). Intraoperative application of electrical stimulation mapping under local or general anesthesia provides the most direct and easy way to localize the perirolandic cortex in most adults (47). When local anesthesia is used, motor responses are usually evoked with currents of 2 to 4 mA. Sensory responses are elicited with stimulation of the postcentral gyrus, often at slightly lower thresholds (48). The threshold for eliciting a motor response in humans is lowest in the PMA. Electrical cortical stimulation studies

uncover the individual variability in the topographic organization of sensorimotor maps in humans with structurally normal anatomy (49). The importance of direct cortical stimulation studies in patients with lesions and/or epileptogenic foci encroaching on the sensorimotor cortex cannot be overemphasized (50). Furthermore, bilateral probabilistic map has proven to become a useful tool to map and anticipate cortical epicenters of human brain functions, including motor and language areas (51).

Supplementary Sensorimotor Area

The SSMA is a distinct anatomic region located on the mesial surface of the superior frontal gyrus and its adjacent dorsal convexity (52). The cerebral cortex of the SSMA corresponds to the mesial portion of area 6 of Brodmann cytoarchitectonic map of the brain (41,53) (see Fig. 11.1). Phylogenetically, the SSMA may be viewed as older motor cortex derived from the anterior cingulate periarchicortical limbic system (54). Similar to the primary motor cortex, the SSMA is referred to as agranular cortex, because the internal granular layer (layer IV) is not prominent. In contrast to area 4, area 6 does not contain Betz cells (53). The medial precentral sulcus defines the border between the PMA for the foot and the posterior limit of the SSMA (13,55). No clear cytoarchitectonic or anatomic boundary separates the SSMA from the adjacent PreMC (56).

The macaque and human mesial area 6 (SSMA) is further subdivided into pre-SSMA (rostrally) and SSMA proper (caudally) on the basis of comparable cytoarchitectonic and transmitter receptor studies (38). Studies in primates suggest that the pre-SSMA holds a hierarchically higher role in motor control. The functional properties of the SSMA subdivisions have not been detailed in humans (57). The border between the pre-SSMA and SSMA proper corresponds to the vertical anterior commissure line (VAC line, i.e., the vertical line passing through the anterior commissure and perpendicular to the AC–PC line, which connects the anterior and posterior commissures) (Fig. 11.7). The border between SSMA proper and PMA corresponds approximately to the VPC line (i.e., the vertical line that traverses the posterior commissure and is perpendicular to the AC–PC line) (58).

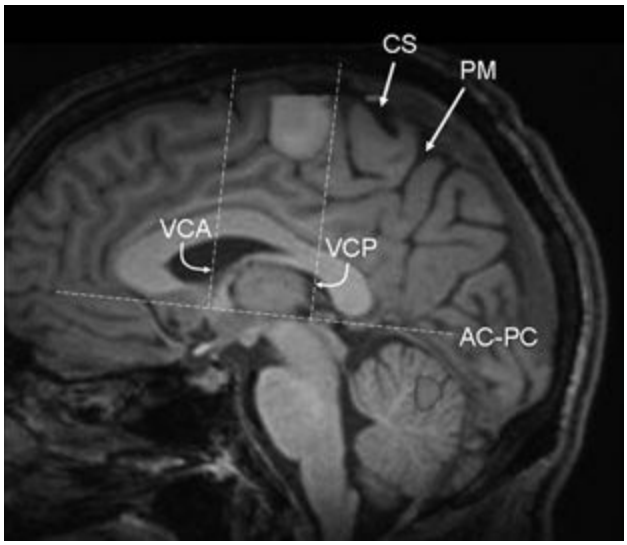

Figure 11.7. Functional MRI using a finger-tapping paradigm (paramedian sagittal plane) shows activation of the supplementary sensorimotor area (SSMA), which lies within the paracentral lobule and is located anteriorly to medial margin of the central sulcus. In addition, cerebellar activation is also present. Note the anatomical relationships of the SSMA to the AC–PC line, as described in the paragraph on Supplementary Motor Area, above. The border between the pre-SSMA anteriorly and SSMA proper corresponds to the VAC line, and the border between SSMA proper and PMA posteriorly corresponds approximately to the VPC line. AC–PC refers to

the line that connects the anterior and posterior commissures, VAC (or VCA as depicted above) refers to the vertical line passing through the anterior commissure and perpendicular to the AC–PC line, VPC (or VCP as depicted above) refers to the vertical line that traverses the posterior commissure and is perpendicular to the AC–PC line. (CS, central sulcus; PM, pars marginalis.)

Stimulation Studies

More than 70 years ago, Foerster was the first to describe motor responses in humans elicited by electrical stimulation of the mesial aspect of the superior frontal gyrus anterior to the primary motor representation of the lower extremity (2). Systematic study of this region with electrical stimulation was carried out at the Montreal Neurological Institute (MNI) during the intraoperative evaluation of patients with intractable focal epilepsy preceding surgical resection (59).

This was the first group to use the term supplementary motor area (SMA). Direct intraoperative electrical stimulation of the SMA produced vocalization, speech arrest, postural movements of all extremities, inhibition of voluntary movements, paresthesias, and autonomic changes. The rich repertoire of combined or postural movements included the so-called fencing posture, a term coined by the MNI group to describe the classical stimulation-induced postural response that consists of elevation of the contralateral arm with the head and eyes turned toward the raised hand (41). The Montreal studies demonstrated that both positive (such as bilateral motor movements) and negative responses (such as speech arrest) could be elicited by stimulating this region. The intraoperative study of the mesial interhemispheric surface carries significant limitations, because of the tedious and potentially dangerous surgical approach (in proximity to the superior sagittal sinus and its cerebral bridging veins), the restricted amount of time, and the relative difficulty in recognizing the specific gyral landmarks during surgery in this region.

With the advent of subdural electrodes, the Cleveland Clinic series of extraoperative stimulation studies showed that positive motor responses were not restricted to the mesial aspect of the superior frontal gyrus, but could also be elicited from its dorsal convexity, the lower half of the paracentral lobule, and the precuneus (60). The same group confirmed the presence of sensory symptoms that were elicited along with the positive motor responses after stimulation of the SMA and coined the term SSMA instead of SMA.

Using depth electrodes, Talairach and Bancaud (61) were the first to describe a somatotopic organization within the SSMA. The Yale group confirmed the presence of somatotopic distribution in the SSMA, where the face, upper extremity, and lower extremity responses are oriented in a rostrocaudal direction, with the lower extremities represented posteriorly, head and face most anteriorly, and the upper extremities between these two regions (62). Likewise, studies of movement-related potentials (MRPs) using subdural electrodes implanted over the SSMA region demonstrated that MRPs for different types of movements (finger, foot, tongue, vocalization, etc.) also have a somatotopic distribution within the SSMA, which is consistent with the organization defined by electrical stimulation (63–65). Notably, fMRI studies using motor activation paradigms, such as finger tapping, for example, demonstrate strong activations of the SSMA in addition to the primary motor cortex (see Fig. 11.7).

Premotor Cortex

Fulton coined the term PreMC in 1935 to describe the third major component of motor cortex (66). This area encompasses the more loosely defined agranular cortex of the lateral frontal convexity rostral to the PMA (11,23), which corresponds to the lateral portion of Brodmann area 6 (see Fig.

11.1). It is difficult to define the anterior border of the agranular PreMC in humans, where a broad zone of progressive transition exists between area 6 and the granular cortex of Brodmann frontal area 9 (67). In the macaque, the PreMC is further subdivided into a dorsal portion on the dorsolateral convexity and a ventral portion on the ventrolateral convexity (11). Despite the lack of direct correlation between microstructure and function in humans, the two subdivisions of the premotor area are considered to have homologous counterparts in the human brain. The motor and premotor cortices, as well as the frontal eye fields (FEFs) and the anterior cingulate cortex of area 24, have reciprocal connections with the SSMA (53). Anatomic labeling experiments in the macaque have demonstrated that the more anterior dorsal PreMC projects to the spinal cord, challenging the notion that the PreMC, unlike the PMA and SSMA, lacks prominent corticospinal connections (23,68,69).

According to the classic schema, the PreMC is responsible for the preparation and organization of movements (56). Several recent studies show that the PreMC also plays a central role in nonmotor attentional and receptive domains. Therefore, our current understanding suggests a dual PreMC function pertaining to motor and cognitive behaviors (70).

Stimulation Studies

On the basis of early electrical stimulation studies of the monkey brain (71), the agranular lateral PreMC (area 6) has been subdivided into a rostral section (6aβ or 6r) and a caudal section (6aα or 6c). Recent quantitative architectonic and neurotransmitter studies have corroborated the presence of similar topographic boundaries in the human brain (38,67). The rostral subdivision covers the anterior part of the precentral gyrus, and its caudal counterpart resides in the posterior part of the superior and middle frontal gyri, in front of the precentral sulcus (72).

Eye movements can be electrically induced from a large area of the human dorsolateral frontal cortex and the precentral gyrus. These stimulation-elicited responses have been attributed to electrical interference with the human homolog of the monkey FEF (73). Electrical stimulation studies in humans have confirmed the functional location of the eye movement sites anterior to the motor representation of the arm and face (73,74). However, some ambiguity exists as regards the exact location of the human FEF within this rather extensive oculomotor region. The divergence is largely caused by the methodologic differences of neuroimaging and electrical cortical stimulation studies.

The electrically defined human FEF is located in the posterior end of the middle frontal gyrus (see Fig. 11.1) immediately anterior to the precentral sulcus (and in proximity to the superior frontal sulcus). Electrical cortical stimulation of this area produces constant oculomotor responses characterized by low stimulation thresholds (73). Conversely, neuroimaging studies of cerebral blood flow (CBF) changes suggest that the homologous region in humans lies posterior to the electrically defined FEF. Indeed, the CBF-defined FEF is located between the central and precentral sulci in front of the primary hand representation, suggesting that the eye movement field lies in Brodmann area 6 (i.e., in a PreMC region homologous to the ventral PreMC) (75,76). More recently, corticocortically evoked potentials have been used to evaluate connections between the premotor and motor cortex in humans implanted with subdural electrodes (77).

FOCAL MOTOR SEIZURES

Focal seizure is the term proposed by the Task Force of the International League Against Epilepsy (ILAE) to describe seizures in which the initial activation involves a limited number of neurons in

part of one hemisphere (78). The terms localization- related or partial seizures have been used to describe the same seizure type. However, the more recently proposed diagnostic scheme of the ILAE Task Force prefers the less ambiguous term focal to partial or localization-related seizures (79).

Motor phenomena constitute the main clinical manifestations of motor seizures. As a rule, consciousness is retained in the majority of seizures arising from discrete motor regions. It is possible, however, for an ictal discharge to remain localized and still produce alteration of consciousness. Furthermore, certain motor manifestations and a patient's anxious reaction to the seizure symptoms may prevent the patient from responding appropriately during seizures. It may, therefore, be difficult to ascertain the level of consciousness in several patients with focal motor seizures. In the past, the presence or absence of altered awareness was used to dichotomize seizures of focal onset into "simple partial" and "complex partial." It is now proposed to move away from this dichotomy, which seems to have "lost its meaningful precision" (79).

Subsequently, the ILAE provided a glossary of descriptive terminology to describe ictal semiology (80). Ictal motor phenomena may be subdivided into **elementary motor manifestations** (such as tonic, clonic, dystonic, versive) and **automatisms**. Automatisms consist of a more or less coordinated, repetitive motor activity (such as oroalimentary, manual or pedal, vocal or verbal, hyperkinetic or hypokinetic) (80). Somatotopic modifiers may be added to describe the body part producing motor activity during seizures.

Another recent seizure classification is based on the clinical symptomatology and is independent of electroencephalographic (EEG), neuroimaging, and historical information (81). This classification uses terms such as focal clonic, focal tonic, or versive, and evolution during the seizure is indicated by arrows. For example, left-hand somatosensory aura → left arm clonic seizure → left versive seizure.

Clinical Semiology

This section reviews the elementary motor phenomena resulting from a variety of focal motor seizures. These seizures typically present with clonic or tonic manifestations. Hyperkinetic manifestations are usually attributed to seizures arising from (or spreading to) the frontal lobe. Other motor automatisms seen with focal seizures (such as oroalimentary, mimetic, or gestural automatisms) are reviewed elsewhere.

In a population-based study conducted in Denmark of 1054 patients with epilepsy who were between the age of 16 and 66 years, 18% had "simple partial" seizures (82). Mauguiere and Courjon examined the presenting seizure type in a large series of 8938 patients with seizures admitted to a single hospital over a 10-year period. They found that 1158 patients (12.9%) had focal tonic or clonic seizures without march (the most common presentation of focal seizures in this series); 582 patients (6.5%) presented with hemitonic or clonic seizures; 461 (5.2%) had adversive seizures; and only 199 (2.2%) had jacksonian seizures (83). Perirolandic epileptogenic lesions often involve both the precentral and postcentral gyri, giving rise to both motor and sensory phenomena. In one video–EEG study of 14 patients with a total of 87 "simple partial" seizures, sensory phenomena were observed in approximately one-third of patients exhibiting focal motor seizures (84).

Postictally, patients may experience a transient functional deficit, such as localized paresis (Todd paralysis), which may last for minutes or hours (up to 48 hours or longer). This interesting clinical phenomenon of "postepileptic paresis" is the signature of a focal seizure and bears the name of Dr. Bentley Todd, who first described it in the mid-19th century (85). Todd paralysis is believed to result

from persistent focal dysfunction of the involved epileptogenic region. Postictal Todd paralysis is a clinical sign of substantial value in lateralizing the hemisphere of seizure onset (86).

Clonic Seizures

Clonic seizures consist of repeated, short contractions of various muscle groups characterized by rhythmic jerking or twitching movements (87). These movements recur at regular intervals of <1 to 2 seconds. Most clonic seizures are brief and last for <1 or 2 minutes. During this period, clonic movements may remain restricted to one region or spread in a jacksonian manner. The majority of focal motor seizures tend to involve the hand and face, although any body part may potentially be affected (88). Such predilection is attributed to the large cortical representation of the hand and face area. The typical manifestation of a localized discharge within the precentral gyrus is clonic twitching of specific contralateral muscle groups, as determined by their proportionate somatotopic representation.

The clonic movements are usually limited to the corresponding area of the body, but may spread during the attack. Such spread (e.g., from the muscles of the face to the ipsilateral hand or arm) is known as the "jacksonian march." During these "jacksonian attacks," motor symptoms travel slowly from one territory to another, typically following the order of the corresponding somatotopic representation. The term jacksonian seizures was proposed by Charcot in 1887 to describe the characteristic march seen with this particular subtype of clonic seizures (89). The continued use of the term serves to remind us of Hughlings Jackson's astute clinical observations, which provided the basis for his revolutionary principles of functional localization long before the era of EEG and neuroimaging correlations (90). In his own words:

> "The part of the body where the convulsion begins indicates the part of the brain where the discharge begins and where the discharging lesion is situated. But from the focus discharging primarily the discharge spreads laterally to the adjacent "healthy" foci. One focus after the other is seized by the radiating waves of impulses. The march of the attack, the order in which the different parts of the body become involved, reveals the arrangement of the corresponding foci in the precentral convolution." (2)

The march usually starts from a distal body region (such as the thumb, fingers, great toe, mouth, or eyelids) and spreads toward a more proximal part. Jackson astutely described three variants: (i) "fits starting in the hand (most often in the thumb or both)," (ii) "fits starting in one side of the face (most often near the mouth)," and (iii) "fits starting in the foot (nearly always in the great toe)" (3). Typically, consciousness remains intact, and secondary generalization of jacksonian seizures is uncommon. At times, the march may skip some areas, a phenomenon that may be related to different seizure thresholds within the symptomatogenic region. Holowach et al. reviewed 60 jacksonian seizures in children and found that the majority (25 out of 60) began in the face (8 in the periocular and 5 in the perioral region), 17 in the hand, 7 in the arm, 2 in the shoulder, and 9 in the leg and foot (91).

Lastly, the term hemiconvulsions refers to unilateral clonic seizures (i.e., clonic activity affecting one side of the body). Prolonged unilateral convulsions followed by the onset of hemiparesis are described in the childhood syndrome of hemiconvulsion–hemiplegia–epilepsy.

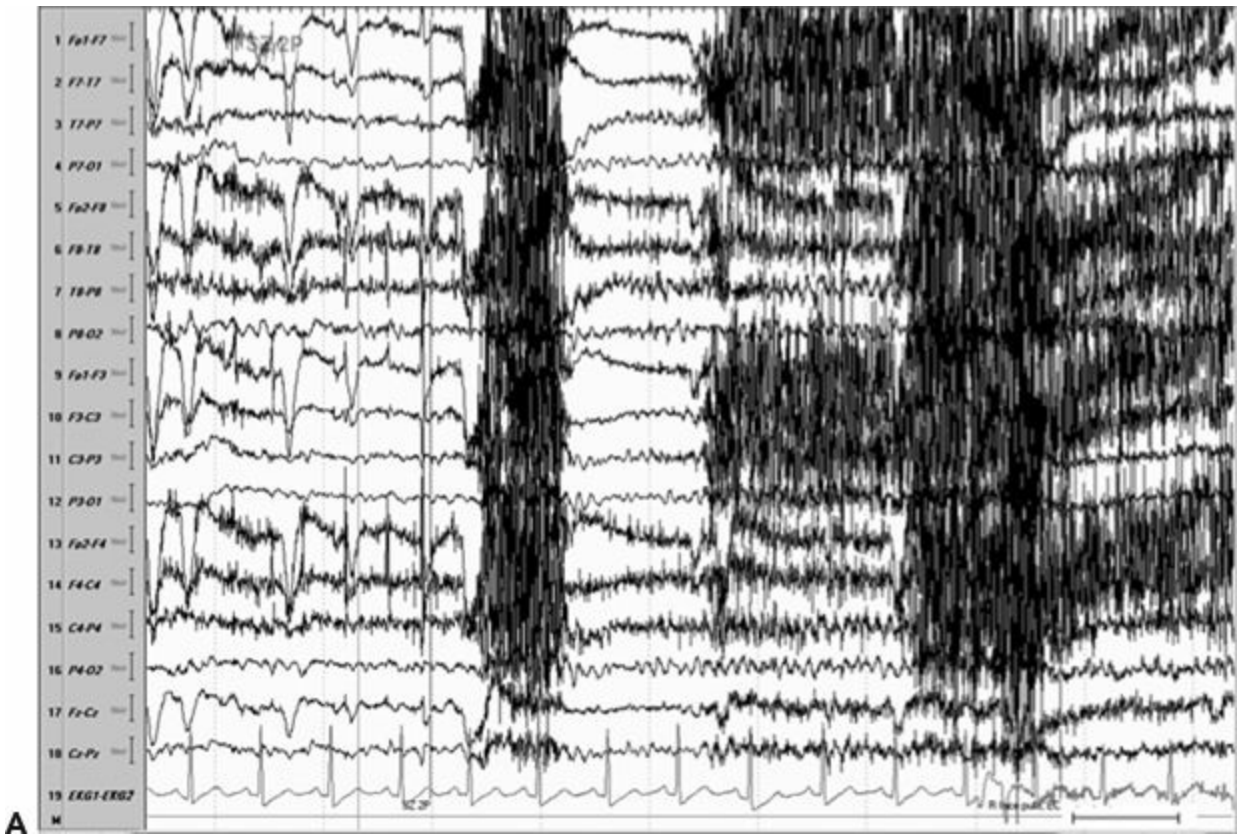
Myoclonus and Myoclonic Seizures

Many types of myoclonic phenomena (e.g., myoclonus caused by spinal cord disease or essential myoclonus) do not have an epileptic origin and need to be differentiated from (focal) myoclonic

seizures. Typically, myoclonic jerks are arrhythmic compared with clonic motor activity. Notable exceptions discussed under the broad definition of myoclonus include the more rhythmic motoric manifestations of epilepsia partialis continua (see below, paragraph on Epilepsia Partialis Continua) and the nonepileptic segmental myoclonus or palatal myoclonus (also called palatal tremor) (92).

Epileptic myoclonus is typically accompanied by an EEG correlate of spike- or multispike-and-wave complexes (93,94). Polygraphic recordings combining EEG with electromyography (EMG) of affected muscles may be necessary to unmask the relationship or the epileptic EEG activity to the myoclonic jerk. Video recordings can be helpful, but cannot replace polygraphy in ambiguous cases. The term myoclonic seizure is reserved for epileptic seizures, whose main components are single or repeated epileptic myoclonias (95). Gastaut (96) distinguished epileptic myoclonic events into generalized, segmental, and focal, according to whether the seizures affected the entire body, one or more limbs, ipsilateral body parts/segments, or only one part of a single limb, respectively.

Although an accurate distinction may oftentimes prove difficult, some authors do not consider epileptic myoclonus as part of focal motor seizures (94). Others view focal cortical myoclonus as one manifestation of focal motor seizures, given that myoclonus in this instance results from a hypersynchronous discharge arising from a distinct population of cortical cells within the PMA and/or premotor areas (97). Focal cortical myoclonus has been described in patients with focal lesions involving the motor cortex, such as tumors, trauma, cortical dysplasia, or vascular lesions (Fig. 11.8). In a report of four children with perirolandic cortical dysplasia presenting with focal cortical myoclonus, the authors observed that localization of the recorded epileptiform discharges correlated with the body part affected by the myoclonus (C3 electrode in two patients whose myoclonus involved predominantly the right upper extremity, C3–T7 electrodes in one patient with myoclonus affecting the face, and Cz electrode in the other patient with focal myoclonus of the left leg) (98).



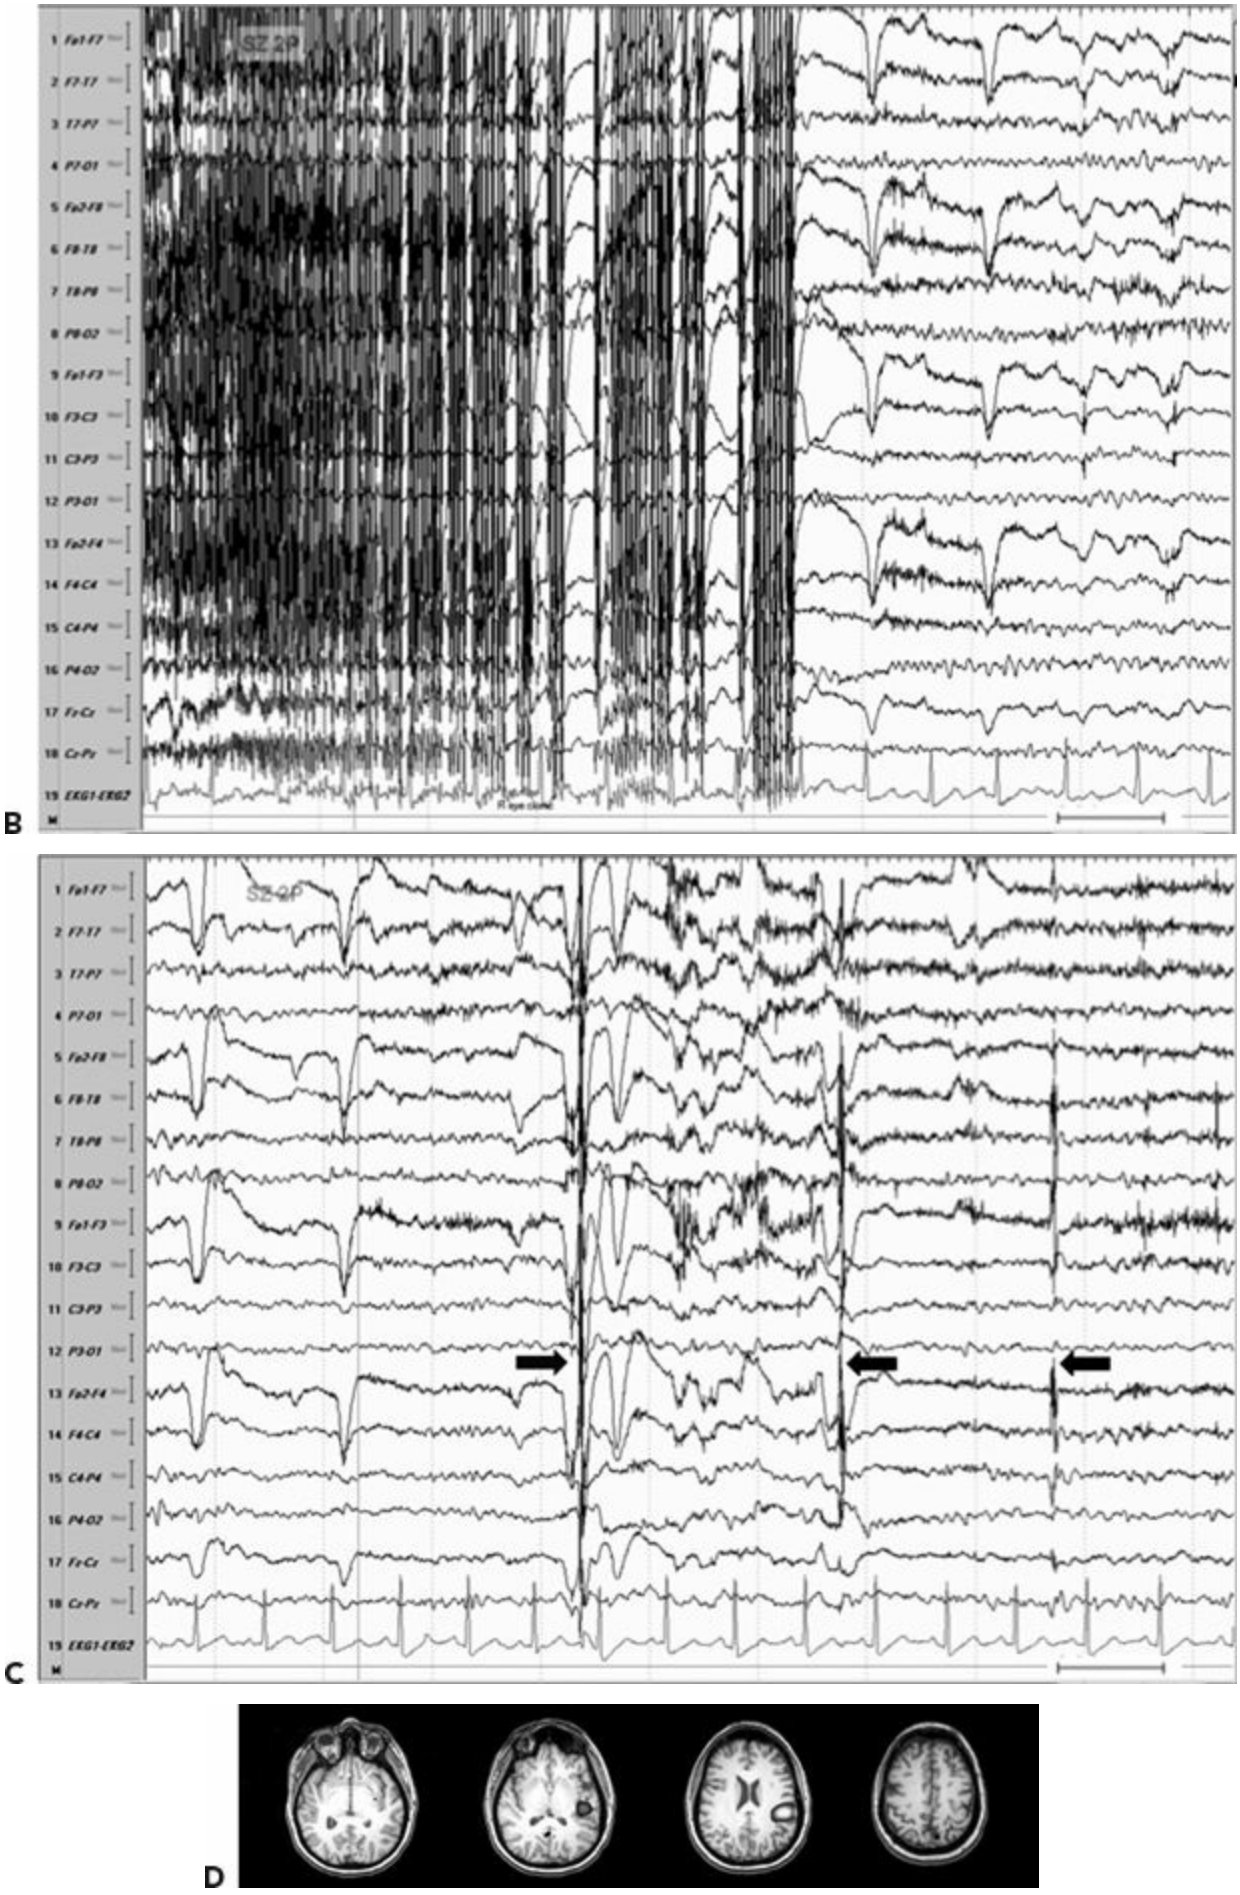


Figure 11.8. Consecutive scalp electroencephalogram tracings (**A** to **C**, longitudinal bipolar montage) during a typical stereotyped event do not disclose a definite evolving ictal pattern, in a 39-year-old patient with exquisitely focal motor seizures since childhood. In the last 3 years, she has been experiencing daily very brief seizures involving the muscles of the lower face on the right side without alteration of awareness. There is no history of jacksonian march or secondarily generalized tonic–clonic seizures. Interictal EEG is normal. Although EEG activity is predominantly obscured by the presence of high- voltage myogenic artifact, the sequence of motor

manifestations can be discerned from the appearance of this same artifact. **A:**Clinical onset in the middle of this 10-second page punctuated by tonic contraction of the right facial musculature with involuntary right eye closure and deviation of the jaw toward the right, associated with voluntary reactive tensing of the entire face, as evidenced by the widespread and asymmetric "tonic muscle artifact." **B:** Clinical evolution with a brief cluster of repetitive focal myoclonic seizures involving the right side of the lower face, as evidenced by the corresponding repetitive, nonrhythmic, and almost instantaneous muscle artifact. Because of its very high voltage, the artifact appears widespread on this printed page. Digital reformatting confirms that the myogenic artifact is in fact picked up predominantly by the right-sided EEG electrodes, which are adjacent and susceptible to the contracting ipsilateral facial muscles. **C:**After the end of this motor sequence, the patient experiences three isolated, less intense, but otherwise identical muscle jerks in the span of 5 seconds, which are associated with myogenic artifact of relatively lower voltage (arrows) interrupting the otherwise normal awake EEG recording. Note that in this instance, the terminal muscle jerk is indeed associated with myogenic artifact primarily involving the right-sided derivations. **D:**Subtraction ictal SPECT (single-photon emission computed tomography) study coregistered to the patient's MRI, as depicted in these selected axial images, revealed a small, discrete, and isolated area of hyperperfusion in the left precentral region, ventral to the expected location of the hand motor area. The patient's MRI was normal except for a small, questionable, but concordant (based on clinical semiology, EEG, and ictal SPECT findings) area of faint signal increase in the depth of the left precentral sulcus at the level of the middle frontal gyrus. Surgical pathology revealed a balloon-cell cortical dysplasia. The location of the lesion (in the depth of the sulcus) and the exquisitely focal nature of the patient's habitual seizures likely account for the lack of interictal and ictal EEG abnormalities in this case.

Finally, the paradoxical term negative myoclonus is reserved for cases of sudden, brief relaxations in tonic muscle contraction (92). Negative myoclonus (which also encompasses the phenomenon of asterixis typically seen in toxic–metabolic encephalopathies) is a nonspecific manifestation and can be associated with a variety of neurologic disorders. Epileptic negative myoclonus can be either unilateral or bilateral and can be seen in relationship with a number of heterogeneous epilepsies ranging from the benign idiopathic epilepsies to severe epileptic encephalopathies (99).

Tonic Seizures

Tonic seizures consist of sustained muscle contractions that usually last for more than 5 to 10 seconds and result in posturing of the limbs or whole body (100). From the standpoint of clinical semiology, tonic seizures can be described according to the distribution and symmetry of tonic contractions with involvement of the axial (neck, trunk, and pelvis) and limb musculature. Generalized tonic seizures involve axial and limb muscles in a symmetric and synchronous fashion. Unequal or asynchronous contraction of muscle groups involving both sides of the body results in bilateral asymmetric tonic seizures. Contraction restricted to a portion of the body on one side only gives rise to focal tonic seizures (101).

In contrast to focal clonic seizures, which represent epileptic activation of a restricted region of the precentral gyrus, tonic motor seizures may implicate a wider area of motor cortex including the SSMA and the PreMC (17,102). Even though focal tonic seizures are attributed to activation of Brodmann area 6 (and the mesial frontal region in particular), some overlap in symptomatology occurs, with ictal involvement of the premotor and/or PMAs (103).

In a video–EEG study of 481 consecutive patients with focal epilepsy—evaluated at two tertiary epilepsy centers over a period of 4 years—a total of 123 patients were observed to have tonic seizure manifestations during at least one of their video–EEG recorded seizures. The vast majority of these patients had extratemporal epilepsy. Tonic seizures more frequently involved both sides of the body (76% bilateral vs. 24% unilateral). Importantly, when seen at the beginning of the seizure evolution, tonic seizures were more frequently associated with frontal lobe epilepsy as compared to epilepsy arising from the posterior neocortex. Furthermore, auras were more likely to precede tonic seizures originating from the parietooccipital regions and were less frequently reported in frontal

lobe epilepsy (104).

Stimulation of the SSMA elicits bilateral, asymmetric tonic contractions affecting primarily the more proximal muscles. Less frequently, focal tonic contractions may be seen. The symptomatogenic zone is less clear in cases of symmetric, bilateral tonic seizures. However, these seizures are believed to be generated by simultaneous bilateral activation of Brodmann area 6, rostral to the precentral region, in both hemispheres (31). It is also possible that generalized tonic seizures result from direct activation of brainstem reticular-activating systems (105,106). The fact that slow-wave and rapid eye movement (REM) sleep, as well as decreased levels of vigilance, appear to facilitate some tonic seizures, for example, in patients with Lennox–Gastaut syndrome, further implicates the brainstem in the generation of these phenomena (107). It becomes evident that different types of tonic seizures utilize different neuroanatomical pathways, which is hardly surprising given that tonic seizures may be a common clinical manifestation resulting from a variety of different pathophysiologies underlying symptomatic and less frequently idiopathic epilepsies.

Nonepileptic focal tonic symptoms can result from subcortical pathology (e.g., spinal cord or brainstem dysfunction in the case of compression or multiple sclerosis). In addition, paroxysmal tonic phenomena may be seen as part of certain movement disorders (such as paroxysmal choreoathetosis or spasmodic torticollis) or other nonepileptic paroxysmal disorders (e.g., in the setting of convulsive syncope) (101).

Oculocephalic Deviation and Versive Seizures

Foerster and Penfield first described versive seizures in 1930. The seizures consist of a sustained, unnatural turning of the eyes and head to one side, as a result of a predominantly tonic contraction of head and eye muscles (108). Although consciousness is often lost by the time a patient experiences version, occasionally, patients may be aware of the forced, involuntary head and eye deviation (45,109).

As discussed, cortical stimulation studies have confirmed the functional location of eye movement sites in proximity to the primary motor representation of the arm and face (74). On stimulating this region, Rasmussen and Penfield (110) observed that the more anterior points were responsible for contralateral rotation. Stimulation of more posterior points (closer to the central sulcus) elicited contralateral, ipsilateral, or upward eye movements. Head rotation was usually seen in conjunction with contralateral eye rotation.

The lateralizing significance of oculocephalic deviation has met with controversy. Indeed, a number of authors use the terms head turning and head version interchangeably (111–113). This lexical ambiguity prompted Wyllie et al. (108) to restrict the term version to “unquestionably forced, involuntary head and eye deviation to one side resulting in sustained unnatural positioning of the head and eyes.” In this important study, the authors reviewed retrospectively all lateral head and eye movements observed during 74 seizures in 37 patients and classified as “nonversive” any mild, unsustained, wandering, or seemingly voluntary head and eye movements. Visual analysis of video recordings was performed without prior knowledge of EEG findings. By adhering to the strict definition of “version,” the authors showed that the presence of a contralateral versive head and eye movement provides reliable lateralizing information (especially when this movement precedes secondary generalization) (108). On the other hand, one should be cautious about interpreting the direction of eye and head turning, if the seizure does not become secondarily generalized (114,115).

Version may result from seizures originating from various locations and spreading to the PreMC.

A noteworthy clinical observation is that extratemporal seizures give rise to version earlier in the seizure (within 18 seconds from seizure onset), compared with seizures of temporal lobe origin (in which version is usually seen after 18 seconds or later) (114).

Seizures Manifested by Vocalization or Arrest of Vocalization

Several types of utterances can occur during epileptic seizures. A prolonged continuous or interrupted vocalization may occur in seizures involving the SSMA or lower PMA on either hemisphere (61). Vocalization, when it occurs as part of SSMA seizures, tends to be more sustained (116). Penfield and Jasper produced such phonatory phenomena in humans by stimulating the SSMA or the PMA below the lip or tongue area (41). Finally, the so-called epileptic cry is frequently seen at the onset of generalized tonic–clonic seizures.

Speech arrest, defined as inability to speak during a seizure despite conscious attempts by the patient (45), may result from involvement of the PMA (117) or SSMA in either the dominant or the nondominant hemisphere. Electrical cortical stimulation studies suggest that the speech arrest observed in cases of SSMA stimulation represents a negative motor response (resulting from inhibition of tongue movement) (118).

EEG Findings

The ability of scalp EEG to detect interictal activity depends on the extent of the irritative zone and the orientation of the dipole. Special techniques may be required to demonstrate epileptiform activity in patients with focal seizures. Sleep recordings, for example, have been reported to increase the yield of interictal epileptiform abnormalities (119–121). Special electrodes (such as sphenoidal, anterior temporal, or ear electrodes) and closely spaced additional scalp electrodes (Fig. 11.9A) may help to distinguish temporal from frontal foci and determine whether the electrical field of a midline sharp wave is higher over the left or right hemisphere (122–124).

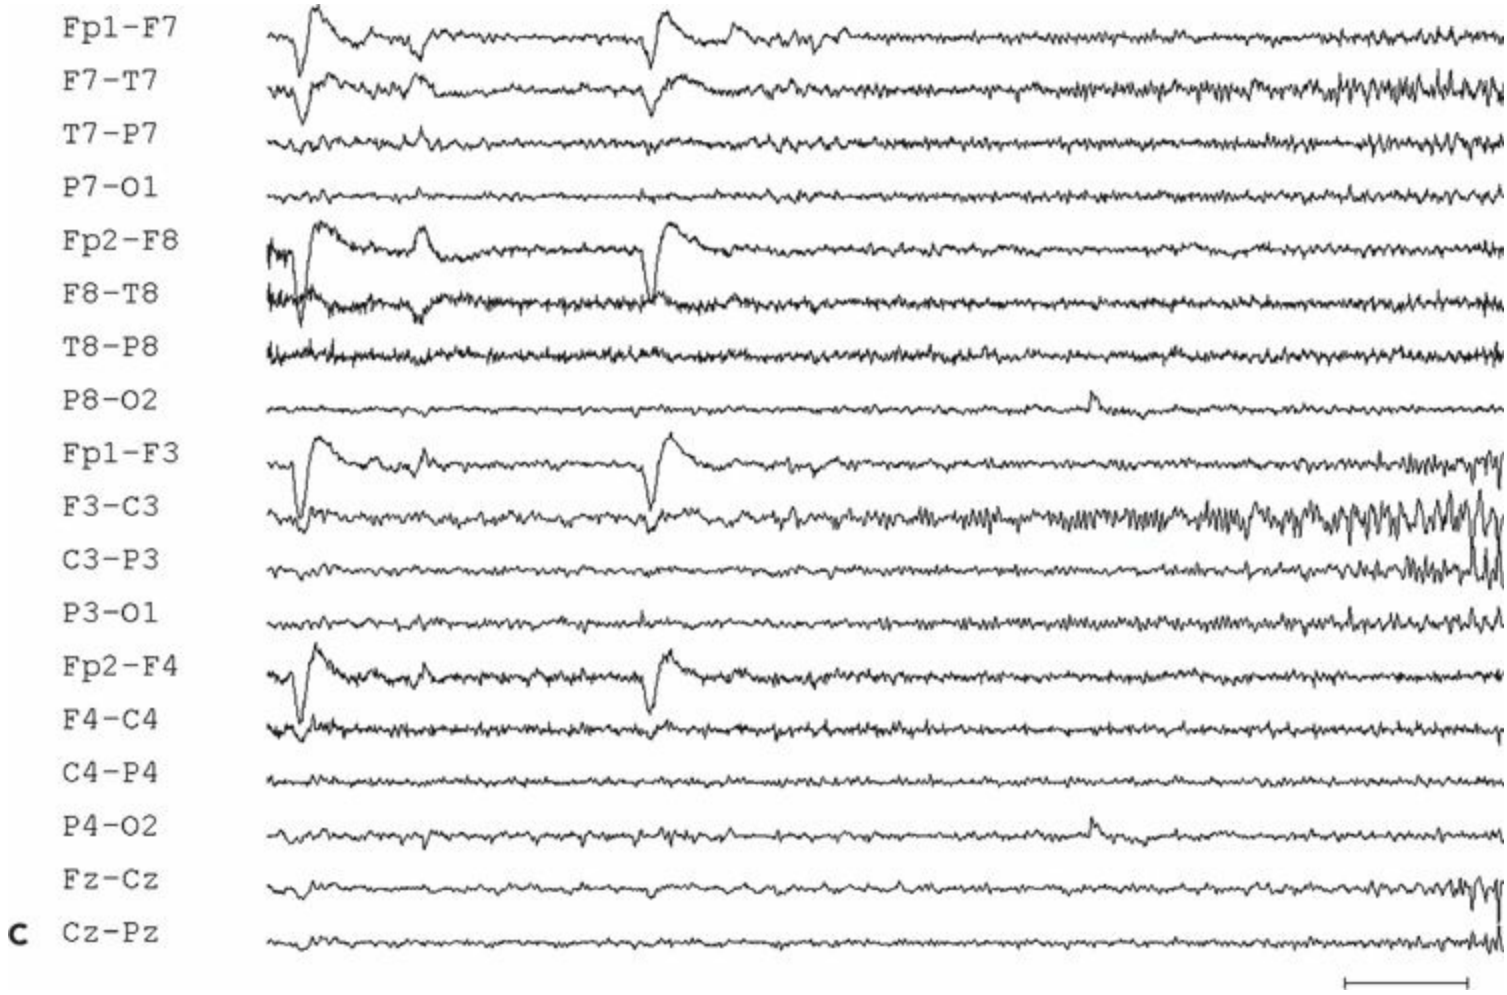

Figure 11.9. Scalp-EEG tracings (**A**, **B**, and **C**) from a 41-year-old patient with intractable left perirolandic epilepsy of unknown etiology since age 11 years. He presented with daily focal motor seizures involving the right leg and shoulder sometimes preceded by a somatosensory aura (tingling sensation in the right foot) and rare secondarily generalized tonic–clonic seizures. **A:**Interictal left centroparietal sharp wave as seen on a longitudinal bipolar (upper part) and referential montage (lower part). The P8 reference derivation of the sharp wave shows maximum negativity at electrode CP3. The addition of closely spaced surface electrodes (placed according to the 10–10 electrode placement system) provides for a more accurate distribution map. In this instance, the potential amplitude at electrode C5 is 85% and at electrodes C3 and CP3 is 83% of the amplitude recorded at the maximally involved electrode CP3. **B:** Periodic epileptiform discharge-like (PLED-like) pattern of left centroparietal sharp waves and polyspikes. This interictal finding was present during the first 24 hours of admission for acute exacerbation of his habitual focal motor seizures. **C:**The ictal onset is punctuated by the appearance of evolving low- to high-amplitude paroxysmal fast activity arising from the left centroparietal region.

Small epileptogenic foci may be entirely missed with interictal (and even ictal) surface EEG recordings (see Fig. 11.8). On the other hand, interictal epileptiform abnormalities may have a misleadingly widespread appearance because of the large distance and intervening cortical area that separates the epileptogenic zone from the scalp EEG electrodes (125).

Random EEG tracings in patients with focal epilepsy may not show evidence of focal epileptiform activity. In a case series of 19 patients with refractory frontal lobe epilepsy, Salanova and associates reported absence of interictal sharp waves in 7 of 19 (37%) patients (126). Secondary bilaterally synchronous discharges may be seen in up to two-thirds of patients with frontal lobe epilepsy (127). EEG interpretation should take into account the possibility of "secondary bilateral synchrony," a term introduced by Tükel and Jasper to describe the bilateral discharges seen in patients with parasagittal epileptogenic lesions (128).

Ictal recordings may show regional seizure patterns (Fig. 11.9C) or may have limited localizing or lateralizing value. As a rule, the patterns are more widespread and more difficult to lateralize compared with those seen with seizures of temporal lobe origin. Studies show that ictal EEG may be

nonlocalizing in more than half of patients with frontal lobe epilepsy (126,129). False localization may occur with an erroneous temporal ictal pattern on surface EEG as a result of underlying frontolimbic connections (125).

Particular EEG patterns may sometimes be seen in relationship to the corresponding seizure type: generalized tonic seizures, for example, may be associated with ictal EEG activity, which consists of repetitive rhythmic spiking of variable frequency (8 to 25 Hz, or faster) and amplitude (130). More recently, investigators have been able to ascertain the presence of gamma rhythms in the frequency range of 50 to 100 Hz associated with generalized tonic seizures during scalp EEG recordings in patients with Lennox–Gastaut syndrome (131).

Invasive recordings using subdural electrodes in frontal lobe epilepsies may only show evidence for a focal onset in a relatively small number of patients; often, a more diffuse "regional" pattern may be seen (126,132). This, of course, depends on the nature, location, extent, and connectivity of the underlying epileptogenic substrate and its relationship to the recording electrodes. In a careful invasive study of patients presenting with circumscribed focal clonic seizures, investigators observed that these seizures were always associated with a localized polyspike-and-wave intracranial ictal EEG pattern involving the subdural electrodes overlying the PMA, while neighboring subdural electrodes not overlying the precentral gyrus showed various other ictal patterns (133). Such ictal patterns associated with focal clonic seizures may occasionally be discernible by scalp EEG recordings.

EPILEPSIA PARTIALIS CONTINUA

Status epilepticus can be broadly divided into status epilepticus with motor or without motor phenomena (134). Subcategories of motor status epilepticus include generalized and secondarily generalized status, as well as focal motor status epilepticus. The latter is characterized by repetitive typical somatomotor seizures with or without jacksonian march originating from the perirolandic region. This condition may occur at the onset or during the course of epilepsies manifesting with focal motor seizures. Consciousness is usually preserved, and cerebral function of the uninvolved cortex remains intact. A variety of motor phenomena may be observed in the context of focal motor status ranging from overt to more subtle motor manifestations, such as epileptic nystagmus, for example, which may be seen in patients with oculoclonic status epilepticus (135,136).

Epilepsia partialis continua of Kojevnikov (EPC or partial continuous epilepsy) constitutes one form of focal motor status epilepticus, characterized by localized unremitting myoclonus. The condition was first described by Kojevnikov in 1895 as a disorder of persistent localized motor seizures (137). In published literature, EPC has been referred to as "Kojevnikov," "Kojewnikow," or "Kozhevnikov" syndrome.

Clinical Semiology

EPC has been regarded by some as "the semiologic epitome of a focal seizure" (138), as it usually involves a restricted area of the motor cortex of one hemisphere and presents with clinically localized motor manifestations. EPC is defined by the occurrence of almost continuous and rhythmic or semirhythmic muscular contractions (myoclonic jerks) that remain localized to a limited area on one side of the body and persist for hours, days, or even years (139,140). The definition has undergone several revisions in the past, reflecting differences of opinion among various authors. In

1989, the ILAE Commission defined EPC as a specific form of continuous somatomotor seizures involving the Rolandic cortex (141). Any muscle group may be involved, but distal musculature is more commonly affected. The myoclonic jerks may appear isolated or in clusters, with a regular or irregular occurrence at a frequency of 1 to 2 per second. In general, unilateral involvement with synchronous activation of agonists and antagonists is observed. The jerks are predominantly seen involving the muscles of the upper half of the body. In a study of 151 patients presenting with EPC, the authors observed that during its course, the disease involved the head in 16% of patients, the head and upper limb in 14%, the upper limb only in 40%, the trunk in 5%, the lower extremity in 14%, and the whole side of the body in 11% (142).

By definition, the jerks are spontaneous, although they may be aggravated by physical activity, psychic exertion, and/or sensory stimuli (143). In most cases, the jerks may be reduced in amplitude but persist during sleep (144,145). Other seizure types (such as jacksonian or generalized seizures) and a variety of neurologic deficits may be seen in these patients depending on the underlying etiology.

The pathophysiology of EPC is not well understood. It has been postulated that the absence of seizure propagation is associated with the specific anatomical location of the epileptic focus within a neocortical area of sufficiently preserved inhibition. Virtually, all authors today agree that involvement of the PMA is indispensable for the generation and sustainment of EPC (146). Bancaud and coworkers divided EPC into two broad categories based on the presence (type 2) or absence (type 1) of a progressive brain lesion (139): Type 1 was associated with a regional nonprogressive lesion in the sensorimotor cortex, whereas type 2 was typically seen in the setting of Rasmussen syndrome.

EPC may develop at any age. The usual etiology of EPC is a focal lesion involving the cortex (principally the sensorimotor cortex) that results from stroke, trauma, infection, metastasis, or primary tumor. A hypoxic, metabolic, or septic encephalopathy may predispose patients with a preexisting focal lesion to develop EPC. All patients presenting with EPC should be carefully evaluated for an underlying lesion that may be amenable to curative resective surgery. In one series, EPC was caused by a variety of different pathologens, including inflammatory and immune-mediated (52%), metabolic (13.7%), structural brain abnormalities (11.8%), cryptogenic (7.8%), vascular (5.9%), dual (5.9%), and postoperative (2%) causes (147). EPC is, of course, a common manifestation of Rasmussen syndrome (seen in almost 50% of cases) (148). Despite its focal expression, EPC in Rasmussen syndrome may be associated with MRI and EEG evidence of more diffuse hemispheric abnormalities. In the UK series of 36 patients from ages 1 to 84 years, who presented with EPC over the period of 1 year, the commonest isolated etiology was Rasmussen syndrome in seven (19%; five were children), followed by stroke in five (14%). In seven patients, the cause of their presentation remained undetermined (140). EPC and its variants have also been reported in the setting of multiple sclerosis (149), human immunodeficiency virus infection (150,151), Creutzfeldt–Jakob disease (152), and other neurodegenerative diseases such as mitochondrial disorders (153,154) or Alpers syndrome (155).

Focal motor seizures or EPC, or both, may be the presenting feature of nonketotic hyperglycemia or may occur as a later complication, especially in the presence of an underlying focal cerebral lesion (156). Hyperglycemia, hyponatremia, mild hyperosmolarity, and lack of ketoacidosis were found to contribute to the development of EPC predominantly in areas of preexisting focal cerebral damage in 21 patients with evidence of nonketotic hyperglycemia (157). One should note, however, that EPC has also been reported in the setting of ketotic hyperglycemia (140,158). Depending on the etiology,

EPC may be an early or late feature in the course of the underlying disease and may be seen either in isolation or in association with other seizure types (159). Similar to EPC, focal somatomotor status may reflect an underlying focal brain lesion (secondary to a vascular, neoplastic, traumatic, or infectious etiology) or may present in the context of toxic–metabolic abnormalities. In patients without preexisting epilepsy, the onset of focal motor status may signify underlying "asymptomatic" ischemia or interterritorial cerebral infarction (infarction in watershed territories).

Subcortical or spinal myoclonus and certain forms of tremor and other extrapyramidal movement disorders should be considered in the differential diagnosis of EPC. Clinical differentiation is often challenging, and special neurophysiologic examinations may be necessary (159,160).

EEG Findings

The conventional scalp EEG may be unrevealing or misleadingly normal. There may be very few or no paroxysmal abnormalities; and the background rhythm may be normal. In some cases, time-locked EEG events preceding the EPC-associated myoclonic jerks can be detected by back averaging. In addition, special stereoencephalographic or electrocorticographic recordings may prove helpful in resolving the underlying spike focus.

In other cases, irregular 0.5- to 3-Hz slowing may be seen in the frontocentral region along with reduction of the beta activity in the same area (45), but there are no characteristic EEG findings to aid in the diagnosis of EPC. In a study of 32 cases, the most common EEG finding was regional spiking (144). Other abnormalities included bursts of sharp waves or spike-and-wave discharges and unilateral or bilateral runs of abnormal rhythms. In a study of 21 adults presenting with EPC, the authors found EEGs to be abnormal in all but one patient. Each patient underwent at least two EEGs in the course of the disease; consequently more than one pattern was seen in some patients. The most common EEG finding was the presence of unilateral lateralized and/or localized spike or sharp wave discharges in ten patients (48%). Other lateralized abnormalities ranged from periodic lateralized epileptiform discharges (PLEDs) in three, paroxysmal slow-wave activity in two, and lateralized continuous slow activity in four patients. Four patients exhibited diffuse, continuous slow activity, one showed paroxysmal generalized slow-wave activity, and one patient had periodic generalized epileptiform discharges (161). In this study, only seven patients (33%) were found to have epileptiform discharges during EPC that correlated to the myoclonic jerks.

On rare occasions, PLEDs and PLED-like patterns that are time locked to the jerks are observed in the course of EPC (162). PLEDs are commonly viewed as a transient interictal pattern (see Fig. 11.9B), which usually disappears within a few days, but may last as long as 3 months or longer (163). PLEDs can occur in a variety of structural and metabolic disorders usually of acute or subacute nature (164,165). It is important to note that depending on the clinical scenario, there are occasions when PLEDs in fact represent an ictal EEG pattern (166). Furthermore, one should not overlook the common occurrence of seizures in association to the presence of PLEDs on EEG recordings—seizures have been reported to occur with a frequency ranging from 58% to 100% in some studies (164). The most common seizure type seen in the presence of PLEDs is focal motor seizures affecting the contralateral body (167), often presenting as status epilepticus or as repetitive focal motor seizures (164,167,168).

In Rasmussen encephalitis, it is important to identify and document MRI evidence of progressive atrophy, which usually involves only one hemisphere. An abnormal EEG with progressive regional or lateralized slowing and ipsilateral regional or multiregional spiking is the rule. In a case report of an

11-year-old girl with Rasmussen syndrome, and a 5-month history of EPC, fluorodeoxyglucose positron emission tomography (FDG-PET) studies demonstrated an area of hypermetabolism in the right central cortex and ipsilateral thalamus. A congruent sharp wave focus was present in the same region on scalp EEG recordings. Using simultaneously recorded EMG of the left tibialis anterior muscle, the authors demonstrated regular jerks, time locked with the right central sharp waves (169). With time, the EEG abnormalities of Rasmussen encephalitis may become bilateral or more widespread, multiregional, or synchronous suggesting progression of a more diffuse process than indicated by the clinical manifestation of EPC.

SUPPLEMENTARY SENSORIMOTOR SEIZURES

Clinical Semiology

Seizures arising from the SSMA are of brief duration, usually lasting only 10 to 40 seconds. Rapid onset of asymmetric tonic posturing involving one or more extremities is characteristically observed (52,170). While it is common for both sides of the body to be affected simultaneously, unilateral tonic motor activity may occur (171). The typical seizure is frequently referred to as a bilateral asymmetric tonic seizure.

Speech arrest and vocalization are common. Somatosensory symptoms, such as numbness, tingling, or pressure sensation, may precede the phase of tonic posturing (41); these body sensations are not well localized in contradistinction to somatosensory symptoms that result from epileptic activation of the postcentral gyrus (172). Common descriptions include a feeling of tension, pulling, or heaviness in an extremity or a sense that the extremity is "about to move" (173). In addition, the sensation of either an urge to perform a movement or an anticipation that some movement is about to occur has been reported in response to electrical stimulation (62). Although consciousness is usually preserved, patients may not be able to respond verbally during the tonic phase. Toward the end of the seizure, a few rhythmic clonic movements of the extremities may be observed (173). Postictal confusion is absent in the majority of SSMA seizures.

Asymmetric involvement of the upper extremities usually manifests with abduction at the shoulders, flexion of one elbow, and extension of the other upper extremity. As a rule, the lower extremities are also involved in the tonic posturing, with abduction at the hips and flexion or extension at the knees (52). Even patients, in whom tonic posturing appears to be unilateral, have bilaterally increased (or decreased) tone (34).

In their original report and illustrations of "somatic sensory seizures" arising from the SSMA, Penfield and Jasper (41) described head turning to the side of the flexed upper extremity. They observed that the head and eyes appear as if looking toward the flexed and raised arm with the patient adopting the so-called fencing posture—a motor response reminiscent of the asymmetric tonic neck reflex (34). Ajmone-Marsan and Ralston (174) subsequently coined the term "M2e" to describe the abduction and elevation of the contralateral arm with external rotation at the shoulder and slight flexion at the elbow. The patient's head and eyes deviate as if looking at the raised arm, while both lower extremities remain extended or slightly flexed at the hips and knees.

In contrast to these early reports, further analysis of SSMA seizures showed that assumption of the classic "fencing" or "M2e" posture is not common (103,175). Among the less common motor manifestations, coarse movements of the tonic postured extremities may be observed (176). If present,

vocalization may be prominent during the tonic phase reflecting the tonic involvement of the diaphragm and laryngeal muscles, which contract against semiclosed vocal cords (173).

Ictal activity may spread to involve the PMA of the face on the dorsolateral convexity, resulting in unilateral clonic movements or contralateral head version. Secondary generalization may lead to a generalized tonic–clonic seizure. Clonic movements can be seen toward the end of the tonic seizure (173). Unusual hyperkinetic automatisms (involving the ipsilateral upper extremity) have been described with seizures involving the SSMA (177). Finally, writhing movements may be seen as some patients attempt to move around or sit up during the tonic seizure.

SSMA seizures may be frequent (up to 5 to 10 per day) and can occur in clusters. They tend to occur predominantly during sleep (172,178). In a systematic review of their relationship with sleep, almost two-thirds of a total of 322 SSMA seizures in 24 patients occurred during sleep, almost exclusively during non–rapid eye movement (NREM) sleep stages I and II—as demonstrated by video–EEG recordings (179).

It should be emphasized that only a minority of patients with seizures displaying the clinical features of SSMA activation ("SSMA seizures") actually have "SSMA epilepsy" (180). In most cases, the SSMA functions as the symptomatogenic zone: the observed seizures reflect the expression of ictal discharges originating from clinically silent regions that have anatomical or functional proximity to the SSMA, such as the basal frontal regions, the dorsolateral convexity of the frontal lobe, and the mesial parietal regions (52). This important point is illustrated by a recent stereo-EEG study of 14 patients with intractable focal epilepsy presenting with SSMA seizure semiology. Invasive EEG recordings showed evidence of seizure origin within the SSMA region in only six (43%) patients. The eight remaining patients were found to have diffuse unilateral or bilateral seizure onset. The authors concluded that SSMA semiology is suggestive of early involvement of this region, but is by no means a reliable indicator that the SSMA itself contains the seizure focus (181). Consequently, the SSMA itself may not need to be sacrificed in patients presenting with intractable SSMA seizures. Moreover, unless the location of the epileptogenic focus/generator has been carefully defined, resection of the SSMA may not be associated with a favorable postoperative outcome (182). Furthermore, the clinical picture of SSMA seizures with involvement of all four extremities and simultaneous preservation of awareness may be misleading, and it is not unusual for patients with this type of paroxysmal activity to be misdiagnosed as having psychogenic nonepileptic seizures (116). Of note, stereo-EEG (SEEG) studies now also suggest involvement of the SMA in startle seizures. Three patients with startle seizures became seizure free after epilepsy surgery in the SMA (183). In these patients resection was guided by SEEG suggesting prominent but not exclusive involvement of the SMA in startle seizures (183).

EEG Findings

Interictal sharp waves, when present, are usually found at the midline, maximum at the vertex, or just adjacent to the midline in the frontocentral region (Fig. 11.10A). Only 50% of 16 patients with supplementary sensorimotor seizures, who underwent evaluation with subdural electrodes, had shown scalp EEG evidence of midline frontocentral interictal epileptiform activity (184).

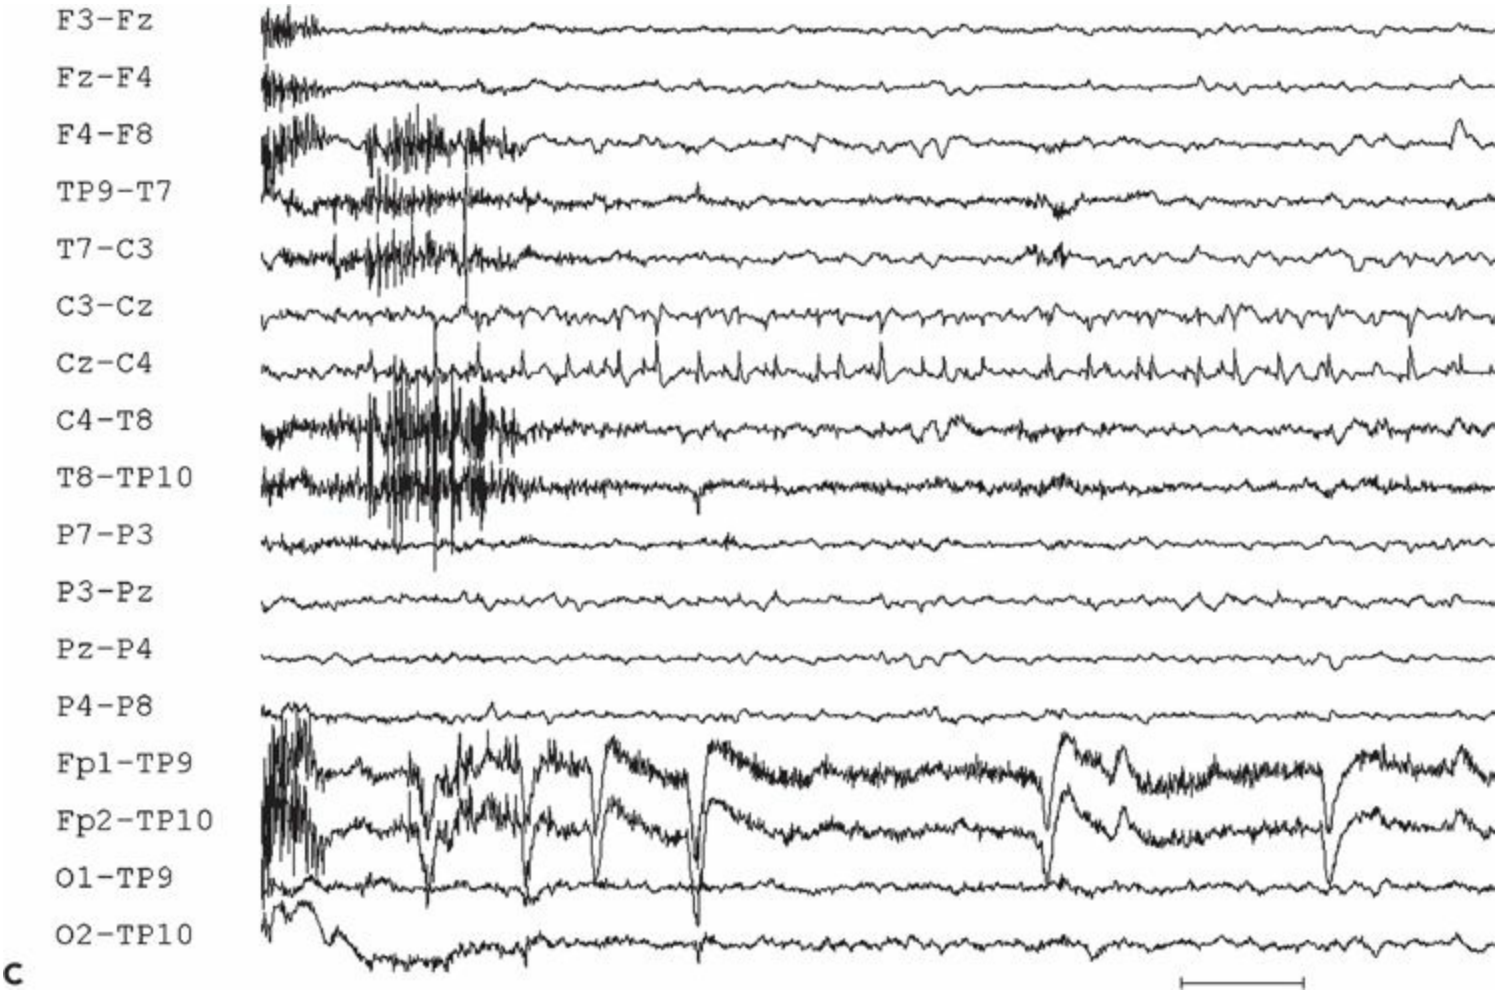

Figure 11.10. Interictal (**A**) and ictal (**B** and **C**) scalp electroencephalogram tracings with a transverse bipolar montage from a 12-year-old girl with left SSMA epilepsy. Bilateral asymmetric tonic seizures arising from sleep and wakefulness were captured during video–electroencephalograph evaluation. **A:**This awake recording shows sharp waves at the vertex (virtually confined to the Cz electrode). Note that the potential amplitude is slightly higher on the left (C3) than on the right (C4) central electrode. **B:**Clinical onset of typical seizure occurring out of sleep coincides with the appearance of bilateral myogenic artifact. Scalp EEG does not reveal a clear ictal pattern at the time of clinical onset. **C:** Rhythmic, repetitive sharp waves are present at the vertex within 15 seconds of clinical onset.

It is important to distinguish midline interictal epileptiform discharges from vertex sharp transients of sleep. This distinction may not be possible, when sharp waves are seen only during sleep. The presence of prominent after-going slow waves, occurrence of polyspikes, and/or consistently asymmetric distribution of the electrical field may raise the suspicion of epileptiform activity (184,185). In general, normal sleep-related transients display a symmetric field pattern, whereas midline sharp waves may be asymmetric. Appearance of the same midline sharp waves or spikes during wakefulness (see Fig. 11.10A) will lead to the correct diagnosis of underlying epilepsy.

During seizures originating from the SSMA (Fig. 11.10B), the EEG is frequently obscured by prominent EMG artifact owing to the associated tonic activity and the midline location of the ictal EEG discharges. However, careful review of the vertex region with the appropriate (usually transverse bipolar) montage and use of closely spaced parasagittal scalp electrodes may reveal the ictal EEG pattern despite considerable EMG artifact. Frequently, an initial high-amplitude slow transient or sharp wave may be seen at the vertex followed by midline low-amplitude fast activity or an electrodecremental pattern (173,185). These early changes are often followed by the development of high-amplitude rhythmic slowing distributed bilaterally in the frontocentral regions. Ictal activity

may remain restricted to the vertex (Fig. 11.10C) or have a more widespread distribution. In general, the lateralizing value of such ictal EEG changes is rather limited. Moreover, paradoxical, erroneous scalp-EEG lateralization is possible, when the generator of sharp waves is situated in the interhemispheric fissure producing a transverse or oblique dipole orientation (186). Lastly, a small percentage of patients with SSMA seizures will have no identifiable scalp EEG change during the ictus.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of focal motor seizures includes nonepileptic myoclonus (187) or tonic spasms (188,189), psychogenic nonepileptic seizures, complex motor stereotypies/tics (190), and other paroxysmal movement disorders such as paroxysmal choreoathetosis (191) and tremor (192).

As mentioned, the absence of abnormalities on outpatient EEGs does not exclude the possibility of focal motor seizures. When available, home videotape recordings can provide valuable diagnostic information by capturing the episodes in question. Otherwise, prolonged inpatient video–EEG monitoring may be necessary. Patients who present with infrequent attacks of unclear etiology pose considerable diagnostic challenges, given the low diagnostic yield of prolonged EEG recordings. Ambulatory EEGs are not particularly helpful in this setting, especially if no ictal EEG patterns are seen during the paroxysmal behavior.

Seizures arising from the frontal lobe can be bizarre (such as seizures characterized by prominent thrashing movements and preserved consciousness) and may be misdiagnosed as nonepileptic seizures of psychogenic origin. The reverse can also be true. Saygi et al. (193) compared the ictal manifestations of 63 frontal lobe seizures in 11 patients with the clinical features of 29 psychogenic seizures in 12 patients. The authors did not find any single clinical criterion that would sufficiently differentiate these two groups. Seizure characteristics favoring an epileptic diagnosis included younger age at onset, stereotyped patterns of movements, turning to a prone position during seizures, shorter duration of seizures, nocturnal occurrence, and the presence of MRI and EEG abnormalities. In another study, which only compared the clinical features of SSMA and nonepileptic seizures, the duration of SSMA seizures was much shorter than that of psychogenic events (116). None of the SSMA seizures lasted longer than 38 seconds, whereas psychogenic seizures had a mean duration of 173 seconds. In addition, SSMA seizures occurred predominantly out of sleep, whereas psychogenic seizures usually occurred from the waking state.

Epileptic motor seizures may manifest themselves at any time of the day or night. However, a number of epilepsy syndromes (including SSMA epilepsy, frontal lobe epilepsy, benign focal epilepsy of childhood, generalized epilepsy, and autosomal dominant nocturnal frontal lobe epilepsy [ADNFLE]) tend to manifest with seizures occurring predominantly during sleep. In addition, sleep-related paroxysmal motor phenomena can be seen with various sleep disorders (including NREM arousal disorders, REM behavior disorder of sleep, and sleep–wake transition disorder). The differential diagnosis of such nocturnal paroxysmal events is broad and often challenging, given the frequently poor clinical description and overlap of clinical manifestations (194).

It is not understood why certain seizure types occur preferentially during sleep (195). In a study of patients with intractable focal epilepsy, continuous video EEG and polysomnography were used to compare sleeping–waking distribution of seizures and quality of sleep organization in 15 patients with frontal lobe epilepsy and 15 patients with temporal lobe epilepsy (196). The authors demonstrated that seizures of frontal lobe origin occurred more frequently during the night compared

with seizures arising from the temporal lobe in this group of patients with pharmacoresistant epilepsy.

More recently, ADNFLE has been identified as a distinctive clinical syndrome (197,198). The disorder is characterized by clusters of brief nocturnal motor seizures with hyperkinetic or tonic manifestations. Stereotyped attacks are frequently seen in individual family members despite the significant intrafamilial variation. Interictal EEGs are frequently normal, and the diagnosis is established on a clinical basis. Seizures usually begin in childhood and may persist throughout life, although the overall seizure frequency tends to decrease over time (197). A strong linkage with the neuronal nicotinic acetylcholine receptor has been established in the years following initial description of this syndrome (199,200).

Several case reports highlight the unusual occurrence of repetitive involuntary movements in the setting of transient cerebral ischemia (the so-called limb-shaking transient ischemic attacks or "limb-shaking TIAs") that may be mistaken for focal motor seizures (201–203). These episodic attacks are often precipitated by standing up or walking and seem to involve only the limbs (hand–arm alone or hand–arm and ipsilateral leg) without spreading to the facial or truncal musculature (201,204). The need to recognize these paroxysmal positive motor manifestations as a sign of severe contralateral carotid occlusive disease is emphasized (201,202).

CHAPTER 12 FOCAL SEIZURES WITH IMPAIRED CONSCIOUSNESS

LARA JEHI AND PRAKASH KOTAGAL

Awareness and responsiveness are the two sides of the coin characterizing a clinically applicable definition of consciousness as proposed by the International Classification of Epileptic Seizures (ICES) (1). These two concepts are intimately related, but it is important to recognize that they are essentially distinct: while consciousness as a whole is clearly impaired in epilepsy patients, who are completely unresponsive during their spells and are later amnestic of their events, the question is a bit more controversial in other cases. For example, we know now that up to 10% of patients with right temporal lobe epilepsies may be fully responsive and interactive during focal seizures associated with automatisms and yet not be able postictally to recall any of the events that occurred during the seizure (2,3). Conversely, some patients may not obey any commands during a seizure but do recall when interviewed postictally all the commands and instructions given during the ictus. This may be seen with several possible scenarios including ictal aphasia, inability to perform voluntary movements secondary to stimulation of negative motor areas, or diversion of attention by a hallucinated experience (4). These examples illustrate the conceptual complexity of assessing consciousness in relation to epileptic seizures and highlight the practical importance of a thorough seizure and postseizure interview while patients are being evaluated in epilepsy clinics and video-EEG monitoring units. Recently, some epilepsy centers have even proposed the use of a standardized "consciousness inventory" to assess the level and content of ictal consciousness (5,6). For the purposes of this chapter, we used the term "focal epilepsy with impaired consciousness" to refer to focal epilepsies where either responsiveness or awareness/recall is disturbed during the ictal period.

Another issue that needs to be spelled out prior to proceeding with this discussion of epilepsy and consciousness would be a clear definition and distinction of the following terms: "complex partial seizure," "dialeptic seizure," and "automotor seizure." The ICES defined "complex partial" as any seizure consisting of a lapse of consciousness and minimum motor activity if the ictal EEG shows focal epileptiform activity. A seizure with exactly the same symptomatology or "semiology" would be classified as an "absence seizure" if the ictal EEG shows generalized spike–wave complexes. The terms complex partial and absence referred therefore to electroclinical complexes where both clinical semiology and knowledge of the ictal EEG patterns—information that is not necessarily always available in an initial outpatient evaluation—are required for an accurate definition. Furthermore, the broad umbrella of "complex partial" seizures encompassed various seizure types that have little in common, except a focal onset. For example, partial seizures arising from the perirolandic region or supplementary motor area may involve impairment of consciousness but are very different from complex partial seizures arising from the mesial temporal lobe with an aura of déjà vu, staring, unresponsiveness, and stereotyped oroalimentary and hand automatisms. These issues lead to the proposition of a five-tier classification system that distinguishes the seizure characteristics (including semiologic features and frequency) of a given patient from the epilepsy

characteristics (including etiology, associated neurologic deficits, and location of the epilepsy, as determined through various diagnostic modalities including EEG and imaging) (7). In this semiologic classification, a seizure is defined solely based on its clinical characteristics. A "dialeptic" (from the Greek word "dialeptin" meaning "to stand still," "to interrupt," or "to pass out") seizure is one with impairment of consciousness as the predominant feature. An "automotor" seizure would be one with predominant automatisms regardless of whether consciousness was impaired or not.

More recently, the International League Against Epilepsy's (ILAE) Commission on Classification and Terminology has eliminated the distinction between "complex partial" and "simple partial" seizures, retaining a single classification of "focal seizures." In this framework, impaired consciousness is equated with other seizure descriptors in its value for performing an accurate seizure characterization and classification (8). This proposal has been controversial as many value the traditional and historical implications of the term "complex partial" seizure (9–12). In this chapter, we use the general term of focal seizures with impaired consciousness, as well as the more specific terms of dialeptic and automotor seizures when a distinction between the two is needed.

In the following sections, we first provide a brief historical overview and briefly discuss features that allow differentiation of focal from generalized seizures causing an impairment of awareness. Then, we focus on characterizing the localizing value of focal seizures with impaired consciousness and discuss lateralizing features that may help in further defining the epileptogenic focus. We then describe typical electroencephalographic findings and conclude with a section on the proposed mechanisms of impaired consciousness in partial epilepsy.

HISTORICAL BACKGROUND

Although descriptions of seizures with loss of consciousness and automatisms suggesting focal origin date to the days of Hippocrates, Galen, and Areatus. Hughlings Jackson first suggested their origin in the temporal lobe and called them "uncinate fits" (13). The introduction of the EEG in 1929 made it possible to identify the characteristic interictal and ictal features of these seizures. In 1937, Gibbs and Lennox proposed the term "psychomotor epilepsy" to describe a characteristic EEG pattern of temporal lobe seizures accompanied by mental, emotional, motor, and autonomic phenomena (14). Gibbs, Gibbs, and Lennox also noted interictal sharp waves in the temporal regions in patients with this seizure type. Penfield and Kristiansen (15) and Penfield and Jasper (16) observed that some patients with seizures and loss of consciousness had extratemporal sharp waves. Jasper et al. first pointed out that the localization of the EEG ictal discharge was more important than its actual pattern and that this pattern originated from "deep within the temporal lobes, near the midline" (17).

The early work of investigators at the Montreal Neurological Institute in Canada and in Paris, France, contributed immensely to our understanding of various types of epilepsy, including temporal and extratemporal, and used information from multiple techniques: scalp recordings, invasive recordings from depth electrodes and intraoperative corticography, and cortical stimulation studies (15,16,18,19). Ajmone-Marsan et al. (20–22) used chemical activation with pentylenetetrazol to study partial seizures from various locations. The Paris group (23) published a number of papers on frontal lobe epilepsy. Tharp (24) was the first to identify seizures with loss of consciousness arising from the orbitofrontal regions.

Early work on the symptomatology of focal seizures with impaired consciousness was based on eyewitness descriptions by family members, nurses, or physicians (18,22). Some studies employed cine film and analyzed photographs taken at 3 per second (20). The introduction of videotape

technology provided an inexpensive and effective way to easily record and play back seizures as often as needed, resulting in a better grasp of phenomenology. The observations of Delgado-Escueta, Theodore, Williamson, Quesney, Bancaud, and others vastly improved our understanding of focal seizures with impaired consciousness (25–30). Crucial insights were provided by Gastaut, who proposed the first ICES in 1970 (31).

In his 1983 monograph, Electroclinical Features of the Psychomotor Seizure, Wieser (32) described the order of symptom onsets and symptom clusters and attempted to correlate these clusters with electrographic activity recorded with depth electrodes. Maldonado et al. (33) also examined the sequences of symptoms in hippocampal–amygdalar–onset seizures. Using methods similar to those of Wieser, Kotagal examined temporal lobe psychomotor seizures in patients who were seizure free after temporal lobectomy (34). Similar methods also have been used to study frontal lobe seizures (35,36).

FOCAL VERSUS GENERALIZED SEIZURES WITH IMPAIRMENT OF CONSCIOUSNESS

Focal seizures with impairment of consciousness can present with or without an aura. The auras last from a few seconds to as long as 1 to 2 minutes before consciousness is actually lost. Impairment of consciousness is maximal initially. Partial recovery later in the seizure may allow the patient to look at an observer walking into the room or interact in some other way with the environment (34). Most of these seizures with automatisms last longer than 30 seconds—up to 1 to 2 minutes (sometimes as long as 10 minutes). Very few are briefer than 10 seconds, which helps to distinguish them clinically from typical absence seizures characterized by 3-Hz spike–wave complexes (29).

Blinking has been described more often in generalized absence as opposed to focal seizures with impaired consciousness. Automotor activity is not restricted to focal seizures, and subtle automatisms may be seen in typical absence (generalized) epilepsy (1). So, a clear distinction between dialeptic seizures seen in the setting of frontal or temporal lobe epilepsy from those in absence epilepsy may not be possible without obtaining an electrophysiologic confirmation and recording an ictal EEG (1).

LOCALIZING VALUE OF FOCAL SEIZURES WITH IMPAIRMENT OF CONSCIOUSNESS

Research during the past two decades has advanced our understanding of the symptomatology of focal seizures with impairment of consciousness arising from various locations (28,34). Most of these seizures arise in the temporal lobe; however, in at least 10% to 30% of patients evaluated in epilepsy surgery programs, the origin is extratemporal and most commonly in the frontal lobe (1).

Escueta et al. (29), described three types of complex partial seizures. Type I (24% to 30% of mesial temporal lobe seizures) begins with a motionless stare or behavioral arrest (phase 1) quickly followed by a period of unresponsiveness and stereotyped automatisms (phase 2) evolving to a final phase of a “clouded state” and semipurposeful reactive automatisms. Type II events are uncommon and similar to type I events except that phase I is absent. Type III complex partial seizures, previously called temporal lobe syncope, begin with a drop attack, followed by confusion, amnesia, and gradual return of composure (29). The localizing value of the motionless stare was believed to indicate mesial temporal lobe epilepsy (29). However, behavioral arrest is also seen in 20% of patients with

frontal lobe epilepsy (37). Types II and III are thought to be of extratemporal origin (38,39).

Different components of consciousness may be impaired depending on the location of the ictal seizure pattern. Frontal lobe seizures are more likely to manifest with loss of orientation behavior and expressive speech; left temporal lobe seizures lead to impairments of memory and expressive and receptive speech; and right temporal lobe seizures rarely involve impairment of consciousness (39).

Seizures of Frontal Lobe Origin

Seizures arising from the frontal lobes occur in up to 30% of patients with focal epilepsy and represent the second most common focal type after temporal lobe seizures (26). In 50% of patients with frontal lobe epilepsy, seizures are accompanied by loss of consciousness. Seizures with loss of consciousness can arise from various locations within the frontal lobe (except from the rolandic strip) (24,35,36,40). Semiologic features include occurrence in clusters, occurrence many times a day, occurrence for brief duration (lasting about 30 seconds with a sudden onset), and minimal postictal confusion. Bizarre attacks with prominent motor automatisms involving the lower extremities (pedaling or bicycling movements), sexual automatisms, and prominent vocalizations are common, and the seizures are remarkably stereotyped for each patient (35,36,38). Identification of seizure onset within the frontal lobe by semiology alone and differentiation of mesial temporal lobe epilepsy and frontal lobe epilepsy may be misleading and difficult; however, analysis of the earliest signs and symptoms, as well as their order of appearance, may allow this distinction in onset (35). Clonic seizures frequently arise from the frontal convexity, tonic seizures from the supplementary motor area, and automotor seizures from the orbitofrontal region (41). Seizures with "motor agitation" and hypermotor features are more likely to arise from the orbitofrontal and frontopolar regions, as opposed to seizures with oroalimentary automatisms, gesturing, fumbling, and looking around, which are more suggestive of a temporal lobe focus (35). In a surgical series of patients with intractable frontal lobe epilepsy, 14 of 26 patients had history of complex partial status epilepticus (41).

The unique symptomatology of supplementary motor seizures includes an onset with abrupt tonic extension of the limbs that is often bilateral but may be asymmetric and is accompanied by nonpurposeful movements of uninvolved limbs and vocalizations. Typically, these occur out of sleep and recur many times a night. Because of their bizarre symptomatology, they are sometimes mistaken for nonepileptic seizures. Consciousness is often preserved in supplementary motor area seizures, and postictally, baseline mentation returns quickly.

Cingulate gyrus seizures may also vary in semiology. Seizures arising from the anterior portion of the cingulate present with predominantly motor manifestations such as bilateral asymmetric tonic seizures, hypermotor seizures, and complex motor seizures, while posterior cingulate cortex epilepsies tend to predominantly have alterations of consciousness (dialeptic seizures) and automatisms of the distal portions of the limbs (automotor seizures) as the main clinical manifestations.

Orbitofrontal seizures manifest prominent autonomic phenomena, with flushing, mydriasis, vocalizations, and automatisms. The vocalizations may consist of unintelligible screaming or loud expletives of words or short sentences. Patients also may get up and run around the room.

Quesney et al. (30) reported that seizures of the anterolateral dorsal convexity may manifest with auras such as dizziness, epigastric sensation, or fear in 50% of patients; behavioral arrest in 20%; and speech arrest in 30%. One-third of the patients exhibited sniffing, chewing or swallowing, laughing, crying, hand automatisms, or kicking. A tendency to partial motor activity in the form of

tonic or clonic movements contralateral to the side of the focus was also noted. Bancaud et al. described speech arrest, visual hallucinations, illusions, and forced thinking in some patients during seizures of dorsolateral frontal origin. These patients may also show contralateral tonic eye and head deviation or asymmetric tonic posturing of the limbs before contralateral clonic activity or secondary generalization. Other patients may have autonomic symptoms such as pallor, flushing, tachycardia, mydriasis, or apnea (26).

Seizures of Temporal Lobe Origin

Approximately 40% to 80% of patients with temporal lobe epilepsy have seizures with stereotyped automatisms. In fact, seizures with predominantly oral and manual automatisms in addition to few other motor manifestations (excluding focal clonic activity and version) are highly suggestive of a temporal lobe origin (28–30,34). Secondary generalization occurs in approximately 60% of temporal lobe seizures (34). Postictally, gradual recovery follows several minutes of confusion; however, patients may carry out automatic behavior, such as getting up, walking about, or running, of which they have no memory. Attempts to restrain them may only aggravate matters. Violence, invariably nondirected, may be seen during this period. The patient is usually amnestic for the seizure but may be able to recall the aura. A few patients may exhibit retrograde amnesia for several minutes before the seizure.

In young children, focal seizures of temporal lobe onset are characterized predominantly by behavioral arrest with unresponsiveness (42); automatisms are usually oroalimentary, whereas discrete manual and gestural automatisms tend to occur in children older than age 5 or 6 years. In younger children, symmetric motor phenomena of the limbs, postures similar to frontal lobe seizures in adults, and head nodding as in infantile spasms were typical (43). Because it is impossible to test for consciousness in infants, focal seizures with impairment of consciousness may manifest as hypomotor seizures with none or only few automatisms. In very young infants, these may also occasionally be accompanied by central apnea (44).

Seizures of Parietal Lobe Origin

Like seizures of occipital lobe onset, focal seizures from the parietal lobe may manifest with loss of consciousness and automatisms when they spread to involve the temporal lobe. Initial sensorimotor phenomena may point to onset in the parietal lobe, as do vestibular hallucinations such as vertigo, described in seizures beginning near the angular gyrus. Language dysfunction may occur in seizures arising from the dominant hemisphere. Also described in parietal lobe complex partial seizures have been auras including epigastric sensations, formed visual hallucinations, behavioral arrest, and panic attacks (45,46). In a study of 40 patients with parietal lobe epilepsy as established by standard presurgical evaluation, including MRI, fluorodeoxyglucose–positron emission tomography, ictal single-photon emission tomography (SPECT), and scalp video-EEG monitoring, with additional intracranial EEG monitoring in selected cases, 27 patients experienced at least one type of aura. The most common auras were somatosensory (13 patients), followed by affective, vertiginous, and visual auras. Seizures had diverse manifestations. Eighteen patients showed simple motor seizure, followed by automotor seizure and dialeptic seizure (46).

A limiting factor in many studies of seizure symptomatology is that relatively few reported patients with extratemporal focal seizures with impaired consciousness become seizure free after

cortical resection, casting some doubt on the localization of the epileptic focus.

Seizures of Occipital Lobe Origin

The following features suggest the occipital lobe as the origin of a focal seizure with impaired consciousness: (i) Visual auras, usually of elementary sensations such as white or colored flashing lights, are often in the part of the visual field corresponding to the focus; the visual phenomena may remain stationary or move across the visual field. (ii) Ictal blindness in the form of a whiteout or blackout may be reported. (iii) Version of the eyes and head to the opposite side is common and is a reliable lateralizing sign; patients may report a sensation of eye pulling to the opposite side even in the absence of eye deviation. (iv) Rapid, forced blinking and oculoclonic activity also may be seen (47–49). Other symptoms may result from spread to the temporal or parietal lobes (49). Suprasylvian spread to the mesial or parietal cortex produces symptomatology similar to that in supplementary motor seizures, whereas spread to the lateral parietal convexity gives rise to sensorimotor phenomena. Spread to the lateral temporal cortex followed by involvement of the mesial structures may produce formed visual hallucinations, followed by automatisms and loss of consciousness. Direct spread to the mesial temporal cortex may mimic mesial temporal epilepsy. The visual auras may be the only clue to recognizing the occipital lobe onset of these seizures; however, the patient may not recall them because of retrograde amnesia if the aura was fleeting or if the seizure is no longer preceded by the aura as it was in the past (47).

In a study of 42 patients with occipital lobe epilepsy, 73% experienced visual auras frequently followed by loss of consciousness possibly as a consequence of ictal spread into the frontotemporal region. Vomiting is more common in benign than in symptomatic occipital lobe seizures and may also represent ictal spread to the temporal lobes (50).

Seizures of Insular Lobe Origin

The insula, also called the “fifth lobe” of the brain, lying under the frontal, parietal, and temporal opercula and covered by middle cerebral artery branches and corresponding veins. Seizures arising from the insula can masquerade as frontal, temporal, or parietal lobe seizures. Seizures arising from the mesial temporal lobe and orbitofrontal cortex often spread to the insula and vice versa. Electrical stimulation of the anterior insular produces viscerosensitive phenomena, whereas posterior insular stimulation results in somatosensory or auditory phenomena (51). Insular origin is suspected when seizures begin with viscerosensitive phenomena (nausea, vomiting, changes in gastric motility, salivation, or gustatory symptoms), motor symptoms (sense of throat constriction, early motor manifestation including tonic, hypermotor, or generalized tonic–clonic movements), and/or sensory phenomena (numbness, tightness, vibration, pain, receptive aphasia, auditory, or vertiginous symptoms) (52,53).

In the absence of a insular lesion seen on MRI, functional imaging (PET, SPECT), and magnetoencephalography, intracranial monitoring is needed for confirming the localization. This is typically done using stereotactically placed depth (SEEG) electrodes. If localization is confirmed, focal resection may be offered, though there is some risk of postoperative deficits such as dysphasia or paresis due to the proximity to blood vessels in this region.

LATERALIZING FEATURES ASSOCIATED WITH

FOCAL SEIZURES WITH IMPAIRED CONSCIOUSNESS

The focal seizures with impaired consciousness and automatisms—or automotor seizures—are the commonest type of seizures observed in video-EEG monitoring units. The number of clinical symptoms per seizure and the duration of the seizures are usually higher than in other motor seizures, especially when observed in relation to temporal lobe epilepsy, allowing for a rich spectrum of lateralizing semiologic findings (54). The following section reviews some of the most salient lateralizing signs potentially seen in this context.

Dystonic Limb Posturing

Unilateral dystonic posturing defined as forced, unnatural, unilateral (or predominantly unilateral) posturing of an arm or leg—in flexion or extension, proximal or distal, or usually with a rotatory component—is probably the most reliable lateralizing sign in temporal lobe automotor seizures (54–56). It could be easily distinguished from tonic posturing, in which there is only extension or flexion without accompanying rotation or assumption of unnatural postures. It occurs contralateral to the epileptogenic zone in about 90% of temporal and extratemporal seizures. When occurring in conjunction with unilateral automatisms of the opposite limb and head turning, it also has an excellent localizing value suggesting a mesial temporal lobe onset (54). It likely reflects direct or indirect basal ganglion activation, in addition to widespread subcortical and cortical involvement of different neural networks, as suggested by associated PET and SPECT changes and invasive EEG recordings (54–57).

Head Version

Classically, a versive head movement is defined as a tonic, unnatural, and forced lateral gyratory head movement, as opposed to head turning or deviation where more natural and unforced head gyratory movements occur. While the lateralizing value of simple head turning or deviation is questionable at best, classical head version strongly lateralizes the seizure onset to the contralateral side in >90% of the cases, especially when it occurs with conjugate eye version and shortly precedes secondary generalization (within <10 seconds) (54,56,58). It occurs in both temporal (about 35% of cases) and extratemporal (20% to 60%) seizures and may be caused by seizure spread to the premotor areas (Brodmann areas 6 and 8) (54).

A careful evaluation of the ictal head movements is also important in determining the lateralizing value of "whole body" versive activity, or gyratory seizures (GSs) defined as a rotation around the body axis during a seizure for at least 180 degrees. In a video-EEG series (59), this occurred more often in frontal lobe epilepsy (4/47 patients) versus temporal lobe epilepsy (8/169 patients). The direction of rotation lateralized seizure onset depending on the seizure evolution: (i) GSs starting with a forced version of the head ensuing into a body rotation lateralized seizure onset zone contralateral to the direction of rotation. (ii) In GSs without a preceding gyratory forced head version, the direction of rotation was toward the side of seizure onset.

Postictal Todd Palsy

Although the occurrence of postictal hemiparesis (Todd palsy) is a very rare occurrence (<1% of seizures), it is a very reliable lateralizing sign suggesting an epileptogenic focus in the contralateral hemisphere. It has, however, also been described in generalized epilepsies and after seizures without focal motor features or secondary generalization (60).

Automatisms

The broad term of "automatisms" refers to stereotyped complex behavior seen during seizures. Gastaut and Broughton (61) listed five subclasses of automatisms: alimentary, mimetic, gestural, ambulatory, and verbal. This list does not include stereotyped bicycling or pedaling movements or sexual automatisms.

Oroalimentary automatisms such as lip smacking, chewing, swallowing, and other tongue movements tend to occur early in the seizure, often with hand automatisms, and may be elicited by electrical stimulation of the amygdala (26). They may occur without loss of consciousness in temporal lobe seizures when the ictal discharge is confined to the amygdala and anterior hippocampus (2). A complex automatism such as singing has been described (62). As such, oroalimentary automatisms have no lateralizing value. Preserved responsiveness during automatisms does, however, lateralize to the nondominant hemisphere: while most automatisms are usually accompanied by impaired consciousness and subsequent amnesia, Ebner et al. (2) found that 10% of patients with right temporal lobe epilepsy had automatisms with preservation of consciousness; this was never observed in those with left temporal lobe epilepsy. Other researchers have made similar observations (54).

Hand automatisms, also referred to as simple discrete movements by Maldonado et al. (33) or bimanual automatisms, are rapid, repetitive, pill-rolling movements of the fingers or fumbling, grasping movements in which the patient may pull at sheets and manipulate any object within reach. Searching movements may also be seen. Some authors believed that unilateral automatisms had a lateralizing value (54). In our experience, they did not, unless accompanied by tonic/dystonic posturing in the opposite limb. In these patients, the seizures may begin with bilateral hand automatisms that are interrupted by dystonic posturing on one side while the automatisms continue on the other side (ipsilateral to the ictal discharge) (55) (Table 12.1).

Table 12.1 Frequency and Reliability of Various Lateralizing Signs Seen in Focal Seizures with Impaired Consciousness

Sign	Frequency	Lateralizing value
Postictal palsy (50)	<1% of patients	Contralateral in 100% of patients
Unilateral dystonic limb posturing (45,47,53)	15%–70% of FLE or TLE patients	Contralateral in >90% of the cases
Head version (29,48)	35% of TLE patients, 20%–60% of FLE patients	Contralateral in >90% of the cases
Unilateral tonic posturing (46)	15%–20% of TLE patients, 50% of FLE patients	Contralateral in 40%–90% of the cases
Unilateral immobile limb (46)	5%–28% of TLE patients	Contralateral in most cases
Unilateral eye blinking (54)	0.8%–1.5% of patients	Ipsilateral in 80% of patients
Postictal nose wiping (55)	50%–85% of mesial TLE patients, 10%–33% of FLE patients	Ipsilateral in 70%–90% of TLE patients, nonlateralizing in FLE patients

FLE, frontal lobe epilepsy; TLE, temporal lobe epilepsy

Like oroalimentary automatisms, the hand automatisms suggest onset from the mesial temporal

region. In extratemporal seizures with unilateral tonic posturing, thrashing to-and-fro movements, which are more proximal and not discrete, are sometimes seen in the opposite limb.

Eye blinking or fluttering may be observed. Although usually symmetric, unilateral blinking has been reported ipsilateral to the seizure focus (63). A mechanism similar to unilateral hand automatisms may be operative, but this has not been documented. Rapid, forced eye blinking when the seizure begins is thought to indicate occipital lobe onset (63). Seizures arising from the occipital region may produce version of the eyes to the opposite side (54).

Truncal or body movements may be seen, usually in the middle or late third of the seizure, when the patient attempts to sit up, turn over, or get out of bed (34).

Bicycling or pedaling movements of the legs are more commonly observed in focal seizures with impaired consciousness arising from the mesial frontal and orbitofrontal regions (30) than in temporal lobe seizures. They are sometimes seen in temporal lobe seizures but probably reflect spread of the ictal discharge to the mesial frontal cortex.

Mimetic automatisms, with changes in facial expression, grimacing, smiling, or pouting, are common in focal seizures with impaired consciousness (54). Crying has been noted in focal seizures with impaired consciousness arising from the nondominant temporal lobe (54).

Sexual or genital automatisms such as pelvic or truncal thrusting, masturbatory activity, or grabbing or fondling of the genitals are relatively uncommon during focal seizures with impaired consciousness. However, they have been reported in focal seizures with impaired consciousness of frontal lobe origin, as well as in those arising from the temporal lobes (54). Leutmezer et al. (64) postulate that discrete genital automatisms such as fondling or grabbing the genitals are seen in temporal lobe seizures, whereas hypermotoric sexual automatisms such as pelvic or truncal thrusting usually occur in frontal lobe seizures.

So, in summary, although various types of automatisms may have a useful localizing value, it is mainly unilateral distal limb automatisms with contralateral dystonia that is useful as a lateralizing sign.

Postictal Nose Wiping

Nose wiping or rubbing that occurs within 60 seconds of the seizure end has good localizing and lateralizing value: it occurs in 50% to 85% of temporal lobe epilepsy patients but in only 10% to 33% of extratemporal epilepsy patients. It is performed with the hand ipsilateral to the epileptogenic focus in 75% to 90% of the cases when seen in the context of a temporal lobe automotor seizure but has no lateralizing value when seen with an extratemporal seizure. Postulated mechanisms leading to its occurrence include ictal activation of the amygdala with subsequent olfactory hallucinations, or increased nasal secretions, and postictal contralateral hand movement abnormalities or neglect (54,65).

ELECTROENCEPHALOGRAPHIC FINDINGS

Interictal Electroencephalography

Most focal seizures with impaired consciousness and automatisms arise from the anterior temporal regions of one side or the other. Temporal intermittent rhythmic delta activity is found in up to 28% of patients evaluated for temporal lobe epilepsy as opposed to only 0.3% of the general population and

is therefore felt to be significantly predictive of temporal lobe epilepsy. Bitemporal sharp-wave foci are noted in 25% to 33% of patients and may be independent or synchronous. Mesial temporal spikes may not be well seen at the surface, and intermittent rhythmic slowing may be the only clue to deep-seated spikes (66). On a single routine EEG recording, 30% to 40% of patients may have normal interictal findings; activating techniques can reduce this to approximately 10% (67).

At the scalp, the field of mesial temporal spikes is often maximal at the anterior temporal electrodes (T_1 or T_2, FT_9 or FT_{10}). When nasopharyngeal or sphenoidal electrodes are used (especially in prolonged monitoring), the amplitude of the spike is usually maximal at these electrodes, consistent with their origin in the amygdalar–hippocampal region (Fig. 12.1).

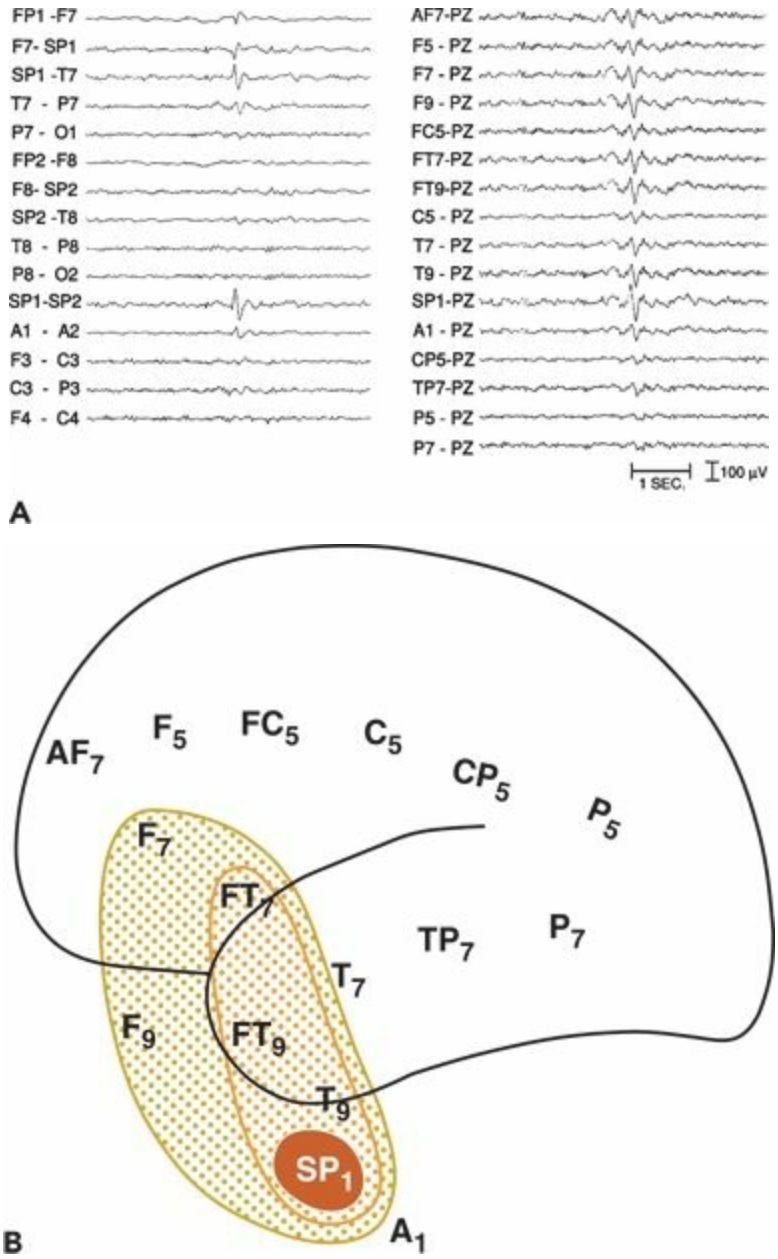

Figure 12.1. Left mesial temporal lobe. Interictal sharp-wave focus **(left)**. **A** and **B:**Distribution of the field of an interictal spike from a patient with temporal lobe epilepsy. The spike amplitude is maximal at SP_1 (measured on referential recordings); >90% at T_9, FT_9, and FT_7 electrodes; and >70% at F_7 and F_9.

Less frequently, sharp-wave foci are seen in the midtemporal or posterior temporal region. Interictal foci may be mapped according to amplitude, and the relative frequency of various sharp-wave foci may be taken into account during monitoring of epilepsy surgery candidates. A fair degree

of correlation is present between the predominant spike focus and side of ictal onset [63% in Wieser et al. (68) series of 133 patients]. Hyperventilation may activate focal temporal slowing or spikes and may provoke a clinical seizure.

In 10% to 30% of patients with focal seizures with impaired consciousness, an extratemporal focus is seen, usually in the frontal lobes (Fig. 12.2). In some patients with mesial frontal foci, the interictal discharge may take the form of a bifrontal spike-and-wave discharge.

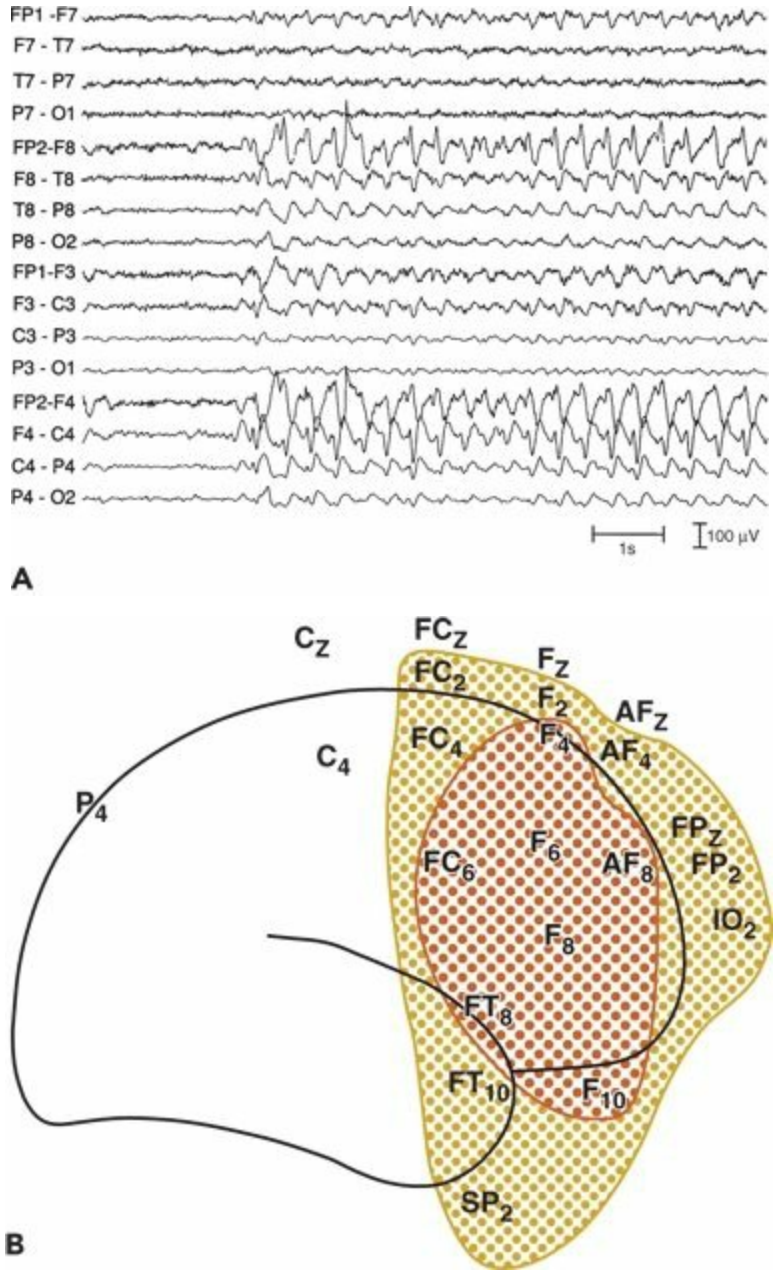

Figure 12.2. Run of focal spike-and-wave discharge in the right frontal lobe with no clinical signs **(left)** and right frontal lobe, interictal spikes **(right)**. **A** and **B:**Distribution of the field of interictal spikes occurring in runs from a patient with frontal lobe complex partial seizures. The field is widespread, involving most of the right frontal convexity.

Care should be taken to exclude nonepileptiform sharp transients such as benign epileptiform transients of sleep or small sharp spikes, wicket spikes, and 14- and 6-Hz spikes. Evidence suggests that when benign epileptiform transients of sleep occur in epileptic individuals, they do so frequently and in runs (69). Transients resembling benign epileptiform transients of sleep sometimes are found to be maximal at the sphenoidal electrode; such discharges should be interpreted cautiously.

Ictal Electroencephalography

Although interictal EEGs may show normal findings in some patients with focal seizures with impaired consciousness, ictal changes are seen in 95% of patients (except during isolated auras) (70). In frontal lobe seizures from the mesial frontal or orbitofrontal cortex, ictal and interictal activities may not be reflected at the surface or are often masked by electromyographic and movement artifacts (Fig. 12.3).

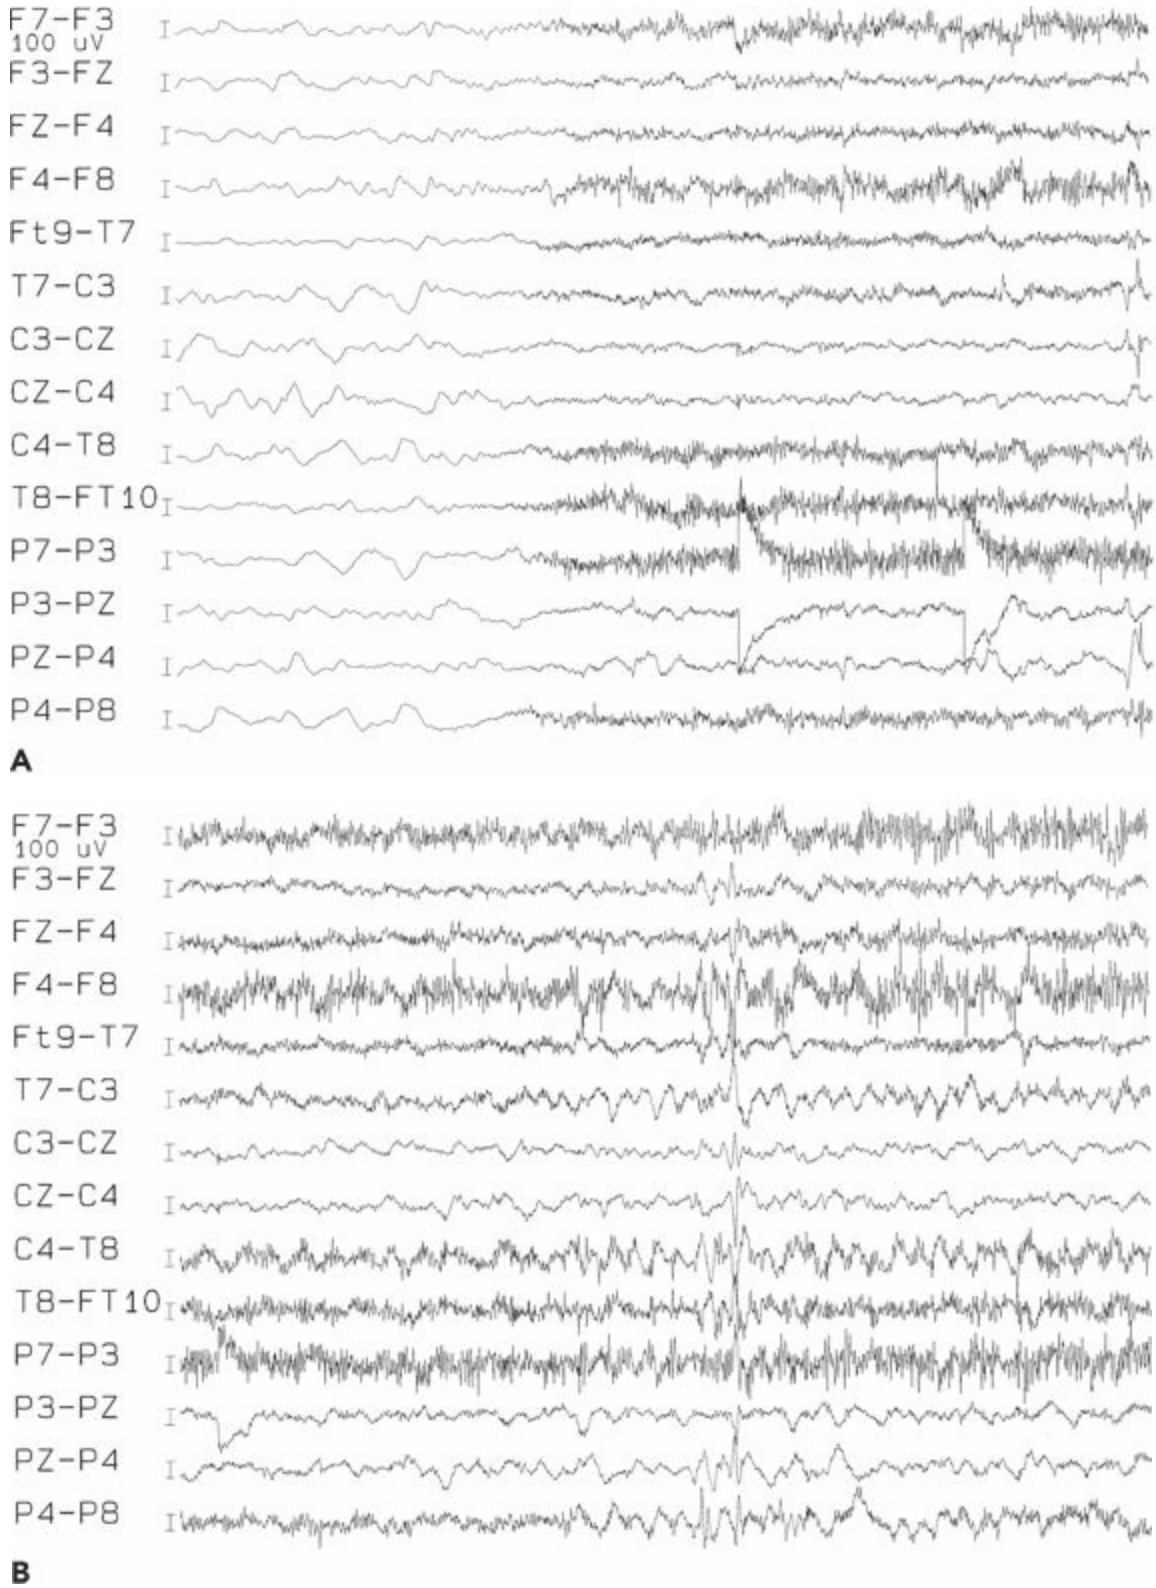

Figure 12.3. A and **B:** Ictal onset of a frontal lobe complex partial seizure arising out of sleep, beginning with low-amplitude fast rhythms, followed by rhythmic slowing near the vertex. The electroencephalographic seizure pattern cannot be lateralized.

An electrodecremental pattern is seen at the onset of a focal seizure with impaired consciousness in about two-thirds of patients. It is usually quite diffuse (perhaps owing to an associated arousal); if focal or accompanied by low-voltage fast activity, it has lateralizing significance. The low-voltage fast activity, best seen with depth electrodes, may appear only as flattening at the surface. Alternatively, diffuse bitemporal slowing, higher on one side, may occur (70,71).

Approximately 50% to 70% of patients with temporal lobe epilepsy exhibit a so-called prototype pattern (71) consisting of a 5- to 7-Hz rhythmic θ discharge in the temporal regions, maximum at the sphenoidal electrode (Fig. 12.4). This pattern may appear as the first visible EEG change or follow diffuse or lateralized slowing in the δ range (often within 30 seconds of clinical onset). Depth electrode studies have shown this pattern to have 80% accuracy in localizing the onset to the ipsilateral mesial temporal structures (72). Postictal slowing is also helpful in lateralization. In patients with unitemporal interictal spikes, the lateralizing value of the ictal data was excellent (70). Seizure rhythms at ictal onset confined to the sphenoidal electrode are often seen in patients with mesial temporal lobe epilepsy as opposed to those with non–temporal lobe epilepsy. Use of coronal transverse montages incorporating the sphenoidal electrodes may permit earlier identification of seizure onset (70).

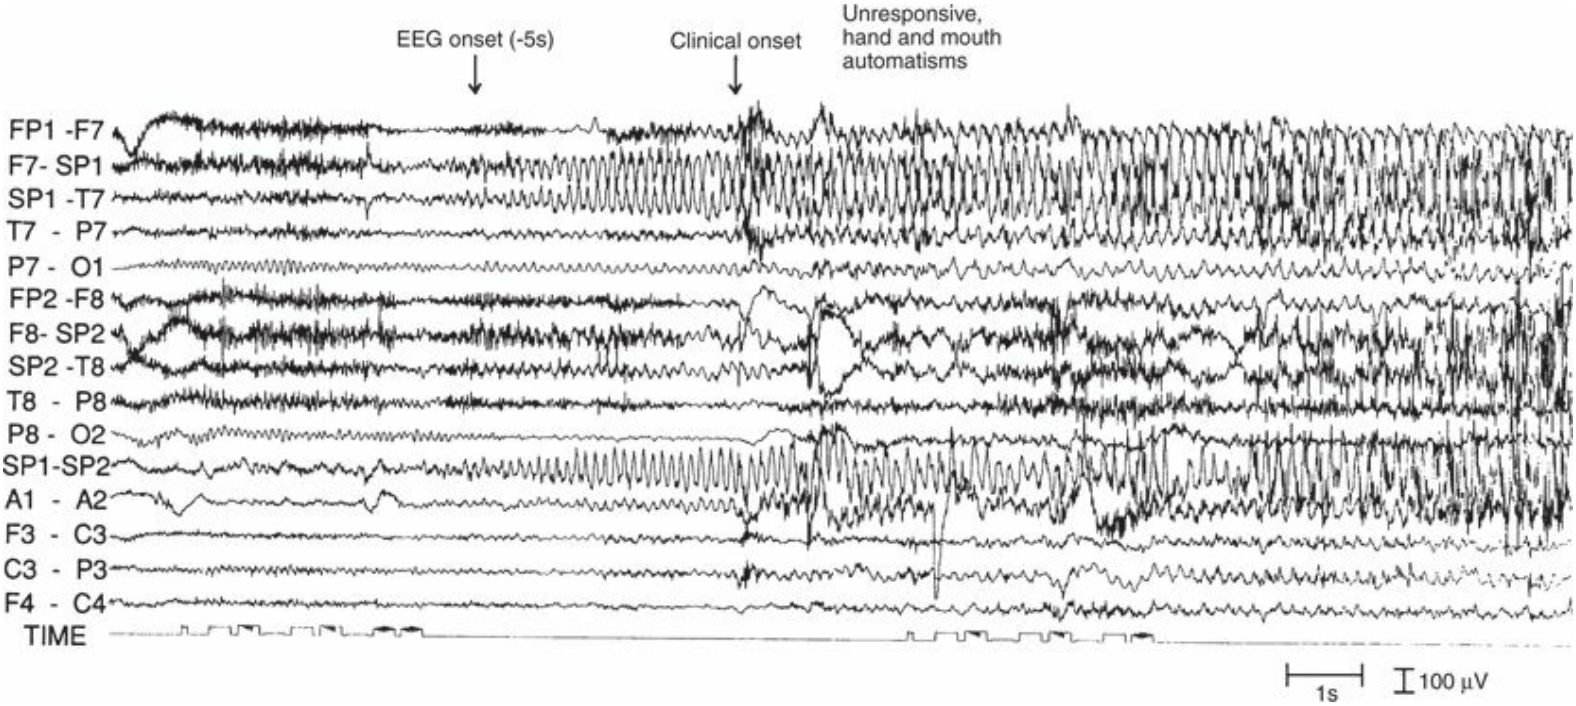

Figure 12.4. Ictal onset of a complex partial seizure (same patient as in Fig. 12.1). A brief electrodecremental response in the left temporal region is followed by the buildup of a rhythmic 5- and 6-Hz theta pattern, maximal at the left sphenoidal electrode. The electroencephalographic changes preceded the clinical onset by 5 seconds.

Although previous reports described false lateralization on the basis of scalp EEG, subsequent systematic studies have shown this to be infrequent except in the presence of a structural lesion that may mask or attenuate the amplitude of the ictal discharge on that side (70). Although lateralization from scalp EEG is usually satisfactory, localization within a lobe is sometimes incorrect, because seizures from an extratemporal site may spread to the temporal lobe and produce similar EEG patterns. The ictal discharge may then propagate to the rest of the hemisphere, or it may propagate bilaterally. Spread to the opposite temporal lobe is common. With some frontal lobe seizures, scalp ictal changes are difficult to appreciate because of electromyographic and movement artifacts. Occasionally, a generalized spike-and-wave discharge with a mesial frontal focus is seen (70).

PATHOPHYSIOLOGY OF IMPAIRED CONSCIOUSNESS IN FOCAL SEIZURES

Gloor believed in 1986 that while a "satisfactory explanation of consciousness . . . may never be possible . . . there are, however, aspects of conscious experience such as perception, cognition, memory, affect, and voluntary motility that are open to neurobiologic research" (4). Since that time, and because of multiple "neurobiologic research" attempts, significant advances have been made in the understanding of altered consciousness in the setting of focal seizures, and various mechanisms have been proposed.

Epileptic Activation of Subcortical Structures, Mainly the Thalamus and Upper Brainstem

Close connections exist between the prefrontal cortex and the nonspecific thalamic nucleus and the midline region of the intralaminar thalamic complex. Since epileptiform discharges arising from various regions within the frontal lobe—including the intermediate frontal region, orbitofrontal region, and cingulate gyrus—may elicit dialeptic seizures, and generalized discharges can be seen with epileptic activation of the mesial frontal lobe (secondary bilateral synchrony), it has been proposed that rapid epileptic spread from all of those frontal regions to the reticular formation is actually responsible for the impaired consciousness observed in frontal lobe epilepsy (1).

In temporal lobe epilepsy, a similar mechanism with additional spread to the upper brainstem structures has been suggested based on ictal SPECT perfusion studies (73) and supported by intracranial recordings demonstrating the more prominent occurrence of bilateral frontoparietal slow waves in seizures with impaired consciousness as opposed to "simple partial" seizures (74). The complete loss of consciousness seen in generalized seizures has been attributed to the involvement of both cortical and subcortical structures with epileptic activity (75). As such, the bilateral involvement of the thalamus and upper brainstem occurring early in generalized epilepsy or as a late spread phenomenon from the mesial temporal structures can selectively impair the frontoparietal association cortices and default mode networks, leading to loss of awareness (76).

Epileptic Activation of the Limbic System

Invasive EEG recordings have shown that ictal discharges in the mesial temporal lobes may be associated with the dialeptic symptomatology (1). In a recent study of 134 patients with focal seizures with impaired consciousness, Heo et al. found that interictal epileptiform discharges (IEDs) localized primarily to the temporal region and were more frequently detected in patients who were unaware of their seizures (94%) than in those who were aware (55%). Bilateral independent IEDs were found more frequently in the unawareness group than in the awareness group (48% vs. 13%). The bilateral presence of lesions was also more frequent in the unawareness group than in the awareness group (16.1% vs. 4.9%). The authors concluded that complete loss of consciousness was caused by rapid spread of ictal discharges to the contralateral hemisphere in association with bilateral independent IEDs and bilateral presence of lesions (77).

Epileptic Disturbance of the Normal Balance Between Excitation and Inhibition of Various Cortical/Subcortical Networks

Some authors suggest that arrest of activity during a seizure may be the result of either interference with the normal activity of the primary motor cortex or epileptic activation of the negative motor areas during frontal lobe involvement, or both (1). Abnormal increased activity in frontoparietal association cortex and related subcortical structures is associated with loss of consciousness in generalized seizures. Abnormal decreased activity in these same networks may cause loss of consciousness in focal seizures with impaired consciousness. Thus, abnormally increased or decreased activity in the same networks can cause loss of consciousness. Information flow during normal conscious processing may require a dynamic balance between these two extremes of excitation and inhibition (78,79).

CHAPTER 13 AUTONOMIC SEIZURES, AUTONOMIC EFFECTS OF SEIZURES, AND SUDEP

BRIAN D. MOSELEY AND ELAINE C. WIRRELL

INTRODUCTION

Autonomic changes are frequently seen in both focal and generalized seizures during the preictal, ictal, and postictal phases (1–6). While all aspects of autonomic function can be affected, cardiac and pulmonary changes that may contribute to sudden unexplained death in epilepsy (SUDEP) have been most robustly explored. Ictal ECG or polygraphic recordings are crucial in detecting and further evaluating these autonomic symptoms and signs. Although intriguing, the relationship between profound cardiorespiratory symptoms and SUDEP has not been clearly established.

AUTONOMIC SEIZURES

In 2007, an international consortium proposed that an "autonomic seizure" be defined as "an epileptic seizure characterized by altered autonomic function of any type at seizure onset or in which manifestations consistent with altered autonomic function are prominent (qualitatively dominant or clinically important) even if not present at seizure onset" (7). "Autonomic status epilepticus" was defined as "an autonomic seizure that lasts more than 30 minutes or a series of such seizures over a 30-minute period without full recovery between seizures."

A diverse number of autonomic signs have been described with seizures. These are summarized in Table 13.1. There is evidence that the autonomic effects of seizures may be different in children than in adults (7,8), and autonomic ictal disturbances are very frequent in seizures in neonates and infants. The types of epilepsies associated with autonomic seizures vary somewhat based on age (Table 13.2) and need to be distinguished from nonepileptic conditions with prominent autonomic features (Table 13.3).

Table 13.1 Autonomic Signs and Symptoms That May Be Seen with Seizures

Cardiovascular changes
Palpitations/chest pain, sinus tachycardia, cardiac arrhythmias, bradycardia, asystole, chest pain, increase (or decrease) of blood pressure

Gastrointestinal
Emesis (nausea, retching, vomiting), epigastric auras, spitting, hunger, borborygmi, diarrhea; fecal incontinence

Genitourinary and sexual
Urinary incontinence, increase of intravesicular pressure, erotic feelings and genital sensations, erection, orgasm

Pupillary
Mydriasis, miosis, hippus

Respiratory
Apnea, hyperventilation, coughing, sighing, increased bronchial secretion, nocturnal acute laryngospasm, respiratory arrest, neurogenic pulmonary edema, postictal nose wiping

Thermoregulatory
Fever

Vasomotor, pilomotor, and secretory

Table 13.2 Autonomic Epilepsies Presenting at Specific Ages

Age range	Epilepsies with prominent autonomic features
Neonate/infant	*Neonatal seizures*—often prominent autonomic features (apnea, tachycardia) with minimal motor changes *Migrating partial seizures of infancy*—apnea, cyanosis, flushing, diaphoresis often with focal clonic activity *Dravet syndrome*—prolonged hemiconvulsive seizures often triggered by hyperthermia *Temporal lobe epilepsy*—staring, ictal emesis, apnea
Child	*Panayiotopoulos syndrome*—ictal emesis, tachycardia, mydriasis *Rolandic epilepsy*—ictal hypersalivation *Temporal lobe epilepsy*
Adolescent/adult	*Temporal lobe epilepsy*—staring with emesis, nausea, changes in heart rate, abdominal rising, piloerection, pupillary abnormalities
All ages	*Epilepsy associated with specific genetic conditions*—Angelman, 18q–, Rett, protocadherin 19

Table 13.3 Nonepileptic Conditions with Prominent Autonomic Features by Age Group at Presentation

Age range	Nonepileptic conditions
Neonate/infant	*Gastroesophageal reflux*—apnea, bradycardia, pallor, hypotonia
	Sandifer syndrome—dystonic posturing, flushing, bradycardia, apnea
	Breath holding—apnea, cyanosis, pallor, bradycardia
	Inborn errors of metabolism—apnea, emesis
	Familial dysautonomia—paroxysmal attacks of vomiting, increased heart rate, blood pressure, sweating, drooling, and flushing
Child	*Breath holding*
	Inborn errors of metabolism
	Infantile gratification behavior—flushing, diaphoresis, tachycardia
	Benign paroxysmal vertigo—nausea, pallor
	Cyclic vomiting syndrome—recurrent episodes of emesis, particularly nocturnal
	Parasomnia—flushing, tachycardia, diaphoresis
	Syncope—pallor, hypotension, bradycardia, diaphoresis, nausea
	Anxiety/panic attack—hyperventilation, tachycardia, hypertension, diaphoresis, nausea and vomiting
Adolescent/adult	*Syncope*
	Anxiety/panic attack
	Postural orthostatic tachycardia syndrome—tachycardia, light-headedness, pallor
All ages	*Migraine*—headache, flushing, emesis, pallor

The pathophysiology of autonomic changes with seizures most likely involves direct excitation or inhibition of the neocortical and limbic cortices involved at seizure onset and their propagation to structures that constitute the central autonomic network (1,9). This network involves an extensive neural circuitry that extends from the forebrain to the brain stem and includes the insular cortex, amygdala, hypothalamus, periaqueductal gray matter, parabrachial complex, nucleus of the tractus solitaries, and ventrolateral medulla. Through this circuitry, autonomic, visceromotor, neuroendocrine, pain, and behavioral responses are controlled. Inputs to the central autonomic network are multiple including viscerosensory inputs relayed through the nucleus of the tractus solitaries and humoral inputs relayed through the circumventricular organs. Higher-order autonomic control is mediated by the prefrontal and insular cortices and amygdala. Electrical stimulation of these regions results in various autonomic signs. Stimulation of the right anterior insular cortex is

reported to elicit tachycardia and pressor responses, whereas bradycardia and depressor responses are reported to occur with left anterior insular stimulation. Stimulation of the medial prefrontal cortex results in changes in blood pressure, heart rate, and gastrointestinal motility. The amygdala and bed nucleus of the stria terminalis are responsible for integrated autonomic and motor responses to emotion.

Children appear to be particularly vulnerable to autonomic seizures and, in particular, ictal emesis. In adults, ictal vomiting is rare and is usually seen later in a seizure once consciousness is impaired and after onset of other temporal lobe symptoms. Conversely, ictal vomiting in children is common and usually seen at seizure onset with intact consciousness and without preceding focal cortical symptoms. It has been suggested that there is a maturation-related susceptibility for the central autonomic network, with children being more vulnerable to emetic disturbances (10). Furthermore, in children, central autonomic networks may have a lower threshold to epileptogenic activation than those producing focal cortical semiology. Regardless of the localization of onset of ictal discharge, the lower threshold autonomic centers may be activated initially, with consequent autonomic manifestations. Other higher threshold cortical regions that produce focal semiology such as motor, sensory, or other symptoms are only activated later and if the ictal discharge reaches a certain threshold.

Specific Epilepsies and Seizures with Prominent Autonomic Features

Neonatal Seizures

Seizures are among the most common neurologic disorders in neonates, with an incidence of 1 to 3 per 1000 live births. Most seizures in neonates are reflective of underlying brain pathology, although the list of potential etiologies is diverse. Seizures in the newborn are usually focal and often have subtle semiology with eye deviation, staring, blinking, nystagmus, mouthing, or chewing. Autonomic features are also very common, including apnea, abnormal respiratory patterns, hiccups, tachycardia, and/or hypertension (11). Profound ictal apnea may be the only manifestation of neonatal seizures arising from either the temporal or the occipital regions (12,13), although associated heart rate changes are rare in ictal apnea (14). The cause of the frequent association between neonatal seizures and autonomic features has not been well studied; however, connections between the posterior limbic cortex, the temporal lobe, and the midbrain respiratory centers have been postulated (13).

Epilepsy of Infancy with Migrating Focal Seizures

This rare but devastating syndrome presents in three distinct phases (15). In the first few weeks to months of life, focal motor seizures, which evolve to bilateral convulsive events, occur. Autonomic features are very common and include apnea, flushing, and cyanosis. The second phase is seen between 1 and 12 months and is characterized by a marked increase in seizure frequency, often to a point where seizures are nearly continuous. Prominent ictal autonomic features persist. The EEG at this time shows the typical migrating and multifocal pattern of ictal epileptiform discharges. During the third phase, which typically is seen between 1 and 5 years of age, the frequency of seizures markedly reduces, although clusters can still occur during intercurrent illnesses. The etiology of many cases is unknown, although a variety of genetic causes have been reported, including SCN1A and

KCNT1 mutations. Therapy is challenging, with some response reported with bromides, a combination of stiripentol and clonazepam, levetiracetam, or rufinamide (16). Two patients with profound ictal apnea and bilateral temporal involvement experienced significant improvement with addition of acetazolamide (17), possibly due to either cessation of bitemporal seizures or induction of metabolic acidosis that resulted in stimulation of central chemoreceptors.

Dravet Syndrome

Dravet syndrome is a devastating epilepsy syndrome that begins in the first 18 months of life with recurrent prolonged seizures, which are intractable to medical therapy. Initial seizures are often hemiconvulsive or evolving to bilateral convulsive activity. By age 2 years, other seizure types including myoclonic jerks, absences, focal seizures, and drop attacks emerge. Focal seizures with prominent autonomic features occur in over half of patients, with pallor, cyanosis, respiratory changes, and drooling, often associated with eye deviation, myoclonus, or focal motor activity. A significant provoking factor for seizures is hyperthermia due to intercurrent illness, postimmunization fever, physical exercise, warm baths, or elevated ambient temperatures. While caregivers frequently report disturbed body temperature regulation, red or bluish hands/feet, alteration in sweating, pupillary dilation, facial or chest flushing, tachycardia at rest, or slow gastric emptying, few studies have carefully evaluated autonomic function in these children.

Approximately 80% of children have a demonstrable mutation in the SCN1A gene. The risk of SUDEP in this cohort is high, with an approximate annual incidence of 0.6% (18) . SCN1A is primarily a neuronal gene; however, several studies have shown that the product of this gene, Nav1.1, is present in the heart in several animal species. It appears important in normal activity of the sinoatrial node, control of heart rate, and heart rate variability (19). A small number of studies have suggested a relative predominance of adrenergic tone in Dravet syndrome, as evidenced by reduced heart rate variability, and P-, QT-, and QTc wave dispersion (20, 21). Such changes may predispose to an increased risk of tachyarrhythmias and possibly explain the higher risk of SUDEP, although further studies are needed.

Panayiotopoulos Syndrome

Autonomic seizures and autonomic status epilepticus are core features of Panayiotopoulos syndrome, a common electroclinical syndrome that affects preschool or early school-aged children (7). Seizures frequently arise from sleep with a collection of autonomic symptoms and mainly emesis, with or without vomiting, tachycardia, syncope-like manifestations, unilateral eye deviation, and progressive altered awareness, which may progress to hemiconvulsions.

EEG studies in children with Panayiotopoulos syndrome typically reveal multiple foci, often with an occipital predominance. Using magnetoencephalography, Saito et al. noted that younger patients had spikes in the calcarine, parietooccipital, or rolandic regions, as opposed to older children in whom frontal foci were seen (22). These results are in keeping with a maturation-related cortical hyperactivity in this syndrome, which may result in activation of the lower-threshold central autonomic network.

Benign Epilepsy with Centrotemporal Spikes

Benign epilepsy with centrotemporal spikes is the most common focal epilepsy seen in children and

typically presents with diurnal focal seizures affecting the ipsilateral lower face and occasional ipsilateral upper extremity and/or nocturnal generalized seizures. One of the characteristic clinical features is profound ictal hypersalivation, which is usually seen with ipsilateral lower facial motor activity and dysarthria. Rarely, this syndrome may present with prolonged hypersalivation and oromotor and speech disturbances suggestive of an anterior opercular syndrome.

Temporal Lobe Epilepsy

Temporal lobe epilepsy often presents with autonomic features, particularly in children. "Abdominal epilepsy" may be seen, characterized by periumbilical, colicky abdominal pain, often accompanied by headache, dizziness, syncope, temporary loss of vision, and impaired consciousness. The duration of abdominal pain is typically no longer than 15 minutes and may be associated with sweating, borborygmi, salivation, and flatus.

Rarely, profound apnea attacks may be the sole manifestation of temporal lobe epilepsy, and this is most commonly seen in preschool children and infants. However, a case of SUDEP in a 30-year-old woman with temporal lobe epilepsy, who had previously documented ictal apnea, suggests that this autonomic disturbance may be a significant risk factor for SUDEP (23). Ictal apnea appears most likely with spread of temporal lobe epilepsy to the contralateral hemisphere (24).

The most common autonomic change seen in temporal lobe epilepsy is ictal tachycardia, which is present in up to 98% of childhood temporal lobe seizures. Ictal bradycardia is less frequent, and while it may be due to activation of the left temporal and insular cortex, a careful study found that it does not have consistent lateralization but rather appears after seizure activity becomes bilateral (25). Cardiac pacing should be considered in cases of ictal asystole.

Autonomic features suggestive of specific lateralization in temporal lobe seizures include both abdominal auras with vomiting and orgasmic auras, which both lateralize to the nondominant temporal lobe. Other symptoms that are not specific to lateralization and that may also be seen with nontemporal foci include postictal cough, flushing, pallor, sweating, piloerection, mydriasis, and miosis.

Epilepsy Associated with Specific Genetic Conditions

Ictal apnea appears to be particularly common in many epilepsies due to specific genetic conditions including protocadherin 19 mutations, 18q− syndrome, 1p36 deletion syndrome, and trisomy 18. Accurate diagnosis of the underlying etiology of autonomic symptoms in these genetic disorders can be quite challenging, as many have autonomic disturbances unrelated to seizures as well. Girls with Rett syndrome typically have peripheral vasomotor disturbances and breathing dysfunction. Additionally, cardiac testing has shown an exaggerated increase in heart rate response to breath holding and prolonged QTc suggestive of cardiorespiratory dysregulation. In 18q−, breathing abnormalities including hyperventilation or apnea crises are common. Video-EEG monitoring may be needed to determine if such symptoms have epileptiform correlate.

SUDDEN UNEXPECTED DEATH IN EPILEPSY

SUDEP is the most important direct epilepsy-related cause of death. It is defined as a sudden, unexpected, witnessed or unwitnessed, nontraumatic, and nondrowning death in a patient with epilepsy. This may or may not occur in the setting of an epileptic seizure and excludes deaths

resulting from status epilepticus. If the above criteria are met and an autopsy is performed, revealing no toxicologic or anatomical cause of death, the death is termed "definite SUDEP." "Probable SUDEP" is diagnosed if the above criteria are met, but an autopsy is not performed. When no autopsy is performed, insufficient evidence relating to the cause of death exists, and SUDEP cannot be excluded, a diagnosis of "possible SUDEP" can be made.

SUDEP has an estimated incidence of 1.8 per 1000 patient-years (26). However, higher incidences (3 to 9/1000 patient-years) have been reported with intractable epilepsy (27). While SUDEP is rarer in the pediatric population, it is still estimated to be between 1 and 2 per 10,000 patient-years (28).

Based on previous studies, the most consistently identified risk factor for SUDEP is poorly controlled generalized tonic–clonic seizures (29–33). Other, less-robust risk factors include antiepileptic drug polytherapy, developmental delay/intellectual disability, nocturnal seizures, young age at seizure onset, and longer duration of epilepsy (29–33). The use of specific drugs such as carbamazepine or lamotrigine has been suggested as potential risk factor however, recent careful studies have refuted these findings (34,35).

Prevention of SUDEP should involve increased efforts to decrease the frequency of generalized tonic–clonic seizures. Furthermore, supervision at night may be associated with a decreased risk of SUDEP (29).

SUDEP AND PERI-ICTAL AUTONOMIC DYSFUNCTION

While the exact pathophysiology of SUDEP has yet to be fully elucidated, ictally mediated autonomic dysfunction is most likely responsible. Such dysfunction may involve cardiac disturbances, including peri-ictal tachycardia, bradycardia, asystole, repolarization (QTc) anomalies, and reduced heart rate variability. Potentially fatal decreases in cerebral oxygenation could also result from peri-ictal hypoxemia and respiratory suppression. Recently, the contribution of postictal generalized EEG suppression to SUDEP has been studied. Through retrospective review of electrophysiologic data from people who later died of SUDEP and prospective studies of those at greatest risk, we continue to learn more about the mechanisms responsible for sudden death.

Peri-Ictal Tachycardia

Given its high prevalence, there is great interest in the potential role of peri-ictal tachycardia in SUDEP. Peri-ictal tachycardia (often defined as a heart rate greater than the 98th percentile for age) is the most commonly observed seizure-related autonomic disturbance, occurring during and/or after a majority of recorded seizures (36). Based on stimulation of the human insular cortex, Oppenheimer et al. (37) hypothesized that tachycardia is more likely to result from seizures lateralizing to the right hemisphere. However, peri-ictal tachycardia has more consistently been documented in association with mesial temporal lobe onset and seizure generalization (36).

Some studies of patients who later died of SUDEP suggest a link between peri-ictal tachycardia and resulting death. When comparing maximal ictal heart rates in patients who later died of definite/probable SUDEP to controls with refractory focal-onset seizures, significantly higher values were found in the SUDEP group (38). In addition, significant postmortem fibrotic changes in the deep and subendocardial myocardium have been detected in SUDEP cases versus controls, which could be

the result of myocardial ischemia from repetitive seizures (39). Sympathetic overactivity may be responsible for such tachycardia and cause transient dilatation of ventricular walls and left ventricular dysfunction. If such stress-induced cardiomyopathy was severe enough to diminish cardiac output, oxygen supply during periods of significant stress might be compromised enough to result in death.

Peri-Ictal Bradycardia and Asystole

Although less frequent than peri-ictal tachycardia, bradycardia and asystole are known autonomic manifestations of seizures. Peri-ictal bradycardia (heart rate less than the 2nd percentile for age) has been documented in 2% to 4% of monitored seizures (36,40). Although the cortical stimulation studies performed by Oppenheimer et al. (37) suggested that bradycardia resulted from left hemispheric epileptiform activity, this has not been consistently supported by subsequent research. Rather, significant decreases in heart rate are more likely to be observed when epileptiform activity is present bilaterally on scalp EEG (25). Peri-ictal asystole (or the absence of a detectable heartbeat for ≥4 seconds) is even rarer, occurring in <0.5% of recorded seizures. Given that some cases of SUDEP have involved an ECG showing bradycardia progressing to asystole, there is significant interest in how such autonomic changes may contribute to sudden death. If true, clinicians could theoretically reduce the risk of SUDEP by advising pacemaker implantation. However, studies documenting earlier seizure cessation in cases of ictal asystole argue against the sole contribution of bradycardia/asystole to SUDEP (41).

Peri-Ictal Cardiac Repolarization (QTc) Abnormalities

A potential cause of lethal cardiac arrhythmias could be peri-ictal QT interval changes. Lengthening of the QT interval may result in torsades de pointes, a form of ventricular tachycardia. Clinically significant QTc prolongation is not rare in the peri-ictal period, occurring in 4.8% to 16.2% of seizures (36). Shortening of the QT interval can also be potentially lethal, facilitating a reentrant ventricular tachycardia. Clinically significant QTc shortening has been observed in 3.8% to 4.8% of seizures (36).

The potential link between cardiac repolarization abnormalities and SUDEP has been strengthened by studies invoking shared genetic mutations. Cardiac depolarization/repolarization anomalies have been documented in two SUDEP victims. One had an SCN5A-encoded cardiac Nav1.5 sodium channel mutation; another had a RYR2-encoded cardiac ryanodine receptor/calcium release channel mutation (42,43). However, only one case of ventricular fibrillation progressing to asystole and death following a monitored focal dyscognitive seizure has been cited (44). Therefore, caution must be utilized when attempting to link all cases of SUDEP to cardiac depolarization/repolarization anomalies.

Heart Rate Variability

Decreases in heart rate variability, which have been associated with an increased risk of sudden cardiac death (45), have been documented in people with epilepsy, including those with chronic temporal lobe epilepsy (46) and Dravet syndrome (21). The decrease in heart rate variability is likely secondary to seizure-related reductions in cardiac sympathetic innervation. Cardiac ^{123}I-metaiodobenzylguanidine uptake, a quantifiable measure of cardiac sympathetic regulation, has been

shown to be reduced in people with chronic temporal lobe epilepsy versus healthy controls (47). Such changes may increase cardiac sensitivity to adrenergic stimulation, increasing the risk of catecholamine-induced arrhythmias and death.

Peri-Ictal Hypoxemia and Apnea

Peri-ictal hypoxemia has been documented using digital pulse oximetry in 25% to 33% of seizures in both adults and children (36,40,48). It is felt that such hypoxemia is likely a consequence of seizure-related hypoventilation. Up to 50% of seizures may be marked by central apnea, with 9% marked by mixed or obstructive apnea (48). This is supported by concurrent rises in end-tidal CO_2 during monitored seizures (48). Such hypoventilation/apnea may be secondary to disruption of brain stem respiratory centers by repetitive seizure discharges. Other potential causes of peri-ictal hypoxemia include a seizure-induced right-to-left shunt and neurogenic pulmonary edema (10).

The role of peri-ictal hypoxemia in SUDEP has been suggested by both postmortem and electrophysiologic studies. Moderate to severe pulmonary edema has been documented in a majority of SUDEP cases at autopsy. Up to 80% of witnessed SUDEP cases have been characterized by respiratory difficulty (49). While attempting to define the role of hypoxemia/apnea in SUDEP, researchers have drawn parallels to sudden infant death syndrome. This is particularly true with regard to dysfunction of the rostral medulla and its centers controlling respiration and gasping (10). Given that such centers are modulated by 5-hydroxytryptamine (serotonin) and norepinephrine, pharmacologic manipulation of these receptors may theoretically reduce the risk of SUDEP. This has been demonstrated in the DBA/2 mouse model of SUDEP, where administration of fluoxetine significantly reduced the risk of respiratory arrest after seizures (50). In humans, only a single small retrospective study has shown a reduced occurrence of ictal hypoxemia during focal-onset seizures without secondary generalization in those taking selective serotonin reuptake inhibitors (51). Therefore, further investigation is needed before clinicians can confidently prescribe such medications to reduce the risk of hypoxemia-related sudden death.

Postictal Generalized EEG Suppression

An area of increasing interest in SUDEP-related research is postictal generalized EEG suppression. This phenomenon is marked by the absence of electroencephalographic activity as measured by scalp EEG viewed at ≤10 mV amplitude. In a retrospective study of 10 patients who later died of SUDEP versus 30 controls, it was shown that postictal generalized EEG suppression was significantly longer in the SUDEP group. The odds of dying from SUDEP were increased when suppression duration was >50 seconds and quadrupled when the duration was >80 seconds (52). It is hypothesized that postictal generalized EEG suppression may result in sudden unexpected death via inhibition of brain stem respiratory centers and resulting apnea. In adults, lower mean oxygen saturation nadirs, longer desaturations, and lower end tidal CO_2 measurements have been documented in seizures marked by postictal generalized EEG suppression (53). It is possible that the cortical neuronal inhibition suggested by suppression on scalp EEG extends to deeper subcortical and brain stem structures, interfering with respiratory drive (52). This phenomenon, especially if part of a vicious cycle of events including reduced activity of pulmonary stretch receptors, increased carotid chemoreceptor sensitivity, and asystole, could result in sudden death. Another possibility is that postictal generalized EEG suppression may reflect the severity of seizure-related intrinsic pulmonary dysfunction. This is

supported by the lack of a significant difference in apnea duration in seizures with and without this finding (53).

CONCLUSIONS

Autonomic changes are common in the peri-ictal period and likely result from direct excitation or inhibition of neocortical and limbic cortices. This may occur at seizure onset or from the propagation of epileptiform activity to structures that constitute the central autonomic network. Children are particularly susceptible to autonomic seizures, possibly secondary to a maturation-related susceptibility of the central autonomic network. This may explain why greater numbers of specific epilepsy syndromes and seizures with prominent autonomic features are documented in the neonatal through early childhood periods versus adulthood. Peri-ictal autonomic changes are of particular interest to clinicians given their proposed association with SUDEP. Peri-ictal tachycardia, bradycardia/asystole, cardiac repolarization (QTc) abnormalities, reduced heart rate variability, hypoxemia/apnea, and postictal generalized EEG suppression have all been theorized to play pivotal roles in the pathophysiology of sudden unexpected death. However, given that each of these phenomena occur vastly more frequently than SUDEP, it is likely one alone is not enough to result in sudden death. Rather, SUDEP may result from several precipitating factors coming together in a "perfect storm" during the peri-ictal period. In identifying patients at greatest risk for SUDEP, it may ultimately prove more useful to look at the concurrence of multiple autonomic events rather than any single disturbance. Only then may it be possible to accurately stratify risk and devise appropriate preventative measures for this devastating condition.

CHAPTER 14 GENERALIZED MOTOR SEIZURES

WILLIAM O. TATUM IV

INTRODUCTION

Generalized seizures may be subdivided into motor and nonmotor seizures (Fig. 14.1). Generalized motor seizures (GMS) are often referred to as convulsive seizures (1). In the revised terminology and classification of the International League Against Epilepsy (ILAE), generalized convulsive seizures arise within and rapidly engage bilaterally distributed cortical, subcortical, and brainstem networks of the brain (1). GMS, which occur in approximately one-half of patients with epilepsy, are among the most common of all the seizure types encountered in children and adults (2). These clinically visible events have an adverse effect upon the quality of life (3), and even infrequent seizures influence driving, employment, psychosocial enhancement, and cognition independent of the adverse effects that may be incurred by medical treatment (4).

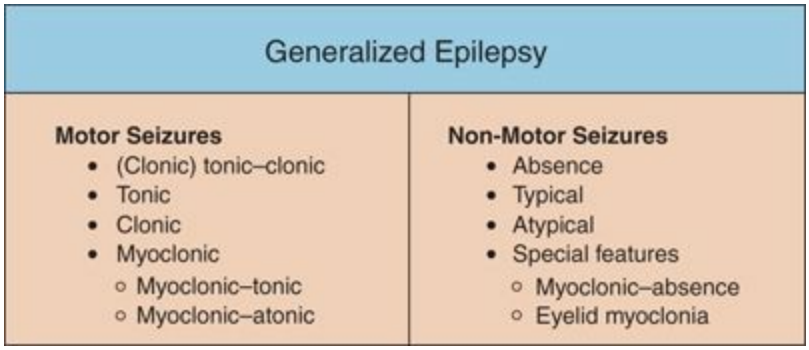

Figure 14.1. Generalized epilepsy subdivided into convulsive (motor) and nonconvulsive (nonmotor) seizures. (Adapted from Berg AT, Berkovic SF, Brodie MJ, et al. Revised terminology and concepts for organization of seizures and epilepsies: report of the ILAE Commission on Classification and Terminology, 2005–2009. Epilepsia. 2010;51(4):676–685.)

GMS may be observed in several different epilepsy syndromes and are associated with various etiologies, including a structural–metabolic (symptomatic), genetic (idiopathic), or unknown (cryptogenic) cause (5). While an inherited pattern is frequently assumed to reflect a genetic cause for GMS, family histories are often absent because complex genetic patterns and de novo mutations are common and are therefore not identified in pedigrees. A genetic component in patients with GMS does not preclude a progressive or structural–metabolic component (i.e., Lafora disease and laforin gene mutation EPM2A/B). Neither does a primary genetic pathogenesis exclude the possibility of a concomitant structural–metabolic cause (Fig. 14.2). Combinations of GMS semiologies and EEG may permit identification of a specific epilepsy syndrome that influences treatment and ultimately prognosis (early myoclonic encephalopathy). This chapter focuses on the electroclinical features of generalized tonic–clonic (GTC), tonic, clonic, and myoclonic seizures.

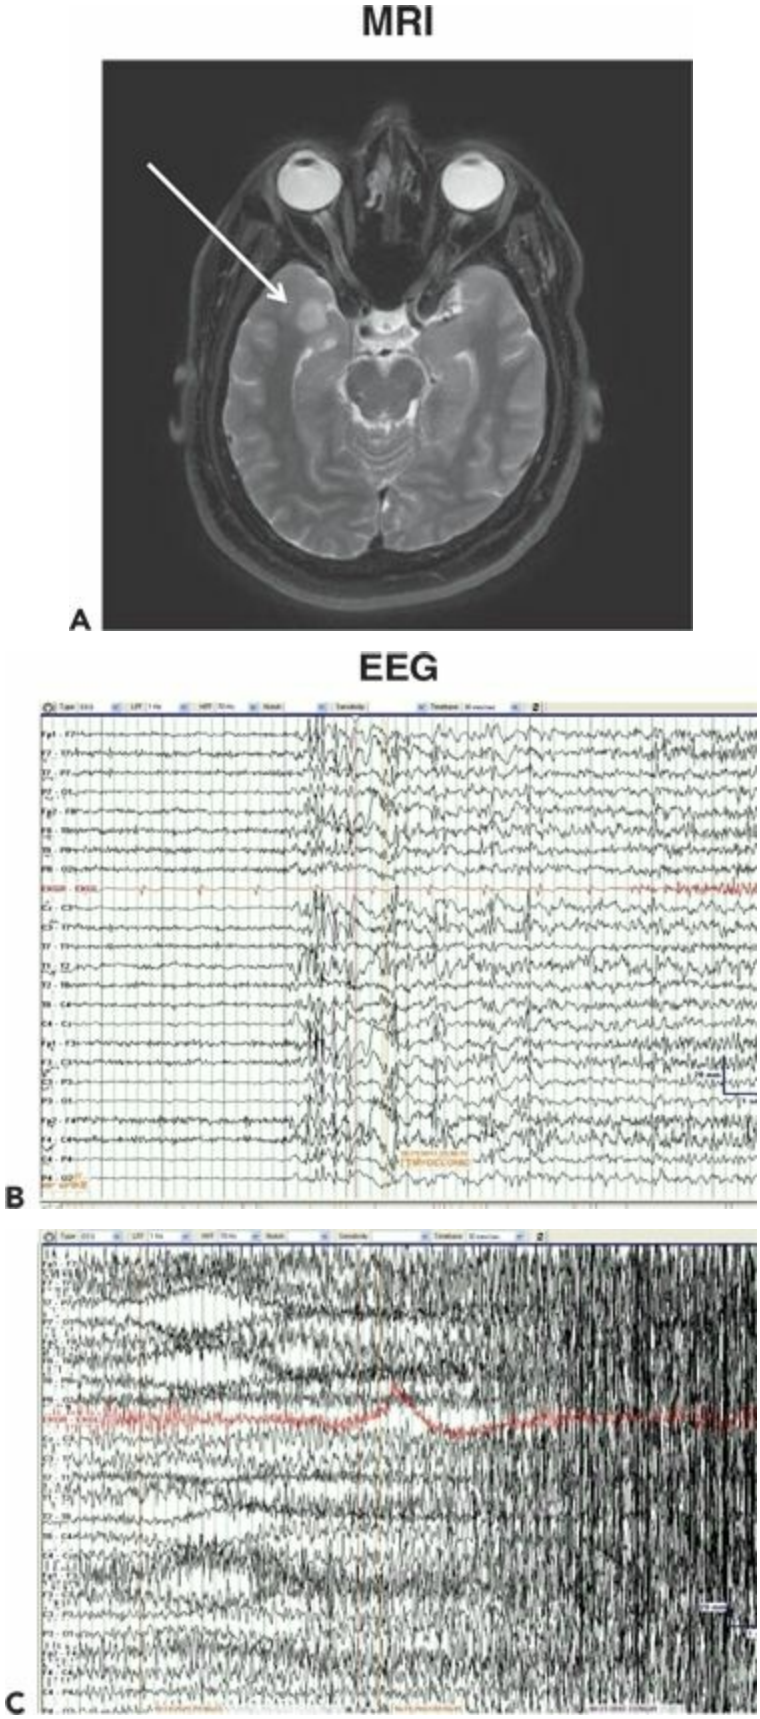

Figure 14.2. A 28-year-old Middle Eastern male was referred for epilepsy surgery. Recurrent GTC seizures were uncontrolled despite ASDs. **A:** MRI brain demonstrated a right temporal lobe lesion (arrow). **B and C:** Historical review suggested myoclonus beginning in adolescence. Video–EEG clearly demonstrated electroclinical myoclonic and GTC seizures confirming JME.

TYPES OF GMS

Generalized Tonic–Clonic

Descriptive terminology used by the ILAE defines a GTC seizure as one with a "tonic followed by a clonic phase" (6). Commonly known as a "grand mal," major motor seizure, or convulsion, the GTC is the most feared of all seizure types by patients, families, and observers. There is a multiplicity of brain disorders that produce GTC seizures. GTC seizures are the most common GMS occurring in 20% to 25% of adults with epilepsy. GTC seizures are rare in neonates and in infants younger than 2 years of age due to the immaturity and lack of organization of the developing brain that is typified by variable neuronal excitability, imperfect myelination, and incomplete interhemispheric connections (7). GTC seizures may occur as a first or solitary seizure and as the sole or mixed manifestation of an epilepsy syndrome. Adult-onset genetic generalized epilepsy (GGE) with GTC seizures may occur in 13.4% to 34.8% of hospitalized patients; however, most appear within the first 2 decades of life (8). In elderly patients, the onset is usually focal and then evolves to a bilateral GTC seizure. Public perception that all patients with epilepsy manifest "grand mal" seizures perpetuates misconception and stigma for patients with epilepsy (3).

Semiology

A GTC seizure has an initial tonic phase followed by a clonic motor phase that is characterized by rhythmic jerking and may result from a generalized or a focal-onset seizure. When the propagation to both hemispheres is rapid and involves the motor cortex, the clinical semiology of a focal seizure evolving to a bilateral convulsion ("secondarily" generalized) may be difficult to separate from a ("primary") GTC seizure that is associated with GGE. Myoclonic jerks may precede a GTC seizure during a myoclonic–tonic–clonic seizure to suggest a GGE such as juvenile myoclonic epilepsy (JME).

A prodrome is a nonictal warning composed of vague nonspecific symptoms that may occur prior to a GTC seizure. It can last from 5 minutes to a day before a seizure and often involve subtle changes in mood, cognition, and headache (9) though it may involve a variety of premonitory sensory, motor, autonomic, or psychic symptoms. As previously noted, motor signs in a GTC seizure involve an initial tonic phase and sudden loss of consciousness (5). Muscular rigidity occurs first with brief flexion followed by more prolonged tonic extension. The brief phase of flexion begins in the axial musculature and subsequently affects the limbs prior to more prolonged tonic extension lasting approximately 15 to 30 seconds. The tonic contraction is most intense in the axial musculature. When muscle contraction occurs in the thorax and abdomen, air is forced through the larynx to produce an "epileptic cry," respiratory stridor, or moan (10). In this phase, an apparent opisthotonic posture with the arms extended and fingers either extended or clenched in a fist is seen (5). The wrists are flexed or extended, and the forearms are pronated, while the legs are extended at the hips, knees, and ankles (Fig. 14.3). During tonic muscular contraction, respiration is inhibited and cyanosis may be evident. The ensuing clonic phase lasts about 30 to 45 seconds and involves initially a centrally spreading tremulousness (5,10). Phasic reduction in muscle tone intermittently occurs to create the generalized clonic jerking (10). Audible respiratory grunting may be heard that wanes in a decrescendo fashion, and the seizure ceases after 1 to 2 minutes (10). The tongue may be bitten, and urinary incontinence may be evident. Most tongue bites associated with GTC seizures have a predisposition for the posterolateral tongue or cheek region (5,10). Hypersalivation also occurs and, with the vascularity of the tongue, may produce copious amounts of blood-tinged sputum (5). Autonomic features include pupillary dilation, tachycardia, and blood pressure elevation (10). Diaphoresis is present during and

after the episode. Following the seizure, hypoventilation is encountered, which may be in the form of stridor with respiratory compromise or aspiration if the airway is not protected. There is marked individual variability between GTC seizures and between seizures in the same individual (5,10). Additionally, focal and lateralizing signs commonly occur in GTC seizures of patients with GGE and do not necessarily imply a focal onset (11).

Figure 14.3. Generalized tonic extensor posturing preceding the clonic phase in a 32-year-old patient experiencing recurrent GTC seizures. Note the forearm pronation, wrist flexion, and partial finger extension.

The postictal state is initially composed of a flaccid unresponsive state of variable duration usually with recovery in 10 to 30 minutes. Confusion, disorientation, somnolence, headache, personality and mood changes, and myalgias may resolve over the next 24 hours. During this time, there is a notable loss of postural tone, unconscious state, and loss of deep tendon reflexes on examination. Ictal hypoventilation and subsequent postictal apnea may contribute to the development of cardiac arrhythmias (Fig. 14.4) (12). During the immediate postictal phase, there is nonspecific relaxation of the urinary sphincter resulting in urinary incontinence. Postictal agitation, confusion, and disorientation are common and characteristic. A postictal migraine-like headache, nausea, and vomiting may occur. Following a seizure, the postictal serum prolactin and creatine kinase may rise, though they have limited sensitivity and specificity as a biomarker for a GTC seizure (13).

Figure 14.4. Cardiac telemetry after GTC seizure. Note the initial premature ventricular beats (white arrows) prior to reestablishing a normal sinus rhythm (yellow arrow).

Electrophysiology

The waking interictal EEG background of patients with GTC seizures associated with GGE is typically normal. Focal features may occur when comorbid conditions are present. Preceding interictal epileptiform discharges (IEDs) in the preseizure period may be seen prior to onset of clinical symptoms (14). Bursts of intermittent rhythmic theta and delta activity is more commonly observed in patients and family members in GGE (15,16). Generalized spike and waves (GSW) usually indicate a GGE when interspike frequencies are 3 Hz or greater in patients with GTC seizures (Fig. 14.5) (5,15–17). Morphology and synchrony may exhibit significant intra- and interindividual variability over long periods of time (11,15). Focal IEDs or focal slowing usually suggests localization-related epilepsy; however, asymmetric discharges may be seen (especially during NREM sleep) in GGE that falsely suggest focal seizures (5,11). Secondary bilateral synchrony may give the false appearance of GSW; however, secondary bilateral synchrony is distinguished from GSW by the presence of persistent focal IED, a distinct morphologic difference between the focal or lateralized and the generalized discharge and the appearance of a consistent "lead" prior to the onset of the generalized epileptiform discharge (ED) (11,18). GTC seizures associated with encephalopathic generalized epilepsy (EGE) have slow background activity, voltage asymmetries, and intermixed focal or generalized theta and delta slowing in the EEG that may be continuous or intermittent, rhythmic, or polymorphic depending upon the degree of encephalopathy (5,7,19).

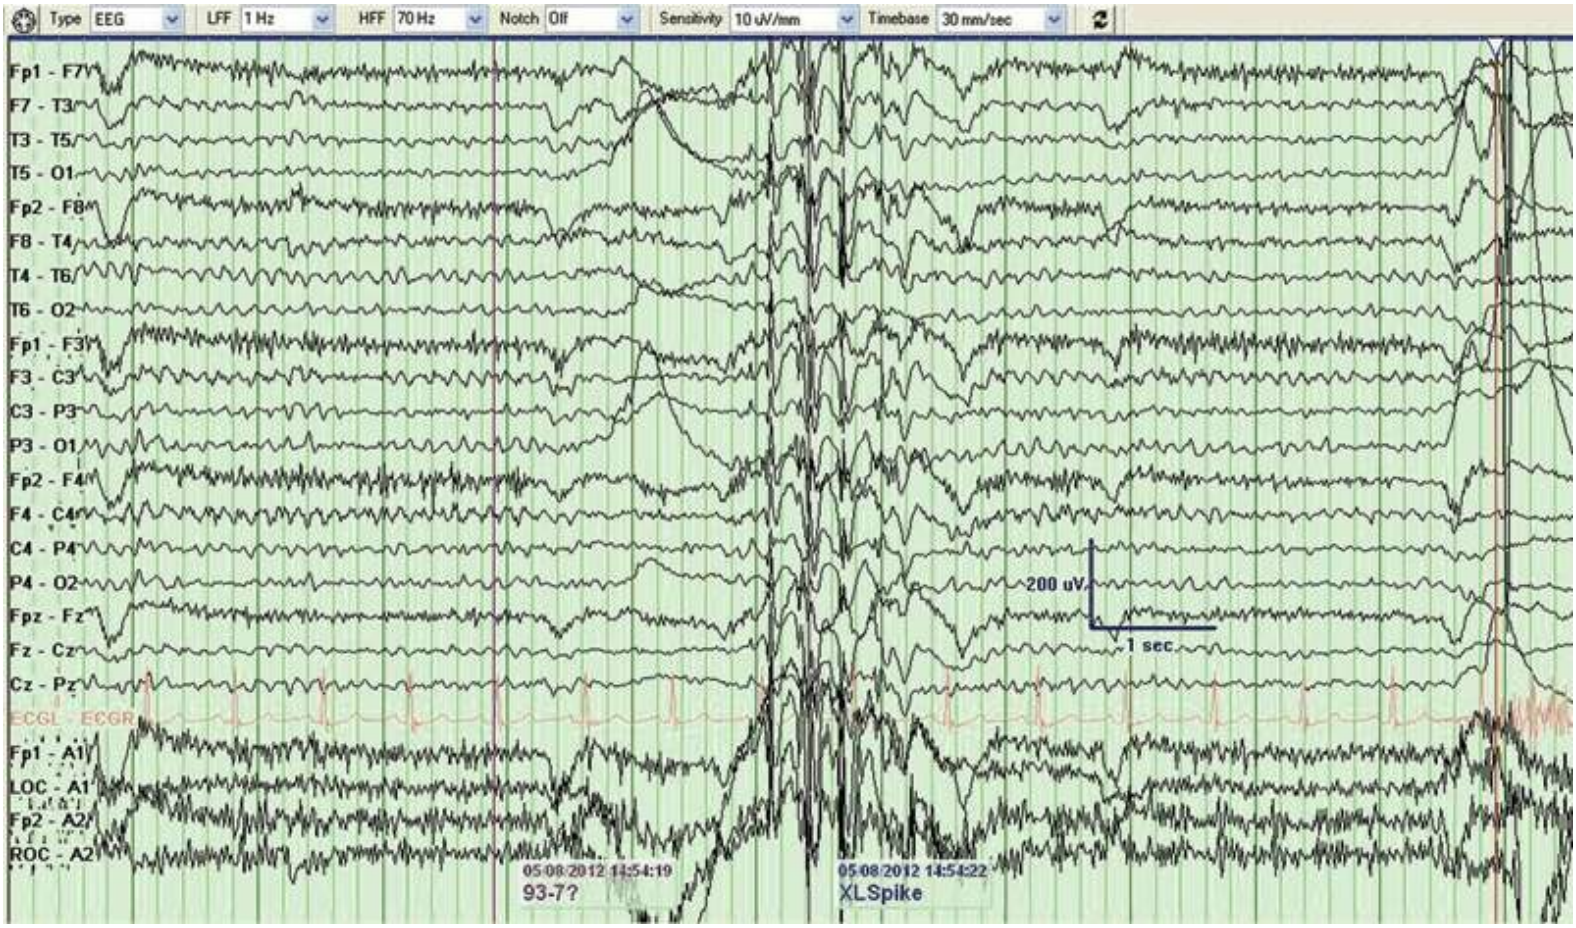

Figure 14.5. EEG with a 1-second burst of 3-Hz generalized spike-and-wave in second 6 in a patient with GTC seizures on awakening. Note: 3-Hz generalized spike-and-wave suggests a "primary" GMS, though it may be infrequently seen as a "secondary" bilateral synchronous discharge on focal origin.

The ictal EEG during a GTC seizure has generalized frontally predominant fast rhythmic spikes during the tonic phase. A 10-Hz discharge followed by a brief attenuation or low-voltage fast activity at a frequency of approximately 20 Hz is seen. Gastaut described the 10-Hz rhythm as the "epileptic recruiting rhythm," which progressively increases in amplitude (Fig. 14.6) (19). Following the tonic phase, the frequency of the ongoing ictal activity decreases as amplitude increases in association with repetitive clonic jerks. During the clonic phase, the initial fast rhythm becomes fragmented by rhythmic slow waves. Intermittent polyspikes are apparent and accompany the clonic jerk with a decreasing slow-wave frequency during the relaxation period (5,10). The postictal phase reveals immediate suppression of the background that evolves to diffuse slowing that gradually returns to the baseline background. During the postictal phase, a nonlocalized GTC seizure may demonstrate focal or lateralizing features that suggest the event was a focal-onset seizure that rapidly evolved to a bilateral convulsion.

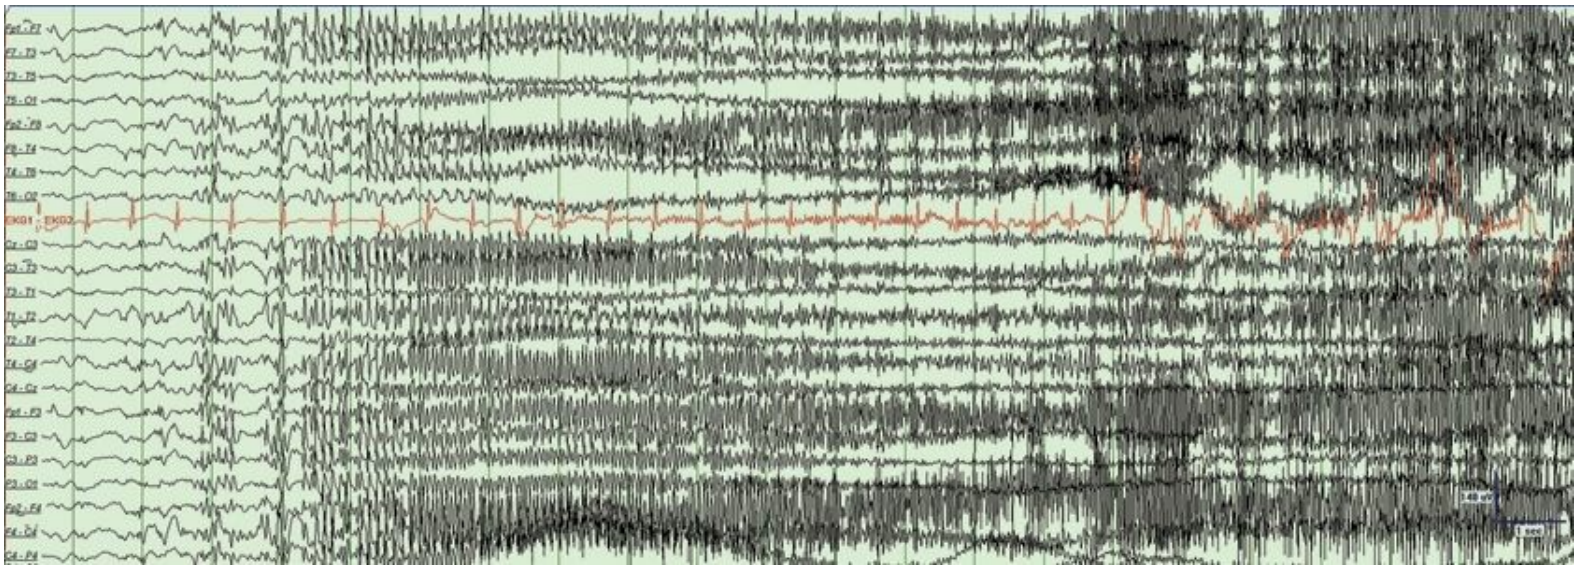

Figure 14.6. EEG during a GTC seizure in a patient with GGE. Notice the generalized onset and evolution during the seizure. (From Tatum WO. Handbook of EEG Interpretation. 2nd ed. New York: Demos Medical Publishing; 2014:135 [reprinted with permission from Demos Medical Publishing].)

Clinical Correlation

Diagnosis is usually not difficult. The aftereffects can include trauma to the head, tongue, and mouth; vertebral compression fracture; posterior shoulder dislocation; aspiration pneumonia; neurogenic pulmonary edema; and cardiac arrhythmia (5,10,20). Sudden unexplained death in epilepsy (SUDEP) may occur following a GTC due to postictal centrally mediated alteration in cardiorespiratory function (20). Some "convulsions" (i.e., benign neonatal familial convulsions) reflect terminology that is actually a misnomer since GTC seizures in infancy are more likely to be focal tonic–clonic seizures due to brain hyperexcitability with or without a genetic basis (16). GGE with sporadic GTC seizures may be self-limiting and express a single seizure semiology (5,16). Other syndromes with GTC seizures persist throughout life (epilepsy with GTC seizures on awakening). Some GGE epilepsy syndromes (JME and juvenile absence epilepsy) have mixed GMS, and some reflect combinations (epilepsy with myoclonic absences) (16,17). New-onset GTC seizures in adulthood likely have a focal onset (Video 14.1) though focal and lateralizing electroclinical signs in patients with GGE should receive consideration (11).

Many physiologic nonepileptic mimics of GTC seizures may occur. In early childhood, breath-holding spells can mimic epileptic GTC seizures. In adulthood, convulsive syncope, metabolic disturbances (electrolyte imbalance), drugs (i.e., bupropion and tramadol), and substance abuse (i.e., cocaine and alcohol) are important causes to consider. Similarly, acute symptomatic seizures within 7 days of a systemic or brain insult does not equate to posttraumatic epilepsy. However, psychogenic nonepileptic seizures exist as a leading cause in the differential diagnosis of GTC and GMS and are best addressed by video-EEG monitoring (21).

Generalized Tonic

A generalized tonic seizure (GTS) is a generalized motor seizure that is composed of generalized tonic muscular contraction with a loss of consciousness. A GTS occurs when the electroclinical onset arises simultaneously from both hemispheres (6,22,23). From infancy to adulthood, GTS may occur. Tonic seizures typically reflect the symptomatic nature of an underlying brain condition or disease

process (22,23) affecting the cerebral cortex in patients with an EGE (see Chapter 20). Despite the apparent homogeneous classification of seizure semiology, various underlying pathophysiologic mechanisms occur. GTS typically occurs with varying degrees of cognitive dysfunction and mental retardation. They are the most characteristic seizure type in the Lennox–Gastaut syndrome (LGS). GTS may present as either the initial or the primary manifestation of this syndrome (22). The prevalence of GTS is inadequately represented given the discrepancy between observed clinical seizure incidence and subclinical seizures noted during polygraphic recording (23). Tonic seizures often have an unknown etiology, although congenital brain malformation, hypoxic–ischemic encephalopathy, and central nervous system infections are the symptomatic causes most often found. Mental retardation is less common when tonic seizures begin later in childhood or in adulthood and is associated with a poor prognosis for seizure control and normal development with seizure onset before the age of 2 years (22–24).

Semiology

GTS may be very brief and appear nonconvulsive. When they are brief or associated with atonic seizures, the semiology may be difficult to differentiate. Video-EEG analysis of drop attacks with the patient in the standing position demonstrates that the first manifestations of GTS occur with either tonic flexion at the hips or propulsive or retropulsive falls (24). This is in contrast to atonic seizures that begin with flexion at the waist and knees, followed by additional knee buckling leading to a fall straight downward (24,25). Taxonomy has included (i) tonic axial seizures with abrupt tonic muscular contraction and rigidity of the neck, facial, and masticatory muscles; (ii) global tonic seizures involving widespread contraction of the axial and appendicular musculature (Video 14.2); and (iii) tonic axorhizomelic seizures as an intermediate form with contraction of the upper limb muscles and deltoid muscles that leads to elevation of the shoulders. Focal seizures with asymmetrical tonic posturing are referred to as tonic postural seizures. Short tonic seizures have high-amplitude, rapid muscular contractions that involve mainly the axis of the body and trunk, maximal in the neck and shoulder girdle, and last only 500 to 800 ms with forward positioning that resembles epileptic spasms (25). When tonic posturing is observed in patients with epileptic spasms, the term tonic spasms describes this drug-resistant seizure type (26). Prolonged tonic seizures may occur with a vibratory component that resembles a GTC seizure (24,26), although GTS are much briefer, averaging 10 to 15 seconds (27).

Tonic seizures may vary from a short, upward deviation of the eyeballs with or without nystagmoid eye movements to more intense generalized symmetrical or asymmetrical tonic stiffening, loss of consciousness, falls, and repeated injury (19,28). Falls from tonic seizures may be forward or backward depending on whether the axial and lower limb musculature is fixed in flexion or (less frequently) in extension. GTS and atonic seizures are referred to as drop attacks, though GTS are associated with falls less consistently than atonic seizures because the leg muscles are often not involved or have an increased extensor tone to maintain an upright posture (23). Scars on the forehead and occipital regions may reflect injury patterns associated with propulsive or retropulsive seizures. Contraction of the respiratory and abdominal muscles may create a high-pitched cry or a period of hypopnea. Seizure intensities may vary among patients and individuals, and combined seizure types may also occur (29). The duration of tonic seizures is several seconds to a minute, although most last for 5 to 20 seconds. Tonic seizures are most frequent during stages I and II of non–rapid eye movement (NREM) sleep (22–24,30). Autonomic features may include respiratory, heart

rate, or blood pressure increases; pupillary dilation; and facial flushing (22). Postictal features demonstrate a variable degree of cognitive and motor recovery, with the depth of the postictal state usually proportional to the seizure intensity (22,23). In patients with LGS, GTS may appear "subclinical" without detailed clinical testing and EEG (31). Tonic status epilepticus is not uncommon and may occur in 54% to 97% of patients with a brief initial tonic component (22).

Electrophysiology

The interictal EEG in patients with GTS is dependent on the specific epileptic syndrome and may change in adulthood (32). In most patients with GTS associated with EGE, a diffusely slow background with multifocal spikes and sharp waves (Figure 14.7b) is present on the EEG reflecting a diffuse structural injury of the brain (22). In patients with LGS beginning before the age of 5 years, generalized slow spike-and-wave complexes (Figure 14.7a) may not appear until the onset of epilepsy is well established (19,22–24,27). Epileptic spasms may have a similar semiology to GTS seizures though the EEG has the characteristic interictal pattern of hypsarrhythmia and an ictal pattern of an electrodecremental response (25,26).

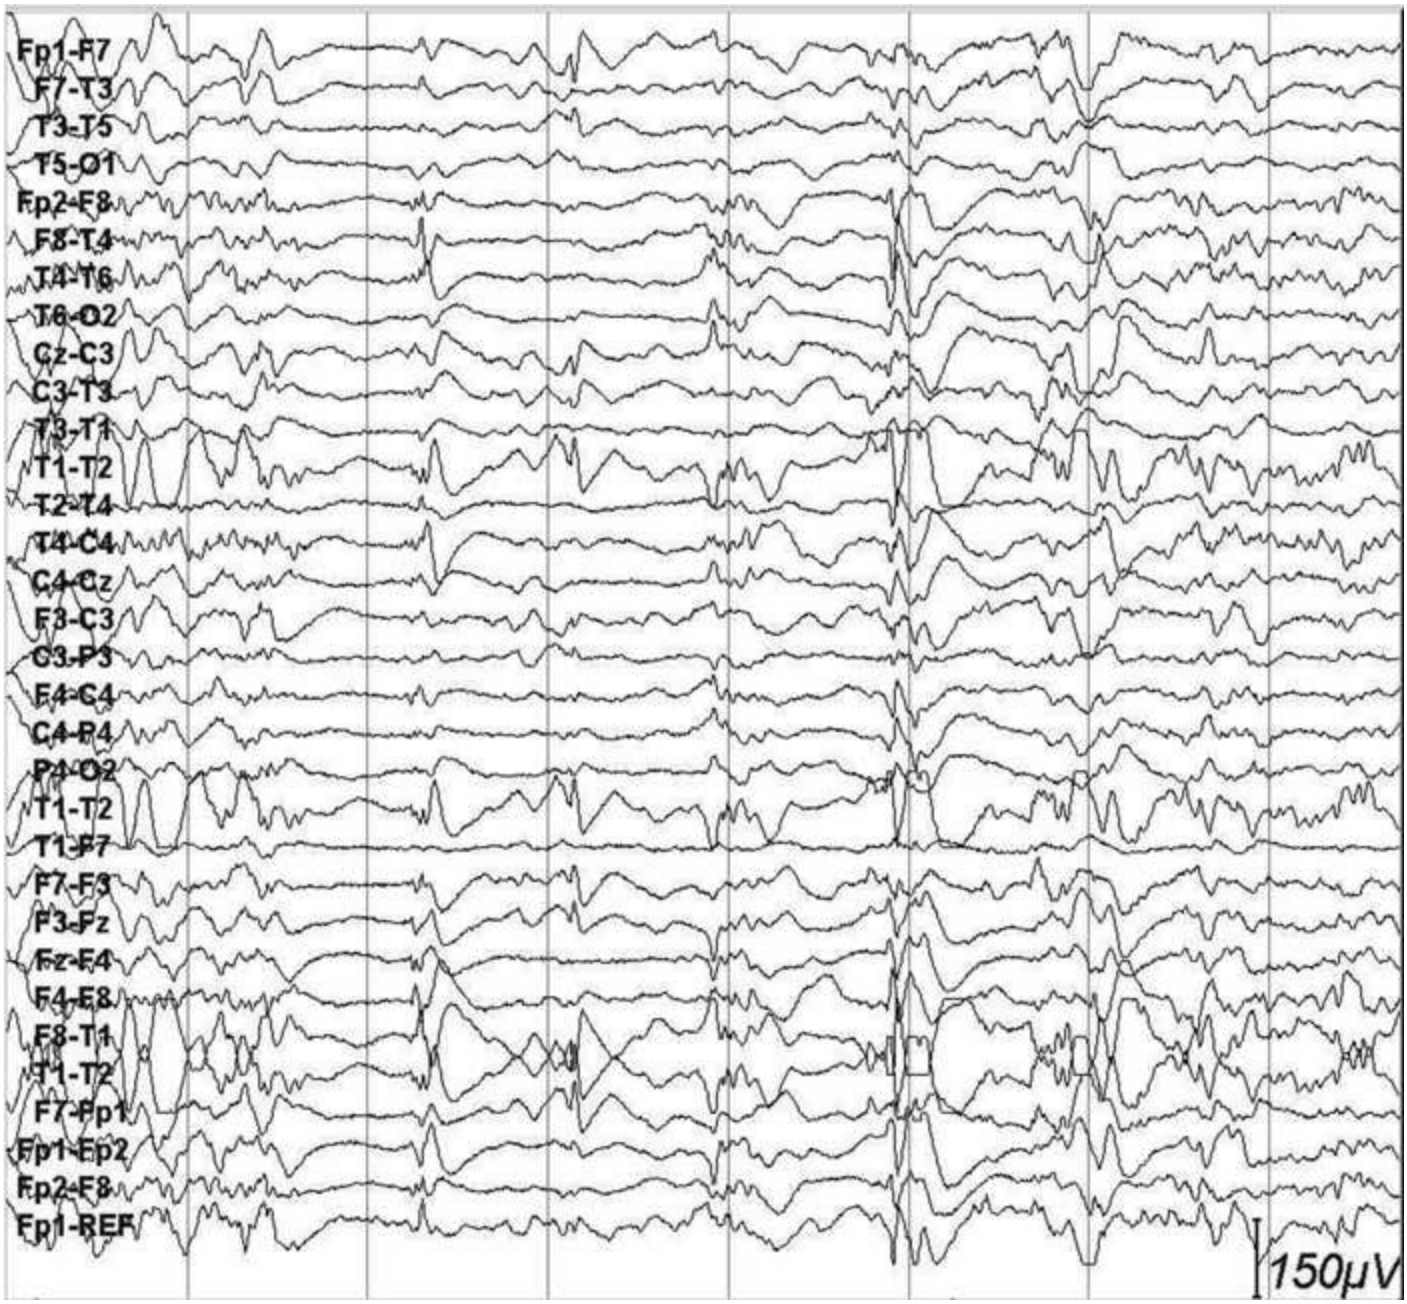

Figure 14.7. (**A**) Slow spike-and-waves and (**B**) multifocal independent spike discharges in two patients with GMS and mixed tonic, tonic–clonic, and myoclonic seizures. (From Tatum WO. Handbook of EEG Interpretation. 2nd ed. New York: Demos Medical Publishing; 2014:135 [reprinted with permission from Demos Medical Publishing].)

The ictal EEG manifestations of GTS associated with EGE are variable. Generalized paroxysmal fast activity (GPFA), generalized background attenuation, low-amplitude rhythmic fast activity of 15 to 25 Hz that progressively increases to 50 to 100 μV, and an initial attenuation followed by the rhythmic fast activity of 10 to 15 Hz that is high amplitude from the seizure onset are common features of GTS on EEG (33). Commonly, generalized frontally predominant initial attenuation of background activity that is associated with desynchronization precedes the appearance of bilateral 10 to 25 Hz spikes with voltages up to >100 μV (34). Attenuation in the EEG reflects a generalized desynchronization with or without rhythmic ictal fast activity. GPFA often appears as the electrographic counterpart of tonic seizures during slow-wave sleep and consists of diffuse, repetitive, medium- to high-amplitude spike discharges that usually have clinical semiologies with increased muscular tone (19,23). The pattern of GPFA on the EEG is a 10-Hz burst of bilateral fast activity that occurs frequently during NREM sleep, disappearing in REM sleep. Bursts of GPFA are identical to the discharges seen with GTS but may have subtle clinical signs such as brief apnea or

mild muscular contraction that is best seen on electromyography (Fig. 14.8). GPFA is not pathognomonic for LGS since extratemporal focal seizures may also manifest similar bursts. A mixture of clinical and EEG patterns seen with GTS may also be associated with other types of GMS (Fig. 14.9) (23,29). Fast ictal spike discharges have been noted in the centromedian nuclei of the thalamus bilaterally with invasive electrodes that correlate with the onset of tonic seizures during concomitant scalp EEG change (35). Rhythmic and morphologically distinct ictal theta and delta have been described in patients with tonic status epilepticus and LGS (36).

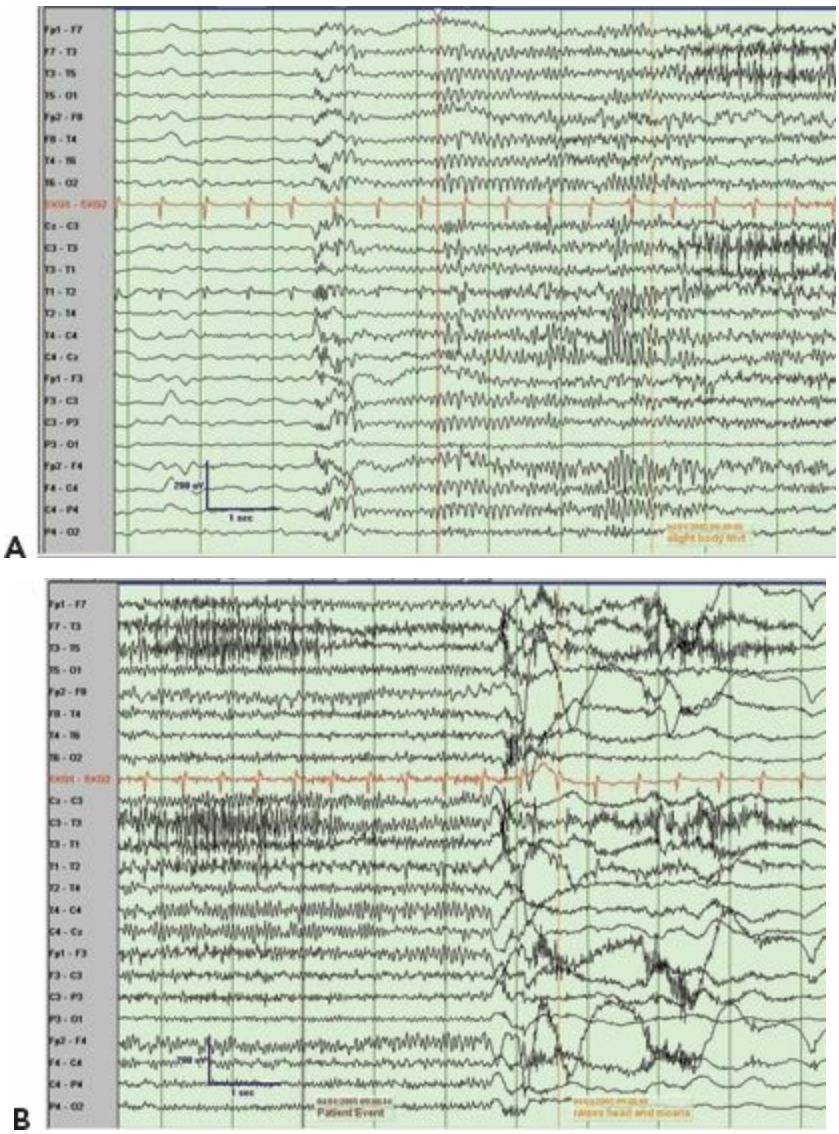

Figure 14.8. EEG of a GTS from sleep. Note the initial generalized polyspike followed by 10-Hz activity **(A)** accompanying a subtle GTS and the minimal myogenic artifact 3.5 seconds following onset **(B)** but the significant postictal slowing.

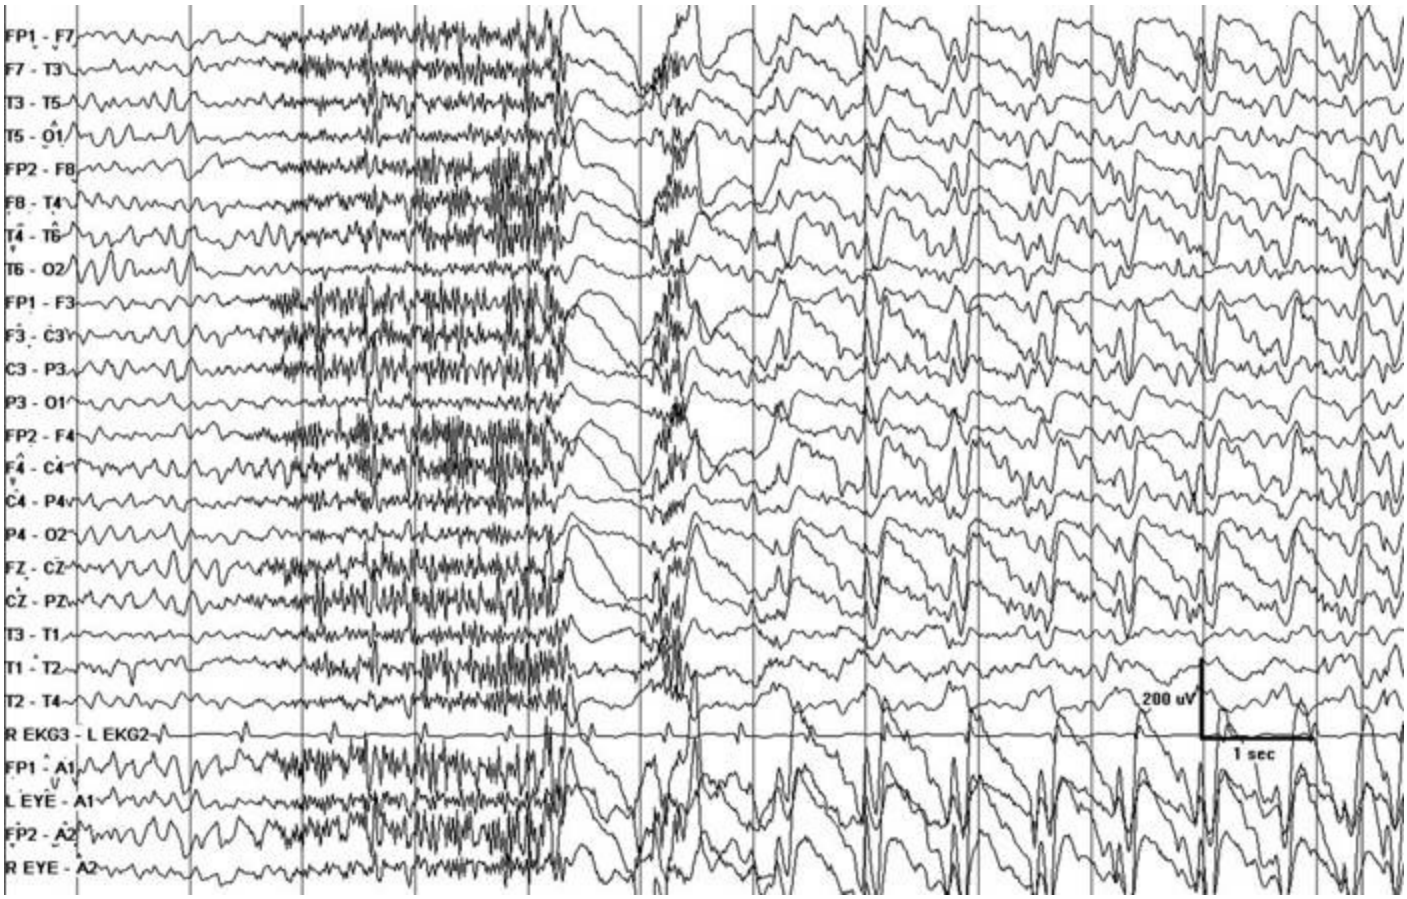

Figure 14.9. EEG demonstrating a burst of polyspikes at the onset (tonic component) that precedes a burst of generalized slow spike and waves (atonic component) during a drop attack.

Tonic postural seizures associated with localization-related epilepsy often have interictal midline spikes in the scalp EEG when they are detected (37). Ictal discharges may arise from an epileptogenic zone in the frontal cortex that is remote from the scalp EEG and be unrevealing. A regional, low-amplitude, high-frequency rhythmic ictal fast frequency discharges (33) or subtle diffuse attenuation of the background may be apparent in some patients (38).

Clinical Correlation

Tonic seizures frequently coexist with mental retardation, an abnormal EEG, and a poor response to therapy. The implication of GTS is based on the clinical history and disease course. GTS represents one of the cardinal seizure types in LGS (22,23,30). Although GTS are characteristic of LGS affecting 74% and 90% of patients (22), they may be virtually absent in other EGEs (i.e., severe myoclonic epilepsy of infancy). Tonic seizures are the most common cause of a sudden fall (drop attacks) in children with LGS (38) and a major cause of morbidity and mortality, often necessitating the use of a protective helmet (22). When seizures are present during neonatal development, GTS represent one of the earliest clinically identifiable semiologies (39). Early infantile epileptic encephalopathy is an EGE that is also characterized by frequent tonic seizures. West syndrome and epileptic spasms are a unique form of GTS, which occurs with a sudden flexion or extension followed by tonic contraction for seconds without clonic jerking. Although epileptic spasms have a semiology that is similar to GTS, spasms are more rapid in onset (lasting for 1 to 2 seconds), occur in clusters, and have hypsarrhythmia on the interictal EEG.

Seizures may appear to possess a generalized semiology even though they have a focal onset.

Secondarily, GTS with asymmetrical tonic abduction and elevation of the arms may mimic tonic seizures in patients with EGE. When tonic postural seizures occur, they are often frequent, nocturnal, and associated with other focal semiologies and episodes of recurrent status epilepticus, given their predisposition to arise from the frontal cortex (40).

Nonepileptic tonic or opisthotonic posturing should also be considered when painful tonic spasms or posturing occur, even though treatment may include antiseizure drugs (ASDs). Nonepileptic tonic posturing is readily differentiated from epileptic tonic seizures by normal interictal and ictal EEG. Video-EEG monitoring has improved our identification, classification, and quantification of patients with GTS in pharmaceutical research and surgical selection.

Generalized Myoclonic Seizures (GMCSs)

A GMCS is a brief generalized motor seizure resulting in a lightning-like jerk. Myoclonus is a brief, sudden, involuntary, shock-like muscular contraction of the body that results in a movement that may be either epileptic or nonepileptic. Nonepileptic myoclonic jerks may be activated during intentional movement (action myoclonus) or occur spontaneously in the face of other neurologic conditions (i.e., spinal cord and cerebellar dysfunction). A GMCS has an electroclinical correlation with myoclonus and an ictal ED on EEG in a patient with epilepsy. A GMCS may occur predominately upon awakening or during transition to sleep. Cortical reflex myoclonus is a term that reflects a motor movement resulting from focal region of brain dysfunction in epilepsy with the clinical manifestations reflecting the area of the brain responsible for motor activation. Reticular reflex myoclonus, on the other hand, may occur with generalized epilepsy but originates in the subcortical structures and brainstem. Myoclonic seizure may occur either as part of a GGE syndrome or as a feature of EGE though rarely as a feature of localization-related epilepsy.

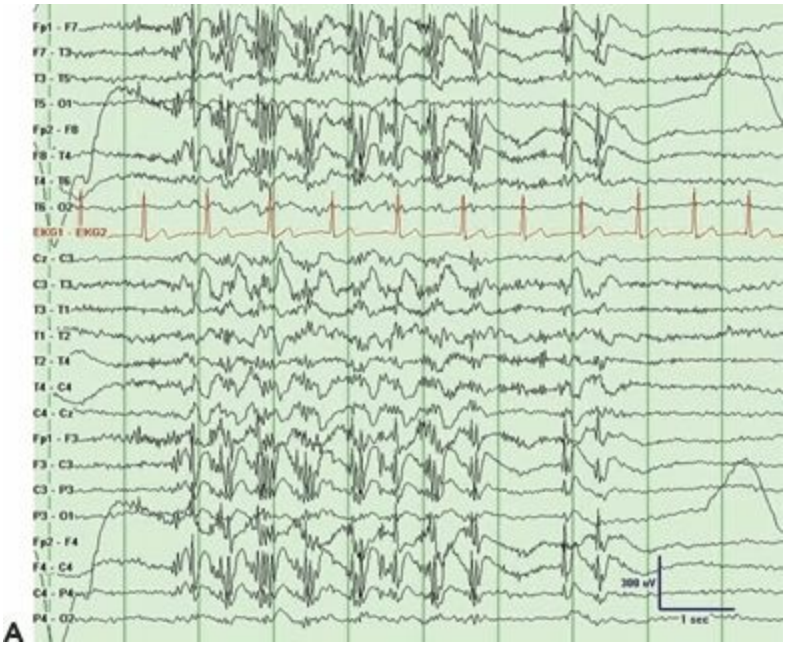
Semiology

GMCSs are characterized by brief, sudden, involuntary muscle contractions involving different combinations of the head, trunk, and limbs (Video 14.3). They are often generalized, but may also be limited to the face and axial musculature (41). They usually occur without detectable loss of consciousness (41). GMCS may be regular or irregular, symmetrical or asymmetrical, and synchronous or asynchronous. They may be isolated or rapidly repetitive. Myoclonic jerks may occur as a positive or negative motor movement, manifesting extra movement or a sudden loss of movement and postural tone (41). Massive epileptic myoclonus implies that a bilateral jerk is large enough to create a fall. Focal seizures with tonic posturing may occasionally mimic myoclonic seizures, though the presence of a relative asymmetry or sustained increase in motor tone should help distinguish this semiology. Seizure combination with myoclonic seizures (myoclonic–tonic, myoclonic–atonic) have been recognized by the new ILAE classification (1). GMCS may occur as part of another seizure type (i.e., epilepsy with myoclonic absence seizures). Myoclonic status epilepticus typically occurs in patients with EGE and occurs less frequently during sleep (42).

Electrophysiology

In general, myoclonic jerks have a high-amplitude, bisynchronous, diffuse spike-and-wave or polyspike-and-wave discharge as their electrophysiologic correlate despite interictal– ictal and syndromic differences (Fig. 14.10). A very brief latency between short bursts of synchronized

electromyographic potentials in both agonist and antagonist muscles and that of the corresponding spikes occur. The spikes are time-locked events that are coupled with the myoclonic jerks that follow. By using back-averaging techniques, latencies are found to occur between 21 and 80 ms (43). When a myoclonic jerk is generated by subcortical structures, a generalized IED follows the first electromyographic sign of myoclonus though a primary epileptogenic mechanism has been controversial (43,44). Negative myoclonus, if due to a lapse of tone, can be seen only during antigravity posture and is coupled with either the slow-wave or the second positive component of a polyspike-and-wave discharge (41,43). Myoclonic seizures have semiologies with an electromyographic pattern, demonstrating a brief synchronous potential of <50 ms that is seen simultaneously in the involved muscle groups (41). During the myoclonic jerks, medium- to high-amplitude repetitive 16-Hz spikes are seen on the surface of the scalp EEG (44). Recordings from thalamic nuclei during myoclonic seizures demonstrate subcortical slow polyspike-and-wave discharges that lead the seizures recorded on the scalp surface in patients with LGS (35). Myoclonic jerks may appear to represent brief GTS but instead are single muscular contractions that last <200 ms, while GTS are more intense and sustained lasting for seconds in duration (22), although they may be associated with a myoclonic (or atonic) component (35). The EEG is critical in defining benign syndromes with GSW (i.e., benign myoclonic epilepsy of infancy) from more malignant epilepsies associated with GMCS and burst suppression (early myoclonic encephalopathy). Giant visual evoked potentials appearing as occipital high-amplitude polyphasic spikes may be observed during intermittent photic stimulation at low repetition rates of <3 Hz in some patients with progressive myoclonus epilepsy (45,46). Focal myoclonias are suspected to be derived from a hyperexcitable cortex responsible for motor activation. Electrographic secondary bilateral synchrony is common in patients with myoclonic jerks and extratemporal focal seizures. Generalized IEDs may show a brief delay in interhemispheric representation as a function of coherence and phase analysis (45).



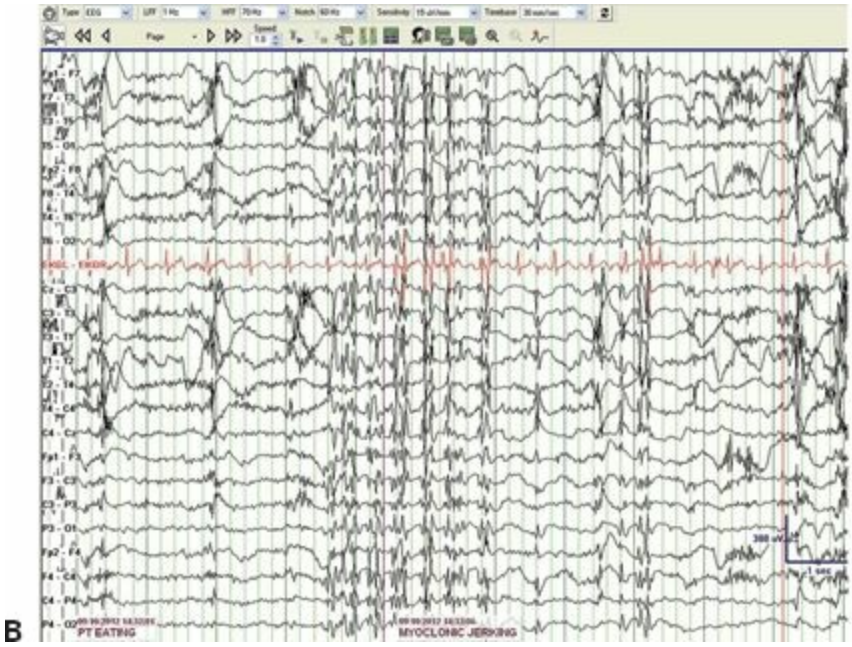


Figure 14.10. Generalized polyspike-and-waves in two patients with myoclonic seizures: (**A**) with JME and (**B**) with progressive myoclonus epilepsy (adult-onset neuronal ceroid lipofuscinosis). Note the waveform similarity despite differences in the interictal (**A**) and ictal state (**B**) and clinical impact of these two syndromes.

Clinical Correlation

Myoclonic seizures are clinically heterogeneous and are associated with many different types of epilepsies and epilepsy syndromes from early infancy into adulthood. Myoclonic seizures may be associated with GGE syndromes (Chapter 17), EGE syndromes (Chapter 20), and mimic epileptic spasms (Chapter 16). There can be semiologic difficulty with distinguishing GMCS from GTS-associated drop attacks. GMCSs and GTC seizures in patients with normal cognition suggest JME, whereas GMCS mixed with other seizure types and mental retardation suggest one of the EGE. Causes of GMCS vary greatly from genetic to acquired causes (45,46). The associated features help to define the epilepsy syndrome rather than the semiology. In JME, the presence of myoclonus preceding GTC seizures helps distinguish a GGE relationship (44). In other epilepsies, GMCSs may also occur with deleterious consequences (epilepsy with myoclonic astatic seizures) to complicate classification between GGE and EGE or as a combined seizure type (epilepsy with myoclonic astatic seizures) (43,44,47). Patients with GGE infrequently manifest drug- resistant myoclonic seizures though it is frequently noted in the setting of developmental delay (44).

A structural–metabolic (or unknown) etiology is often found when myoclonic seizures begin before the age of 4 years (43). Febrile seizures and subsequent GMCS often herald a malignant epilepsy during infancy and early childhood (early myoclonic encephalopathy and Dravet syndrome) (43). Myoclonic seizures may be distinguished by the associated background EEG features such as hypsarrhythmia in spasms and burst suppression in early myoclonic encephalopathy. This is in contrast to the EEG of GGE and GMCS that is typically associated with generalized polyspikes. The progressive myoclonic epilepsies (see Chapter 19) with cognitive deterioration and abnormal neurologic signs are a rare, but extremely debilitating and progressive, heterogeneous subgroup of EGE with myoclonic seizures as the hallmark of the conditions (46).

Generalized Clonic Seizures (GCSs)

A GCS is a convulsive seizure that involves bilateral rhythmic or semirhythmic contractions of a

group of muscles in the body. The absence of a tonic component serves to distinguish it from a GTC seizure. However, electrical brain stimulation of the primary motor cortex in humans elicits repetitive clonic muscle contractions and, with subdural recordings, has demonstrated a brief tonic component prior to clonic jerking (48). Clonic seizures are most frequently observed in very young children. GCSs are more common than GTC seizures during the neonatal period due to the immature myelination of the brain that occurs at this age (49). GCS are more likely to occur in children with other GMS types such as GTC and myoclonic seizures. GCS seizures frequently occur in patients with focal epilepsy, especially in the frontal lobe. Frontal lobe epilepsy with or without impaired consciousness may also occur with axial clonic jerks (i.e., anterior frontopolar region) and focal clonic jerks (i.e., opercular and dorsolateral) and may also manifest bilateral clonic jerking that is symmetric or asymmetric (Video 14.4).

Semiology

Clonic seizures are often asymmetrical and consist of a brief onset and offset (33). The clonic jerking of a GCS seizure has a decrescendo frequency of repetitive clonic jerks that maintain the same level of intensity despite declining frequency (33,50). GCS may involve a discrete group of muscles preferentially, though the arms, neck, and facial muscles are most commonly involved. The clonic jerking is more sustained and rhythmic than the single lightning-like jerks that occur with myoclonic seizures and without a prominent tonic phase seen with GTC seizures. When clonic seizures are generalized, they are associated with impairment of consciousness. The duration of the seizures varies, and when prolonged, generalized clonic status epilepticus may occur. GCS may also appear multifocal with clonic movements that appear to migrate over the body or even from limb to limb with variable impairment of consciousness (3,49,50). The presence of autonomic features and significant postictal state is atypical for a GCS (33,50). When it occurs, the postictal phase is usually brief. Other GMS may be coupled with a clonic phase (i.e., clonic–tonic–clonic seizure). GCSs may be slow to propagate and may yield focal clonic jerking that exhibits a "jacksonian march" as the propagation of electrical activity spreads from one region of the brain to adjacent areas recruiting the face, arm, and leg musculature that is innervated by the contralateral neocortex. Clonic status epilepticus may occur and is relatively rare in adults and much more common in infants (49,50).

Electrophysiology

The interictal EEG in patients with GCS may offer nonspecific clues to the etiology. Background abnormalities are much more likely to predict the presence of seizures. Spike- and polyspike-and-wave discharges may be present (Fig. 14.11) (49). In the neonatal period, there is less diagnostic specificity when seizures occur (33,50). GCS are often accompanied by a generalized 10-Hz rhythm that is intermixed with slow waves of variable frequency (50). However, GCS may have an overlap with the EEG such that no changes are detectable (or interpretable due to artifact) on scalp EEG when a focal seizure originates in a distant or small portion of cortex (Fig. 14.12). In one series that analyzed the electroclinical spectrum of approximately 100 infantile seizures, 6/69 manifested GCS (49). The ictal EEG consisted of diffuse repetitive EDs that have been reported to be frontal or occipital predominant (49). Seizure termination may be poorly defined with alternating ictal and background rhythms gradually leading to resolution (33,49,50). For those with abrupt seizure termination, return of background activity or diffuse attenuation or slowing was noted. In adults, focal clonic seizures are associated with a polyspike-and-wave pattern in the EEG of the primary motor

area. Compound muscle action potentials occurring simultaneously in agonist and antagonist muscles followed the polyspikes in the intracranial EEG with a latency of 17 to 50 ms in 1 study, with the muscle contractions occurring during the slow waves (48). Clonic status epilepticus may follow another form of status (i.e., myoclonic status epilepticus) and appear with variable EEG ictal patterns commonly associated with rhythmic bilateral bursts of high-amplitude delta activity with intermixed spikes and polyspikes.

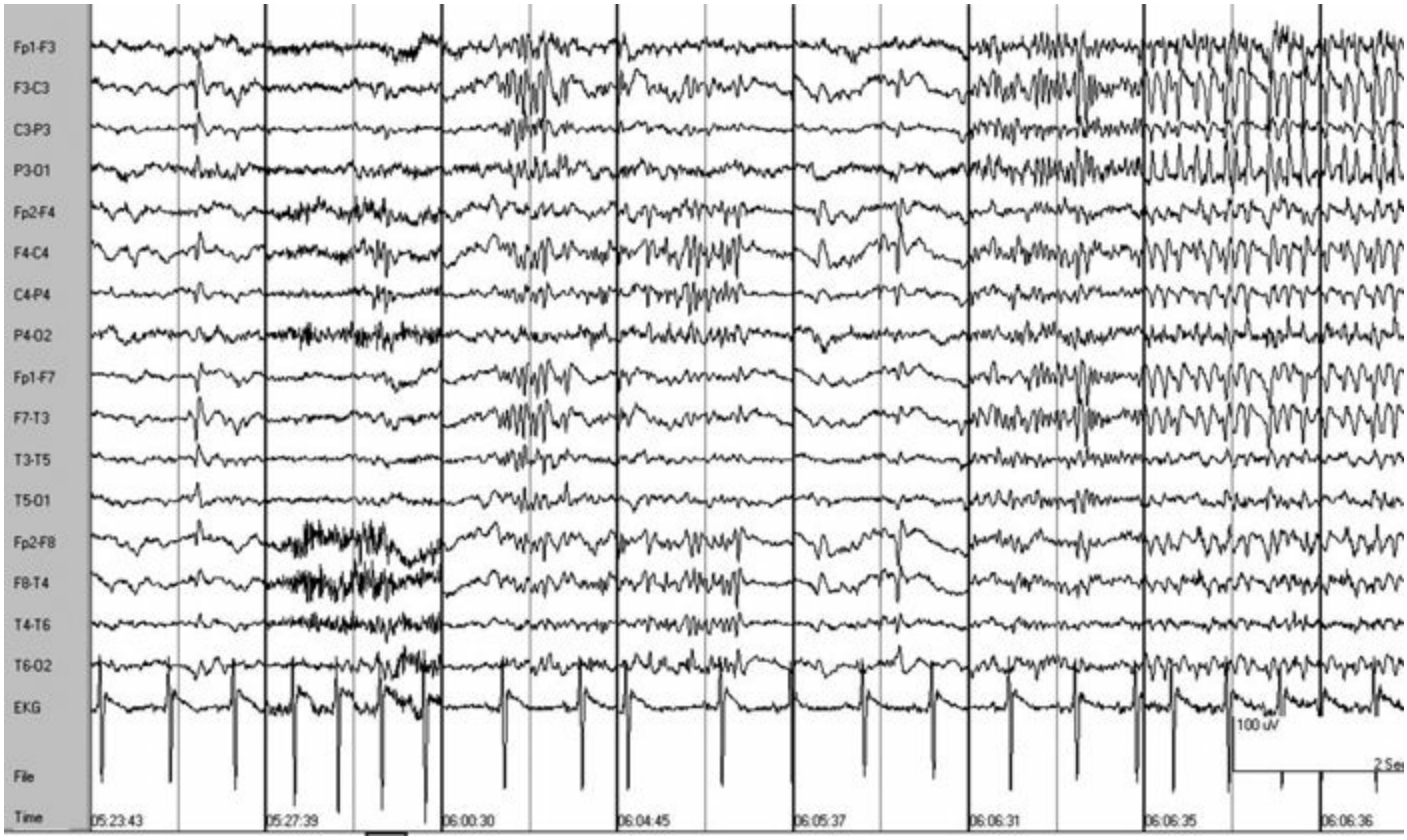

Figure 14.11. Ambulatory EEG with 2-second segments of lateralized spikes (seconds 1 and 5), lateralized bursts of polyspikes (seconds 3 and 4), GPFA (second 6), and diffuse polyspikes (second 7) in a patient with EGE and mixed seizure types including GMS.

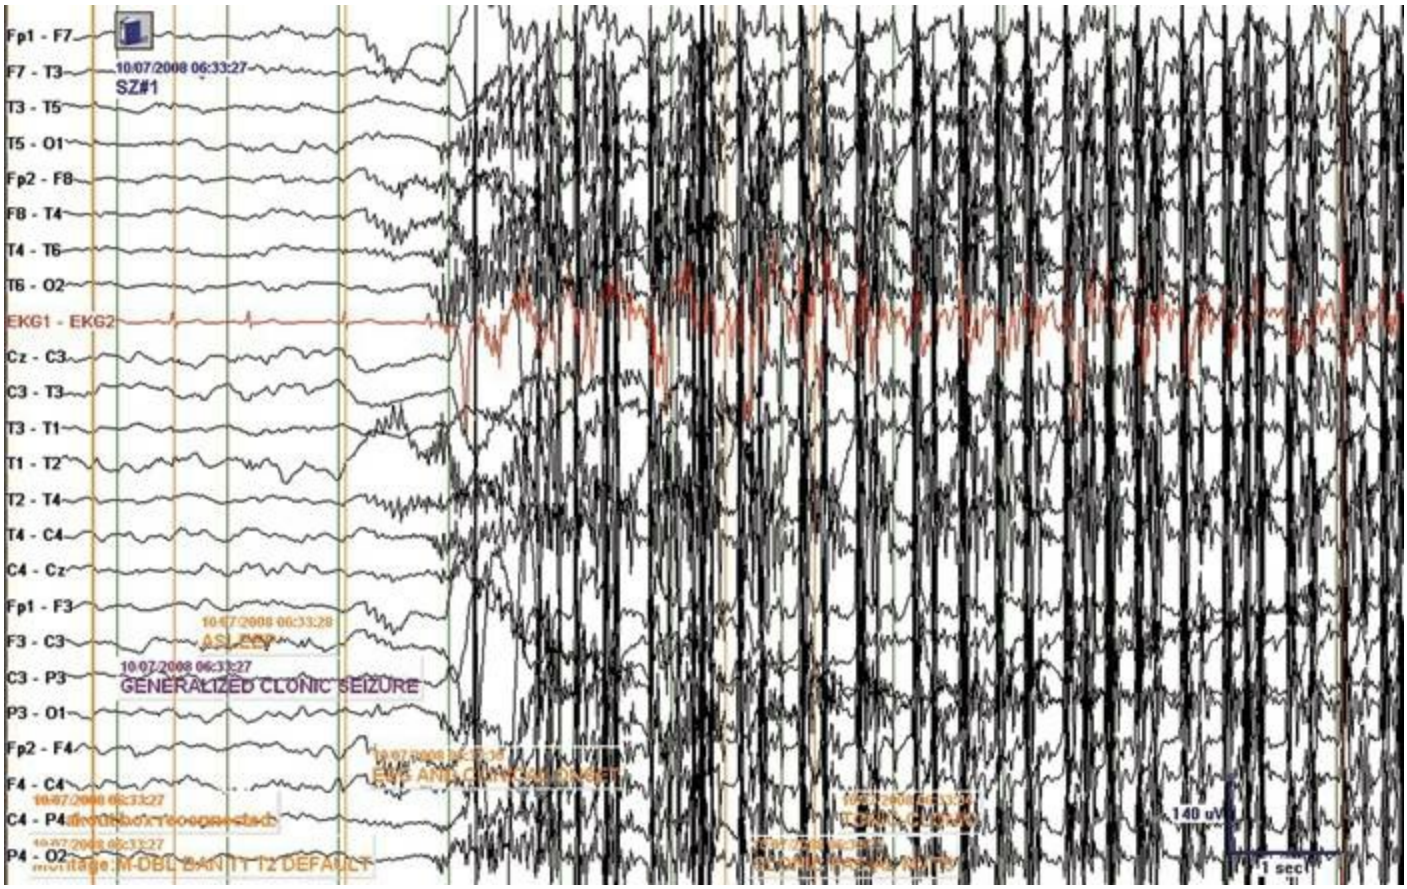

Figure 14.12. GCS in a 14-year-old with mental retardation and long-standing drug-resistant GMS. Note the phasic myogenic artifact at the start and throughout the seizure with mild increase in frequency but without change in the apparent amplitude.

Clinical Correlation

When ictal activity involves the primary motor cortex, clonic convulsions of the body can occur (48,50,51). GCS are usually noted in the neonatal or early infantile period (49). They are not characteristic of any particular epileptic syndrome, but an underlying structural–metabolic etiology is more likely with GCS than with GTS (50). GCS are typically focal- onset seizures in the adult, though in the neonate and infant are more likely to appear bilateral, despite a focal onset. Benign neonatal convulsions may demonstrate frequently repeated clonic (or apneic) seizures that occur about the fifth day of life (aka fifth day fits); however, no etiology or concomitant structural–metabolic component is typically found. When inherited in an autosomal dominant fashion, benign neonatal familial convulsions reveal a family history of similar GCS. Other more malignant epilepsies (Dravet syndrome) may have normal development during the first year of life until developing a generalized or unilateral febrile clonic seizure that heralds the onset of this devastating epilepsy syndrome. Nonepileptic clonic jerks may be seen in convulsive syncope and breath-holding spells, as well as in the recovery phase of patients who experience cataplexy, and are important mimics of clonic seizures that require a different approach to management (50).

Pathophysiology

The pathophysiologic basis for GMS is incompletely understood (19,25,33,41). Some of the key neural connections that are involved with GMS have been elucidated with brain stimulation and from epilepsy surgery patients. In addition, a genetic basis for many of the individuals that possess these seizure types is common and is continuing to unfold (47,50). A heterogenous group of structural

pathologies underlie similar ictal semiologies that are associated with GMS, but despite the vast differences in neuroanatomical substrates, the end result is a generalized motor seizure that bears a similar alteration in motor behavior.

The GTC seizures associated with GGE arise from corticoreticular and thalamocortical pathways, though the precise mechanisms for initiation, propagation, and termination are not fully understood (52). GGE with GTC seizures have been associated with gene mutations involving ion channels, including the sodium channel (SCN1A and SCN1B), calcium channel (CACNA1H), and chloride channel (CLCN2) (16,53). Animal models (e.g., genetically epilepsy-prone rat that when exposed to audiogenic kindling can have seizures that mimic a GTC seizure) have implicated brainstem structures (lateral geniculate body, ascending paths through anterior thalamus and mamillary bodies, and the substantia nigra and locus caeruleus) in the pathogenesis of generalized seizures (54). The spread of hyperexcitability to subcortical, thalamic, brainstem, and spinal cord structures corresponds with the tonic phase of the seizure. Following this, an inhibitory impulse at the level of the thalamus interrupts the tonic phase creating the discontinuous bursts of electrical activity that are manifest clinically as repetitive clonic jerks. GTC seizures that begin from a focal onset have received more extensive evaluation than those that occur in association with the GGE (55).

The pathophysiology of GTS suggests recruitment of the subcortical and the corticoreticular system, which connects the frontal attention areas to the pontine reticular formation and is normally responsible for postural tone and orienting behavior (25,56). A subcortical–cortical polysynaptic connection seems plausible given the clinical observation that corpus callosotomy has a beneficial effect in patients with GTS (22,23). A heterogeneous combination of several seizure types may also coexist, yet share a single epileptogenic symptomatic substrate (22,24,30). Tonic postural (focal) seizures usually arise from the contralateral mesial frontal or parietal cortex from a structural basis or, less frequently, through genetic means (i.e., autosomal dominant frontal lobe epilepsy). The maximal electroshock animal model produces generalized tonic extensor rigidity during electrical stimulation that serves as a mimic of human focal seizures (57). Other animal models demonstrate that an intact brainstem is required to produce a tonic seizure and that it is not solely dependent on intact frontal cortex (58). The reticular formation within the upper midbrainstem is probably involved, given that electrical stimulation will reproduce similar behaviors and lesions in that area suppress them (57). In humans, MRI has demonstrated altered anatomic architecture near the red nucleus of the brainstem in patients with GTS, providing further support for brainstem involvement (59). Limiting extrapyramidal motor inhibition with tonic spasms as a release phenomenon has also been postulated (25). The GABA–chloride ionophore complex appears to play a role in the development of GTS (22,23).

GMCSs are hypothesized to be produced by both cortical and subcortical generators that involve the thalamocortical and reticular projections (43). Because of the wide variety of mechanisms associated with the clinical expression of myoclonic seizures, no single pathology has been identified (41). In patients with EGE, a wide range of pathologic substrates may exist, although frontal lobe abnormalities may favor a predisposition (45). A genetic propensity for the existence of a structural lesion underscores the best-described pathophysiologic mechanisms for myoclonic seizures, with various modes of inheritance observed. For example, the progressive myoclonus epilepsy syndromes have isolated gene loci involved in the majority of the disorders (46). Myoclonic seizures associated with X-linked inheritance, chromosomal abnormalities, mutant mitochondrial DNA, ion channelopathies, and defects of neurotransmitter systems form part of the wide variety of the genetic influences that have been reported (41,45,46).

In GCS similar to GTC, the motor neocortical structures are implicated in the hypersynchronous cortical neuronal discharges associated with seizures (48–51). Hemiclonic seizures (sometimes alternating) may occur (i.e., Dravet syndrome) though, commonly, GCS appear as GMS if they arise from a region adjacent to the motor strip and exhibit rapid propagation either through the corpus callosum or the rostral brainstem (48,51). The pathogenetic mechanism for clonic contractions noted with these seizures is unclear (49,51).

TREATMENT

Many ASD trials conducted are based upon the epilepsy syndrome classification (i.e., partial epilepsy) as opposed to individual seizure type. Over 30% of patients with GGEs and GTC seizures may be refractory to treatment (60). If the patient is not controlled on a newer ASD, it may be useful to try valproate (VPA) at maximal doses even if it has been used earlier at conventional levels. When large-scale randomized clinical trials compared ASDs concentrating on individual seizure types (complex partial and secondarily generalized seizures), no significant differences were seen with older ASDs in the efficacy of GTC seizures (61). A follow-up Veterans Affairs cooperative study comparing VPA and carbamazepine (CBZ) demonstrated no difference in the efficacy of GTC seizures, despite smaller studies suggesting the superiority of VPA in the treatment of GTC seizures (62). Large pragmatic ASD drug trials incorporating the newer ASDs were evaluated in 2 large studies in the United Kingdom: the Standard and New Antiepileptic Drugs (SANAD) trials. One arm (Arm B) of the study evaluated patients with generalized epilepsy and found that VPA was better tolerated than topiramate and more effective than lamotrigine (63). VPA has demonstrated noninferiority in multiple trials assessing GTC seizures and is considered a first-line treatment (64). In addition, lamotrigine (LTG), topiramate (TPM), levetiracetam (LEV) and possibly zonisamide (ZNS), barbiturates, and benzodiazepines are ASDs effective in GTC seizures with a broad spectrum of activity.

GTS are a clinical marker for medical intractability in patients with epilepsy (22,23). VPA is a useful ASD with an intravenous preparation available for replacement therapy and rapid loading. VPA and LTG may demonstrate synergy in patients with GTS in combination. Patients with LGS who have GTS may respond to CBZ; however, it can aggravate myoclonic and atypical absence seizures. LTG, TPM, ZNS, and LEV are ASDs that may be useful in patients with mixed seizures that include GTS. Rufinamide and clobazam are newer ASD treatment options that are useful in the treatment of patients with mixed seizure types that include GTS (65). Phenytoin (PHT) is an effective treatment for patients with tonic status epilepticus (22,40). Tonic seizures have occurred paradoxically from IV benzodiazepine administration (22). Resective surgery may be an effective option for patients with tonic seizures in whom a focal structural lesion is responsible for the seizures (65,66), though it is rarely efficacious when mixed seizure types associated with EGE exist (66,67). Corpus callosal section is an effective palliative treatment for most patients with drop attacks due to GTS (68). Vagus nerve stimulation (VNS) is a less invasive adjunctive treatment that may be useful (67). Stimulation of the anterior nucleus of the thalamus may be promising for patients with GTS given the pathophysiology involving subcortical structures (22). The modified Atkins diet that is high in fat and low in carbohydrates may also be beneficial for patients GTS (69).

Myoclonic seizures are usually responsive to VPA in the majority of cases, though the teratogenic potential for the female population has limited use during the child-bearing years. VPA resistance or unusual presentations of medical illness with myoclonic seizures may occur with seizures of frontal

lobe origin. LEV is probably the most commonly used alternative to VPA and is effective against GTC seizures as well. VPA, LEV, LTG, TPM, ZNS, and clonazepam may all be effective ASDs in the treatment of patients with myoclonic seizures (64). LTG has been used as an initial treatment approach in female patients due to teratogenic concerns though caution is advised because of the possibility of aggravating myoclonic seizures (63). PHT, CBZ, gabapentin, tiagabine, pregabalin, and vigabatrin may aggravate GMCS and should be avoided (70). Other less commonly used agents include acetazolamide, piracetam, and stiripentol (22,70). The ketogenic diet should be considered if ASDs are ineffective for myoclonic seizures though exacerbation of behavioral problems and metabolic acidosis should be considered (especially with TPM and ZNS) (69,70). VNS may also be a useful adjunct in patients with myoclonic seizures with a broad spectrum of activity (67).

Early use of phenobarbital in the neonatal period for clonic seizures is tempered by the limited evidence for its efficacy and the results from animal studies that raise concern for deleterious effects during early development (50,70). Benzodiazepines and PHT have also been considered one of the first-line therapies when clonic seizures occur in the neonatal and early childhood period (49,70). ASD use in adolescence and adulthood for GCS should have broad spectrum of activity when other seizure types are encountered though a primary focal onset should be considered and surgical evaluation excluded for those with a lesion on brain MRI (48,51).

VPA may be useful in many patients with GMS though idiosyncratic risks with VPA treatment are increased in those <2 years of age, treated with polytherapy, and patients with inborn errors of metabolism (70). People with myoclonic epilepsy with ragged red fibers (MERRF) should avoid VPA due to the potential for reduction in the cellular uptake of carnitine and metabolic dysfunction that may result in hepatic failure. Felbamate has demonstrated a broad spectrum of activity though its use is limited by adverse effects. Combinations of ASD (i.e., VPA and LTG) may also provide a synergistic result (71). Implications of genetic mechanisms suggest avoiding sodium channel blockers in certain epilepsies (i.e., Dravet syndrome due to SCN1A mutation). Overall factors predicting a favorable health-related quality of life in newly diagnosed epilepsy with any of the GMS have included the number of ASDs, the presence of a comorbid behavior or cognitive problem, parental depression, and family functioning and demands (72). Active interventions, including education, information on consulting services, seizure tracking cards, and reminders to take ASDs, aid compliance and reduce GTC seizures (73). Children, as well as adults, with both focal and GMS seizures may respond favorably to VNS not only for seizures but for mood disorders (level C) (67). VNS has been recommended prior to corpus callosotomy by some and may facilitate ASD reduction improving over time (67). Children with swallowing problems and GMS should be monitored closely for potential aspiration. Corpus callosotomy is the surgical procedure of choice for disabling GMS when resection is not feasible though it renders few patients seizure-free (66). Generalized tonic and GTC seizures are often improved with up to 80% reduction, whereas myoclonic seizures and focal seizures are not (66). A palliative benefit is noted in most patients, and an improved response to ASD therapy may follow sectioning (66).

SUMMARY

GMS are the sentinel of epilepsy by virtue of their convulsive nature. Video–EEG monitoring is the gold standard for identifying nonepileptic mimics and classification. Many causes exist though pathogenic mechanisms remain largely unknown. The most frequently encountered GMS are GTC seizures involving most age groups and epilepsy syndromes. SUDEP is a real outcome for patients

with drug-resistant GMS most likely to occur in patients with GTC seizures (20). Counseling patients about lifestyle management to ensure safety is an important goal to guide realistic expectations of outcome. Broad-spectrum ASDs are the mainstay of medical therapy for patients with GMS and unclassified epilepsy. Newer ASDs (65), evolving pharmacogenomics (16), dietary manipulation (69), emerging surgical techniques, and new forms of neurostimulation may provide new hope to patients when GMS are uncontrolled (72).

CHAPTER 15 ABSENCE SEIZURES

EMILY ROBBINS AND DENNIS J. DLUGOS

BACKGROUND

An absence seizure is characterized by a sudden interruption of activity, followed by a blank stare and possible upward rotation of the eyes. The event lasts a few seconds to half a minute and ends with a sudden return to activity (1). Absence seizures can be typical or atypical, and can occur as part of at least five epileptic syndromes, including childhood absence epilepsy (CAE), juvenile absence epilepsy (JAE), juvenile myoclonic epilepsy (JME), myoclonic absence epilepsy (MAE), and Lennox–Gastaut syndrome (LGS). CAE is common, accounting for 10% to 17% of all childhood epilepsy, and is slightly more common in girls than boys (2–4).

"Typical" and "atypical" absence seizures are sometimes considered two distinct seizures types. Yet, it is important to recognize that they exist along a continuum with a significant amount of overlap in patient characteristics, seizure semiology, and EEG features (Table 15.1). The clearest distinguishing features between typical and atypical absence seizures are the presence of any associated neurodevelopmental disabilities in the patient: Patients with typical absence seizures are at an increased risk for attention deficit hyperactivity disorder (ADHD), learning differences, and mood disorders (5), while patients with atypical absence seizures usually have overt developmental delay and intellectual disability (6).

Table 15.1 Features of Typical and Atypical Absences Seizures

Features	Typical absence	Atypical absence
Development	Normal; increased risk ADHD/ learning difficulties/mood disorders	Delayed → Intellectual disability
Seizure onset	Abrupt	Insidious
Seizure duration	~10 s	>10 s
Provoked by HV	Very likely	Less likely
Postictal period	Absent or brief	Present
Associations	Automatisms	Changes in tone
Ictal EEG	3 Hz per second spike-and-wave	Heterogenous; <2.5 Hz per second spike-and-wave
Interictal EEG	Usually normal or short GSW bursts	Abnormal: background slowing, disorganization, focal epileptiform abnormalities

TYPICAL ABSENCE SEIZURES

Clinical Features

Typical absence seizures last an average of 10 seconds, are usually provoked by hyperventilation, and postictal confusion is either absent or very brief (7,8). The International League Against Epilepsy (ILAE) classification recognizes seven subforms of typical absences (2):

- Absence with impaired consciousness only
- Absence with mild clonic components
- Absence with atonic components
- Absence with tonic components
- Absence with automatisms
- Absence with autonomic phenomenon

Most patients exhibit a mix of these subforms. In the majority of absence seizures, the first clinical sign is arrest of activity, but other initial signs include eyelid movements, eye opening, altered awareness, or automatisms. As the seizure evolves, other clinical signs may develop. In a clinical and EEG study including 339 typical absence seizures in 47 children, the first clinical sign occurred at an average of 1 second into the seizure (SD 1.29, range 0 to 9 seconds), and included arrest of activity (46%), eyelid movement (28%), eye opening (19%), altered awareness (7%), or automatisms (4%) (9). Most children who were engaged in an activity prior to the episode had an arrest of activity, though 8% continued their activity. If awake with eyes initially closed, the eyes opened in 59% of all the seizures and in at least one seizure in 95% of children. Some children opened their eyes at the beginning of the seizure and others a few seconds into the seizure. Staring was seen in 78% of children who had their eyes open. The direction of the eye stare tended to be consistent in an individual child, but varied among children. Consistent myoclonic movements involving muscles of the head, face, trunk, and limbs were seen in four children. Automatisms were seen in 41% of seizures and were mostly oral (72%). The child was unaware of the automatisms in 75% of cases and partially aware in 20%. Response testing revealed that 75% were completely unaware, with no response to testing and no memory of the events, during at least part of the seizure, and an additional 20% were partially unaware.

In untreated patients, absence seizures are frequent and are quickly documented on routine EEG testing, with most seizures occurring within 10 minutes of EEG recording, and more than 90% of seizures occurring before or during a trial of hyperventilation (8).

TYPICAL ABSENCE SEIZURES

EEG Features

Absence seizures are characterized electrographically by bilateral, synchronous, symmetric spike-and-wave discharges at a frequency of approximately 3 Hz, a finding first published in 1935 by Frederic Gibbs and William Lennox (10) (Fig. 15.1).

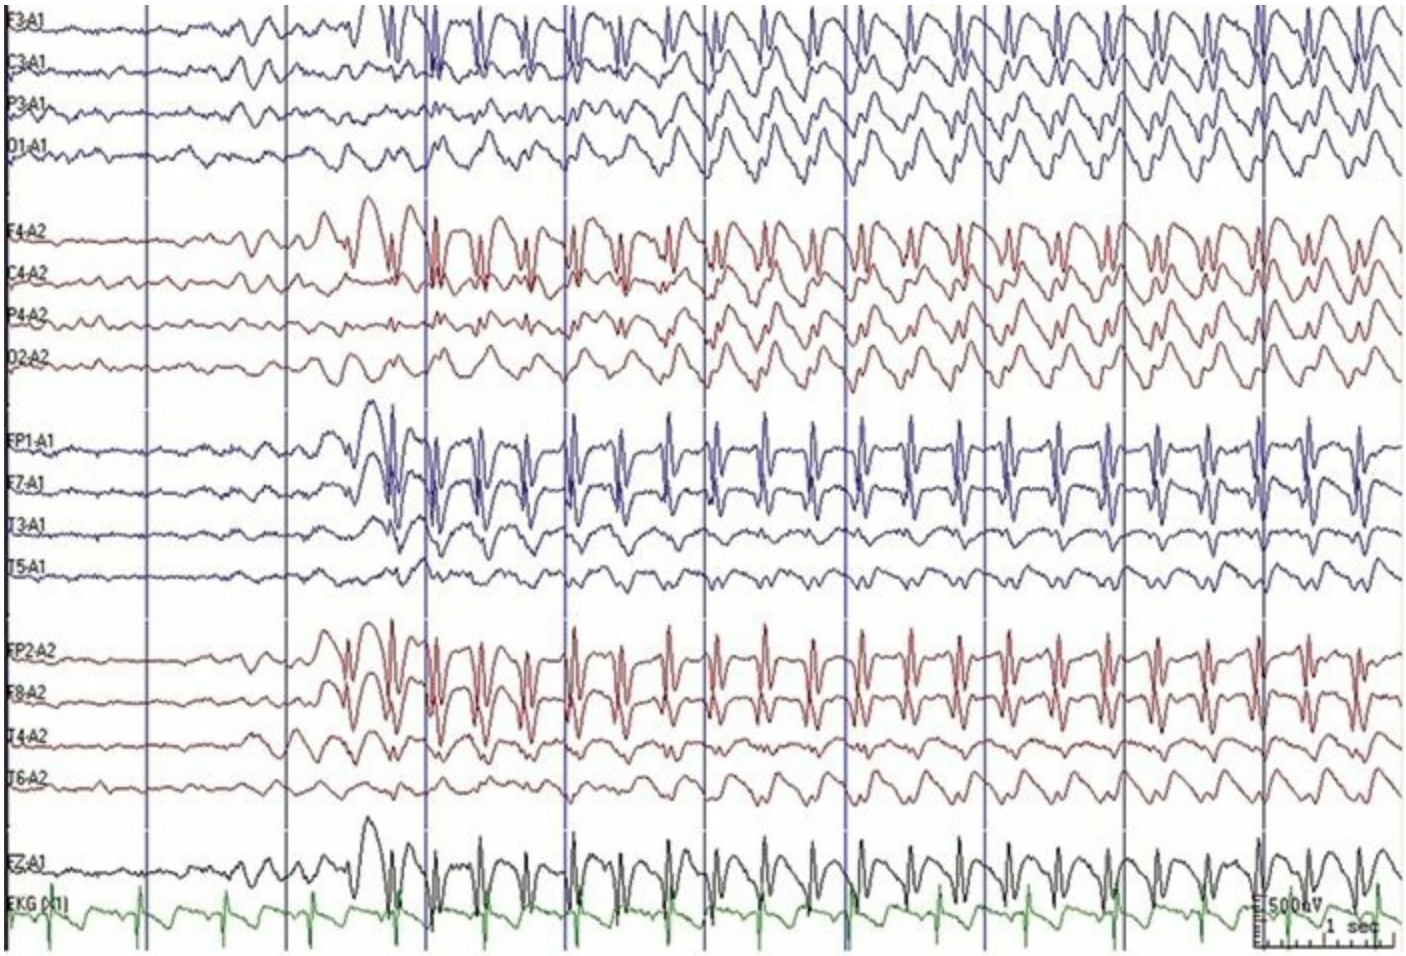

Figure 15.1. EEG during hyperventilation showing generalized, 3 Hz spike-and-wave discharge. Use of an ipsilateral ear reference montage often provides a clear display of spike-and-wave morphology.

In a recent randomized clinical trial of newly diagnosed patients with CAE (5,8,11), the median time to first seizure across 440 patients on a pre-treatment EEG was 6.0 minutes (range 0 to 59 minutes). The median number of seizures per 1-hour study EEG was 5 (range 1 to 60), and the median seizure duration was 10.8 seconds (range 3.3 to 77.6 seconds). The median duration of shortest seizure per EEG was 7.5 seconds (range 3 to 77.6 seconds), whereas the median longest seizure per EEG was 14.9 seconds (range 3.6 to 105.3 seconds). At least one seizure lasting 20 seconds or longer was noted in 29% of subjects (129/440).

Generalized spike wave (GSW) frequency at seizure onset is typically 3 Hz, with a range of 2.7 to 4.0 Hz. Toward the end of the discharge, the frequency often slows and the spikes become less obvious or disappear. The electrical field of the GSW burst is maximally negative at the bifrontal or frontopolar electrodes. Within a sample of 721 GSW bursts reviewed by three EEG readers for morphologic characteristics, 84% (604/721) of bursts contained single spike-and-wave discharges at onset, 3% (21/721) contained polyspike-and-wave discharges at onset, and consensus on spike morphology could not be reached with 13% of bursts (96/721) (8). Since only 3% of bursts contained definite polyspikes and 13% of bursts contained unclear spike morphology, usually because of inconsistent morphology based on electrode location or montage, GSW morphology may not be a reliable and reproducible variable to consider when evaluating EEG features and treatment response, later evolution of other seizure types, or outcome.

EEG variations may be present in typical absence seizures. The ictal onset can be asymmetric for about 0.5 seconds prior to generalization on scalp EEG. While most bursts are frontally predominant at onset, some are predominant in the occipital regions. Unilateral discharges are very rare in

untreated patients, but can be seen occasionally once treatment is begun. Fragments of GSW bursts are also seen, and are especially common after treatment is begun. Photoparoxysmal response is uncommon in typical absence seizures, seen in only 1% to 15% of patients (8,12).

The interictal EEG in most children with CAE is usually normal, unless short fragments of GSW bursts are present. Rhythmic posterior bilateral delta activity, ranging from 2.5 to 4 Hz, is seen in 21% to 32% of patients (8,9); frontal intermittent rhythmic delta activity in 4.5%; focal sharp waves (distinct from fragments of GSW) in 2.5%; and focal slowing in 0.7% (8). During sleep, GSW bursts become more irregular in frequency and morphology, with polyspike and wave discharges seen in 40% of children (9).

ATYPICAL ABSENCE SEIZURES

Clinical Features

Patients with atypical absence seizures often have a structural or metabolic (remote symptomatic) etiology for their epilepsy, and baseline rates of developmental delay and intellectual disability are as high as 95% (6). Since typical and atypical absence seizures can both include complex automatisms, incontinence, and changes in tone (13), a classification of atypical absence seizures should not be based on seizure semiology alone, but rather on a combination of patient factors, ictal semiology, and EEG features. In general, atypical absence seizures have a more insidious onset and offset, are longer in duration, include hypertonic or atonic components, and are less likely provoked by hyperventilation than typical absence seizures (2,6).

EEG Features

Typical and atypical absences share many similar clinical and EEG features, and should be considered as a part of the same continuum (14). Patients with atypical absence seizures have a more heterogeneous ictal recording, often with unclear ictal onset and offset, asymmetric spike-wave discharges, GSW frequencies of 2.5 Hz or less, and are less likely to activate with hyperventilation (2,6). Ictal duration can be unusually brief (<3 seconds) or long (>60 seconds). Interictal abnormalities often include background slowing and disorganization, focal or multi-focal slowing, focal or multi-focal sharp waves, and fragmentary and asymmetric spike-and-slow-wave complexes (2,6).

EPILEPSY SYNDROMES

Typical absence seizures are a core feature of at least five epilepsy syndromes: CAE, JAE, JME, MAE, and LGS.

CAE is defined by frequent daily absence seizures in normal school age children with EEG showing bilateral, synchronous, symmetric, approximate 3-Hz spike wave discharges, superimposed on a normal EEG background (2,5).

JAE occurs in older children, with onset between ages 8 and 16 with a peak age between 10 and 12 years (15,16). The syndrome includes absence, generalized tonic clonic seizures (GTCs) and myoclonic seizures and typically requires long-term treatment. The absences in JAE can be frequent, although usually less frequent than CAE, and are typically not triggered by hyperventilation (2,5,17).

In JME, absence seizures occur in about one-third of patients and are usually infrequent and not associated with automatisms, making an accurate absence seizure count challenging to obtain. They generally respond well to treatment, although long-term treatment is usually required (2,17). The overlap between JAE, JME, and primary GTCs upon awakening can be substantial, but the presence of myoclonic seizures should prompt careful consideration of a diagnosis of JME.

Atypical absence seizures are seen in MAE and LGS. Both syndromes occur in children with associated neurodevelopmental disabilities and other seizure types. Absences in MAE are often associated with rhythmic myoclonic jerks, and are treatment-resistant (2,17). In LGS, tonic and atonic seizures, plus atypical absence seizures, are the core seizure types. Absence seizures in LGS are challenging to monitor, since clinical signs can be subtle and the children typically have coexistent cognitive and behavioral disabilities.

Eyelid myoclonia with absences (Jeavons syndrome) includes typical absence seizures with the usual ictal signature of approximate 3 Hz GSW and episodes of rapid eye flutter with retention of awareness (eyelid myoclonia). In Jeavons syndrome, the eyelid myoclonia typically correlates with GSW or polyspike and wave discharges on EEG. Some patients with absence seizures have paroxysmal eyelid movements with no ictal change on scalp EEG other than eye flutter artifact. This condition can be easily confused with Jeavons syndrome, and differentiation between the two requires EEG. However, neither the ictal eyelid myoclonia of Jeavons syndrome nor the paroxysmal eyelid movements sometimes associated with absence seizures typically respond to treatment with antiepileptic drugs (18–20).

Absence status epilepticus, which can involve typical or atypical absence seizures, is defined as prolonged absence seizures lasting more than half an hour, with continuous impairment of consciousness and generalized discharges of 1 to 4 Hz spikes or polyspikes and slow waves on the EEG. Absence status can be a seemingly unprovoked exacerbation of an underlying seizure disorder or may be associated with inappropriate antiepileptic drug choice, drug intoxication, drug withdrawal, or electrolyte disturbance (21). Once absence status is successfully treated or stops spontaneously, the patient typically returns to baseline without deleterious effects, as long as injuries are avoided.

Pathogenesis

Absence seizures are provoked by an abnormal thalamo-cortical circuitry that activates abnormal oscillatory rhythms, which then generate 3 Hz spike-and-wave discharges (22). The cellular mechanism involves low-current T-type calcium channels, which are blocked by ethosuximide (ESM) (17). $GABA_B$ receptors appears to play a role in the generation of absence seizures as suggested by the observation that $GABA_B$ receptor agonists worsen and $GABA_B$ receptor antagonists suppress absences (22).

Genetic factors play an important role in the pathogenesis of typical absence seizures, as suggested by a high concordance rate among twins (23). Mutations in genes that encode $GABA_A$ receptor (24), voltage-gated chloride channels (25), and T-type calcium channels (26) have been identified. However, the vast majority of patients with absence seizures do not have an identifiable genetic cause at this time.

About 10% of patients with early-onset absence epilepsy, defined as onset age before 4 years of age, have glucose transporter 1 (GLUT1) deficiency caused by a mutation in SLC2A1. GLUT1 is a protein that facilitates the transport of glucose across the blood–brain barrier (27,28). GLUT1

deficiency can be diagnosed by gene testing or by the presence of hypoglycorrhachia (fasting CSF glucose <2.2, CSF/plasma glucose ratio <0.45) (27). This diagnosis is important because seizures caused by GLUT1 deficiency can be treated with the ketogenetic diet. SCL2A1 mutations do not appear to play a major role in absence epilepsies beginning after the age of four (28).

Differential Diagnosis

Absence seizures may be confused with normal daydreaming, inattentiveness associated with ADHD, tics with eye blinking or facial movements, or focal seizures with impairment of awareness. However, in a child with absence seizures, a careful history will usually reveal stereotypic episodes of arrest of activity, decreased responsiveness, associated ocular, facial or extremity automatisms, and a quick return to baseline. Isolated staring episodes without other features are almost never absence seizures, but rather reflect normal behavior or inattentive ADHD. Clinical signs suggesting that the staring episodes are nonepileptic include: the events do not interrupt play; the events were first noticed by a professional such as a teacher, rather than a parent; and the staring child is responsive to touch or "interruptible" by other external stimuli (Table 15.2). Each of these features has close to 80% specificity for suggesting nonepileptic staring episodes. Twitches of the arms or legs, incontinence, or upward eye movement are more likely to be seen in epileptic seizures (29).

Table 15.2 Clinical Signs Suggesting that Staring Episodes are Nonepileptic. Specificity is the Percentage of Children without Epilepsy who are Correctly Identified as Not Having Epilepsy

Clinical sign	Specificity for nonepileptic staring episode (%)
Do not interrupt play	~80
First noticed by professional, not parent	~80
Staring interruptible by stimuli (touch, sound)	~80

Diagnostic Evaluation

For most children, routine EEG will confirm the diagnosis of untreated absence seizures within 10 minutes, if a trial of hyperventilation is performed early in the EEG recording (8). In the CAE treatment trial, only 6% of patients required more than 30 minutes of EEG recording to confirm the diagnosis, and 92% of patients had seizures before or during the first trial of hyperventilation (8). Once treatment has been initiated, treatment response should be assessed by clinical history, office-based trials of hyperventilation, and routine EEG, since approximately 30% of patients who are seizure-free by parent-teacher report have seizures on a 1-hour EEG recording (12).

Treatment

Based on the results of the CAE treatment trial, published in 2010, ESM has class I evidence as the optimal initial treatment for CAE (5). This double-blind, randomized, controlled trial enrolled 453 children with newly diagnosed and untreated CAE, who were randomly assigned to treatment with

ethosuximide (ESM, n = 156), lamotrigine (LTG, n = 149), or valproic acid (VPA, n = 148). The primary outcome measure was freedom-from-failure (FFF), defined as no clinical or electrographic seizures at 16 to 20 weeks of therapy and no treatment-limiting adverse effects. The FFF rates for ESM and VPA were similar (53% and 58%, respectively, P = 0.35) and were higher than the FFF rate for LTG (29%, P < 0.001 when compared to both ESM and VPA). Discontinuation rates due to adverse events were not significantly different between the three drugs. However, post-treatment attentional dysfunction was more common with VPA than with ESM (49% and 33%, respectively, P = 0.03). The study concluded that while ESM and VPA were more effective than LTG in the treatment of CAE, ESM is the optimal initial treatment for CAE as it was associated with fewer adverse attentional effects.

At 12 months of follow-up, ESM and VPA remained superior to LTG, but the VPA group experienced higher rates of drug discontinuation and attentional dysfunction. VPA-associated weight gain also became apparent at 12 months follow-up (12). Across all three treatment groups, only 37% of all subjects continued on their first medication at 12 months. FFF rates for ESM and VPA were similar (45% and 44%, respectively, P = 0.82) and were higher than LTG (21%, P < 0.001 when compared to both ESM and VPA). Almost two-thirds of the 125 subjects with treatment failure due to lack of seizure control were in the LTG group. The largest subgroup (42%) of the 115 subjects discontinuing due to adverse events was in the VPA group. The previously reported higher rate of attentional dysfunction seen at 16 to 20 weeks in the VPA group compared with the ESM or LTG groups persisted at 12 months (P < 0.01).

Strikingly, even the best initial monotherapy fails in 55% of children with CAE over the first 12 months (12). Overall, ESM provides the best, though still very suboptimal, combination of efficacy and tolerability, and does not worsen inattention. VPA is as effective as ESM for seizure control, but has higher rates of adverse effects and worsens inattention. LTG is not as effective in controlling seizures, but is well-tolerated and does not worsen inattention. If ESM fails, then either VPA or LTG are possible second-line choices depending on seizure burden, attentional difficulties, body mass index, and other factors. If all three drugs fail in monotherapy, then combination therapy can be considered (17), although high-quality evidence to support its use is lacking.

Other medication treatment options for CAE, either alone or in combination, based on case series and case reports, include zonisamide (30); benzodiazepines, particularly clonazepam (16); acetazolamide (13); levetiracetam (31); or felbamate (32). Ketogenic diet (33), vagus nerve stimulation (34), and amantadine (35) have also been reported in small case series to have efficacy in some patients with treatment-resistant absence seizures.

Importantly, carbamazepine, vigabatrin, and tiagabine are contraindicted in the treatment of absence seizures, since these agents have been reported to worsen absence seizures and precipitate absence status epilepticus (7,21,36).

Prognosis

Seizure Outcomes

In the CAE treatment trial, longer pre-treatment seizure duration was associated with better drug response outcome at 16 to 20 weeks. Children whose shortest seizure lasted longer than 7.5 seconds had better response to initial treatment than those with briefer seizures. However, patients with any seizures longer than 20 seconds were more likely to display attentional difficulties (8). These

findings underscore the complex relationship between seizures and inattention in CAE.

Reported long-term remission rates for absence seizures in CAE range from 56% to 84% (33,37). In small series, factors associated with persistent seizures past puberty include onset after 8 years of age, GTCs at the time of absence seizures, myoclonic jerks, eyelid or perioral myoclonia, family history of GTCs, absence status, and background slowing on EEG (38,39). Focal interictal spikes have not been shown to be related to outcome (40).

A retrospective cohort study of 115 patients found that age of onset $\geq$8 years and family history of GTCs in patients with CAE predict development of GTCs, but polyspike and wave discharges do not. It is possible that CAE with GTCs is a distinctive syndrome from CAE without GTCs (41).

One retrospective chart review of 119 patients found that typical absence seizures are more likely to respond to the initial antiepileptic drug compared to atypical absences, but the remission at 2 years is similar in the two groups (14).

There are few outcome studies of JAE. GTCs are seen in 47% to 95% of patients, and remission rates range from 37% to 62% (15,39,42,43). Some studies (15,42) have found that myoclonus and GTCs are associated with persistent seizures, but other studies have not confirmed this finding (39). Another case series of CAE and JAE found that patients who responded to initial AED therapy were more likely to achieve remission and not progress to JME (38).

Psychosocial Outcome

CAE is often described as a benign epilepsy, with few associated cognitive and behavioral challenges. However, there is a growing evidence suggesting that the psychosocial impact of CAE is grossly underestimated and the need for early detection and treatment of comorbid cognitive and psychological difficulties (37,44,45). In the CAE treatment trial, baseline rates of inattention were 30% to 42%, inattention did not improve even with successful seizure treatment, and VPA worsened inattention. This finding dismisses the notion that successful treatment of seizures also improves comorbid inattention in CAE.

Children with CAE, when compared to matched controls, also have increased risk of cognitive deficits (25% of CAE children), linguistic deficits (43%), psychiatric diagnoses (61%), particularly ADHD and anxiety disorders, and clinically relevant scores (30%) on a child behavior checklist. Only 23% of the patients in this study had interventions directed at these co-morbid conditions (44).

Long-term outcome is also very concerning. A population- based study from Nova Scotia found that young adults with a history of typical absence seizures had greater psychosocial difficulties later in life compared to children with a non-CNS chronic disease (juvenile rheumatoid arthritis). Findings are summarized in Table 15.3. On every measure, young adults with a history in CAE fared worse than young adults with JRA (37). Most patients in this study had entered remission of their seizures and, while persistence of seizures predicted even worse psychosocial outcomes, remission of seizures did not ensure favorable psychosocial outcome (37).

Table 15.3 Psychosocial Outcome of Patients with CAE Compared with JRA in their Mid-20s

	CAE patients (%)	JRA patients (%)	Odds ratio (CI)
Not a high school graduate	36	14	3.7 (1.3–10.4)
Special classes	16	3	5.7 (1.1–40.5)
Repeated a grade before diagnosis	20	3	7.6 (1.4–52.8)
Ever considered a behavior problem	41	10	6.4 (2.2–19.9)
Unplanned pregnancy	34	3	19.3 (2.3–426.1)
Psychiatric or emotional problems	54	31	2.6 (1.1–5.9)
Unskilled laborer	53	16	5.9 (1.6–24.0)
Manager or professional	0	29	Undefined
Not employed in area of training	50	14	5.7 (1.2–33.9)

Adapted from Wirrell EC, Camfield CS, Camfield PR, et al. Long-term psychosocial outcome in typical absence epilepsy. Sometimes a wolf in sheeps' clothing. *Arch Pediatr Adolesc Med.* 1997;151(2):152–158.

Whether early recognition and management of the many nonictal manifestations associated with typical absence seizures will improve long-term psychosocial outcome is unknown, but it is clear that successful seizure control with tolerable side effects—only achieved in <50% of children—should not be the sole therapeutic goal. Atypical absence seizures have long been noted to be associated with significant neurodevelopmental comorbidities. It is now clear that the nonictal manifestations associated with typical absence seizures also demand early recognition and intervention.

CHAPTER 16 EPILEPTIC SPASMS

KELLY G. KNUPP AND INGRID TUXHORN

Infantile spasms (IS) were first described in 1841 by James West in a letter to the Lancet titled "On a particular form of infantile convulsions" after he had observed these events in his own son (1). He described a "peculiar seizure disorder," which was later named West syndrome in his honor, that manifested with axial spasms (brief extension or flexion of the arms and legs typically associated with a drop of the head) occurring in clusters and failure of normal development. With the clinical application of electroencephalography (EEG) approximately 100 years later by Gibbs in the 1950s, the triad of West syndrome as an epileptic encephalopathy of infancy manifesting with spasms, psychomotor retardation, and hypsarrhythmia as a specific electroencephalographic signature was completely described (2). Hypsarrhythmia, as further described in the chapter, is a chaotic EEG pattern of high amplitude with multifocal spike–wave discharges.

An epileptic spasm (ES) is a brief bilateral arm and leg stiffening lasting 1 to 2 seconds in duration. An ES can be an isolated event or, more typically, occur in a cluster. It is a pervasive seizure type occurring in a number of epilepsy syndromes of infancy and childhood such as the West syndrome, Ohtahara syndrome or early epileptic encephalopathy with burst suppression, and Lennox–Gastaut syndrome (LGS). However, older children and even adults may have seizures that are semiologically similar to IS, so that the general term epileptic spasms may be more encompassing and appropriate (3). Similarly, the etiologies are quite varied, and although the prognosis is frequently guarded and often grave, a small proportion of children may show complete recovery without sequelae.

Historically, ES has evolved from a syndrome diagnosis to a seizure type as well as from a generalized seizure to its current classification of "unknown" seizure type. ESs manifesting in infancy were considered to be a generalized seizure type in the past classification framework of the International League Against Epilepsy (ILAE), when IS were placed among the generalized seizure disorders in the first 1970 classification schema. In the 1981 revision schema, IS were not featured, while in the 1989 epilepsy classification update, IS were reintroduced as an age-related generalized seizure type and epilepsy. In the 2001 and 2006 ILAE task force reports on epileptic syndromes, the concept of epileptic encephalopathies was introduced for the first time and specific age-related features were further characterized. Of the eight epileptic encephalopathies featured, early myoclonic encephalopathy, Ohtahara syndrome, and West syndrome are invariably associated with IS or ES as a leading seizure type, while Dravet syndrome and LGS only variably so (4). With the recent extensive use of video-EEG monitoring, it has become more obvious that ES, particularly in infancy, may be a feature of a generalized as well as a focal epilepsy and is due to varied etiologies and pathologies that may include metabolic and structural brain disease. Therefore, it is important to emphasize that IS and ES are not a diagnosis but an age-related seizure type seen in a number of epilepsy syndromes. This is an important consideration for appropriate medical or surgical management that significantly impacts on the short- and long-term prognosis. In the most recent report of the ILAE Commission on Classification and Terminology in 2010, ESs are listed as "unknown, insufficient evidence to

characterize as focal, generalized, or both" recognizing the various etiologies that can be associated with this seizure type (5).

EPIDEMIOLOGY

Epidemiologic studies from various countries show an incidence of ES of approximately 2 to 5 per 10,000 live births worldwide (6–10), with an estimated lifetime prevalence by age 10 years of 1.5 to 2 per 10,000 children (7,11). The lower prevalence rates most likely are a result of the associated mortality, evolution of ES into other seizure types, and incomplete determination in population-based studies of older children (12). A genetic predisposition may exist as ES have been reported in both monozygotic and dizygotic twins (13,14). Boys appear to be affected in 60% of cases, but in some studies, sex differences are inconsistent (6,9,15).

CLINICAL SEMIOLOGY OF ES

ES are seizures usually associated with a severe developmental epilepsy syndrome with onset in the first year of life, peaking between 3 and 10 months of age (16).

ES are brief axial movements with extension or flexion of the arms and legs that frequently appear in clusters. The seizure starts with a phasic contraction that lasts for <2 seconds, followed by an ensuing tonic contraction for 2 to 10 seconds, although only the phasic contraction may be present (17). Sometimes called tonic spasms, prolonged muscle or tonic contractions are seen in intractable cases (17). The three types of spasms—flexion, extension, and mixed—are classified by the type of contraction. In flexion spasms, the trunk, arms, legs, and head flex. In extension spasms, the back arches and arms and legs extend, while mixed spasms combine extension of the legs and flexion of the neck, trunk, and arms. Mixed spasms are the most common type, accounting for 42% of all ES. Flexion spasms account for 35% and extensor spasms comprise only 23% of all ES (17). Many children have more than one type, even in the same cluster, often influenced by position (18). If the trunk remains vertical, the resemblance is to a flexion spasm; if the patient is horizontal, what looks like an extension spasm is seen (19). The contractions themselves also may vary in intensity, and ES can range from only a subtle head drop, upward eye deviation, or shoulder shrug, which usually occurs at the beginning of an episode, building up to more marked muscle contractions (18,20). Videotelemetry with electromyography (EMG) of ES has shown that the first activated muscle can vary in the same patient between different clusters or even from spasm to spasm within the same cluster, while the EEG shows no variation of the patterns. Even if the same muscle were initially activated with every spasm, the ensuing sequence or pattern of muscle involvement may differ within the same cluster (21).

The initial spasms, at the onset of the epilepsy, are usually mild before they become more characteristic and full-blown, as described above, which may produce a delay in diagnosis. This subtlety also can occur when spasms resolve, leading to need to clarify with EEG true treatment response.

Complex rotation of the eyes, deviation, or nystagmoid movements may occur in two-thirds of all ES (17). Eye movements may be independent of the spasm or may precede its development by weeks, which may result in delayed diagnosis of the epileptic nature, or occur as part of the motor features associated with the spasm (20). In addition, abnormal eye movements may suggest altered consciousness, but decreased responsiveness may follow ES or occur independently as a second

seizure type. Between spasms, most children cry, although this is probably not an ictal phenomenon but may be a result of surprise or pain (17). Up to 60% of all patients have respiratory pauses during the spasm, while pulse changes occur less often. Some spasms are induced by sound or touch, rarely by photic stimulation (22).

Rarely, one arm or leg is more extended or the head deviates to one side. Spasms are usually asymmetric on the side contralateral to a unilateral lesion such as hemimegalencephaly. Symmetric spasms and a symptomatic etiology usually indicate diffuse lesions such as in Down syndrome or neurofibromatosis (23); however, some children with focal or unilateral lesions may have only symmetric spasms (22,23). Recently, videotelemetry has allowed more frequent detection of asymmetric spasms. These patients may either have consistently asymmetric spasms or alternate between asymmetric or symmetric spasms.

Spasms may be intermixed with other seizure types in one-third to one-half of patients (24–26). The muscle contraction in spasms is faster than that in tonic seizures but slower than that in myoclonic seizures (27,28). Tonic seizures can occur simultaneously with or precede spasms and may be difficult to differentiate, requiring videotelemetry to define the seizure type. Tonic seizures last longer than spasms and lack the initial phasic component. Both may be generated by a similar mechanism or have a similar origin such as the brainstem (17).

Asymmetry of eye movements and head, neck, and limb jerks during the spasms is often documented by video-EEG recording implying a focal component. Focal seizures may occur before, during, or after a spasm and frequently precede a cluster of spasms (19).

There is frequently a diurnal variation of spasm frequency. Most spasms occur on awakening or after feeding, less often during sleep, and typical clusters last <1 to 5 minutes (17). Clusters typically consist of 3 to 20 spasms and occur several times a day, although single spasms may also occur (12). The spasms decrease in intensity at the end of longer clusters; however, the number and type of spasms may vary markedly from week to week with less day-to-day variation (17,29).

Focal seizures suggest a symptomatic cortical lesion, and a symptomatic etiology is likely if the focal seizure precedes the spasms (30). Focal seizures may precede the spasms or appear to induce the appearance of spasms. Such spasms are usually asymmetric with the predominant side conforming to that of the preceding focal seizure.

The effects of brain maturation on seizure semiology have been recently studied in children with well-defined “pure cultures” of temporal and extratemporal lobe focal epilepsy (31). It has been shown that axial or bilateral motor components comprising brief ES (depending on the patient’s age) frequently appear in an age-dependent fashion in young children with well-localized temporal lobe seizure onset (31). The more typical behavioral, psychomotor-type semiology only invariably manifests after 4 years of age while there is an inverse linear correlation of the motor ES components with age, and very young children may only manifest with ES. Only later does the semiology transition from the ES seizure type to the more adult focal dyscognitive seizure type. The semiology of temporal lobe epilepsy may, therefore, mimic generalized epilepsy with ES in the very young child or infant. Animal studies in immature rats, investigating the ontogenetic expression of drug-induced limbic seizures, have shown a similar age- dependent phenomenology in addition to high after-discharge thresholds that suggest a relative resistance of the immature limbic system to synchronization, so that extratemporal and possibly subcortical neuronal networks primarily contribute to the seizure semiology and not to the limbic system (32).

ASSOCIATED NEUROLOGIC FINDINGS

Psychomotor development may be normal or abnormal prior to onset of ES and reflects the etiology and presence of an underlying brain injury.

Abnormal neurologic findings on presentation of ES are quite frequent and may include motor impairments including tetraparesis, diplegia, hemiplegia, ataxia, athetosis, as well as blindness, deafness, and microcephaly. These findings have been described in 30% to 89% of patients and may be considered a prognostic factor for underlying brain injury as 85% to 90% of this group will eventually have developmental delay (11,15,33,34). Other studies have documented mental retardation in 75% and cerebral palsy in 50% of patients (11,25,26,35–37). Children with ES of unknown etiology are frequently neurologically normal prior to the onset of ES. Deterioration and loss of acquired milestones including head control, reaching for objects, and visual tracking may be affected. Loss of visual tracking may reflect the degree of epileptic encephalopathy present and appears to be a neurologic risk factor for poor prognosis of psychomotor development (38).

ETIOLOGY

A variety of disorders can cause ESs, with the etiology driving management, prognosis, and overall outcome. Preexisting brain damage has been demonstrated in 60% to 90% of cases reflecting pre-, peri-, or postnatal brain injury that may usually be determined by history and clinical neurologic examination. Children with a known etiology account for 70% to 80% of all cases and generally have a poorer prognosis than those with unknown etiology (9,26,39–41). Those with a structural etiology usually have more focality on neurologic examination, a history of focal seizures evolving into spasms, or lateralization on EEG (42).

Prenatal causes include congenital malformation, congenital infections, neurocutaneous disorders, chromosomal abnormalities, metabolic disorders, and congenital syndromes. Prenatal etiologies account for 30% to 45%, perhaps as many as 50%, of all cases (24,37,43,44). Tuberous sclerosis may be found as a cause in 10% to 30% of patients whose spasms are the result of a prenatal etiology (6,25,43,44). There is some radiologic evidence that a larger tuber burden is more likely to produce spasms rather than focal seizures, but this may also reflect an age-specific seizure manifestation (45). Although focal seizures are most common with focal cortical dysplasia (FCD), ES can occur (46); positron emission tomography (PET) scans may help to identify these patients (47). Occipital lesions are associated with earlier onset of ES than are frontal lesions (48). Neurofibromatosis type I has been associated with spasms, but these children usually have a better prognosis than other symptomatic etiologies (49). Chromosomal abnormalities, most commonly Down syndrome (44,50), represent approximately 13% of prenatal etiologies; these children usually do not have a poor prognosis compared to other symptomatic cases (51,52). There may be dual etiologies in this group of patients such as hypoxia (53).

Perinatal causes account for 14% to 25% of spasms but may be decreasing in frequency (54), perhaps because of a lowered incidence of neonatal hypoglycemia (55). Perinatal causes include hypoxic–ischemic encephalopathy and hypoglycemia. The difference may be relative, however, and reflect an increased survival in low birth weight infants rather than a true decrease in perinatal causes. Hypoxic–ischemic encephalopathy often involves severe neonatal electroencephalographic findings such as markedly or maximally depressed backgrounds in the first week of life (56). In children with cerebral palsy, deep white matter injuries are not associated with West syndrome;

therefore, spasms are less likely in premature infants (55). Spasms associated with periventricular leukomalacia typically have an EEG with hypsarrhythmia and an EEG prior to ES onset often demonstrates irregular polyspike and wave discharges that are located more posteriorly than anteriorly (28,57).

Postnatal causes include meningoencephalitis and other types of infections, stroke and trauma, hypoxic–ischemic insult such as near drowning and cardiac arrest, and tumors.

Besides the above-mentioned acquired brain injuries, cerebral malformations may account for up to 30% of cases and may include the various neurocutaneous syndromes (e.g., tuberous sclerosis complex, TSC), Aicardi syndrome, polymicrogyria, lissencephaly, hemimegalencephaly, schizencephaly, and FCD.

In addition, rare inborn errors of metabolism may manifest with infantile seizures and encephalopathy resembling ES. These conditions include Menkes disease, phenylketonuria and tetrahydrobiopterin deficiency, and mitochondrial diseases.

When the underlying cause cannot be identified, spasms are classified as unknown; in the past, this category accounted for up to 50% of cases. However, with increasing recognition of genetic etiologies and the advent of magnetic resonance imaging (MRI), only 10% to 15% of cases are still unknown (29,58–61). In fact, some imaging studies that were normal early in life may later demonstrate lesions on MRI after normal myelination has progressed (62). This time window in the first and second year of life may require serial imaging to detect the underlying pathology that will usually turn out to be type 1 FCD. ^{18}FDG-PET may also increase the likelihood for finding a malformation of cortical development not visualized with MRI scan in some cryptogenic patients.

Patients for whom a diagnosis is not established (unknown etiology), and previously identified as idiopathic, often are products of a normal pregnancy and birth, with normal development prior to the onset of spasms and normal findings on physical examination. The spasms begin abruptly without a background of previous focal seizures. Results of neuroimaging and laboratory evaluations are frequently normal. These patients have been shown to have higher levels of CSF corticotropin, serum progesterone, CSF GABA, and CSF nerve growth factor (63), which may reflect brain damage from the spasms or that stress hormones may play a role in the pathogenesis of spasms.

Although most children with spasms have no family history, 7% to 17% may have a positive history of febrile seizures, which may reach an incidence of up to 40% in unknown cases (25). Autosomal dominant inheritance is found in patients with TSC and neurofibromatosis type I presenting as ES. Sex-linked dominant inheritance may be seen in incontinentia pigmenti, double cortex syndrome, and lissencephaly. Some families have been reported with an X-linked transmission that has been mapped to regions Xp11.4-Xpter and Xp21.3-Xp22.1 and that also is associated with mental retardation (64). One of these loci is implicated in neuroaxonal processing (radixin, RDXP2) (65). ARX gene mutations were subsequently located in this same region at Xp22.13 (66–68). Chromosomal translocations may also be implicated in Down syndrome presenting with ES.

INTERICTAL AND ICTAL EEG

ES are commonly associated with the characteristic interictal EEG pattern termed hypsarrhythmia, which translates from the Greek as high-amplitude irregular waves. This pathognomonic electrographic pattern consists of random high-voltage slow waves and spikes that may vary from moment to moment in localization, amplitude, and duration (20). As early as 1952, Gibbs and Gibbs noted that the abnormality was almost continuous and represents a highly abnormal, chaotically

disorganized EEG pattern signaling the grave prognosis of a severe epileptic encephalopathy. The spike discharges are usually multifocal, independently arising from multiple regions of the brain. Rarely, the spike discharges may generalize, but it is not common to have rhythmic, repetitive, and synchronously organized runs of spike discharge patterns that resemble the petit mal variant or slow spike–wave EEG phenotype. Synchrony may significantly increase with age, while increasing asynchrony may occur with advancing sleep stages. On serial EEG recordings, fluctuation and a waxing and waning of the basic pattern may be seen (69–71). The interictal pattern may vary with some aspects being determined by the underlying pathology, some by the type of epilepsy syndrome, but also by age, sleep stages, and a variable combination of these (Figs. 16.1–16.6).

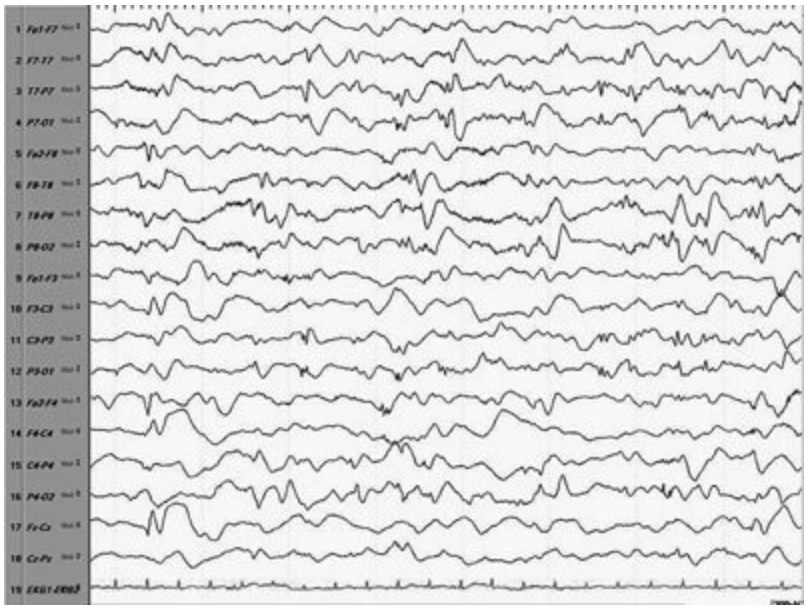

Figure 16.1. EEG showing classic hypsarrhythmia consisting of high-amplitude polymorphic delta waves and multiregional spike waves.

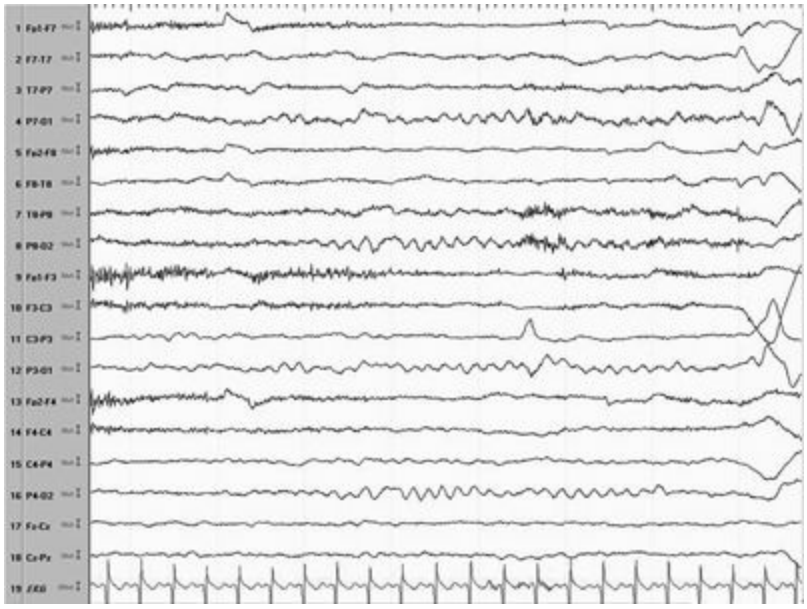

Figure 16.2. EEG of a patient in Figure 16.1 shows normal background and resolution of hypsarrhythmia within 4 weeks on ACTH.

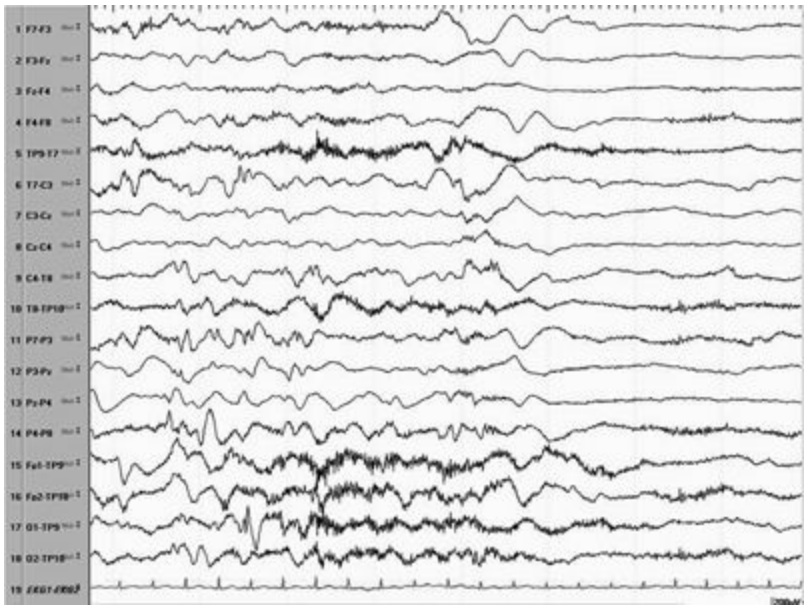

Figure 16.3. Electrodecremental pattern associated with an IS preceded by a broad central slow wave.

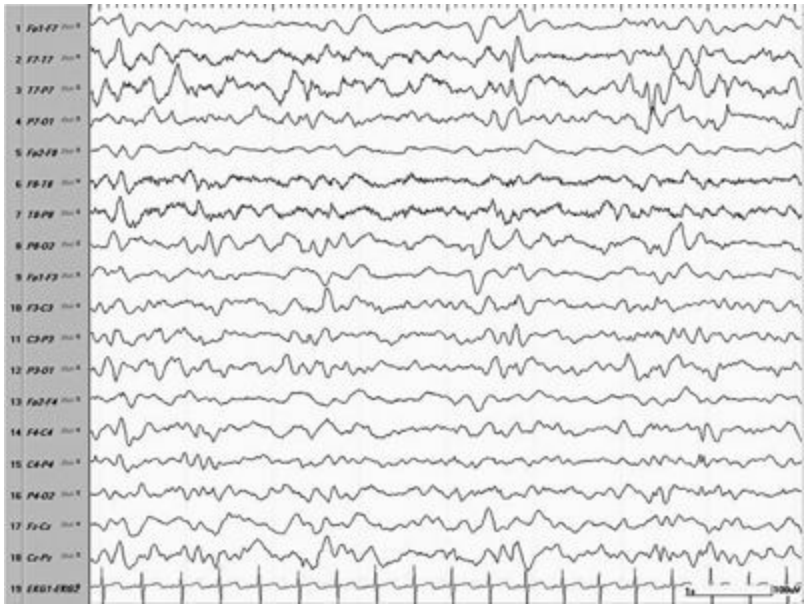

Figure 16.4. EEG showing a modified hypsarrhythmia pattern consisting of more lateralized high-amplitude multifocal spikes over the left hemisphere, suggesting a structural lesion.

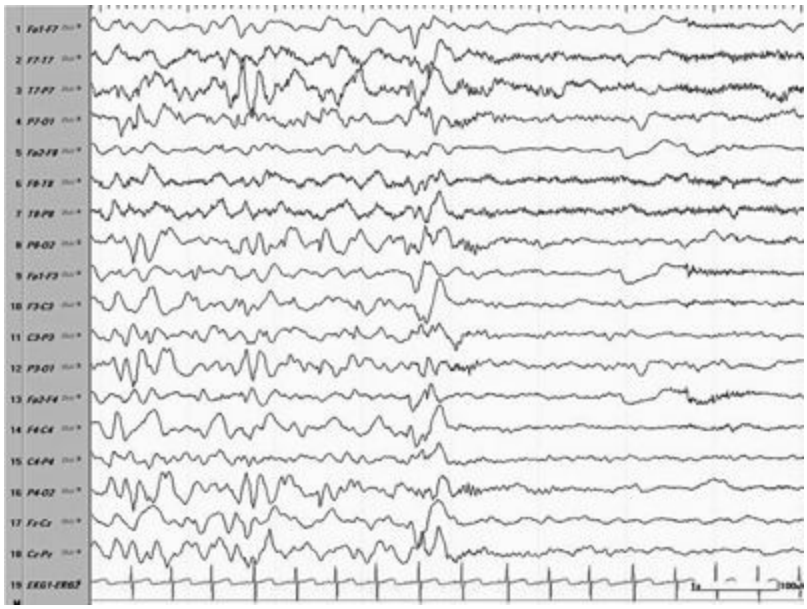

Figure 16.5. EEG showing an ictal change associated with an ES in the form of a generalized wave followed by an electrodecremental pattern.

Figure 16.6. Modified hypsarrhythmia in an older child with more synchronized posterior hypersynchronous activity.

Rarely, the interictal EEG may be normal early in the onset of ES and should, therefore, be repeated serially at close intervals if there is a high index of suspicion for the diagnosis of ES (17). By the same token, ES caused by a localized cortical pathology involving a single lobe or hemisphere may not be associated with hypsarrhythmia, and focal slow-wave activity or a persistently interictal spike focus localizing to one brain region even in the presence of multifocal spikes may point to focal epileptiform pathology such as cortical dysplasia, porencephaly, or a developmental tumor. Hypsarrhythmia may precede the presentation of ES and be found incidentally with routine EEG surveillance or patterns that evolve into hypsarrhythmia may be present prior to evolution of ES that may allow early detection of infants who are at risk for ES (72–74).

The background activity never approaches normal frequencies or amplitudes and is characteristically of high voltage (500 to 1000 mV), disorganized, and asynchronous with a waxing and waning quality (2).

The sleep–wake cycle has a significant effect on the manifestation of the pattern of hypsarrhythmia. During non–rapid eye movement (REM) sleep, there may be fragmentation of the hypsarrhythmic pattern, while by the end of REM sleep or during arousal from sleep, near-normal activity may occur; this "pseudonormalization" may also immediately precede a cluster of spasms (75,76). Long-term monitoring has disclosed variable patterns throughout the day, with more hypsarrhythmia noted in slow-wave sleep and less in REM sleep (22). Fast-wave bursts were seen during REM sleep in 35% of patients with spasms, sometimes occurring periodically until clinical spasms appeared and the patient awakens (21). Spasms may start subclinically in REM sleep (76).

Any variation in the characteristic hypsarrhythmic pattern as described above has been termed modified hypsarrhythmia and includes background synchronization, very focal features, voltage asymmetries, generalized background burst suppression, and slow waves without spikes (17). In an analysis of pretreatment electroencephalograms, the modified pattern occurred in up to 36 (69%) of 53 patients with spasms; cortical dysplasia was associated with hemihypsarrhythmia or burst suppression (77).

Regarding the role of the EEG as a prognostic tool, a burst–suppression pattern, as seen in children with Ohtahara syndrome, suggests a poor prognosis; a lower-voltage EEG may indicate a better outcome (77), as may preservation of hypsarrhythmia between spasms (28,54), faster background activity, and absence of postictal electrodecremental responses (as described in the following paragraph). However, children with more typical features of hypsarrhythmia such as disorganization, slowing, high-amplitude, spike, and electrodecremental discharges independent of seizures, absent normal sleep architecture, burst suppression, hemihypsarrhythmia, occipital hypsarrhythmia, interhemispheric asymmetry, and interhemispheric synchronization may predict a more severe developmental and epilepsy seizure prognosis (77). In late-onset ES, a more organized electroencephalographic background predicts better development while persistent hypsarrhythmia and a disorganized background may be a risk factor for poorer prognosis (78).

The most common ictal discharge that has been described consists of an initial multiphasic, high-amplitude slow wave, sometimes of positive polarity or less frequently a de novo low-amplitude, brief, fast frequency discharge (19,28). The generalized positive slow waves are followed by attenuation or an electrodecremental response, observed mainly at PZ (parietal midline), FZ/PZ, or FZ (frontal midline) with some variable degree of laterality (17,23). Because the decremental activity follows the slow wave and clinical spasm, it most likely is a postictal phenomenon (19,28), and the slow wave corresponds to the actual ES. An electrodecremental response can also be seen in the absence of a clinical seizure (12). Slow-sharp and slow-wave complexes, although less frequent with spasms, differ from the elongated appearance of those in myoclonic seizures (28). Diffuse attenuation, generalized spike wave, paroxysmal fast activity or fast frequencies, and slow wave are also associated with ES. There is no correlation between the semiology of the spasms and the different ictal patterns. The ictal pattern usually is brief, only lasting for approximately 1 second, while longer patterns are usually also associated with behavioral arrest (22). EMG shows that the axial muscles contract earlier than the limb muscles and the head earlier than the arms (23). A review of the EEG and behavioral changes before and between the spasms suggests that a cluster of spasms may represent a single sustained ictal event rather than brief, repetitive seizures (79). Pseudonormalization and high-amplitude slowing may precede the spasms and are associated with decreased activity and interaction (76), while subclinical discharges without clinical manifestations are also possible at the end of a spasm cluster; however, surface EMG may confirm subclinical contractions without actual perceptible movement on video-EEG during the subclinical discharges

(28).

Fast activity is often associated with tonic spasms with sustained tonic muscle contraction and may be more common in asymmetric spasms, suggesting a cortical onset for spasms (76,78,80–82). Fast activity can also fade during repeated spasms or in partial seizures that occur with spasms (83).

CURRENT MODELS AND THEORIES OF THE PATHOPHYSIOLOGY OF ES

Several promising animal models to study the pathophysiology of ES have recently emerged. However, an ideal model that recapitulates every aspect of human ES does not yet exist. The ideal model would develop ES at the appropriate age and possess an EEG background similar to hypsarrhythmia; the extensor or flexor spasms would occur in clusters and have an associated slow wave followed by an electrodecrement, and the response to currently available medications would mimic that seen in humans. Some of the issues are interspecies differences in brain development and the lack of comparative developmental biomarkers across the species for variable seizure phenotypes and EEG signatures. However, each model will hopefully add another piece to the puzzle to give a clearer picture that will potentially translate experimental findings into clinically useful therapies. Several different models have been recently reviewed: (i) the corticotropin-releasing hormone (CRH) model examining the role of stress and response to adrenocorticotropic hormone (ACTH) in the developing brain; (ii) the N-methyl-D-aspartic acid model examining cryptogenic IS; (iii) the tetrodotoxin model examining hyperexcitability provoked by a decrease of neuronal activity; (iv) the multiple hit model examining cortical and subcortical lesions mimicking symptomatic IS; (v) the aristaless gene (ARX) mutation models, a genetic knockout model and a knockin model that recapitulates human mutations of ARX with an IS and MR phenotype and may prove the hypothesis that a deficiency of cortical interneuronal GABAergic inhibition (interneuonopathy) underlies developmental epileptic encephalopathies; and lastly (vi), the Down syndrome model, Ts65Dn Mouse model, that suggests that $GABA_B$ receptor alterations (agonists) may be a spasm-provoking mechanism (84,85).

From a recent human tissue study of four infants with FCD and IS treated with surgical resection, $GABA_A$ receptor abnormalities have been described using a novel technique of electrophysiologic recording after oocyte membrane injection from cortical brain tissue of these infants. Characterization of the cortical $GABA_A$ receptor properties demonstrated unaltered intrinsic physiology but altered neuromodulation to neurosteroids and zinc, which parallels the response of IS to ACTH (86).

Current theories on the generation of ES are that they represent a nonspecific age-dependent reaction of the immature brain to injury involving subcortical structures that acts diffusely on the cortex, leading to the hypsarrhythmic electroencephalogram pattern and the generalized spasms (12). Individual case reports have described abnormalities in the pons and involvement of the serotonergic, noradrenergic, or cholinergic neurons in the brainstem nuclei to support this assumption (87–89). Brainstem origin has also been postulated on the basis of abnormalities in brainstem auditory-evoked responses in patients with spasms and disruptions of REM sleep (90–92). In addition, ES and hypsarrhythmia have been noted in children with severe cortical injury or absence of cortex, supporting this theory. Because hypsarrhythmia occurs mainly during sleep and the brainstem controls sleep cycles, this sleep association again suggests that the brainstem plays a role in the manifestations of ES (92,93).

The frequent intermixture of focal seizures with generalized or asymmetric spasms suggests a cortical–subcortical interaction, a hypothesis supported by the effectiveness of cortical resection in controlling generalized ES (19). In other words, the cortical lesion interacts with developing brainstem pathways, causing motor spasms that are similar to startle or cortical reflex myoclonus (83,94).

Further supporting the brainstem hypothesis are results of PET scans in patients with ES showing hypermetabolism of the lenticular nuclei (95). That serotonergic ([^{11}C]-methyl-L-tryptophan) and α-aminobutyric acid (GABA)-ergic ([^{11}C]-flumazenil) tracers may be more effective than FDG-PET in defining a focus in patients with ES also suggests brainstem involvement, because the raphe–cortical or striatal projections use serotonin as a neurotransmitter, and these pathways cause the diffuse hypsarrhythmic patterns on EEG (41). On ictal single photon emission computed tomography (CT) studies, both subcortical and cortical structures were activated (96).

The response to corticotropin suggests involvement of the hypothalamus and pituitary–adrenal axis. Baram has proposed that a nonspecific stressor releases the proconvulsant CRH, which may be the final common pathway for the multitude of etiologies of ES (97). CRH causes severe seizures and death in neurons associated with learning and memory, and its effects are especially important in infants because CRH receptors are most abundant during the early developmental period (98). To support the hypothesis that corticotropin inhibits the release and production of CRH through a negative feedback mechanism, Nagamitsu et al. (99) measured CSF levels of β-endorphin (also derived from a common precursor of corticotropin), corticotropin, and CRH (which releases both corticotropin and β-endorphin) in 20 patients with spasms. The CSF levels of β-endorphin and corticotropin were lower than in controls, as was the CRH level, although not significantly. Riikonen (63) observed that CSF corticotropin levels were higher in infants with cryptogenic than symptomatic spasms.

Because ES typically begin at the time when the first immunizations are administered, the question has been whether the association is causative or coincidental. Numerous anecdotal reports have noted the appearance of ES within a few hours to a few days after a diphtheria, pertussis, tetanus vaccination, although all controlled studies to date have failed to demonstrate any association (100–102). Some proposed immunologic mechanisms have been based on antibodies to brain tissue in blood samples from patients with ES (103,104), or increased numbers of activated B and T cells in the blood (83), or increased levels of HLA-DRw52 antigen (34). Calcium-mediated mechanisms have been postulated, but further studies are needed to substantiate this (105). mTOR pathways have also been implicated in TSC patients as well as children with cortical dysplasia and hemimegencephaly (106).

DIFFERENTIAL DIAGNOSIS AND EVALUATION

The true epileptic nature of spasms may be easily missed in the beginning and considered to be colic, gastroesophageal reflux, or paroxysmal crying (16). Other paroxysmal disorders that may mimic ES include benign myoclonus of infancy in which the interictal and ictal EEGs are normal, including in sleep; hyperekplexia, in which the jerks may be triggered by touching the nose; Sandifer syndrome due to gastroesophageal reflux, paroxysmal tonic upward gaze, jactatio capitis, spasmus nutans, breath-holding spells, and infantile gratification behavior (16).

West syndrome is the classic epileptic encephalopathy of infancy associated with ES and is characterized by a triad of ES, hypsarrhythmia, and developmental failure or regression. Over the

years, salaam seizures, jackknife seizures, axial spasms, periodic spasms, and serial spasms have been used as synonyms for ES.

The age of onset is typically between 4 and 8 months (17), but ES can occur as early as 2 weeks or as late as 18 months of age (12,107) and, rarely, can begin in adulthood. In some studies (107), late-onset spasms may be cryptogenic or associated with cortical dysplasia, hypoxic–ischemic encephalopathy, or genetic anomalies and were refractory to medications (17). Late-onset spasms may be intermixed with atonic, tonic, partial, myoclonic, or generalized tonic–clonic seizures or atypical absences. The characteristic spasms generally resolve spontaneously or evolve to other generalized seizure types or focal seizures but may persist as ES in 15% to 23% of patients beyond 3 to 7 years of age (35,36).

Watanabe has suggested that a subset of the cryptogenic group may be truly an "idiopathic" form of West syndrome (54). These patients have normal development, and the spasms usually remit after a short period. Developmental regression and focal interictal EEG abnormalities are usually not present; symmetric hypsarrhythmia reappears between each spasm in a cluster; and a family history of seizures is common. This group may represent from approximately half to 80% of the cryptogenic cases (25,97), referred to as "unknown" in the updated classification.

West syndrome may eventually evolve into LGS in many children ranging from 3% to 54% in various studies (108,109). Tonic seizures usually coexist with and are more marked during this stage of the syndrome. Seizure clustering is seen more frequently in West syndrome, but less frequently in LGS (23). Clusters of ES will usually become single spasms in LGS in parallel, with the changed interictal pattern from hypsarrhythmia to a generalized slow spike-and-wave pattern at 1 to 2.5 Hz (94).

The epileptic encephalopathy associated with ES needs to be differentiated from more benign epilepsy syndromes, particularly benign familial infantile convulsions (BFIC) and benign myoclonic epilepsy of infancy (BMEI) (110–112). A firm diagnosis is necessary before initiation of therapy because many common medications (specifically corticotropin and vigabatrin [VBG]) carry a higher risk of morbidity or mortality than most commonly used anticonvulsants. Like IS, the seizures associated with BFIC and BMEI present in the first year of life. The seizures of BFIC are usually focal, but the EEG may be normal (111). Myoclonic seizures in BMEI can occur in clusters. The EEG may be normal or show generalized spike-and-wave discharges but not the hypsarrhythmia or multifocal independent spike discharges typically seen in West syndrome. Because patients with ES may not display the distinguishing EEG abnormalities early in the disease, a normal or mildly abnormal record does not rule out West syndrome in the early disease stage, and follow-up EEG studies are essential for clarification. A pattern of normal development prior to seizure onset and continued normal development after seizures start is highly suggestive of benign epilepsy syndromes and not an epileptic encephalopathy with IS. In contrast, children experiencing IS may or may not be normal at seizure onset but will invariably demonstrate either developmental regression or failure to achieve developmental milestones in a timely fashion.

As with all forms of epilepsy, the evaluation begins with the history and physical/neurologic examination. The skin should be examined for evidence of neurocutaneous disorders and the fundi for a cherry-red macula suggestive of a storage or mitochondrial disorder or for chorioretinitis indicating possible transplacental infection. In one study, nearly half of all of the etiologic diagnoses were established or suspected by the historical and physical data. Many diagnoses, however, require confirmatory MRI, and once imaging is complete, approximately 70% of patients will have a confirmed etiologic diagnosis (113). In many cases, expensive and time-consuming laboratory studies

can be avoided. In the remaining 30% of cases, an etiology will be established for no more than one-third, leaving about 10% of cases in which a diagnosis is determined by results of lumbar puncture or metabolic or genetic testing. A more recent prospect study found etiologies in 61% of children, 33% had no etiology, and 6% were not fully evaluated. (61)

Neuroimaging

Much of the decrease in unknown cases is a result of the advances in MRI techniques of the past 10 to 15 years. Comparing etiologic categories of IS, Riikonen noted that identification of brain malformations increased from 10% between 1960 and 1977 to nearly 35% between 1977 and 1991 (114). Imaging should be considered essential to the evaluation. MRI is preferred to CT scanning because of the greater sensitivity for brain malformations and is not associated with the risk of radiation exposure. CT, however, can show subtle calcifications caused by transplacental infections. In a study of 86 patients with IS, MRI assigned 91% to a symptomatic etiology, most commonly hypoxic–ischemic encephalopathy (30%) (115) characterized by diffuse atrophy and thinning of the corpus callosum. Delayed myelination in 27% of patients did not appear to be associated with any specific etiology (Table 16.1).

Table 16.1 Magnetic Resonance Imaging Findings Implying a Genetic Etiology

Abnormality	Possible genetic association
Lissencephaly	
▪ Posterior predominant lissencephaly or Miller–Dieker syndrome	*LIS1* gene on chromosome 17
▪ Anterior predominant lissencephaly or band heterotopia	*DCX* gene on X chromosome
▪ Lissencephaly with cerebellar hypoplasia	*RELN* gene
Cortical tubers, periventricular nodules	Tuberous sclerosis; *TSC1* or *TSC2* mutations; 75%–85% are spontaneous mutations; parents should be evaluated
Perisylvian polymicrogyria	Some are familial; multiple associations X-linked recessive X-linked dominant Autosomal recessive 22q11.2 deletions
Cerebral calcifications	Transplacental infections
Loss of cerebral white matter	Pyruvate carboxylase deficiency
Hypoplasia of corpus callosum	Nonketotic hyperglycemia

Some MRI abnormalities suggest specific etiologies, many genetically based, which may require further evaluation. Genetic etiologies including Rett syndrome due to various mutations in the MECP2 gene, atypical Rett syndrome due to CDKL5 mutations, and X-linked ARX homeobox gene mutations need to also be considered in the etiologic diagnosis and diagnosed with chromosomal microarrays and specific mutational studies. Additional genetic and metabolic etiologies are continuing to be added to this list as our understanding of the genetic contributions to ES advances (116). Additional associated genetic diagnoses to consider include STXBP1, SCN2A, FOXG1, PCDH19, SLC2A1,

ALDH7A1, and POLG. The number of identified genes is growing, and therefore, a complete list is not possible. Improved genetic technology now allows large gene panels to be performed earlier leading to increased genetic diagnosis.

Metabolic Studies

Metabolic studies are indicated to identify more than 50 disorders associated with infantile seizures (117–119). A trial of folinic acid is warranted (120), as is a 100-mg intravenous pyridoxine bolus to exclude pyridoxine-dependent seizures. It is important to remember that further testing is required to completely exclude this diagnosis. Complete blood count, electrolytes (looking for an anion gap), and glucose determinations are appropriate. Measurements of uric acid, transaminases, lactate, pyruvate, ammonia, urine organic acids, and serum amino acids will identify the vast majority of inborn errors of metabolism linked to ES. In the past, phenylketonuria was a relatively common inborn error identified by testing that has been nearly eliminated by neonatal screening. Nevertheless, such screening is not routine in all countries, and measurement of urine amino acid levels will detect phenylketonuria and maple syrup urine disease, as well as other, rarer, metabolic diseases. Zellweger syndrome and neonatal adrenoleukodystrophy are other rare causes of ES that can be diagnosed with the serum very–long-chain fatty acid test (Table 16.2).

Table 16.2 Etiologies of Infantile Spasms Due to Specific Etiologies That May Respond to Specific Therapies

Symptomatic IS	Therapy
Pyridoxine-dependent seizures	Pyridoxine[a]
Phenylketonuria	Diet[a]
Maple syrup urine disease	Diet[a]
Glucose transporter defect	Ketogenic diet
Tumor	Surgery to remove tumor[b]
Arteriovenous malformation	Surgery to treat the malformation[b]
Sturge–Weber syndrome	Early surgery if medications fail[a]
Tuberous sclerosis	Vigabatrin, possible surgery if medications fail[a]
Biotinidase deficiency	Biotin[a]
Menkes disease	Copper histidinate[a]
Hyperammonemia disorders	Possible diet, depending on the disorder[a]
Nonketotic hyperglycinuria	Benzoate[a]
Cortical dysplasias	Possible cortical resection if medications fail[b]
Focal cortical dysplasia	Surgery if medications fail
Hemimegalencephaly	Surgery if medications fail

[a]Symptomatic with a specific therapy and a genetic etiology.
[b]Symptomatic with a specific therapy without an identified genetic etiology.

Lumbar Puncture

A few very rare disorders, such as nonketotic hyperglycinemia, may be detected only by study of the CSF (121). In addition to routine evaluations for glucose, protein, and cells, the CSF should be assessed for amino acids plus lactate and pyruvate to detect possible mitochondrial disorders. CSF

neurotransmitters are needed if cerebral folate deficiency is considered as an etiology, and CSF glucose will allow one to discern glucose transporter defects.

PHARMACOLOGIC TREATMENT

Recovery is only considered to have occurred when both the ES and the EEG abnormality of hypsarrhythmia have responded to treatment and ceased. More than 100 years after James West's initial description of IS, the effectiveness of steroids was first recognized and to date only two medications have class 1 evidence of efficacy: corticotropin and VBG (122,123). Corticotropin and, as of 2009, vigabatrin are approved by the Food and Drug Administration for use in the United States. In addition, some patients respond to valproic acid, lamotrigine, high-dose pyridoxine, topiramate, and zonisamide, while most conventional antiepileptic drugs are ineffective. Some drugs such as carbamazepine or oxcarbazepine may even worsen the seizures, which should be considered when IS are associated with focal features.

Corticotropin and Steroids

The effectiveness of corticotropin and steroids underscores how ES differ from all other epilepsy syndromes. In 1958, Sorel et al. (122) administered 4 to 10 IU/day of corticotropin to seven patients, four of whom responded within a few days while therapy failed in only one patient. In the 45 years since that report, efficacy has been repeatedly confirmed, but agreement is still lacking on the most appropriate dose and duration of treatment. Dosing is complicated by the existence of natural and synthetic forms of corticotropin. Studies of the synthetic product generally used much lower doses than studies of the natural product. It is estimated that 1 IU of synthetic corticotropin is equivalent to 40 IU of natural corticotropin. The synthetic version is used primarily in Japan where a low dose is 0.2 IU/kg/day and a high dose is 1 IU/kg/day. Even with the low dose, 75% of patients responded in one study (124). In contrast, natural corticotropin at doses up to 150 IU/m^2 body surface area/day succeeded in 14 of 15 patients; 5 later had relapses for a long-term response rate of 60% (125). A review of seven studies did not confirm a better response with 150 IU/m^2/day and 40 IU/m^2/day being a common dose (36). The overall long-term response rate ranged from 53% to 91%. Current dosing recommendations are now on the package insert.

Despite its effectiveness for ES, no medication carries a higher potential for significant side effects. Most children develop a Cushing syndrome with obesity, plethora, hypertension, and intense irritability. All patients are at risk for arterial hypertension, electrolyte imbalance, gastric ulcer, growth retardation, cardiomyopathy, or immunosuppression with increased risk of infection. In one study, the risk of serious side effects was 43% with 160 IU/m^2/day; the incidence was lower with lower doses (126). Death from infection and cardiomyopathy has ranged from 2% to 5% in some series. Sepsis, tuberculosis, meningoencephalitis, and protracted cytomegalovirus infection have been reported. Corticotropin exacerbates the seizures in a few infants, and treatment for more than a few weeks leads to steroid insufficiency if the drug is stopped abruptly (127). Parents must be fully informed of the associated morbidity and mortality risks (reported at approximately 2% to 5%) before the therapy begins, and these must be balanced against the virtual certainty of mental retardation if the spasms are not rapidly controlled. Careful follow-up with regular measurements of blood pressure, electrolytes, and urinalysis is mandatory. The current risk-to-benefit assessment favors corticotropin, but if another, less hazardous medication proves to be as effective; it would be

the drug of choice.

There are few comparative trials of the efficacy of steroids and ACTH but one double-blind trial showed that a 2-week trial of high-dose ACTH was superior to 2 weeks of prednisone, while another found no difference with either compound (128). In addition, some patients may respond to one drug but not the other. Following response to steroids or corticotropin, the relapse rate is high and variably reported between 33% and 56% (35). Relapses usually occur within the first 2 months following the end of treatment, but a second course may give a remission and response in up to 75% of patients (36). Recovery of mental function has been reported between 14% and 58%, particularly in patients with a cryptogenic etiology (125).

Vigabatrin

This drug has been reported to be effective in the treatment of ES of all etiologies, and in patients with TSC, it was superior to steroids (129). In 1991, 29 of 68 patients with medically refractory ES achieved complete resolution with VGB as add-on therapy, as did 12 of 14 patients who had TSC (130). VGB also might be effective in Down syndrome (131).

Since 1997, several controlled trials have been reported. Vigevano and Cilio (132) administered either corticotropin 10 IU/day or VGB 100 to 150 mg/kg/day to children with newly diagnosed IS. Eleven of twenty-three VGB patients responded (one late relapse) compared to 14 of 19 corticotropin patients (six late relapses). Vigabatrin was more effective in patients with TSC or cerebral malformations; corticotropin was more effective in patients with perinatal hypoxic–ischemic encephalopathy. There was no difference in cryptogenic cases. Appleton and colleagues (133) used VGB or placebo for 5 days, followed by open-label VGB. Seven of twenty patients in the VGB group were seizure free at the end of 5 days, as were 2 of 20 in the placebo group. For 14 days, Elterman et al. (134) treated 75 patients with 18 to 36 mg/kg/day (low dose) and 67 patients with 100 to 148 mg/kg/day (high dose) of VGB. Eight low-dose patients and 24 high-dose patients achieved complete control. In a study involving underlying TSC, all 11 patients treated with VGB responded, compared with only 5 of 11 patients treated with hydrocortisone (135). An American Academy of Neurology practice parameter published in 2012 stated that VGB "may be useful for short-term treatment of IS" (136).

VGB appears to be well tolerated. The reports of hypotonia, somnolence, or insomnia (137) are expected in a drug that enhances GABA activity. Constriction of peripheral visual fields, which substantially limits the drug's use, was not reported until 1997 (138) and now affects from 15% to 50% of patients. In one report (139), constriction occurred in more than 90% of patients who had been taking VGB for a mean of 8.5 years. Foveal function also may be impaired (140). Most studies have suggested that the constriction is not reversible; however, 8 of 12 patients who underwent full withdrawal improved significantly; none of the 12 who continued taking the drug did so (138). The problem is mild enough that most patients are unaware of the disturbance, which becomes apparent only on perimetric studies.

Unfortunately, visual fields are virtually impossible to evaluate in very young children, many with cortical visual impairment and visual inattention unrelated to VGB therapy. Given the catastrophic nature of IS, visual field constriction may be an acceptable price for seizure control and improved opportunity for normal development (139).

VGB has also been reported to be associated with MRI T2 signal abnormalities in the deep grey nuclei (141–143). These characteristic changes involve the basal ganglia, thalamus, dentate nucleus,

brainstem, and cerebellum. Restricted diffusion may also be seen with diffusion-weighted imaging and apparent diffusion coefficient maps. Changes appear to resolve with discontinuation of medication, reduction of dose and while medication has continued. Age and dose of VGB appear to risk factors for MRI changes. No clear clinical changes have been associated with reported MRI changes. It is thought that this likely correlates to intramyelinic edema that has been seen in animal models (144,145).

Valproic Acid

Before the availability of VGB around the world, single reports of seizure response to valproic acid were reported with tolerable side effects. In a 1981 report, valproic acid produced an "excellent" response in 4 of 18 patients treated with 20 mg/kg/day (146). A year later, 7 of 19 patients achieved good control (11 had also been treated with corticotropin) (147). Seizures were controlled in 11 of 22 patients treated with up to 100 mg/kg/day for 4 weeks (148). Other patients later responded but also received dexamethasone or carbamazepine, so the effect of valproic acid was less clear. Prospective randomized studies of efficacy against IS are lacking. Because liver failure is a risk in children younger than 2 years of age (149), although none of the reported patients were affected, valproic acid should be used cautiously and probably not as a first line of therapy for IS, particularly if metabolic etiologies have not been excluded (150).

Pyridoxine

A trial of 100 mg of pyridoxine intravenously is appropriate for patients with an unclear etiologic diagnosis because pyridoxine (vitamin B_6) dependence can be a rare but highly treatable cause of ES (151). Seizures caused by pyridoxine-dependent epilepsy typically cease immediately following intravenous administration of vitamin B_6 but may take several days. As early as 1968, however, it has been known that long-term oral administration of high doses of pyridoxine has been effective against non–pyridoxine-dependent seizures (152). In 1993, 5 of 17 patients treated with 100 to 300 mg/kg/day responded within 4 weeks—most within 1 week (153). In Japan, high-dose vitamin B_6 has been the drug of choice (153,154), with reported response rates of 10% to 30%. Loss of appetite, irritability, and vomiting are modest compared with the side effects of corticotropin or VGB, but there may be a high risk of gastric hemorrhage. Pyridoxine is not used as frequently outside of Japan, but given its relatively low-risk profile, a 1- to 2-week trial of 100 to 400 mg may be reasonable before or in addition to other therapies.

Nitrazepam

One of the earliest nonsteroid treatments for IS, the benzodiazepines succeed only occasionally but may be useful if more effective therapies have failed (155–157). Nitrazepam administered to 24 children controlled IS in 11, but hypotonia was reported as a significant side effect (158). A multicenter, randomized comparison of corticotropin and nitrazepam demonstrated no statistical difference between the two medications in significantly reducing spasms (159). Side effects with corticotropin were more severe, leading to discontinuation in six patients. Many reports noted an increase in oral secretions and a higher incidence of aspiration and pneumonia with nitrazepam. Several deaths occurred in one series (160). The incidence of mortality was 3.98 deaths per 100

patient-years when young epilepsy patients were taking nitrazepam and 0.26 deaths per 100 patient-years if the medication had been discontinued (161).

Other Antiepileptic Drugs

None of the new anticonvulsants have enough evidence of efficacy to permit a recommendation. The Japanese experience suggests that zonisamide may be effective in about one-third of patients (162), but controlled and comparison trials are lacking. Five of twenty-five patients had a complete clinical and electrographic response to doses ranging from 8 to 32 mg/kg/day; most responses occurred in 1 to 2 weeks (163). Zonisamide was well tolerated, but 20% of the patients in one study experienced anorexia and one patient lost weight (164). If the more than 30% efficacy figures hold up in controlled studies, zonisamide could become a first-line therapy.

Topiramate up to 25 mg/kg/day was effective in 5 of 11 patients with intractable ES (165). In another study, seizures decreased in 43% of 14 patients but worsened in 29%; no patient became seizure free (166). A prospective study with topiramate in doses up to 8 mg/kg/day found that 10 of 40 patients with new-onset ES responded to topiramate measured by seizure freedom (167). Before reports of aplastic anemia, three of four patients with medically intractable IS responded to felbamate as add-on therapy (168). Because aplastic anemia has not been noted in prepubertal patients, felbamate may be as safe as some other drugs and could be recommended if other medications have failed.

Anecdotal evidence, but no prospective controlled trials, supports the efficacy of lamotrigine. One report noted that 25 of 30 patients became seizure free (169). The usual dose is 6 to 10 mg/kg/day; however, three patients in whom VGB and corticotropin had failed responded to <1 mg/kg/day (169). Use of a low dose is important because rash, the major side effect, depends to some extent on how rapidly the dose is increased. The usual recommendation is a slow rise over 2 months to the minimum expected therapeutic dose. Given the need to control IS as soon as possible, this 2-month requirement decreases the therapeutic value of lamotrigine. If the very low dose is effective, however, lamotrigine becomes a fallback drug (170).

KETOGENIC DIET

The ketogenic diet is a decades-old therapy enjoying a resurgence of interest and widespread application. Two retrospective reports of 40 children suggest control of spasms in 20% to 35% of patients with otherwise intractable disease (171,172). An additional retrospective review of initial treatment of ES with ketogenic diet found seizure freedom within 1 month in 8 of 13 infants (62%) although compared to 18 of 20 treated with ACTH (90%). There was a longer lag in improvement of EEG with ketogenic diet (173). A prospective study for treatment of refractory ES found response rates of 35% at 1 month and 25% at 3 months, although additional medication had been added by 3 months (174). Children younger than 1 year of age can achieve ketosis and may benefit from the diet. Despite generally good tolerability, renal stones, gastritis, hyperlipidemia, and gastroesophageal reflux may occur. More recently, there has been a report of 40% seizure freedom (n = 19) with Modified Atkins Diet (175). This option may be more tolerable to some families.

INTRAVENOUS IMMUNOGLOBULIN

High-dose intravenous immunoglobulin (IVIG) is another effective nonantiepileptic drug therapy that may be effective in a variety of seizure disorders, especially when associated with an epileptic encephalopathy. All six children with unknown ES, but only one of five symptomatic patients, achieved complete remission (176). IVIG may also improve juvenile spasms, which are electrically and clinically similar to IS but occurring in older children (177). Doses range from 100 to 200 mg/kg administered every 2 to 3 weeks to 400 mg/kg/day for 5 consecutive days. Actual efficacy is unclear, however, and the most appropriate doses and duration have not been determined.

SURGICAL MANAGEMENT

Removal of an epileptogenic cortical lesion may be highly effective in treating IS and hypsarrhythmia. Patients with single lesions including tumors, FCD, porencephaly, hemimegalencephaly, and catastrophic epilepsy are ideal surgical candidates who should be selected early for surgery as there is compelling evidence that earlier surgery and shorter duration of epilepsy predict improved cognitive outcome (178).

A history of focal seizures that preceded or accompanied IS, cortical disturbances on MRI, or localized EEG abnormalities that suggest a cortical defect should prompt referral to a pediatric epilepsy surgery center (179).

COURSE AND PROGNOSIS

Prognostic features are overall difficult to assess. Signs of brain injury usually preclude complete recovery even in cases where seizure remission is achieved. In cryptogenic cases without evidence of brain lesions, the best outcome appears to be predictable in patients who do not lose visual eye contact (38). Although IS are self-limited and approximately 6% to 15% will recover spontaneously after a few weeks or months, control of epilepsy is difficult to predict in the individual case.

However, ES are a seizure type that are generally associated with a severe epileptic encephalopathy and carry a grave prognosis associated with significant morbidity and also mortality. Intractable epilepsy, mental retardation, and autism are possible consequences of ES. Mortality is increased in the acute short term due to treatment complications and neurologic morbidity underlying various etiologies. In addition, the long-term mortality may be high: a 25- to 35-year follow-up of 214 patients demonstrated that 31% died, many in the first 3 years of life (36,180). Eight of the 24 deaths by age 3 years were a consequence of complications of corticotropin therapy. The most common cause of death overall was infection. Of the 147 survivors, 25 (17%) had an intelligence quotient (IQ) of 85 or higher; 11 others (7%) were in the dull- normal range with IQs of 68 to 84; and 45% were retarded. Overall outcome is driven by the underlying etiology and seizure control. While some etiologies, such as severe hypoxic– ischemic encephalopathy and lissencephaly, will lead to death or mental retardation regardless of whether IS develop, children with cryptogenic spasms or spasms caused by FCD may have a normal or near-normal developmental outcome if the second factor, seizure control, is achieved. Accurate diagnosis and appropriate medical or surgical management need to be the gold standard in these cases to reduce the severe cognitive sequelae of this epileptic encephalopathy.

SECTION B EPILEPSY CONDITIONS: DIAGNOSIS AND TREATMENT

ASSOCIATE EDITOR: TOBIAS LODDENKEMPER

CHAPTER 17 PRESUMED GENETIC AND BENIGN FOCAL EPILEPSIES OF CHILDHOOD

ELAINE C. WIRRELL, CAROL S. CAMFIELD, AND PETER R. CAMFIELD

The idiopathic focal epilepsies (IFEs) of childhood account for 10% to 20% of all pediatric epilepsies and are characterized by the following features (1,2):

- Age-dependent occurrence, with specific peak ages for each subtype.
- Absence of significant structural lesions on neuroimaging.
- Normal neurologic status without prior neurologic insult.
- Favorable long-term outcome, with remission occurring prior to adolescence in most children.
- Genetic predisposition.
- Specific semiology: Most seizures are focal motor or sensory with dyscognitive features, although focal dyscognitive and focal evolving to bilateral convulsive seizures also may be seen; nocturnal occurrence is common, and frequency is usually low.
- Rapid response to antiepileptic medication in the majority.
- Specific electroencephalographic (EEG) features: Spikes of distinctive morphology and variable location superimposed on a normal background, with occasional multifocal sharp waves or brief bursts of generalized spike–wave; epileptiform discharges are often activated by sleep.

Table 17.1 summarizes the core/classic features of the presumed genetic and benign focal epilepsies of childhood.

Table 17.1 Benign Focal Epilepsy Syndromes

Syndrome	Age of presentation	Clinical features	EEG features	Prognosis
Benign epilepsy with centrotemporal spikes	Range, 3–13 y Peak, 7–8 y	Diurnal or nocturnal simple partial seizures affecting the lower face with numbness, clonic activity, drooling, and/or dysarthria, nocturnal generalized seizures	High-voltage centrotemporal spikes with horizontal dipole, activated with sleep; normal background	Remission by adolescence
Panayiotopoulos syndrome	Range, 2–8 y Peak, 5 y	Nocturnal seizures with tonic eye deviation, nausea, and vomiting; often prolonged	High-amplitude, repetitive, occipital, centrotemporal, or parietal spike and wave, with fixation-off sensitivity EEG may be normal or nonspecific	Remission within 1–2 y after onset
Late-onset benign occipital epilepsy (Gastaut type)	Range, 3–16 y Peak, 8 y	Brief diurnal seizures with elementary visual hallucinations, often with migraine-like, postictal headache	As above	Five percent suffer recurrent seizures in adulthood
Benign epilepsy in infancy	Range, 3–10 mo Peak, 4–6 mo	Clusters of seizures with motion arrest, decreased responsiveness, staring, simple automatisms, mild convulsive movements with possible secondary generalization	Normal- or low-voltage rolandic or vertex spikes in sleep	Remission by age 2 y
Benign familial infantile seizures	First days to months of life	Focal-onset seizures that may evolve to bilateral convulsive seizures. May have coexisting neurologic disorders Inherited in autosomal dominant manner	Benign familial infantile or neonatal–infantile seizures—interictal EEG often normal; ictal EEG shows fast activity in posterior head regions Benign familial neonatal seizures—interictal EEG may be normal or show rolandic discharges	Usually excellent with ultimate remission. Rare cases can result in epileptic encephalopathy
Autosomal dominant frontal lobe epilepsy	Teens to adulthood	Nocturnal seizures with hypermotor semiology	Normal or frontal spikes	Usually easily controlled with medication
Familial temporal lobe epilepsy	Usually second or third decade	Lateral: focal seizures with elementary auditory auras, aphasic seizures, often with progression to bilaterally convulsive seizures Mesial: autonomic aura, déjà vu, then may progress to focal dyscognitive seizure	Temporal spikes	Most respond well to antiepileptic medication
Possible benign focal epilepsy syndromes				
Benign partial epilepsy in adolescence	Range, adolescence Peak, 13–14 y	Motor or sensory symptoms, often with jacksonian march; auditory, olfactory, or gustatory symptoms never seen	Normal or nonspecific epileptiform discharge	Infrequent seizures that usually abate after a brief period

Benign frontal epilepsy	Range, 4–8 y	Head version ±trunk turning; fencing posture, sometimes followed by truncal, bipedal, or pelvic movements	Unilateral or bilateral frontal or posterior–frontal spikes	May persist into adulthood
Benign partial epilepsy in infancy with midline spikes and waves during sleep	Range, 4 mo–2 y	Cyanosis and motion arrest, at times with stiffening	Low-voltage, fast spike followed by higher bell-shaped slow wave over midline region in sleep	Remission by age 2–3 y
Benign partial epilepsy with extreme somatosensory-evoked potentials	Range, 4–6 y	Diurnal partial motor seizures with head and body version	High-voltage spikes in parietal and parasagittal regions evoked by tapping of the feet	Resolution by adolescence
Benign partial epilepsy with affective symptoms	Range, 2–9 y	Brief episodes with sudden fear, screaming, autonomic disturbance, automatisms, and altered awareness	Rolandic-like spikes in the frontotemporal and parietotemporal regions in wakefulness and sleep	Remission within 1–2 y

mo, months; y, years.

BENIGN EPILEPSY WITH CENTROTEMPORAL SPIKES

In 1958, Nayrac and Beaussart (3) described the clinical symptoms of benign childhood epilepsy with centrotemporal spikes (BECTS), and its excellent prognosis was recognized early on. In distinction to other focal epilepsies, rolandic spikes were reported to be unrelated to structural pathology (4) and, at times, observed without clinical seizures (5). Although BECTS is easily recognized in its "pure" form, atypical features are common and may make a confident diagnosis difficult.

Epidemiology

BECTS accounts for 6% to 10% of all childhood epilepsies. Onset is between 3 and 13 years, with a peak at 7 to 8 years and with resolution by age 16 (6). Boys are more commonly affected (7).

Genetics

The clinical genetics of BECTS is not clearly understood. Early work suggested an autosomal dominant inheritance of centrotemporal spikes (8,9); however, no causal gene has been found. Additionally, while such spikes are characteristically seen in BECTS, they are not pathognomonic and are also present in more complex epilepsy syndromes and autism spectrum disorders. In a study of 18 twin pairs, where one twin had classic BECTS, all 18 were discordant, suggesting that noninherited factors are important in development of epilepsy (10). In a genetic study of 53 probands with BECTS, 9.8% of the first-degree, 3% of the second-degree, and 1.5% of the third-degree relatives had a history of seizures, although epilepsy types were heterogeneous (11). Of affected first-degree relatives, 38% had febrile seizures, 19% BECTS, and 10% epilepsy–aphasia spectrum disorder. Thus, while BECTS does have a genetic component consistent with complex inheritance,

acquired or environmental factors are likely necessary for expression of the seizure disorder. Furthermore, BECTS likely represents the mild end of an epilepsy–aphasia spectrum, with rare severe forms including Landau–Kleffner or continuous spike–wave in sleep.

Pathophysiology

BECTS most likely represents a "hereditary impairment in brain maturation" (12). Mechanisms might include "pruning" of axonal branches and synaptic connections that are more abundant in early childhood or the developmental regulation of voltage-dependent ion channels.

Clinical Manifestations

Seizures typically occur either shortly after falling asleep or before awakening. However, 15% have seizures in both sleep and wakefulness and 20% to 30% in the waking state alone (7,13). The classic semiology involves the lower face unilaterally with paresthesias of the tongue, lips, gum, and cheek; clonic or tonic activity of the face, lips, and tongue; dysarthria; and drooling. Very young children commonly present with hemiconvulsions instead of the typical facial seizure (13). Rarely, partial motor seizures may change sides without becoming generalized (13). Evolution to bilateral convulsive seizures is common during sleep.

Seizures often occur in clusters, followed by long seizure- free intervals. Single seizures are seen in 13% to 21% (14,15). Frequent seizures are uncommon (6%) and usually seen in those with onset before 3 years of age (15). There is no known correlation between severity of the EEG abnormality, seizure frequency, and final outcome (13). Postictal Todd's paresis occurs in 7% to 16% and may suggest focal onset in patients who present with a generalized nocturnal seizure (16).

Most seizures are brief; however, status epilepticus has been described (16). Temporary oromotor and speech disturbances with intermittent facial twitching suggestive of functional impairment in the anterior opercular region and correlating with nearly continuous spike discharge in the perisylvian region may persist for weeks and may not respond well to antiepileptic therapy (17). Steroids, however, may be of benefit in this setting (17).

BECTS can rarely evolve along the epilepsy–aphasia spectrum either to Landau–Kleffner, with progressive language deterioration and auditory agnosia, or to continuous spike–wave in sleep. Additionally, evolution to "atypical benign partial epilepsy" or "pseudo–Lennox" syndrome, with atonic, atypical absence, and myoclonic seizures, nonconvulsive status epilepticus, and cognitive and behavioral disturbances, has been reported (18). With this syndrome, sleep EEGs show nearly continuous, bilaterally synchronous anterior spike-and-wave activity, and although ultimate seizure remission occurs, many children are left with varying degrees of intellectual disability.

The medical history of BECTS is usually uneventful, although 6% to10% experience neonatal difficulties and up to 16% have antecedent febrile seizures (13). Comorbid migraine is also more prevalent (19).

EEG Manifestations

The characteristic EEG findings are high-amplitude diphasic spikes or sharp waves with prominent aftercoming slow waves (Fig. 17.1). Spikes have a characteristic horizontal, anterior–posterior dipole, with maximal negativity in centrotemporal (inferior rolandic) and with positivity in frontal regions (20). They frequently cluster and are markedly activated in drowsiness and non–rapid eye

movement sleep (Fig. 17.2). The focus is unilateral in 60% of cases, bilateral in 40%, and may be synchronous or asynchronous (13). While the location is usually centrotemporal, a study of children with typical BECTS undergoing 24-hour EEGs showed that 21% had a single focus outside the centrotemporal area and half lacked a horizontal dipole (21). Follow-up recordings showed shifts in foci both toward and away from the centrotemporal area. Additionally, cases with both generalized spike-and-wave discharge and centrotemporal spikes in the same EEG have been reported (22). Usually, the background is normal, although mild slowing has been observed (16). With remission, spikes disappear first from the waking record and later from the sleep recording (13). Few reports of recorded rolandic seizures exist (Fig. 17.3), but two unique features are noted (13,23). Ictal spike-and-wave discharges may show dipole reversal, with electropositivity in the centrotemporal region and negativity in the frontal area; postictal slowing is not seen.

Figure 17.1. Typical rolandic spikes at C3 and C4-T4.

Figure 17.2. Marked activation of rolandic spikes with sleep.

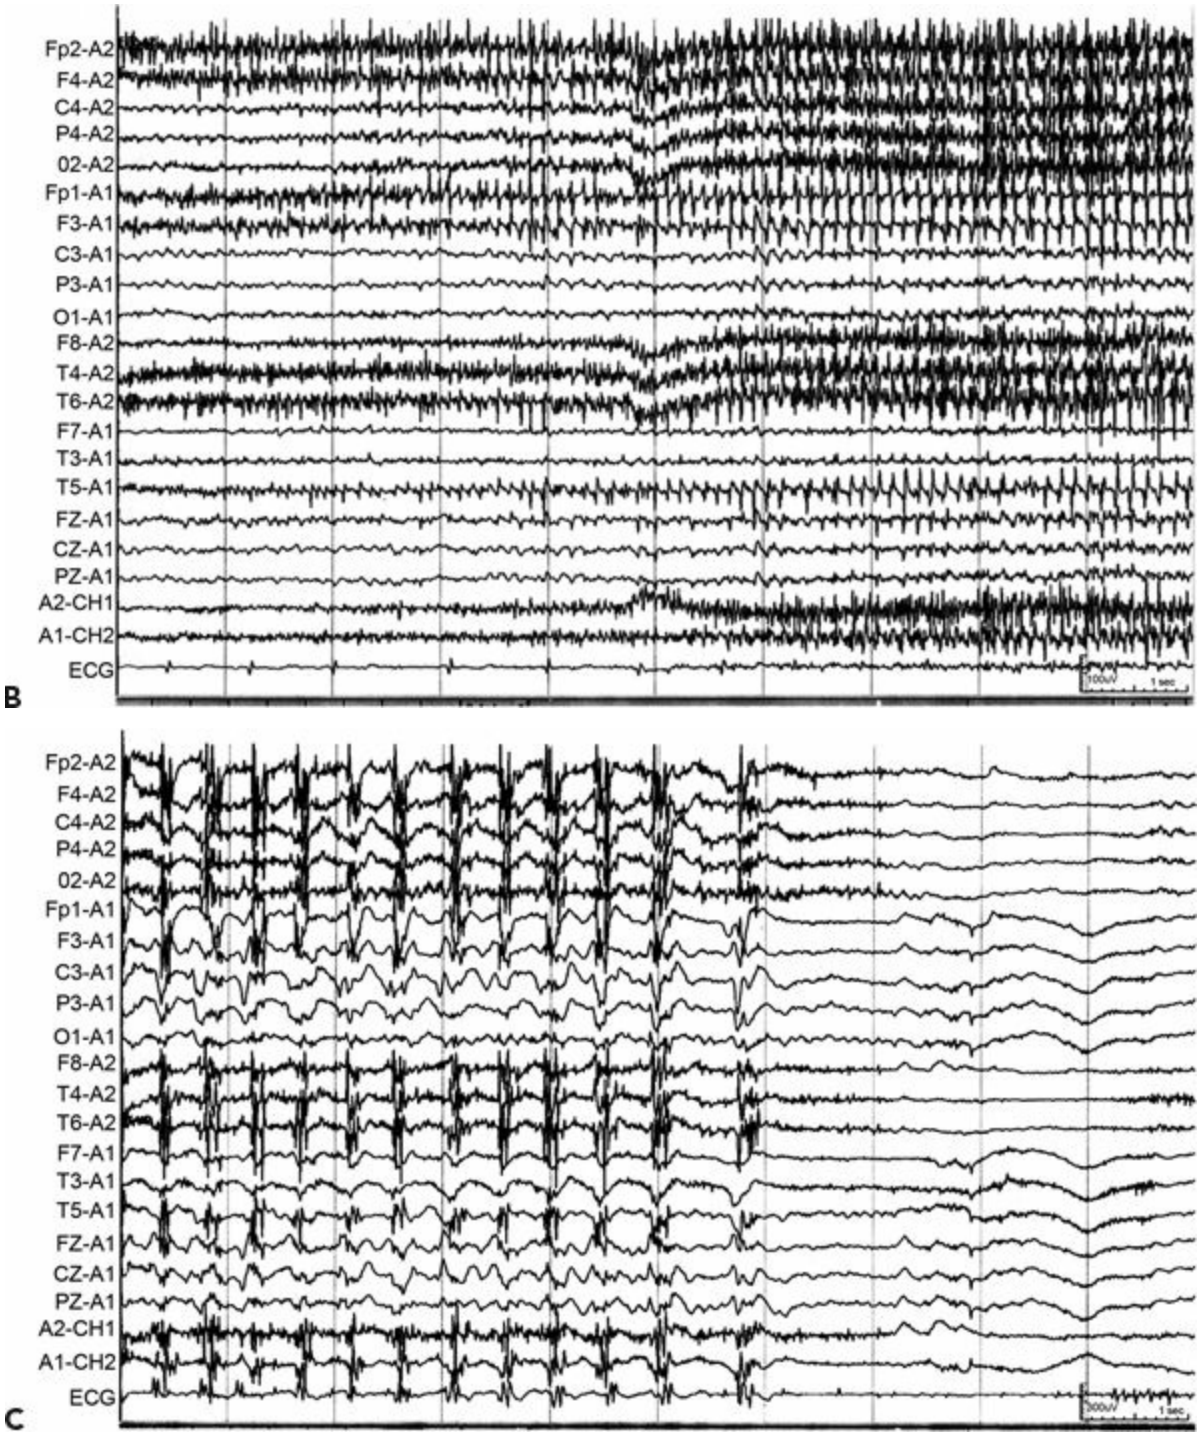

Figure 17.3. Recorded rolandic seizure. **A:** Start of seizure; note onset of rhythmic activity at C3/P3. **B:** Ten seconds later. **C:** End of seizure. (Courtesy of Mary Connolly, Children's Hospital and University of British Columbia.)

Typical rolandic discharges are seen in 0.7% of EEG recordings during wakefulness in children without a history of seizures (24). The percentage of children with rolandic sharp waves who develop clinically apparent seizures is unclear, although it is probably <10%, on the basis of reported incidences of BECTS and of rolandic EEG discharge in normal children. Therefore, rolandic discharges should be considered an incidental finding in children with spells or seizures whose semiology is not suggestive of BECTS. Rolandic spikes have also been reported in children with brain tumors, cortical dysplasia, fragile X syndrome, and Rett syndrome.

Neuropsychological Aspects

Some children with BECTS have abnormal cognitive and behavior maturation, with impaired

attention, executive function, and language (23), and both structural as well as functional causes for these impairments have been suggested. Structural brain changes in regions critical for motor processing and executive function have been shown (25). Bilateral putamen and left caudate hypertrophy were noted at initial diagnosis, and such changes appeared developmentally adaptive, with improved cognitive performance on tests of executive function seen in those with greater putaminal volumes. Functional MRI studies have also suggested that reorganization of language (particularly anterior language regions) occurs in more bilateral or right-hemispheric networks as a compensatory strategy to stabilize language performance (26). However, neurocognitive deficits may also be functionally related to epileptiform discharges, as they correlate with the amount and location of interictal spike discharge and, like the seizures and discharges, resolve over time (27).

Investigations

If the clinical history and EEG suggest BECTS and the child is neurologically and developmentally intact, no further investigations are required. An MRI scan should be considered in patients with atypical features. Several studies have shown MRI abnormalities including hippocampal asymmetry, white matter abnormalities, or developmental lesions in a minority of cases (28,29). However, the presence of such lesions does not alter the benign course of BECTS.

Treatment

Children with BECTS achieve remission regardless of antiepileptic drug therapy. We are unaware of any peer-reviewed reports of children with BECTS dying of sudden unexpected death in epilepsy or sustaining brain injury from a seizure. A no-medication strategy is reasonable for the majority of children who have infrequent, nocturnal, focal seizures. If recurrent generalized or diurnal seizures occur, or if they are sufficiently disturbing to the child or the family, treatment is generally started.

Only sulthiame and gabapentin have been studied in randomized, placebo-controlled trials. On the basis of case series and a recent meta-analysis of 794 children (30), antiepileptic drugs prescribed for focal seizures have equivalent efficacy, with 50% to 65% having no further seizures once medication is started. Gabapentin tended to be more effective than placebo in a study of 220 children although the results did not reach statistical significance (31). Sulthiame significantly improves the EEG and decreases clinical seizures. In a randomized, double-blind trial comparing sulthiame to placebo in 66 children, 81% taking sulthiame completed 6 months of therapy with no further seizures or adverse events, compared with only 29% taking placebo ($P < 0.00002$) (32). Of 25 children remaining on sulthiame at 6 months, 10 (40%) had a normal EEG, compared with only 1 of 10 (10%) in the placebo group.

Rarely, antiepileptic drugs may aggravate BECTS, resulting in evolution to continuous spike and wave during slow sleep with neuropsychological deterioration. Such deterioration has been reported with carbamazepine, phenobarbital, and lamotrigine.

Prognosis

The long-term prognosis of BECTS is excellent, even if seizures are initially frequent and troublesome. In a meta-analysis, 50% of patients were in remission at age 6 years, 92% at age 12 years, and 99.8% at age 18 years (Fig. 17.4) (30). Remission occurs sooner in children who are older at onset and in those with sporadic seizures or seizure clusters (14). Conversely, short intervals

between the initial seizures and younger age at onset predict higher seizure frequency. Although learning and behavior problems may be seen in the acute phase, long-term psychosocial outcome is excellent (33), with no increase in psychiatric problems or personality problems, and excellent occupational status.

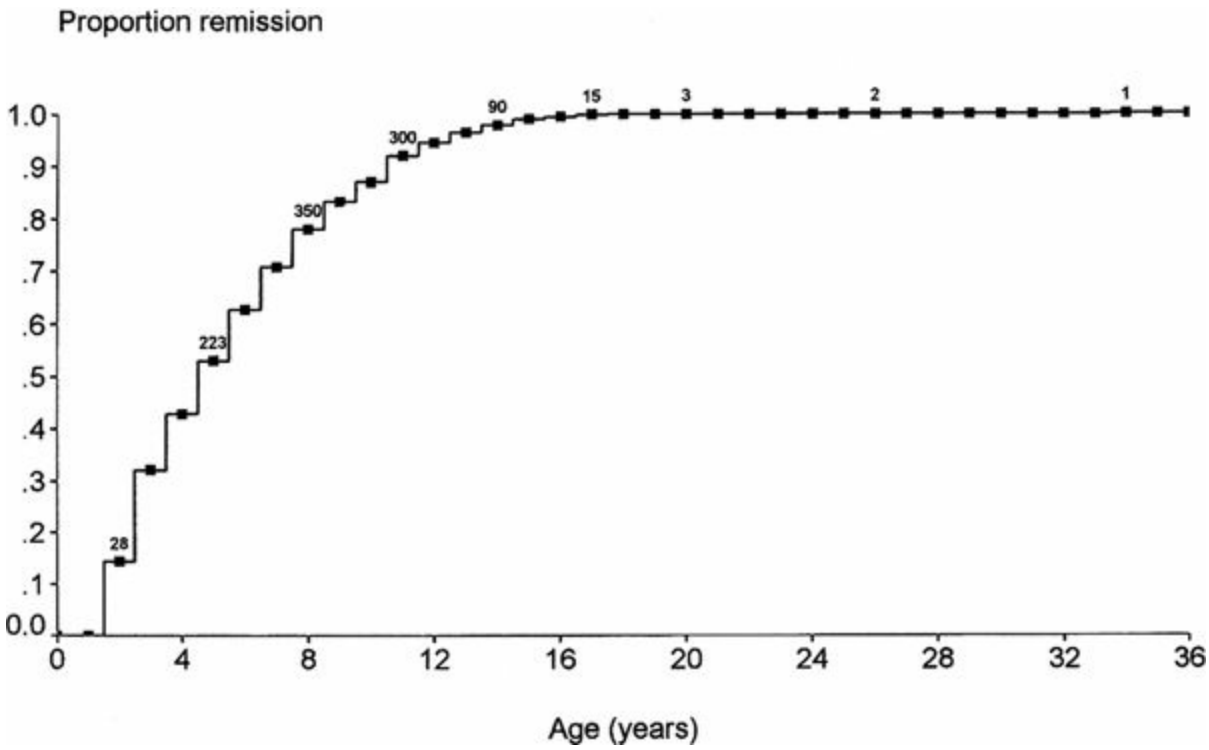

Figure 17.4. Remission of BECTS by age. Numbers in the figure represent the number of patients in the analysis. (From Bouma PAD, Bovenkerk AC, Westendorp RGJ, et al. The course of benign partial epilepsy of childhood with centrotemporal spikes: a meta-analysis. Neurology. 1997;48:430–437.)

PANAYIOTOPOULOS SYNDROME (EARLY ONSET BENIGN OCCIPITAL EPILEPSY)

Gibbs and Gibbs were the first to recognize that some children with occipital epilepsy had a benign course (34). Two syndromes are identified—early onset (Panayiotopoulos syndrome or PS), which is a clearly delineated syndrome based on over 500 published cases (35), and late onset (Gastaut type), which is much less well defined.

Epidemiology

PS accounts for 1% to 2% of children with focal epilepsy (36,37), about one-third the incidence of BECTS. The peak age of onset is 5 years (range, 3 to 8 years) with a female preponderance.

Genetics

Approximately 10% of PS patients have a first-degree relative with epilepsy (37–39), and 5% to 17% has a history of febrile seizures. In a study of 16 probands with PS including 7 twins, Taylor found that monozygotic twin pairs did not show a higher concordance rate than dizygotic twin pairs, suggesting that nonconventional genetic influences or environmental factors play a major role (39).

Rarely, SCN1A mutations may be found in atypical PS if the seizures have a very early age of onset and are frequent (40).

Pathophysiology

It is speculated that PS is the result of a combination of multifocal cortical hyperexcitability and an unstable autonomic nervous system (41). If the cortical region exceeds a critical epileptogenic level, the autonomic nervous system is first activated and then becomes involved in cortical/subcortical self-sustaining oscillations. These temporarily synchronize with resultant focal cortical symptoms.

Clinical Manifestations

Children with PS are typically otherwise normal. Seizures are nearly always nocturnal and present with autonomic symptoms especially nausea, retching, and vomiting (36,38). Other autonomic symptoms may include pallor, urinary or fecal incontinence, hypersalivation, mydriasis, miosis, coughing, respiratory or cardiac irregularities, or even syncope (42). Tonic eye deviation is common while other ictal visual symptoms, such as visual hallucinations, affect <10% (38). Consciousness may be impaired, and seizures can evolve to hemi- or generalized convulsions. Seizures last frequently longer than 30 minutes—one-third of patients develop focal status epilepticus (35,36). Seizure frequency varies, and one-third of patients experience only a single event (36,38,39). Rarely, PS evolves atypically with the appearance of many seizure types including absences, atonic seizures, and intellectual deterioration (36).

EEG Manifestations

The interictal EEG in PS shows spikes in variable locations that often shift foci on subsequent recordings. Spike location is variable and does not always involve the occipital regions—an equal number of cases show centrotemporal/parietal foci, and discharges are primarily multifocal, high-voltage, frequent, and increased in sleep (38). Occasionally, EEGs can be normal or show irregular, generalized spike–wave discharge (36).

Magnetoencephalography shows dipole clusters along the parietooccipital, calcarine, and rolandic fissures, and a superficial rather than deep dipole source location of the occipital spikes suggests a benign disorder rather than symptomatic occipital epilepsy (43). Sometimes, runs of repetitive occipital spikes and sharp waves are seen (Fig. 17.5) (36).

Figure 17.5. Posterior temporal–occipital spikes in a 4-year-old girl who presented with a 65-minute seizure consisting of focal eye deviation and retching.

The ictal EEG shows rhythmic theta or delta activity with intermixed spikes that usually start posteriorly, although anterior onset has been reported (35,36). Some studies suggest that, in rare cases, PS may evolve to continuous spike–wave in slow-wave sleep.

Neuropsychology

Specchio (36) evaluated 17 cases of PS after their first seizure compared with age- and sex-matched controls and found no differences between verbal and performance IQ scores on the Wechsler Intelligence Scale-Revised. This study supports the generally accepted clinical dictum that most children with PS have no cognitive deficits.

Investigations

Imaging is not required with a typical clinical history of PS and an EEG showing occipital paroxysms with fixation-off sensitivity. MRI should be considered if the EEG or clinical picture is atypical.

Treatment

Most children with PS have infrequent seizures and do not require antiepileptic drug treatment. Intermittent use of benzodiazepines could be considered for the child with prolonged events. No particular antiepileptic drug has been shown to be superior (35), although carbamazepine is most

frequently prescribed. Spikes may persist for several years after clinical remission.

Prognosis

In PS, remission of active epilepsy occurs 1 to 2 years from onset. As in BECTS, even those with many seizures usually achieve long-term remission.

LATE-ONSET (GASTAUT TYPE) BENIGN OCCIPITAL EPILEPSY

Late-onset BOE is a rarer and less distinct electroclinical syndrome that begins in mid- to late childhood, with a peak age of 8 years (range, 3 to 16 years); both sexes are equally affected (44). The diagnosis of late-onset BOE should be made cautiously, as the semiology may also be seen with lesional occipital epilepsy, and the prognosis is not always benign (44).

Clinical Manifestations

Late-onset BOE manifests as frequent (>15) diurnal, brief, visual seizures consisting of elementary visual hallucinations or brief amaurosis, which may result in brief but total blindness (44). Typically, hallucinations consist of moving, multicolored, circular patterns, which can multiply during the seizure, and more complex hallucinations (faces or figures) or visual illusions (i.e., micropsia or palinopsia) are rare. Sensory illusions of ocular movement or pain, tonic eye and head deviation, or eyelid closure may coexist. Consciousness is typically intact unless there is secondary generalization. There is a complex relationship with migraine. Headache may precede the seizure or occur at the onset (45), and postictal headache, indistinguishable from migraine, is seen in 25% to 50% of cases. Helpful features to distinguish late-onset BOE from the visual aura of migraine is that the latter evolves more slowly (over 10 to 20 minutes rather than 1 to 3 minutes) and tends to be achromatic and linear rather than multicolored and circular (46).

EEG Manifestations

Runs of occipital spikes are characteristic, and extraoccipital spikes are uncommon (44). The spikes may show “fixation-off sensitivity,” that is, they attenuate with eye opening and are induced by elimination of central vision by eye closure, darkness, or vision through +10 spherical lenses (Fig 17.6) (47). However, this finding does not reliably distinguish lesional from benign occipital epilepsies. The ictal EEG in late-onset BOE shows fast rhythms appearing in the occipital lobe at the onset of visual symptoms.

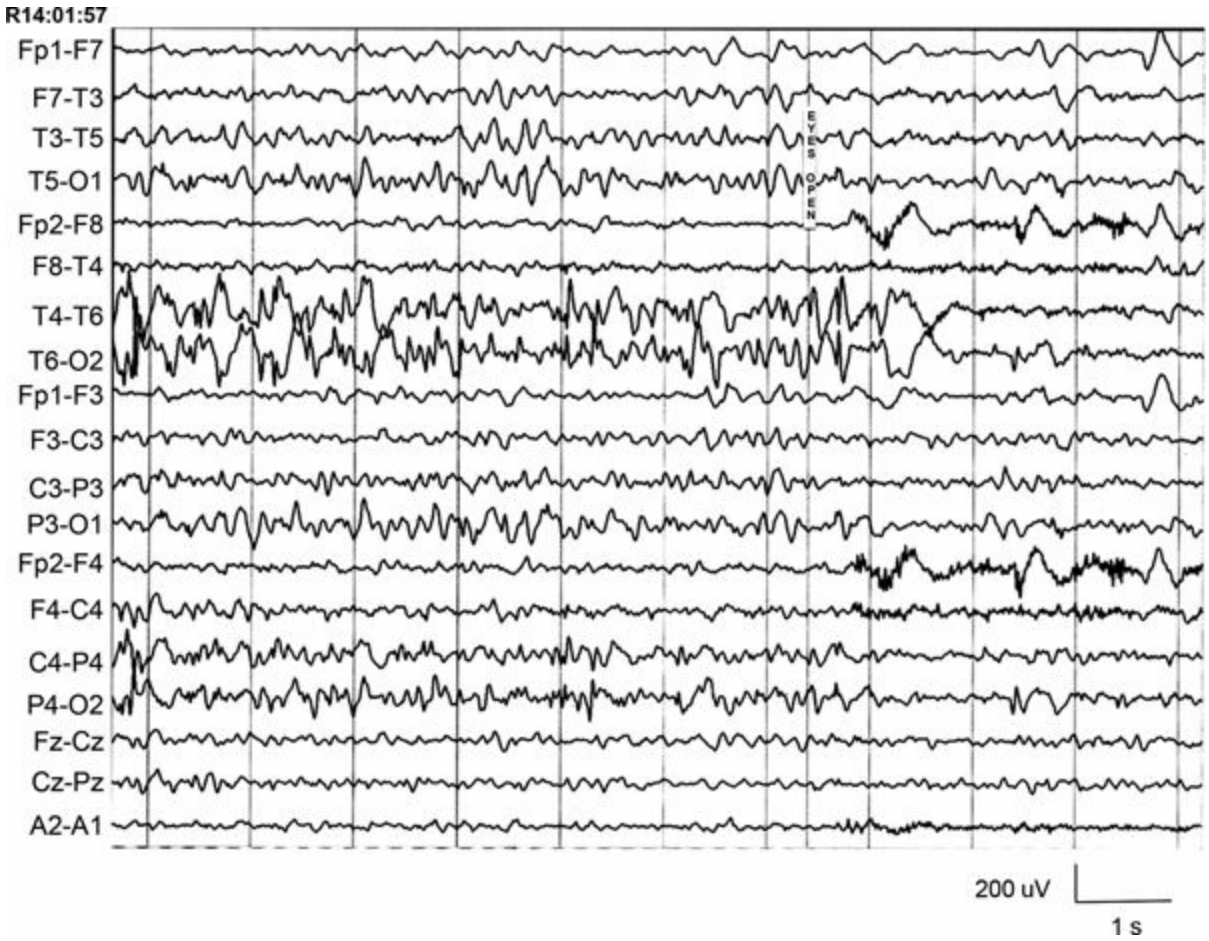

Figure 17.6. Prominent fixation-off sensitivity with eye closure in the same 4-year-old girl.

Investigations

MRI should usually be obtained because lesional occipital lobe epilepsy due to such etiologies as cortical dysplasia, mitochondrial disease, Lafora disease, or celiac disease may mimic Gastaut-type BOE.

Treatment

Most cases require treatment, as seizures are more frequent, although only 60% of 63 patients reported by Gastaut achieved complete seizure control (44).

Prognosis

The prognosis is less clear in late-onset BOE, although Gastaut reported that 5% of his 63 cases had recurrent seizures into adulthood (44).

BENIGN FOCAL EPILEPSIES IN INFANCY

Several variants of benign focal epilepsy in infancy have been described (48), and the ILAE currently recognizes both benign epilepsy in infancy (BEI) and benign familial infantile epilepsy. Clear distinction between each of these syndromes can be challenging, and further progress in genetics may improve our understanding of many of these entities.

Benign Epilepsy in Infancy

Watanabe proposed this disorder in 1987 (49,50) and described two forms: one with focal dyscognitive seizures alone and another with focal evolving to bilateral convulsive seizures. BEI represents approximately 7% to 29% of all epilepsies in the first 2 years of life (51,52). Both reports noted that the form with secondarily generalized seizures was slightly more common, accounting for 64% to 73% of all BPEI cases. Peak age at onset is 4 to 6 months, with a range of 3 to 10 months.

Developmentally normal infants typically present with clusters of seizures consisting of motion arrest, decreased responsiveness, staring, simple automatisms, and mild convulsive movements, with possible evolution to bilateral convulsive activity. Neuroimaging is normal. The interictal EEG is usually normal, but infants may show low-voltage rolandic and vertex spikes in sleep (53). Ictal recordings in infants with focal dyscognitive seizures alone demonstrate an EEG seizure pattern that is maximal in the temporal–occipital regions. In patients with bilateral convulsive semiology, EEG seizures are located in the central–parietal–occipital region. Seizures are easily controlled with antiepileptic drugs, and remission occurs in 91% within 4 months and in all children by age 2 years (52).

To determine how accurately BEI can be diagnosed in infancy, Okumura et al. (54) followed up 39 children who were believed to have the syndrome after 5 years. Eighty-five percent of cases had achieved remission, were no longer treated with antiepileptic drugs, and were developmentally normal. However, the diagnosis appeared incorrect in the remaining 15%, who had recurrent seizures after 2 years and/or showed developmental delay, emphasizing the need for close follow-up of these children.

Benign Familial Infantile Seizures and Other Benign Familial Neonatal and Infantile Epilepsies

Infants with benign familial infantile seizures (BFIS) are developmentally normal and present with clusters of focal seizures between 4 and 8 months of age, consisting of psychomotor arrest, cyanosis, head or eye deviation, tonic contraction, and bilateral clonic jerks (48). This condition is autosomal dominantly inherited, and other neurologic disorders including paroxysmal choreoathetosis and familial hemiplegic migraine may also coexist. The interictal EEG is normal, and ictal studies show fast activity in the parietooccipital region.

Benign familial neonatal–infantile seizures are also autosomal dominant and present between 2 days and 7 months. Clinical seizures manifest with focal motor manifestations that evolve to bilateral convulsive seizures. Interictal EEG may be normal or show posterior discharges.

Benign familial neonatal seizures present between days 2 and 28 of life with focal-onset seizures. The interictal EEG is typically normal. However, focal discharges may be seen, particularly in the rolandic region.

Seizures in the familial focal infantile epilepsies typically respond well to antiepileptic medication and resolve by early childhood. Several genes have now been identified that lead to familial seizures in the first year of life. Age at onset and comorbid neurologic symptoms can provide clues to the most likely gene, with benign familial neonatal seizures predominantly involving KCNQ2 and, less commonly, KCNQ3, with benign familial neonatal–infantile seizures involving either KCNQ2 or SCN2A, and with BFIS most often involving PRRT2 (often with coexisting paroxysmal choreoathetosis). However, SCN2A, KCNQ2, and KCNQ3 may also result in BFIS. Very rarely,

KCNQ2 mutations may lead to a severe epileptic encephalopathy with medically intractable epilepsy and profound neurologic disability.

Benign Focal Epilepsy in Infancy with Midline Spikes and Waves During Sleep

In this syndrome, neurologically and developmentally normal children present with brief sporadic seizures consisting of cyanosis, staring, motion arrest, and stiffening between 4 and 30 months of age (48). Seizures cluster in 31% of cases. Automatisms or lateralizing signs are rare, and secondary generalization has not been reported. A family history of epilepsy is present in 47% of cases. The EEG shows a low-voltage, fast spike followed by a higher bell-shaped slow wave over the midline region during sleep only, which spreads to the central or, less commonly, to the temporal region. Outcome is excellent—seizures resolve by 2 to 3 years of age, and many cases do not require antiepileptic drug treatment.

AUTOSOMAL DOMINANT FRONTAL LOBE EPILEPSY

This syndrome presents in adolescence or young adulthood with nocturnal seizures of frontal lobe semiology that present out of sleep. Typically, seizures are frequent and often hypermotor, with moaning, rocking, grabbing, or extension and abduction of the arms. The interictal EEG may be normal or show frontal spikes, and ictal recordings show fast, bifrontal discharge. Mutations in CHRNA4, CHRNB2, and CHRNA2 are causative, and functional studies suggest these mutations result in activation of a potassium channel (KCNT1) in the central nervous system. Most patients respond favorable to carbamazepine with good seizure control. Although remission may occur, for many patients this disorder is lifelong.

FAMILIAL TEMPORAL LOBE EPILEPSY

Autosomal dominant lateral TLE, also known as autosomal dominant partial epilepsy with auditory features, is associated with mutations in the leucine-rich, glioma-inactivated 1 (LGI1) gene in approximately 50% of families (55). Median age at onset is in late adolescence (range 1 to 60 years), and the focal seizures have prominent elementary auditory auras. Aphasic seizures are seen in 17% of cases and secondarily generalized seizures in 90%. Neuroimaging is usually normal, and the clinical course is benign, with most patients achieving good control with antiepileptic medications. In a review of 100 individuals from 20 families, Crompton et al. (56) characterized the clinical features of familial mesial TLE, which they propose is inherited in a polygenic (rather than autosomal dominant) manner. Median age at seizure onset was 15 years (range 3 to 46 years), antecedent febrile seizures were seen in 9.8%, and nearly all patients had normal neuroimaging. Seizure semiology is characterized by déjà vu, fear, and nausea, with evolution to focal seizures with or without loss of awareness. Most patients had a relatively benign course with good response to medication.

OTHER POSSIBLE BENIGN FOCAL EPILEPSY

SYNDROMES

Other syndromes that have not been completely described to know whether they stand the test of time as a benign focal epilepsy of childhood are of interest but not placed in this chapter (Table 17.1). These include benign frontal epilepsy, benign partial epilepsy with extreme somatosensory evoked potentials, benign partial epilepsy with affective symptoms, and benign partial epilepsy of adolescence.

SUMMARY

The IFEs of childhood account for a significant proportion of seizure disorders in pediatric patients. In its classic form, BECTS is easily recognizable, occurring in neurologically normal children and having a distinct semiology and EEG pattern. PS, with characteristic ictal semiology, also lends itself to a confident diagnosis. Such is not the case for the other IFEs or for BECTS or early-onset BOE with atypical clinical or electrographic features. These diagnoses may be made definitively only in retrospect.

Minor cognitive changes during the active period of epilepsy occur in some children with IFE but also appear to remit with time. Many children with IFEs, however, will not require antiepileptic drugs, as most have infrequent seizures. Recognition of these benign epilepsy syndromes is important for appropriate counseling of the child and family.

CHAPTER 18 IDIOPATHIC GENERALIZED EPILEPSY SYNDROMES OF CHILDHOOD AND ADOLESCENCE

STEPHEN HANTUS

Idiopathic generalized epilepsy (IGE) represents 20% of all epilepsies. The diagnosis is often made in childhood or adolescence and may become self-limited or persist into adulthood. With proper diagnosis and medical management, these epilepsy syndromes are controlled with medications in 80% of cases. Diagnosis is important as certain medications can aggravate these epilepsies and lead to increased seizures and pseudointractability. Proper medication management is often able to allow patients to live an otherwise unaffected life, although persistent social and psychological problems are reported in some studies (1,2).

IGEs are defined by the International League Against Epilepsy (ILAE) as an epilepsy that arises spontaneously, with no associated structural lesion or neurologic sign or symptom, and is of presumed genetic origin (3,4). IGEs are a group of epilepsies that give rise to three types of seizures that occur in various combinations depending on the syndrome.

TYPICAL ABSENCE SEIZURES

These seizures are clinically characterized by unresponsiveness of short duration (5 to 15 seconds) with abrupt onset and termination. Patients are unresponsive during the seizures and have no memory of these brief events. Occasionally, there is associated eye fluttering or automatisms. There is little or no postictal confusion or disorientation associated with this seizure type. Electroencephalogram (EEG) demonstrates the typical 3-Hz spike-and-wave complexes that are often most prominent during hyperventilation.

MYOCLONIC SEIZURES

This is a seizure type characterized by brief jerks (10 to 100 ms on average) that occur sporadically and often involve the upper extremities bilaterally as well as the trunk. They are often described as “shock-like” muscle contractions and occur most frequently in the morning. Patients typically deny any alteration in consciousness during these jerks and have no associated postictal confusion or disorientation. Jerks may be minor causing barely perceptible movements up to larger jerks that result in dropping objects or falling. EEG demonstrates generalized polyspike discharges prior to the muscle jerk of the myoclonic seizure, which is often apparent on scalp EEG but is at times only appreciated with back averaging of EEG data.

GENERALIZED TONIC–CLONIC SEIZURES

These seizures typically last 1 to 3 minutes and are associated with loss of consciousness and a muscular convulsion. The tonic phase lasts for 10 to 45 seconds and may involve bilateral arm stiffening and often a vocalization. This is followed by a clonic phase with rhythmic jerking of various muscle groups. There is often an extensive postictal period of confusion and disorientation that may last from 5 minutes to several hours. EEG during these seizures shows generalized spike-and-wave discharges that evolve in frequency and amplitude.

IDIOPATHIC GENERALIZED EPILEPSY SYNDROMES

IGE syndromes are best viewed as a spectrum of disorders with these three seizure types expressed in variable amounts as different clinical phenotypes. These syndromes often have overlapping genetic etiologies as well. It is most important to distinguish the focal/localization-related epilepsies from the generalized epilepsies because the treatment and prognosis are very different. The risk of intractability is much higher in focal epilepsies, and the drugs that treat focal epilepsy can exacerbate IGE. The following section describes the diagnostic criteria of the IGE syndromes and what is known about their etiology and prognosis.

CHILDHOOD ABSENCE EPILEPSY

Childhood absence epilepsy (CAE) is a widely recognized syndrome with absence seizures as the only manifestation in many patients, while generalized tonic–clonic (GTC) seizures can also occur in up to 40%, although GTC seizures are more common in the juvenile form (5,6).

Epidemiology

CAE has been estimated to comprise 2% to 8% of epilepsy in the total population but appears to be heavily age dependent. Studies of childhood cohorts (0- to 15-year age group) estimate 13% to 18%, with a smaller proportion of 3% to 6% in patients in the older than 15-year age group. Large epidemiologic studies in Europe and the United States have shown an incidence of 6 to 8 per 100,000 in the 0- to 15-year age group (7). There has been a female predominance noted in several studies (5,8).

Clinical Features

CAE characteristically begins between the ages of 4 and 8 years with absence seizures, but the age of onset can vary between ages 2 to 10 years (9). The absence seizures are often provoked by having the patient hyperventilate in the office, effective in up to 98% of patients. A smaller number of patients (16% noted in one study) are found to be photosensitive (10). In addition to the typical abrupt loss of consciousness and quick recovery of a typical absence, automatisms, transient loss of tone, fluttering of the eyelids, and brief myoclonic jerks are also common. Seizures typically last from 5 to 15 seconds and without medications may occur hundreds of times per day. Patients with CAE have been noted to have cognitive, linguistic, and psychiatric comorbidities (11). In the study by Caplan et al.

(11), one-fourth of patients had subtle cognitive difficulties, almost half had linguistic deficits, and approximately 67% had a psychiatric diagnosis with attention deficit hyperactivity disorder and anxiety being most common. There is some indication that treatment with medications can improve some neurocognitive skills (e.g., visual memory), and the results are dependent on seizure control (12). Although it is a defining characteristic that patients with CAE (and IGEs in general) have normal intelligence, recent studies have emphasized that untreated behavioral and psychiatric problems are common (11,13).

IGEs are also by definition not related to a structural or anatomic cause, and normal imaging with magnetic resonance imaging (MRI) is the most common clinical finding. However, there are some volumetric studies that suggest that the anterior half to the thalamus is larger in patients with absence epilepsy, suggesting a possible structural correlate (14). This finding was not present in patients with other seizure types (GTC seizures).

EEG

The EEG in CAE shows monomorphic high-voltage generalized spike-and-slow-wave complexes at 3 Hz (2.5 to 4.0 Hz). These spike-and-wave complexes may occur interictally or as an ictal pattern depending on the duration and responsiveness of the patient. The typical length of an ictal event is 5 to 15 seconds and may begin with 3.0-to 3.5-Hz spike-and-wave complexes that may slow to 2.5- to 3.0-Hz discharges. Responsiveness is typically tested during the SWC discharges to assess whether the event is considered a seizure or interictal discharge. The background EEG is typically normal. In up to 50% of patients, bursts of rhythmic slowing lasting 2 to 4 seconds can be seen in the occipital leads. A small study suggested that occipital intermittent rhythmic delta activity indicated a good prognosis for response to medication in typical absence epilepsy (15).

Generalized epilepsies have been considered to arise from the bilateral, global neocortex by definition but have been noted to have a frontal predominance on EEG. The use of dense array EEG (256 channels) and software to superimpose the electrical signals over the patients MRI has suggested that there are discrete areas that are activated during an absence seizure (16,17). Dense array EEG suggests a corticothalamic circuit involving the medial frontal and orbitofrontal cortex maximally.

Genetics

Classic family studies have suggested that one-third of patients with CAE have a family history of epilepsy and siblings of affected individuals have an approximately 10% chance of suffering seizures (18). The essential genetic nature of IGE is demonstrated in twin studies that show an 81% concordance among monozygotic twins, while dizygotic twins are only 26% concordant for epilepsy (19). The genetics of CAE is a complex pattern with most patients having multiple genetic factors likely contributing to their epilepsy and rare cases with a monogenetic etiology reported (20). Most of the genes that have been identified are subunits of ion channels, with some exceptions. Identified mutations have been shown in the γ-aminobutyric acid receptor γ2 (GABRG2), γ-aminobutyric acid receptor α1 (GABRA1), γ-aminobutyric acid receptor β3 (GABRB3), chloride channel receptor 2 (CLCN2), the calcium channel voltage-dependent, T-type α1H subunit (CACNA1H) genes, and γ3 subunit of neuronal voltage-gated calcium channel (21). A study that examined gene expression in monozygotic twins that were discordant for epilepsy identified altered expression of early growth

response 1 (EGR 1) and reticulocalbin 2 (RCN 2), suggesting a role for these proteins in CAE (22).

Treatment

Medical treatment has been shown to suppress absence seizures in more than 80% of patients. Studies that have compared ethosuximide, valproate, and lamotrigine were not able to establish a difference in efficacy and are all considered first-line medications (23). Ethosuximide does not protect against GTC seizures and has neurotoxic and gastrointestinal side effects that limit its use. Valproate is effective as a broad-spectrum agent treating absence, GTC seizures, and myoclonic seizures. Valproate use is limited due to side effects of weight gain and potential teratogenicity. Lamotrigine is effective in treating absence, has fewer cognitive side effects, and is the preferred medication for females due to the lower rate of teratogenicity as compared to valproate (23). Levetiracetam and zonisamide have been shown to decrease absence seizures by 50% to 60% in small studies and are considered second-line medications (24,25). Refractory absence epilepsy occurs in 5% to 20% of cases (5). Treatment with an inappropriate antiepileptic drug (AED) is a frequent cause of "pseudointractability," as some drugs have been shown to exacerbate absences (26,27). Carbamazepine is the most frequent cause of worsening seizures and has been associated with absence status epilepticus (26). Phenytoin, tiagabine, vigabatrin, and oxcarbazepine have also been shown to cause a paradoxical increase in seizures in patients with absence epilepsy. Combinations of medications, particularly with valproate, have been shown to be more effective than single medications alone (27).

The decision to stop therapy is often difficult. A minimum seizure-free interval of 2 years is typically recommended before withdrawal of medication. However, each case must be evaluated individually in terms of the attitude of the patient and the family, participation in sports, occupation, and driving an automobile. The EEG findings may help guide the decision, but the presence of occasional brief epileptiform discharges should not preclude drug withdrawal in the seizure-free patient (28).

Prognosis

CAE is one of the relatively benign childhood epilepsies, but not all patients become seizure free. Approximately 50% of patients with CAE will have a spontaneous remission by the age of 10 to 12 years, with a range of 21% to 89% remission (29). In patients with absence seizures only, the seizure-free rate is approximately 80%, while patients with GTC seizures and absence were only 30% seizure free (29). Early institution of effective therapy is believed to improve prognosis in terms of the later development of tonic–clonic seizures and relapse of absences. A Dutch study with long-term follow-up (12 to 17 years) indicated that seizure freedom in the first 6 months of treatment predicted outcome, while EEG and baseline characteristics did not impact outcome (30).

JUVENILE ABSENCE EPILEPSY

Juvenile absence epilepsy (JAE) has a number of features that are clinically distinct from those of the other absence epilepsies and has been recognized as a separate syndrome (3,4). JAE has later age at onset with fewer seizures on average and is more often associated with GTCs. It is often diagnosed retrospectively after a GTC seizure occurs or other associated features are noted.

Epidemiology

There are no definitive epidemiologic studies for JAE, but large studies of absence epilepsy have shown a peak at age 6 to 7 years (consistent with the peak ages of the onset of CAE) and another around age 12 (7). Several cohort studies have estimated that JAE comprises 0.2% to 3.0% of childhood epilepsies. Juvenile myoclonic epilepsy (JME) has a prevalence of 0.1 per 100,000 persons in the general population, which is much less common than CAE (7,31).

Clinical Features

Most cases begin during or near puberty, with a range of 10 to 17 years and an average onset at age 12 (7,31). The absences are less frequent than those of CAE and occur once per day or several per week (as compared to the 100 per day often seen in CAE). The absences of JAE have been described in various clinical reports as resulting in less severe loss of consciousness, having a retropulsive component (backward motion of the eyes), and lasting longer than CAE at approximately 10 to 60 seconds (8,32). GTC seizures have been reported in 47% to 80% of patients with JAE and frequently occur upon awakening (8,31). Myoclonic jerks are less frequent and occur in 10% to 15% of patients and illustrate the clinical overlap with some features of JME (8).

EEG

JAE is associated with generalized spike-and-wave discharges that occur typically at 3 to 4 Hz, which is slightly faster than CAE. They have also been reported to be slightly less rhythmic and less organized than the spike-and-wave complexes seen in CAE. Photosensitivity is rare but appears to be more common in females and in the juvenile form (33,34). The interictal background activity is normal.

Genetics

The genetic origin of JAE remains largely undiscovered at this point. It is known from twin studies that genetics play a large role in JAE (35) and that patients with JAE have a family history of epilepsy in 29% to 35% of cases (8,31). Sander et al. reported that the kainate-selective glutamate receptor gene (GRIK1) is a susceptibility gene for developing JAE (36). The chloride channel ClCN2 has also been implicated in CAE, and JME is also thought to play a role in JAE (37).

Treatment

Valproate has been the historically most effective treatment choice. It treats the absences and also treats the possible associated GTC seizures and/or myoclonic jerks. However, due to the side effects of weight gain and teratogenicity, it is generally used with caution in young females. Lamotrigine has also been shown to be an effective choice, treating absence seizures as well as GTC seizures. If myoclonus is present, then treatment with levetiracetam may be an alternative to valproate. Due to the frequent occurrence of GTC seizures with JAE, ethosuximide is not recommended as first-line medication. Education about avoiding sleep deprivation and alcohol consumption is also important in adolescent patients.

Prognosis

The response of JAE to pharmacologic therapy is typically very good. Valproate alone has been shown to treat over 80% of cases. However, the seizure-free rates tend to be less than in patients with CAE (8). Patients with GTC seizures tended to have a worse prognosis (8).

JUVENILE MYOCLONIC EPILEPSY

JME is a well-known IGE syndrome that involves adolescents. JME often goes undiagnosed until a GTC seizure occurs, because myoclonic jerks are often ignored or attributed to morning clumsiness. Increased awareness by clinicians and the availability of video-EEG has helped make this diagnosis more expedient.

Epidemiology

The incidence of JME has been estimated to be 1 per 100,000 persons, with a prevalence of 0.1 to 0.2 per 100,000. The frequency of JME in large cohorts has been estimated to be 5% to 10% of all epilepsies and 18% of IGEs (7). Certain populations or family groups have been reported to have a higher incidence of JME such as Saudi Arabia and sections of India (38,39).

Clinical Features

The age of onset for JME is typically 12 to 18 years, with a peak onset at age 15, but can manifest in all age groups (40). The clinical presentation of JME is typically a GTC seizure that occurs in the morning after a night of sleep deprivation and/or alcohol consumption in an otherwise healthy individual. A detailed history will often reveal whole-body jerks that occur mostly in the morning and result in spilling drinks, dropping objects, and/or brief spells of unresponsiveness that have occurred for several months prior to the GTC seizure. Patients with JME will most frequently have myoclonic seizures (100%), with 87% to 95% having GTC seizures and 10% to 33% having absence seizures (41,42).

Myoclonic seizures are brief jerks that affect the neck, shoulders, arms, or legs. The jerks are more frequent in the upper than in the lower extremities and are typically bilateral and symmetric, but on occasion may be unilateral (43). Asymmetric myoclonic seizures may delay the diagnosis of JME, and video-EEG should be used to make the definitive diagnosis (43). Myoclonic jerks of the upper extremities can often cause patients to drop objects and can interfere with morning activities such as eating breakfast, brushing teeth, or applying cosmetics. The jerks can be single or repetitive and often involve extensor muscles. Falling to the floor is uncommon, but falls may occur when patients are in an awkward position and are surprised by the jerk. The amplitude of the jerk is variable but is typically not forceful or massive, and recovery is immediate with no loss of consciousness. Some patients report electric shock type feelings only, with no physical signs of the myoclonic seizure. The relatively mild myoclonic seizures in JME are in contrast to the myoclonic seizures in Lennox–Gastaut syndrome and some progressive myoclonic epilepsies, which are massive and propel patients to the ground with great force.

GTC seizures in JME are often described as clonic–tonic–clonic due to the several repetitive myoclonic jerks that often precede a GTC seizure. The patient has no loss of awareness during the myoclonic jerks, and this serves as a warning to some patients to get to a safe place seconds prior to

a GTC seizure (41). Consciousness is abruptly lost with the onset of the GTC seizure, with tonic extension of the head, face, neck, trunk, and extremities. The tonic phase lasts for 10 to 30 seconds and leads to the final phase of clonic trunk and limb jerks. Patients often emit a high-pitched "ictal cry" during the initial tonic phase. Due to the forceful contraction of many agonist and antagonist muscles simultaneously, patients are often very sore and tired after the seizure. Tongue and/or lip biting and loss of urinary or bowel continence is common. After the seizure, confusion and disorientation typically take 5 to 30 minutes to resolve. Patients typically have no memory of the event.

Absence seizures in JME are less common, occurring in 10% to 33% of patients and tend to be relatively infrequent, of short duration, and not associated with automatisms. In a prospective video-EEG study of JME patients, 16 of 42 (31.9%) were found to have absence seizures (44). When the seizures occurred prior to the age of 10, the patient would stop activities, not answer questions, and stare without postictal symptoms and without memory of the event. When the seizures occurred after the age of 10, the manifestations were usually less severe and consisted of subjective instant loss of contact and concentration or of brief impairment of concentration revealed by testing only (44).

Precipitating factors are commonly reported in patients with JME. Myoclonic and GTC seizures occur most often in the morning or upon awakening (42). Studies of cortical excitability with transcranial magnetic stimulation suggest an increase in cortical excitability/loss of intracortical inhibition in the early morning hours with drug-naive JME patients (45). Sleep deprivation, fatigue, alcohol use, photic stimulation (video games, strobe lights), and menstruation have also been shown to precipitate seizures in patients with JME (41,46). Patients should be counseled to maintain good sleep hygiene and to avoid excessive alcohol consumption since these precipitants can contribute to poor seizure control despite good AED management.

The neurologic exam in JME patients is generally normal, although some neuropsychological tests have suggested cognitive dysfunction with deficits in executive function and expressive language consistent with frontal lobe dysfunction (47,48). The neuroimaging studies in patients with JME typically do not reveal the etiology for the epilepsy but may show nonspecific abnormalities or subtle changes in cortical volumes (49). A quantitative voxel-based MRI study has shown increased cortical gray matter in the medial frontal lobes in 40% of patients with JME (50). FDG-PET and proton MRS studies have also shown metabolic frontal lobe dysfunction in JME patients (51,52). However, not all studies have been able to duplicate the frontal dysfunction in JME patients, demonstrating the pathophysiologic diversity of this condition (53).

EEG

The interictal EEG in JME is abnormal in 50% to 85% of untreated patients, while only 5% to 10% of patients treated with AEDs will have an abnormal EEG (42,54). The characteristic EEG pattern of JME consists of discharges of diffuse bilateral, symmetric, and synchronous 4- to 6-Hz polyspike-and-wave complexes (Fig. 18.1). These discharges may be accentuated over the frontocentral regions. The interictal complexes usually have two or more higher-voltage (150 to 300 μV) surface negative spikes that are maximum in the anterior head regions. Focal abnormalities have been reported in up to 30% of cases (42). Response to photic stimulation with myoclonic seizures or epileptiform discharges after 12- to 16-Hz stimulation is common and occurs in 30% to 50% of cases of JME (34,42). Dense array EEG studies have contested the "generalized" nature of the interictal discharges in JME and have suggested that they are localized to a thalamocortical network that

involves the medial orbitofrontal cortex and anterior basal–medial temporal lobes maximally (55).

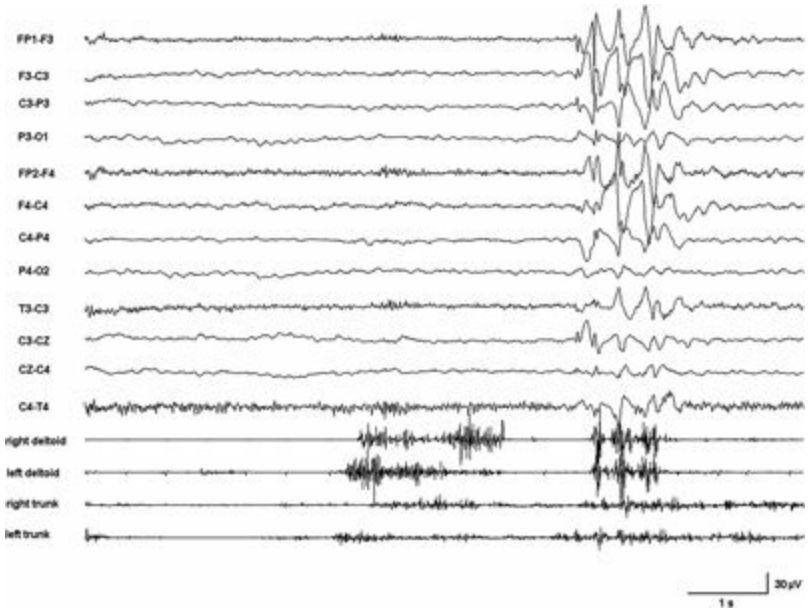

Figure 18.1. Interictal 4- to 6-Hz polyspike-and-wave discharge of frontocentral predominance in JME. No clinical changes were seen, and the patient could recall a word given during the discharge.

Genetics

The genetic nature of JME has been well established and is likely complex and polygenic in most patients, though some rare monogenic forms are being identified. About 40% of patients with JME report a positive family history for epilepsy (56). Genetics studies to date suggest that JME is a heterogeneous condition with multiple different mutations and susceptibility loci that have different modes of inheritance and possible mechanisms of action (21). Autosomal recessive, autosomal dominant, and complex polygenic models have been proposed in different family pedigrees (21). Analysis of JME families has identified linkages to multiple chromosomal loci that may contain genes that are causative or increase the susceptibility for developing JME. Chromosomal locations that demonstrate increased susceptibility in JME families include 6p12-p11 (EFHC1), 6p21 (BRD2/RING3), 15q13-14 (Cx-36), 5q34 (GABRA1), 2q22-23 (CACNB4), 1p36.33 (GABRD), 3q21.1 (CASR), 18q21 (ME2), 19q13 (SCN1B), and Xp11.4-11.3 (EFHC2) (20,21,57–60). Several studies have also identified mutations that are rare but appear to be causative in selected families. Mutations have been identified in EFHC1/Myoclonin1, CLCN2, GABRA1, and CACNB4 (57). In addition, single nucleotide polymorphism susceptibility alleles have been identified in the bromodomain- containing protein 2 (BRD2) and connexin 36 (Cx-36) (61–63).

EFHC1/Myoclonin1

Studies of multiple families of JME have implicated the 6p12-p11 region as a susceptibility focus, and the potential gene was referred to as EJM1. Mutational analysis was able to narrow this locus to the candidate gene EFHC1, which encodes for the protein Myoclonin1 (64). Proposed mechanisms of action for EFHC1/Myoclonin1 include promoting apoptosis, regulating R-type calcium currents, cell cycle regulation, and neuronal migration (64–66). Animal studies have shown that mice deficient in EFHC1 have spontaneous myoclonus and increased seizure susceptibility (67). Mutations of EFHC1/Myoclonin1 have been reported in 9% of JME patients in Mexico and Honduras and 3% of

JME patients in Japan, which is more frequent than any other identified mutations in JME thus far (66).

CLCN2

Mutations of the CLCN2 chloride channels were found in three families of JME patients (37). The proposed mechanism was a reduction in chloride channel activity and increased neuronal excitability. The mutations were detected in patients with JME and also some apparently unaffected family members as well but not in a control population (68). The authors concluded that CLCN2 mutations may act as susceptibility factors for epilepsy among other unknown genetic alterations (68).

GABRA1

Studies of a large French–Canadian family with JME led to the discovery of a mutation in the α1 subunit of the γ-aminobutyric acid receptor subtype A (GABRA1). Studies in vitro suggested a loss of gamma-aminobutyric acid (GABA)-activated currents in receptors containing the mutant subunit (69). Expression of the mutant protein revealed a misfolded protein with impaired insertion into the plasma membrane (70). The proposed mechanism of action is a loss of inhibitory signals due to the defective GABA receptors and subsequent increased cortical excitability (69).

CACNB4

A female patient diagnosed with JME was found to have a mutation in the calcium channel β4 subunit (CACNB4) and her daughter with the same mutation had epilepsy with 3-Hz spike-and-wave complexes (71). A father and son with absence and GTC seizures have also been identified. The proposed mode of inheritance is autosomal dominant. This mutation is thought to impair the channel function by shifting the voltage dependence of activation and inactivation. Additional mutations of the same subunit were associated with epilepsy and episodic ataxia (71).

It should be noted that although progress in identifying a few of the genes involved in JME is beginning to emerge, the vast majority of genes and combinations of genes that are involved are yet to be discovered (20,21). While the clinical presentation in JME is fairly homogenous, the pathogenesis appears to be complex and diverse (41).

Treatment

Appropriate management of a patient with JME requires consideration of multiple factors including AED selection, avoiding precipitating factors, and anticipating special considerations that might impact their care (pregnancy, driving, behavioral issues). Response to medical therapy is generally good, with 60% to 80% seizure-free rate on medications. However, noncompliance and lifestyle choices that involve sleep deprivation, alcohol use, and other precipitants often lead to breakthrough seizures. AED selection is also critical as some AEDs can exacerbate JME and lead to a pseudointractable state (26,32). Quality of life dramatically improves if a patient is able to reach seizure freedom, which can lead to driving, employment, and a higher likelihood of social success. In addition to an appropriate AED choice, patients should be counseled to obtain adequate sleep, avoid alcohol, and wear polarized sunglasses if their seizures are sensitive to photic stimulation.

Valproate

Valproic acid is the treatment of choice for JME as it effectively treats absence, myoclonic, and GTC seizures in 86% to 90% of patients (72,73). A recent large, unblinded, randomized, controlled study of patients with IGE treated with Standard and New Antiepileptic Drugs (SANAD) suggested that valproate was preferred to lamotrigine due to better control of seizures and preferred over topiramate due to lower rates of discontinuation due to side effects (74). Valproate is associated with a number of side effects that can sometimes limit its use or warrant reconsideration, including weight gain, hair loss, tremor, and teratogenicity. Weight gain is a frequent reason for discontinuing valproate, with 50% to 70% of patients gaining more than 4 kg (75). The standard dosing of valproate is 20 to 30 mg/kg/day, but patients with JME often respond to low doses, such as 500 mg/day (76). Valproate at low doses (below 1000 mg/day) and with extended-release preparations has significantly less side effects and is often well tolerated.

Lamotrigine

Lamotrigine is a useful alternative for patients with JME, especially when valproate alone is not effective or not well tolerated. In a retrospective cohort study, no difference in seizure control was found between valproate monotherapy and lamotrigine monotherapy, and the authors concluded that lamotrigine was an acceptable alternative to valproate (77). When compared in a randomized, controlled trial (SANAD), valproate had better efficacy in terms of seizure control than lamotrigine (74). There have also been some reports of exacerbation of myoclonic seizures with lamotrigine (78). In a study using lamotrigine as an add-on agent in treatment-resistant generalized epilepsy, 80% of patients had a >50% reduction in seizure frequency and 25% became seizure free (75). In an open-label study of lamotrigine monotherapy in patients who had failed valproate, there was no significant change in their underlying seizures, but 67% of patients reported improvement in their global clinical status on lamotrigine and 76% of patients rated lamotrigine as better tolerated than valproate (79). The major side effect of lamotrigine reported was a rash, which in some patients can be severe. An allergic skin reaction occurs in approximately 10% of patients with severe rash (such as Steven–Johnson syndrome) occurring in 0.3% of adults and 1% of children (80). The lamotrigine-associated rash may be more severe when combined with valproic acid (80). Lamotrigine is well tolerated and effective as an adjunctive therapy for JME, but concerns over decreased seizure control compared to valproate and exacerbation of myoclonic seizures in some patients limit its use as a monotherapy.

Topiramate

Topiramate is another possible adjunctive or alternative therapy to valproate, but there are limited data on application in patients with JME. In double-blind, placebo-controlled studies of topiramate, 73% of patients in the JME subgroup had a >50% reduction in primary GTC seizures and 16% became seizure free (81). In a randomized open-label comparison, topiramate and valproate had similar rates of seizure freedom (67% and 57%, respectively), and in both treatment groups, 11% of patients stopped the medication due to adverse effects (82). In the SANAD study, topiramate had similar efficacy to valproate but was associated with more side effects (74). Typical side effects with topiramate include cognitive dysfunction, anomia, weight loss, and nephrolithiasis.

Levetiracetam

A number of studies have shown the efficacy of levetiracetam as an adjunctive therapy for IGE, and its features of no known drug interactions and overall good tolerability have made this drug a useful asset. Using a retrospective design, Kumar (83) reported 25 IGE patients treated with levetiracetam and found that 68% of patients had some improvement in their seizures and 16% became seizure free. In an open-label study, Kraus et al. (84) studied 55 patients with GTC, myoclonic, and absence seizures and found that 76% had a >50% reduction in seizures and 40% became seizure free. These authors also found that 15% of patients discontinued levetiracetam due to adverse events (with sedation being the most common). In a multicenter, double-blind, placebo-controlled study, Berkovic et al. examined 164 patients with IGE. They reported that 72.2% of patients had a >50% reduction in seizures, with 34% of patients seizure free from GTC seizures and 24% seizure free from all seizure types (85). Levetiracetam was well tolerated in this study, and only 1.3% of patients discontinued therapy due to adverse events. A randomized, double-blind, placebo-controlled, multicenter trial by Noachtar et al. addressed the effects of levetiracetam on myoclonic seizures (86). They examined 120 patients and found that 58.3% of patients with myoclonic seizures had a >50% seizure reduction within days/week. The rate of myoclonic seizure freedom was 25%, and seizure freedom from all seizure types was seen in 21%. Levetiracetam has been shown to be efficacious as an adjunctive therapy in JME for all seizure types including myoclonic seizures. Adverse events of somnolence, headache, and irritability are relatively rare in 1% to 15% of patients.

Zonisamide

There have been relatively few studies on the efficacy of zonisamide in IGE and JME, but initial data have shown efficacy as an adjunctive agent for multiple seizure types, including JME. Zonisamide has been available in Japan since 1989, and much of the data derive from the Japanese experience. In a prospective postmarketing survey, Yamauchi et al. (87) reported that 78% of patients with IGE and 50% of patients with myoclonic seizures had a >50% seizure reduction with zonisamide. Yagi reported on pooled zonisamide efficacy data of 1008 patients collected from controlled and uncontrolled phase II and phase III studies and found 59% of GTC seizures, 62% of absence seizures, and 43% of myoclonic seizures were reduced by >50% (88). In a small retrospective open-label study, Kothare et al. reported that 80% of patients with JME had a >50% reduction in seizures on zonisamide monotherapy (89). They also reported seizure freedom in 69% of GTC seizures, 62% of myoclonic seizures, and 38% of absence seizures. Preliminary data suggest that zonisamide is efficacious as an adjunctive medication for JME, but further data from randomized, controlled trials will help delineate this. The advantages of zonisamide are once-daily dosing. Common side effects include weight loss, cognitive problems, and nephrolithiasis.

A number of medications have been reported to exacerbate JME, especially myoclonic seizures (26). The most common medications causing seizure aggravation are carbamazepine and oxcarbazepine. Phenytoin, gabapentin, and vigabatrin may also exacerbate seizures in JME or do not have efficacy.

Special Considerations of Treating JME in Pregnancy

Childbearing-age women represent 25% of patients treated for epilepsy, and the possibility of pregnancy often influences AED selection (90). While all of the AEDs have some risk of teratogenicity, valproate has the highest risk, especially when given in doses >1000 mg/day (6% to 11% chance of birth defects) (91). This is balanced by the evidence that valproate is the clinically

most effective medication to prevent seizures based on the SANAD study (74). Lamotrigine has been the best studied of the newer medications in pregnancy, has been followed in multiple pregnancy registries, and has a reported 2.7% risk of major congenital malformations (92,93). However, the actual risk of birth defects with lamotrigine is unclear since pregnancy induces the clearance of this drug by up to 94%, and this decrease in drug levels is not accounted for in the pregnancy registries (94). There has also been increased seizure frequency in mothers taking lamotrigine during pregnancy (94). There has been some indication of a dose-responsive risk of birth defects with lamotrigine, with an increased malformation rate in patients taking more than 200 mg/day, reported in the UK pregnancy registry but not in the International Lamotrigine Pregnancy registry (92,93). There is little information on other medications in JME during pregnancy such as topiramate, zonisamide, levetiracetam, and clobazam. Monotherapy in general had less risk of malformations (3.7%) than does polytherapy (6.0%) regardless of AEDs involved (93). There is some evidence that exposure to AEDs during pregnancy can affect the cognitive development of the fetus, with valproate associated with worse cognitive outcomes (91,95). In the Neurodevelopmental Effects of Antiepileptic Drugs study, children exposed to valproate had a lower intelligence quotient on average by 9 points compared to patients exposed to lamotrigine (95). The effect of valproate was dose dependent and was not observed at dosages below 800 mg/day.

A cautious and informed approach is needed when treating female patients in their childbearing years. Valproate is generally considered the most efficacious drug at suppressing the seizures in JME and is a reasonable choice if doses of <800 to 1000 mg/day can be used. Lamotrigine has shown fewer incidences of birth defects and potential cognitive problems but has fewer efficacies in preventing maternal seizures, and increased seizure frequency has been reported (94), in particular exacerbation of myoclonic seizures. Young women with JME should not be discouraged from having children in general, as >90% of women have normal pregnancies. However, placement on monotherapy and preconceptual planning should be encouraged to reduce the risk of fetal malformations and potential cognitive delays.

Prognosis

The prognosis for JME is generally considered excellent as the majority of patients can be treated successfully with AEDs. Seizure-freedom rates of 60% to 90% have been reported. It has been noted that while response to medication is good, patients tend to have breakthrough seizures due to noncompliance, sleep deprivation, alcohol use, or other precipitants. Achieving seizure freedom often involves lifestyle modifications as well as compliance with AEDs. Multiple studies in the past have suggested that JME is often a lifelong condition (96). Delgado-Escueta and Enrile-Bacsal have reported a 90% relapse rate with withdrawal of medications in the past. However, a more recent longitudinal study followed patients with JME for 25 years and found that 48% had voluntarily stopped their medications, 17% were without seizures on no medication, and 13% had myoclonus only, also without medication (1). It should also be noted that 36% of patients followed in the study had an episode of convulsive status epilepticus and 13% had medically intractable seizures. While a small percentage of patients with JME could likely come off medications at some time interval as suggested in the study, determining who will remain seizure free and who will continue to have seizures is less clear.

EPILEPSY WITH GENERALIZED TONIC–CLONIC SEIZURES ONLY

Epilepsy with GTC seizures only has recently been described by the ILAE in their most recent proposed diagnostic scheme for people with epileptic seizures and epilepsy as a separate syndrome (3). It includes "epilepsy with GTC seizures on awakening," which was previously described as a separate syndrome. The diagnosis of this syndrome can be challenging as many IGEs as well as focal epilepsies have some component of GTC seizures.

Epidemiology

There is limited information on the epidemiology of patients presenting with GTC seizures only. In a population-based study, epilepsy with grand mal upon awakening was reported as a major feature in 23% of generalized epilepsies (97). A population-based study in France reported an incidence of 1.8 per 100,000 people (97).

Clinical Features

The peak age of onset is at 15 with an age range between 5 and 50 years (7). Neurologic exam and imaging is normal, and other tests except for the EEG do not reveal any other neurologic abnormalities.

The predominant seizure type is GTC. Absence seizures and myoclonic seizures are seen less frequently. Seizures are mainly provoked by alcohol and sleep deprivation and can also be brought out by photic stimulation. Seizures tend to worsen with age. Wolf reported GTC seizures on awakening in 17% to 53%, during wakefulness in 23% to 36%, during sleep in 27% to 44%, and not related to wake or sleep patterns in 13% to 26% of patients (98). In the subcategory of GTC seizures on awakening, GTC seizures occur in more than 90% within 1 to 2 hours after awakening or at the end of the day (during relaxation), with only rare myoclonic or dialeptic seizures. Unterberger et al. compared epilepsy with GTC seizures on awakening and randomly occurring GTC seizures and found that patients with early morning seizures had a longer duration of epilepsy, a higher relapse rate, and a stronger relationship to seizure provoking factors (99).

EEG

Interictal features on EEG consist of generalized epileptiform discharges presenting either as generalized 4- to 5-Hz spike-and-wave complexes or as generalized polyspikes. Discharges can be seen bilaterally with occasional asynchrony or asymmetry of bursts.

Ictal EEG is characterized by generalized fast rhythmic spiking, with a bifrontal maximum during the tonic phase of a GTC seizure. EEG activity is frequently obscured by tonic or clonic muscle artifact. Spiking can be asymmetric and asynchronous. This activity slows down and evolves into discontinuous repetitive generalized bursts of generalized (poly) spikes and waves intermingled with rhythmic slow waves. Clonic jerks start approximately at a spike frequency of 4 Hz. Postictally, electrical activity is reduced and can occasionally appear silent (<10 μV) for a brief period and is usually followed by irregular diffuse slowing.

Genetics

Patients with epilepsy with GTC seizures only frequently have a positive family history of epilepsy. Most recently, different mutations in unrelated families of the chloride channel-2 gene (CLCN2) on chromosome 3q26-qter have been found to be associated with GTC seizures on awakening (37). Interestingly, CAE, JAE, and JME were also found in families with this mutation (37).

Treatment

Monotherapy with lamotrigine or valproate is recommended, with valproate having higher efficacy and lamotrigine fewer side effects (74). Other options include topiramate, levetiracetam, and zonisamide. If the maximum tolerated dose does not reduce seizure frequency, an alternative medication should be tried. In case of monotherapy failure, combination therapy of lamotrigine and valproate may be effective (100). Gabapentin is not helpful, and tiagabine and vigabatrin may exacerbate seizures in some cases (26). Additionally, the prevention of precipitating factors of seizures such as sleep deprivation and alcohol intake drug treatment is beneficial.

Prognosis

The prognosis of patients with GTC seizures only is very good and usually better than in patients with focal epilepsy and secondary generalized seizures (101). Up to 95% of patients with GTC seizures of unknown origin will have a continuous 5-year seizure-free period within 20 years after epilepsy onset (101). Twenty-one percent of patients who have been seizure free for 5 years or longer relapse within a 20-year observation period (101). Frequency of GTC seizure at the time of diagnosis predicts outcome and remission (102). Failure to remit within 2 years of diagnosis reduces the chance of remission in the following years (103).

GENERALIZED EPILEPSY WITH FEBRILE SEIZURES PLUS (GEFS+)

Generalized epilepsy with febrile seizures plus (GEFS+) is a heterogeneous disorder with some features of an IGE. Generalized epilepsy seizure types as well as febrile seizures, focal seizures, and progressive epilepsy syndromes such as Dravet syndrome have been described (104,105). There is an underlying genetic basis for this disorder with four genes identified thus far, but the clinical features of GEFS+ are divergent from typical IGE in some patients. GEFS+ illustrates the complexity of epilepsy syndromes with multiple different phenotypes arising from the same mutation and different mutations giving rise to clinically similar phenotypes, all-in-one syndrome.

Epidemiology

The epidemiology of GEFS+ has not been studied in a large epidemiologic study, and the incidence/prevalence is unknown. It has been speculated that GEFS+ is a common childhood syndrome, and detailing this will be a challenge given the clinical heterogeneity that has been attributed to this syndrome thus far (106).

Clinical Features

Most patients with GEFS+ present with febrile seizures in the typical ages between 3 months and 6 years, then continue to either have additional febrile seizures outside of this age range or begin having afebrile seizures as well (104,105). Seizures can persist into late adolescence or longer and may remit in the early teenage years. A history of febrile seizures in other family members is crucial to the diagnosis.

Febrile seizures begin approximately at the age of 1 year, slightly earlier than in the average infant with febrile seizures. Onset of afebrile seizures may overlap with febrile seizures or may occur after a seizure-free interval between febrile and afebrile seizures.

Neurologic exam is normal in the majority of patients described but may also show cognitive impairment and developmental abnormalities (104,106,107).

Clinical seizures consist of febrile seizures in association with afebrile seizures presenting as GTC seizures or dialeptic seizures (absences). Other seizure types of myoclonic–astatic, atonic, tonic, and complex partial seizures have also been described (104,106,107). Seizures usually persist beyond 6 years of age until adolescence or longer.

EEG

The syndrome lacks a clear electroclinical pattern, and interictal EEG can be normal. However, interictal epileptiform discharges frequently consist of irregular generalized spike and waves or polyspikes with infrequent 2- to 3-Hz generalized spike-and-wave complexes (104). Due to variable clinical presentations, interictal EEG may also present with focal epileptiform discharges, for example, in the frontal, temporal, and occipital regions (108).

Genetics

Mode of inheritance has been described as autosomal dominant with incomplete penetrance in a number of family pedigrees (104–108).

Five genes have been associated with GEFS+ thus far, three genes encode for a sodium channel subunit and two encode for $GABA_A$ receptor subunit. SCN1A encodes the α1 subunit of the neuronal voltage-gated sodium channel and was implicated in GEFS+ by identified mutations (109). It is suspected to increase excitability by decreasing the inactivation of the channel. SCN1B, which encodes the β1 subunit of the neuronal voltage-gated sodium channel, has also been found to be mutated in families with GEFS+ (110). This mutation is suspected to interfere with the modulation of the gating of the sodium channel leading to neuronal hyperexcitability. SCN2A has also been implicated by a missense mutation in a patient with GEFS+ (111). The γ-2 subunit of the $GABA_A$ receptor (GABRG2) has also been shown to be mutated in patients with the clinical phenotype of GEFS+ at that benzodiazepine-binding site (112). The mutation is predicted to reduce the flow through the channel, decreasing its inhibitory effect.

Treatment

The decision to treat pharmacologically should be made based on seizure frequency and severity of afebrile seizures. Clinical presentation and individual seizure types should determine the treatment approach and selection of AED if applicable. Due to paucity of reported cases, only little information

on the efficacy of specific pharmacologic treatments is available. Gerard et al. report pharmacologic treatment in 6 out of 15 affected individuals "with success and seizure control in most" after analysis of a multigeneration pedigree of GEFS+ patients in France (113). Interestingly, in one family with a mutation in the GABRG2 gene (GEFS+ type 3), decreased benzodiazepine sensitivity has been reported (114).

Prognosis

The prognosis is usually very good but is dependent on the variable clinical phenotypes associated with GEFS+. Spontaneous remission occurs frequently in the early teenage years (10 to 12 years) (112). However, seizures can persist, and several other epilepsy syndromes can develop (CAE, JME, myoclonic–astatic epilepsy, focal epilepsy) (112,115).

IDIOPATHIC GENERALIZED EPILEPSY SYNDROMES AS PART OF THE GENERALIZED EPILEPSY SPECTRUM

Overall, there are many similarities among the above-described types of IGE syndromes. According to Janz (2), 4.6% of cases of CAE evolve into JME when patients reach the usual age of JME onset. A population-based study of 81 children with CAE found that 15% had progressed to JME 9 to 25 years after seizure onset (116). In this study, the development of GTC or myoclonic seizures in a patient with CAE receiving AEDs made the progression to JME very likely (116). Syndromes manifest with the same seizure types, have similar EEG changes, may evolve into one another, and have overlapping genetic origins. Neurologic exams as well as imaging studies are typically normal. Therefore, IGEs may be viewed as a continuous spectrum of conditions, representing common clinical presentations, and overlapping and complex genetic etiologies.

CHAPTER 19 PROGRESSIVE AND INFANTILE MYOCLONIC EPILEPSIES

BERND AXEL NEUBAUER, ANDREAS HAHN, AND INGRID TUXHORN

Myoclonus is characterized by brief, shock-like jerks that may be generalized, confined to larger or smaller muscle groups, or restricted even to a single muscle. It is termed epileptic when occurring in combination with cortical epileptiform discharges. Electromyographic (EMG) bursts lasting 10 to 100 ms may be preceded by discharges (spikes or polyspikes in general) that are easily visible on surface electroencephalography (EEG) (Fig. 19.1) or that are only detectable when jerk-locked back averaging or other sophisticated techniques are applied. Epileptic negative myoclonus is defined as an interruption of tonic muscular activity for <500 ms without evidence of antecedent myoclonia (Fig. 19.2). The term clonic means the rhythmic repetition of a myoclonic jerk, mainly at a rate of 2 to 3 seconds. Myoclonic seizures predominantly affect limb, axial, neck, and shoulder muscles, and less frequently facial and extraocular muscles. Rarely, myoclonic seizures occur in series and evolve into a myoclonic status epilepticus, with or without complete loss of consciousness. In most epilepsy syndromes with myoclonic seizures as the cardinal feature, additional seizure types occur at lesser frequency. Mostly, these other seizure types include generalized tonic–clonic seizures (GTCS), generalized clonic seizures, atonic seizures, absence seizures, and atypical absences (1).

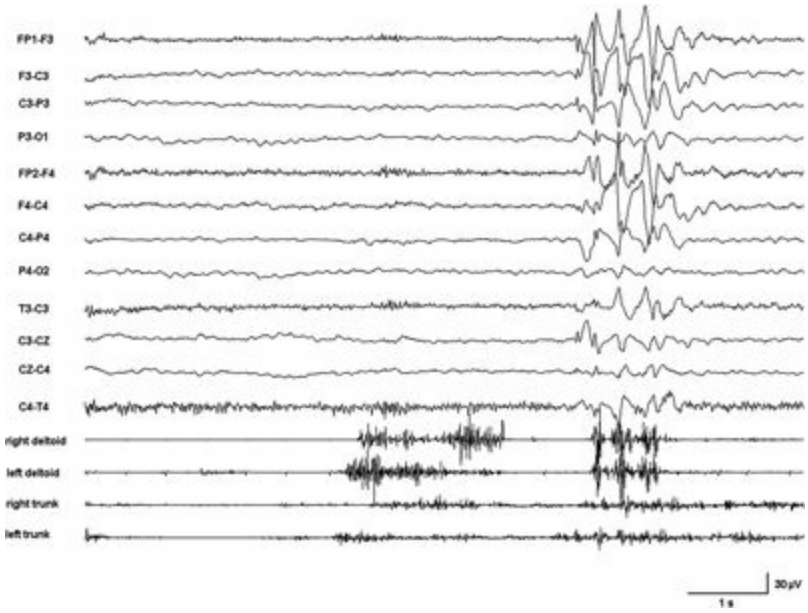

Figure 19.1. EEG–EMG recording with surface electrodes in a 3-year-old boy with MAE (Doose syndrome). Three brief and symmetric myoclonic jerks each time-locked to single generalized single spike–wave discharges are recorded from both deltoid muscles.

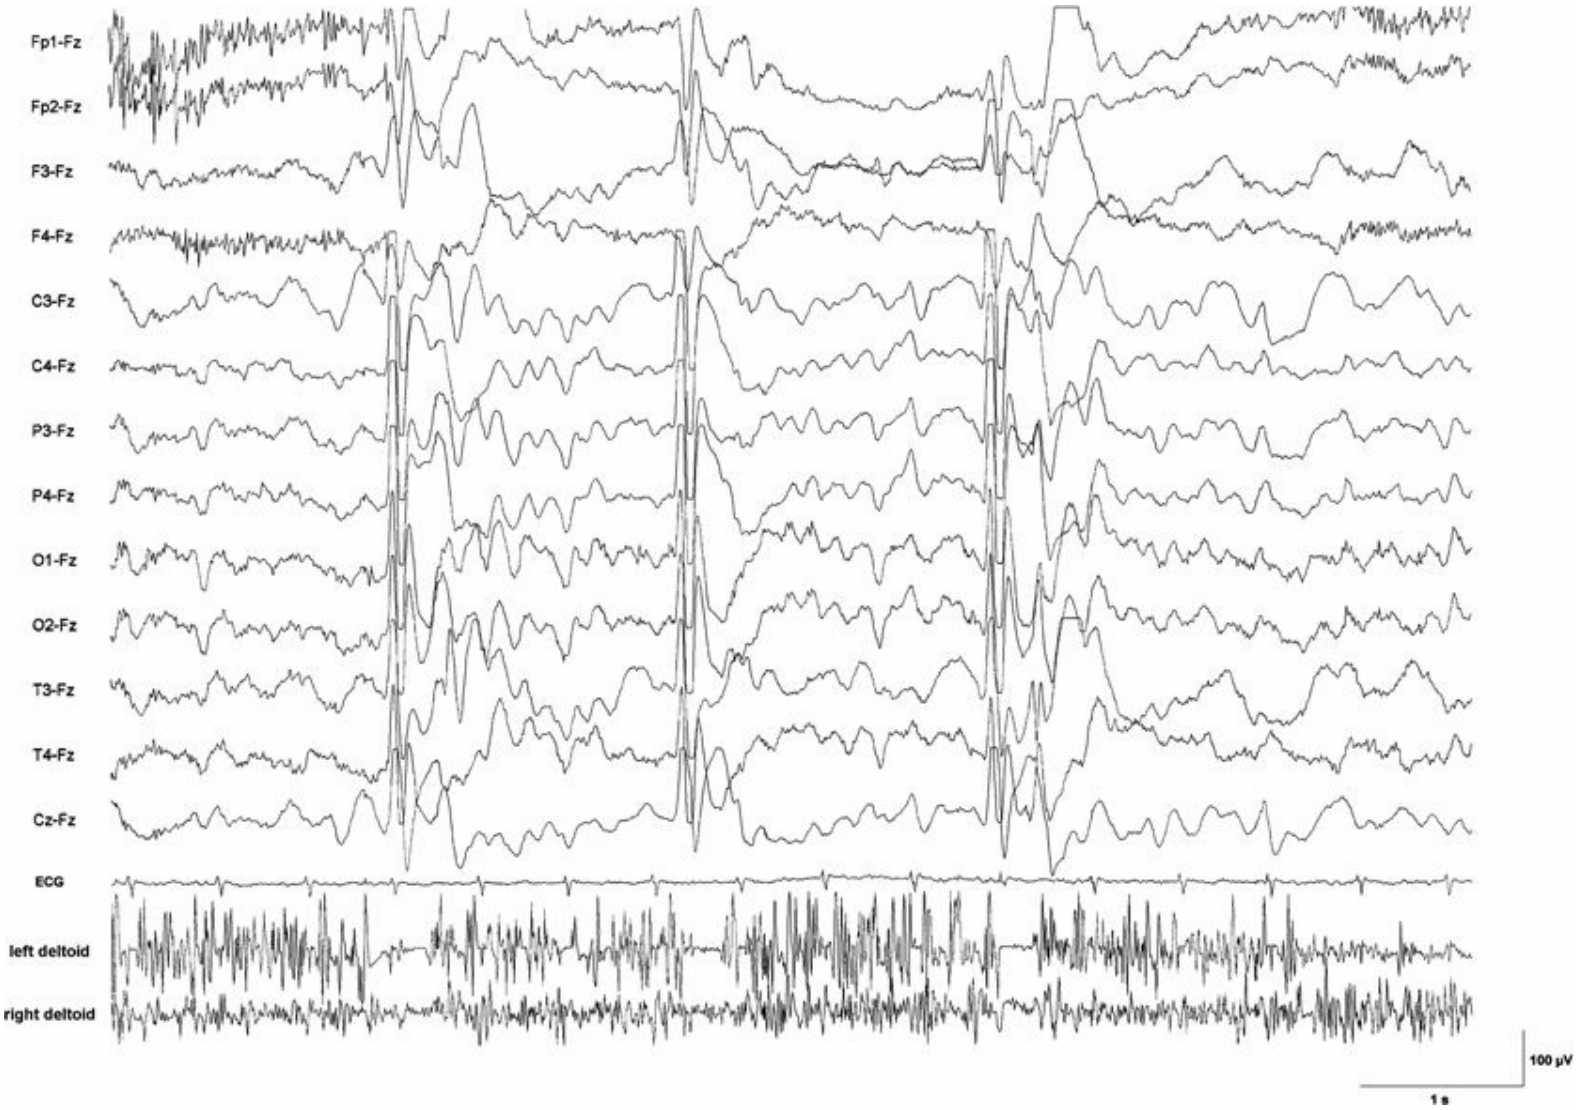

Figure 19.2. EEG–EMG recording with surface electrodes in a 6-year-old boy with epileptic negative myoclonus due to lesion-related epilepsy. Silent periods in the EMG from the deltoid muscles lasting between 100 and 150 ms are time-locked to a generalized sharp slow-wave complex. Clinically, each brief EMG pause was associated with nodding of the head and sinking of the arms during sustained muscle contraction.

ETIOLOGY

Myoclonic epilepsies are predominantly genetic in origin. In terms of classification, they may be grouped as genetic epilepsies (e.g., benign myoclonic epilepsy in infancy [BMEI]), epileptic encephalopathies (e.g., Dravet syndrome), or progressive myoclonic epilepsies (e.g., Unverricht–Lundborg disease).

BMEI usually presents in normally developed children, and in the majority of cases, antiepileptic treatment may be weaned after some years of active epilepsy. Behavioral and cognitive prognosis is good in the majority of cases. Familial cases are extremely rare, with the exception of one case identified in the context of a generalized epilepsy with febrile seizures plus (GEFS+) family (2) and a family with three affected children (3). However, a positive family history for febrile seizures or idiopathic epilepsies was repeatedly reported (4). Altogether, classification as a genetic generalized epilepsy syndrome seems unequivocal. The etiology is most likely oligogenic or complex (several genes and possibly environmental factors involved).

Myoclonic astatic epilepsy (MAE) or Doose syndrome, initially described by Doose et al. (5), was reported to be an idiopathic generalized epilepsy syndrome. The separation of this syndrome

from a group of epilepsies that were formerly classified as symptomatic (many of them as Lennox–Gastaut syndrome) was only reluctantly accepted. This is mirrored by the fact that MAE was classified among the "cryptogenic or symptomatic generalized epilepsies and syndromes" for many years. Now it is recognized that the initial description of Doose et al. included cases that, from today's point of view, might also be diagnosed as benign myoclonic and severe myoclonic epilepsies, but the current classification scheme now accepts Doose syndrome as a genetic epilepsy syndrome (6). As with BMEI, familial cases are exceptional, but retrospective studies demonstrated positive family histories for febrile seizures and idiopathic epilepsy syndromes at a clearly elevated rate (7). Although in single cases genetic defects in the genes (mostly SCN1A) known to be involved in GEFS+ families were reported, the majority of patients do not carry an identifiable defect in these genes (8).

Severe myoclonic epilepsy of infancy (SMEI) or Dravet syndrome from one point of view may be classified as an idiopathic genetic disorder, since children are healthy and normally developed until onset of the epilepsy, and there is a clear genetic cause (usually a SCN1A defect) in the majority of cases. The syndrome may even be observed in GEFS+ families (9). However, Dravet syndrome is a devastating disorder with an extremely severe course in most patients; hence, it was declared an epileptic encephalopathy (6).

Progressive myoclonus epilepsies (PME) are defined as neurometabolic or neurodegenerative diseases with myoclonias and myoclonic seizures as dominating clinical features. Frequently, myoclonic seizures represent the initial clinical symptom. These disorders are in general progressive; however, course varies from moderately mild (e.g., Unverricht–Lundborg) to rapidly progressive and fatal (e.g., neuronal ceroid lipofuscinoses [NCL] type 2). PME follow a monogenic, mostly autosomal recessive mode of inheritance (10). Some diseases such as Rett-like syndrome (CDKL-5 defects) are usually not regarded as "classic" PME but may at certain stages and in individual patients show the typical symptomatology and course of a PME. These disorders, which frequently manifest during infancy or early childhood, may be summarized as progressive encephalopathies with myoclonic seizures (Table 19.1).

Table 19.1 Progressive Myoclonic Epilepsies and Progressive Encephalopathies with Myoclonic Seizures

- *With manifestation during neonatal period/early infancy*
  - Pyridoxine-dependent/pyridoxal phosphate–dependent epilepsy/folinic acid–responsive seizures
  - Nonketotic hyperglycinemia
  - Sulphite oxidase deficiency/molybdenum cofactor deficit
  - X-linked cyclin-dependent kinase-like 5 (*CDKL5*) encephalopathy
  - X-linked myoclonic epilepsy with spasticity and intellectual disability associated with mutations in the *ARX* gene
  - Others (e.g., aminoacidopathies, organic acidurias, deficits of β-oxidation of fatty acids, CDG syndrome variants, GABA-transaminase deficiency, Zellweger syndrome/other peroxisomal disorders, urea cycle deficits)
- *With manifestation during late infancy/early childhood*
  - Glucose transporter (GLUT-1) deficiency (De Vivo disease)
  - Early infantile neuronal ceroid lipofuscinosis (*CLN 1*)
  - Late infantile neuronal ceroid lipofuscinosis (*CLN 2*)
  - Holocarboxylase synthetase deficiency/biotinidase deficiency
  - Disorders with 5-MTHF depletion in CFS (e.g., FOLR1 mutation)
  - Progressive myoclonic epilepsy with mutation in KCDT7
  - Childhood spinal muscular atrophy with progressive myoclonic epilepsy (ASAH1)
  - Others (e.g., glutathione peroxidase deficiency, methylenetetrahydrofolate reductase deficiency, hereditary anomalies in serine synthesis, Menkes disease, mitochondrial disorders, GM2 gangliosidosis, succinic semialdehyde dehydrogenase deficiency)
- *With manifestation during late childhood/adolescence*
  - Juvenile neuronal ceroid lipofuscinosis (*CLN3*)
  - Adult neuronal ceroid lipofuscinosis (*CNL 4*)
  - Neuronal ceroid lipofuscinosis variants (*CLN 3, CLN 5, CLN 6*)
  - Myoclonic epilepsy with ragged red fibers
  - Unverricht–Lundborg disease
  - Lafora disease
  - Sialidosis types I and II
  - Galactosialidosis
  - Neuroserpinosis
  - Dentato-rubro-pallido-luysian atrophy
  - Juvenile form of Huntington disease
  - Gaucher disease (type III)
  - Action myoclonus–renal failure syndrome
  - Leukoencephalopathy with vanishing white matter
  - Progressive ataxia–myoclonic epilepsy with mutation in PRICKLE1 gene
  - North Sea progressive myoclonus epilepsy (GOSR2)
  - Progressive myoclonic epilepsy with mutation in COL6A2

BENIGN MYOCLONIC EPILEPSY IN INFANCY

Definition and Epidemiology

BMEI is a rare epilepsy syndrome. Its classic description was done by Dravet and Bureau (11). Altogether about 110 cases have been reported, and it is estimated that BMEI accounts for <1% of childhood epilepsies (12). BMEI is mainly recognized in Europe (France, Italy), and it may be suspected that in cases with rare myoclonic seizures or seizures that respond quickly to therapy, correct classification may not be applied, thereby underestimating its real prevalence. Some cases may overlap with MAE (Doose syndrome). In one patient who was initially diagnosed with BMEI, later a SLC2A1 (glucose transporter-1) defect was established (4).

Symptomatology

Onset is mostly between 4 months and 3 years but may extend up to the 5 years. Febrile seizures antecedent to myoclonic seizures are reported in about 30% of cases. In the beginning, myoclonic seizures are often rare and brief, involving predominantly the upper limbs. But intensity and frequency of the seizures increase often early during course. In the largest series reported, polygraphic video–EEG recordings revealed that myoclonic seizures consisted of axial jerks with head drop, elevation and extension of both arms, flexion of the legs, and upward gaze. Myoclonic seizures may vary in intensity ranging from simple head nods to severe falls, when generalized. Seizures may occur repetitively but usually only in short trains lasting 1 to 3 seconds. Usually they are symmetrical, but rarely may be unilateral. In about a third of patients, they are triggered by stimuli-like noise, startle, or photic stimulation. Drowsiness is also known to provoke myoclonic seizures (4).

EEG

Background activity is normal. Myoclonic jerks are associated with generalized spike–waves and polyspike–waves. Ictal spikes last for 1 to 3 seconds. Most, if not all, myoclonic seizures are associated with discharges on the surface EEG. EEG discharges are generalized with a frontocentral accentuation. After the myoclonia, there may be a short atonia that may result in a drop, that is, a myoclonic astatic seizure. Focal abnormalities, usually spike–waves in sleep recordings, were reported in some patients (4). Its significance is unknown.

Treatment and Prognosis

Valproic acid is the drug of first choice and is usually the only drug needed to control the seizures in the majority of cases. Some authors recommend high plasma levels at the start of treatment (up to 100 mg/L) (13). Ethosuximide, benzodiazepines, and phenobarbital were also effective in the few cases reported who did not receive valproic acid. Altogether there seems to be no specific difference in treatment compared to MAE. Untreated cases continue with pure myoclonic seizures even if the epilepsy lasts for years. Developmental delay and behavioral disturbances are reported in a substantial number of patients. Precise numbers vary substantially between different series, ranging from 0% to 86% (14). A rate of 20% to 30% seems acceptable. This renders the term “benign” questionable and makes it difficult to differentiate cases with frequent generalized myoclonic seizures and evolving developmental delay from patients with MAE. Bureau and Dravet are convinced that mental prognosis depends on early diagnosis and successful treatment (4). However, there are no

controlled studies with antiepileptic drugs (AED) on record, and there are no good data on required treatment duration. By definition, myoclonic seizures will disappear eventually in all cases. Most reported children older than 6 years were already weaned off medication without seizure relapse. But in some patients, generalized tonic–clonic seizures (GTCS) occurred when valproate treatment was stopped. While a subgroup with overt reflex seizures appears to be very easily controlled by AED, cases with marked photosensitivity may be more difficult to control (4).

MYOCLONIC ASTATIC EPILEPSY/DOOSE SYNDROME

DEFINITION AND EPIDEMIOLOGY

The prominent genetic etiology together with the characteristic seizure symptomatology dominated by myoclonic and myoclonic astatic seizures led Doose et al. (5) to delineate MAE as an idiopathic (today: genetic) generalized epilepsy syndrome of its own right. MAE, as a rule, occurs in children with an uneventful history. The epilepsy starts in 94% during the first 5 years of age and accounts for 1% to 2% of all childhood epilepsies (15). Doose et al. reported that in about 20%, the seizures have their onset during the first year of life (7,16). Today, many authors feel that onset before the second year of life is exceptional. The age of peak presentation is 3 years (17). Like most other myoclonic epilepsies of early childhood, it affects more boys than girls. The sex ratio is about 2.7/1 (16). If the inclusion criteria include all children older than 1 year, this ratio might even reach 3/1 (17).

Symptomatology

In about 60% of cases, the epilepsy starts with febrile or afebrile GTCS. Alternating grand mal (i.e., hemi–grand mal, unilateral seizures) is a possible presentation. Some days or short weeks later, myoclonic and/or myoclonic–astatic seizures set in abundance, frequently in combination with brief absences. At first, this occurs predominantly after awakening. Tonic axial seizures may manifest during long-term course, frequently occurring during sleep. Myoclonic seizures consist of symmetric, mostly generalized jerks, accentuated in the arms and the shoulders, and are frequently associated with a simultaneous flexion of the head. The intensity of these seizures is variable and ranges from violent myoclonic jerks with sudden falls to abortive forms merely presenting as short irregular twitches of the face. Myoclonic–astatic seizures are characterized by a loss of muscle tone preceded by a (short) myoclonia. In polygraphic recordings, the loss of muscle tone corresponds to a silent period in the EMG that is paralleled by the slow wave in the EEG following the spikes or polyspikes of the myoclonus. Myoclonic seizures with and without discernable myotonia frequently occur together. The initial myoclonia and the subsequent myotonia equally contribute to the characteristic myoclonic astatic seizure (18–20). Absences are seen in more than half of the children with MAE. Myoclonic and astatic seizures, when they come in series, are frequently accompanied by absences often combined with myoclonic jerks. A unique type of nonconvulsive status epilepticus (“status of minor seizures”) is a rather specific finding observed in 36% (5,7,18) to 95% (17) of MAE patients. The characteristic clinical picture is a somnolent, stuporous child with subtle myoclonic seizures, frequently involving the face and the extremities. The child is unresponsive, drools, has a slurred speech, or is even aphasic. This status may continue for days if not interrupted by adequate means.

EEG

Background activity is of special interest in MAE. In cases starting with GTCS, the EEG may stay entirely normal for weeks. However, almost in all instances, a rhythmic, parietally accentuated 4- to 7-Hz activity develops early in the course. This rhythmic slowing of background activity was frequently questioned and falsely attributed to drowsiness. In patients with MAE (and other idiopathic generalized epilepsies of early childhood with myoclonic seizures), it represents a constant trait that is not related to the state of vigilance. This has been documented by EEG recordings of children who were kept attentive by displaying cartoons and so on (20). During the early stages, spikes, irregular spikes, and polyspikes may well be absent and appear only after some delay starting during sleep. If myoclonic seizures dominate the course at a given time, the EEG shows short paroxysms of irregular spikes and polyspikes. In children with astatic and myoclonic astatic seizures, 2- to 3-Hz spikes and waves appear. As the epilepsy progresses, typical absence patterns may appear. During a status of myoclonic–astatic seizures, the EEG displays continuous spike–waves with interposed slow waves. Especially in younger children, an irregular polymorphous hypersynchronous activity, sometimes resembling hypsarrhythmia may be recorded. During nocturnal tonic seizures, typical 10- to 15-Hz spike series can be observed. In distinction to the tonic seizures observed in Lennox–Gastaut syndrome, the EEG onset is generalized in MAE.

Therapy and Prognosis

Revised treatment standards over the last years have significantly improved outcome and prognosis (21). Valproic acid is still the drug of first choice. If efforts fail to achieve complete remission, the decision which drug to use next depends on the predominating seizure type. If absences prevail, ethosuximide should be commenced as the next step. If GTCS represent the leading semiology, bromide is frequently the most effective drug, even superior to phenobarbital or primidone (22). Lamotrigine may be effective but is also known to provoke myoclonic seizures in generalized myoclonic epilepsies. It therefore may represent a valuable option but has to be used with caution (23). Basing on the broad mechanism of action, topiramate is an additional possibility. However, no data on its effectiveness in MAE are yet available. Carbamazepine, phenytoin, and vigabatrin should be avoided, for they frequently provoke seizure exacerbation (17,24,25). In cases with refractory nonconvulsive status epilepticus adrenocorticotropic hormone (ACTH) or high-dose steroid pulse therapy may be alternatives to be considered (24). Zonisamide is effective in myoclonic epilepsies of different etiology (26). Levetiracetam may be used successfully in myoclonic epilepsies; however, it may also aggravate seizures (27). Ketogenic diet is a further possibility that was reported as effective (28).

Already from the early descriptions of the disorder, it becomes clear that outcome is highly variable. The spectrum ranges from complete remission (frequently obtained within the first 3 years) and totally normal intellectual development to therapy resistant epilepsy with severe cognitive disability (5,21,24,29). Over the years, however, therapeutic possibilities constantly improved, and the danger of seizure and epilepsy aggravation by carbamazepine and phenytoin was more and more recognized. In a series of 81 patients with MAE, 68% became eventually seizure free. In this retrospective Japanese series, ACTH, ethosuximide, and ketogenic diet proved especially effective (21). Repetitive nonconvulsive status epilepticus (“status of minor seizures”) and nocturnal tonic seizures were frequently associated with an unfavorable prognosis (16,21). This is, however, not unequivocal (17).

SEVERE MYOCLONIC EPILEPSY OF INFANCY/DRAVET SYNDROME

Definition and Epidemiology

This electroclinical syndrome was delineated by Dravet (30) in 1978 and soon was labeled SMEI. Later, it was recognized that in a substantial number of cases, myoclonic seizures and single other features may be lacking, and still the epilepsy will take the same course. This led to the proposal to rename the epilepsy to Dravet syndrome, which is now recognized as an epileptic encephalopathy (6). In order to include cases that seemed to belong to the same entity but lacked single features of classic SMEI, recently the term "borderline SMEI" (SMEB) was introduced. Different variants of what is now called SMEB were earlier recognized independently by different authors, such as "intractable childhood epilepsy with GCTS," "severe idiopathic epilepsy of infancy with generalized tonic–clonic convulsions," "severe polymorphic epilepsy of infants," and even a few others (8).

The rate of cases with Dravet syndrome seems to augment constantly as the syndrome may be diagnosed increasingly frequently by SCN1A (α subunit of the neuronal type I sodium channel) gene analysis (31,32). This unique opportunity has sharpened the diagnostic view of the medical community. After one has succeeded in diagnosing a few cases, it frequently becomes an experience of pattern recognition. Therefore, the formerly calculated incidence of 1/40,000 may be an underestimate (33). It is of note that many epileptic vaccine encephalopathies in which an immunization-provoked fever triggered the epilepsy were retrospectively identified as having a SCN1A mutation (34).

Symptomatology

The disease most frequently starts with febrile seizures within the first year of life, in an up to then healthy child. These seizures may initially be indiscernible from regular febrile seizures but frequently become prolonged. Fever, infections without fever, vaccinations, hot baths, or even only hot weather may trigger recurrent seizures. These may occur generalized or unilateral affecting different sides of the body on different occasions (i.e., alternating hemi–grand mal, unilateral seizures, hemiclonic convulsions). The tendency to suffer temperature-sensitive seizures seems to persist over many years. In the series of Dravet et al. (33), short, single myoclonias were noted by some parents before onset of febrile seizures. Even though approximately 70% of cases begin with generalized or unilateral febrile seizures, focal seizures may occur already early in the course, but this is not the rule. Febrile seizures typically occur repeatedly within the first year of life and are frequently the dominating manifestation of the epilepsy in the first 9 months of age. Later, afebrile generalized seizures add to the febrile seizures and are soon followed by myoclonic seizures and atypical absences (33).

Dravet et al. (33) define "steady-state seizures" as those that prevail in many cases throughout the course. The authors recognize 10 different seizure types:

1. "GTCS" are basically identical to those encountered in idiopathic generalized epilepsy syndromes.
2. "Hemiclonic convulsions" are frequent in the first 3 years of life, and then they become

rare. Postictal hemiparesis is a frequent feature. If they—by chance—reoccur on a specific side of the body, they may falsely be taken for focal seizures.

3. "Falsely generalized seizures" clinically appear like GTCS. On polygraphic recordings, this seizure can be resolved as bilateral asymmetric tonic contractions of different muscle groups.
4. "Unstable seizures" are clinically related to "falsely generalized seizures" with concomitant focal EEG discharges that change their origin between and during seizures.
5. Myoclonic seizures predominantly affect the axial muscles and may range from mild to severe, from simple head nodding to violent thrashes involving the entire body. Severe myoclonic seizures may result in falls and injuries. Repeated twitching of the head is a third observed type. These seizures may precede generalized tonic–clonic convulsions. Interictal myoclonias (without concomitant epileptic discharges on surface EEG) are a frequent feature, mainly observed in periods with high seizure frequency (roughly 70% of cases). Myoclonic seizures may abate over time.
6. Atypical absences may appear at any age during course; however, mostly after the first year of life. In our view, absences are not always "atypical" because regular 3-Hz spike slow-wave absences may be recorded. Absences may range from pure impairment of consciousness to absences with intermixed myoclonic seizures. Duration varies between 3 and 10 seconds in most cases.
7. Simple and complex focal seizures, frequently associated with strong autonomic reactions such as pallor, cyanosis, and sweating, are detectable in about two-thirds of cases. They may start already within the first year of life, but usually begin later. Adversive seizures and clonic seizures frequently in combination are typical manifestations.
8. Tonic seizures are rare in this syndrome. They seem to resemble those seen in Lennox–Gastaut syndrome, often with a myoclonic component.
9. Obtundation states are episodes of reduced attention (drowsy states). They occur in more than one-third of children. Usually, they are associated with erratic myoclonias involving the limbs or the face. These drowsy states may continue for hours or even days. In the EEG, dysrhythmic slow waves intermingled with spikes and sharp waves are characteristic. This state may evolve from an overt seizure or end in one.
10. A status of generalized tonic–clonic convulsions may occur without warning. Frequently fever, infection, or even photic stimulation may act provocative. If the status is then falsely treated by phenytoin (a sodium channel blocker), it may have an unfavorable outcome.

Besides intractable epilepsy, a variable degree of developmental delay (usually severe) characterizes the course. Children frequently develop an ill-defined moderately severe ataxia (60% to 70%) and mild pyramidal signs. Usually, ataxia is not disabling, will not prevent from walking, and will attenuate over the years. Besides fever, infection, and hot weather conditions, seizures may also be triggered by (hot) water immersion, joyful mood (e.g., birthday party), or physical exercise. Hyperkinetic behavior, especially at times of high seizure frequency, and autistic features are frequent findings. In general, the more severe the epilepsy, the more marked will be the developmental and behavioral problems. Death is reported in about 10% of larger historic series. Causes were mixed, ranging from status epilepticus to drowning, sudden unexplained death in epilepsy, and accidents (33).

EEG

In the first 1 or 2 years of life, the interictal EEG is frequently normal. Photosensitivity may be found in about 40% of cases. Over time, the background activity deteriorates. As reported by Doose, a rhythmic theta activity with accentuation over the central channels and independent of vigilance develops (20) (Fig. 19.3). Generalized regular and irregular spike–waves as well as multifocal spikes and sharp waves may evolve during the course. In unilateral seizures, lateralized spike–wave or slow spike–wave activity with intermittent irregular spike–wave is observed. In "falsely generalized seizures," an initial amplitude reduction and spike–wave and slow spike–wave activity with changing asymmetry are observed. In unstable seizures, the epileptic EEG activity is similar but migrates from one brain region to another during the same seizure. In myoclonic seizures, spike–wave and polyspike–wave discharges occur simultaneously with the myoclonias. Absences are accompanied by irregular 2.5 to 3.5 generalized spike–wave discharges lasting mostly 3 to 10 seconds. Obtundation states (nonconvulsive status epilepticus) are characterized by generalized spike–wave and slow spike–wave discharges with intermixed fast and slow activities (30).

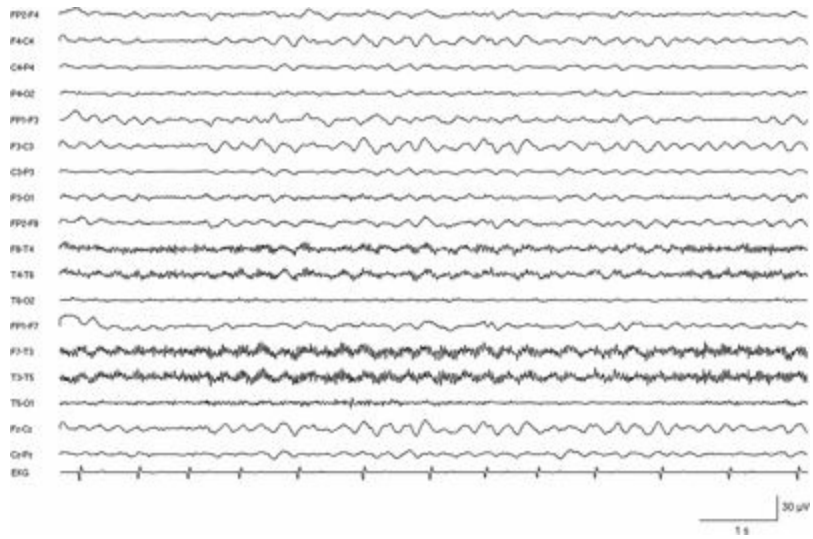

Figure 19.3. EEG recording in a severely retarded 14-year-old girl with SMEI showing persistent rhythmic slowing of background activity.

Treatment and Prognosis

Maybe the most important therapy option is to avoid provocative AED. In most cases of Dravet syndrome, SCN1A, the major sodium channel of inhibitory interneurons is reduced in activity or function to as low as 50% of normal. Application of sodium channel blockers (e.g., carbamazepine, oxcarbazepine, phenytoin, lamotrigine) may further aggravate this defect, resulting in seizure provocation up to status epilepticus. Head-to-head studies are impossible to conduct; however, retrospective analyses and clinical observation show that several agents are effective. Frequently, in the first 2 years of life, valproic acid is commenced. The next step would be to add either clobazam or topiramate, or successively both (35). If generalized tonic–clonic (especially fever- or infection-triggered) seizures and status still prevail, bromides (potassium bromide) may be of great help (22). From our point of view, bromides are possibly the most powerful drugs available for children with Dravet syndrome. Its potency in this syndrome should not be underestimated, but however, bromides predominantly control only GTCS. Children already treated with valproate and clobazam had a 70%

seizure reduction under added stiripentol. The reduction of clonic and tonic–clonic seizures was most marked (36). Other drugs used with partial success are zonisamide, phenobarbital, and chloral hydrate. In addition, the ketogenic diet was reported to be successful (37,38). In children with a severe course, implantation of a permanent IV line (e.g., Port-a-Cath) is helpful to prevent or shorten repeated status epilepticus by rapidly administering phenobarbital and benzodiazepines.

Prognosis is dismal in basically all patients who bear the diagnosis of Dravet syndrome by right. Developmental delay usually becomes evident during the second or third year of life. Complete seizure freedom is not a realistic option. However, in some cases, reasonable results may be obtained by antiepileptic (combination) therapy. There are cases in the borderland (SMEB) who come closer to the clinical spectrum of GEFS+ and who may respond better to therapy.

Genetics and Molecular Diagnostics

Family history was formerly reported to be frequently positive for febrile convulsions and idiopathic epilepsy syndromes. However, a recent study could not reproduce these findings (39). By far, the most cases of Dravet syndrome are caused by defects in the SCN1A gene. In cases diagnosed by applying strict inclusion criteria (SMEI), heterozygous SCN1A mutations may be detected in up to 80% of cases (40). Other genes like SCN1B, SCN2A, and GABRG2 were detected in single patients or families with Dravet syndrome, but quantitatively do not play a significant role. About 95% of SCN1A mutations detected in Dravet syndrome patients appear de novo. The remaining 5% that are inherited are usually connected with milder epilepsy phenotypes resembling the GEFS+ spectrum. This is consistent with a mostly negative family history. SCN1A mutations are distributed over the entire gene. Truncating mutations are found in about 50% of SMEI patients. The remaining are mostly missense mutations loosely clustering at the ion pore positions of the channel protein. Splice site mutations and heterozygous deletions ranging from single exons to the entire gene are rare. Borderland patients (SMEB) also frequently show SCN1A mutations, but to a lesser degree (60% to 70%).

The spectrum of epilepsies associated with the SCN1A gene, however, is broader than Dravet syndrome (SMEI and SMEB) and GEFS+. It also covers some less well-defined infantile epileptic encephalopathies. All of them start within the first year of life and are therapy resistant. These are denoted “cryptogenic generalized epilepsy,” “cryptogenic focal epilepsy,” and “severe infantile multifocal epilepsy” (40).

Selection criteria to maximize chances of a SCN1A mutation detection are given in Table 19.2 (31). If four or more criteria are fulfilled, detection chances are about 70% or higher, using a combination of DNA sequencing and exon quantification assay (e.g., MLPA (multiplex ligation dependent probe amplification)).

Table 19.2 Common Features Recognized in Children with SCN1A Mutations that may be Used as a Guidance in Order to Estimate Chances of Detection in Mutational Analysis

1. Normal development prior to start of epilepsy (~99% of reported cases)
2. Onset of febrile or afebrile GTCS within the first year of life (~96% of reported cases)
3. Unilateral motor seizures (~73% of reported cases)
4. Myoclonic seizures (~75% of reported cases)
5. Temperature sensitivity (~74% of reported cases)
6. Therapy resistance, continuous seizures to adulthood (~89% of reported cases)
7. Development of mostly mild to moderate ataxia (~70% of reported cases)
8. Mental decline (~92% of reported cases)

From Ebach K, Joos H, Doose H, et al. SCN1A mutation analysis in myoclonic astatic epilepsy and severe idiopathic generalized epilepsy of infancy with generalized tonic–clonic seizures. *Neuropediatrics.* 2005;36(3):210–213.

In girls with Dravet (like) syndrome, PCDH19 defects are an important differential diagnosis and may be detected in about 15% of SCN1A-negative females. Juberg and Hellman (41) reported in 1971 on a syndrome named "epilepsy and mental retardation limited to females." The publication was not really reflected for many years, because it reported a by then mostly unknown exceptional mode of inheritance, namely "X-linked dominant with male sparing." Later the syndrome was rediscovered and defined in more detail by Dibbens et al. (42). Salient features are (41–43):

1. Only females affected
2. Epilepsy as a frequent phenotype (90%)
3. Seizure onset mostly in the second year of life (6 to 36 months)
4. GTCS, clonic seizures, myoclonic seizures, absences, unilateral seizures, focal seizures, febrile seizures
5. Seizures may remit spontaneously (mean 12 years)
6. Low intelligence in about 70% of cases
7. Developmental regression in about 50% of cases
8. Behavioral comorbidities are frequent (obsessive–compulsive, attention deficits, etc.)
9. Several reports of sudden unexpected death in epilepsy
10. No specific EEG pattern

PROGRESSIVE MYOCLONUS EPILEPSIES

Unverricht–Lundborg disease, Lafora disease, myoclonic epilepsy with ragged red fibers (MERRF), NCL, sialidosis, and dentato-rubro-pallido-luysian atrophy (DRPLA) are the archetypes of this disease group. Other disorders with variable phenotypes may—in some of the affected—take the course of a PME (see Table 19.1). PME are rare and comprise <1% of epilepsies. In their early course, some of them may be difficult to differentiate from idiopathic generalized epilepsies. Precise personal and family history and a thorough clinical and neurologic examination are pertinent to obtain diagnostic clues at an early stage (44). Extremely enlarged somatosensory evoked (Fig. 19.4) or

visually evoked potentials induced by flashlight, an enhanced long-latency reflex in response to electric stimuli referred to as C-reflex, and an abnormal reaction to paired pulse transcranial magnetic stimulation all reflecting increased cortical excitation or decreased cortical inhibition may be diagnostically helpful neurophysiologic findings. Examination of the eye background is also important, since this may reveal optic atrophy, a cherry red spot or retinitis pigmentosa.

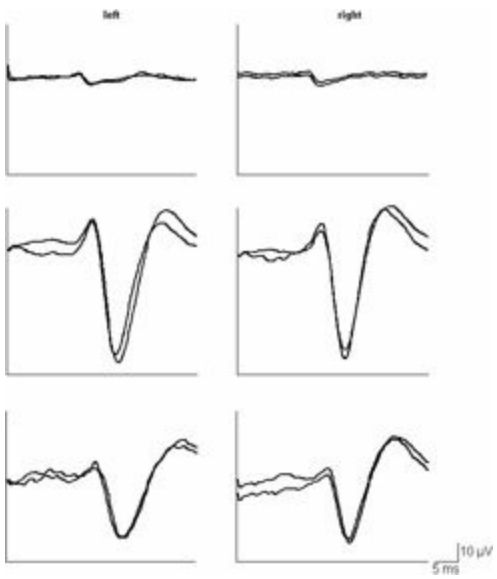

Figure 19.4. Somatosensory evoked potentials (SEPs) in a 13-year-old boy with progressive myoclonus epilepsy (PME) and in a healthy male of same age **(top)**. Giant SEPs are recorded in the patient with PME reflecting extreme cortical hyperexitability to sensory stimuli **(middle)**. Notice the substantial reduction of the SEP amplitude during treatment with levetiracetam **(bottom)**.

UNVERRICHT–LUNDBORG DISEASE

This disease clusters in Finland and in Mediterranean countries, where the prevalence reaches up to 1/20,000. The age of onset ranges from 6 to 18 years. The disorder is characterized by stimulus-sensitive myoclonus, elicited by passive joint movement, startle, and light. Myoclonus becomes more and more severe, until finally patients are wheelchair dependent. Ataxia, intention tremor, and dysarthria develop. Generalized tonic–clonic convulsions are the presenting sign in 50% of cases. Absences are also observed. Epilepsy is usually easy to control. Mental decline occurs late and is frequently mild. In the beginning, the EEG is indiscernible from idiopathic generalized epilepsy. Over time, background activity deteriorates, and frequent spikes and polyspikes are seen. Photosensitivity is a constant feature (Fig. 19.5). Reduced cortical inhibition results in giant somatosensory potentials. The disease stabilizes over time and the affected survive to old age (45).

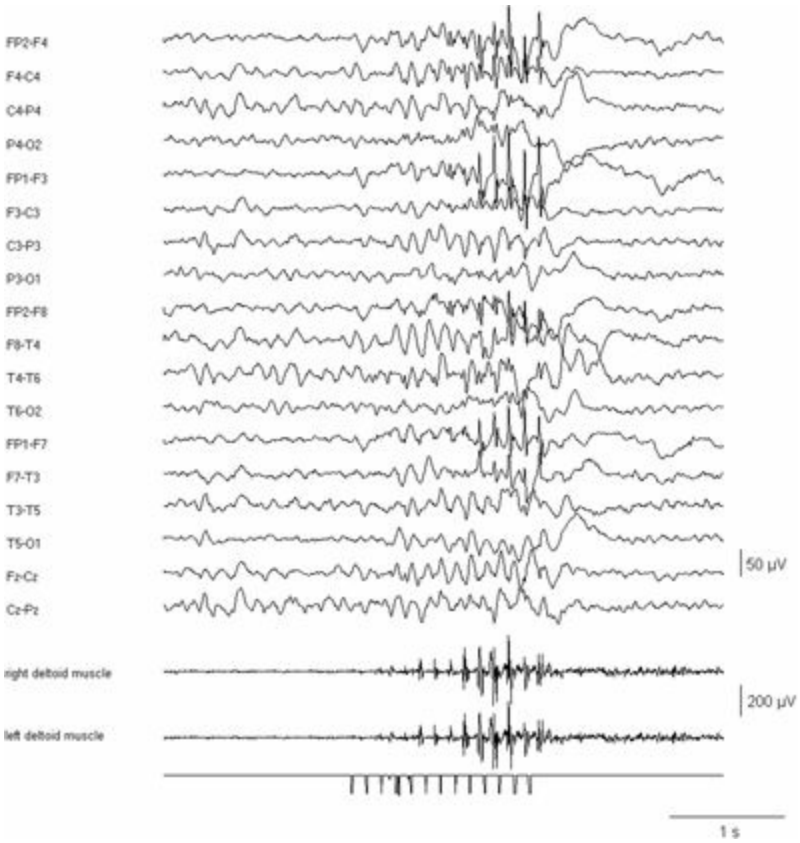

Figure 19.5. Marked photosensitivity at low stimulation rate associated with myoclonic jerks in a 15-year-old girl with Unverricht–Lundborg disease.

Recessive mutations in cystatin B (CSTB, EPM1), a protease inhibitor, are causative for the disease. The disease mechanism is still to be elucidated, but recent research suggests that CSTB is important to defend cerebellar neurons from oxidative stress (46). The most common mutation is an expanded dodecamer repeat in the untranslated 5′ promotor region. Point mutations within the gene are much rarer (44,45).

Valproate and add on clobazam are effective to control seizures and ameliorate myoclonus. Myoclonus responds to piracetam and possibly to levetiracetam. Other agents and vagus nerve stimulation have been used with success in some patients. Phenytoin is strictly to be avoided, for it aggravates the disease (45).

Lafora Disease

Lafora body disease is an autosomal recessively inherited generalized polyglucosan storage disorder that takes a rapidly progressive course. It is characterized by epilepsy, stimulus-sensitive myoclonus, blindness, and mental deterioration. Mutations in the EPM2A gene (laforin) cause about 60% of cases, and mutations in EPM2B gene (malin) are found in about 35% of patients. Polyglucosan inclusion bodies may be detected in (e.g., axillary) sweat glands by biopsy. How polyglucosan inclusion bodies accumulate is still not entirely understood. The disorder is most prevalent in the Mediterranean countries (46).

The disease starts with seizures in normally developed children between 6 and 19 years. Febrile seizures may precede, and initially it may be difficult to differentiate the presentation from juvenile myoclonic epilepsy. Visual seizures, absences, generalized tonic–clonic seizures, and astatic seizures are characteristic. Myoclonus is usually mild at the beginning but becomes disabling over time.

Patients usually die within one decade after onset of the symptoms, frequently in status epilepticus. The EEG is normal at the beginning, but later background activity deteriorates with interposed generalized spikes, polyspikes, and occipital sharp slow waves (Fig. 19.6). Therapy of epilepsy and myoclonus is unspecific (44,46,47).

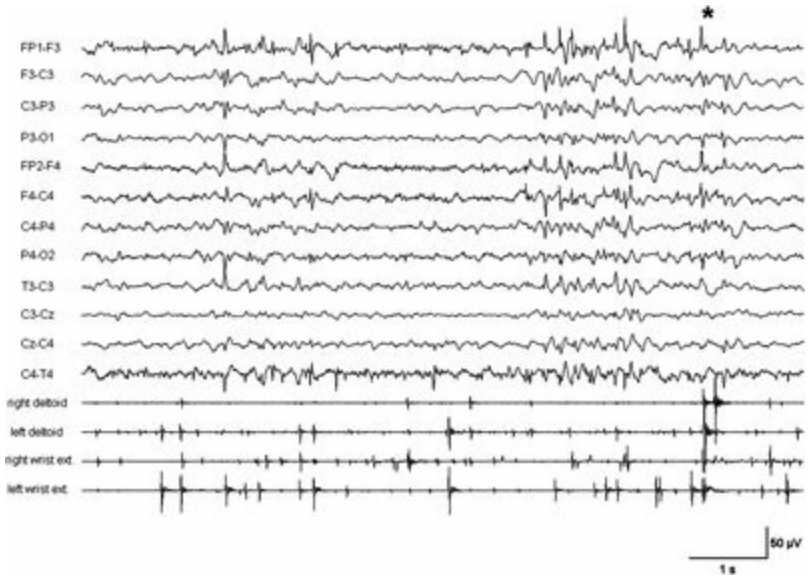

Figure 19.6. EEG–EMG recording in a 14-year-old girl affected by Lafora body disease. Numerous predominantly multifocal and asynchronous positive myoclonic jerks of short duration (50 to 100 ms) and varying intensity are recorded from different muscles. Note that only one myoclonic jerk is associated with a spike–wave discharge in the EEG (asterisk).

Myoclonic Epilepsy with Ragged Red Fibers

MERRF is one of the more common forms of PME (44,48). It may be sporadic or familial. Some cases show a clear maternal mode of inheritance while others are sporadic or autosomal inherited. In approximately 90% of cases, three point mutations of the tRNALys gene may be revealed (8344A>G, 8356T>C, and 8363G>A). In adults, ragged red fibers representing aggregates of abnormal mitochondria are detectable in 90% of cases. In children, these numbers are much smaller. Cytochrome C oxidase-negative fibers in muscle biopsy are a further characteristic finding. The syndrome is clinically variable as patients may carry different proportions of defective mitochondria in single tissues ("heteroplasmia"). Typical manifestations include generalized epilepsy, myoclonus, and ataxia. The onset may range from childhood to young adulthood with remarkable intrafamilial variation. The disease may present insidiously or set in as a metabolic crisis. Optional additional features are cognitive impairment, spasticity, myopathy, deafness, failure to thrive, lipomas, neuropathy, optic atrophy, cardiomyopathy, external ophthalmoplegia, and diabetes. MERRF may clinically overlap with MELAS (mitochondrial encephalopathy, lactic acidosis, and stroke like episodes). In full-blown cases, the EEG is grossly abnormal, but unspecific. It may show background slowing with rhythmic delta activity, bilateral synchronous spike–waves, irregular spike–waves, and occipital spikes and sharp waves. Many patients are photosensitive and also show a photomyoclonic response. In MRI, signal intensity changes may be seen in the basal ganglia (Fig. 19.7). Cortical atrophy may be present early or will ensue over time. There are no approved therapies. Valproate may result in metabolic crisis and hepatic failure, probably because it reduces the cellular uptake of carnitine. However, many patients who were erroneously treated did well with valproate for many years. L-carnitine supplementation may be indicated, but its effectiveness is unproven (44,48).

Figure 19.7. T2-weighted MRI in an 8-year-old girl with MERRF demonstrating bilateral signal hyperintensities of the caudate nuclei.

Neuronal Ceroid Lipofuscinoses

NCL constitute the most frequent neurodegenerative disorder in children. The majority of them are inherited in an autosomal recessive manner. Epileptic seizures, progressive psychomotor decline, visual failure, and early death are the characteristic clinical features. Abnormal amounts of lipopigments are stored in the lysosomes of neurons and other cells. Until now, eight genes have been identified (CLN1, CLN2, CLN3, CLN5, CLN6, CLN7, CLN8, and CLN10). Two further genes are predicted to exist but still await identification (CLN4, CLN9). Despite large efforts during the last years, the pathomechanisms underlying protein dysfunction remain still elusive (49). MRI reveals progressive cerebral and cerebellar atrophy with signal hyperintensities observed in the white matter on T2-weighted images. Muscle, skin, conjunctival, rectal, or brain biopsies show inclusions of different shapes, depending on the specific type of NCL. The most relevant form in childhood is the "late infantile variant" (NCL type 2, Jansky–Bielschowsky disease). The disease starts at 2 to 4 years. Generalized tonic–clonic convulsions, astatic seizures, and atypical absences are characteristic. Developmental regression is recognized shortly after onset of the epilepsy while spasticity and ataxia follow early on. Loss of vision occurs at 4 to 6 years, and patients die about 5 years after onset of first symptoms. EEG frequently shows massive background slowing from the beginning of the epilepsy. Slowing is pronounced over the occipital regions. Generalized irregular spike–waves are present. The characteristic EEG response to low frequency photic stimulation (1 to 3 Hz) may not be present at the beginning of the seizures. Visual evoked potentials lack cortical inhibition and have greatly increased amplitude ("giant visual potentials"). Curvilinear bodies may be detected by skin biopsy or buffy coat (Fig. 19.8). The causative enzyme is tripeptidyl peptidase 1

(TPP1). A multitude of mutations have been detected in the encoding gene. Enzyme activity can be measured even from dried blood spots (44,50).

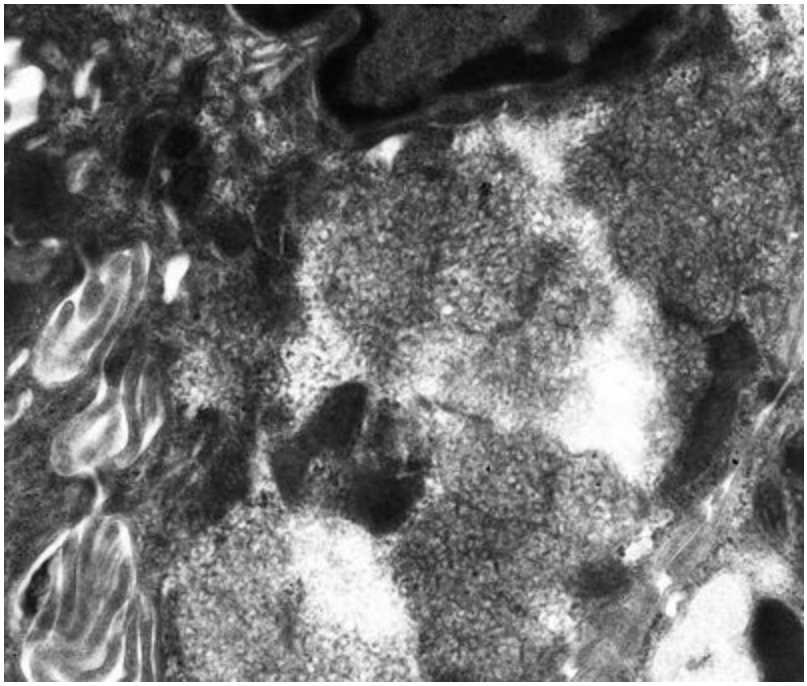

Figure 19.8. Electron microscopic image of a skin biopsy from a 3-year-old boy with NCL type 2 showing curvilinear inclusion bodies. (Courtesy of Dr. Anne Schänzer, Institute of Neuropathology, Giessen, Germany.)

There are several other rare variants of the late infantile type, which are mostly restricted to certain ethnic groups. Among those are the "late infantile finish variant" (NCL type 5), the "late infantile variant" (NCL type 6), and the "Turkish variant late infantile form" (NCL type 7) (44,50).

Juvenile NCL (NCL type 3, Batten disease, Spielmeyer–Vogt–Sjögren disease), the most common variant, presents with loss of vision before the onset of epilepsy. Generalized tonic–clonic convulsions are frequent. Myoclonus remains subtle. Disease onset is at 4 to 7 years of age. Behavioral problems and psychotic symptoms are prevalent. Later, dementia and extrapyramidal signs will develop. The course is relentless. Death occurs within 5 to 10 years after onset. The causative gene is identified, but its function remains unknown. Multiple gene defects are on record. The most common one is a deletion of exons 7 and 8. In skin biopsy, a "fingerprint" pattern is detectable, and lymphocytes may show vacuoles reflecting enlarged lysosomes. Some rare patients show defects in the CLN1 gene (44).

The adult type (NCL type 4 or Kuf disease) is a rare autosomal dominant disorder that may begin in adolescence or adulthood. Dementia, ataxia, and later myoclonus and seizures will develop. Vision remains intact. Most patients die within 10 years. EEG shows background slowing and generalized spike–wave discharges. Photosensitivity at low frequencies (1 to 3 Hz) may be present. Visual evoked potentials remain normal while somatosensory potentials are enlarged. There is no known gene (50).

Sialidoses

Sialidosis type 1 (cherry red spot myoclonus syndrome) is an autosomal recessive disorder caused by a deficiency of neuraminidase A (51). Sialylated oligosaccharides are detectable in urine. Multiple gene defects of the gene Neu1 are on record. Truncating mutations are most common. Action and

intention tremor and generalized tonic–clonic convulsions start in adolescence or early adulthood. Visual impairment is mild or even absent, and cognitive decline occurs during course. Spasticity, ataxia, and a painful sensory peripheral neuropathy may be observed. There is no hepatomegaly or skeletal dysplasia. Vacuolated Kupffer cells are hallmarks in histology. EEG shows few epileptic discharges and a low-amplitude fast background activity. Myoclonic attacks are paralleled by central 10 to 20 Hz activity. Somatosensory potentials are enlarged, and visual evoked potentials are reduced in amplitude (44,51).

Sialidosis type II is also caused by neuraminidase deficiency but runs a more severe course than type I. Affected patients show dysostosis multiplex, hepatosplenomegaly, mental deterioration, corneal clouding, and a Hurler-like phenotype. Onset ranges from the neonatal period to adolescence. EEG features are similar to sialidosis type 1 (44,51).

Dentato-Rubro-Pallido-Luysian Atrophy

DRPLA is a rare autosomal dominant repeat extension disorder with the highest prevalence in Japan. The disease is variable with three different main phenotypes recognized. General symptoms include epilepsy, extrapyramidal symptomatology, myoclonus, and dementia (52). One form presents as a PME, one as a pseudo-Huntington disease, and one as the ataxo-choreoathetoid form. The PME form has its onset before 20 years of age. Seizures, myoclonus, and mental deterioration are characteristic. EEG shows a normal background activity, spike–waves, and frequently photosensitivity (44,52).

Other Rare Types of Progressive Myoclonus Epilepsies

Gaucher disease is caused by a deficiency of the lysosomal enzyme glucocerebrosidase, which cleaves glucose from cerebroside. The subacute neuronopathic form of the disease (type III) may manifest as a typical PME. Hepatomegaly, splenomegaly, thrombopenia, anemia, and osseus symptoms such as osteopenia, pain, and deformations are systemic signs of the disease. Myoclonus, myoclonic seizures, and GCTS may occur in adolescents and young adults. Typically, the EEG shows generalized spike–waves and marked photosensitivity. Beneath a mild mental decline, supranuclear horizontal ophthalmoplegia, ataxia, dystonia, and spasticity are additional, but inconstant neurologic symptoms. Enzyme replacement therapy is available for Gaucher disease and has been shown to prevent or reverse systemic signs, but its value in improving the neurologic manifestations of the disease has not yet been demonstrated (53).

Huntington disease may manifest as early as during the first decade of life. Such children may suffer from severe dystonia and rapidly progressive myoclonus epilepsy. Since the disorder is caused by an autosomal dominant trinucleotide “CAG” (Cytosine, Adenine, and Guanine) repeat expansion in the so-called Huntingtin gene, careful anamnesis should identify at least one other near relative with Huntington disease (44).

The clinical and electroencephalographic findings in patients with Galactosialidosis are similar to those observed in subjects affected by sialidosis type II. But in divergence from sialidosis type I and II, there is a combined deficiency of sialidase and β-galactosidase due to a primary defect in protective protein/cathepsin A. Three subtypes are recognized: the early infantile type, the late infantile type, and the juvenile/adult type (54).

The list of neurometabolic disorders that, in single cases, may present as a PME is even longer, and some authors also mention neuroaxonal dystrophy, pantothenate kinase associated

neurodegeneration (neurodegeneration with brain iron accumulation, Hallervorden-Spatz disease), and GM2 gangliosidosis. In virtually all cases, other clinical symptoms, besides myoclonic seizures, will aid diagnostic efforts.

PROGRESSIVE ENCEPHALOPATHIES WITH MYOCLONIC SEIZURES

Vitamin B_6 (pyridoxine) is present in various dietary products. The phosphorylated active form pyridoxal phosphate is required as a cofactor to glutamic acid decarboxylase that catalyzes the conversion of glutamate to the inhibitory neurotransmitter GABA (γ-amino-butyric acid). Pyridoxine-dependent epilepsy is a rare autosomal recessive disorder (55). Typically, first seizures occur within hours after birth and are not sufficiently controlled by conventional antiepileptic medication. Impressively, seizures resolve within minutes and the EEG normalizes within hours after intravenous administration of 50 to 100 mg pyridoxine. Affected infants show hyperexitability with marked agitation, irritability, hypervigilance, and startle responses to touch and sounds. Usually, various seizure types are observed including myoclonic, partial clonic, and generalized clonic seizures. Lifelong pyridoxine medication is necessary, but even in early treated subjects, mental retardation seems not to be uncommon. Besides this classic type, an increasing number of patients with otherwise therapy- resistant myoclonic, focal clonic, partial motor, generalized tonic–clonic, and complex partial seizures, beginning beyond the neonatal period is been reported. ALHD7A1 encoding for antiquitin, which is the α-aminoadipic acid semialdehyde dehydrogenase in the pipecolic acid pathway of lysine catabolism, has been identified as the causative gene. Deficiency of the encoded enzyme results in accumulation of Δ^1-piperidine-6-carboxylate that reacts with pyridoxal phosphate, thereby causing inactivation of the latter (56).

Some patients presenting with intractable epilepsy during the neonatal period did not respond to administration of vitamin B_6, but their seizures ceased when they were treated with pyridoxal phosphate (pyridoxal phosphate–dependent epilepsy). Because of CSF abnormalities indicating a reduction of intracellular pyridoxal phosphate in patients in whom pyridoxal phosphate stopped the seizures where pyridoxine had failed, Mills et al. (57) sequenced the pyridox(am)ine 5′-phosphate oxidase (PNPO) gene and found homozygous missense, splice site, and stop codon mutations in five affected infants. Except for one, all patients died within the neonatal period. Whether mutations of the PNPO gene also contribute to less severe forms of pyridoxal phosphate–dependent seizures remains to be elucidated.

Several patients with otherwise intractable neonatal seizures responding to treatment with folinic acid had also been described. Most patients presented with myoclonic or clonic seizures, apneas, and irritability within the first 5 days of life. An autosomal recessively inherited abnormality of folate metabolism has been postulated, but no specific defect could be identified. Recent research revealed that folinic acid–responsive seizures are identical to pyridoxine-dependent epilepsy (58). However, it has been recommended to treat all patients affected by α-aminoadipic semialdehyde dehydrogenase deficiency with pyridoxine, folinic acid, and a low lysine diet (58).

Biotin is a water-soluble vitamin that is an indispensable coenzyme for four important carboxylases. There are two autosomal recessive defects of biotin metabolism, holocarboxylase synthetase deficiency and biotinidase deficiency, which result in multiple carboxylase deficiency and which can be effectively treated with pharmacologic doses of biotin (59). While the very rare

holocarboxylase synthetase deficiency manifests during the neonatal period, the first signs of biotinidase deficiency emerge by 3 to 6 months or even later. Frequently, therapy-resistant myoclonic or tonic seizures are the initial symptoms. Erythematous or seborrheic skin lesions beginning around the mouth, conjunctivitis, and alopecia are important diagnostics that are present in about 70% of cases. Without biotin treatment, irreversible neurologic damage including psychomotor retardation, ataxia, optic atrophy, and deafness can occur (59).

In addition, myoclonic seizures may represent a prominent symptom in a variety of other metabolic encephalopathies presenting during infancy or early childhood (see Table 19.1).

RECENTLY RECOGNIZED TYPES OF PROGRESSIVE MYOCLONUS EPILEPSIES AND PROGRESSIVE MYOCLONIC ENCEPHALOPATHIES

Leukoencephalopathy with vanishing white matter is caused by mutations in genes encoding for the subunits of the eukaryotic subscription factor 2B (eIF2B). Although epileptic seizures are frequent in affected infants and children, the disease is usually not linked to PME. But recently, Jansen et al. (60) reported on a young adult showing symptoms that justified the diagnosis of PME and who was found to have a homozygous mutation in EIF2B5 after other causes underlying PME had been ruled out.

Action myoclonus-renal failure syndrome is a rare autosomal recessive disorder first reported in the French-Canadian population. Recently, it has been shown that the disease is caused by mutations in the SCARB2/LIMP2 gene encoding for the lysosomal membrane protein SCARB2. Severe focal glomerulosclerosis and PME associated with accumulation of storage material in the brain are the clinicopathologic hallmarks of the disease. An increasingly disabling action myoclonus and cerebellar features emerge during the second or third decade of life. Proteinuria progressing to renal failure may occur before or after the onset of neurologic symptoms (61). Polyneuropathy and dilated cardiomyopathy represent further potential features of the disease (62).

Familial encephalopathy with neuroserpin inclusion bodies is a very rare disease that has been identified as a cause of PME (63). The disorder may manifest as early as during the second or third decade and may take a rapidly progressive course. It is transmitted in an autosomal dominant mode and caused by heterozygous point mutations in the SERPIN1 gene. Neuroserpin belongs to the superfamily of SERPIN (serine proteinase inhibitor), but its exact function in the CNS is still not clear. Mutated neuroserpin accumulates in neuronal inclusions (Collins bodies) throughout the gray matter of the cerebral cortex and in certain subcortical nuclei (63,64) but is not detected in muscle, skin, and rectal biopsies (64).

GLUT-1 deficiency that was first described by de Vivo in 1991 is caused by a defect in the facilitative glucose transporter GLUT1. Impaired glucose transport across brain tissue barriers is reflected by hypoglycorrhachia and results in an epileptic encephalopathy with developmental delay and motor disorders. Usually, patients present with seizures during infancy. Among other seizure types, myoclonic seizures, myoclonias, and prolonged absence seizures with myoclonias can be observed. In some subjects, seizure frequency is increased, and the EEG is more abnormal during fasting than shortly after a meal. In most patients, motor and mental development is substantially delayed, and microcephaly evolves in a substantial number. Typically, CSF glucose levels are <0.33

g/L, and glucose CSF/blood ratios are lower than 0.35. But the diagnosis may be missed if lumbar puncture is not performed after a sufficient period of fasting. EEG findings are variable and compromise multifocal or generalized paroxysmal abnormalities and slowing of background activity. Epileptic seizures do not respond well to anticonvulsants but usually cease when commencing a ketogenic diet. The phenotype of GLUT-I deficiency has been expanded during the last years, and now encompasses older children with exertion-induced dystonia, and patients with seizures and EEG findings, resembling those seen in myoclonic–astatic epilepsy or other types of idiopathic generalized epilepsies with early onset (65).

X-linked cyclin-dependent kinase-like 5 encephalopathy is caused by mutations in the CDKL5 gene. The phenotype is reminiscent of the Hanefeld variant of Rett syndrome. As in girls with Rett syndrome, patients are severely mentally retarded, have autistic features, no purposeful hand use, and demonstrate the characteristic stereotypic hand movements. While classic Rett syndrome is caused by mutations in the gene encoding for methyl CpG binding protein 2 (MECP2), the product of the CDKL5 gene has been shown to be involved in the activation of MECP2. Typically, frequent brief tonic and tonic–clonic seizures start within the first 3 months of life. From 6 months to 3 years, infantile spasms intermixed with short tonic seizures are the dominating seizure types, while profound psychomotor retardation and severe muscular hypotonia become evident. In some subjects, seizures may respond to anticonvulsant therapy, whereas in others, the occurrence of myoclonias and myoclonic seizures heralds the terminal stage of epilepsy (66).

Mutations of the human Aristaless-related homeobox (ARX) gene are associated with a variety of pathologic conditions including X-linked syndromic and nonsyndromic mental retardation, dystonia, and X-linked lissencephaly with abnormal genitalia. Polyamine tract expansions of the ARX gene are the commonly observed genetic defect in subjects with X-linked infantile spasms, whereas longer expansions have been detected in two males with early infantile epileptic encephalopathy with suppression-burst pattern (Ohtahara syndrome) (67). In addition, Scheffer et al. described a family with six affected boys over two generations who had a missense mutation in the ARX gene. Since all boys had myoclonic seizures as the dominating seizure type, spasticity, and profound mental retardation, the authors termed the disorder X-linked myoclonic epilepsy with spasticity and intellectual disability (68).

Several unrelated, genetically determined disorders with reduced 5-methyltetrahydrofolate (5-MTHF) levels in the CSF have been delineated during the last years. If 5-MTHF depletion goes unnoticed or is left untreated, regression of psychomotor development, progressive ataxia, and myoclonic epilepsy in conjunction with abnormal brain myelination are characteristic features (69).

Mutations in the potassium channel–related gene KCTD7 have been described in patients with PME from different ethnicities. Usually, a difficult to treat myoclonic epilepsy starts within the second year of life. In the beginning, seizures and EEG findings resemble closely those observed in MAE. But progressive loss of mental and motor skills becomes apparent within 2 years after onset of first symptoms. Lack of storage material in skin biopsy and normal eye background helps to distinguish this peculiar type of PME from NCL forms manifesting in late infancy or early childhood (70).

Childhood spinal muscular atrophy associated with PME (SMA-PME) has been recognized as a specific entity. Recently, exome sequencing in three unrelated families revealed homozygous missense mutations in the ASAH1 gene, encoding the enzyme acid ceramidase. While enzyme activities <10% seem to result in classical Farber disease, an infantile, rapidly progressive lysosomal storage disorder characterized by subcutaneous lipogranulomata, joint pain, and

hoarseness of the voice, higher residual activity appears to result in SMA-PME (71).

In patients with PME out of three families originating from the Middle East, a homozygous mutation in the PRICKLE1 gene has been identified, encoding a protein in the noncanonical WNT signaling pathway. Patients affected by this type of Progressive myoclonus Epilepsy-Ataxia syndrome usually present with symptoms similar to those seen in Unverricht–Lundborg disease. In most cases, ataxia is the initial symptom, while seizures start between 5 and 10 years of age. Cognitive decline is mild or even absent, whereas myoclonus affecting limb, bulbar, and occasionally facial muscles worsens. Impaired upward gaze represents a peculiar neurologic feature (72).

A single homozygous mutation in the Golgi SNAP receptor complex 2 gene (GOSR2) has been reported in 12 patients with a peculiar type of PME. Since all patients stem from countries bounding the North Sea, the term "North Sea" progressive myoclonus epilepsy has been coined. Affected individuals develop ataxia by an average age of 2 years, followed by onset of various seizure types 3 to 5 years later. Scoliosis emerging during adolescence and moderately elevated CK values are characteristic features of the disorder. The EEG showed generalized spike–waves with occipital predominance and photosensitivity in all cases. The course of disease is progressive, and all affected individuals became wheelchair bound at a mean age of 13 years (73).

PME in conjunction with a homozygous COL6A2 mutation has been recently reported in a consanguineous Iranian family. While COL6A2 was shown to be expressed in the cerebral cortex, its pathogenic role in epilepsy pathogenesis is elusive (74).

MANAGEMENT OF PROGRESSIVE MYOCLONIC EPILEPSIES

Therapy is mainly symptomatic. Seizures and myoclonus may be treated with valproic acid, benzodiazepines, levetiracetam, zonisamide, and phenobarbital. Myoclonus may respond well to a high dose of piracetam. Phenytoin, carbamazepine, oxcarbazepine, gabapentin, tiagabine, and vigabatrin may aggravate myoclonus. In Unverricht–Lundborg disease, phenytoin is strictly contraindicated. Acetylcysteine has been shown to be effective in a mouse model of Unverricht–Lundborg disease. Lamotrigine may aggravate or attenuate myoclonus. Therefore, it should be tested with caution. In mitochondrial disorders (MERRF, MELAS), valproic acid should be avoided. Vagus nerve stimulation may offer help when other therapeutic options are lacking (10,44).

CHAPTER 20 ENCEPHALOPATHIC GENERALIZED EPILEPSY AND LENNOX–GASTAUT SYNDROME

S. PARRISH WINESETT AND WILLIAM O. TATUM IV

Encephalopathic generalized epilepsy (EGE) constitutes a heterogeneous group of conditions associated with cognitive dysfunction, multiple seizure types, and epileptiform abnormalities on the EEG. Patients with EGE often require more thorough reassessment in the clinical practice of epileptology due to frequent, refractory seizures requiring care as well as due to related comorbidities. The Lennox–Gastaut syndrome (LGS) is the prototypic EGE. Patients with LGS have a unique electroclinical profile characterized by frequent uncontrolled seizures, mental retardation (MR), and the presence of slow spike-and-wave (SSW) on the interictal electroencephalogram (EEG). The EEG was initially used to help classify the epileptic encephalopathies in 1945, when William Lennox noted that unlike those patients with the 3-Hz generalized spike-and-waves (GSW), the "petit mal variant" with SSW often occurred in brain-injured patients with no clinical accompaniment during the discharge and a poor prognosis. Under the direction of Henri Gastaut, Charlotte Dravet detailed the clinical profile that included cognitive impairment and multiple seizure types, and emphasized the interictal features of SSW on the EEG while awake and generalized paroxysmal fast activity (GPFA) during sleep (1). Subsequently, Doose et al. (2) noted a lack of homogeneity in patients with SSW including a group of patients with a clinical picture dominated by myoclonic and atonic seizures with a variable and sometimes more favorable prognosis, which was attributed to a subset of patients with myoclonic astatic epilepsy (MAE). In 1982, Jean Aicardi described atypical benign partial epilepsy of childhood with continuous SSW in sleep. This condition was termed the "pseudo-Lennox–Gastaut" syndrome due to the electroclinical features that included multiple seizure types and frequent association with falls (3). Other EGEs include early-onset infantile epileptic encephalopathies (Ohtahara syndrome and early myoclonic encephalopathy [EME]) and epileptic spasms (please see Chapter 16). In particular, Ohtahara syndrome, West syndrome (WS), and LGS may manifest from similar etiologic causes as an age-related expression of EGE.

EGE may manifest as drug-resistant epilepsy with multiple seizure types, arrested psychomotor development, and behavioral disorders but occur without SSW. Patients with epilepsy and multiple independent spike foci (MISF) may be clinically similar to LGS but manifest a nonprogressive course without SSW on the EEG (4). Other patients with encephalopathy and epilepsy may have SSW on EEG due to secondary bilateral synchrony (SBS) and a predominance of focal seizures with rapid secondarily generalized motor seizures that mimic the electroclinical presentation associated with EGE to suggest LGS (5). This chapter explores the spectrum of clinical features that are critical for diagnosis and treatment in patients with EGE and LGS.

LENNOX–GASTAUT SYNDROME

The LGS is the prototypic EGE and represents a common devastating epilepsy syndrome that typically begins within the second and sixth year of life. LGS accounts for approximately 1% to 4% of all childhood epilepsies (1,6). It is an epilepsy syndrome that is characteristically refractory to antiseizure drugs (ASDs). Some authors have used the term LGS to identify any severe epilepsy syndrome of childhood with MR that includes different types of seizures with drop attacks or injury and refractory to ASD treatment (1). Additionally, LGS has been applied to any severe childhood epilepsy that is associated with SSW on the EEG (7). In this chapter, we exclude the latter two broader interpretations and only describe patients presenting with the typical clinical triad of LGS:

1. Multiple mixed seizure types including tonic, atonic, and atypical absence with a high seizure frequency, often with a history of status epilepticus (SE).
2. Impaired intellectual function or behavior disturbance.
3. Interictal EEG demonstrating an abnormal diffusely slow background with SSW while awake. There may also be frequent MISF and bursts of GPFA during sleep.

When all the components are present, the diagnosis is clear. Unfortunately, all of the features of LGS may not be present at the time of presentation.

DEMOGRAPHICS

Population-based studies demonstrate that EGE is not uncommon, representing approximately 11.6% of all childhood epilepsies in one study (8). In one group of patients with EGE, LGS was the final diagnosis in 20%, while 16% had WS, 11% had myoclonic astatic (Doose) syndrome, and 3% had Dravet syndrome (8). However, more than 40% could not be classified into a recognizable syndrome (8). In a southeastern metropolitan city of the United States, the incidence of LGS at age 10 years was 0.26 per 1000 children or approximating 4% of all childhood epilepsy (6).

PATHOPHYSIOLOGY

There are a variety of pathophysiologies that underlie both EGE and the LGS. EGE and the LGS are usually subdivided into structural–metabolic (symptomatic) and unknown (cryptogenic) forms. The majority of patients with LGS have a demonstrable etiology identified. A symptomatic cause for LGS accounts for approximately 70% of the cases (9,10). Most causes are present within the first year of life though the electroclinical syndrome may be identified later. The reason for the commonality of this constellation of multiple seizure types, MR, and SSW on EEG is unclear. The various etiologies include hypoxic–ischemic encephalopathy, stroke and intracerebral hemorrhage, perinatal meningoencephalitis, traumatic brain injury, brain tumors, vascular malformations, and malformations of cortical development (9). In LGS due to unknown cause, patients may have normal development prior to the onset. In a cohort of patients with LGS and an unknown (cryptogenic) etiology living in Atlanta, Georgia, this subgroup represented 44% of LGS patients (6). Conversely, 39% of the children with LGS had preceding ES (11). There is a low incidence of inheritance in LGS due to structural–metabolic causes with a family history present in <10% of patients (1,10,12).

CLINICAL COURSE

The clinical presentation varies depending on whether the etiology has a symptomatic basis or an unknown etiology (7). In symptomatic cases, the syndrome is most readily diagnosed after the patient has evolved from another type of epilepsy such as WS. Most known causes are present in the first year of life (1). The initial presentation in very young children with unknown etiology usually consists of atonic seizures manifesting as head drops (7). Cognitive deterioration may precede the onset of recurrent seizures (13). In older children, drop attacks (tonic and atonic seizures) and behavioral disturbances are more common (7). Infrequently, the onset of the clinical triad of LGS may develop during adolescence (12).

The natural history of LGS usually involves progressive intellectual deterioration as well as frequent seizures and episodes of SE. There can be periods of remission, but they are brief. Seizures persist despite ASDs in the majority, with <10% experiencing remission (6,8).

Individual Seizure Types

The seizure types that define LGS are tonic seizures, atonic, and atypical absences, and different seizure types typically coexist. Myoclonic, clonic, focal, and generalized tonic–clonic (GTC) seizures may also occur as the initial seizure type, particularly in symptomatic LGS.

Tonic seizures are the most common and characteristic seizure type that is seen in LGS, differentiating it from other epileptic encephalopathies. Polygraphic recording with video demonstrates tonic seizures in over 75% of patients (12). Tonic seizures manifest as a paroxysmal increase in muscle tone that may result in a drop attack or may be quite subtle and often goes undetected without video-EEG (1,10,12). The ictal EEG of tonic seizures classically reflects the abrupt onset of low-voltage 15- to 25-Hz ictal generalized fast activity, voltage attenuation, or rhythmic high-amplitude 10- to 15-Hz activity seizure onset (1). Atonic seizures clinically present with a sudden loss of postural tone that occurs without warning, and like tonic seizures, may result in falling. They can be subtle and may only manifest with a simple head nod or involve the axial musculature resulting in a fall. Atonic seizures are a common seizure type that occurs in patients with LGS; however, the majority of epileptic falls in LGS result from tonic seizures (1). The ictal EEG correlate for atonic seizures is most often a burst of generalized spike- or polyspike-and-wave discharges. Atypical absence seizures are seen in more than 75% of LGS patients (12). Atypical absences are characterized by a transitory fixed stare with brief loss of consciousness. Seizures are often delayed up to 1 second after the onset is noted on EEG and may last <30 seconds but are usually longer than typical absence seizures. Patients may continue purposeful activity during atypical absences, and the seizure may be difficult to recognize with the associated comorbid cognitive dysfunction. Unlike typical absences, these seizures are not precipitated by hyperventilation or intermittent photic stimulation. The EEG correlate of atypical absence seizures consists of generalized SSW with a repetition rate of 1.5 to 2.5 Hz that is similar to the interictal SSW pattern, but usually more regular and of higher amplitude (1). Myoclonic seizures are not specific for LGS or the EGE and may also occur in the other generalized epilepsies (e.g., juvenile myoclonic epilepsy). They are seen in approximately 30% of patients diagnosed with LGS (12). When patients demonstrate prominent myoclonus with additional mixed seizure types, a myoclonic variant of LGS has been described that may be associated with a better prognosis (10). Ictal EEG demonstrates bursts of polyspike-and-waves during the episodes of myoclonus (1).

Status Epilepticus

At least half of LGS patients will experience episodes of SE, and while nonconvulsive SE often occurs, any of the seizure types present in LGS may result in SE (14). There is concern that many of the cases of SE are precipitated by overtreatment with hypnotic/sedative ASDs including the barbiturates and benzodiazepines (1). Tonic status and atypical absence SE are most common. Tonic SE can be life threatening because of accompanying autonomic symptoms such as apnea and bronchial hypersecretion that may lead to respiratory compromise (10). Commonly, mixed episodes of SE may present with features of both tonic seizures and atypical absence seizures lasting as long as several days (1). Atypical absence seizures that result in nonconvulsive SE as well as tonic seizures that result in convulsive SE can occur and can be refractory to treatment (14). Atypical absence SE manifesting as impairment of consciousness can be difficult to recognize in LGS patients who are often cognitively delayed at baseline (14). Symptoms may appear as confusion, lethargy, or behavioral changes that defy recognition as a seizure. The EEG during SE may not appear to be distinctly different than the interictal EEG with bursts and runs of SSW. However, during SE, the SSW may appear more persistent and regular as compared to baseline recordings in the same patient (14).

COGNITIVE ASPECTS OF EGE

MR is a component of EGE and one criteria of the classic triad found in patients with LGS. However, MR is not seen in all patients. Up to 10% of patients remain in the normal IQ range although most still demonstrate some degree of slow mental processing (6). Symptomatic patients generally are delayed prior to the onset of LGS, and they often have marked cognitive delay. Symptomatic cases of LGS were found to have a 72% risk of severe MR, while cases without a known cause had only a 22% risk (12). When a known cause is not present in patients with LGS, most do not have developmental delay at the onset (12). It remains unclear if the underlying EGE syndrome and associated MR are progressive, independent of the effect of uncontrolled seizures (7). Further complicating are the effects that may result from ASD polytherapy that is often utilized.

Morbidity and Mortality

A high incidence of injuries is associated with drop attacks (predominantly tonic and atonic seizures). Tonic seizures are the most common cause of falls in children with LGS and a major cause of morbidity, and repeated injury is often encountered (15). Seizures that result in drop attacks often necessitate the use of a protective helmet to prevent head injury during the course of a fall. Other facial and dental injuries are also common. Beyond the frequent injuries from breakthrough seizures, behavioral and cognitive problems often lead to overtreatment with medication that can compromise balance and gait and lead to and worsening of gait, with an iatrogenically induced component of morbidity. Mortality is often associated with accidental injury and is estimated up to 10% over a 10-year follow-up period (15).

EEG

LGS is characterized by the presence of diffusely slow background and SSW on the interictal EEG during the awake state. The presence of SSW is one of the cardinal features in the diagnosis of LGS

(Fig. 20.1). There is controversy about including GPFA as one of the criteria for diagnosis (1,10). The SSW pattern of LGS consists of a spike (20 to 70 ms) or more commonly a sharp wave (70 to 200 ms) that is followed by an after-going surface electronegative slow wave of 350 to 400 ms in duration (16). The SSW discharges are not always symmetrical and may be lateralized to one hemisphere. Photic stimulation, hyperventilation, and sleep do not activate the SSW in LGS like they do in other generalized epilepsy syndromes. Occasionally, the frequency of SSW can approximate 3 Hz though usually a frequency of 1.5 to 2.5 Hz is seen. When the SSW is present only during sleep, then atypical benign partial epilepsy with continuous spike-and-wave of sleep should be considered. In addition, Landau–Kleffner syndrome (with electrical SE in sleep) and the syndrome of continuous spike-and-waves of slow sleep may also manifests SSW on EEG during sleep, though distinct electroclinical differences assist in the syndromic differentiation from LGS.

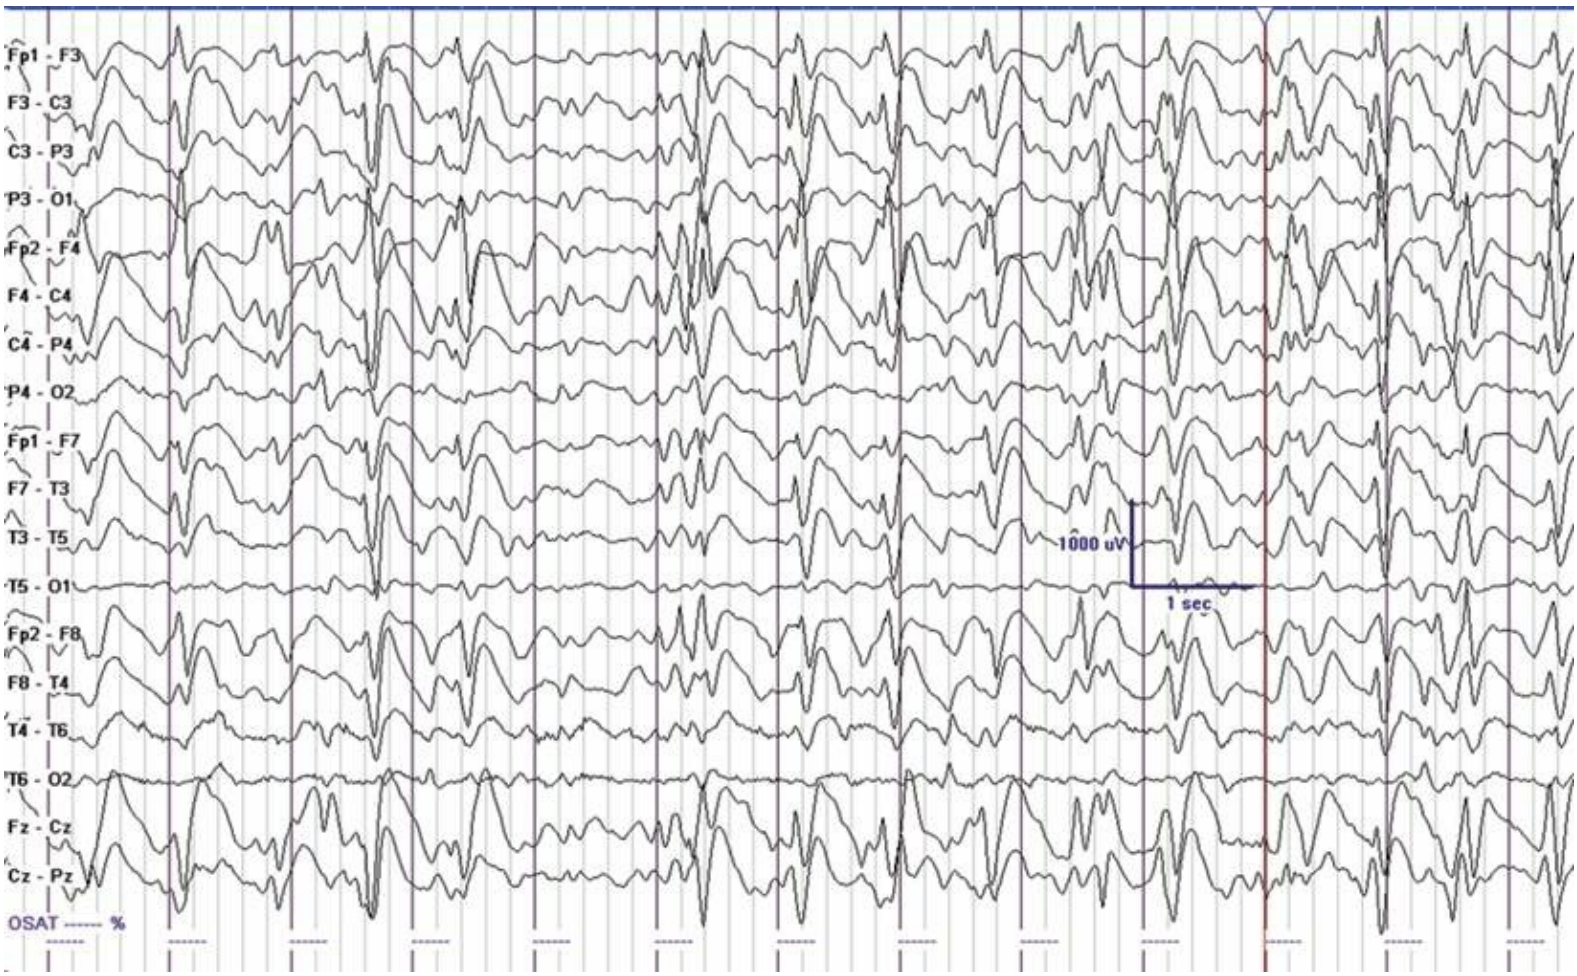

Figure 20.1. Diffuse slow spike-and-wave complexes on interictal EEG in a 7-year-old with LGS.

The finding of SSW on the EEG is an ominous finding. Drug-resistant generalized epilepsy is present in most patients with SSW (16). In one unselected group of patients with SSW on EEG, a >95% likelihood of manifesting seizures was predicted, with a >60% chance of having multiple seizure types, and a 70% chance of having difficult to control seizures (16).

It has been noted that children with interictal SSW discharges had underlying diffuse structural brain injury and subsequently a poor prognosis (16). Antecedent conditions associated with LGS almost always involve the cerebral cortex (1). Bilateral frontal lesions and diffuse dysplastic lesions of the cortex are commonly implicated. Interestingly, patients with Aicardi syndrome do not have LGS, suggesting that presence of the corpus callosum may be important (10). Lissencephaly is rarely

associated with LGS (10). GPFA and tonic seizures are important because they help differentiate LGS from other epileptic encephalopathies that may have a better prognosis. The electrographic pattern of GPFA is a 10-Hz burst of bilateral fast activity that occurs during non–rapid eye movement sleep (Fig. 20.2). These bursts are generally brief and may appear frequently during sleep and disappear during rapid eye movement sleep (10). They are identical to the discharges seen with tonic seizures but may have minimal clinical signs such as brief apnea or mild axial tonic features that are best illustrated on electromyography. GPFA is not pathognomonic for LGS since it may also occur in localization-related epilepsy with focal seizures that arise from extratemporal (often frontal lobe) origins. Patients with EGE, tonic seizures as the predominant seizure type, and GPFA on EEG had a worse prognosis than did patients presenting with predominantly atypical absence, myoclonic or atonic seizures (17).

Figure 20.2. GPFA in a 4-year-old with EGE and mixed seizures. Tonic seizures were noted in sleep with eye opening, mild axial stiffening, and apnea. (Courtesy of Joseph Casadonte, MD.)

DIFFERENTIAL DIAGNOSIS

Most of the epileptic encephalopathies evolve over the first few years after the clinical presentation. In contrast to LGS, certain epileptic encephalopathies, such as severe myoclonic epilepsy of infancy (SMEI) (aka Dravet syndrome) and epilepsy with MISF, rarely have SSW (4,18). If SSW are intermixed with 3-Hz or faster GSW, then genetic generalized epilepsy should be considered, especially in patients with normal mental status. If there are predominantly SSW during sleep, and

focal interictal electrical discharges while awake, then atypical benign partial epilepsy with continuous SSW of sleep is an important differential diagnosis. Focal abnormalities on neuroimaging, EEG, clinical semiology, and physical examination may suggest localization-related epilepsy with focal seizures and SBS on EEG when intermixed features are encountered that are not state specific. This is particularly important as resective surgery in localization-related epilepsy may be a treatment option when patient have focal seizures in the setting of bilateral EEG abnormalities or SBS. The most difficult diagnostic distinction is between MAE and LGS (Table 20.1).

Table 20.1 Summary of the Encephalopathic Generalized Epilepsy Syndromes and Clinical Features

Syndrome vs. clinical features	Lennox–Gastaut syndrome (4,10,14)	Myoclonic-astatic epilepsy (2,14,19)	Severe myoclonic epilepsy of infancy (10,18,20)	Epilepsy with MISF (4,21)	Localization-related epilepsy with secondary bilateral synchrony (22,23)	Landau–Kleffner syndrome and atypical benign partial epilepsy with CSWS (3,10)
Clinical seizure types	Atypical absence (75%), tonic–atonic seizures (75%), myoclonic (30%), partial (15%), and GTC (7%) seizures	Myoclonic, myoclonic-astatic seizures, partial seizures rare	Febrile seizures followed by afebrile U/L clonic and GTC seizures. Later myoclonic, atypical absence, and complex partial.	GTC, tonic, partial, myoclonic, atypical absence, and atonic seizures	Partial, atypical absence, and GTC seizures	Partial seizures, clusters of atonic and myoclonic seizures in ABPE with CSWS. LKS with associated auditory agnosia.
MRI	Normal or nonspecific abnormal	Normal	Normal	Normal or abnormal	Normal or abnormal	Usually normal
Interictal EEG pattern	Awake = SSW Asleep = GPFA Background with diffuse slowing often multifocal spikes	GSW, often mixture of SSW and fast (>3 Hz) GSW	Multifocal and generalized spikes; PPR in 40%	Multifocal spikes	Frontal or bifrontal predominant GSW often 3 Hz or <3 Hz	Focal temporal predominant spikes; SSW during sleep
Course	Often severe mental retardation	50% with resolution of seizures in 3 y and 50% with normal IQ	Mental retardation, persistent seizures	Variable	Variable	Possible good outcome if steroid responsive
Prognosis	Progressive deterioration despite broad spectrum AEDs	Often stabilizes with AEDs after the first 3 y, often dramatic response to ketogenic diet	Progressive deterioration initially followed by a static phase	Static	Static; may respond to surgical intervention	Variable; may respond to steroid therapy

GTC, generalized tonic–clonic; U/L, unilateral; PPR, photoparoxysmal response; GPFA, generalized paroxysmal fast activity; GSW, generalized spike-and-waves; SSW, slow spike-and-waves; AED, antiepileptic drugs; CSWS, continous spike and wave during slow wave sleep; LKS, Landau Kleffner Syndrome.

West Syndrome

WS is present in 2 to 5 per 100,000 children and consists of a triad that includes ES, developmental arrest, and a unique EEG abnormality referred to as hypsarrhythmia (see Chapter 16) (Fig. 20.3). Hypsarrhythmia is an interictal chaotic, very high-voltage, asynchronous background with intermixed multifocal spikes and sharp waves that is associated with ES. Hypsarrhythmia in the setting of WS may precede LGS and may later on evolve into a SSW pattern (see Chapter 17) (see Fig. 20.3). A history of ES may occur in up to 40% of children with LGS though variable EEG patterns may be evident (1,6,8,9). Parallel associations among ES, MISF, and LGS exist. For example, patients with Down syndrome may have ES and hypsarrhythmia on the EEG that transition to EGE with MISF or to LGS in approximately 5% of patients (24). The onset of WS is usually between 4 and 7 months of age including 90% that are associated with neurologic abnormalities from underlying structural, genetic, or inborn errors of metabolism present (25).

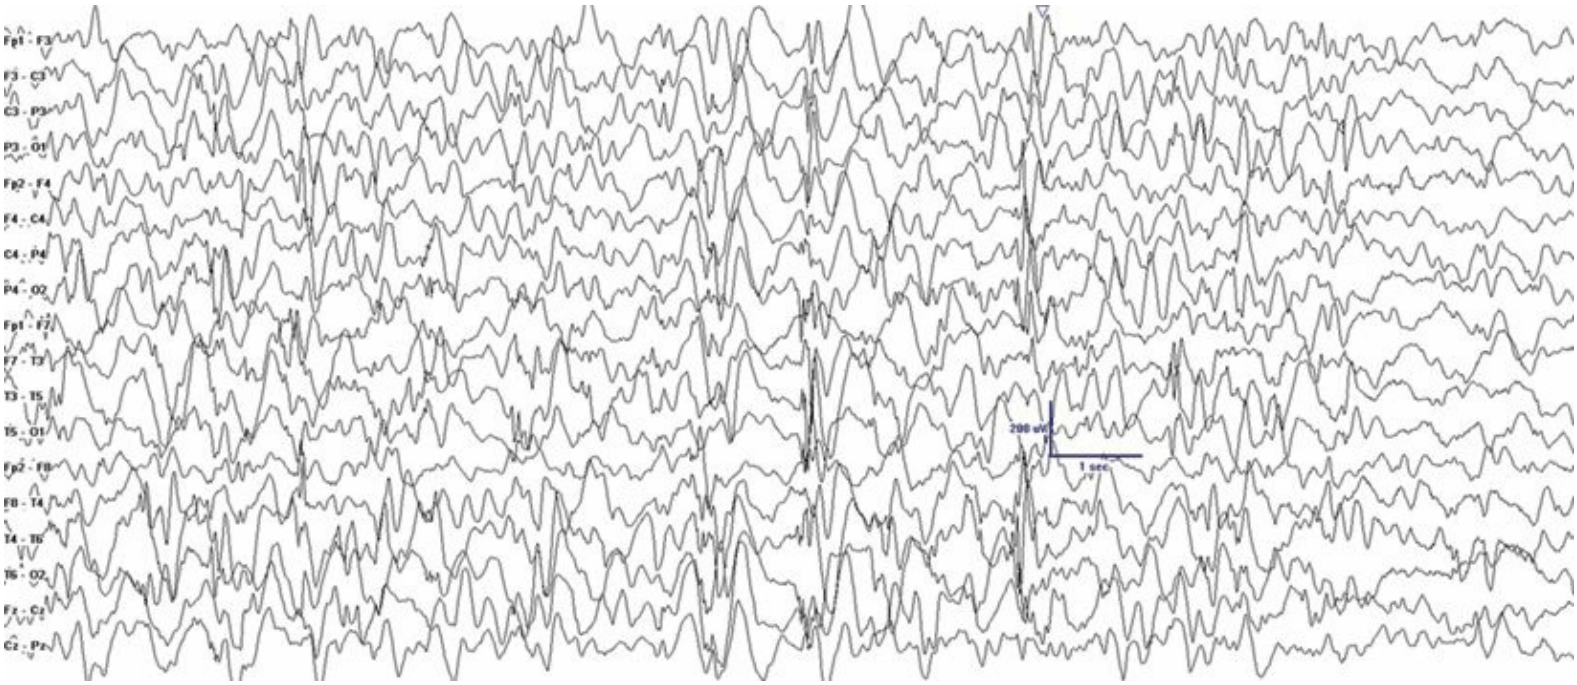

Figure 20.3. Hypsarrhythmia depicted on ictal EEG in a 7-month-old with new-onset epileptic spasms. A 2-week course of ACTH was followed by resolution of hypsarrhythmia and spasms.

Myoclonic Astatic Epilepsy

MAE was first described by Doose as a childhood EGE syndrome characterized by seizure types that are similar to those seen with LGS including atypical absence, myoclonic, atonic, tonic, and tonic–clonic seizures (2). In contrast to LGS, MAE has more prominent myoclonic seizures and less prominent tonic seizures early in the course of the condition. Focal seizures are rare. MAE usually presents between 7 months and 6 years of age. The characteristic massive myoclonic seizures are brief symmetrical jerks involving the neck, shoulders, and arms followed by an abrupt loss of muscle tone that usually results in a fall (astatic seizure). Patients with MAE may also present with pure atonic seizures, atypical absence, GTC seizures, or with episodes of nonconvulsive SE. Most patients are neurologically normal at onset, and there is a family history of epilepsy in 40% of patients (2). The ictal EEG shows spike- or polyspike-and-wave discharges at a frequency of 2 to 4 Hz. The interictal EEG may be normal. When it is abnormal, it may show brief bursts of 3-Hz GSW, 4- to 7-Hz parietal theta, and 4-Hz occipital slowing consistently blocked by eye opening (Fig. 20.4) (26). In contrast to the uniformly poor prognosis of LGS, seizures are controlled in at least half of the patients with MAE within 3 years, and more than 50% of patients will have a normal IQ in this subgroup (14). Valproic acid (VPA), lamotrigine (LTG), and ethosuximide have been generally used for treatment (14). Carbamazepine, phenytoin, and vigabatrin may worsen minor motor seizures. Many centers now consider the ketogenic diet (KD) after failure of one to two drugs or even as a first-line therapy because of its often superior seizure control in this syndrome (20).

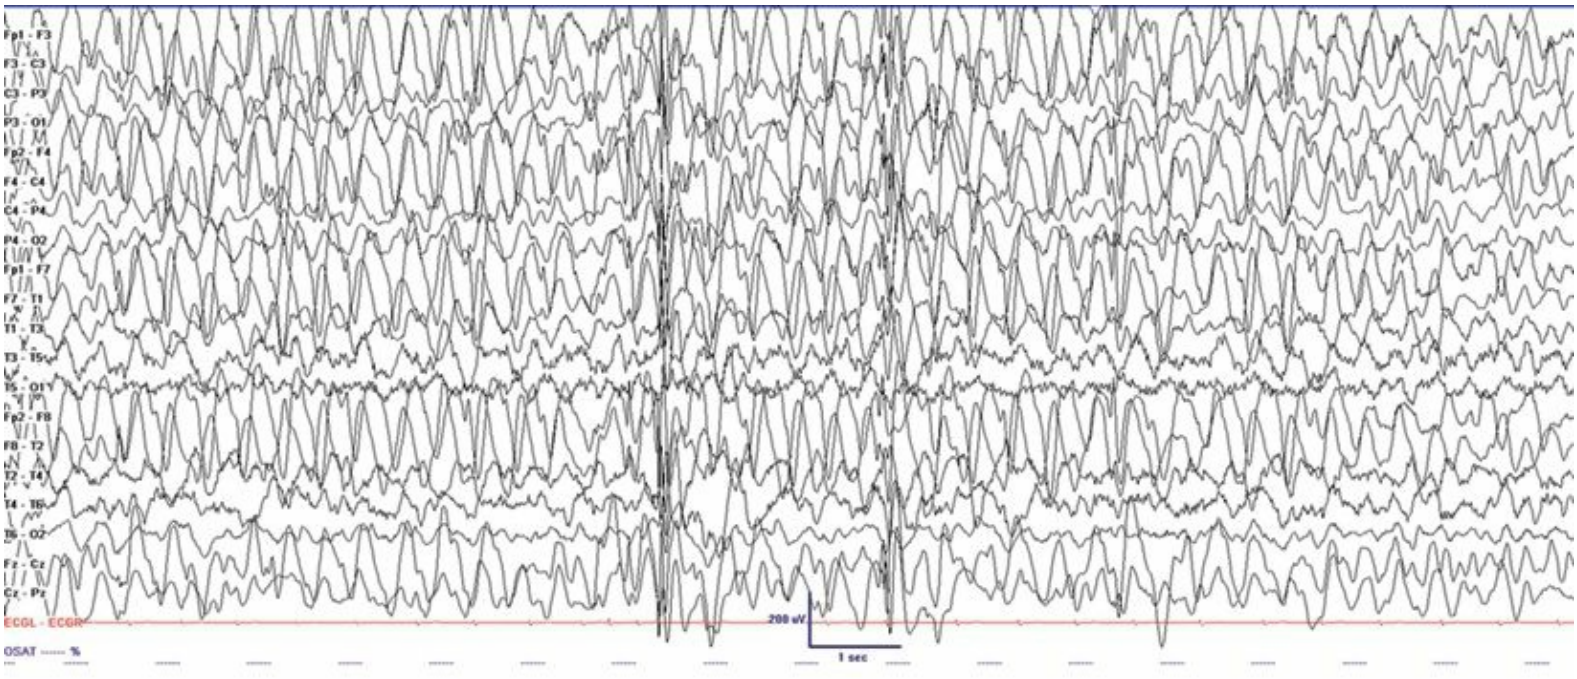

Figure 20.4. Generalized spike-and-wave at varying frequencies in a 2-year-old patient with MAE. Treatment with KD normalized the EEG.

Dravet Syndrome

SMEI also known as Dravet syndrome is a childhood epileptic encephalopathy that usually presents with prolonged febrile seizures during the first year of life. Febrile hemiclonic or GTC seizures are common presentations (18). During the second and third years of life, myoclonic seizures and atypical absences subsequently appear. The myoclonic seizures may be massive and associated with falls. Tonic–clonic and focal seizures are also common. Tonic seizures are rare, and when present, they are infrequent. The EEG is often initially normal but may show SSW as an ictal correlate during atypical absence seizures. Over time, focal abnormalities may develop in addition to generalized spike- and polyspike-and-wave discharges that are usually associated with myoclonic seizures. Stimulus-provoked seizures can occur, particularly light or stress induced, and therefore testing for photosensitivity may be useful (18). Although the myoclonic seizures may resolve, other seizure types persist, and there is progressive cognitive deterioration and overall poor developmental prognosis, with ongoing difficult-to-control seizures. After age 5 years, GTC seizures with nocturnal predominance are usually the predominant seizure type. Behavioral disorders are common. Ataxia is frequently seen, and adolescents may develop a peculiar crouched gait (18). As genetic techniques have improved, patients have shown SCN1A mutations in approximately 70% to 80% of Dravet patients, with 95% of these mutations occurring de novo (27). There is a wide spectrum of epilepsies associated with mutations of SCN1A including generalized epilepsy with febrile seizures plus (GEF+). SCN1A mutations are estimated to cause 7% of severe epilepsies in children under the age of 3 years. The mutation is suspected to cause dysfunction of interneurons involved in the inhibitory circuit of the brain (18). Mortality in SMEI is estimated to be 15% by age 20. SUDEP is well described in this disease (18). Treatment is difficult, and VPA, levetiracetam (LEV), zonisamide (ZNS), topiramate (TPM), and clobazam (CLB) are often used. Stiripentol, in conjunction with VPA and/or CLB, has been shown to be helpful in reducing frequency of seizures (28). A Dravet-like phenotype with a better prognosis is also seen in patients with mutations of protocadherin 19 (PCDH19) in females (29).

Early-Onset Epileptic Encephalopathies

Early infantile epileptic encephalopathy (EIEE) or Ohtahara syndrome accounts for only 0.2% of the early childhood epilepsies. It presents with drug-resistant tonic epileptic spasms, burst suppression on EEG, and has an overall poor prognosis. Seizure onset is within the first 3 months of life and asymmetric tonic seizures and focal seizures occur in approximately one-third of patients. EIEE often evolves to WS between 3 and 6 months of age and subsequently into LGS between 1 and 3 years of age (30). The cause is often symptomatic, and a high mortality rate is encountered in infancy. It generally is associated with malformations of cortical development. Another early epileptic encephalopathy is EME. It presents in the first month with vigorous myoclonias and multifocal seizures. Both EIEE and EME patients later in the course of development manifest tonic seizures and with a burst suppression pattern on EEG. Differences between the two entities include tonic seizures as the main type of seizures in EIEE, in addition to an earlier onset, and the presence of burst suppression in both the awake and sleep state (30). The similarity of the EEG patterns has led authors to question whether EIEE and EME are separate entities (22). DNA sequencing has led to identification of genes that can help define a genetic basis for some of the early-onset epileptic encephalopathies (EIEE, EME, and WS).

Atypical Benign Partial Epilepsy with Continuous Spike-and-Wave of Sleep

This syndrome presents with developmental stagnation or regression and includes features of EGE and localization- related epilepsy. Due to developmental decline and often medical intractability during the acute stage when presenting with continuous spike-and-wave in slow sleep, it has also been termed “pseudo-LGS” (10). Atypical benign partial epilepsy with continuous spike-and-waves in sleep may present with clusters of myoclonic and atonic seizures but not tonic seizures between 2 and 6 years of age. The seizures cluster lasting 2 to 4 weeks and then are separated by seizure-free periods (3). This differentiates this syndrome from LGS where tonic seizures are common and remissions do not occur. The EEG shows diffuse SSW discharges during sleep (Fig. 20.5). Central spikes are usually prominent in this syndrome similar to other forms of more benign focal epilepsy. Remission occurs before age 15, but patients may be left with a permanent cognitive impairment (3).

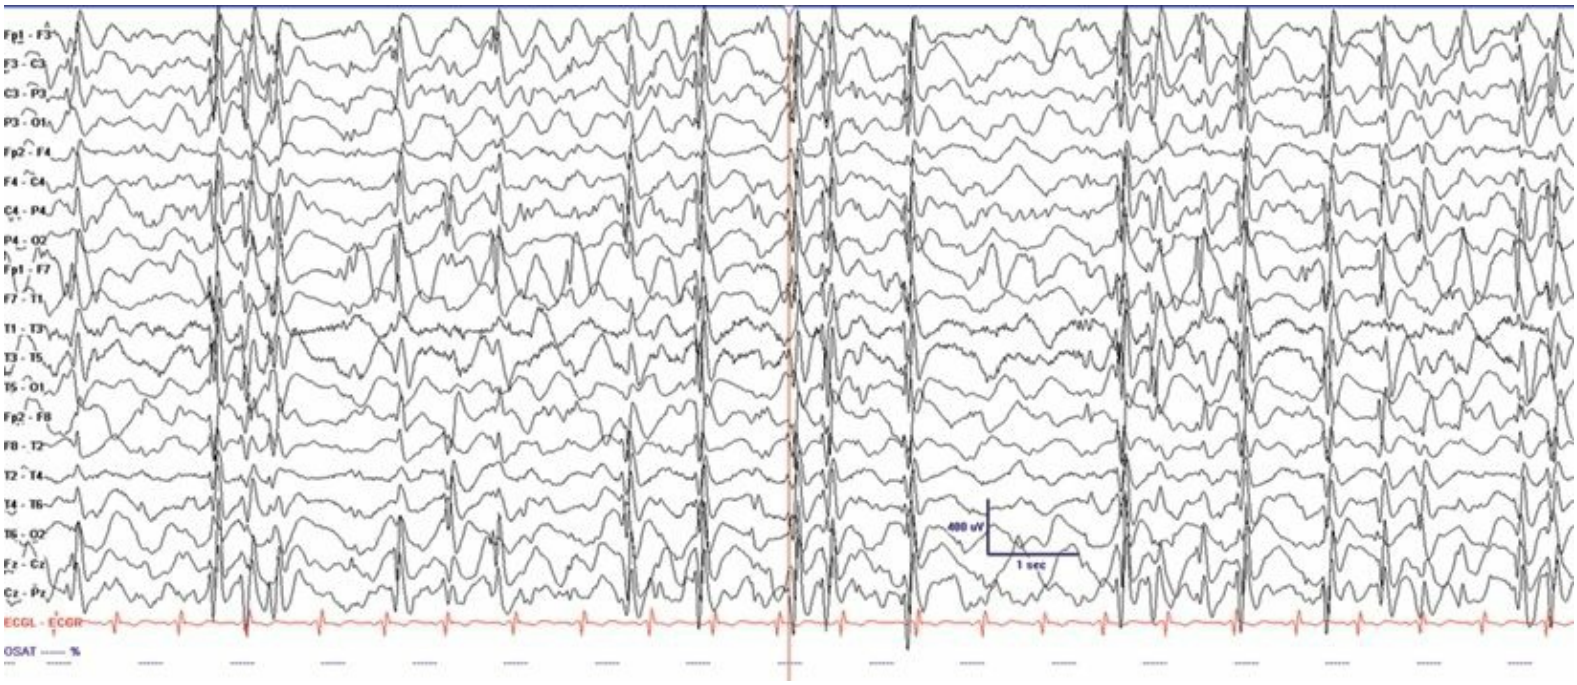

Figure 20.5. Electrical SE in slow-wave sleep in a 7-year-old child with Landau–Kleffner syndrome.

Localization-Related Epilepsy with Secondary Bilateral Synchrony

Focal epilepsy with SBS is usually present when there is a focal EEG spike that leads into a generalized discharge resembling SSW. Because of the limitations of surface scalp EEG recordings, there may be variability in the presence of a preceding focal discharge before the generalized burst in seen. Characterization of the discharges shows that they tend to have a frontal predominance at 2 to 2.5 Hz. The interval between the focal discharge and the onset of the generalized discharge is very brief but is greater than the mean callosal transmission time and may further decrease in duration as the discharge continues (5). Since the primary focus may not be discernable on routine EEG, it may mimic a generalized discharge. Foci in the frontal lobes are most often associated with this phenomenon, but this fast spread of an initially focal discharge can also be seen elsewhere along the midline of the brain (21). Furthermore, clinical seizures associated with this phenomenon may imitate absence seizures further providing a challenge to differentiate a generalized from focal seizure.

Severe Epilepsy with Multiple Independent Spike Foci

EGE with MISF has been proposed as an independent entity (31) that is clinically related to LGS due to associated MR and drug-resistant seizures. Three or more epileptic foci are present with at least one in each hemisphere. In patients with this EEG finding, more than 50% of patients had more than one type of seizure and 50% were having daily seizures (4). This is particularly true for patients presenting with spikes at least every 10 seconds (4). When EGE with MISF is present, a variety of seizures including GTC, focal, tonic, myoclonic, atypical absence, and atonic seizures may be seen. It has extensive overlap with the other epileptic encephalopathies and may frequently transition in an age-dependent fashion to other epilepsies including LGS, EIEE, and WS (31). It may also be seen in up to 20% of symptomatic LGS patients as they age, but rarely in those without a structural–metabolic basis (32). Like LGS, EGE with MISF may be seen in patients with extensive bilateral cerebral pathology and manifests as severe drug-resistant epilepsy. When the EEG features of MISF are present, a more variable prognosis with a larger potential for normal cognitive development is

present, and up to one-third of patients may be developmentally normal (4).

Genetic Syndromes Causing EGE

Angelman syndrome (AS) is characterized by severe developmental delay, absent speech, paroxysms of laughter, a puppet- like gait with ataxia, and jerky movements (also referred to as "happy puppet syndrome" in the past although some consider this term now obsolete), in addition to other distinctive clinical features. Patients with AS also have intractable epilepsy and EEG characteristics that may be confused with LGS (33). Seizure types that may be observed include atypical absence, myoclonic, clonic, and complex partial seizures. Characteristic EEG findings are diffuse, bilateral, frontally predominant, high-amplitude delta waves with a notched or triphasic-like slow waves that mimic SSW complexes. The notched appearance of the sharp waves superimpose upon the slower delta activity. The frequency may be 2 to 2.5 Hz and is maximal in the prefrontal derivations, similar to the SSW seen in LGS (Fig. 20.6). Due to the notched appearance of sharp waves, the findings have also been referred to as "ill-defined slow spike-and-wave" (33). The 10-Hz GPFA seen in LGS is not seen in AS (33).

Figure 20.6. "Ill-defined" slow spike-and-wave on interictal EEG in a 4-year-old patient with Angelman syndrome.(Courtesy of Maria Gieron-Korthals, MD.)

Rett syndrome is encountered between 6 months and 3 years of age and occurs only in females. Epilepsy in typical Rett syndrome usually presents after age 3 years (34). Rett syndrome is

characterized by initial normal development followed by cognitive regression, autistic features, microcephaly, ataxia, and hand-wringing movements in addition to multiple seizure types that include absence, myoclonic, and atonic seizures mimicking LGS. The EEG may show progressively worsening slowing of the background activity with needle-like central spikes that are activated by somatosensory stimulation. A unique feature includes a 4- to 6-Hz rhythmic theta pattern maximal centrally (35). Rett Syndrome may also present with SSW (Fig. 20.7). Paroxysmal nonepileptic events are common in patients with Rett syndrome, and video EEG can be helpful to distinguish epileptic and nonepileptic events. There are atypical variants in which epilepsy often presents in infancy without initial normal development. In typical Rett syndrome, there is an associated mutation in the MECP2 gene at Xp28.2 in 93% of cases. In atypical variants, MECP2 mutations are responsible for 50% to 70%. Other causes include MECP2 duplications, CDKL5 mutations, and FOXG1 mutations (34).

Figure 20.7. Slow spike-and-wave in an 8-year-old child with Rett syndrome.(Courtesy of Selim R. Benbadis, MD.)

There are also chromosomal abnormalities that cause LGS and EGE. Genetic testing is important in all epilepsies where the etiology is uncertain, especially when dysmorphic features are present. Ring chromosome syndromes, including ring 14 and 20, often include epileptic seizures. In addition, inverted duplicated 15 syndrome (IDIC 15), Wolf–Hirschhorn syndrome, Down syndrome (trisomy 21), and a chromosomal abnormality associated with DEL 1p36 are associated with cognitive deficits and epilepsy. Ring chromosome 20 may present with minimal dysmorphic features, normal initial development, and with developmental regression after the onset of epilepsy. The lack of clear dysmorphic features can detract from the consideration of a chromosomal alteration (36).

DIAGNOSTIC EVALUATION

High-resolution neuroimaging is essential to detect the many diverse structural lesions that may cause EGE and LGS potentially impacting the diagnosis and treatment. It is helpful to have specific neuroimaging protocols that are designed to detect neuronal migration disorders in this group that might further implicate an underlying pathophysiology for diagnosis as well as identifying a potentially surgically remediable lesion. PET scans of the brain obtained in patients with LGS (37) have yielded variable findings and may reflect the varying etiologies. However, FDG-PET brain scans have proven useful during the workup for resective epilepsy surgery when focal seizures with SBS mimicking an EGE are the disabling seizure type. EEG is the cornerstone to the diagnosis in patients with epileptic encephalopathies. Hypsarrhythmia, SSW, GPFA, MISF, and interictal disturbances of the waking background are notorious features seen in patients with EGE and LGS. Video-EEG monitoring may differentiate and classify the ictal electroclinical behavior for medical and nonmedical treatment options.

Patients with an obvious cause for EGE may need a less extensive evaluation. In patients with an early-onset epileptic encephalopathy, evaluations are directed to exclude potentially treatable causes. Metabolic etiologies should address metabolic derangements including the aminoacidopathies, urea cycle defects, organic acidopathies, mitochondrial disorders, and neurotransmitter disorders. Genetic testing should be performed when epileptic encephalopathies are encountered especially when dysmorphic features or congenital abnormalities are present. An analysis with fluorescein in situ hybridization using regional-specific probes or CGH chromosomal microarrays should be considered if routine karyotyping is unrevealing and a chromosomal syndrome is suspected since not all deletions and translocations are readily identifiable. Epilepsy gene panels that are now commercially available utilizing large panels of gene probes may assist in directing a specific diagnosis.

TREATMENT

The treatment of patients with EGE and LGS includes efforts at managing the underlying cause of the associated cognitive or behavioral dysfunction, attempting to control seizures, and providing support for the family or caretakers involved with their care. ASDs are the mainstay of therapy for patients with EGE and LGS despite the characteristic drug resistance. The challenge for the clinician is often to optimize quality of life for the patient and caretakers while weighing seizure reduction against side effects and overuse of ASDs. The multiple seizure types associated with LGS often require broad-spectrum AEDs singly or in combinations. VPA, LTG, and TPM are the most widely used agents and have proven useful in LGS (10,38,39). FBM has been shown to have a significant effect on both seizure reduction as well as demonstrating a favorable neurocognitive profile; however, its use is limited by serious side effects including the occurrence of hepatic failure and aplastic anemia (40). Two newer ASDs CLB and rufinamide were recently approved for the treatment of LGS (41,42). Many other medications have purported benefit including LEV, ZNS, and clonazepam (CLZ) though these may require more evidence to demonstrate consistent efficacy. Clobazam may be preferable to CLZ given the lower likelihood of sedation. Benzodiazepines in particular may evoke sedation and provoke atypical absence seizures and tonic SE. Oversedation from ASDs may paradoxically worsen seizure control, hamper development, and limit functional skills as much as intermittent seizures. In clinical practice, simplifying ASDs may surprisingly improve seizure control and functionality (1).

Intravenous immunoglobulin has previously been used successfully in patients with LGS (19). Corticosteroids and ACTH may be effective early in the treatment of cryptogenic LGS though steroids usually have a limited role due to the high rates of relapse following discontinuation though they may be used in pulse doses for episodes of nonconvulsive SE (10).

NONMEDICAL THERAPIES

The KD is a specialized high-fat, low-carbohydrate diet that may be useful for EGE and LGS. It may be particularly helpful in decreasing the number of atonic seizures and should be considered an option when medical therapy is ineffective (see Chapter 70). The use of the KD and a reduction in the number of AEDs may be useful not only for seizure frequency but also for functionality. There is some evidence that adults with refractory epilepsy may benefit from the diet even when less restrictions are used (such as the modified Atkins diet) (43).

Surgical options are usually palliative, with corpus callosotomy and vagus nerve stimulation (VNS) most frequently utilized (see Chapter 71). Corpus callosotomy is a surgical procedure that disconnects the anterior two-thirds to three-fourths of the cerebral hemispheres to prevent seizure propagation and eliminate the risk of falls and injury by reducing spread of generalized seizures (see Chapter 88). Sectioning the anterior portion of the corpus callosum is effective in 50% to 75% of cases while complete callosotomy may reach 80% to 90% reduction of drop attacks associated with generalized tonic and atonic seizures (44).

VNS can be helpful in LGS although it may be as effective as in focal seizures (45). In a study of LGS and Lennox-like syndrome patients at one center, 24 consecutive patients subjected to callosotomy were compared to 20 consecutive patients implanted with VNS (23). In this study, callosotomy was found to be more effective in decreasing the frequency of atonic seizures while VNS was more effective in decreasing the frequency of myoclonic seizures (23). There were similar decreases in GTC and atypical absence seizures and no effect of either intervention on tonic seizures (23). In the past, resective surgery has been thought to provide no clear benefit to patients with LGS, based on the hypothesis that tonic seizures are often due to bilateral cortical dysfunction. However, LGS has been shown to be associated with focal lesions (46) and hypothalamic hamartomas (47) prompting considerations for resective surgery. A recent series reported that 24 of 39 carefully selected patients with LGS had a successful outcome following surgical resection (48). Newer techniques may advance surgery in this difficult population in the future.

PROGNOSIS

The prognosis of the EGEs and of LGS overall is poor. Few patients lead independent lives as an adult as a result of daily seizures, cognitive, or behavioral abnormalities. Refractory seizures are the rule, and normal intellectual function rarely occurs (8). An onset before age 3 is more likely to be associated with MR with the majority of individuals requiring special classes or sheltered workshop environments. Some patients show deterioration of previously established function especially when seizures are frequent (32). Though tonic seizures may persist, the SSW pattern may resolve and rarely newer types of seizure semiologies will evolve to dominate the clinical profile such as focal seizures. Approximately half of symptomatic LGS and one-third with unknown causes lose the complete electroclinical complement of characteristics for LGS evolving into another form of EGE, epilepsy with MISF or LRE (32). Patients with an early age of onset, frequent disabling seizures,

repeated episodes of SE, and a preceding history of IS associated with WS have a relatively worse prognosis for normal cognitive development (1). Patients with LGS followed for a mean of 35.7 years showed that the main seizure type in patients as adults was tonic seizures during sleep. Other types of seizures were less common. The EEG in the awake state showed a gradual normalization with improved background activity and less epileptic abnormalities during the awake state and persistence of subtle tonic seizures and associated generalized PFA during sleep. Unfortunately, most adult patients remained moderately or severely mentally retarded despite the improvement in seizure activity and EEG abnormalities (49). More than 75% of patients with EGE and LGS survive for over 20 years, and therefore, preparation of the patient and families for adult living arrangements such as group homes and appropriate vocational opportunities needs to be an ongoing part of care of adolescent patients. In addition, the need for guardianship and future medical care should be discussed.

CONCLUSION

There are few patients as challenging to care for as those with LGS and EGE. Seizures are usually resistant to treatment, and the overall prognosis for normal cognitive development is poor. It is crucial to distinguish patients with EGE from those with LRE who may possess a surgically remediable condition or those with a more favorable prognosis such as MAE. Similarly, identifying refractory epilepsies with a genetic component such as AS, Rett syndrome, and those epilepsies associated with a SCN1A mutation are important when considering treatment and to provide genetic counseling. In EGE, the benefit of treatment with ASDs with respect to the goal of seizure reduction must be realistically balanced with the risks of overmedication. When ASDs are ineffective and injury is recurrent, alternative therapies such as KD, VNS, and corpus callosotomy should also be considered. Last but not least, support for caretakers and families of patients with EGE and LGS is crucial as refractory seizures that cause injury create considerable anguish for caretakers and family alike, and protective measures should be considered at home and also at school. While protective helmets may help prevent injury, they stigmatize patients with uncontrolled seizures and an effort should be made to seek the least intrusive methods to balance safety with psychosocial development.

CHAPTER 21 CONTINUOUS SPIKE-AND-WAVE DURING SLEEP INCLUDING LANDAU–KLEFFNER SYNDROME

IVÁN SÁNCHEZ FERNÁNDEZ AND TOBIAS LODDENKEMPER

INTRODUCTION

Continuous spike-and-wave during sleep (CSWS) is an epileptic encephalopathy characterized by three defining features: (i) seizures, (ii) an electroencephalographic (EEG) pattern of almost continuous spiking during non–rapid eye movement (non-REM) sleep termed "electrical status epilepticus in sleep" (ESES), and (iii) global and severe regression in most or all developmental domains (1–4). The aim of this chapter is to summarize the main characteristics of CSWS, Landau–Kleffner syndrome (LKS), and related syndromes and to suggest an approach to treatment. In this review, we consider CSWS, LKS, and the "benign" pediatric focal epilepsy syndromes ("benign" epilepsy of childhood with centrotemporal spikes, Panayiotopoulos syndrome, and Gastaut-type late-onset childhood occipital epilepsy) as related entities in the context of a broader "seizure susceptibility syndrome."

CONTINUOUS SPIKE-AND-WAVE DURING SLEEP

Use of Terminology

"ESES" and "CSWS" have been used in the literature as interchangeable terms to refer to either the EEG pattern of almost continuous spiking during non-REM sleep or the electroclinical syndrome of epileptic encephalopathy with global regression. A survey on the use of CSWS/ESES terminology among neurologists and epileptologists in North America demonstrated a very heterogeneous understanding of terms, concepts, and defining features (5). In this chapter, we use the term "ESES" when referring to the EEG pattern and the term "CSWS" when referring to the epileptic encephalopathy. We have arbitrarily adopted this use of terminology for consistency with the International League Against Epilepsy classifications, but we acknowledge that the future development of a universally agreed upon terminology is critical to the advancement in the understanding of this syndrome.

Epidemiology

CSWS is an age-related epileptic encephalopathy that occurs only in children and adolescents. CSWS is more common in males (6–8). The prevalence of CSWS ranges from 0.2% to 7% depending on the study setting and inclusion criteria (7,9–12). In tertiary pediatric epilepsy centers, prevalence is

approximately 0.2% to 0.6% (10,12), and in epilepsy surgery series, it is found in 1.3% to 2% (9,11) of patients. These figures may include a considerable referral bias, and the prevalence of CSWS in less specialized settings may actually be lower. However, recognition of the ESES pattern requires an EEG with sufficient sleep, and therefore, CSWS could also be underdiagnosed. The EEG pattern of ESES may be even more frequent than previously thought as suggested by a retrospective review of 1497 overnight EEG recordings that identified 102 children (7%) with ESES, although these patients had different clinical presentations (7).

Electroclinical Presentation

Clinical Characteristics

In addition to ESES, seizures, and regression, children with an underlying structural brain lesion may have additional clinical characteristics such as focal neurologic findings associated with their brain lesion.

Overview and Clinical Stages.

Both normally developing children and children with developmental delays can develop CSWS. Clinical characteristics of CSWS usually follow sequential stages and an age-related timeline. There are three major clinical events in the evolution of CSWS: seizure onset, developmental regression, and seizure freedom. These clinical events delineate four stages of the disease: dormant, prodromal, acute, and residual (Fig. 21.1) (13).

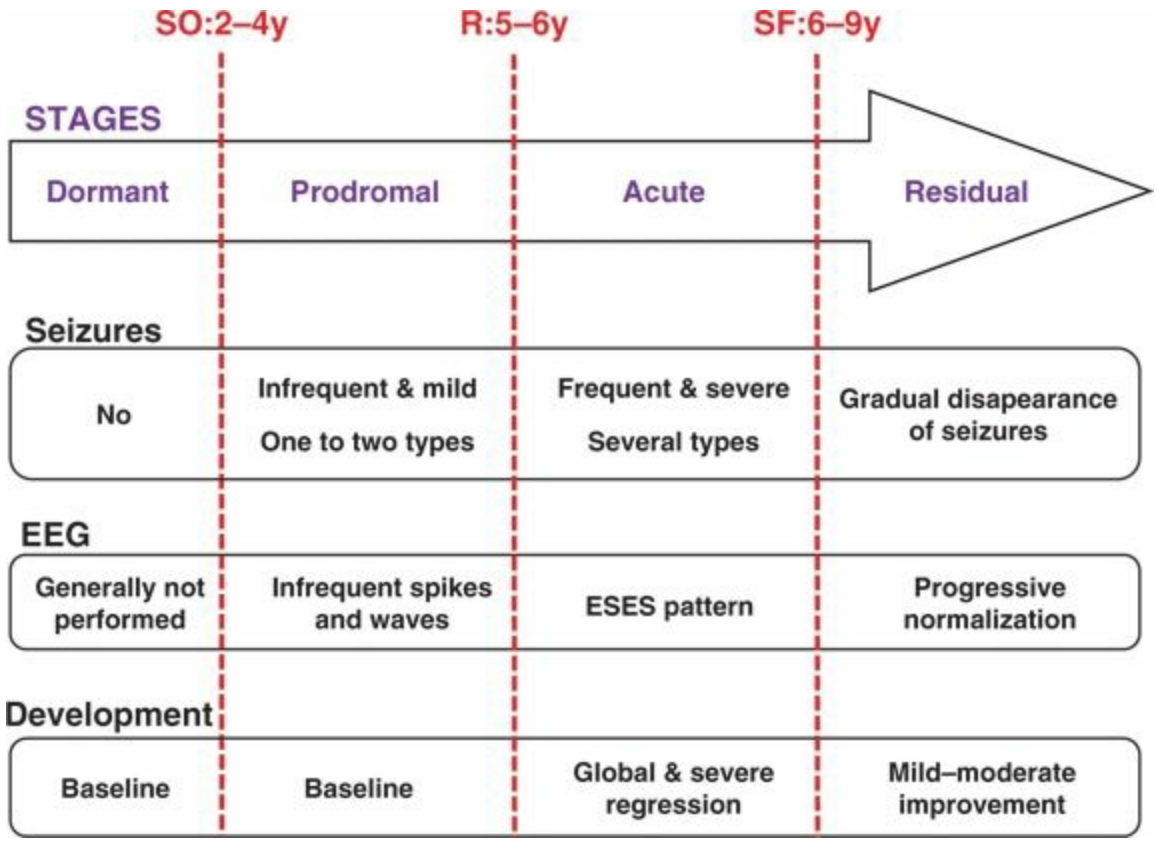

Figure 21.1. Graphic representation of continuous spike-and-wave during sleep evolution over time. The age of clinical events varies in individual patients but tends to peak at approximately the displayed ages. EEG, electroencephalogram; R, regression; SF, seizure freedom; SO, seizure onset; y, years.) (Modified from Sánchez Fernández I, Loddenkemper T, Peters JM, et al. Electrical status

epilepticus in sleep: clinical presentation and pathophysiology. Pediatr Neurol. 2012;47(6):390–410.)

Seizures are the most common presenting sign in CSWS. The age at seizure onset is typically between 2 and 4 years with a bimodal distribution. Seizure onset clusters at around 2 years of age in patients with underlying structural brain lesions and at around 4 years of age in patients with CSWS of unknown etiology (2). During the prodromal stage, seizures are infrequent and relatively easy to control, and development is not severely affected. Seizures typically occur years before the ESES pattern is recognized on EEG. Therefore, recognition of CSWS during the prodromal stage does not typically occur.

Subacute worsening involving seizures, developmental regression, and worsening of EEG abnormalities occurs at approximately 5 to 6 years of age. This subacute regression heralds the acute stage. During the acute stage, seizures become more frequent and difficult to control, patients suffer a global and severe developmental regression, and almost continuous spiking during non-REM sleep appears on the EEG. CSWS is typically diagnosed during this acute stage. After a variable number of years, seizures tend to resolve spontaneously with a peak time of seizure freedom at approximately 6 to 9 years of age (2).

In the residual stage that follows seizure freedom, there is a gradual normalization of the EEG pattern and mild-to-moderate cognitive improvement, although severe residual cognitive impairments often remain (2,4).

Seizures.

During the prodromal stage, seizures typically occur out of sleep (3). Seizures are infrequent and most patients have only one seizure type. Seizure types during this prodromal stage include focal or unilateral motor seizures, focal dyscognitive seizures, absence seizures, and generalized tonic–clonic seizures. During the acute stage, most patients manifest several seizures of several different types per day, and seizures are often difficult to control (2,4,14). Unilateral seizures become rare, atonic and bilateral motor seizures appear, and atypical absence seizures increase in frequency. Absence seizures may also evolve into absence status epilepticus (2,4). The lack of tonic seizures is a typical feature of CSWS and permits differentiation from patients with Lennox–Gastaut syndrome (2,4).

Development.

Developmental regression in CSWS involves a wide spectrum of behavioral, cognitive, language, social, and motor milestones in varying but often severe degrees. Regression includes a decrease in overall intelligence, learning disorders, memory problems, and attention span (1,4,15,16). Language regresses in the form of a subacute and progressive aphasic disorder with spontaneous fluctuations over time. Behavior becomes disruptive, and behavioral manifestations include hyperactivity, impulsivity, and even aggression. Deterioration of fine and gross motor skills as well as loss of social skills add to the severe functional deterioration.

EEG Characteristics

Evolution of the EEG Characteristics.

The EEG hallmark of CSWS is ESES, a pattern of almost continuous spike-and-wave that occupies most or all of the EEG tracing during non-REM sleep (2–4). However, the ESES pattern is typically

preceded by earlier and milder EEG abnormalities. In the few patients who underwent an EEG during the dormant stage, mild EEG abnormalities and infrequent epileptiform discharges have been detected. During the prodromal stage, epileptiform discharges are rare and occur essentially only during sleep. This pattern worsens progressively, and epileptiform discharges become also abundant during wakefulness, with additional marked potentiation of epileptiform discharges in the transition from wakefulness to sleep. A clinical presentation with almost continuous spike-and-wave during non-REM sleep is typical during the acute stage (Fig. 21.2).

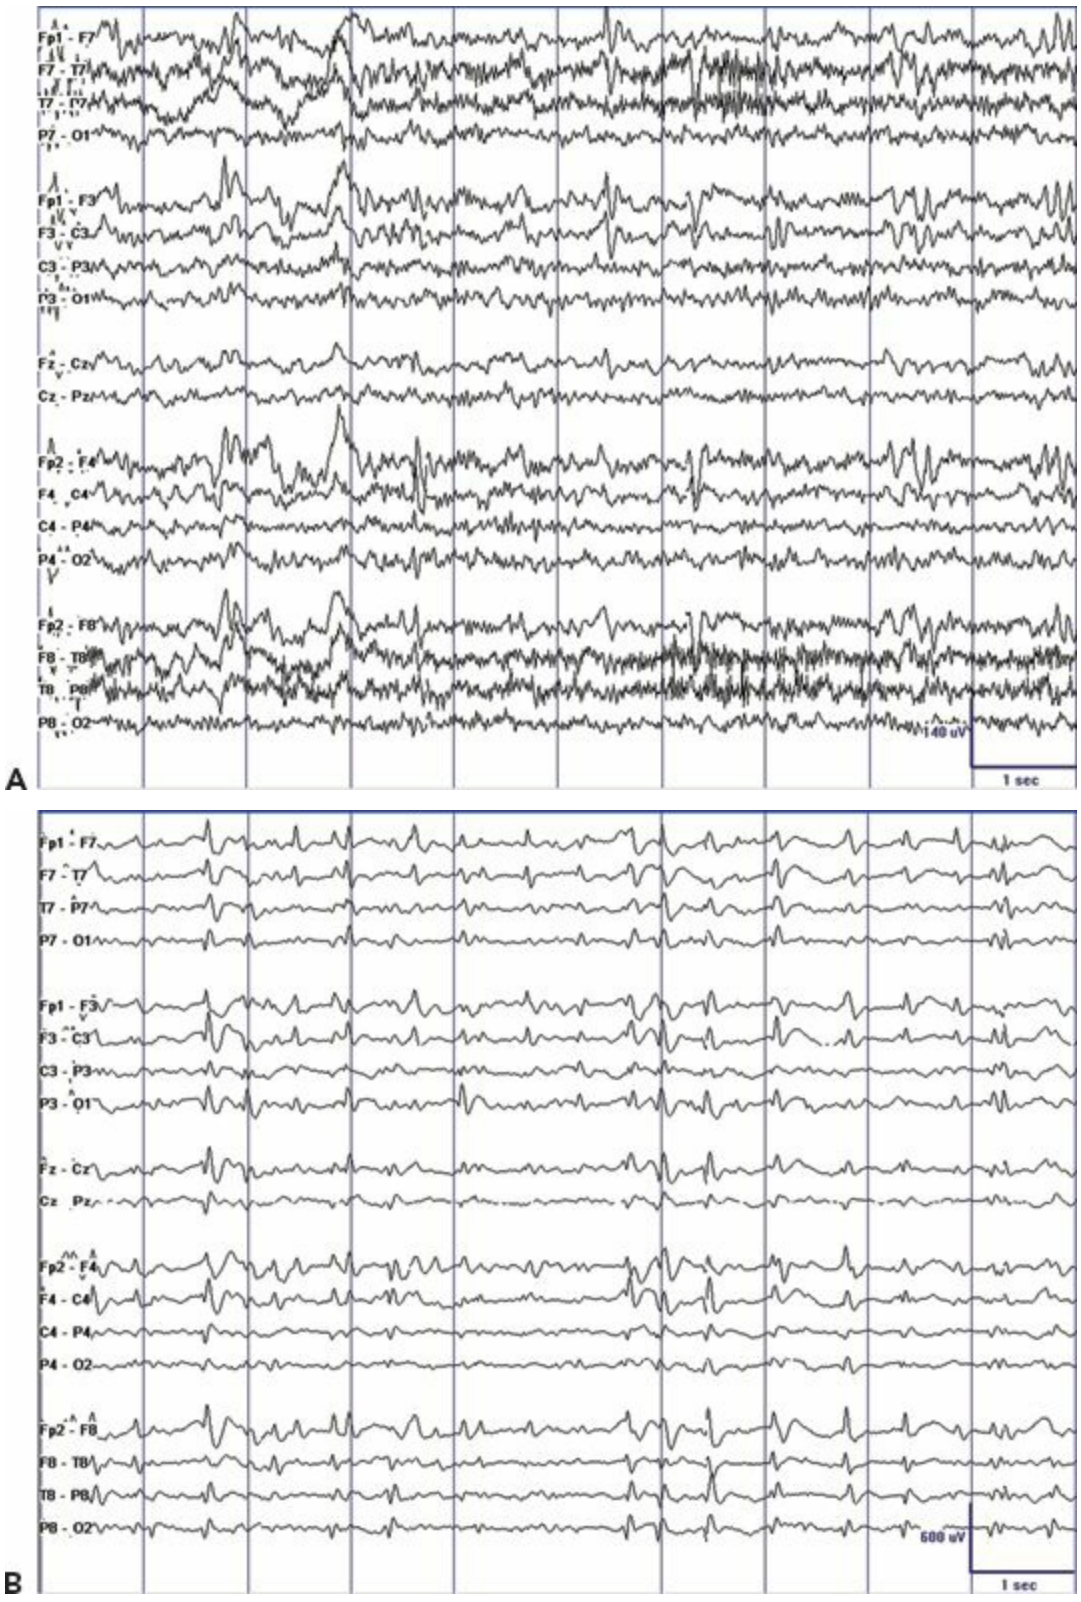

Figure 21.2. EEG tracings illustrating the dramatic sleep potentiation of epileptiform activity in the transition from wakefulness to sleep. **A:** During wakefulness, infrequent and relatively low-amplitude spikes occur in the setting of a normal background. **B:** During

non-REM sleep, almost continuous spike-and-wave replace the normal sleep graphoelements of non-REM sleep. Also note the difference in voltage.

Classical Definition of the ESES Pattern.

The EEG pattern of ESES is classically defined by the presence of generalized bilateral and symmetric 1.5- to 3-Hz spike–waves that occupy at least 85% of the EEG tracing during non-REM sleep (4,17). The originally proposed cutoff value of 85% has largely been followed in the literature. However, the definition of the International League Against Epilepsy does not include a specific threshold percentage and only requires that spike-and-wave be "continuous" and "diffuse" (18). Consequently, there have been authors who used lower cutoff values (6,7,19,20) or did not consider a specific threshold (14). Further, the percentages of epileptiform activity vary over time in the same patient (13). Therefore, a more flexible criterion such as "a dramatic activation of epileptiform discharges by sleep" may be considered in the definition of ESES in the future (1).

Quantification of Epileptiform Activity.

The classical quantification of epileptiform activity in ESES is the spike–wave index, expressed as a percentage of slow sleep occupied by spike–waves (3,4). Most authors refer to this percentage without defining the method or the EEG segment considered for calculation. Quantification of epileptiform activity in ESES can be assessed as the percentage of 1-second bins with at least one spike-and-wave in each second (13,21) or as the total number of spike–waves per unit of time (13). Another difficulty in the reproducibility of methods for quantification of epileptiform activity is that there is no consensus regarding the specific portion of the EEG tracing used for the calculation of epileptiform activity: Some authors use whole-night sleep recordings, and others use selected segments of non-REM sleep (5). Different timings of EEG assessment with respect to sleep and circadian phases as well as different methods of quantification may result in considerable variation in percentages among studies. Efforts are under way to create a better defined and reproducible method of epileptiform activity quantification.

Lateralization of Epileptiform Activity.

The first descriptions of the ESES EEG pattern required bilateral, symmetric, or diffuse EEG manifestations (17,18). However, markedly asymmetric, bilateral, or even more focal examples of ESES have been published, and series that compared the clinical features of patients with generalized versus those with more focal ESES did not find marked differences in clinical presentation (7,14,22).

Criteria for ESES.

Based on the above considerations, three essential features emerge when describing the EEG pattern of ESES: (i) a marked activation or potentiation of epileptiform discharges in the transition from wakefulness to sleep, (ii) leading to a (near)-continuous pattern of slow spike-and-wave, and (iii) that occupy a "significant proportion" of the non-REM sleep EEG tracing with a cutoff value ranging from 25% to 85% in the literature (2).

Age of ESES in the EEG.

The age at detection of the ESES pattern depends both on the definition of this pattern as well as on the frequency of routine, prolonged, or overnight EEG recordings with sufficient periods of sleep

captured in the EEG tracing. With these limitations in mind, the ESES pattern appears at approximately 4 to 8 years of age and remits at around 8 to 9 years of age, broadly coinciding in time with the acute stage of CSWS (2).

Pathophysiology and Etiology

The cause of CSWS and the pathophysiologic mechanisms that lead to age-specific clinical and EEG abnormalities are unknown. The ESES pattern is thought to be related to a disruption of the physiologic corticothalamocortical circuitry, which may also be involved in the generation of sleep spindles (23). When structural or functional insults disrupt this circuitry, physiologic sleep spindles may be replaced by generalized spike-and-wave, and, in some cases, evolve to ESES.

It is currently unknown to what extent this EEG pattern is causal in developmental regression seen in CSWS and whether effective treatment of ESES improves developmental prognosis in patients with CSWS. Early developmental structural brain lesions have been identified as one important etiology in CSWS, with genetic predisposition possibly playing an additional role.

Early Developmental Lesions

Several case reports and small case series have found an association between CSWS and malformations of cortical development (24) and with early vascular lesions that involve the thalamus and basal ganglia (25–27). Larger studies also support the hypothesis that insults to the developing brain are associated with the development of the ESES pattern on EEG and with CSWS. In a series that studied 32 patients with prenatal or perinatal thalamic lesions, a dramatic sleep potentiation of epileptiform activity occurred in 29 cases (90.6%) (28). In a series of 67 patients with ESES and neuroimaging, 33 patients (49.3%) presented with early developmental lesions, with no information on thalamic involvement (7). In another series, 18 of 44 (41%) patients with ESES had structural lesions of the brain, but no details on thalamic involvement were available (29). In a series of 14 survivors of neonatal thalamic hemorrhage secondary to cerebral sinovenous thrombosis, 7 (50%) had sleep potentiation of epileptiform activity (30). In another series of 100 patients with ESES, 48 (48%) had early developmental lesions and 14 of these demonstrated thalamic involvement (31). In this series, patients with ESES were compared with a control group of patients with epilepsy but without ESES (31). Patients with ESES had a higher frequency of early developmental lesions (48% vs. 19%, odds ratio = 3.9, 95% CI: 1.71 to 8.9) and a higher frequency of thalamic lesions (14% vs. 2%, odds ratio = 7.49, 95% CI: 0.95 to 58.76) than did patients with epilepsy without ESES (31). In all of the above-mentioned series, the lesion occurred typically perinatally or early in life, with a predominance of vascular etiology in all series (Fig. 21.3). Taken together, these studies demonstrate that vascular brain lesions affecting the thalamus early during brain development are common in patients with ESES and may potentially play a causal role. However, these series also indicate that in more than half of patients, the cause cannot be attributed to a macroscopic structural brain abnormality. In those cases, a similar functional disruption of the corticothalamocortical neuronal networks without macroscopic correlate on MRI may play a role.

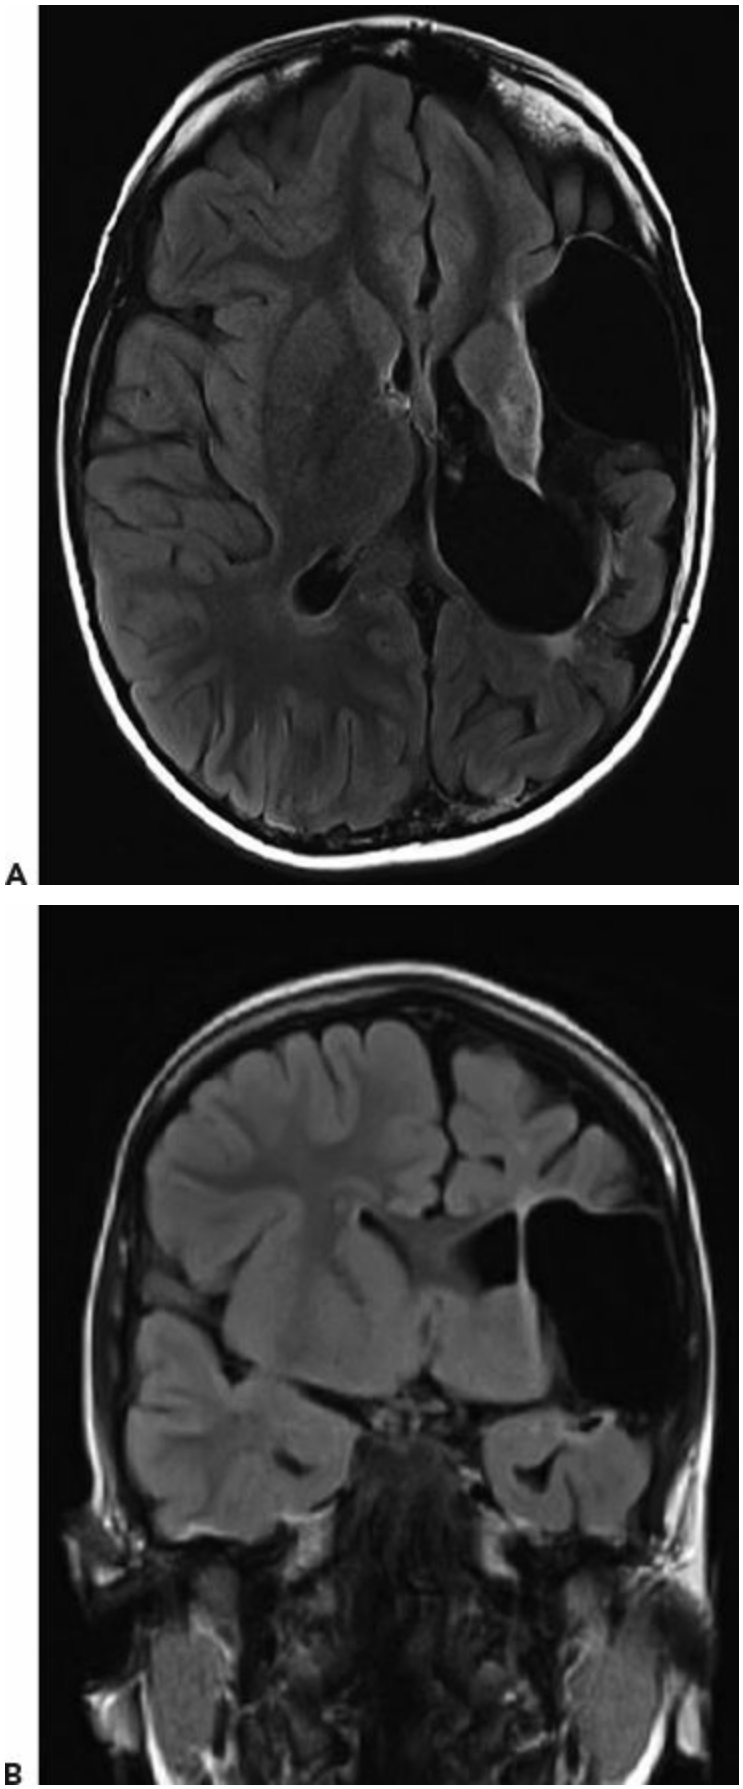

Figure 21.3. Early developmental lesion in a patient with CSWS. An extensive cystic encephalomalacia affects the left hemisphere in the distribution of the left middle cerebral artery. The patient suffered a perinatal stroke. **A:** Axial view, T2-weighted FLAIR MRI. **B:** Coronal view, T2-weighted FLAIR MRI.

Evolution into CSWS from Other Epileptic Syndromes

"Benign" pediatric focal epilepsy syndromes ("benign" epilepsy of childhood with centrotemporal spikes, Panayiotopoulos syndrome, and Gastaut-type late-onset childhood occipital epilepsy) share some common features with CSWS and LKS:

1. Age-related evolution
2. Epileptiform discharges that are of disproportionate severity in comparison with the associated clinical features
3. Sleep potentiation of epileptiform activity
4. Persistence of epileptiform discharges for years after seizure freedom.
5. Because of these similarities, it has been proposed that "benign" pediatric focal epileptic syndromes may represent a milder variation within this electroclinical spectrum.

A shared pathophysiology with different severities could potentially account for the electroclinical continuum of CSWS, LKS, and "benign" focal pediatric epilepsy syndromes. Furthermore, a genetically determined disruption of brain maturation during the first years of life may lead to hyperexcitable neuronal networks in selected cases, while other insults may also play a role. The location of the disrupted and hence hyperexcitable network then translates into different clinical features: the lower rolandic cortex that represents the face and the oropharynx could lead to the clinical features of "benign" epilepsy with centrotemporal spikes, the central autonomic neuronal networks could manifest their discharges as Panayiotopoulos syndrome, the occipital lobe that represents the cortical visual system could express their abnormalities as Gastaut-type late-onset childhood occipital epilepsy, and the involvement of the language cortex could manifest as LKS (32,33). More severe disruptions of neuronal networks as seen due to larger early developmental lesions could lead to CSWS (23,28,31). This framework of a common "seizure susceptibility syndrome" suggests that most affected children (>90%) manifest only with epileptiform discharges without clinical correlate, around 9% may present with benign pediatric focal epileptic syndromes, and in <1% of children, frequent and difficult-to-control seizures and severe neuropsychological regression may occur (33).

Frequently, patients present with electroclinical characteristics that are intermediate between the different syndromes. Further, patients with CSWS often initially present with "benign" pediatric focal epilepsy syndromes or other forms of epilepsy that later evolve into CSWS (14,34).

Genetic Predisposition

Genetic factors have been implicated in selected cases of CSWS and familial antecedents of seizures (including febrile seizures) are found in approximately 10% to 15% of the cases (4,32). A growing number of case reports and small series describe associations with copy number variations and different mutations in several chromosomes (Table 21.1). To date, the causal role of these heterogeneous genetic factors in CSWS is largely undefined. Some of these genetic variants may not be associated with CSWS per se, but with different neurologic conditions that result in the final common pathway of ESES and/or CSWS. Recently, heterozygous mutations in GRIN2A (codifying for the NMDA receptor) have been found in 27 of 359 (7.5%) patients with "seizure susceptibility syndrome" and appear to be specifically correlated with its pathophysiology (33).

Table 21.1 Genetic Factors That Have Been Described in Association with CSWS or with ESES

Study	Type of study	Association
Case reports (1995) (35)	Case series	CSWS occurred in two monozygotic twins
Praline et al. (2006) (36)	Case series	Two siblings with ESES and different clinical presentation
Verhoeven et al. (2012) (37)	Case report	One patient with CSWS and dysmorphic features carried a de novo 8q12.3q13.2 microdeletion
Coutelier et al. (2008) (38)	Case report	One patient with CSWS carried a G392R mutation in neuroserpin of probable pathogenic significance (the mutation led to a progressive neurodegenerative disease and CSWS)
Nakayama et al. (2012) (39)	Case series	Two patients with CSWS and dysmorphic features carried an unbalanced translocation between 8p and 9p
Giorda et al. (2009) (40) and Broli et al. (2011) (41)	Case series	Five patients with CSWS carried a Xp11.22-p11.23 duplication

CSWS, continuous spike-and-wave during sleep; ESES, electrical status epilepticus in sleep.
Modified from Sánchez Fernández I, Chapman KE, Peters JM, et al. Continuous spikes and waves during sleep: electroclinical presentation and suggestions for management. *Epilepsy Res Treat.* 2013;2013:583531.

Treatment

Treatment for CSWS is based on case reports and small uncontrolled series. Comparison of treatment strategies between different series is challenging because of heterogeneous patient populations, different drug doses, frequent polytherapy, variable durations of treatment, different measures of outcome, and naturally occurring fluctuations in severity over time. We will review the characteristics of different treatment options and then provide general suggestions for management.

Benzodiazepines

Benzodiazepines have demonstrated efficacy in reducing epileptiform activity. Transitory resolution of the ESES pattern was observed after the administration of clonazepam (6,8). However, the shorter half-life of diazepam may have contributed to a more frequent use in CSWS. In a series of four patients with CSWS refractory to valproate and ethosuximide, a short cycle of high-dose oral or rectal diazepam (0.5 to 1 mg/kg/day for 6 to 7 days) showed short-term efficacy in two patients (6). In a series of 15 patients with CSWS, all patients responded to high-dose rectal diazepam (46). High-dose oral diazepam (0.75 to 1 mg/kg/day for 3 weeks) was also efficacious in 3 out of 8 (37.5%) patients, but the response was temporary (14). In 29 patients with ESES and different clinical presentations, the mean epileptiform activity decreased from 77% to 41% after nocturnal administration of 1 mg/kg of oral diazepam (47). This reduction in epileptiform activity persisted for several months (48), but whether this reduction in epileptiform activity is accompanied by a sustained improvement in clinical neuropsychological features remains to be proven. Other series showed that 9 of 10 patients did not respond to valproate and benzodiazepines, and 3 patients experienced

adverse behavioral side effects (16). Adverse effects of high-dose diazepam treatment are generally considered mild and self-limited (46,47), but severe behavioral disinhibition that at times necessitates discontinuation have also been described in a few children (1,48). Small series suggest that the benzodiazepine derivative clobazam is also successful in the treatment of CSWS (30) and deserves further study.

Conventional Antiepileptic Drugs

The most commonly used antiepileptic drugs for CSWS include valproate, ethosuximide, and levetiracetam (49). In a series of 15 patients with CSWS treated with high-dose valproate alone or with valproate and ethosuximide, 10 cases (67%) responded with long-term control of their epilepsy and partial recovery of cognitive function (6). In a separate study, the combination of valproate and ethosuximide was effective in two additional patients (50). In contrast, other series did not report similar improvements after treatment with comparable medication regimens. Valproate was not effective in a series of 28 patients (14). Valproate and benzodiazepines did not lead to any improvement in seven patients and were associated with adverse behavioral reactions in three children (16). Levetiracetam was effective in several case series and also in the only placebo-controlled double-blind crossover study in patients with ESES. In this cross-over study of 18 patients, levetiracetam reduced epileptiform activity from a spike index of 56 to 37, although 3 other patients discontinued treatment because of negative cognitive side effects (51). Other drugs with some effectiveness in small series include sulthiame (14,52) and lamotrigine (24,53). Most clinicians avoid phenytoin, phenobarbital, and, especially, carbamazepine and oxcarbazepine because these drugs have been associated with exacerbation of epileptiform discharges in patients with ESES (53,54). In particular, carbamazepine and oxcarbazepine have been associated in some patients with "benign" focal epilepsies of childhood with deterioration and transformation into CSWS, although a clear causal effect has not been demonstrated (7,55).

Corticosteroids

Corticosteroids lead to improvement or even resolution of ESES in selected cases of CSWS. In a series of 44 children with ESES and clinical presentations of variable severity, prolonged corticosteroid treatment (hydrocortisone 5 mg/kg/day during the first month, 4 mg/kg/day during the second month, 3 mg/kg/day during the third month, and 2 mg/kg/day during the next 9 months followed by slow withdrawal for a total treatment duration of 21 months) led to reductions of seizures or neuropsychological improvement in 34 of 44 (77.3%) cases, with 34 patients achieving complete control of seizures and normalization of EEG abnormalities in 21 patients. The long-term remission rate was 45% (29). Inclusion of milder clinical presentations in this series may make it difficult to compare the results of this study with the results of other CSWS series that included patients with more prominent global cognitive deterioration (29). In a different study, 11 of 17 patients with CSWS responded to different corticosteroids (prednisone, methylprednisolone, or adrenocorticotropic hormone) (14). The intramuscular administration of 0.001 to 0.04 mg/kg/day of adrenocorticotropic hormone was reported to be effective in one of four patients (6). Although generally regarded effective, the side effects of corticosteroids frequently limit their long-term use.

Immune Modulation Therapy

Very limited data are available on intravenous immunoglobulins, but some series report a response to treatment in a few cases. Variable outcome results, high cost, and risks of complications associated with immunoglobulins may have prevented widespread use in the treatment of CSWS to date (14,56).

Surgery

Selected patients with CSWS may benefit from surgical treatment. In CSWS, the ESES pattern and the seizures tend to spontaneously resolve with time, and therefore, ESES as a sole indication for epilepsy surgery is debated (24). However, in patients with severe developmental regression, a well-defined structural lesion and ongoing intractable seizures, epilepsy surgery may be a very effective treatment for seizures and epileptiform activity, with some improvement in developmental regression (11). Potential surgical interventions include multiple subpial transections (MSTs), focal resective surgery of the epileptogenic zone, hemispherectomy, and corpus callosotomy. MST consists of multiple small superficial parallel cuts in the cortex that theoretically sever only the local corticocortical connections in an attempt to disrupt local horizontal epileptic circuitry without altering the vertical neural columns and their function. MSTs led to recovery of age- appropriate speech in 7 of 14 patients with ESES and acquired aphasia (57) whereas other series report less prominent language improvement (58,59). Two patients with CSWS secondary to neonatal stroke markedly improved after hemispherectomy (60). In another study, two patients with CSWS secondary to early developmental lesions in the thalamus became seizure free after a hemispherectomy in one and after an extensive corticectomy around a large porencephalic cyst in the other (28). Additionally, 13 patients with CSWS secondary to different early developmental lesions underwent various surgical procedures including anterior callosotomy (6 patients), complete callosotomy (3 patients), hemispherectomy (2 patients), and lobar resection (2 patients). Subjects achieved an overall improvement in seizure control and EEG features in most cases (15). Improvements after surgery included resolution of ESES, seizure freedom or improved seizure control, and improvements in cognitive function, with varying results among patients. Data on the long-term neurocognitive outcome of surgically managed CSWS patients are not available.

Suggestions for Management

The current literature does not permit the development of an evidence-based management approach to CSWS (Fig. 21.4). In practice, most patients with CSWS were already on a standard antiepileptic drug (valproate, levetiracetam, etc.) after seizure onset and prior to the diagnosis of CSWS. Once patients enter the acute phase, standard antiepileptic drugs, corticosteroids, and benzodiazepines may be considered as first choices depending on the particular patient and the familiarity of the physician with these drugs. Several groups have reported the usefulness of benzodiazepines, and one protocol includes application of nocturnal diazepam 1 mg/kg up to 40 mg during the first night while monitoring vital signs in the hospital followed by 0.5 mg/kg (maximum: 20 mg) upon discharge and every following night for 1 to 3 months (47,48). For chronic CSWS management, and particularly for seizure control, standard antiepileptic drugs such as valproate, levetiracetam, and ethosuximide are frequently used. Polytherapy is often needed. Medication selection should be guided by presenting seizure types. Other options include treatment with corticosteroids or adrenocorticotropic hormone. Epilepsy surgery should be considered, especially in patients with an early unilateral developmental lesion, even when the epileptiform activity on EEG is generalized. For the acute control of very active nighttime epileptiform discharges, high-dose benzodiazepines have been used over a period of

a few months. While adequate control of seizures improves the quality of life of the patients and should be pursued, it is unknown how aggressively interictal epileptiform activity in relationship with neurocognitive regression should be treated. Only prospective studies that correlate the response to treatment of interictal epileptiform activity with the improvement in neurocognitive function will be able to answer that relevant question.

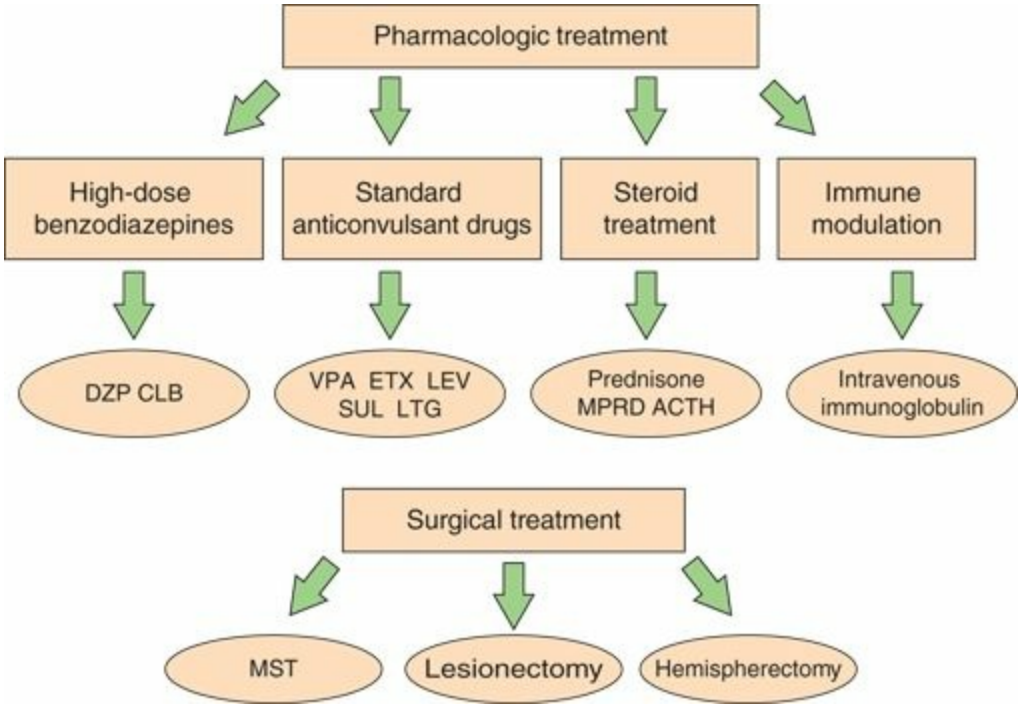

Figure 21.4. Options for the management of patients with CSWS. Options for chronic management are high-dose benzodiazepines, standard antiepileptic drugs in different combinations, and corticosteroids and immune-modulating agents. These options are considered first choice by different authors, although standard antiepileptic drugs are generally started prior to diagnosis of CSWS. Epilepsy surgery is reserved for a few selected refractory cases. ACTH, adrenocorticotropic hormone. (From Sánchez Fernández I, Chapman KE, Peters JM, et al. Continuous spikes and waves during sleep: electroclinical presentation and suggestions for management. Epilepsy Res Treat. 2013;2013:583531.)

Outcome

Important outcome variables in CSWS may be summarized in terms of clinical seizures, EEG, and neurocognition:

1 . Seizures. Clinical seizures usually resolve with age, and this age-related pattern is universal and independent of etiology, as illustrated by remissions in patients with a static structural brain lesion (24,28) and even in patients with a progressive neurodegenerative disorder (20).
2. EEG. ESES progressively resolves, and the physiologic sleep patterns frequently reappear around the same age as seizure freedom, although in some patients there is a prolonged period during which EEG abnormalities persist and can be very active even after seizure freedom (61).
3 . Development and cognitive function. A mild to moderate improvement in cognitive function is expected at the beginning of the residual stage. However, a functionally normal or near-normal outcome is very rare and at least 50% of patients remain impaired (1,4).

It is not currently known whether an effective treatment of CSWS modifies outcome (2). At a minimum, most clinicians elect to treat clinical seizures. Many will also attempt to target EEG features based on expert opinion and some studies in the literature that suggest improved cognition at times of improvement or resolution of EEG features (11,62). Despite these practices, it is important to note that to date, there is no clear evidence for or against treatment of interictal spiking patterns. It is a well-documented fact that interictal epileptiform activity disrupts cognitive processes in the short term (63,64). However, the effect of chronic epileptiform activity on cognition and the efficacy of treating epileptiform discharges for achieving better cognitive outcome remain to be clarified.

LANDAU–KLEFFNER SYNDROME

William Landau and Frank Kleffner originally described the syndrome of acquired epileptic aphasia in a series of five children in 1957 (65).

Epidemiology

LKS is an age-related epileptic encephalopathy that only occurs in children and adolescents. Some consider this clinical presentation a milder manifestation of CSWS with regression mainly in the language and at times behavioral domains. There is overlap with CSWS and distinctions are sometimes difficult to delineate. Therefore, there are limited epidemiologic data. LKS is a rare condition as illustrated by the fact that in a study of 440 epileptic children studied in an outpatient setting, only 1 (0.2%) had LKS (10). The peak age of onset is 3 to 6 years with boys affected twice as frequently as girls (2).

Electroclinical Presentation

The main characteristics of LKS can be summarized in terms of seizures, development, and EEG features.

Seizures

Seizures are infrequent and easy to treat. Approximately 20% to 30% of patients with LKS may not have any clinical seizures. The most common seizure type consists of focal motor seizures, and these occur mostly out of sleep (1,66).

Development

The most striking manifestation of LKS is the loss of language skills in children with previously normal to mildly delayed speech development. This regression typically manifests first as loss of receptive language in the form of a verbal auditory agnosia, frequently mimicking deafness. This is followed by loss of expressive language (67). The aphasia presents with subacute onset and progressive course with spontaneous fluctuations over time. Behavioral and cognitive deterioration can accompany the language regression with various degrees of severity.

EEG Features

Interictal epileptiform discharges tend to be maximal in the temporoparietal–occipital lobes. There is marked spread and potentiation of epileptiform activity during non-REM sleep. While epileptiform activity in CSWS is usually generalized with a bifrontal maximum, epileptiform discharges in LKS are typically unilateral or clearly lateralized (67).

Etiology

Structural lesions are very infrequent in LKS, and neuroimaging is not usually recommended (2). Copy number variations have been described in association with LKS, although their pathogenic significance is unclear (42).

Treatment

Seizures are easily controlled with antiepileptic drugs such as valproate, ethosuximide, clonazepam, or clobazam. Carbamazepine and oxcarbazepine are generally avoided because they have been associated with exacerbation of epileptiform discharges (54,68). Corticosteroids have been associated with improvement of the disease (29,69,70). Additionally, intravenous immunoglobulins have been successfully used in selected cases (71,72). The focus of epileptic discharges usually involves eloquent language cortex, and therefore, resective surgery is usually not an option. However, MSTs have been tried, with variable results (58,59,73).

Outcome

Seizures, when present, remit spontaneously, and the EEG pattern normalizes over time. Language improves to some degree after a variable number of years, but less than one-quarter of patients regain baseline language skills (74).

OUTLOOK

The development and validation of a common terminology and conceptualization of CSWS is critical to advance the field. A better understanding of the etiology and pathophysiology in cases with non-macroscopic lesions on MRI may unveil new treatment approaches. Finally, a most relevant question remains in CSWS: does a successful treatment of ESES improve developmental and cognitive features? The answer to this question may improve the management and eventually the outcome of patients with CSWS and many other epileptic patients with interictal and apparently subclinical discharges.

CHAPTER 22 EPILEPSY WITH REFLEX SEIZURES

CHRISTINE LINEHAN AND ANNE T. BERG

DEFINITION AND CLASSIFICATION

Although seizures occur usually unexpectedly, at least 50% of patients recognize a general or more specific precipitating factor (1). Emotional stress and physical stress are by far the most recognized factors. Physical stress includes fever, sleep deprivation, hyperventilation, drug or alcohol withdrawal, menstruation, and physical exercise. Mental or emotional stress is less clearly demonstrable and can be due to either happy occasions (birthday, Santa Claus, etc.) or more negative experiences (problems at work, and major life events like death and divorce) (2).

Seizures provoked by the above-mentioned general factors alone are, however, not considered to be reflex seizures. The provoking factor needs to be specific. Usually, the triggers are brief and sudden like flashing lights, sudden noises, and tapping, provoking especially myoclonic jerks, although they can be more complex and gradual like reading, thinking, eating, bathing, drawing, gaming, and listening to music, with less sudden seizure expressions (temporal lobe type of seizures).

In most hospital-based studies, about 6% of epilepsy patients recognize specific factors as their only or predominant precipitant of seizures. In a survey of seizure-provoking factors in a community-based cohort of adolescent (>12 years) and adult epilepsy patients, a total of 47% reported at least one factor that could provoke their seizures. Of these subjects, seizures provoked by specific factors were mentioned to be evoked predominantly by flickering lights (sunlight, stroboscope light, TV, or video games) and sounds in 17% and 5%, respectively (3); thus, more than 8% of epilepsy patients mention reflex seizures.

Reflex seizures may be classified as occurring in generalized or in focal epilepsy syndromes (4). Reflex seizures that occur in patients who also have spontaneous seizures are generally listed as seizure types, for example, photosensitive seizures in patients with juvenile myoclonic epilepsy (JME). Reflex seizures can also be classified according to the seizure trigger. If the trigger is exceptionally specific or exotic, the epilepsy is even named after the provocative factor like mahjong epilepsy, telephone epilepsy, vacuum cleaner epilepsy, and tooth-brushing epilepsy (5–8). However, it is questionable whether it is useful to make such detailed subdivisions (9).

The use of the term reflex has been and still is controversial. Marshall Hall (10) first applied it to epilepsy in 1850; he differentiated seizures precipitated by peripheral stimuli (eccentric or reflex) from central causes. About a century later, in the 1960s, Servit, a neo-Pavlovian, stated that the genesis of epilepsy can be considered as a reflex mechanism (11). Arguing that no reflex arc is involved in reflex epilepsy, others proposed terms such as sensory precipitation (12,13) or stimulus-sensitive epilepsies with simple and complex forms (14).

The International League Against Epilepsy (ILAE) (15) describes in 1989 reflex epilepsies as "epilepsies characterized by specific modes of seizure precipitation." The classification proposal of

Engel from 2001 (16) redefines reflex epilepsy syndromes as "syndromes in which all epileptic seizures are precipitated by sensory stimuli." Apart from the fact that reflex epilepsies are characterized by seizures, specific syndromes among the reflex epilepsies have also been recognized: idiopathic photosensitive occipital lobe epilepsy (IPOE), other visual-sensitive epilepsies, primary reading epilepsy, language- induced epilepsy, seizures induced by thinking, eating epilepsy, and musicogenic epilepsy (16). At the same time, the ILAE task force published a glossary of descriptive terminology for ictal semiology (17). In this glossary, a provocative factor is described as "a transient and sporadic endogenous or exogenous element capable of augmenting seizure incidence in persons with chronic epilepsy and evoking seizures in susceptible individuals without epilepsy." This article therefore distinguishes between reactive seizures (due to illness, sleep loss, or emotional stress) and reflex seizures (objectively and consistently demonstrated to be evoked by a specific afferent stimulus or by an activity of the patient). Afferent stimuli can be elementary (i.e., unstructured [light flashes, startle, a monotone]) or elaborate (i.e., structured, [a symphony]). Activity may be elementary (e.g., motor [a movement]), elaborate (e.g., cognitive function [reading, chess playing]), or both (reading aloud).

The more recent ILAE report on classification and terminology (18) has mentioned only reflex epilepsies as an electroclinical syndrome or other epilepsies with a less specific age relationship; the fact that reflex seizures were not included at all has been criticized by Panayiotopoulos (19). As an advocate of the multifactorial Lennox theory of the epileptic threshold, Shorvon introduces in his etiologic classification (2011) a new, broader, category of epilepsy, namely "provoked epilepsy" that includes the reflex epilepsies (20). This provoked epilepsy is defined as an epilepsy in which a specific systemic or environmental factor is the predominant cause of the seizures and in which there are no gross causative neuroanatomic or neuropathologic changes. Thus, until today, the definition and classification of reflex seizures and reflex epilepsies remain a point of discussion and debate: is there really a dichotomy between reflex and spontaneous seizures and—if so—to what extent? (9,20,21).

Most epileptologists refer to reflex epilepsy when a certain stimulus regularly elicits a response in the form of abnormal, paroxysmal, electroencephalographic (EEG) activity associated with or without a clinical seizure. Although some investigators restrict the term reflex epilepsy to cases in which a certain stimulus always induces seizures (22), it may include cases in which typical spontaneous seizures occur without the trigger and in which triggers do not always induce a seizure (23).

In a recent inventory of definitions used in the literature between 2002 and 2012, it was demonstrated that few definitions were identical, and definitions of a particular type varied considerably with a wide range of components being referred to as part of reflex seizures (21). Consensus on terminology thus does not exist at this moment. Reflex seizures may not differ in semiology from those encountered in other forms of epilepsy, but understanding of the seizure trigger is important in the management of the patient and helps study mechanisms of epileptogenicity. Interesting in that respect is the documentation of a 57-year-old man with temporal lobe epilepsy, who had 40% of his seizures provoked by tooth brushing, looking at the toothbrush, or even thinking about the brush (24). In this case, a somewhat wider epileptogenic network seems to be involved than usually based on the broader range of triggers.

The term "epilepsy with reflex seizures," or perhaps provoked epilepsy as suggested by Shorvon (20), to underline the unmistakable interaction between the various general and specific factors, would better reflect clinical reality and more accurately describe cases with both reflex and

spontaneous attacks.

Reflex seizures have long fascinated epileptologists. Photosensitivity or better visual sensitivity, thus comprising all types of visual stimuli like TV screens, video games, and striped patterns, is mostly recognized and studied, while making up for 90% of all reflex epilepsy patients (25). After introducing the rather simple provocation method of intermittent photic stimulation (IPS) during an EEG in the early fifties, visual sensitivity has over the years been studied intensively both clinically and electroencephalographically. Apart from epileptic photosensitivity to flickering light and other visual stimuli, other cases of reflex epilepsy such as thinking- and reading-evoked seizures are rare and permit glimpses into the organization of cognitive function.

The identification of a patient with reflex epilepsy depends on the physician's awareness and on the observations of the patient and witnesses. The epileptogenic trigger must occur often enough in everyday life so that the patient suspects its relation to the resulting seizures. If the trigger is ubiquitous, however, the seizures appear to occur by chance or with no obvious antecedent. If longer stimulation is necessary like in reading and musicogenic epilepsy, detecting a relationship between the stimulus and seizure is much more difficult. Many different triggers have been recognized and studied (5–8).

This chapter reviews the neurophysiology of reflex epilepsy from available human and animal studies. We also discuss clinical features of reflex seizures classified by the triggering stimulus.

BASIC MECHANISMS OF REFLEX EPILEPSY

There are two types of reflex epilepsy animal models. In the first, irritative cortical lesions are created, and their activation by specific stimuli is studied. The second model type involves naturally occurring reflex epilepsies or seizures induced by specific sensory stimulation in genetically predisposed animals.

The first approach has been used since 1929, when Clementi (26) induced convulsions with IPS after applying strychnine to the visual cortex. This technique also demonstrated that strychninization of auditory (27), gustatory (28), and olfactory cortex (29) produced focal irritative lesions that may produce seizures with the appropriate afferent stimulus. EEG studies showed that the clinical seizures (chewing movements), which were induced by photic stimulation in rabbits with strychnine lesions of the visual cortex, resulted from rapid transmission of the epileptic discharge from the visual cortex to masticatory areas (30). The EEG spread of paroxysmal discharges from the visual cortex may also occur in fronto-rolandic areas during seizures (31). The ictal EEG spread was thought to represent corticocortical conduction (17,31), although later work with pentylenetetrazol also implicated thalamic relays (32) and demonstrated spread of the visual evoked potential to the brain stem reticular formation (33). Hunter and Ingvar (34) identified a subcortical pathway involving the thalamus and reticular system and an independent corticocortical system for spread of visual-evoked responses to the frontal lobe. In cats and monkeys, the fronto-rolandic region was also shown to receive spreading-evoked paroxysmal activity from auditory and other stimuli (35,36).

The second approach, the study of naturally occurring or induced reflex seizures in genetically susceptible animals, has been pursued in domestic fowl and chickens with photosensitivity (37,38), rodents susceptible to sound-induced convulsions (39), the E1 mouse sensitive to vestibular stimulation (40), and the Mongolian gerbil sensitive to a variety of stimuli (41,42).

The species in which the reflex seizures and EEG findings are quite similar to those in humans is the baboon Papio hamadryas papio, better known as Papio papio from Senegal (43), except that the

light-induced epileptic discharges in baboons occur in the fronto-rolandic area rather than in the occipital lobe (44). Additionally, there is a statistically significant association of spontaneous epileptiform discharges and seizures with photosensitivity (45,46). Like in humans, photosensitivity is maximal when the animals had their eyes closed during IPS or with chemically induced pupillary dilation (47). When the light source is closer (8 cm vs. 25 cm) and its surface area is larger (128 cm^2 vs. 8 cm^2), IPS is more likely to trigger epileptic discharges. However, unlike in humans, colors of shorter wavelengths, such as blue-green and dark green, are more effective in producing EEG afterdischarges than are colors of longer wavelengths, such as red.

EEG, visual evoked potentials, intracerebral recordings, lesions, and pharmacologic studies show that visual afferents are necessary to trigger fronto-rolandic light-induced epileptic discharges. The occipital lobe does not generate this abnormal activity but sends corticocortical visual afferents to hyperexcitable frontal cortex, which is responsible for the epileptiform activity (48). The interhemispheric synchronization of the light-induced paroxysmal EEG activity and seizures depends mainly on the corpus callosum and not on the brain stem. Brain stem reticular activation depends initially on frontal cortical mechanisms until a seizure is about to begin, at which point the cortex can no longer control reticular activation. The genetically determined hyperexcitability may be related to cortical biochemical abnormalities, involving regulation of extracellular calcium concentration (49,50) or an imbalance between excitatory and inhibitory neurotransmitter amino acids (51) similar to those described in feline generalized penicillin epilepsy and in human epilepsy (52).

In recent studies in members of the baboon subspecies Papio hamadryas anubis or Papio hamadryas cynocephalus or hybrids housed in the Southwest National Primate Research Center at the SFBR in San Antonio, photosensitive baboons demonstrated increased cerebral blood flow using functional PET in the right orbitofrontal and anterior cingulate region compared to nonepileptic nonhuman primate controls. There were significant activations in the parietal and motor cortices, but no activation of the occipital lobes. In the control animals, there was an expected activation of the striate and peristriate cortices and posterior cingulate gyrus. While the activations of the motor cortices were expected due to activation of discrete myoclonic seizures, the role of the frontal and parietal lobe activations in the photosensitive baboons was unclear. The absence of occipital activation and deactivation of the posterior cingulate gyrus suggested inhibition in these areas (53).

In human epileptic photosensitivity, generalized epileptiform activity and clinical seizures can be activated by the occipital trigger. Studies in photosensitive patients who are also sensitive to black and white striped patterns suggest that generalized seizures and EEG paroxysmal activity can occur in these subjects if normal excitation of the visual cortex involves a certain “critical mass” of cortical area with synchronization and subsequent spreading of excitation (54–57). Wilkins et al. (58) suggested that a similar mechanism involving recruitment of a critical mass of parietal rather than visual cortex is responsible for generalized seizures induced by thinking or by spatial tasks. Studies of reading epilepsy also suggest that increased task difficulty, complexity, or duration increase the chance of EEG or clinical activation (59,60).

Wieser (61) proposed a neurophysiologic model for critical mass, referring to the group 1 and group 2 epileptic neurons of the chronic experimental epileptic focus described by Wyler and Ward (62). Group 1 neurons produce abundant, spontaneous, high-frequency bursts of action potentials. Group 2 neurons have a variable interspike interval, and their spontaneous epileptic activity is less marked. Moreover, these properties are influenced by external stimuli that can promote or inhibit the incorporation of group 2 neurons into the effective quantity of epileptic tissue and thus trigger or inhibit a seizure. The stimuli effective in eliciting reflex seizures would act on this population of

neurons, recruiting them into the highly epileptic group 1 neuron pool to form the critical mass needed to produce epileptogenic EEG activity or clinical seizures. This mechanism can also explain conditioning (63) and deconditioning (64) of reflex epileptic responses. A further generalizing system must also be postulated to account for the seizures observed with photic or cognitive stimulation, analogous to the corticocortical pathways linking occipital cortex with fronto-rolandic cortex in Papio papio. A role for reticulothalamic structures has been suggested but seems unnecessary, at least in certain animal models in which corticocortical spread of evoked epileptic activity persists after mesencephalic and diencephalic ablation (34).

Patients and parents may report that emotion plays a fundamental role in seizure induction, and such an observation has been also described recently in a 9-year-old girl by Gilboa (65).

Gras et al. (66) emphasized the influence of emotional content in activating EEG spikes in a patient with reading epilepsy. An emotional component was also obvious in several cases of musicogenic and eating epilepsy. Similarly, Scollo-Lavizzari and Hess (67) showed that the mere sight, memory, or anticipation of releasing stimuli could elicit the same epileptiform EEG abnormalities and seizures as did the stimulus itself.

Fenwick (68) described psychogenic seizures as epileptic seizures generated by an action of mind, self-induced attacks (e.g., by thinking sad thoughts), and those unintentionally triggered by specific mental activity such as thinking. This use of the term psychogenic seizures, common in European epileptology, does not refer to nonepileptic events. Fenwick related seizure induction and inhibition in some individuals with or without typical reflex seizures to the neuronal excitation and inhibition accompanying mental activity. He also referred to the alumina cream model, with recruitment of group 2 neurons and evoked change in neuronal activity surrounding the seizure focus as factors in seizure occurrence, spread, and inhibition.

Wolf (69) believed that two pathophysiologic theories have arisen in the discussion of reflex epilepsies. For primary reading epilepsy, he observed that seizure evocation would depend on involvement of the multiple processes used for reading, an activity involving both hemispheres, with a functional rather than a topographic anatomy. “Maximal interactive neuronal performance is at least a facilitating factor,” (69) he wrote and suggested that the functional complexity of the epileptogenic tasks leads to seizure precipitation. He contrasted this with the suggestion described previously that the latency, dependence on task duration and complexity, and influence of nonspecific factors such as attention and arousal often observed in these seizures depend on the ad hoc recruitment of a critical mass of epileptogenic tissue to produce a clinical seizure or paroxysmal EEG activity in response to the different characteristics of an effective triggering stimulus. In seizures induced by reading, thinking, IPS, and striped patterns, the relatively localized trigger induces generalized or bilateral EEG abnormalities and seizures. The recruitment that produces these seizures, however, need not be confined to physically contiguous brain tissue or fixed neuronal links. Instead, it may depend on activity of a function-related network of both established and plastic links between brain regions, modified by the effects of factors such as arousal. These two approaches share much common ground.

Disorders of cortical development based on genetic predisposition may be present in some patients with reflex seizures: musicogenic reflex epilepsy was shown in a patient with Dravet syndrome (70).

Reportedly normal imaging may be misleading; subtle changes or dysplastic lesions may be missed without special magnetic resonance imaging (MRI) techniques or may only be found in a surgical pathology specimen (71–75).

Of special interest is also the case history of a 19-year-old male with thinking-induced seizures

that occurred exclusively during acute bacterial meningitis (76). SPECT and MRI studies in patients with eating epilepsy have shown lesions near the perisylvian region (77). Future fMRI and PET studies should elucidate the preferred networks of the reflex stimulus, although many individual (genetic) differences may exist.

SEIZURES INDUCED BY VISUAL TRIGGERS

Epilepsy with reflex seizures evoked by a variety of visual stimuli in daily life (78,79) is clearly the most common reflex epilepsy. Even epidemics have occurred: after a specific Pokemon cartoon TV transmission in Japan, studies have shown that about 1% of the viewers, mainly children, had provoked seizures (in about 75% it was the first seizure) and 10% had symptoms of headache, nausea, blurred vision, vertigo, etc. (80,81). In about 40% of these cases, photoparoxysmal EEG responses or photoparoxysmal responses (PPRs) were found.

Complaints of headache are found significantly more often in photosensitive patients (twice as often) and it is also a regular finding during a PPR (78,82). Headache can also be the sole manifestation of an epileptic event and remaining complaint after AED treatment (83), especially in families with both migraine and epilepsy (84). Conversely, if children and adolescents complain about headache and are diagnosed as having migraine with aura, a PPR is found in about 30% (85).

Following the Pokemon incident, subjects known to have visually induced seizures were examined whether color modulation could be an independent factor in human epileptic photosensitivity. Among photosensitive epilepsy patients sensitive to flash and pattern stimulation, 25 of 43 were sensitive to color stimulation, particularly at frequencies below 30 per second. Red was the most effective color, and red-blue was the most provocative alternating stimulus. They concluded that "color sensitivity follows two different mechanisms: one, dependent on color modulation, plays a role at lower frequencies (5 to 30 Hz). Another, dependent on single-color light- intensity modulation, correlates with white light sensitivity and is activated at higher frequencies." This also suggests a mechanism to explain observations that colored spectacles adapted to the patient's color sensitivity may be useful for treatment (86).

Of the several abnormal EEG responses described in the laboratory, IPS and especially evoked generalized paroxysmal epileptiform discharges (e.g., spikes, polyspikes, spike-and-wave complexes) are clearly linked to epilepsy in humans. About 5% of all patients with epilepsy show this response to IPS (78,87) and 1.4% of healthy schoolchildren. No follow-up studies have been performed in these children in order to know if clinical seizures did occur later in life.

Family studies indicate an autosomal dominant mode of inheritance of PPRs with age- and sex-dependent penetrance (88,89). Several molecular genetic studies in generalized epilepsy patients with a PPR have shown evidence for linkage to chromosomes 7q32; 16p13 (90) and to 6p21.2; 13q31.3 (91). Combination of both studies and additional samples from other European countries identified 16p13.3, 5q35.3, and 8q21.13, with replication of only 16p13.3 (92). Continued research is necessary taking EEG patterns and clinical information into account.

Photosensitivity occurs most frequently in adolescents and women, but studies of the epileptic response to IPS are complicated by differences in how IPS is performed. An expert panel has recommended a protocol for performing IPS and guidelines for interpreting the EEG responses (93,94). This is also shown in a review with video (55).

Sensitivity to IPS is often divided into three groups: patients with light-induced seizures only, patients with photosensitivity and other seizure types, and asymptomatic individuals with isolated

PPRs (nonepilepsy patients or family members of epilepsy patients). However, half of known photosensitive patients questioned immediately after stimulation, denied having had brief but clear-cut seizures induced by IPS and documented by video–EEG monitoring (95). In combination with the observation that patients can start having overt (light- induced) seizures several years after discovery of a PPR as seen in family studies, any subdivision should be taken as flexible as possible. Until now, no controlled studies have been performed on evolution of the various physiologic phenomena in combination with clinical data. A flexible system using all available information can be used as a temporary informative classification. The following working categories can be discerned (82):

1. Normal individuals (no history of epileptic seizures) with a PPR in the EEG
2. A first visually induced seizure in special circumstances (TV, stroboscopic lights, video games, etc.), with or without a PPR
3. Recurrent visually induced seizures, with or without a PPR
4. Spontaneous seizures and a PPR
5. Visually induced and spontaneous seizures, without a PPR
6. Visually induced and spontaneous seizures, with a PPR

Decision about treatment should, however, always be made on an individual level based on prevention of seizures as primary goal, rather than classification in a subgroup. Criteria like extent of sensitivity to visual stimuli (range of flash frequencies, size of patterns, reaction to TV/computer screens) and severity of seizures or complaints in combination with age and lifestyle are important.

For educational purposes, we discuss two commonly encountered discriminative clinical manifestations in more detail: (i) recurrent visually induced seizures and (ii) spontaneous seizures and a PPR. In reality and dependent on available EEG, clinical, and follow-up information data, there is an overlap. Although most patients are sensitive to various visual triggers (96), patients can similarly be roughly divided in those primarily sensitive to flicker (the majority) and those sensitive to pattern. A specific category of patients are the self-inducers; they use their sensitivity to visual stimuli to evoke PPRs. Self-induction is therefore described in a subsection.

Patients with Recurrent Visually Induced Seizures

According to Jeavons (97), 40% of photosensitive patients have generalized seizures provoked exclusively by a flickering light source, and television is the most common precipitating factor. Video games may also trigger these generalized seizures (96,98). Other typical environmental stimuli include discothèque (stroboscopic) lights and sunlight reflected from snow or the sea or interrupted by roadside structures or trees. Rotating helicopter rotors and tower-mounted wind turbines, which can reflect or break up light into flicker, also present risk (99,100).

In this category, female adolescents are typically overrepresented. Reviews of the topic have been provided by several authors (78,87,95,101). The seizures are generalized tonic–clonic in 84% of patients (102), absences in 6%, partial motor seizures (possibly asymmetric myoclonus in some cases) in 2.5%, and myoclonic seizures in 1.5% of patients. Subtle myoclonic seizures may go unnoticed until an obvious seizure occurs. The developmental and neurologic examinations are normal. The resting EEG may be normal in about one-half of patients, but spike-and-wave complexes may be seen with eye closure. IPS evokes a PPR in virtually all patients. Depending on the photic stimulus and on the patient's degree of photosensitivity, the clinical response ranges from subtle

eyelid myoclonus to a generalized tonic–clonic convulsion.

These photosensitive patients are typically conceptualized as having a variety of genetic generalized epilepsy, but cases occur in which EEG and clinical evidence favors the occipital lobe origin, as predicted by theoretical and animal models (103,104). IPS can also induce clear-cut partial seizures originating in the occipital lobe (105,106). As in more typical photosensitive subjects, environmental triggers include television and video games. Many of these patients have IPOE, a relatively benign, age-related syndrome without spontaneous seizures, although cases with occipital lesions have been reported, including patients with celiac disease. The clinical seizure pattern depends on the pattern of spread. The visual stimulus triggers initial visual symptoms that may be followed by versive movements and motor seizures; however, migraine-like symptoms of throbbing headache, nausea, and sometimes vomiting are common and can lead to delayed or incorrect diagnosis.

Since the seizures are provoked by visual stimuli, the best prevention is avoidance, or modification of the environmental light stimuli, such as increasing the distance from the television set, watching a small screen in a well-lighted room, using a remote control so that the set need not be approached, and monocular viewing or the use of polarized spectacles to block one eye, should provide protection (97,107). Colored spectacles may be useful in selected cases (108,109).

Drug treatment is needed if these measures are impractical or unsuccessful or if photosensitivity is severe. The drug of choice, in particular in male patients, is valproate. Valproate abolishes PPRs in 54% of patients and markedly reduces it in additional 24% (110). In females, preference goes to levetiracetam (95) and lamotrigine. Benzodiazepines such as clobazam (111) may be also useful. About one-fourth of patients lose their photosensitivity by 25 years (112). Because this resolution usually occurs only in the third decade, too early withdrawal of treatment may facilitate seizure recurrence; serial EEG recording to determine the photosensitivity range may be helpful in assessment and during follow-up (94,95).

Patients with Spontaneous Seizures and PPR

Jeavons and Harding (102) found that about one-third of their photosensitive patients with environmentally precipitated attacks also had spontaneous seizures. Spike-and-wave activity was common in the resting EEG patterns of patients with spontaneous seizures, and only 39% of patients had normal resting EEGs. PPRs may accompany idiopathic generalized epilepsies, especially JME, and is associated with onset in childhood and adolescence, normal intellectual development and neurologic examination, normal EEG background rhythm, and generally good response to treatment. Photosensitive benign myoclonic epilepsy may also begin in infancy, with a generally good prognosis though the events may be overlooked by the parents for some time before diagnosis (113). PPRs also may occur with severe myoclonic epilepsy of infancy or Dravet syndrome (114) or with diseases associated with progressive myoclonic epilepsy syndromes like Lafora body disease, Unverricht–Lundborg disease, and the neuronal ceroid lipofuscinoses (114). Photosensitivity is generally seen in eyelid myoclonia with absences (EMA) but not in benign occipital epilepsies of childhood of the Gastaut or Panayiotopoulos types despite the florid EEG abnormalities (114).

Seizures Induced by Patterns

Absences, myoclonus, or more rarely, tonic–clonic seizures may occur in response to epileptogenic

patterns. These are striped and include common objects such as the television screen at short distances, video games, curtains or wallpaper, escalator steps, and striped clothing. Pattern sensitivity is seen in about 70% of photosensitive patients tested with patterned IPS in the EEG laboratory, but sensitivity to stationary striped patterns affects only about 30% (56). However, clinical pattern sensitivity is not easily recognized: patients often may not make the association, the family may be unaware of it, and physicians may not inquire about it.

Wilkins et al. (55,57,115–117) studied the properties of epileptogenic patterns, isolating visual arc size, brightness, contrast, orientation, duty cycle, and sensitivity to movement and binocularity. They concluded that the seizures involve excitation and synchronization of a sufficiently large number of cells in the primary visual cortex with subsequent generalization. We can compare this with the previously described animal experiments and Wieser's theory. Pattern sensitivity optimally requires binocular viewing, and treatment may be aided by avoidance of environmental stimuli (admittedly often impractical) as well as by alternating occlusion of one eye with polarizing spectacles and increased distance from the television set. A high degree of pattern sensitivity requires antiepileptic drug treatment, as described for the predominantly flicker-sensitive patients.

Seizures Induced by Television and Other Electronic Screens

Television likely remains the most common environmental trigger of photosensitive seizures. A television screen produces flicker at the main frequencies, generating IPS at 60 Hz in North America and 50 Hz in Europe. Jeavons and Harding (102) found that photosensitivity was more common at the lower frequency, which partly explained the higher incidence of television-induced seizures in Europe as compared to North America. Television-induced seizures, however, are not related to alternating current (AC) frequency flicker alone. Wilkins et al. (116,117) described two types of television-sensitive patients: those sensitive to IPS at 50 Hz, who apparently were sensitive to whole-screen flicker even at distances >1 m from the screen, and patients not sensitive to the mains frequency flicker but who responded to the vibrating pattern of interleaved lines at half the AC frequency, which can be discerned only near the screen. They emphasized that increased distance from the screen decreased the ability to resolve the line pattern and that a small screen evoked less epileptiform activity than a large one. Binocular viewing was also needed to trigger attacks.

Not surprisingly, domestic video games using the home television screen viewed at close distances for long periods and sometimes under conditions of sleep deprivation and possible alcohol or nonmedical drug use can trigger seizures in predisposed individuals. Some individuals are not photosensitive and may have seizures by chance or induced by thinking or other factors. These events, however, have caused many patients with epilepsy to believe erroneously that they are at risk of seizures evoked by video games, and they need accurate information about their personal risk (118).

Not all seizures triggered by television and similar screens fit this pattern. Seizures can be triggered even at greater distances and by noninterlaced screens without flicker. Flashing or patterned screen content is implicated in such episodes including that from video games. Nevertheless, the 50/25-Hz frequency appears to be a powerful determinant of screen sensitivity, and in countries with 50-Hz AC, special 100-Hz television sets have been shown to reduce the risk of attacks (119). Other preventive measures include watching a small screen from afar in a well-lighted room, using a remote control to avoid approaching the set, and covering one eye and looking away if the picture flickers or if myoclonia occurs (120).

Broadcasting of certain forms of flashing or patterned screen content has been responsible for

outbreaks of photosensitive seizures, most notably in Japan where 685 people, mostly children and young adults with no history of epilepsy, were hospitalized after viewing a cartoon (121). The details of triggering factors in screen images have been summarized (122) and were used to develop broadcast standards in the United Kingdom and Japan, which now reduce this risk. Electronic filters have also been proposed (123). Modern displays, like liquid crystal, organic and polymer light-emitting diodes, and plasma-driven panels, all generate their light output in a different way, and it will probably depend on the size of the screen, the contrast, and the luminance as to whether these provoke seizures in photosensitive patients.

Further outbreaks are to be expected if viewers, especially mass audiences of adolescents, are exposed to such screen content when guidelines do not exist or are violated (124). The diversity in screens and programs combined with at random exposure to potentially epileptogenic triggers might make it much more difficult to recognize this form of photosensitivity.

Self-Induced Seizures

Reports of self-induced epileptic attacks using visual sensitivity antedated the discovery of the photoconvulsive EEG response (125). Regarded as rare, self-induction was reported particularly in mentally retarded children and adolescents, with a female preponderance (78,87,126,127). More recent information, however, shows that although some affected patients are mentally challenged, most patients have relatively normal or only mildly delayed development (128–130). When carefully sought, the syndrome is not rare; it was found in about 40% of photosensitive patients studied by Kasteleijn-Nolst Trenité et al. (128). The EEG usually shows spontaneous generalized spikes or spike-and-wave complexes, and about 75% of patients are sensitive to IPS. The self-induced seizures are usually myoclonic, especially with palpebral myoclonus, or absences, and some patients have EMA. Patients induce seizures with manoeuvers that cause flicker, such as waving a hand with fingers spread apart in front of their eyes or gazing at a vertically rolling television image. Monitoring (130,131) shows that these behaviors, once thought to be part of the seizure, precede the attacks and are responsible for inducing them. The compulsive nature of this behavior has been observed often and has been likened to self-stimulation (132) in experimental animals. Patients have reported intensely pleasant sensations and relief of stress with self-induced photosensitive absence seizures (129,130). Frank sexual arousal has been described (133,134). Patients are often unwilling to give up their seizures, and noncompliance with standard, well-tolerated antiepileptic drugs is common (128,129). Treatment is difficult, however, even in compliant patients (127). Drugs that suppress self-stimulation in animals, such as chlorpromazine and pimozide, may block the pleasurable response without affecting the response to IPS and have partially reduced or completely terminated self-induction (127,135). The effectiveness of valproate in reducing or abolishing photosensitivity has resulted in virtual disappearance of this form of self-induction, which is now encountered in patients for whom the drug has not been prescribed and in those with inadequate drug levels for any reason.

Quesney et al. (136) proposed a dopaminergic mechanism in human epileptic photosensitivity based on the transient abolition of photosensitivity with apomorphine, and bromocriptine and parenteral L-dopa have been reported to alleviate photosensitivity (137,138). Based on these findings, a candidate linkage study on the five dopamine receptor gene regions of DRD1 to DRD5 was performed in families with PPR, but none of these loci were found to be linked to the PPR (139).

In Dravet patients who self-induce, treatment with the serotonergic drug fenfluramine and the

voltage-gated calcium channel blocker verapamil has been effective (140,141). However, many patients appear not to want treatment for their self-induced attacks. Photosensitive patients may induce seizures with maneuvers that do not produce flicker. These attacks are similar to flicker-induced seizures, but the inducing behaviors are not. Pattern-sensitive patients may be irresistibly drawn to television screens, which they must approach closely to resolve the epileptogenic pattern of vibrating lines, or they may spend hours gazing through venetian blinds or at other sources of pattern stimulation. Those sensitive to eye closure have been observed to use forceful slow upward gaze with eyelid flutter (142,143) to induce paroxysmal EEG discharge and, at times, frank seizures. These patients are often children, who describe the responses as pleasant: "as nice as being hugged, but not as nice as eating pudding" (Kasteleijn, personal observation). We have noticed that these tonic eyeball movements are always associated with spike-and-wave activity in young individuals. As they mature, their movements may persist but no longer elicit epileptiform activity and can be likened to a tic learned in response to positive reinforcement. These observations and the compulsive seizure-inducing behavior of many such patients suggest that, as in flicker- induced seizures, the self-induced attacks provide pleasure or relieve stress. Experience suggests that treatment is similarly difficult (128). They must be distinguished from rare seizures occurring with eyes closed or with loss of central fixation. Panayiotopoulos et al. (144,145) studied these extensively and described the syndromes in which they occur.

SEIZURES INDUCED BY COMPLEX NONVISUAL ACTIVITY

Reflex epilepsy with nonvisual stimuli is rare though reflex seizures with JME are more common than previously thought (146,147). In a Brazilian study, the following triggers were found to be provocative in adult JME patients based on questionnaires: thinking and concentration (23%), praxis (20%), visual stimuli (15%), speaking in public (11%), reading (7%), calculating and writing (5%), music-related activities (5%), and drawing (3%).

Seizures may be classified as those with relatively simple somatosensory triggers (bathing, rubbing, etc.) and those triggered by complex activity, such as thinking, eating, listening to music, or gaming [for reviews, see Gastaut and Tassinari (142) and Striano et al. (148)]. There are clear differences between populations regarding prevalence of specific reflex stimuli: in India, eating and hot water bathing (pouring hot water on the head) are the most prevalent triggering factors (149), while in Caucasians, language-related stimuli like reading and writing are more common.

Seizures Induced by Thinking and Gaming

Wilkins et al. (58) introduced the term seizures induced by thinking to describe a patient who reported seizures induced by mental arithmetic but who proved also to be sensitive to tasks involving manipulation of spatial information with or without any motor activity. Other complex mental activities have been reported to trigger seizures, such as card games and board games, such as checkers (British, draughts), mahjong, go and Baduk games, or making complex decisions. A rather consistent electroclinical syndrome emerges, most succinctly called seizures induced by thinking, reviewed in Andermann et al. (150). EEG monitoring during detailed neuropsychological testing is not always performed, and this peculiar type of reflex epilepsy might thus be more common than originally estimated. Reading is not usually an effective trigger, and unlike reading epilepsy, most

patients also have apparently spontaneous attacks. The seizures are typically generalized myoclonus, absences, or tonic–clonic attacks, and the induced EEG abnormalities are almost always generalized spike-and-wave or polyspike-and-wave activity. Focal spiking is found in only about 10% of patients, and photosensitivity is seen in about 25%. Although numbers are small, most subjects are men. The mean age of onset is 15 years. Family histories of epilepsy are neither typical nor helpful in the diagnosis. Avoidance of triggering stimuli is practical only when activation is related to cards or other games, but drugs effective in idiopathic generalized epilepsies have been most useful. Epileptogenic tasks in these patients involve the processing of spatial information and possibly sequential decisions. The generalized seizures and EEG discharges may depend on initial involvement of parietal or, possibly, frontal cortex and subsequent generalization, much as pattern-sensitive seizures depend on initial activation of primary visual cortex. Recent studies provide more detail on the cerebral representation of calculation and spatial thought and document a bilateral functional network activated by such tasks (151). Similar results were found in a Korean study in 11 patients with seizures exclusively being experienced while playing Go–stop or Baduk games with one interesting difference: the mean age at onset was 53.7 years, and they had played the games without any problem for many years since adolescence (152).

Praxis-Induced Seizures

Japanese investigators (153) have described praxis-induced seizures as myoclonic seizures, absences, or generalized convulsions triggered by activities as in seizures induced by thinking but with the difference that precipitation depends on using a part of the body to perform the task (e.g., typing). Hand or finger movements without "action-programming activity" (defined as "higher mental activity requiring hand movement" and apparently synonymous with praxis) are not effective triggers (154). EEG responses consist of bisynchronous spike or polyspike-and-wave bursts at times predominant over centroparietal regions. Most subjects have JME; some had another idiopathic generalized epilepsy syndrome. None had clear-cut localization-related epilepsy. In its milder forms, such as the morning myoclonic jerk of the arm manipulating a utensil (M. Seino, personal communication, 1999), this phenomenon resembles cortical reflex myoclonus as part of a "continuum of epileptic activity centered on the sensorimotor cortex" (155). It also appears to be another manifestation of triggering of a generalized or bilateral epileptiform response by a local or functional trigger (156), in this case requiring participation of the rolandic region of one or both hemispheres, which may be regionally hyperexcitable in JME (157). The seizures of idiopathic generalized epilepsy may involve only selected thalamocortical networks (158), and this seems especially so in JME (159).

Seizures Induced by Reading

Bickford et al. (160), in 1956, first identified primary and secondary forms of reading epilepsy. The primary form consists of attacks triggered exclusively by reading, without spontaneous seizures. Age at onset is typically between 12 and 25 years. Patients report characteristic jaw jerks or clicks. If reading continues, a generalized convulsion may occur. Prolonged reading-induced partial seizures with ictal dyslexia, bilateral myoclonic seizures, and absences have been reported. The resting EEG pattern is normal, but during reading, abnormal paroxysmal activity is recorded, often consisting of sharp theta activity that may be generalized (142,160–163) or localized to either temporoparietal

region, especially on the dominant side (164,165). These abnormalities frequently are correlated with the jaw jerks, and monitoring also shows perioral reflex myoclonus similar to that seen in JME. Bilateral or asymmetric myoclonic attacks or jerks of the arms and head also similar to those of JME may also occur, with bilaterally synchronous spike-and-wave activity.

Patients with primary reading epilepsy are typically developmentally normal, with normal neurologic examinations. No structural lesions have been demonstrated. A family history of epilepsy is common, and familial reading epilepsy has been reported (165,166). Patients with secondary reading epilepsy also have spontaneous seizures without jaw jerking and often have an abnormal baseline EEG. Primary reading epilepsy was classified as an idiopathic, age-related, localization-related epilepsy, but its focal nature has recently been questioned (16,167). Attacks are induced by reading and may be reproduced easily in sensitive subjects. Functional MRI has shown (168) activations in most subjects in areas overlapping or adjacent to those physiologically activated during language and facial motor tasks, including subcortical structures as also noted by Archer et al. (169). Reading epilepsy seems to be an example of activation of a hyperexcitable network, which can produce seizures when sufficient critical mass is incorporated by adequate stimuli to produce a seizure, at times a seizure of apparently generalized epilepsy. We have noted that it may rely on both existing and reorganized functional links between brain regions and need not be confined to physically contiguous brain sites or established neuronal links.

The triggering stimulus in reading epilepsy is unknown, but several authors have speculated about the origin. Bickford et al. (160) proposed that normal sensory stimuli influenced some hyperexcitable cortical focus. Critchley et al. (164) emphasized several factors: the visual pattern of printed words, attention, proprioceptive input from jaw and extraocular muscles, and conditioning. Forster (64) theorized that the seizures were evoked by higher cognitive functions; however, patients with primary reading epilepsy are not photosensitive, deny other precipitating cognitive stimuli, and do not appear to have thinking-induced seizures. Patients with the latter almost always deny activation by reading. A recent detailed study in one patient showed that the alphabetical nature of written stimuli triggered his seizures (170). Another single patient with otherwise clear-cut primary reading epilepsy reported induction by card playing while drinking beer (171). Comprehension of the material being read is essential in some cases and irrelevant in others, suggesting that attention is not sufficient to precipitate seizures. Studies suggest that increased difficulty, complexity, or duration of a task increases the chance of EEG or clinical activation (59,60).

Functional imaging has shown that these seizures result from activation of parts of a speech and language network in both hemispheres (172), confirming that the hyperexcitable neuronal tissue forming the critical mass is not necessarily contiguous but is functionally linked, as discussed by Salek-Haddadi et al. (168), by Rémillard et al. (173), and by Safi et al. (170). A mechanism similar to that in pattern-sensitive epilepsy, in which generalized activity is activated by the occipital cortical stimuli, may operate in some cases of primary reading epilepsy in which bilateral myoclonic attacks or bilaterally synchronous epileptiform activity is triggered.

Primary reading epilepsy generally responds well to valproate, and benzodiazepines or lamotrigine is expected to be useful as well, but patients often decline treatment especially if they have only jaw jerks. Exquisite treatment response to levetiracetam was reported in two patients, one with primary and one with secondary reading epilepsy (174).

Language-Induced Epilepsy

Geschwind and Sherwin (175) described a patient whose seizures were induced by three components of language: speaking, reading, and writing. Some other cases have been reported since. Similar to those in primary reading epilepsy, the seizures consist of jaw jerks, with focal (161,176–178) or generalized (175) abnormal paroxysmal EEG activity during language tasks. In some patients, isolated components of language were the only effective seizure triggers. Writing (179,180), typing (132), listening to spoken language (181), and singing or recitation (182) have been reported as isolated triggers. Writing or speaking may activate patients with reading epilepsy (178,183), and exceptionally, reading epilepsy occurred in a patient who was also activated by card games (172). We consider activation by drawing (184) to be part of seizures induced by thinking, and other patients believed to have language-induced epilepsy may have thinking-induced seizures. This heterogeneity suggests that the definition of a language-induced epilepsy is not clear-cut. Cases may form part of relatively more stereotyped syndromes of reading epilepsy, whose definition should be broadened. Alternatively, Koutroumanidis et al. (172) suggested that primary reading epilepsy might be classified as a variant of a more broadly defined language-induced epilepsy. The association of reflex language-induced epilepsy and idiopathic generalized epilepsy was explored by Valenti et al. (184) and is of interest since some patients with reading epilepsy also seem to have an underlying generalized epilepsy.

Seizures Induced by Music

The rare musicogenic epilepsy consists of seizures provoked by hearing music. The music that triggers seizures is often remarkably specific in any one patient, and no consistent epileptogenic features of musical sound can be identified. A startle effect is not required. Many patients have spontaneous attacks as well. Some attacks can be provoked by music and by nonmusical sounds such as ringing or whirring noises from telephones or vacuum cleaners (6,7). In some patients, an effective musical stimulus often induces emotional and autonomic manifestations before the clinical seizure begins. Patients may report triggers with personal emotional significance. However, in some patients, the triggers have no particular connotations (185), while in others, they may (186). Triggers without particular emotional significance can induce the typical autonomic features before the clinical attack (187,188). Establishment of the seizure as a conditioned response has also been suggested (142,185,187,189), but this view is not generally accepted (190). A case with self-induction possibly motivated by emotional factors has been described (191). Musicogenic attacks may appear only in adulthood, often in the context of a preexisting symptomatic localization-related epilepsy. Many case reports antedate intensive monitoring and modern imaging, but the seizures appear to be simple or complex partial, and epileptiform EEG abnormalities are recorded focally from either temporal lobe but more frequently over the right side. Mesial temporal and lateral temporal seizure onsets have been documented (192).

The pathophysiology of musicogenic epilepsy is obscure. Studies in epileptic subjects not sensitive to music show that musical stimuli may have widespread effects on neuronal activity in human temporal lobes, extending well beyond the rather restricted primary auditory area (193); that different components of music have different effects, possibly with specialized lateralization and localization; and that the effects of music differ from those of speech (194,195). Components of musical stimuli such as melodic contour and perception of unfamiliar pitch patterns are processed by cortical subsystems rather than by a nonspecific music area of the brain (196–198). Functional imaging of musical perception has been reviewed (199). Wieser et al. (200) suggested a right

temporal predominance for musicogenic seizures. Right anterior and mesial hyperperfusion during ictal single- photon emission computed tomography has been documented (199,201), and later, detailed coregistration functional imaging supported a privileged role for right temporolimbic activation (202). Zifkin and Zatorre (203) note that more complex musical processing tasks activate more cortical and subcortical territory bilaterally, although with right hemisphere predominance. Hyperexcitable cortical areas could be stimulated to different degrees and extents by different musical stimuli in patients sensitive to these triggers. Gloor (204) suggested that responses to limbic stimulation in epileptic subjects depend on widespread neuronal matrices linked through connections that have become strengthened through repeated use of interest in considering the delay from seizure onset to the development of sensitivity to music and the extent of the networks involved in musical perception.

The extreme specificity of the stimulus in some patients and the delay from stimulus to seizure onset can be useful in preventing attacks, but these seizures usually occur in patients with partial seizures, and appropriate antiepileptic drugs are generally required. Intractable seizures should prompt evaluation for surgical treatment. Furthermore, in musicians, right temporal lobectomy can cause loss of musicality (205).

Seizures Induced by Eating

Boudouresques and Gastaut (206) first described eating epilepsy in four patients who experienced seizures after a heavy meal. Gastric distention may have been at least partly responsible for the attacks (207), but many such seizures occurred early in the meal and were unrelated to gastric distention (208,209). The clinical characteristics are usually stereotyped in individual patients, but there are few common features among patients. Some patients have seizures at the very sight or smell of food, whereas others have them only in the middle of a meal or shortly afterward. In some patients, the seizures may be associated with the emotional or autonomic components of eating; in others, they are associated with sensory afferents from the tongue or pharynx. These seizures have also been documented in young children, in whom they can be mistaken for gastroesophageal reflux (210).

Seizures with eating are almost always related to a symptomatic partial epilepsy. Cases in which the seizures were generalized from onset are exceptional (211). Rémillard et al. (173) suggested that seizures in patients with temporolimbic epilepsy are activated by eating from the beginning of their seizure disorder and continue to have most seizures with meals. In contrast, patients with localized extralimbic, usually postcentral, seizure onset develop reflex activation of seizures later in their course, with less constant triggering by eating and more prominent spontaneous seizures. These patients typically have more obvious lesions and findings on neurologic examination.

The mechanism of eating epilepsy is unclear. Several investigators suggest that interaction of limbic and extralimbic cortices (212) and contributions from subcortical structures, such as from the hypothalamus (67,206,213), are particularly important. Other proposed triggering mechanisms include a conditioned response, mastication (213), stimulation of the esophagus (214), and satisfaction of a basic drive (210). Rémillard et al. (173) suggested that seizures with extralimbic, suprasylvian onset, often involving obvious structural lesions, may be activated by specific thalamocortical afferents. Detailed studies of three male and three female patients with eating epilepsy in India showed ictal rhythmic slowing/fast activity in parietotemporal (n = 2) or frontotemporal (n = 4) regions with subsequent secondary generalization in three. Ictal and interictal SPECT imaging showed changes in frontal lobe (n = 1), anterior temporal lobe (n = 1), and

parietoinsular region (n = 1), suggesting that these areas are part of the ictal onset zone (77).

That obvious combinations of several stimuli are required in some cases (215,216) added to the circumstantial evidence favoring an interaction among cortical areas and diencephalic structures, which in other cases could involve less obvious combinations of stimuli. When the abnormal cortex is located in regions responding to proprioceptive and other sensory afferents (especially lingual, buccal, or pharyngeal) activated by the extensive sensory input generated by a complex behavior such as eating, patients may be more sensitive to the physical manipulation of food, texture, temperature, and chewing. They may also have seizures induced by activities such as brushing teeth. These patients have extralimbic seizure onset. This mechanism may be similar to that described for other proprioceptive or somatosensory-induced seizures (155). A similar mechanism, but with afferents recruiting hyperexcitable temporolimbic structures, may also operate in subjects with temporolimbic seizure onset, who may be more sensitive to gustatory, olfactory, affective, or emotional stimuli or to stimuli arising from more distal parts of the gut. Alerting stimuli have been reported to abolish attacks (217), providing further circumstantial evidence for the participation of an increasing cortical mass and of subcortical influences in some cases of reflex epilepsy.

The extraordinarily high frequency of seizures associated with meals in Sri Lanka (218) may be ascribed to the inclusion of all attacks occurring from 0.5 hours before to 0.5 hours after eating. This does not correspond to eating epilepsy as defined here.

Proprioceptive-Induced Seizures and Startle Epilepsy

Proprioceptive-induced seizures include those that appear to be evoked by active or passive movements. Gowers (219) first described seizures induced by movement in humans, and they have been characterized as movement-induced seizures. Studies in the monkey by Chauvel and Lamarche (220) suggest that proprioception is the most important trigger and that the term movement-induced seizures is incorrect. Spontaneous and reflex seizures were observed with a chronic alumina focus in the cortical foot area. Reflex motor attacks were triggered by active or passive movement of the contralateral limb and by tapping the hindlimb tendons. The stimuli activating proprioceptive afferents to a hyperexcitable cortical area triggered seizures. Seizures could not be elicited in the curarized animal. In humans, focal reflex or posture-induced seizures can be transiently observed in patients with nonketotic hyperglycemia, resolving only with metabolic correction. Interictal focal neurologic deficits are seen as evidence of underlying cortical dysfunction (216,221). Proprioceptive afferents, rather than the observed movements, are implicated in seizure precipitation in animal studies and probably in humans (222), although the case reported by Gabor (223) is a possible exception. Arseni et al. (224) and Oller-Daurella and Dini (225) have confirmed the epileptic nature of these attacks.

Startle epilepsy involves seizures induced by sudden and unexpected stimuli (226,227). Typically lateralized and tonic, the seizures are often associated with developmental delay; gross neurologic signs, such as hemiplegia; and cerebral lesions (228–230). Computed tomography scans often show unilateral or bilateral mesial frontal lesions (225); patients with normal scans have had dysplastic lesions identified on MRI (231). Electroencephalograms with depth electrodes have shown initial ictal discharge in the supplementary motor area (232) and mesial frontal cortex (233). These represent a symptomatic localization-related epilepsy and are often medically intractable. Most patients have other spontaneous seizures.

Proprioceptive-induced seizures can be confused with nonepileptic conditions. Clinical and EEG

findings should permit differentiation of startle epilepsy from startle disease or hyperekplexia and from other excessive startle disorders (234–236) and should exclude cataplexy and myoclonic epilepsy syndromes. Apparent movement-induced seizures without startle must be distinguished from paroxysmal kinesigenic choreoathetosis, in which movements are clearly tonic and choreoathetoid, consciousness is preserved, and the EEG pattern remains normal during attacks (seizures induced by somatosensory stimulation). Seizures may be induced by tapping or rubbing individual regions of the body (155). These are partial seizures, often with initial localized sensory symptoms and tonic features, and typically occur in patients with lesions involving postrolandic cortex. A well-defined trigger zone may be found, for example, in patients whose seizures are triggered by brushing the teeth (237). Drugs for partial seizures are needed, but the seizures may be intractable and require evaluation for surgery.

Reflex drop attacks elicited by walking (238) are seen rarely in patients with reflex interictal spikes evoked by percussion of the foot (239). We consider these to be a variety of seizures induced by proprioceptive stimulation. They are interesting because, unexpectedly, individuals with the interictal-evoked spikes do not usually have such attacks. This disorder probably represents a form of idiopathic localization-related epilepsy of childhood, distinct because of the parietal lobe involvement, though underlying dysplastic lesions cannot be excluded. Participation of a more elaborate network for motor programming cannot be excluded in some cases especially if the effective stimulus seems restricted to activities such as walking (240).

Touch-Evoked Seizures

Seizures can be evoked by simple touch (i.e., “tap” seizures), apparently unrelated to proprioceptive afferents (241,242), although startle may be important. These reflex-generalized myoclonic attacks and associated bilateral spike-and-wave EEG discharges occur without evidence of lateralized lesions; the family history may be positive (243). Seizures typically occur in normal infants and toddlers and can represent an idiopathic and relatively benign generalized myoclonic epilepsy syndrome rather than a progressive myoclonic encephalopathy (244,245). They usually respond to valproate, but prolonged treatment may not be needed.

Seizures Induced by Hot Water

Seizures triggered by immersion in hot water were first described in 1945 (246). The condition is rare in Japan, the Americas, and Europe but seems to be more common in India (247,248). Little EEG documentation is available, but the epileptic nature of these attacks has been confirmed in some patients (249,250). Indian patients are typically boys, with a mean age at onset of 13.4 years. Patients experience complex partial or generalized tonic–clonic seizures during ritual bathing when jugs of hot water are poured over the head. Startle and vasovagal events cannot be excluded in many cases nor can they be discounted in some North American, European, and Japanese reports. These cases typically involve younger children than in India, with complex partial seizures occurring as soon as the child is immersed in hot water; sensitivity often diminishes with time (251). A mechanism involving defective thermoregulation has been proposed, and some of the attacks may be a form of situation-related seizure with age-dependent occurrence similar to febrile convulsions (246). However, many Turkish subjects have interictal temporal EEG abnormalities and complex partial seizures (252); spontaneous seizures have been reported in most Turkish subjects if the reflex attacks

begin after early childhood (252).

Miscellaneous Reflex Seizures

Other unusual reflex stimuli have been described, usually as occasional clinical case reports but more recently with improved EEG and radiologic documentation. Vestibular stimuli have been reported to induce seizures. It is important to exclude startle effects with caloric stimulation, for example, and to take into account the time required for caloric stimulation to be effective (253).

Klass and Daly reported the extraordinary case of a child with generalized seizures self-induced by looking at his own hand. By 4 years of age, medications were withdrawn, and no further seizures, reflex or otherwise, occurred in 26 years of follow-up (254). The EEG was said to be normal. A similar case has been reported (64). Other remarkable reflex seizures are those provoked by micturition (255).

CONCLUSIONS

Reflex seizures and reflex epilepsy continue to challenge and puzzle neurologists and neurophysiologists. Intensive monitoring and advances in imaging have helped to clarify some of the mechanisms involved in these cases, which must represent some of nature's more complex experiments. Cortical and subcortical networks are involved.

Reflex seizures can occur with any epilepsy type, and although the stimulus might be very specific, the epilepsy phenotype is not. Treatment or better prevention of seizures is achieved in many patients primarily by avoidance (for example, no more disco visits) or modification (different TV set and vacuum cleaner; wearing blue lenses) of the specific stimulus or change in behavior (no more self-induction). If AEDs are nevertheless necessary to suppress seizures, drugs active in focal as well as generalized epilepsies have been found successful.

Continued progress in understanding the basic mechanisms of epilepsy through reflex seizures depends on the skill and imagination of neurologists and at least as much on their patients, for whom these studies are dedicated (256–262).

CHAPTER 23 RASMUSSEN SYNDROME

FRANÇOIS DUBEAU

Rasmussen encephalitis (RE) is a sporadic, progressive, inflammatory disorder of childhood, associated with hemispheric atrophy, severe focal epilepsy, intellectual decline, and hemiparesis. Neuropathologic features described in the surgical specimens show characteristics of chronic inflammation such as perivascular and leptomeningeal lymphocytic infiltration, microglial nodules, astrocytosis, and neuronal degeneration. There are variants of this syndrome with regard to age at onset, staging, localization, progression, and outcome. Treatment options are limited. Antiepileptic drugs (AEDs) usually show no significant benefit. Immunotherapy trials (undertaken mostly after the 1990s) showed some improvement in symptoms and disease progression in a proportion of patients. Only hemispherectomy, or variants of functional hemispherectomy, seems to produce persistent relief of seizures and functional improvement.

The disorder was first described by Dr. Theodore Rasmussen in 1958, who, together with Jerzy Olszewski and Donald Lloyd-Smith, published the clinical and histopathologic features of three patients with focal seizures caused by chronic focal encephalitis (1). The original proband, FS, a 10-year-old boy, was referred in 1945 to Dr. Wilder Penfield by Dr. Edgar Fincher, chief of neurosurgery at Emory University in Atlanta, Georgia, because of intractable right-sided focal motor seizures starting at 6 years of age. FS developed a right hemiparesis and underwent, between 1941 and 1956, three surgical interventions (two at the Montreal Neurological Hospital and Institute [MNHI]) at 7, 10, and 21 years of age in an attempt to control the evolution of the disease. In the first chapter of the monograph on chronic encephalitis published by Dr. Frederick Andermann in 1991, Dr. Rasmussen reported a letter by Dr. Fincher to Dr. Penfield (dated 1956) urging him to consider a more extensive cortical excision and concluded, “I note in your discussion that you list the cause as unknown, but if this youngster doesn’t have a chronic low-grade encephalitic process which has likely, by now, burned itself out, I will buy you a new hat.” The last intervention was a left hemispherectomy performed by Dr. Rasmussen, and histology showed sparse perivascular inflammation and glial nodules. FS remained seizure free until his last follow-up at 51 years of age. He had a mild intellectual disability and a fixed right hemiplegia. He developed hydrocephalus as a late complication of the surgical procedure and required a shunt. Dr. Penfield, who was consulted in this case, remained skeptical of the postulate that the syndrome was a primary inflammatory disorder, and he raised most of the issues that continue to be debated: if it is an encephalitic process, would it not involve both hemispheres? Is the encephalitic process the result of recurrent seizures caused by a small focal lesion in one hemisphere? Why it is that epileptic seizures are destructive in one case and not in another? Dr. Rasmussen himself recognized that Fincher’s 1941 diagnosis of chronic encephalitis in FS’s case was made 14 years before case 2 of the original 1958 report (1). The story does not say, however, if Dr. Penfield had to provide his colleague and friend Dr. Fincher with a new hat (2).

This diagnosis, later recognized as “Rasmussen encephalitis (RE) or syndrome,” became the subject of extensive discussion in the literature, initially debating the best timing for surgery and best

surgical approaches and, more recently, the etiology and pathogenesis of this unusual and enigmatic disease (3). A large number of publications can now be found in the literature, and two international symposia were held in Montreal, first in 1988 and again in 2002. In 2004, a European Consensus Group proposed formal diagnostic criteria and therapeutic avenues for the management of RE patients (4). The obvious interest for this disease, which is usually described in children, was initially driven by the severity and inescapability of its course, which rapidly led to its description as a prototype of "catastrophic epilepsy." Physicians and scientists became interested by the unusual pathogenesis and evolution of the syndrome and are now trying to reconcile the apparent focal nature of the disease with the postulated viral and autoimmune etiologies that may or may not be mutually exclusive. This chapter reviews and updates a number of issues regarding RE, particularly the putative humoral and cellular immune mechanisms of the disease, the variability of the clinical presentations, and the indications and rationale of new medical therapies, such as immunomodulation and receptor-directed pharmacotherapy.

CLINICAL PRESENTATIONS

Typical Course

In the early stages of the disease, the major issue is diagnosis. A combination of characteristic clinical, electrophysiologic, and imaging findings aids in the diagnosis. The 48 patients studied at the MNHI were collected over a period of 30 years and consisted mostly of referrals from outside Canada. Although now easier to recognize, this disease remains rare. During the last two decades, no more than one to two new cases are identified at the MNHI per year. This is a small number compared to the 100 to 150 inpatients with intractable focal epilepsy due to other causes studied each year at the center. Typically, the disease starts in healthy children between 1 and 13 years (mean age, 6.8 years) with 80% developing seizures before the age of 10 years (5). There is no difference in incidence between the sexes. In approximately half the patients, a history of infectious or inflammatory episode was described 6 months prior to the onset of seizures.

The first sign of the disease is the development of seizures. They are usually partial or secondarily generalized tonic–clonic seizures; 20% of patients in the MNHI series presented with status epilepticus as the first manifestation. Early seizures could be polymorphic with variable semiology, but motor manifestations are almost always reported. Other variable semiology of seizures with somatosensory, autonomic, visual, and psychic features has been described (5,6). The seizures rapidly become refractory, with little response to AEDs. Epilepsia partialis continua (EPC) and other forms of focal seizures are particularly unresponsive to AEDs (7,8). A review of the AED therapy in 25 patients of the initial MNHI series revealed that no specific agent or combination therapy appeared to be more effective or less toxic than other regimens (7). Our experience with more recently approved AEDs in other patients with RE did not support improved effectiveness or tolerability for newer agents. Levetiracetam, topiramate, and even felbamate may theoretically have a role in the treatment of RE, because levetiracetam has efficacy in treating cortical myoclonus, and topiramate and felbamate have a direct effect on glutamate receptors and release of N-methyl-D-glutamine (NMDA).

A variety of seizure types develop over time. The most common are focal motor and EPC (in 56% of the patients), with scalp electroencephalogram (EEG) patterns suggesting perirolandic onset.

Secondarily, generalized motor seizures are also common in many patients, but these appear to be easier to control with AEDs. Other, less frequent types of motor seizures include Jacksonian march (12%), posturing (25%), or versive movements of the head and eyes (13%), suggesting involvement of the primary motor, premotor, and supplementary motor areas. Drop attacks, however, are rare. Focal seizures with somatosensory (22% of the patients), visual (16%), or auditory (2%) manifestations are less frequent and appear later in the course of the disease, suggesting that the epileptogenic process has migrated from frontocentral regions to more posterior cortical areas. Adult-onset variant (see below under: Clinical Variants of Rasmussen Encephalitis: Late-onset Adolescent and Adult Variants) is also characterized by different early and late features reflecting a progressive involvement of different brain structures from the temporal and frontal lobes to perisylvian and insular regions.

Oguni et al. (5) divided the progression of the disease into three stages: stage 1, from the onset of the seizures and before the development of a fixed hemiparesis (3 months to 10 years, mean duration, 2.8 years); stage 2, from the development of a fixed hemiparesis (occurring in all 48 patients) to the completion of neurologic deterioration, including intellectual decline (85%), visual (49%) and sensory (29%) cortical deficits, and speech problems (dysarthria 23%, dysphasia 19%) dependent or independent of the burden of seizure activity (2 months to 10 years, mean duration, 3.7 years); and stage 3, stabilization of the condition in which further progression no longer occurs, and even the seizures tend to decrease in severity and frequency.

Bien et al. (9) presented the clinical natural history of RE in parallel with the time course of brain destruction as measured by serial magnetic resonance imaging (MRI), in a series of 13 patients studied histologically. They separated the progression of the disease into prodromal (during this stage, patients had rare seizures and minimal neurologic deterioration), acute (a period of intense seizure occurrence, neurologic deterioration associated with the affected hemisphere and atrophy of one hemisphere), and residual (with a marked reduction in seizure frequency) stages comparable to the three stages presented by Oguni et al. However, Bien et al. distinguished two patterns of disease depending on the age at onset of the disorder: one with an earlier and more severe disorder starting during childhood (mean age at first seizure, 4.4 years; range, 1.6 to 6.4 years) and a second with a more protracted and milder course starting during adolescence or adult life (mean age at first seizure, 21.9 years; range, 6.4 to 40.9 years), the second pattern representing a now well-described variant of RE (see below).

The main two aspects of the clinical phenotype of RE consist of progressive functional neurologic decline and pharmacologically intractable epilepsy (3). The progressive neurologic deficit, usually fixed at one point in time, with a more severe decline in children compared to adolescents and adults, is caused by the chronic inflammatory process. The degree of the deficit may, however, be fluctuating due to seizure severity. The disease is also characterized by the epilepsy, usually but not necessarily severe, that persists throughout the evolution of the process.

Clinical Variants of Rasmussen Encephalitis

RE has been known for more than 50 years. After the initial description, it became clear that the disease is clinically heterogeneous despite the pathologic hallmark of chronic inflammation in the affected hemisphere. This heterogeneity may be explained by different etiologies (viral, viral-, and nonviral-mediated autoimmune disease), by different reactions of the host's immune system to exogenous or endogenous insults (age, genetic background, presence of another lesion, or "double

pathology"), and by the modulating effect of a variety of antiviral, immunosuppressant, and immunomodulatory agents, or receptor-directed pharmacotherapy used in variable combinations and durations to treat these patients. Atypical or unusual clinical features include early onset (usually younger than 2 years of age) with rapid progression of the disease; bilateral cerebral involvement; relatively late onset during adolescence or adult life with slow progression; atypical anatomic location of the initial brain MRI findings; focal and chronic protracted, subcortical, or even multifocal variants of RE; and double pathology.

Bilateral Hemispheric Involvement

Typically, the disease affects only one hemisphere, and most autopsy studies confirmed unilateral cerebral involvement (10). Over time, however, there may be some contralateral ventricular enlargement and cortical atrophy attributed either to the effect of recurrent seizures and secondary epileptogenesis or to wallerian degeneration (11). Patients with definite bilateral inflammatory involvement are exceptional and such involvement has been described in approximately 20 patients (12–18) including some with atypical or doubtful bilateral RE (given the lack of histologic confirmation of bilateral involvement). Bilateral disease tends to occur in children with early onset (before age 2 years) but was also described in the late-onset adolescent or adult forms. A small number had received high-dose steroids or an intrathecal antiviral agent, which suggested that early aggressive immunologic therapy may have predisposed them to contralateral spread of the disease. Thus, there seems to be an early-onset variant of RE in which there is an increased risk of bilateral disease, a more malignant course, and a high mortality. Bilateral RE may be related to immaturity of the immune system or to a possible adverse effect of immunotherapy.

Late-Onset Adolescent and Adult Variants

In the first edition of this book, we evaluated the proportion of late-onset RE to be approximately 10% of the total number of patients. A thorough review of the literature seems to confirm that the adolescent or adult variant is more common than initially thought. From 1960 to 2013, we identified at least 40 papers in which over 90 cases of late-onset RE are reported (9,12,19–37). In the MNHI series, 9 (16%) of 55 patients collected between 1945 and 2000 started to have seizures after the age of 12 years. The largest series, described by Hart et al. (21), included 13 adults and adolescents collected from five centers. In comparison with the childhood form, late-onset RE has a more variable evolution, a generally more insidious onset of focal neurologic defects and cognitive impairment, and an increased incidence of occipital involvement (23% in the series described by Hart et al. vs. 7% in children younger than 12 years old in the MNHI series). Hemiparesis and hemispheric atrophy are often late and may not be as severe when compared with the more typical childhood form. Occasionally, the outcome in late-onset RE is similar to or worse than in children, but because of the generally more benign and protracted course, early hemispherectomy seems less appropriate in this group of patients in whom neurologic deficits are usually less pronounced. Moreover, because of a lack of plasticity in adults, the decision for hemispherectomy is complicated because of potential risk of new irreversible postoperative deficits in the form of severe motor, visual, and speech and language (dominant hemisphere) impairment.

Focal and Chronic Protracted Variants

There are rare reports of patients with RE whose seizures were relatively well controlled with AEDs or focal resections, and in whom the neurologic status stabilized spontaneously (21,30,33,38). Rasmussen had already suggested the existence of a "nonprogressive focal form of encephalitis." With Aguilar, he reviewed 512 surgical specimens from 449 patients and found 32 cases with histologic evidence suggesting the presence of active encephalitis (19). Twelve demonstrated progressive neurologic deterioration compatible with RE, and 20 (4.4%) showed no or mild neurologic deterioration. In his review of patients who underwent temporal resections for intractable focal seizures, Laxer (38) found five patients (3.8% of a series of 160 patients) with what he thought was a benign, focal, nonprogressive form of RE. These patients (children or adults) with no evidence of progression are clinically indistinguishable from those with refractory seizures due to other causes, including mesial temporal sclerosis.

Delayed Seizure–Onset Variant

Bien et al. (39) described five children with RE and delayed seizure onset. All had slowly progressive hemiparesis, contralateral brain atrophy, and four had pathologic features characteristic of RE. Mean age at disease onset was 6.1 (4.8 to 7) years. Two children had seizures 0.5 and 0.6 years after disease onset and the other three were still seizure free at the time of the report (1.3 to 1.9 years after disease onset). Interestingly, the authors demonstrated that the progression of the hemiatrophy in these five patients was similar to the one observed in RE cases with seizures. These two studies reemphasized the fact that patients with RE may present a more insidious course, and the disease should be suspected in cases with new-onset progressive unilateral neurologic deficits.

Basal Ganglia Involvement

EPC and other types of focal motor seizures are a common finding in patients with RE. Chorea, athetosis, and dystonia were infrequently described and may have been overlooked because of the preponderance of the epileptic manifestations and of the hemiparesis. In 27 of the 48 patients of the MNHI series who had EPC, nine additionally had writhing or choreiform movements, and a diagnosis of Sydenham chorea was made in three of the patients early in the disease course (5). Matthews et al. (40) described a 10-year-old girl with a 1-year history of progressive right-sided hemiparesis, EPC, and secondary generalized seizures. MRI showed diffuse cortical and subcortical changes maximum in the perisylvian frontotemporoparietal area. At examination, she had choreic movements of the right arm and hand in addition to EPC. Tien et al. (41) were the first to describe atrophy of the caudate and putamen with abnormal high signals and severe left hemispheric atrophy in an 8.5-year-old girl with intractable focal motor seizures. They interpreted these findings as the result of gliosis and chronic brain damage. Topçu et al. (8) described a patient who developed hemidystonia as a result of involvement of the contralateral basal ganglia. The movement disorder appeared 3 years after the onset of seizures. A rather typical subsequent evolution suggested RE. The movement disorder started during intravenous immunoglobulin (IVIg) and interferon therapy and did not respond to anticholinergic drugs or to a frontal resection. Ben-Zeev et al. (42), Koehn and Zupanc (43), Frucht (24), Lascelles et al. (44), and, finally, Kinay et al. (31) each reported a case of RE whose clinical presentation was dominated by a hemidyskinesia, with EPC in three of those patients, and progressive hemiparesis. Two cases showed selective frontal cortical and caudate atrophy on MRI; one developed progressive left basal ganglia atrophy and later focal frontotemporoparietal atrophy; one had only pronounced right caudate, globus pallidus, and putamen atrophy; and one showed

progressive right frontoinsular and later diffuse hemispheric atrophy with also progressive atrophy of the right caudate head and putamen. In the case of Frucht, IVIg dramatically improved both the hyperkinetic movements and the EPC, but the effect was transient, suggesting a common neuroanatomic mechanism or humoral autoimmune process. In a series of 21 patients with RE, Bhatjiwale et al. (32) looked specifically at the involvement of the basal ganglia. Fifteen (71%) patients showed mild to severe basal ganglion involvement on imaging in three different patterns: predominantly cortical in six cases, predominantly basal ganglia in six cases, and both cortical and basal ganglia involvement in three cases. In five cases, the changes found in the basal ganglia were static, whereas in the others, there was steady progression. The caudate nucleus was generally more prominently involved, usually in association with frontal atrophy. Five cases also showed putaminal involvement, always with temporoinsular atrophy. Interestingly, two of the six patients with prominent basal ganglia involvement had dystonia as a presenting feature. The authors postulated that the disease may proceed from different foci, including cases where RE seems to start in the deep gray matter. Similar findings were recently described by the Italian Study Group on Rasmussen encephalitis (45), which found basal ganglia atrophy in 9 of 13 patients studied. They suggested that atrophy of the basal ganglia represents only secondary change because of disconnection from the affected overlying frontal and insular cortex.

Brainstem Variant

McDonald et al. (46) reported a 3-year-old boy with RE manifested by chronic brainstem encephalitis. After a prolonged febrile seizure associated with an acute varicella infection, he developed recurrent partial motor seizures, EPC, and left hemiparesis within a few weeks. After a few more weeks, signs of brainstem involvement appeared, repeated MRI showed increased signal in the pons, but a complete infectious and inflammatory evaluation, including brain biopsy, was negative. He died 14 months after the onset of his illness. Neuropathologic findings in the brainstem were typical of those found in RE. Bilateral mesial temporal sclerosis was also present. The authors proposed that this case represents a rare focal form of RE with primary involvement of the brainstem and hemiparesis and mesial temporal sclerosis resulting from seizure activity. This was an isolated case report in a complicated patient, and existence of this variant was then questionable. However, recently, a case of adult-onset RE was described with a relatively typical evolution with EPC, focal motor seizures, progressive impaired motor function of the right hemibody, and progressive atrophy of the left hemisphere maximal in the perisylvian regions (29). The diagnosis of RE was confirmed 2.5 years after onset by a brain biopsy, and the disease progressed in spite of IVIg. The patient rapidly became hemiplegic but also seizure free at about the same time. One year later, this patient was admitted because of swallowing problems, palatal paresis, and a flaccid dysarthria. MRI showed a progression of the left hemispheric atrophy and an increase in signal extending in the left mesencephalon and pons but sparing the medulla, without contrast enhancement. Authors suggested that the brainstem involvement represented a late relapse of disease activity involving the brainstem.

Multifocal Variant

Maeda et al. (47) described a 6-year-old girl with typical RE. One year following the onset of seizures, MRI-FLAIR (fluid- attenuated inversion recovery) sequences showed multiple high-signal-intensity areas in the right hemisphere, and a methionine-PET (positron emission tomography) performed at the same time exhibited multifocal methionine uptake areas concordant with the MRI

lesions, suggesting multiple independent sites of chronic inflammation. The authors proposed that the inflammatory process in RE may spread from multifocal lesions and not necessarily originate from localized temporal, insular, or frontocentral lesions, as usually described, before spreading across adjacent regions to the entire hemisphere.

Double Pathology

A small number of reports have documented coexisting brain pathologies with RE (10,35,48–51): tumors (anaplastic astrocytoma, ganglioglioma, anaplastic ependymoma), dysgenetic tissue or focal cortical dysplasia, multifocal perivasculitis, and cavernous angiomas with signs of vasculitis were described. Double pathology in RE supports the theory of focal disruption (trauma, infection, or other pathology) of the blood–brain barrier (BBB). This increased permeability of the BBB may provide access of antibodies produced by the host to neurons expressing the target receptor and production of focal inflammation (2). So far, however, only one case of double pathology provided reasonable support for this hypothesis (50). Strongly positive anti-GluR3 (glutamate receptor 3 subunit) antibodies were measured in one case of RE with concomitant cortical dysplasia in a 2.5-year-old girl with catastrophic epilepsy starting at age 2 years. She underwent a right, partial frontal lobectomy, plasmapheresis, and therapy with IVIg with a transient response, and, finally, a right functional hemispherectomy with good seizure control. GluR3 antibodies were measured serially throughout the course of her treatment and correlated with her clinical status. They were undetectable 1 year after her last surgery.

There are also reports of coexisting autoimmune diseases such as Parry-Romberg syndrome (52) or linear scleroderma (53) and systemic lupus erythematosus (25) with changes mimicking RE. A case of adult-onset RE associated with a typical narcolepsy syndrome in a previously healthy 40-year-old man was also reported (26). Over the course of a few months, the patient developed narcolepsy with confirmatory polysomnography, a HLA type DQB1*0602 and no detectable cerebrospinal fluid (CSF) hypocretin. Within 2 years, he developed refractory temporal lobe seizures. His brain MRI was initially normal and subsequently showed progressive T2 signal changes in the left temporal, insular and inferior frontal regions sparing the hypothalamus and brainstem. Pathology from a first partial temporal lobe resection was consistent with RE. Over the next 5 years, the patient remained refractory to antiepileptic medication but showed no progressive neurologic deficits or further MRI anomalies and still normal hypothalamus and brainstem. The authors suggested that these two co-occurring rare conditions could be explained by a common autoimmune process affecting the cortex and the hypothalamic hypocretin neurons. Also, the coexistence of a postviral acute disseminated encephalomyelitis progressing 6 months later to EPC with clinical and imaging features of a RE was described in a 15-year-old boy (54). Both disorders have an immunologic basis, and the authors again proposed that they represented manifestations of a common autoimmune disorder of the central nervous system (CNS). The association of RE and CNS granulomatous disease with mutations NOD2/CARD15 was described in a 12-year-old girl (55). The patient presented with typical clinical features of RE in addition to two sequential biopsies that also supported the two diagnosis. She was subsequently found to have three mutations in the NOD2/CARD15 gene. Family history was positive for a paternal uncle with Crohn disease and a paternal grandfather with inflammatory arthritis. Moreover, her clinical manifestations, the seizures and the hemiparesis, and the MRI lesions improved dramatically after she received infliximab, a TNF-α inhibitor. Finally, the association of RE and Behçet disease has been described in the same family (a son and his father,

respectively) suggesting a common genetic susceptibility to develop autoimmune conditions (31). Inflammatory changes suggestive of RE have also been observed in disorders with impaired immunity such as agammaglobulinemia (56) and multiple endocrinopathies, chronic mucocutaneous candidiasis, and impaired cellular immunity (57). The occurrence of two conditions presumably caused by impaired immunity in the same individual may strengthen the view that immune- mediated mechanisms are responsible for the development of RE.

Finally, the rare association of uveitis or choroiditis with typical features of RE has led to the speculation that a viral infection may have been responsible for both (58). In all cases, the ocular pathology was ipsilateral to the involved hemisphere that showed chronic encephalitis. It was hypothesized that a primary ocular infection, in particular a viral infection with herpes simplex virus, varicella-zoster virus, Epstein–Barr virus, cytomegalovirus, measles, or rubella, followed by vascular or neurotropic spread to the brain, was a possible mechanism for development of RE. Another patient with adult-onset RE presented with bilateral uveitis that occurred late (19 years after onset) in the course of the disease (34). Anti-GluR ε2 IgG and IgM antibodies were detected in her serum in association with the brain and ophthalmologic inflammatory processes. According to authors, the patient responded favorably to immunotherapy and interferon β-1b.

ELECTROENCEPHALOGRAPHY

Few studies specifically reported the EEG changes associated with RE (6,59) or tried to correlate the clinical and EEG features of the disease over time (6,59,60). So and Gloor (59) reported the scalp (339 studies) and perioperative (58 electrocorticograms) EEG findings in the MNHI series of 49 patients with RE. They summarized the EEG features as follows: (a) disturbance of background activity in all except one patient with more severe slowing and relative depression of background rhythms in the diseased hemisphere; polymorphic or rhythmic delta activity was found in all (more commonly bilateral with lateralized preponderance); (b) interictal epileptiform activity in 94% of patients, rarely focal (more commonly multifocal and lateralized to one hemisphere or bilateral independent, but strongly lateralized discharges with or without bilateral synchrony); (c) clinical or subclinical seizure onsets were variable and occasionally focal, but more often poorly localized, lateralized, bilateral, or even generalized; and (d) no clear electroclinical correlation apparent in many of the recorded clinical seizures, in particular in EPC. The electrographic lateralization of these abnormalities (focal slowing, progressive unilateral deterioration of background activity, ictal, and multifocal interictal hemispheric epileptiform activity) was sufficiently concordant with the clinical lateralization to provide essential information about the abnormal hemisphere in 90% of cases. These EEG features, indicative of a widespread destructive and epileptogenic process, in the specific clinical context of catastrophic epilepsy and worsening neurologic deficits involving one hemisphere, suggest the diagnosis of chronic encephalitis.

The evolution of the EEG was studied longitudinally in a small number of patients (6,59,60). The studies showed progression of the EEG abnormalities. At the onset of the disease, EEG abnormalities tended to be lateralized and nonspecific, with unilateral slowing of background activity. As the disease progressed, it tended to become bilateral and widespread, multifocal or synchronous, suggesting a more diffuse hemispheric process, but not always confined to one hemisphere. It is not clear if this late bilateralization of the EEG abnormalities represented functional interference, secondary epileptogenesis, or, much less likely, an inflammatory process directly involving the contralateral hemisphere.

Longaretti et al. (60) recently reviewed EEG in RE and focal cortical dysplasia (19 and 17 patients, respectively) for early indicators of either pathology. They found no specific EEG changes at diagnosis of epilepsy that help differentiating the two conditions. Interestingly, the EEG was even normal in the initial phase of RE (as for many dysgenetic cases), in 20% of the children at 3 months and in 12% at 6 months. They found, however, that lateralized slow-wave activity and the emergence of epileptiform activity over the unaffected hemisphere were both suggestive of RE as the condition evolves. Also, significant cognitive decline was observed more often in RE patients with independent epileptic activity in the unaffected hemisphere (none of those children presented with evidence of bilateral disease on imaging or during the course of the process), suggesting that RE has the potential to be an epileptic encephalopathy.

Finally, persistent ictal EEG discharges after a functional hemispherectomy suggest that the inflammatory process may continue even in a disconnected hemisphere (61).

IMAGING

Anatomic Imaging

Imaging studies, although not specific, are extremely important for the diagnosis of RE. Typically, they show progressive, lateralized atrophy coupled with localized or lateralized functional abnormalities (6,9,34,38,49,62–65). Brain magnetic resonance studies early in the course of the illness may be normal, rapidly followed by a combination of characteristic features that parallel the clinical and electrophysiologic deterioration, reflecting the nature of the pathologic process. Recent studies using serial MRIs in a relatively large number of patients with RE provided better insight into the early, progressive, and late gray and white matter changes expected in this disease: cortical swelling, atrophy of cortical gray matter and deep gray matter nuclei, particularly the caudate, a hyperintense signal in gray and white matter, and secondary changes (6,9,32,38,65). In the early phase of the disease, when the MRI still appears normal, a few studies demonstrated abnormalities of perfusion or metabolism by single photon emission computed tomography (SPECT) or PET, suggesting that these imaging procedures may aid in early identification of the disease and of the abnormal hemisphere (34,64,66–68). In some studies, PET was found to detect lesions sooner and depict their extent better than concomitant MRI (68). Rapidly on early magnetic resonance scans, however, the cortex shows focal hyperintense signals on T2 or FLAIR sequences (38) and may appear swollen. This can be explained by brain edema at the onset of inflammation (65) or, alternatively, by recurrent focal seizures. Bien et al (65) compared MR images with surgical specimens obtained from 10 RE patients. In those areas with increased signal, the number of T cells, microglial nodules, and GFAP-positive astrocytes was increased compared to areas showing more atrophy and no increased signal. They demonstrated that the densities of T cells, microglial nodules, and astrocytes were inversely correlated to disease duration. Very early signal change in the white matter (within 4 months) is also frequent, usually focal, with or without swelling (38). Later, progressive atrophy of the affected hemisphere occurs, reflecting the manner in which the disease spreads, and with most of the hemispheric volume loss occurring during the first 2 years (9,38,64). The cortical atrophy is initially temporal, frontoinsular, or frontocentral and, more rarely, parietooccipital, later spreading across the hemisphere. Basal ganglion involvement, mostly of the putamen and caudate, is also characteristic and may be a result of direct damage by the pathologic

process or secondary to changes caused by disconnection of the basal ganglia from the affected overlying frontocentral and insular cortices (32,38). MRI brain volumetry studies performed in a large series of patients with RE confirmed that the unaffected contralateral hemisphere also undergo progressive tissue loss although at a lower rate and with a much lesser magnitude compared to the affected hemisphere (11). Other secondary changes usually associated with severe hemispheric tissue loss are atrophy of the brainstem, particularly of the cerebral peduncle and pons, thinning of the corpus callosum, and atrophy of the contralateral cerebellar hemisphere (38). Gadolinium enhancement on MRI is rarely observed (38,49,64,65). Finally, the finding of calcifications is atypical and should raise doubts on the diagnosis of RE. The European consensus group suggested cranial CT to document or exclude calcifications (4).

Functional Imaging

Several studies, often case reports, have emphasized the utility of functional imaging such as PET, SPECT, and proton magnetic resonance spectroscopy (MRS) in the diagnosis and follow-up. Functional abnormalities may be useful in cases in which MRI is normal, usually at the onset of the disease, or when structural imaging fails to provide satisfactory localizing information. Combined anatomic and functional neuroimaging may serve to focus the diagnostic workup, hasten brain biopsy for definitive diagnosis, or define the appropriate surgical approach. It may be useful to follow the evolution of the disease or the result of treatment. Finally, functional studies may provide insight into the cortical reorganization of speech areas and of the motor and somatosensory cortices.

Fiorella et al. (64) reviewed 2-deoxy-2-[^{18}F]-fluoro-D-glucose PET (FDG-PET) and MRI studies of 11 patients with surgically proven RE. All had diffuse, unilateral cerebral hypometabolism on PET images, closely correlated with the distribution of cerebral atrophy on MRI. Even subtle diffuse atrophic changes were accompanied by marked decreases in cerebral glucose use that, according to the authors, increased diagnostic confidence and aided in the identification of the abnormal hemisphere. During ictal studies, patients had multiple foci of hypermetabolism, indicative of multifocal seizure activity within the affected hemisphere, and never showed such changes in the contralateral one. Similar findings had been reported in smaller series (38,66,69). Although MRI alone is generally sufficient to identify the affected hemisphere, FDG-PET confirms the findings in each case. Blood flow or perfusion studies using Oxygen-15 PET showed a similar correlation, with regions of perfusion change corresponding with structural MRI changes (66). Using a specific radioligand ([^{11}C](R)-PK11195) for peripheral benzodiazepine-binding sites on cells of mononuclear phagocyte lineage, Banati et al. (70) demonstrated in vivo the widespread activation of microglia in three patients, which is usually found by neuropathologic study. Also, a [^{11}C]methionine-PET demonstrated in a 6-year-old girl with RE multifocal uptake regions, which corresponded to high-signal-intensity areas described on FLAIR MR imaging and suggesting sites of underlying inflammation (47).

SPECT was used to study regional blood flow in a number of patients (8,45,60,67,69,71). The findings may be of some help and more sensitive than anatomic neuroimaging early in the disease but are nonspecific. As with FDG-PET, the regions of functional change usually correlate with anatomic abnormalities. Interictal SPECT scans reveal diminished perfusion in a large zone surrounding the epileptic area shown on EEG. This hypoperfusion may show some variability depending on fluctuation of the epileptic activity. Ictal studies often show zones of hyperperfusion representing likely areas of more intense seizure activity. MRS has been used in a number of patients with RE

(33,38,72–75). Localized proton MRS was described for the first time in two patients by Matthews et al. (40). They showed reduced N-acetylaspartate (NAA) concentrations—a compound exclusively found in neurons and their processes—in diseased areas in two patients, suggesting neuronal loss. In addition, MRS showed increased lactate in a patient with EPC, probably the result of excessive and repetitive seizure activity. These findings were confirmed by Peeling and Sutherland (72) and by Cendes et al. (73). Peeling and Sutherland also showed that the concentration of NAA in vitro (MRS on tissue obtained from surgical patients) was reduced in proportion to the severity and extent of the encephalitis. Cendes and colleagues did sequential studies at 1 year in three patients and demonstrated progression of the MRS changes. They noted that those changes were more widespread than the structural changes seen on anatomic MRI. Tegkul et al. (75) also did sequential NAA/Cr ratios in three patients with RE and demonstrated progressive reduction of the ratios related to the duration and progressive course of the disease. They measured interleukin-6 (a proinflammatory cytokine produced by astrocytes and microglial cells) response in their CSF and serum and found that the magnitude of the responses in the CSF was correlated with the severity of neuronal damage as measured by MRS. Overall, the studies using NAA indicate that MRS can identify and quantify neuronal damage and loss throughout the affected hemisphere, including areas that appear anatomically normal. In addition to NAA and lactate, other compounds measured included choline, creatine, myo-inositol, glutamine, and glutamate. Choline is usually elevated, which probably indicates demyelination and increased membrane turnover (67,73). Myo-inositol, a glial cell marker, was found to be elevated in a small number of patients (67,74), indicating glial proliferation or prominent gliotic activity. Hypothetically, myo-inositol signal should increase with the progression of the disease. Lactate was almost always elevated, and this increase probably results from ongoing or repetitive focal epileptic activity rather than from an inflammatory process itself (72,73). The largest peaks in lactate were usually detected in patients with EPC. Glutamine and glutamate levels were also elevated in two patients so far, a finding of interest considering the potential role of excitatory neurotransmitters in the disease (67).

ETIOLOGY AND PATHOGENESIS

The etiology and pathogenesis of RE remain unknown. Typical histologic findings reported in surgical or autopsy specimens are perivascular lymphocytic cuffing, proliferation of microglial nodules, neuronal loss, and gliosis in the affected hemisphere. The microglial nodules are associated with frequent nonspecific neuronophagia and occur particularly near perivascular cuffs of lymphocytes and monocytes. There is some evidence of spongiosis, but this is not as widespread as in the true spongiform encephalopathies. Lesions tend to extend in a confluent rather than a multifocal manner. Finally, the main inflammatory changes are found in the cortex, and their intensity is inversely correlated with disease duration, with slow progress toward a “burnt-out” stage (9,10,76). A neuropathology study of 45 hemispherectomies in RE patients (76) showed the multifocality (contradicting the previous impression of a centrifugal pattern of the cortical pathology) and heterogeneity of the pathologic changes in each patient, findings consistent with a progressive process of neuronal damage (at multiple times and in various sites). Pathologic changes ranged from early inflammation to extensive neuronal cell death and cavitation, and the presence of T lymphocytes and neuroglial reactions suggested an immune-mediated process involving the cerebral cortex and white matter. Three mechanisms or processes, not mutually exclusive, have been proposed to explain the initiation and unusual evolution of this rare clinical syndrome: first, viral infections directly inducing

central nervous system (CNS) injury; second, a viral-triggered autoimmune CNS process; and third, a primary autoimmune CNS process. It is also possible that RE has a noninflammatory origin and that the observed inflammation merely represents a response to injury or insult, possibly in the setting of a genetic predisposition.

The observation of the type of inflammatory process found within the lesions has led over the last few years to multifaceted approaches to uncover a possible infectious or immune- mediated (humoral or cellular) etiology. Epidemiologic studies have not identified a genetic, environmental (geographical or seasonal), or clustering effect and failed to demonstrate any association between exposure to various factors, including viruses, and the subsequent development of RE. In many cases, there is no apparent increase in preexistent febrile convulsions, or immediately preceding or associated infectious illness. Serologic studies to detect antecedent viral infection have been contradictory or inconclusive (12,77,78), the search for a pathogenic virus has so far mostly focused on the herpes virus family, and direct brain tissue analysis has also yielded inconsistent results (12,78,79). Expression of the interferon- induced MxA protein was test negative in several cases of RE also arguing against a viral etiology (80). The role of an infectious agent, and the viral hypothesis, in the causation of RE remains, at best, uncertain. It should be noted, however, that a few patients were reported to improve with antiviral therapy (15,81,82).

Systemic (38–41,44) and CSF compartment immune responses still fail to indicate clear evidence of either ongoing or deficient immune reactivity (83). A primary role for pathogenic antibodies in the etiology of RE was proposed after Rogers and colleagues (84) described rabbits immunized with fusion proteins containing a portion of the GluR3. Those animals developed intractable seizures, and, on histopathologic examination, their brains showed changes characteristic of RE with perivascular lymphocytic infiltrate and microglial nodules. The subsequent finding of autoantibodies to GluR3 in the sera of some affected patients with RE led to the definition of a GluR3 autoantibody hypothesis and allowed new speculation into its pathogenesis. GluR3 autoantibodies may cause damage to the brain, and eventually epilepsy, by excitotoxic mechanisms. In the animal model, GluR3 autoantibodies appear to activate the excitatory receptor that leads to massive influx of ions, neuronal cell death, local inflammation, and further disruption of the BBB, allowing entry of more autoantibodies (85). Another proposed mechanism suggests that GluR3 autoantibodies can cause damage by activating complement cascades that lead to neuronal cell death and inflammation (86). These hypotheses prompted a number of open-label therapeutic attempts to modulate the immune system of patients, especially by removing or annihilating the circulating pathogenic factors presumably responsible for the disease (84,86–88). Among cases with no detectable anti-GluR3 antibodies, several were also described to respond well to immunosuppressive treatments (2,20). Other reports in several patients showed no response to plasma exchange (20,87). Finally, more recent work shows that anti-GluR3 antibodies are not specific for RE but can be detected in other neurologic disorders, particularly in non-RE patients with catastrophic epilepsy. Since the sensitivity of detection is low for the RE population and the presence of GluR3 antibodies does not distinguish RE from other forms of epilepsy, the anti-GluR3 antibody test is not useful for a diagnosis of RE (89–93). In one study, GluR3 antibodies were found in the serum of 5/6 and CSF of 4/4 patients with RE and 12/71 patients with other epilepsies (94).

Some patients also harbored additional autoimmune antibodies (in serum of 5/6 patients with RE; e.g., anti-GAD, anticardiolipin, anti-dsDNA, anti-RNP, anti-SS-A). In another study, the same group (95) found elevated levels of GluR3B in the serum of two monozygotic twins, one with presumed RE and the other healthy. More interestingly, both twins also exhibited elevated titers of anti-dsDNA,

anti-GAD, anti-cardiolipin, anti-RNP, anti-SS-A, and anti-beta2GPI and elevated levels of different cytokines—the formers tended to be more elevated in RE twin and the latters more elevated in the healthy one. The reasons for these findings are unknown, but the authors speculated that they represented immune responses to a common injury leading in one to an immune or autoimmune epilepsy disorder. Whether GluR3 autoantibodies in severe forms of epilepsy are responsible for the seizures or whether they result from an underlying degenerative or inflammatory process is still unclear. Passive transfer of the disease into naive animals remains unsuccessful so far, and additional animal models of this illness are lacking.

Various other autoantibodies against neural molecules were described in RE: autoantibodies against munc-18 (96), neuronal acetylcholine receptor α7 subunit (93,97), glutamic acid decarboxylase (anti-GAD) (94), and NMDAAR2A to 2D, specifically GluR ε_2 (27,98), have been reported in some patients. Again, however, these autoantibodies could be detected in neurologic diseases other than RE, confirming that none of the described autoantibodies is specifically associated with this disease, and that a variety of autoantibodies to neuronal and synaptic structures can be found that may contribute to the inflammatory process, or represent an epiphenomenon of an activated immune system. Takahashi et al. (98) showed that GluR ε_2 were present only in patients with EPC (15 patients, including 10 with histologically proven or clinical RE, 3 with acute encephalitis/encephalopathy, and 2 with nonprogressive EPC), and antibodies were directed primarily against cytoplasmic epitopes, suggesting the involvement of T-cell–mediated autoimmunity. To summarize, it may very well be that the antibodies are related to epilepsy rather than specific for RE and are markers for neuronal damage rather than causative (99).

Reports indeed suggested that a T-cell–mediated inflammatory response may be another initiating or perpetuating mechanism in RE. Active inflammatory brain lesions contain large numbers of T lymphocytes. These are recruited early within the lesions, suggesting that a T-cell–dependent immune response contributes to the onset and evolution of the disease. Li et al. (100) analyzed T-cell receptor expression in the lesions of patients with RE and found that the local immune response includes restricted T-cell populations that are likely to have expanded from a small number of precursor T cells, responding themselves to discrete antigenic epitopes. However, the nature of the antigen that triggers such a response is unknown. Nevertheless, more recent work provides further credence to the hypothesis that a T-cell–mediated cytotoxic reaction ($CD8^+$ T-cell cytotoxicity) induces damage, correlating with activation of the granzyme B pathway, and apoptotic death of cortical neurons in RE (91). In an attempt to combine existing knowledge, these investigators (101–103) proposed a new scheme of pathogenesis: an initial unihemispheric focal event leading to BBB opening, the onset of a cytotoxic T-cell response and then spreading of the immune attack across the affected hemisphere. First, a focal event initiates the process (e.g., infection, trauma, immune-mediated brain damage, even focal seizure activity) and an immune reaction with antigen presentation in the CNS and entry of cytotoxic T lymphocytes into the CNS across the disrupted BBB. Second, activated cytotoxic T lymphocytes attack CNS neurons while the inflammatory process, together with the release of cytokines, causes a spread of the inflammatory reaction and recruitment of more activated cytotoxic T lymphocytes. Third, the generation of potentially antigenic fragments, including GluR3 and others to be identified, gives rise to autoantibodies (101) and may lead to an antibody-mediated "second wave of attack." More recently, the same investigators added to this scheme of pathogenesis that astrocytic apoptosis and loss are also features of RE (102). They suggested a specific attack by cytotoxic T lymphocytes responsible for astrocytic degeneration, which in turn would contribute to more neuronal

dysfunction and death.

CRITERIA FOR (EARLY) DIAGNOSIS

The clinical changes of RE are nonspecific, particularly at the beginning of the disease, and clearly at this stage, the major issue is diagnosis. We now have better diagnostic criteria that can lead to early diagnosis (Table 23.1) (3,4,9,12,45,64). The onset in a previously healthy child is of rapidly increasing frequency and severity of simple focal, usually motor, seizures often followed by postictal deficit. This, and a lack of evidence of anatomic abnormalities on early brain MRI, should raise suspicion regarding the diagnosis of RE. Further course and evaluation with scalp EEG showing unilateral findings with focal or regional slowing, deterioration of background activity, multifocal interictal epileptiform discharges, and seizure onset or EPC, particularly corresponding to the cortical motor area, are major neurophysiologic features in favor of RE. Early MRI characteristics include the association of focal white matter hyperintensity and cortical swelling with hyperintense signal, particularly in the insular and peri-insular regions. This is later followed by hemispheric atrophy that is usually predominant in the peri-insular and frontal regions and the head of the caudate nucleus contralateral to the clinical manifestations. Gadolinium enhancement is unusual in RE, and calcifications are not present. Functional imaging studies may reveal abnormalities before any visible structural changes. Typically, FDG-PET shows diffuse hemispheric glucose hypometabolism. SPECT shows unilateral interictal hypoperfusion and ictal multifocal areas of hyperperfusion confirming the lateralized hemispheric nature of the lesion and its extent. MRS may also help in the early detection of brain damage and shows a lateralized decrease in NAA intensity relative to creatine, suggesting neuronal loss or damage in one hemisphere. No laboratory test can support the diagnosis of RE. There is no consistent systemic and CSF response that may contribute to the diagnosis, and, in fact, the most common feature is the lack of cellular or protein response including oligoclonal bands in the CSF of patients with RE. Brain biopsy is often used as a diagnostic tool to confirm the diagnosis. However, histologic findings in RE are nonspecific chronic inflammatory changes that may be subtle enough to be missed by an inexperienced pathologist. Furthermore, the brain involvement may be patchy, and a normal biopsy, particularly when obtained from small stereotactic needles, does not rule out the diagnosis of RE. In some experienced centers, brain biopsy is not routinely done, and clinical evolution in association with scalp EEG and brain MRI are considered diagnostic of RE. Granata et al. (6) suggested that the association of refractory focal seizures with a predominant motor component and with contralateral focal EEG and neuroimaging changes could allow a diagnosis of RE 4 to 6 months after the appearance of the first symptoms.

Table 23.1 Criteria for (Early) Diagnosis of Rasmussen Encephalitis

Clinical	■ Refractory focal motor seizures rapidly increasing in frequency and severity, and often polymorphic ■ Epilepsia partialis continua ■ Unilateral cortical deficits: Motor, progressive hemiparesis, and cognitive deterioration
Electroencephalography	■ Focal or regional slow-wave activity contralateral to motor manifestations ■ Multifocal, usually lateralized, interictal, and ictal epileptiform discharges ■ Progressive, lateralized impoverishment of background activity
Imaging	■ *MRI*: focal cortical swelling with hyperintensity and white matter signal hyperintensity (T2/Flair hyperintense signal), insular cortical atrophy, atrophy of the head of caudate nucleus, and progressive gray and white matter atrophy, unilateral. No gadolinium enhancement and no calcifications on head CT ■ *PET*: unilateral, hemispheric, but during early stage may be restricted to frontal and temporal regions, glucose hypometabolism ■ *SPECT*: unilateral interictal hemispheric hypoperfusion and ictal multifocal hyperperfusion ■ *MRS*: unilateral reduced NAA, and increased lactate, choline, myoinositol, and glutamine/glutamate
Blood	■ None, except inconsistent finding of anti-GluR3 antibodies
Cerebrospinal fluid	■ None, except sometimes presence of oligoclonal bands and inconsistent elevated levels of anti-GluR3 antibodies
Histopathology	■ Activated microglial cells forming typically, but not necessarily, microglial nodules, perivascular lymphocytic infiltration, neuron degeneration, reactive astrogliosis, and spongy degeneration ■ Combination of active and remote, multifocal, intracortical and white matter lesions

CT, computed tomography; GluR3, glutamate receptor 3 subunit; MRI, magnetic resonance imaging; MRS, magnetic resonance spectroscopy; NAA, *N*-acetylaspartate; PET, positron emission tomography; SPECT, single photon emission computed tomography.

The differential diagnosis is large and encompasses progressive, unilateral, neurologic disorders due to inflammatory or infectious processes, developmental, metabolic or degenerative diseases, and neoplastic, paraneoplastic, vascular, or even toxic neuropathogeneses (4). It includes focal cortical dysplasia and tuberous sclerosis, mitochondrial encephalopathy, such as mitochondrial encephalopathy with lactic acidosis and stroke-like episodes, brain tumors, focal unihemispheric cerebral vasculitis, degenerative cortical gray matter diseases, and some forms of meningoencephalitis or disseminated encephalomyelitis. Although several diagnostic criteria have been proposed, especially for an early diagnosis of RE, the correct identification of patients with this disease remains a matter of experience, particularly if specific investigative or therapeutic interventions are considered. When a constellation of clinical and laboratory findings highlights the possibility of RE, close follow-up is necessary to assess progression of the disease and eventually confirm its diagnosis.

MEDICAL AND SURGICAL TREATMENTS

The typical evolution of RE is characterized by the development of intractable seizures, progressive neurologic deficits, and intellectual impairment. AEDs quite consistently fail to provide any significant improvement in seizures. This has led clinicians to try a variety of empiric treatments, including antiviral agents and immunomodulatory or immunosuppressive therapies. Surgery, and specifically hemispherectomy, appears to be successful in arresting the disease process. However, the ensuing neurologic deficits due to surgery usually lead to reluctance to carry out this procedure until significant hemiparesis or other functional deficits have already occurred. Apart from the surgical treatment, there is no established treatment for RE. However, with increased experience and knowledge on the pathogenesis of RE, very promising, therapeutic, options are available, and long-term immunotherapies have now a more rational basis for their use and clearer indications (3). These therapies should probably be considered at the early stages of the disease to halt its progression, in cases where surgery is not possible, for instance when important functional brain areas are involved or in severe bilateral or other unusual variants of RE.

Antiepileptic Drug Therapy

Guidelines for AED treatment in RE are difficult to define and have always been empirical. No AED, or any polytherapy regimen, has been proven to be superior (7), and the choice of the ideal AED rests on its clinical efficacy and side effect profile. Because of the nature of this disease, the danger of overtreatment is high. AED pharmacokinetics, toxicity, and interactions may be better determinants of AED selection and combination therapy. EPC is particularly difficult to treat, but AEDs can reduce the frequency and severity of other focal and secondarily generalized seizures. Since the author's original report on AED efficacy in RE, several new agents have been introduced. Drugs such as topiramate and felbamate that act on excitatory neurotransmitters or those that may affect cortically generated myoclonus, like levetiracetam in EPC, may have a more specific role in treatment. Improved tolerability and better pharmacokinetic profiles and interactions may argue in favor of the newer AEDs.

Antiviral Therapy

Most treatments directed at aborting the progression of the disease were based on the assumption that RE is either an infectious, viral, or an autoimmune disorder. Examples of antiviral treatments are scarce, and only three reports are published: two on the treatment of eight patients with ganciclovir (82), a potent anticytomegalovirus drug, and another on the treatment of a single patient with zidovudine (15). Although some improvement was documented in four of the nine patients, no further reports using antiviral agents in RE have been published; this treatment appeared to be effective only when given early in the course of the disease in three of them raising the possibility that the inaugural insult was maybe indeed viral (82).

Immune Therapy

Evidence implicating humoral and cellular immune responses in the pathophysiology of RE has led to various therapeutic initiatives. A number of case reports and small series suggesting potential therapeutic roles of immune-directed interventions have now been published. These include interferon, steroids, IVIg, plasmapheresis, selective immunoglobulin G immunoadsorption by protein A, and immunosuppression or immunomodulation with drugs such as cyclophosphamide, azathioprine, tacrolimus, rituximab, and even thalidomide. Rarely, such approaches have been associated with sustained cessation of seizure activity and arrest in the progression of the inflammatory process. In the majority of the cases, only transient or partial improvements because of immunomodulator or immunosuppressor use have been noted. Of potential importance is the observation that, to date, the more aggressive immune therapies have been deferred to later stages of the disease, where the burden of the disease is considered to outweigh the toxicity of these interventions. The challenge is to develop safe therapeutic protocols that can be tested in patients soon after the diagnosis and at a time when less damage has occurred and the process may have a better chance to respond to therapy. Eventually, regimens that strike the proper balance between safety and efficacy in typical RE could be applied to the more unusual variants (3).

Interferon-α

Intraventricular interferon-α has been tried in two children (80,81) with the rationale that interferons have both immunomodulating (enhancement of phagocytic activity of macrophages and augmentation of the cytotoxicity of target-specific lymphocytes) and antiviral activity (inhibition of viral replication in virus-infected cells). In both cases, improvement of the epileptic and neurologic syndrome was observed. Interferon β-1b has been used in a case of adult-onset RE, concomitantly or sequentially with steroids and immunosuppressants, and authors reported that treatment reduced seizure frequency, prevented exacerbation of other CNS symptoms, and slowed development of brain hemiatrophy (34).

Steroids

Relatively low- and high-dose steroid regimens were used either alone or in association with other agents such as IVIg. Initial reports were somewhat discouraging (56), but eventually, the use of high-dose intravenous (IV) boluses led to encouraging results. When applied during the first year of the disease, pulse IV steroids were effective in suppressing, at least temporarily, the inflammatory process (13,14,20). The proposed modes of action of steroids include an antiepileptic effect, an improvement of BBB function—and hence reduction of entry into the brain of potentially deleterious toxic or immune mediators—and a direct anti-inflammatory effect. Because of a less favorable

response and of the adverse effects of prolonged high-dose steroids, Hart et al. (13) suggested the use of IVIg as initial treatment followed by high-dose steroids, or both, to control seizures and improve the end point of the disease. Granata et al. (25) have proposed a protocol for administration of immunomodulatory treatments in children and adults with RE. Corticosteroids were given alone or in combination with plasmapheresis, IVIg, protein A Ig immunoadsorption, or cyclophosphamide with positive but time-limited clinical responses in 11 of 15 patients. The long-term efficacy of steroids in RE remains unknown, but there are reports supporting steroid use (13,14,25), specifically pulsed steroid courses to stop status epilepticus (13,25). Also, one has to weigh the risks of long-term steroid therapy and maybe more importantly of delaying unduly the most appropriate treatment for this severe condition, which, in the majority of the patients, remains on the long run surgery of the affected hemisphere.

Immunoglobulin

The use of IVIg in RE was first described by Walsh (104) in a 9-year-old child who received repeated infusions of IVIg over a period of several months with initial improvement but later followed by protracted deterioration and cessation of the treatment. Eight subsequent studies reported on the effect of IVIg, alone or in combination with other treatment modalities (13,20,22,23,25). These reports show similar results with initial benefit, but with a much less clear-cut, long-term effect. IVIg is usually much better tolerated than steroids. The basis for a potential therapeutic effect of immunoglobulin in RE is not known but may reflect the functions of natural antibodies in maintaining immune homeostasis in healthy people. Leach et al. (22) showed a delayed but more persistent response in two adults and suggested that IVIg is more effective in adults than in children. They also proposed that IVIg may have a disease-modifying effect. This phenomenon is probably real but, to date, no one has shown that the early use of immune therapy can modify the long-term course of RE. In a recent report (105), guidelines on the use of IVIg for neurologic conditions were presented by a Canadian expert panel. The expert panel stated that in view of the seriousness of potential adverse events and current lack of data surrounding their frequency and in view of the relatively high costs, IVIg should be prescribed only for appropriate clinical indications for which there is a known benefit. They identified five reports of IVIg use for RE and recommended that IVIg may be an option as a short-term, temporary measure for patients with RE.

Plasmapheresis and Selective IgG Immunoadsorption

Plasma exchange is used with the assumption that circulating factors, likely autoantibodies, are pathogenic in at least some patients (20,25,84,87,88). The majority of patients treated with apheresis showed repeated, and at times dramatic, but transient responses. Because of the lack of long-term efficacy, the complications, and the expense, plasmapheresis should probably be used as adjunctive therapy and may be especially useful in patients with acute deterioration, such as status epilepticus.

Immunosuppressive and Immunomodulation Therapy

Immunosuppressants are used in other autoimmune disorders and also in the prevention and treatment of transplant rejection. They act against the activation of T cells, which, in view of the recent findings of cytotoxic T-lymphocyte–mediated damage in RE, may lead to their acquiring a more prominent role in medical treatment.

Few studies reported on the use of cyclophosphamide in no more than half a dozen patients (20,25,87). It was proposed that intermittent cyclophosphamide may well replace steroid therapy because it is associated with less risk of systemic complications. The experience in this small number of patients is suggesting that neither acute nor chronic use of cyclophosphamide produces significant change on seizure frequency or disease progression.

Seven patients with RE were treated with oral tacrolimus (median follow-up, 25.4 months) with superior outcome regarding neurologic function and progression rate of atrophy but no better seizure outcome as compared to 12 untreated RE patients (106). There were no major side effects. A randomized prospective study comparing IVIG and tacrolimus in RE is currently underway (107).

Following demonstration of antibodies directed against brain tissue in RE and the real but modest effects on disease with immunomodulation (steroids, IVIg, apharesis, and immunosuppressants), a pilot study is now also ongoing with rituximab to directly target the B cells thought to be involved in the process (108). Recently, a single case report described a patient with RE that entered a seizure-free period after being treated with IgG immunoadsorption and intravenous rituximab (109). This suggests that rituximab, a monoclonal anti-CD20 that causes depletion of B cells, may also have an effect on T cells.

Thalidomide was used for the first time by Ravenscroft et al. (110) in a 7-year-old male with RE and high level of CSF tumor necrosis factor-α, leading to a dramatic and sustained clinical response. This prompted a second case report of a 13-year-old girl with very refractory RE since age 5 in whom thalidomide was administered because of a life-threatening condition (111). Prior to thalidomide administration, she received sequentially acyclovir, IVIg, IV and oral steroids, a partial left parasagittal frontoparietal resection, plasma exchanges, and cyclophosphamide. After thalidomide was started, she rapidly improved and during the following 3 years received oral thalidomide 300 mg/day (in addition to valproic acid, clonazepam, piracetam) with a significant and sustained reduction in the frequency and intensity of her seizures. She only developed moderate neutropenia attributed to the drug.

Other Nonsurgical or Semi-Invasive Approaches

Repetitive transcranial magnetic stimulation by reducing cortical excitability can suppress at least momentarily seizure activity and hence may be a useful noninvasive palliative tool in some cases; only one case has been reported (112) and clearly further explorations are needed. Two other patients with adolescent and adult-onset RE (both had brain biopsies) received transcranial direct current stimulation at 1- and 2-mA intensity for 60 minutes in four sessions over a period of 2 months. There were no complications. One patient showed a significant reduction in seizure frequency and the other became seizure free (at follow-up evaluations at 6 and 12 months), and both patients showed improvement in cognition and alertness (37). Finally, a single patient, also with an adult-onset RE, experienced a significant and persistent (over 2 years) reduction in seizure frequency (>50%) and improvement of her neurologic and cognitive condition after vagal nerve device implantation and vagal nerve stimulation (36).

Botulinum toxin was marginally used in attempts to control focal seizures or hyperkinetic movements in RE. To date, only two patients were reported with such treatment (113,114). Finally, to our knowledge, no patient with RE showed significant benefit from deep brain stimulation.

Surgery

The only effective surgical procedure seems to be the resection or disconnection of the affected hemisphere (63,115,116). Alternative procedures such as partial corticectomies, subpial transection, and callosal section have limited results and did not render patients seizure free (117–120). Kossoff et al. (116) demonstrated the benefits of hemispherectomy in children with RE. They showed that 91% of 46 children (mean age at surgery, 9.2 years) with severe RE who underwent hemispherectomy (in the majority hemidecortication) between 1975 and 2002 became seizure free (65%) or had nondisabling seizures (26%) that often did not require medications. Patients were walking independently, and all were talking at the time of their most recent follow-up, with relatively minor or moderate residual speech problems. Twenty-one patients had left-sided pathology (presumably involving the dominant hemisphere in most) with a mean age at surgery of 8.8 years.

Hemispherectomy, hemidecortication, functional hemispherectomy, or hemispherotomy have proven efficacy for control of seizures in patients with RE (3,25,63,115,116,121–126). The decision on how early in the course of the disease surgery should be undertaken depends on the certainty of the diagnosis, the severity and frequency of the seizures, and the impact on the psychosocial development of the patient. The natural evolution of the disease and the severity of the epilepsy often justify early intervention, even prior to maximal neurologic deficit. Finally, involvement of the dominant hemisphere by the disease process provides important observations on brain plasticity, especially on the shift of language (4,122,127). Recent reports looking at language outcomes after long-term RE, serial Amobarbital tests, functional MRI studies, and hemispherectomy illustrate the great plasticity of the child's brain and the ability of the nondominant hemisphere to take over some language function even at a relatively late age. The decision about such a radical procedure requires considerable time and thought, and the psychological preparation of the patients and their families is essential (3,63,128,129).

CONCLUSION AND FUTURE PERSPECTIVES

Rasmussen's encephalitis, although a rare disorder, is now much better delineated and understood by the wider clinical and scientific community. However, recognition of the disease in a naive patient to make an early diagnosis continues to be a challenge. Although confirmation of the clinical diagnosis of RE rests on pathologic findings, in vivo combinations of diagnostic approaches such as clinical course, scalp EEG findings, and high-resolution MRI suggest the diagnosis with a high degree of accuracy. The syndrome, however, appears more clinically heterogeneous than initially thought; localized, protracted, or slowly progressive forms of the disease have now been described suggesting that distinct pathophysiologic mechanisms may be at play. Evidence implicating immune responses in the pathophysiology of RE has accumulated involving both B- and T-cell–mediated processes, but the mechanisms by which the immune system is activated remain to be elucidated. The identification of autoantigens provides evidence that RE can be associated with an immune attack on synaptic antigens and impaired synaptic function leading to seizures and cell death. In addition, T-cell–mediated cytotoxicity may lead to neuronal damage and apoptotic death. Identification of the initiating event (possibly the antigen that triggered the autoimmune response) and of the sequence of immune responses occurring in the course of the disease will hopefully allow timely and specific short- or long-term immunotherapy. Patients with RE, however, usually present with rapid progression, and questions on the type and timing of surgical intervention are still being raised. Most patients will fare better with earlier surgery, and only hemispherectomy techniques can provide definitive and satisfactory results with good seizure, cognitive, and psychosocial outcome.

ACKNOWLEDGMENT

I thank Drs. Frederick Andermann and Amit Bar-Or for thoughtful comments.

CHAPTER 24 TEMPORAL LOBE EPILEPSIES

NORMAN K. SO

This chapter on temporal lobe epilepsies (TLEs), and the next on extratemporal epilepsies, present an updated appreciation of the many expressions and manifestations of focal epilepsy. Specifically, this chapter outlines the following:

- Familial and genetic TLEs (also see Chapter 4)
- Mesial temporal epilepsy with defined pathology (and bitemporal epilepsy)
- Other subcompartments of TLE and concept of temporal plus epilepsy
- Dual pathology in TLE (also see Chapter 26)
- Atypical manifestations of TLE and pseudotemporal epilepsy
- Unusual causes of TLE (also see Chapter 33)

FAMILIAL TEMPORAL LOBE EPILEPSIES

Traditional attention to family history revealed some large familial cohorts to show clinical features of TLE with a classical autosomal dominant pattern of inheritance. They account for a relatively small percentage of all patients with TLE. Gene localization or linkage has been successful in some forms. Diagnosis is not really possible other than by a careful family history as genetic testing is not usually indicated and unlikely to provide additional prognostic information.

The best characterized epilepsy syndrome is autosomal dominant lateral temporal epilepsy or autosomal dominant partial epilepsy with auditory features (ADPEAF). Patients describe prominent elementary or complex auditory aura (buzzing, ringing, altered sounds, voices, etc.) in isolation or evolving into complex partial seizures and secondarily generalized tonic–clonic seizures. Some patients report that sudden loud sounds can trigger a seizure. As genetic analysis in families proceed, other affected family members are found to show more variability in clinical expression, with some experiencing visual, cephalic, vertiginous, or psychic auras, and aphasic seizures (1,2). Age at onset ranges broadly from 2 to 60 years but is most common in teenage years. Overall seizure frequency is low and usually amenable to medical treatment. To date, MRI studies have not shown an abnormality. Genetic linkage was found to chromosome 10q, and point mutations or less commonly a microdeletion of the leucine-rich glioma inactivated 1 (LGI1) gene can be identified in 30% to 50% of families (2–5). This mutation of the LGI1 gene was found in a transgenic mice model to block postnatal retinogeniculate axon pruning producing defects in sensory axon remodeling (6). Autoantibodies to LGI1 are also recognized as a cause of limbic encephalitis, but the clinical manifestations in these patients are quite different.

Familial mesial temporal lobe epilepsy (FMTLE) is also recognized but is proving to be more complex and heterogeneous. Clinical recognition comes from taking a good family history. The

original concept of the condition comprised autosomal dominant inheritance with incomplete penetrance; prominent psychic (déjà vu, dreamy states, affective), abdominal, and other auras; less frequent complex partial or tonic–clonic seizures; and a relatively benign prognosis with relatively few disabling seizures and good response to medications (6). Families in earlier reports did not present with a history of febrile seizures, but later ones did, and in some patients, the two forms of seizures were associated (7). Seizure onset starts most commonly in late childhood to early adult life but has a broad range. FMTLE is now recognized as heterogeneous in its evolution and prognosis. Some families had normal MRIs, while others showed evidence of hippocampal atrophy and sclerosis (8,9). MRI evidence of hippocampal atrophy or signal change correlated with disease duration and refractoriness. Refractory patients with hippocampal disease benefited from surgical resection. Several candidate gene loci have been mapped in FMTLE, to chromosome 3q, 4q, 5q, 12q, and 18q, without much consistency in the different reports.

MESIAL TEMPORAL LOBE EPILEPSY WITH DEFINED PATHOLOGIES (AND BITEMPORAL EPILEPSY)

Most consider mesial TLE with mesial temporal sclerosis (MTS) a distinct entity, whether as a syndrome or a "constellation" in an ILAE proposal. Clinically, a history of a childhood cerebral insult is often found, most commonly that of an early convulsion in as many as 50% to 81%, which included febrile seizures (with complicated features in half) or status epilepticus (10,11). There remain many questions on the relationship between the early convulsive insult and later development of MTS, namely the degree of cause and effect, the role of a preexisting developmental predisposition, and also if later seizures contribute to progressive hippocampal damage. In the prospective FEBSTAT study of children who had febrile status epilepticus, acute hippocampal injury was detected by MRI in 11.5% within the first week, and developmental hippocampal abnormalities such as malrotation were found in 10.5% as compared to a rate of 2% in controls (12). Other recognized early-life risk factors for MTS include birth trauma, childhood cerebral infections, and head injury, while infarction in the vascular territory of the posterior cerebral artery can damage the hippocampus at any age. This still leaves a sizeable number of patients with mesial TLE and MTS, in whom no history of an insult or discernible etiology can be found. Seizures can begin in childhood or later, with a possible delay in diagnosis as early manifestations might be mistaken for childhood anxiety, stomach upset, or other behavior disorders. When they begin in childhood, early treatment is often successful leading to medication withdrawal after a few years, with seizures returning after a latent period in adolescent or adult life, either spontaneously or coinciding with menarche or other circumstances that might have lowered the seizure threshold. The disease is thereafter persistent, and a majority of patients end up with difficult-to-control or refractory epilepsy (13). Patients often experience abdominal, autonomic, emotional, or psychic auras, which can coexist as multiple sensations, while other special sensory (olfactory and gustatory) and somatosensory auras are also possible. Complex partial seizures with predominant dyscognitive/dialeptic features and oroalimentary and distal extremity automatisms are common. Some present with pure amnesic seizures. Certain semiological signs that have lateralizing value in mesial TLE include dystonic posturing of the hand (contralateral to the ictal discharge), unilateral eyelid quivering or blinking (ipsilateral), unilateral hand automatisms (ipsilateral), ictal and postictal dysphasia (dominant

hemisphere), and ictal responsive speech with automatisms (nondominant), among other less established lateralizing signs (see Chapter 12 in this volume). Progression to secondary generalized tonic–clonic seizures can occur, which together with falls, injuries, urinary incontinence, and inappropriate amnestic behaviors (like undressing) leads to social debility and morbidity. Ictal asystole can be another complication during these seizures. When the disease is refractory to medications, there is often a downhill course not only from seizure-related injuries but also in other cognitive and emotional domains. After many years, patients may lose the aura they used to have, exhibit more disabling seizures, suffer more injuries, report greater memory difficulty, and exhibit increased comorbid anxiety, depression, and altered personality.

Common EEG findings include intermittent slow waves over one or the other temporal region, with or without rhythmicity (14). Interictal epileptiform discharges are detected in 80% to 90% of patients (15), with a field topography showing maximal voltage at mesial (sphenoidal) or anterior basal temporal (rows 9 and 10 in the 10–10 nomenclature, as in FT9, FT10, T9, and T10) electrodes (16). Discharges when strictly unilateral almost always correlate with the side of seizure onset, but bilateral discharges are found in 30% to 40% or more. Discharges increase in frequency and topographical area in slow-wave sleep. An ictal pattern of sharply contoured rhythmic theta (>5 Hz) activity over one temporal region whether at onset, or emerging later within 30 seconds, if sustained, is found to correlate with the lobe of seizure onset. This pattern is, however, found in only about 50% to 60% of seizures in patients with verified mesial TLE, and other patterns, localizing or nonlocalizing, account for the remainder. This classic pattern, while most common in mesial TLE, is not pathognomonic and can be seen as a result of spread from another lobe.

The most common pathology in mesial TLE is that of MTS, which encompasses not just hippocampal atrophy and sclerosis with its subtypes (17) but also extensive changes in the entorhinal cortex (parahippocampal gyrus) and variable portions of the temporal lobe to the fornix. The pathology involves bilateral temporal structures in about 60% of autopsied cases (18,19). On structural MRI, this can be visualized, measured, and quantified as changes in signal, volume, and cortical thickness (20). There are further extensive functional alterations throughout the limbic system, unilaterally and often bilaterally as revealed by MRI techniques (spectroscopy, diffusions tensor imaging, tractography), and positron emission tomography. Furthermore, hippocampal atrophy and sclerosis may occur in the following settings: Febrile status epilepticus can cause acute injury in the hippocampus and the adjacent medial temporal structures. Additionally, preexisting hippocampal anomalies such as malrotation may predispose to febrile status. Furthermore, hippocampal atrophy can progress over time, and bilateral disease is common. There is secondary atrophy and cortical thinning in the entorhinal and temporal neocortex in disease of long duration. Some patients have such subtle pathology of the hippocampus that it cannot be detected by MRI and is only seen on pathologic studies.

Other pathologies in the mesial temporal region, which includes the amygdala, hippocampus, parahippocampal gyrus, basal temporal cortex as the fusiform gyrus, can present with a similar electroclinical picture. This arises from rapid recruitment of the temporal limbic system in the seizure network. The pathologies include all types of tumors particularly glioneuronal tumors such as ganglioglioma and dysembryoplastic neuroepithelial tumor; cavernous hemangioma and other arteriovenous malformations; focal cortical dysplasia; traumatic encephalomalacia; strokes; postencephalitic damage; and damage from other cerebral infections (abscess, neurocysticercosis) (21,22).

The treatment of mesial TLE deploys all options available. For patients with a defined pathology

or suspected pathology and medically refractory epilepsy, surgical resection provides the greatest chance of complete seizure control. In the process of presurgical evaluation, a proportion of patients with mesial TLE, in the range of 5% to 10%, are found to have independent seizures from each temporal lobe, or bitemporal epilepsy. As noted, bilateral MTS is common when assessed by MRI or pathology. One explanation of bilateral disease is that the original pathology or insult affected both temporal lobes. This seems understandable when the patient had a history of a complicated febrile seizure, status epilepticus, or encephalitis early in life. Rarely, the patient suffered separate pathologies affecting each temporal lobe, for instance childhood meningitis with MTS on one side and an acquired lesion like a tumor on the other. There are, however, still many cases in which we have a poor understanding of why there is bilateral epileptogenicity. They include patients who have no MRI abnormality. Secondary epileptogenesis had been proposed as a mechanism in bitemporal epilepsy, but its role remains unclear. Clinically, patients with bitemporal epilepsy often exhibit more severe disease in all aspects: increased seizure burden, cognitive complaints, and comorbidities. These patients are usually more prone to suffer postictal psychosis, and they are usually medically refractory. Additionally, these patients also pose a challenge during presurgical evaluations and not all patients may be candidates for surgical resection (23).

OTHER SUBCOMPARTMENTS OF TEMPORAL LOBE EPILEPSY AND CONCEPT OF TEMPORAL PLUS EPILEPSY

Several authors distinguish between mesial limbic TLE and lateral neocortical TLE (Fig. 24.1). Many papers were published comparing these two groups in their etiology, semiology, and electrophysiologic features (24–26). Mesial TLE seizures are more likely to show psychic and emotional auras, and complex partial seizures with unilateral hand dystonia. Seizures in lateral TLE are more likely to have auditory, visual and somatosensory aura, and early signs of contralateral motor involvement (clonic, tonic, versive). However, this dichotomization may be too rudimentary, and classic descriptions of the different compartments of TLE by the French school of Bancaud and Talairach in Paris, further elaborated in the 1963 monograph by Wieser (27), may serve as an even more detailed approach. The “temporobasal limbic” type fits in what is said of mesial TLE. The “temporal pole” subtype describes a seizure initiated in the temporal polar cortex or the amygdala. Clinical manifestations overlap with mesial TLE. However, there may be more prominent autonomic features of heart rate and respiratory alteration, and emotional manifestations such as fear and crying out loud. In the most extreme form, fearful vocalizations are followed by complex agitated movements, and these correlate with propagation of the ictal discharge to the orbito- and mesial frontal regions (28). The “temporal perisylvian” or “opercular” subtype seizures usually arise from the superior temporal gyrus, planum temporale, Heschl gyrus, and insula. An auditory aura is the most specific feature, but vertiginous, gustatory, and somatosensory auras are also suggestive. Somatic sensations are complex involving ipsilateral, contralateral, or bilateral segments, from activation of the second sensory area or insula. Profuse salivation may occur. In the dominant hemisphere, the patient may experience early conscious auditory agnosia or dysphasia. Further clinical manifestations are highly variable as the ictal discharge can first propagate into the frontal or parietal cortex or insula and rapidly to the contralateral hemisphere. With the “posterior neocortical” subtype, seizures arise from varying portions of the lateral or basal temporal neocortex extending to the parietal and

occipital lobes that constitute somatosensory or visual association cortices. Superiorly, it overlaps with "opercular" type in the presence of vertiginous and somatosensory aura. Inferiorly, ill-defined or complex visual aura may be reported. In the dominant hemisphere, conscious dysphasia may be appreciated. Subsequent spread to the temporal limbic network results in a seizure with a more mesial TLE flavor, but the spread can also be suprasylvian evoking contralateral motor manifestations with version. Scalp EEG in these nonmesial TLE subtypes can differ from that of mesial TLE. Interictal EEG discharges may show voltage maxima away from the mesial and basal temporal areas and instead over frontal, posterior temporal, or parietal areas. Complex polyspikes, and rhythmic or repetitive spikes in the EEG, are now recognized as suspect for underlying focal cortical dysplasia. Ictal EEG patterns are more often lateralized rather than well localized to one temporal region. Considerable overlap occurs though in the EEG of mesial and nonmesial TLE.

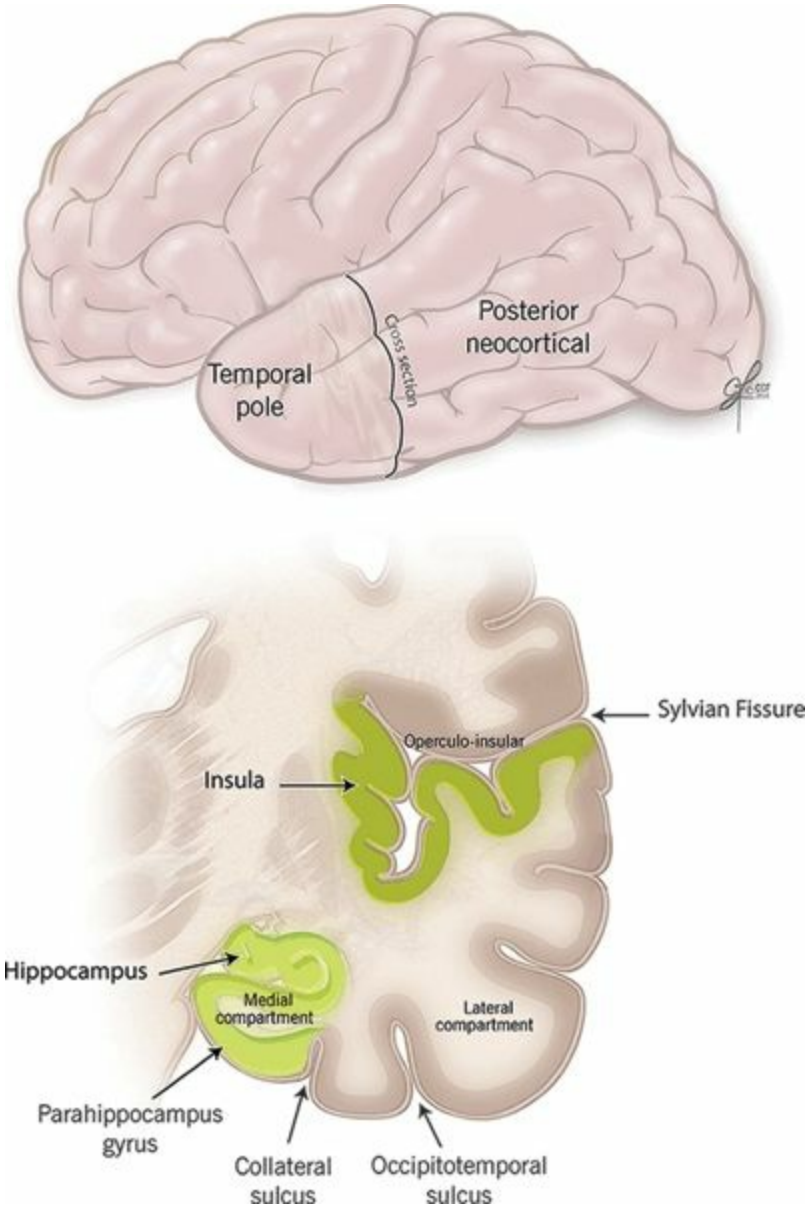

Figure 24.1. The different compartments of TLE. (Reprinted with permission, Cleveland Clinic Center for Medical Art & Photography © 2014. All Rights Reserved.)

The pathology of nonmesial TLE subtypes runs through the usual categories, including tumors, vascular malformations, and encephalomalacia secondary to stroke and head trauma. But in medically refractory patients who had epilepsy surgery, the most important pathology is that of focal cortical

dysplasia (29). As is discussed next, hippocampal sclerosis can coexist with another distinct pathology. The corresponding findings on imaging may be variable depending on the pathology. Many of the patients with nonmesial TLE who do not have an obvious lesion are called "MRI negative." PET scans can show temporal hypometabolism in these "MRI-negative" cases, and pathology of resection specimens frequently reveals subtle focal cortical dysplasia.

These subcompartments of TLE lead naturally to the "Temporal Plus" concept. In a series of 80 patients (30) investigated by stereo-EEG (SEEG), 22 (27.5%) were classified into the Temporal Plus category based on the topography of initial EEG seizure onset, of which 9 involved the inferior frontal cortex, 7 the suprasylvian opercular cortex, and 6 the temporoparietooccipital junction. Hippocampal sclerosis by MRI was found in 77% of these patients, and they were treated surgically by resection of the temporal lobe and the additional cortical areas identified. When contrasted with patients with TLE proper, differences are found in auras, seizure manifestations, and scalp EEG along the lines expected based on the nonmesial TLE subtypes discussed. What remains far from agreement is the frequency of occurrence of Temporal Plus. The Grenoble cohort gave a high estimate of 27.5% in suspected TLE. By contrast, in the first 100 SEEG implantations into all lobes at Cleveland Clinic (31), only 5% had simultaneous frontal and temporal onsets treated by combined resection of the orbital or inferior frontal cortex and temporal lobectomy. There were no cases of temporoinsular epilepsy, but there were examples of frontoinsular or operculoinsular epilepsy. The biologic or pathologic basis of "Temporal Plus" can only be speculated upon. When there is a combination of hippocampal sclerosis and epileptogenicity beyond the temporal lobe, the situation can be viewed as an example of dual pathology. In this setting, pathologies such as focal cortical dysplasia or traumatic encephalomalacia are not necessarily bound to anatomical lobar boundaries.

DUAL PATHOLOGY IN TEMPORAL LOBE EPILEPSY

The term has been used in different ways, leading to possible misconceptions if definitions are not stated at outset. Experimentally, it has been applied to the creation of a two "hit" model of epilepsy, for instance, first irradiating rodent pups in utero who are then subjected to a second insult in the postnatal period. From the pathologist's point of view, it means two separate definable pathologies. In practice, this usually means the presence of either hippocampal sclerosis or cortical dysplasia with another defined pathology (17,29). It is well known that cortical dysplasia is often associated with or contiguous to a neurodevelopmental tumor such as ganglioglioma and dysembryoplastic neuroepithelial tumor, wherever its location. Cortical dysplasia can present with hippocampal sclerosis in the same temporal lobe. The coexistence of focal cortical dysplasia with another pathology, be it tumor, hippocampal sclerosis, vascular malformation, or other, is now classified as FCD type III (29). Finally, dual pathology is also used to indicate the presence of two macroscopic and topographically separate structural abnormality detected by MRI.

Based on pathologic examinations, the presence of both hippocampal sclerosis and surrounding cortical dysplasia or other definition of malformation of cortical development occurs in 35% to 45% of temporal lobe resections (32,33). Others have defined one pathology, that of hippocampal sclerosis by imaging, and the other of cortical dysplasia by pathology in the resected specimen (34) and found that both coexist in 38%. Controversy abounds on what constitutes a true marker of a significant developmental abnormality in imaging studies of TLE. In one series of 30 patients with

MRI-visualized temporal lobe developmental malformation based on blurring or signal change (but only 4 confirmed by pathology), 65% had associated hippocampal sclerosis based on MRI visual analysis and 87% by volumetric analysis (35). However, the histopathologic correlation of gray–white blurring and white matter signal increase in the anterior temporal lobe is a matter of controversy. One study found increased heterotopic neurons in the white matter (36). Others could not confirm these findings but identified a correlation of anterior temporal white matter blurring on MRI with myelin loss, increased water content, and axon degeneration (37,38), which may serve as markers of more prolonged or severe disease.

When dual pathology is defined by macroscopic findings on MRI, the incidence appears to be about 15%. In 100 patients with MRI volumetric or histologic evidence of hippocampal sclerosis, malformations of cortical development were found in 15% (39). But of interest, many of the malformations were either bilateral or on the side contralateral to the diseased hippocampus. Separately, in 167 patients with macroscopic lesions, whether temporal or extratemporal, 15% had an atrophic hippocampus defined by abnormal volumetric ratio (40). Atrophy is more common in patients with porencephalic cyst (31%), malformation of cortical development (25%), and gliosis (23.5%) as compared to tumors (2%) or vascular malformations (9%). Interestingly, the side of hippocampal atrophy can be found opposite to the side of the lesion. A history of febrile seizures occurred more frequently in those with hippocampal atrophy.

The clinical questions relevant to dual pathology include how each contributes to the epileptogenic process, whether one is the cause and the other the effect, and if resection of both is required for lasting seizure control in those considered for epilepsy surgery. Cortical dysplasia next to a neurodevelopmental tumor is frequently epileptogenic or at least potentially epileptogenic. Thus, invasive EEG recordings typically show seizure onset from an area next to the tumor, and a lesionectomy without removal of the surrounding epileptogenic areas more often results in surgical failure to control seizures. When cortical dysplasia occurs with hippocampal sclerosis in the same temporal lobe, there are more seizure onsets from the neocortical structures, either simultaneous with the hippocampus or independently as studied by combined subdural and depth electrodes (41). For this type of dual pathology with hippocampal sclerosis and histologic cortical dysplasia in the same temporal lobe, there is no major difference in postsurgical seizure outcome as compared to patients with focal cortical dysplasia alone, at least when followed over a 2-year period (42,43), although longer-term follow-up is necessary to learn if this pathology predisposes to late recurrences. When dual pathology is defined by two macroscopic lesions, it makes sense to remove both if they are amenable to safe resection within the same temporal lobe. The principle of removing both lesions becomes less certain when the distance separating the two gets bigger and bigger, as for instance, when there is hippocampal sclerosis in the temporal lobe and a separate lesion in the frontal, parietal, or occipital lobe (Fig. 24.2). Some authors recommend removal of both pathologies, but the experience is based on very small numbers (44). It becomes even more challenging when the lesions are in opposite hemispheres, or when hippocampal sclerosis coexists with diffuse cortical malformations in both hemispheres. For the foreseeable future, such cases will require invasive EEG evaluation to guide surgical planning on an individual basis.

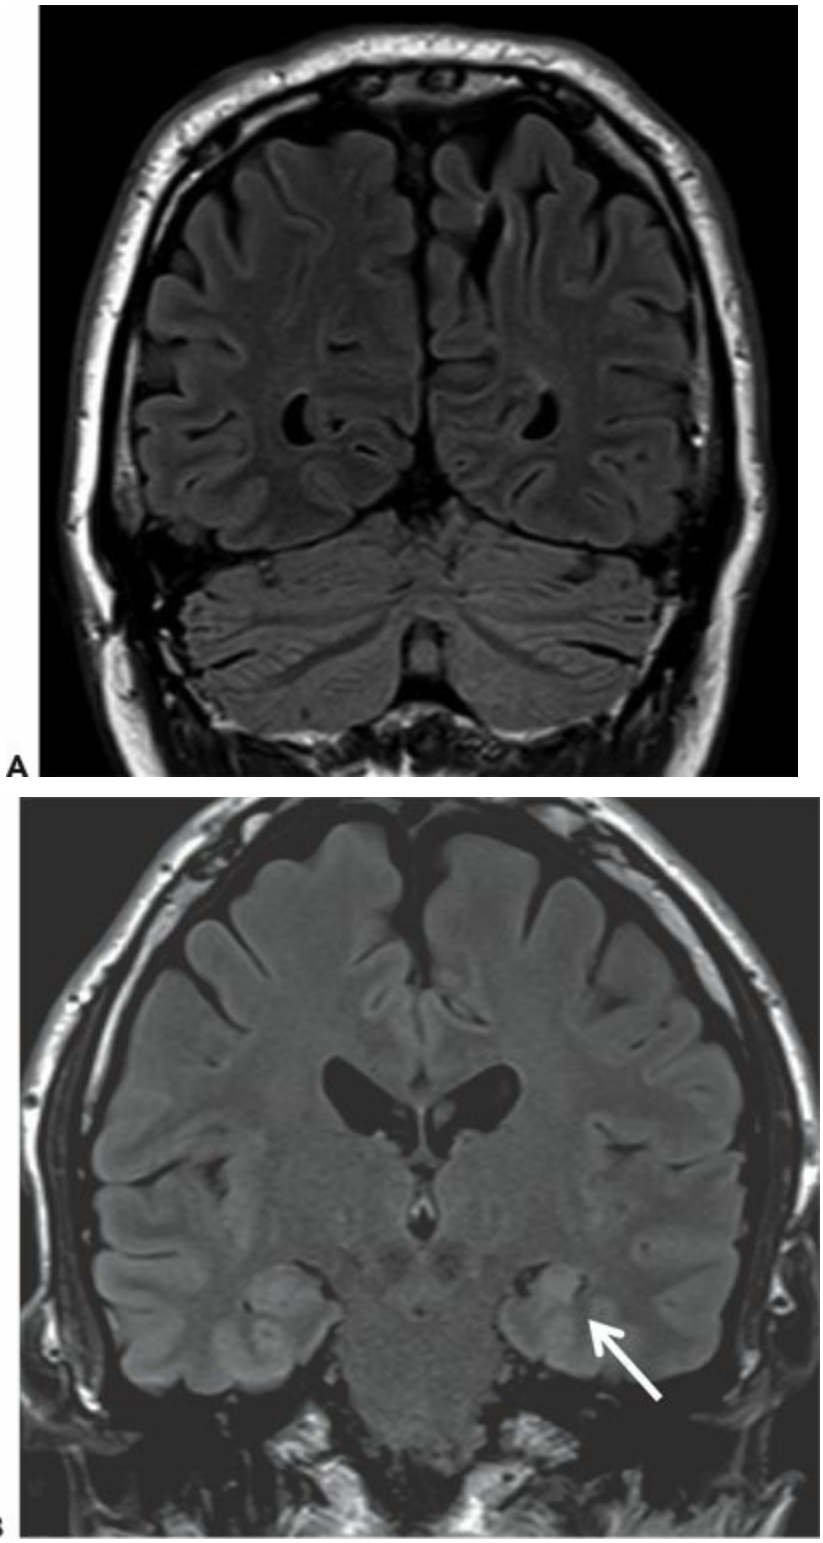

Figure 24.2. Case history: The patient had surgical correction of craniosynostosis as an infant. Seizure onset was at the age of 40 years. Early on, he had an aura of "being on the outside looking in," but later, his seizure semiology changed and the aura presented with light-headedness and dizziness. Seizures evolved into chewing and hand automatisms, with right facial tonic deviation, followed by progression into a generalized convulsion. Scalp EEG showed left (60%) and right (40%) temporal sharp waves, with scalp ictal EEG patterns lateralized to the left hemisphere. SEEG investigation showed seizures arising from the left hippocampus and entorhinal cortex. He underwent left anterior temporal lobectomy and became seizure free. **A:** Left mesial parietal encephalomalacia. **B:** Left hippocampal atrophy and sclerosis (arrow).

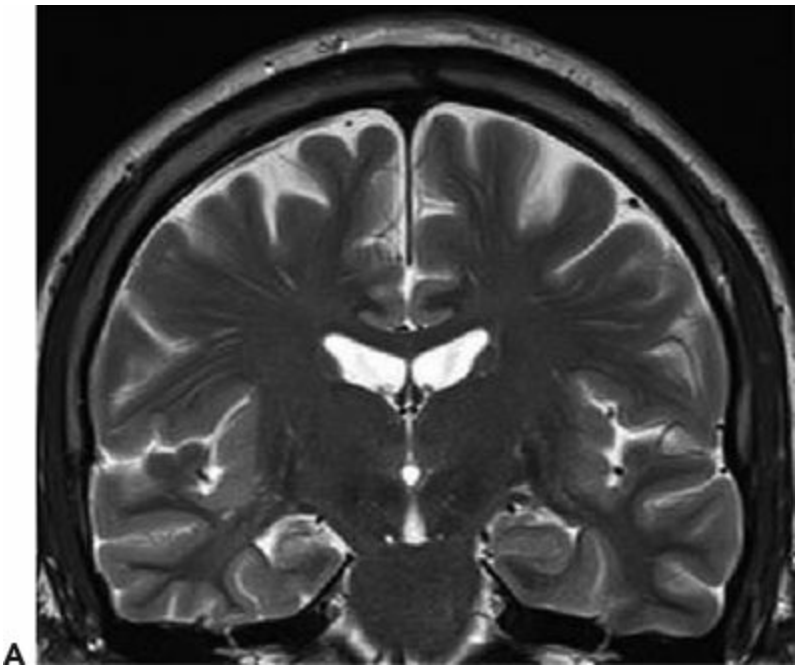
ATYPICAL MANIFESTATIONS OF TEMPORAL LOBE EPILEPSY AND PSEUDOTEMPORAL

The picture of TLE in childhood can be different, particularly due to modification by maturational factors. In the first few years of life, a child is unlikely to report auras but is likely to show behaviors in response to the experience, for instance by running to a parent for help. Early on, motor features can be rather nondescript with bilateral tonic or clonic limb movements or head nods (45). Seizures frequently manifest clinically with behavioral arrest and posturing or by a paucity of movements, a hypomotor seizure (46).

Other atypical manifestation include the coexistence of focal and generalized EEG discharges and seizures, exclusively generalized EEG discharge and seizures, and TLE looking like extratemporal epilepsy. In the latter, having an appreciation of the subcompartments of TLE and how seizures spread outside of the temporal lobe to other networks may help explain the extratemporal features. The coexistence of focal and generalized EEG features in patients with TLE is well known but the incidence unclear. In 101 patients who became seizure free after temporal resection (10), 38% had bilaterally synchronous spike–wave complexes as an interictal finding. This is surprisingly high as compared to 1% seen in the 67 TLE patients who were rendered seizure free after resection at a different center (15). Hypotheses to explain the coexistence of focal and generalized EEG features include an inherited trait of generalized epilepsy and other unknown synchronizing mechanisms producing bilateral generalized discharges, potentially in the setting of early developmental lesions. Less than 1% of patients truly express both clinical and EEG features of focal and generalized epilepsy, either chronologically with generalized seizures presenting earlier or concurrently (47). Even less frequent, generalized EEG discharges and seizures can be the only expression of surgically treated TLE (Fig. 24.3).



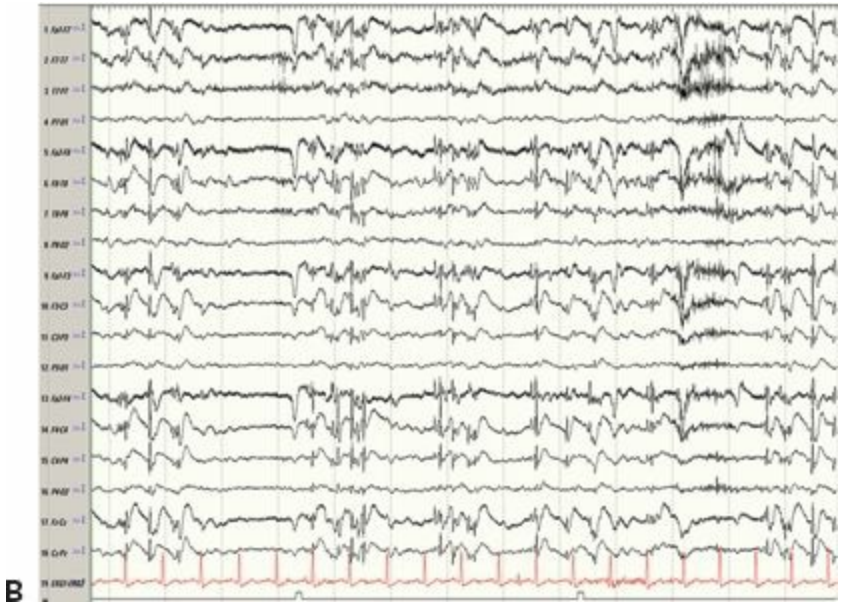


Figure 24.3. Case history: A 44-year-old man had febrile seizures twice at 2 years of age followed by afebrile seizures. Clinically, he had an aura of dizziness, and then either stared or entered a generalized tonic–clonic seizure. PET showed right temporal hypometabolism. Ictal SPECT (SISCOM) showed right temporal hyperperfusion. He has been seizure free after a right temporal lobectomy. **A:** Right hippocampal atrophy. **B:** Ictal EEG 6 minutes after initial onset. One minute later, the patient became unresponsive and entered a generalized tonic–clonic seizure.

It is also possible to mistake extratemporal epilepsy for TLE as encompassed by the term "pseudotemporal" epilepsy (48). The error is most commonly committed after a too cursory analysis of clinical semiology and scalp EEG findings. The eventual clues revealing seizures to arise from outside of the temporal lobe usually derive from the symptoms of the initial aura and imaging findings. Here, the temporal lobe acts as a "sink" to a propagated source, making the interictal and ictal EEGs, and part of the seizure evolution indistinguishable from that of TLE proper (49).

UNUSUAL CAUSES OF TEMPORAL LOBE EPILEPSY

A rare cause of TLE is an encephalocele or encephaloceles on the floor of the temporal fossa. They are most commonly found at the temporal tip near the ridge of the sphenoid bone. In earlier case reports, the pathology was often not suspected and only uncovered during surgery (50). The clinical and EEG manifestations are indistinguishable from mesial TLE, and therefore, these findings were previously regarded as MRI-negative TLE. But improvements in MR and CT imaging now nearly always permit preoperative diagnosis as long as the studies are done and looked at properly (51). Imaging reveals erosion of the greater wing of the sphenoid bone and protrusion of either CSF or brain signal material below the temporal floor (Fig. 24.4). Single or multiple adjacent encephaloceles are seen at operation. Pathology reveals a mix of gliosis, disorganization, or dysplasia in the prolapsed part of the cortex and sometimes with similar pathology in the amygdala. This is a surgically remediable pathology of TLE.

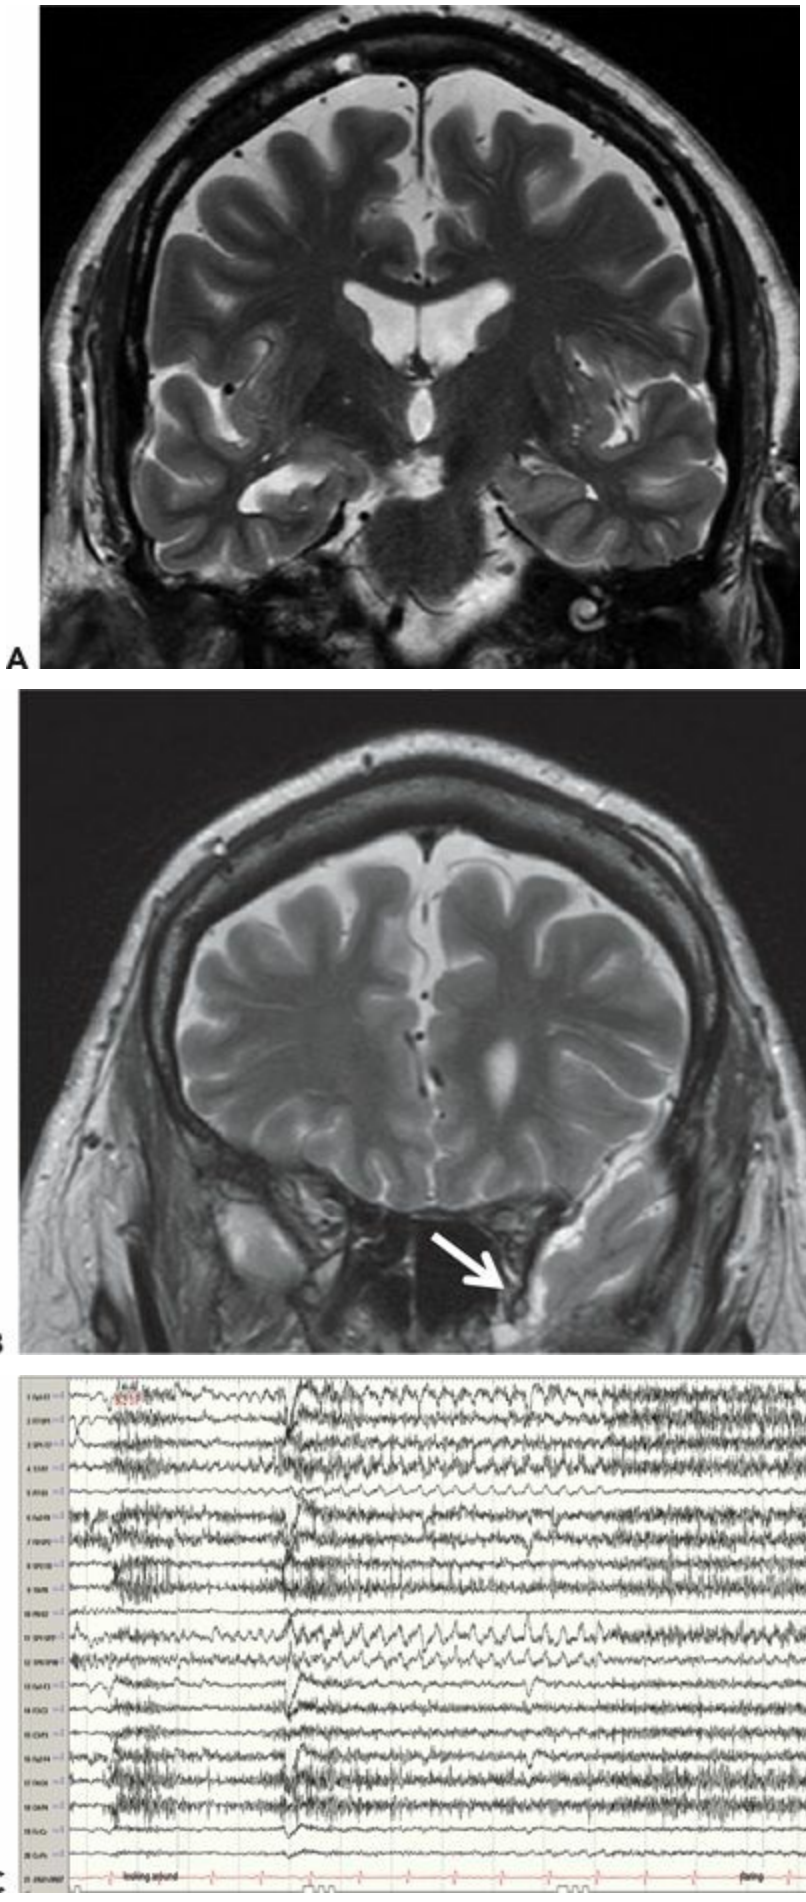

Figure 24.4. Case history: This is a 71-year-old man with seizures since the age of 48 years. Seizures occur without aura or warning. He either stares off or enters a generalized tonic–clonic seizure. Cursory examination of the MRI raised question of right hippocampal atrophy. Interictal sharp waves are left (70%) and left (30%) anterior and mesial temporal while three seizures recorded showed a left temporal-onset pattern. PET study confirmed left temporal hypometabolism. **A:** Right hippocampal atrophy. **B:** Left anterior temporal

encephalocele (white arrow). **C:** Ictal EEG onset in form of rhythmic 3-Hz sharp waves from left anterior temporal region.

Compelling pathologic reports of chronic inflammation, namely the presence of perivascular lymphocytic infiltrates and microglial nodules, intermittently surfaced in the literature of patients surgically treated for TLE (52,53). These pathologic features of chronic inflammation are similar to those found in Rasmussen encephalitis. The TLE cases, however, presented more often with adult age onset and did not exhibit a progressive course of hemispherical damage and malignant epilepsy as seen in typical Rasmussen encephalitis. The jury is still out if this is a real entity or related to neuropathologic criteria that may differ from center to center.

Knowledge on autoimmune mechanisms that can cause epilepsy is rapidly expanding. Autoimmune conditions can be broadly divided into paraneoplastic and nonparaneoplastic conditions, and those with antibodies directed against either intracellular or cell surface antigens (54). When causing epilepsy, the mesial temporal structures are frequently involved; hence, the term limbic encephalitis is used. Clinical, EEG, and imaging features converge in the temporal lobe (55–57). Auras are frequent and prominent, occur independently, and may evolve into complex partial and secondarily generalized seizures. Two-thirds have additional neurocognitive decline. Interictal and ictal EEG findings are usually consistent with mesial TLE. MRI findings often go through a series of changes. Acutely, there is swelling and signal change in the amygdala and hippocampus in more than half of the cases, and less commonly in other temporal structures, which may contrast enhance (a third) and less commonly show restricted diffusion. Later, swelling in the mesial structures subsides and converts to atrophy and sclerosis. One or both temporal lobes can be involved. Although autoimmune limbic encephalitis can occur at all ages (youngest 2.5 years in one series), distinguishing features alerting to the diagnosis include later-onset peaking in the 50s or 60s, abrupt explosive onset, daily seizures (80%), and rapid neurocognitive decline. In addition to identification of an autoantibody, one other test that can be considered diagnostic is the presence of bilateral limbic hypermetabolism on FDG-PET scan. Some of the most common antibodies linked to limbic encephalitis against intracellular antigens include ANNA1 and 2, CRMP-5, amphiphysin, Ma, and GAD antibodies, and all are strongly associated with an underlying malignancy. Additionally, antibodies to cell surface components, such as those to voltage-gated potassium channel complex (VGKC, and associated LGI1, CASPR2), NMDA, GABA, may or may not have an underlying neoplasm; in fact, the majority of VGKC cases are now thought to be autoimmune and not necessarily paraneoplastic and may be the most commonly found antibody in adult patients presenting primarily with seizures (56). Recognition of this diagnosis is important to screen for malignancy and to guide treatment. Effective treatment is contingent on removal of the malignancy when present, or immunotherapy that typically starts with intravenous steroids and immune globulin but may require immunosuppressive drugs for long-term control.

CHAPTER 25 THE EXTRATEMPORAL EPILEPSIES

CARLA LOPINTO-KHOURY AND MICHAEL R. SPERLING

INTRODUCTION AND OVERVIEW

Seizures arising from frontal, parietal, and occipital lobes constitute extratemporal localization-related epilepsies (LRE). They encompass a wide variety of seizure types and syndromes caused by a broad array of conditions, ranging from relatively benign genetic epilepsies to those due to progressive lesions. Their prevalence is not well defined. A study conducted in Rochester, Minnesota, found that patients with partial seizures accounted for 59% of the total population with active epilepsy in 1980, which is probably an underestimation (1); the investigators did not distinguish between temporal and extratemporal lobe epilepsies. The National General Practice Study in the United Kingdom found temporal lobe epilepsy (TLE) in 27% and frontotemporal in 5.6%, so the extratemporal epilepsies constitute perhaps two-thirds to three-quarters of all LRE (2).

Of the extratemporal lobe epilepsies, frontal lobe epilepsy (FLE) is the most common by far, followed by occipital and then parietal lobe epilepsies. This is not surprising based on the relative percentage of cerebral volume each lobe occupies. Clinical seizure patterns are quite varied among the extratemporal lobe epilepsies, with unique clinical presentations and specific seizure types. Diagnosing extratemporal lobe epilepsy (ETLE) is often challenging, as seizure propagation may cause misleading behavior and scalp electroencephalogram (EEG) findings. Many patients may have epilepsy that spans more than one lobe (depending upon lesion size), and the temporal lobe may be involved in the epileptic process along with extratemporal cortex in some patients. Hence, the diagnosis is often muddled, for the epileptogenic process is frequently not as crisply localized as might be wished.

Extratemporal epilepsies may be caused by a wide variety of conditions, including inherited syndromes (e.g., benign epilepsy of childhood with centrotemporal spikes, autosomal dominant FLE, occipital lobe epilepsy, and others) and acquired conditions (e.g., infections, tumors, trauma, stroke, vascular malformations, cortical dysplasias, and others). The extratemporal epilepsies are distinguished primarily by the phenomenology of their seizures, and prognosis largely depends upon the nature of the underlying syndrome (whether a benign genetic cause or not). Treatment for all focal epilepsies usually begins with antiepileptic medication, using drugs that are suitable for all focal epilepsy, as there is no specific therapeutic regimen optimal for ETLE. The prognosis is nonuniform, and surgical management for refractory cases may require extensive evaluation due to challenges with localization and the potential for functional deficits. This chapter discusses the frontal, occipital, and parietal lobe epilepsies, reviewing clinical seizure patterns, specific syndromes and etiologies, and the issues related to evaluation and management for each lobe in turn.

FRONTAL LOBE EPILEPSY

FLE surgery is the second most common type of epilepsy surgery performed; however, FLE may constitute as much as 60% of the LRE population (2). The frontal lobe occupies the largest volume of the brain and may be anatomically subdivided into the anterior frontopolar, orbitofrontal, mesial (or medial), dorsolateral, and opercular regions.

Diagnosing FLE clinically may be difficult, but some features help to distinguish FLE from TLE. The seizure frequency in FLE may be higher than 30 per month, even upward of 100 per month. In addition, patients often have seizures with an older age of onset, that is, after age 5 (3). Semiologic features that help distinguish FLE from TLE include bilateral limb movement at the onset of seizures, absence of oroalimentary automatisms, and a very brief or absent postictal confusional state (4). Vocalization is common, and the seizure duration is generally shorter than the typical temporal lobe seizure, usually <1 minute. Auras may occur with frontal lobe seizures, for instance, localized somatosensory auras may herald a supplementary motor area (SMA) seizure, and fear may denote the state of a seizure originating in the cingulate gyrus.

A variety of conditions may cause FLE. Malformations of cortical development (MCD) represent the largest fraction of patients in whom epilepsy surgery is performed; however, trauma, stroke, and neoplasm (both benign and malignant) are common acquired causes. Other developmental anomalies, meningitis or encephalitis, hamartomas, vascular malformations including arteriovenous malformations, and cavernous hemangiomas, are encountered as well. Genetic causes have also been discovered. Autosomal dominant nocturnal FLE and benign epilepsy with centrotemporal spikes are perhaps the most common observed syndromes. These are further discussed elsewhere.

Seizure Types

Frontopolar Seizures

Seizures originating in the frontopolar regions are perhaps most often due to head trauma. The frontopolar region is susceptible to head trauma, which can cause encephalomalacia and gliosis, though other etiologies can occur (e.g., tumor, vascular malformations). If auras are experienced, they may present with forced thinking, but often, auras do not occur in seizures arising from the frontal pole. Rather, secondary generalization is often the first manifestation. Lengthy seizures with partial responsiveness similar to atypical absence can rarely be seen as well, progressing to tonic or tonic–clonic seizures (5,6).

Orbitofrontal Seizures

Seizures of orbitofrontal origin produce a variety of symptoms, which often are more representative of their pattern of spread rather than where they originate. In children, complex partial seizures without secondary generalization can be associated with autonomic arousal including fear, flushing, piloerection and abdominal pain, and vocalizations with manual automatisms. EEG may demonstrate a pattern of periodic bifrontal sharp and slow waves. Behavior may in part be due to spread to the hypothalamus and temporal lobe (7). Other investigators have found hypermotor activity along with automatisms (and loss of awareness in some patients) and also noted asymmetric tonic posturing, frequent head and body turning, and ictal laughter. Scalp EEG findings may not be localized, and

intracranial EEG may be needed for diagnosis (8). Olfactory hallucinations may also occur, presumably related to spread (5). Sphenoidal electrodes might improve the sensitivity of scalp EEG, but often, orbitofrontal seizures have misleading EEG localization. Because of the close connections to the temporal lobes, patients with orbitofrontal seizures may be misdiagnosed as having TLE.

Medial Frontal Seizures

The mesial frontal lobe consists of the medial aspect of the motor strip, SMA, and the anterior cingulate gyrus.

Supplementary Motor Area.

The supplementary motor area, also called the supplementary sensorimotor area, is located immediately anterior to the motor strip on the medial surface of the frontal lobes. Supplementary motor seizures have well-defined clinical characteristics. Patients frequently report somatosensory aura such as numbness in a contralateral limb, which is followed by unilateral or bilateral tonic limb posturing. This has been described as showing a "fencer" posture, the "figure of four" sign, or "M2e" posturing. Patients may then also have whole body movements, vocalizations, and perhaps emotional semiology, with late head and eye version (9). Negative motor seizures rarely may occur as well, with inability to voluntarily move the extremities while the patient is awake. SMA seizures often are nocturnal and occur in clusters, and awareness and consciousness are usually retained unless secondary generalization occurs (10). Surgical removal of the SMA may result in transient akinetic mutism and either unilateral or bilateral weakness or apraxia (the "SMA syndrome"), which usually resolves in 1 to 4 weeks after surgery, but may last as long as 6 months (11,12). Figure 25.1 demonstrates the findings in a patient with SMA epilepsy.

Figure 25.1. Dorsolateral FLE with seizures arising from the motor strip: a 21-year-old woman with simple partial seizures since a viral illness at age 9. Seizures began to cluster at age 19 after 10 years of response to medical therapy. The clinical pattern was an aura of nonspecific aura of dizziness, followed by right leg greater than arm tonic stiffening with preserved awareness. Stage I evaluation (**A**) shows CZ beta, which was not clearly determined to be ictal, and abundant muscle artifact. Stage II evaluation with left dorsolateral and interhemispheric subdural electrodes (map, **B**, MRI in **C**) showed ictal onset in primary motor cortex and gamma at

contacts 8, 9, 12, and 13 in the left posterior grid (**D**). Subpial transections over the ictal onset zone were performed.

Anterior Cingulate.

The anterior cingulate gyrus has extensive connections throughout the frontal lobe as well as the limbic system, brainstem, and thalamus. It is involved in emotions, autonomic functions, perception of pain, and motor planning (13). Whereas the amygdala is implicated in the generation of fear in auras of TLE, the cingulate gyrus in the medial frontal lobe is thought to be the generator of fear auras in patients with FLE. This may relate to propagation of ictal discharges to the amygdala. Patients with proven lesional cingulate epilepsy have complex, hypermotor behaviors such as running, kicking, grasping, or thrashing. Behavioral changes including postictal or interictal agitation are seen, which can resolve after lesionectomy (14).

Primary Motor Area

Primary motor cortex in the medial frontal lobe (interhemispheric region) is responsible for movement of the lower extremity and sphincter control. Seizures arising from the leg motor cortex produce clonic movement of the thigh, leg, or foot and may produce bladder or bowel incontinence.

Dorsolateral Frontal Seizures

The dorsolateral frontal lobe includes the lateral primary motor strip, perirolandic region, and premotor areas. Seizures arising from premotor dorsolateral frontal cortex can cause tonic posturing of the arm or face, sensory phenomenon, or psychosensory auras including forced thinking (as seen with frontopolar seizures). Early spread to motor cortex will cause clonic activity while still conscious, whereas temporal lobe seizures are more likely to produce experiential or epigastric auras with motor activity once consciousness is impaired (15). Seizure propagation to Broca's area may cause speech arrest, and contralateral head and eye version commonly occur with spread to the frontal eye fields. The EEG more often shows localized findings than with mesial or orbitofrontal seizure origin because of the close proximity of the cortex to the scalp. The scalp ictal EEG often shows fast activity in the beta frequency range, in contrast to temporal lobe seizures, which more often begin with rhythmic theta discharges. Ictal beta at seizure onset is often well localized in dorsolateral frontal lobe seizures and predicts a good postsurgical outcome, but the same is not necessarily true for all FLE patients (16,17).

Seizures that arise from the primary motor strip differ clinically from those of the SMA or premotor area in that they usually begin with contralateral facial or hand clonic activity followed by spread to the rest of that side of the body (i.e., a jacksonian pattern of spread), with speech arrest and then head and eye version. Patients might remain awake, or these seizures might generalize. Progression to asymmetric tonic limb posturing occurs as the seizure spreads to the SMA (9). These seizures usually have ictal EEG localized to the perirolandic area. Surgical resection of the motor strip will produce permanent weakness and clumsiness unlike the transient deficit associated with SMA resection. Figure 25.2 provides an example of a patient with epilepsy localized to the motor cortex.

Frontal Opercular and Insular Seizures

The operculum is the region of cortex overlying the insula and is subdivided into frontal, temporal, and parietal opercular cortices. The insula is considered by some as an anatomic part of the temporal lobe and a distinct lobar entity by others. This section will discuss seizures that arise from the frontal operculum and insula where they are confluent, as a subdivision of frontal lobe seizures.

Seizures arising from the frontal operculum often present with gustatory auras, apraxias of swallowing or mastication, and dysarthria. Patients may chew, may salivate, and may complain of abnormal laryngeal sensations, paresthesias in the arm and face, choking sensation, and trouble breathing. Early spread in a posterior and superior direction often causes facial clonic activity. An acquired epileptiform opercular syndrome has been described with ictal manifestations of above symptoms in addition to other seizure types. This has clinical similarities to the structural disease in Foix–Chavany–Marie syndrome and is analogous to Landau–Kleffner syndrome, but with symptoms localizing to the anterior rather than posterior operculum (18). Stereotactic EEG studies show that seizures with frontal opercular and insular onset produce the aforementioned symptoms at onset with hypermotor or asymmetric tonic posturing during sleep (19). This probably reflects variable spread patterns to mesial frontal structures (i.e., anterior cingulate or SMA cortex).

Localization of Frontal Lobe Seizures by EEG

The interictal EEG is often not helpful in the localization of frontal lobe seizures. Only a small proportion of patients have spikes restricted to the frontal lobe focus. Some patients have bifrontal or

generalized spike-and-wave discharges, while others may have only temporal lobe interictal spikes. Other individuals have multifocal spikes, and some patients have a normal interictal EEG (3).

The ictal EEG is often unrevealing in frontal lobe seizures, sometimes obscured by movement and muscle artifact, and at other times either negative or poorly localized. Focal seizure onset occasionally is noted in the scalp EEG, usually with high-frequency beta frequency onset, but more often, the ictal EEG does not provide adequate localizing information. This may be due to the fact that much frontal cortex is buried, either within sulci or in medial or basal regions that are poorly sampled by the scalp EEG and by rapid contralateral spread of ictal discharges via the corpus callosum. Seizures beginning in mesial frontal lobe are particularly difficult to record with scalp EEG. Half of patients with mesial FLE will have generalized epileptiform patterns, nonlateralized midline discharges, or no EEG findings when seizures begin. FLE arising in dorsolateral cortex more often appear lateralized than mesial FLE in the ictal EEG, though remain less well localized than temporal lobe seizures. Incorrect seizure lateralization is more often observed in lateral FLE patients than in mesial FLE patients (20).

When the scalp ictal EEG is nonlocalized—as is common in the extratemporal lobe epilepsies—noninvasive neuroimaging techniques other than magnetic resonance imaging (MRI) including PET-FDG, magnetoencephalography, ictal single photon emission tomography, and functional MRI (including with simultaneous EEG) may help to localize the source of seizures and guide intracranial electrode placement that is required.

A recent series of FLE patients localized by FNIRS (functional near-infrared spectroscopy) showed the promise of this novel technique as an adjunct to video–EEG monitoring (21).

Differential Diagnosis

The clinical patterns of frontal lobe seizures include bizarre behaviors, which may be confused for nonepileptic events. Patients may be misdiagnosed as having parasomnias or receive a diagnosis of psychogenic nonepileptic seizures (PNES) and mistakenly thought to have a primary psychiatric disease. The challenge in diagnosing FLE is partly due to odd ictal behaviors, which may be confounded by ambiguous EEG findings as noted above. It is important to recognize stereotypy of behavior and nocturnal clustering, which suggest frontal lobe seizures rather than PNES or parasomnias. Patients with FLE may have preserved awareness during bilateral body movement, which may include bicycling and large thrashing movements. Ictal eye closure, pelvic thrusting, and prolonged seizure duration (i.e., >5 minutes) suggest PNES rather than FLE.

Surgical Considerations

After failure of medical therapy, surgical planning for FLE should take into account the possibility of eloquent cortex (e.g., areas important for language, movement, personality) in the epileptogenic zone. Intracranial EEG may be performed with subdural grids to over Broca regions and the motor strip, which can be mapped either intraoperatively or extraoperatively at the bedside with electrical stimulation of the cortex. If the seizure focus overlies eloquent cortex, performing multiple subpial transections to preserve columnar organization can minimize postoperative functional deficits or responsive neurostimulation (RNS) can be performed (22). The addition of an anterior corpus callosotomy (ACC) may be considered for FLE patients with frequent secondary generalization, since that procedure alone often offers benefit. For patients who have multifocal or bilateral onset zones,

RNS implantation may also be considered. Deep brain stimulation of the centromedian nucleus was performed experimentally in patients with FLE, but might be more suitable for patients with generalized epilepsy syndromes (23). Vagus nerve stimulation also may be considered for refractory cases that are not candidates for focal resection or fail resective therapy.

Outcome of Surgery for Frontal Lobe Epilepsy

Frontal lobe resections have the worst seizure-free outcomes for epilepsy surgery, with 27% of patients found to be seizure free after surgery in a large metaanalysis (24), though some individual series demonstrate a seizure-free rate as high as 60% (17). In children, frontal lobe resections more often resulted in unsatisfactory outcomes than posterior resections in a meta-analysis of nonlesional cases. The authors found that complex partial seizures rather than generalized tonic–clonic seizures and focal cortical dysplasia identified on pathology were associated with better outcomes (25).

The class I outcome in the series of 16 patients reported by Laskowitz et al. (3) in 1995 was 67%. Fourteen of them had frontal lobe resections, of which half were accompanied by ACC. The remaining two patients received ACC alone. Follow-up was at least 5 years with a mean follow-up period of 46 months. Electrocorticography was performed intraoperatively for most patients, and five patients underwent chronic intracranial monitoring. A lower preoperative seizure frequency was associated with seizure-free outcome as was a later age at onset (3). Another series reported 55% seizure freedom at 1 year, which dropped to 27% at 5 years (26). The presence of generalized interictal spikes, extrafrontal MRI findings including hippocampal sclerosis, a normal MRI with either normal pathology or malformation of cortical development, acute postoperative seizures, and postoperative interictal spikes on EEG correlated with a recurrence of seizures postoperatively (26).

A more recent series at the same center of a larger cohort found 66% seizure freedom at 1-year, 52% at 2-year, and 44% at 5-year follow-up. Longer seizure duration (>5 years) was predictive of poor outcome especially in children and those with MCD and tumors (27). Another recent study of 58 FLE patients who underwent focal resection with long-term follow-up demonstrated a favorable outcome in 60% of patients. They did not find any difference in outcome based on the location of resection (28). An intracranial EEG study noted that an ictal onset zone of <2 cm and delayed spread of the ictal discharges to other lobes were associated with postoperative seizure freedom. Dominant resections were more often followed by poor outcome, probably because the presence of adjacent language cortex limited resection size (17).

OCCIPITAL LOBE EPILEPSY

Occipital lobe seizures may arise from either primary visual or association cortex. Elementary visual auras such as seeing lights and shapes arise from primary cortex, while more complex hallucinations arise from adjacent association cortex in occipital, posterior temporal, or parietal lobes. Eye blinking, eye flutter, and amaurosis are other common clinical phenomena. Gaze deviation, typically ipsilateral, without impairment of consciousness also has been reported (29).

In children occipital lobe epilepsy may be caused by a variety of conditions, such as trauma, tumors, and stroke, but specific causes include celiac disease, childhood occipital epilepsy syndromes including Panayiotopoulos and Gastaut types, mitochondrial disease, and posterior reversible encephalopathy syndrome. Lafora body disease is a form of progressive myoclonic epilepsy in which patients may experience occipital seizures early in the course of illness. Celiac

disease is associated with occipitoparietal lobe calcifications and epilepsy (30). The typical calcifications occur unilaterally and are sinuous and double contoured with associated microgyria. These findings may be confused with Sturge–Weber syndrome but have a different pathophysiology. Children often do not have intestinal symptoms when diagnosed with epilepsy, although some may have had an intestinal syndrome in infancy. Folate levels are characteristically low. Antigliadin antibodies and intestinal biopsy help diagnose the condition, and seizures can be successfully treated with a gluten-free diet when initiated early (31).

Occipital lobe epilepsy can also be difficult to diagnose. The occipital lobe has three surfaces, the mesial, lateral, and inferior surfaces. Mesial and inferior generators are often difficult to identify and lateralize with scalp EEG. Incorrect localization and lateralization are seen commonly, and generalized seizure patterns can be seen in over one-quarter of patients (20). Patients with occipital epilepsy often have coexisting temporal lobe abnormalities in the EEG and may have dual pathology affecting both occipital and temporal lobes (32).

Surgical Considerations

After surgery, 46% of patients are seizure-free based on a meta-analysis with long-term follow-up (24). Satisfactory (meaning Engel I and II) outcomes have been reported between 45% and 70% in studies done since the year 2000, and more recently published series have shown better outcomes than older series with as many as 68% achieving class I or II outcome (33). Although only small series have been reported, it has been noted that resections that include the temporal lobe and hippocampus result in favorable outcomes, which may be due to close connections to mesial temporal structures (32). Also, ample coverage of all three surfaces of the occipital lobe with intracranial electrodes (the lateral, mesial, and tentorial surfaces) is associated with better outcome (32). Cortical mapping to determine the extent of primary visual cortex and utilizing intracranial visual evoked potentials may help minimize postoperative hemianopsias. The desire to spare the visual fields is the main factor limiting the extent of surgical resection, and perhaps seizure-free rates. Figure 25.3 demonstrates an example of occipital lobe epilepsy.

PARIETAL LOBE EPILEPSY

The parietal lobe is the least common form of LRE, estimated to be the primary origin of seizures in perhaps 6% to 10% of patients. The diagnosis of parietal lobe epilepsy is perhaps the most challenging of all the extratemporal epilepsies when considering clinical symptoms and signs alone, because the parietal association cortex is often silent, and ictal symptoms only occur after propagation to adjacent lobes. Somatosensory auras, including a sensation of limb movement, and affective and vertiginous auras have been reported, as well as visual auras and rarely, painful sensations (34,35). Progression to tonic posturing is seen when superior or mesial parietal lobe foci spread to the SMA in the frontal lobe; oral and manual automatisms are seen when inferior and lateral parietal lobe seizures spread to the temporal lobes (36).

The interictal EEG of PLE is often unrevealing, and localization with scalp EEG is quite challenging. In one study (20), fewer than half of PLE patients were correctly localized on scalp

EEG, in part because more than one-third of PLE patients had generalized seizure patterns. Independent contralateral EEG discharges were also common (20).

Surgical outcome is similar to FLE cases, and 46% of patients were seizure free after surgery in the largest series of 82 patients (36). A more recent series of 26 patients noted a 54% seizure-free rate (34). Contralateral sensory loss and Gerstmann syndrome are potential postsurgical complications. Cortical mapping with somatosensory evoked potentials may help define primary sensory cortex when planning the extent of surgical resection.

LOCALIZATION OF EXTRATEMPORAL LOBE EPILEPSY

Problems in diagnosing and localizing the extratemporal lobe epilepsies have been discussed in detail above. One must be wary when multifocal or bilateral structural disease is present, and skepticism is always required when interpreting the scalp EEG. Close connections between different lobes of the brain, for example, parietal and frontal lobes or occipital and temporal lobes, may cause rapid and misleading propagation patterns in the EEG. Propagation pathways between the frontal and occipital lobes may also lead to misleading findings (31). Symptoms can be misleading as well; for instance, eye deviation usually is produced by activation of the frontal eye fields but can be seen with occipital foci, which produce ipsilateral version. Sensory disturbances commonly appear with frontal lobe lesions, but parietal lobe seizures produce these as well, and complex visual disturbances may be from the occipital, posterior temporal, or parietal association cortices.

CONCLUSION

The extratemporal lobe epilepsies constitute a fascinating set of conditions to diagnose and manage. They are underrepresented in the medical literature due to the aforementioned difficulties in establishing a correct diagnosis and because ETLE is often not surgically remediable, which can bias literature reports. Specific syndromes such as benign epilepsy of childhood with centrotemporal spikes or celiac disease have a good prognosis, however, and patients and their families can be reassured. The physician faced with a patient with medically refractory LRE should be knowledgeable of the clinical patterns described above to help guide further investigations when surgery is considered. Despite these hurdles, surgical success rates are good, and it is hoped that improved technology and cumulative experience will lead to better outcomes.

ACKNOWLEDGMENT

The authors would like to acknowledge special thanks to Dale Wyeth for assistance with figure preparation.

CHAPTER 26 MALFORMATIONS OF CORTICAL DEVELOPMENT AND EPILEPSY

GHAYDA M. MIRZAA, RUBEN KUZNIECKY, AND RENZO GUERRINI

The formation and development of the human cerebral cortex is a complex dynamic process that can be broken down into partially overlapping stages occurring over the span of several gestational weeks (1). In a simplified fashion, during the first stage, stem cells deep in the forebrain within the ventricular and subventricular zones lining the cerebral cavity proliferate and differentiate into young neurons or glial cells. During the second stage, neurons migrate away from their place of origin toward the pial surface and settle within the cortical plate. When neurons reach their destination, they arrange themselves into specific "architectonic" patterns, and this third phase involves final organization within the typical six layers of cortex, associated with synaptogenesis and apoptosis.

Any disruption of this process, whether by genetic or environmental factors, may result in malformations of cortical development (MCD). High-resolution magnetic resonance imaging (MRI) facilitates identification of MCD earlier in life, leading to improved diagnosis and clinical management at a younger age, and progress in understanding their pathogenesis. This chapter reviews common cortical malformations associated with epilepsy.

CLASSIFICATION

The 1996 classification scheme categorizes MCD based on the timing of disruption during the developmental stages of the human cortex (cell proliferation, neuronal migration, and cortical organization). Since then, scientific progress in imaging and molecular biology of brain development led to dramatically increased awareness, recognition, and understanding of MCD and related clinical presentations and comorbidities. The most recent update to the classification scheme in 2012 adapts to this gain in knowledge and is therefore genotype based, allowing a better conceptual understanding of these disorders (2). Table 26.1 lists these broad categories, and Table 26.2 outlines the most common genes identified in relation to MCD (3). The nomenclature and classification will undoubtedly continue to evolve during the upcoming years.

Table 26.1 Classification Scheme for Malformations of Cortical Development [a]

I. Malformations due to abnormal neuronal and glial proliferation or apoptosis
   A. Decreased proliferation/increased apoptosis or increased proliferation/decreased apoptosis—abnormalities of brain size
      1. Microcephaly (MIC)
         a. MIC with normal to thin cortex
         b. Microlissencephaly (extreme MIC with thick cortex)
         c. MIC with PMG
      2. Megalencephaly
   B. Abnormal proliferation (abnormal cell types)
      1. Nonneoplastic
         a. Cortical hamartomas of TSC
         b. Cortical dysplasia with balloon cells
         c. Hemimegalencephaly
      2. Neoplastic (associated with disordered cortex)
         a. Dysembryoplastic neuroepithelial tumor
         b. Ganglioglioma
         c. Gangliocytoma

II. Malformations due to abnormal neuronal migration
   A. Lissencephaly and subcortical band heterotopia
   B. Cobblestone complex/congenital muscular dystrophy syndromes
   C. Heterotopias
      1. Subependymal (periventricular) nodular heterotopia
      2. Subcortical (other than band heterotopias) heterotopia
      3. Marginal glioneuronal heterotopia

III. Malformations due to abnormal cortical organization (including late neuronal migration)
   A. PMG and schizencephaly
      1. Bilateral PMG syndromes
      2. Schizencephaly (PMG with clefts)
      3. PMG or schizencephaly as part of multiple congenital anomaly/ID syndromes
   B. Cortical dysplasia with balloon cells
   C. Microdysgenesis

IV. Malformations of cortical development, not otherwise classified
   A. Malformations secondary to inborn errors of metabolism
      1. Mitochondrial and pyruvate metabolic disorders
      2. Peroxisomal disorders

[a]These categories are further listed in an expanded format in reference (3).

Table 26.2 Genetic Etiologies of Malformations of Cortical Development

Malformations and syndromes	Gene[a]
A. Malformations due to abnormal neuronal and glial proliferation or apoptosis	
Decreased proliferation/increased apoptosis or increased proliferation/decreased apoptosis—abnormalities of brain size	
1. Microcephaly (MIC)	
MIC—mild–moderate phenotype (with simplified gyral pattern, normal stature, and relatively high function)	*ASPM*, *MCPH1*, *CDK5RAP2*, *CENPJ*, *STIL*, *CEP152*, *CEP135*, *CDK6*
MIC—severe phenotypes	*CENPJ*
Amish lethal MIC	*SLC25A19*
MIC with other brain abnormalities (PMG, heterotopia)	*ARFGEF2*, *WDR62*, *PNKP*, *NDE1*
MIC postnatal with disproportionate pontocerebellar hypoplasia	*CASK*
MIC with poor growth (microcephalic osteodysplastic primordial dwarfism, Seckel syndrome)	*ATR*, *PCNT*, *CEP152*, *CENPJ*, *ORC1*, *ORC4*, *ORC6*, *CDC6*, *CDT1*, *CEP63*, *RBBP8*, *RNU4ATAC*, *CEP135*
Microlissencephaly (MLIS)	
MLIS group a, $a = p$	
Barth MLIS syndrome (group b), $a = p$	
2. Megalencephaly (MEG)	
MEG—isolated or familial	
PTEN-related MEG–autism (also associated with Cowden syndrome, Bannayan–Riley–Ruvalcaba syndrome, and FCD)	*PTEN*
Megalencephaly-capillary malformation (MCAP) syndrome	*PIK3CA*
MEG–polymicrogyria–polydactyly–hydrocephalus (MPPH) syndrome	*AKT3*, *PIK3R2*, *CCND2*
Thanatophoric dysplasia	*FGFR3*
Abnormal proliferation (abnormal cell types)	
1. Hemimegalencephaly (HMEG)	*PIK3CA*, *MTOR*, *AKT3*
2. Focal cortical dysplasia	*PTEN*
3. Tuberous sclerosis complex	*TSC1*, *TSC2*
B. Malformations due to abnormal neuronal migration	
1. Lissencephaly (LIS)	
Classic LIS	
Miller–Dieker syndrome (MDS), $a = p$	*LIS1* + *YWHAE (contiguous gene deletion syndrome of 17p13.3)*
Isolated LIS sequence,	
$a = p$, $p > a$	*LIS1 (PAFAH1B1)*
$a = p$, $a > p$	*DCX (males)*
Other causes of LIS $a = p$, $a > p$	*TUBA1A*, *DYNC1H1*, *KIF2A*, *TUBB2B*, *TUBG1*
Baraitser–Winter syndrome (BWS), $a > p$	*ACTG1*, *ACTB*
Subcortical band heterotopias, $a = p$, $a > p$	*DCX (females)*
LIS with cerebellar hypoplasia (LCH)	
LCH group a, $a = p$, $a > p$, $p > a$	*LIS1*, *DCX*
LCH group b, $a > p$	*RELN*, *VLDLR*
LCH group c-d-f	*TUBA1A*
XLAG, $p > a$	*ARX*
LIS with agenesis of the corpus callosum (ACC), other types	
2. Cobblestone cortical malformations (AR)	
Fukuyama congenital muscular dystrophy	*FKTN*
Walker–Warburg syndrome (WWS)	*POMT2*, *POMGnT1*, *FKRP*, *FKTN*, *LARGE*, *POMT1*
Muscle–eye–brain (MEB) disease	*POMT2*, *POMGnT1*, *FKRP*, *LARGE*, *POMT1*
Mental retardation, MIC, and CMD	*POMT1*, *POMT2*
Bilateral frontoparietal cobblestone malformation (previously PMG)	*GPR56*
Dandy–Walker malformation with CDG	*B4GALT1*
CHIME-like syndrome	*SRD5A3*
CEDNIK syndrome	*SNAP29*
3. Heterotopia (XL, AD)	
Classical bilateral periventricular nodular heterotopia (PNH)	*FLNA*
Ehlers–Danlos syndrome and PNH	*FLNA*
Facial dysmorphism, severe constipation, and PNH	*FLNA*
Fragile-X syndrome and PNH	*FMR1*
Williams syndrome and PNH	
PNH with limb abnormalities (limb reduction abnormality or syndactyly)	
ACC and PNH	
ACC, PMG, and PNH	

Heterotopia (AR)	
MIC and PNH	*ARFGEF2*
Donnai–Barrow syndrome and PNH	*LRP2*
C. Malformations due to abnormal cortical organization	
PMG (XL, AD)	
Rolandic seizures, oromotor dyspraxia	*SRPX2*
ACC, MIC, and PMG	*TBR2 (EOMES)*
PMG, PNH, MIC	*ARFGEF2*
PMG, fetal brain disruption	*NDE1*
PMG, MIC	*WDR62*
Aniridia plus	*PAX6*
Facial dysmorphism and PMG	
MIC, hydrocephalus, and PMG	
DiGeorge syndrome	
Goldberg–Shprintzen syndrome	*KIAA1279*
Micro syndrome	*RAB3GAP1, RAB3GAP2, RAB18*
PMG, CBLH, MIC, ACC	*TUBA1A, TUBB2B, TUB3, TUBA8, TUBB5*

[a]The references for genes associated with MCD can be accessed through the Developmental Brain Disorders Database (DBDB) at https://www.dbdb.urmc.rochester.edu/home. This database is a publicly available, curated database that is dynamically linked to PubMed, GeneReviews, and the UCSC Genome Browser.

MALFORMATIONS OF CORTICAL DEVELOPMENT

Accurate diagnosis of MCD relies primarily on recognition of the malformation on brain MRI, which, in turn, determines correct prognosis and genetic counseling. In the following sections, the genetic, imaging, and functional aspects of the most common MCD are discussed, with special emphasis on epilepsy associated with these disorders.

MCD DUE TO ABNORMAL PROLIFERATION/APOPTOSIS (ABNORMALITIES OF BRAIN SIZE)

Malformations in this group are characterized by an increase or decrease in the number of neurons and glia with corresponding changes in brain size, designated as either microcephaly (MIC) or megalencephaly (MEG). The most common types of MIC and MEG are not typically included under brain malformations because brain structure appears grossly normal in isolated forms. However, detailed studies of neuronal cell types are not available. Furthermore, MIC and MEG often coexist with other developmental brain disorders such as polymicrogyria (PMG) and periventricular nodular heterotopia (PNH) in distinct phenotypes.

Microcephaly Syndromes

MIC is defined as head circumference 3 standard deviations (SDs) or more below the mean for the individual's age and gender. Historically, a confusing combination of terms has been used to describe and classify different types of MIC. When severe congenital MIC is the only abnormality on evaluation, that is, without other brain or somatic abnormalities, the terms primary MIC and

microcephaly vera have been historically used though these terms are often poorly understood (4). Most patients with congenital MIC fall broadly into two clinical groups (5). The first group comprises children with extreme MIC but only moderate neurologic problems, usually moderate intellectual disability (ID) without spasticity or epilepsy. Several genes associated with this phenotype have been identified (see Table 26.2). The second and more important group from an epilepsy standpoint consists of congenital MIC with severe spasticity and epilepsy (6). Children in this group present with severe ID, spastic quadriparesis, gastroesophageal reflux, and poor feeding, leading to failure to thrive. Early-onset intractable epilepsy is common. Brain MRI universally shows a simplified gyral pattern. Other neuroimaging features in this group include increased extra-axial space, delayed myelination, agenesis of the corpus callosum, and disproportionate hypoplasia of the brainstem and/or cerebellum. This clinical spectrum constitutes pathogenetically heterogeneous conditions, as several genes have now been identified in this group (see Table 26.2).

Children with severe congenital MIC are often erroneously diagnosed with lissencephaly (LIS) because of reduced number of broad gyri. However, the cortex is not as thick as in true LIS (Fig. 26.1). The term microlissencephaly applies to the few patients with severe congenital MIC and a truly thickened cortex, and these patients also usually present with intractable epilepsy. By far, the majority of congenital MIC syndromes are inherited in an autosomal recessive manner.

Figure 26.1. Microcephaly. Sagittal MRI demonstrates MIC (<3 SD) with relative preservation of normal sulcal cerebral anatomy.

Postnatal MIC, on the other hand, is characterized by borderline small head size (2 to 3 SD below the mean) at birth that later progresses. Postnatal MIC is a feature of more than 300 developmental syndromes that are beyond the scope of this chapter.

Megalencephaly Syndromes

MEG is defined as an oversized and overweight brain that exceeds the mean by 2 or 3 SD for age and gender. MEG may occur as a mild familial variant with normal brain structure or as part of a growing number of genetic syndromes, including metabolic and nonmetabolic disorders (6). The clinical findings of individuals with MEG vary, but neurologic problems are usually mild to moderate, particularly in the familial form. A subset of patients have severe ID, intractable epilepsy, and other neurologic abnormalities. These severe outcomes are related to the presence of other cortical brain abnormalities, such as PMG. The most common MEG syndromes are associated with characteristic

somatic and neuroimaging features (see Table 26.2).

MCD DUE TO ABNORMAL PROLIFERATION (ABNORMAL CELL TYPES)

Malformations in this group are characterized by abnormal neurons and, often, glia as well. These are usually localized malformations. In some patients, abnormal cell types have been classified as neoplastic, although the malignant potential is low. The most common of these is tuberous sclerosis complex (TSC) (reviewed in Chapter 30).

Hemimegalencephaly

Hemimegalencephaly (HMEG) is a brain malformation characterized by an enlarged and dysplastic cerebral hemisphere (Fig. 26.2). The overgrowth and dysplasia may involve an entire hemisphere, part of a hemisphere, and/or part of the contralateral hemisphere as well. Macroscopically, the involved hemisphere is enlarged with cortical dysgenesis, white matter hypertrophy, and a dilated and dysmorphic lateral ventricle. There is no clear predilection for right or left sides. The microscopic features of HMEG vary significantly and may include PMG, heterotopic gray matter, cortical dysplasia (cortical dyslamination, bizarre enlarged neurons, balloon cells), blurring of the gray–white junction, and increase in the number of neurons and astrocytes (7).

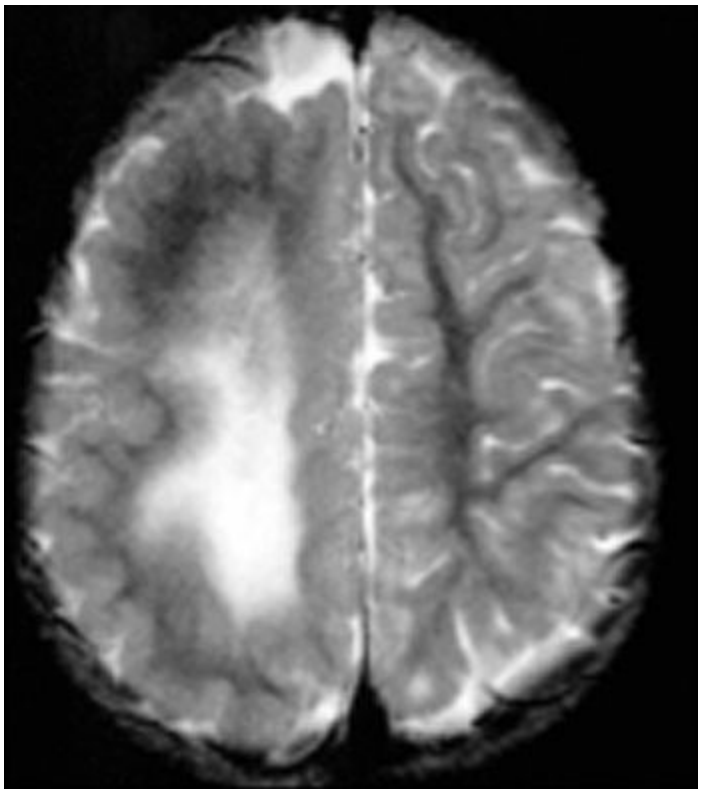

Figure 26.2. Hemimegalencephaly. Axial MRI shows large hemisphere with white matter changes. Note the smooth cortex in the posterior region.

HMEG is most often isolated but can be sporadically associated with neurocutaneous syndromes such as linear nevus sebaceous syndrome, hypomelanosis of Ito, TSC, and neurofibromatosis. HMEG with somatic overgrowth has been reported in Klippel–Trenaunay syndrome and Proteus syndrome

(6). Postzygotic activating mutations in components of the phosphatidylinositol-3-kinase (PI3K)-v-akt murine thymoma viral oncogene homolog (AKT) pathway have been identified in individuals with HMEG (8). Mutations of the same genes have been identified in children with MEG syndromes, such as the megalencephaly capillary malformation (MCAP) and the megalencephaly–polymicrogyria–postaxial polydactyly–hydrocephalus (MPPH) syndromes (9). These mutations lead to gain of function and activation of the PI3K-AKT pathway, a critical cellular pathway that regulates diverse cellular functions such as cell growth, proliferation, survival, apoptosis, tumorigenesis, and brain development.

The classic clinical triad of HMEG is (i) intractable partial seizures with onset in the neonatal period or early infancy, (ii) unilateral or focal neurologic signs (hemiparesis, hemianopia), and (iii) intellectual disability. Seizures are typically partial and almost always intractable to medical therapy. Infantile spasms, tonic seizures, or electroclinical features of Ohtahara syndrome or West syndrome may occur (10).

The MRI appearance of HMEG is characteristic. Most affected individuals have moderate to severe enlargement of one cerebral hemisphere. In some, enlargement may be localized to the frontal or temporoparietal regions, but in others, it may extend to distinct regions of the contralateral hemisphere. Gray matter is almost uniformly abnormal showing areas of thickening and simplification or overfolding, resembling pachygyria or PMG, respectively. The underlying hemispheric white matter may be increased or decreased, with abnormal signal characteristics in some patients. Heterotopia is commonly seen, and the ventricular system is enlarged and/or dysplastic in most patients. Electroencephalographic abnormalities are often broadly distributed throughout the abnormal hemisphere, and most severe cases exhibit a suppression burst pattern early on.

Predictors of poor outcome in HMEG are severity of hemiparesis, smoothness of the cortical surface on MRI, and abnormal activity on electroencephalography (EEG). Anatomical or functional hemispherectomy may improve both epilepsy and ID in selected patients (11). However, some patients do poorly with hemispheric surgery, possibly due to more widespread but asymmetric malformations.

Focal Cortical Dysplasia

The term focal cortical dysplasia (FCD) designates a spectrum of abnormalities of the laminar structure of the cortex, variably associated with cytopathologic features including giant (or cytomegalic) neurons, dysmorphic neurons, and balloon cells (Fig. 26.3). There have been various attempts to classify FCD based on subtle histologic characteristics, and the most recent classification considers clinical presentation and imaging findings, in addition to histopathologic features (12). According to this system, FCD type I refers to isolated lesions, which present either as radial (type Ia) or as tangential (type Ib) dyslamination of the neocortex, microscopically identified in one or multiple lobes. FCD type II is an isolated lesion characterized by cortical dyslamination and dysmorphic neurons without (type IIa) or with balloon cells (type IIb). FCD type III occurs in combination with hippocampal sclerosis (type IIIa) or with epilepsy-associated tumors (type IIIb). FCD type IIIc is found adjacent to vascular malformations, whereas FCD type IIId can be diagnosed in association with epileptogenic lesions acquired in early life (i.e., traumatic injury, ischemic injury, or encephalitis). The pathologic features of the tubers of TSC and FCD type IIb have significant overlap.

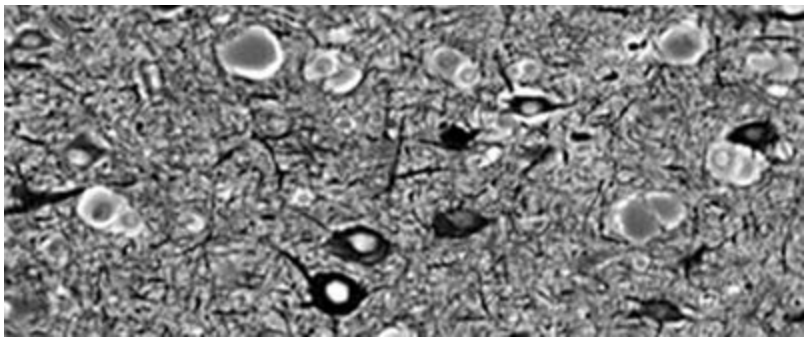

Figure 26.3. Focal cortical dysplasia. Silver staining showing irregular arrangement of big neurons and pale brown balloon cells.

According to the prevailing hypothesis, FCD originates from abnormal migration, maturation, and cell death during ontogenesis (13). The close cytoarchitectural similarities between FCD and cortical tubers of TSC prompted the hypothesis of a common pathogenetic basis, and a study has supported the role of the TSC1 gene in the pathogenesis of FCD, although these data remain to be further substantiated (14). In one paper, human papillomavirus (HPV) infection was implicated in FCD type IIB. The specific HPV 16 oncoprotein E6 (HPV16 E6) is a potent activator of mTORC1 signaling, further suggesting a relationship between FCD and the PI3K-AKT-mTOR pathway (15). Importantly, histopathologic similarities between FCD, HMEG, and the dysembryoplastic neuroepithelial tumors, two highly epileptogenic developmental lesions, further support the hypothesis of a developmental origin. Finally, FCD has been postulated to be linked to perinatal or early postnatal brain injury, with subsequent cell differentiation in the scarred area.

The most common clinical sequelae of FCD are seizures, ID, and focal neurologic deficits. Epilepsy is usually focal, intractable, and often complicated by focal status epilepticus. FCD has been shown to be intrinsically epileptogenic in vivo using electrocorticography during epilepsy surgery and in vitro using cortex resected from patients with intractable epilepsy (16,17).

FCD is rarely visible by computerized tomography (CT), and the mildest malformations may not be visible on current MRIs. Other lesions can be detected by blurring of the cortex–white matter junction on T1-weighted images as well as cortical thickening or abnormal T2 or fluid-attenuated inversion recovery hyperintensity in the white matter of a gyrus or in the depth of a sulcus. The term transmantle dysplasia applies to a band of abnormal signal intensity that extends from the cortex to the superolateral margin of the lateral ventricle (Fig. 26.4). Another subtype of FCD is bottom of the sulcus focal cortical dysplasia (18). This type of FCD can be very small in size and may be easily overlooked on imaging. However, once diagnosed, patients may benefit greatly from surgery as the lesions can often be resected in total.

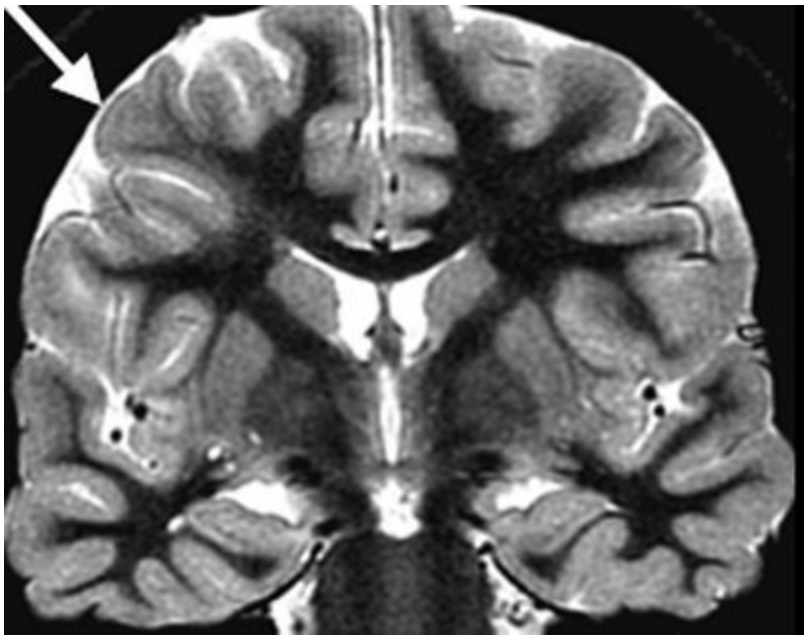

Figure 26.4. Coronal T2W MRI showing an area of irregular cortical folding (arrow) with blurring of the gray–white matter junction and underlying increased signal intensity in the white matter, extending from the subcortex to the ventricular wall. This combination of findings is consistent with FCD.

Cortical Dysplasia with Neoplastic Changes

Several low-grade, primarily neuronal, neoplasms are associated with cortical dysplasia, including dysembryoplastic neuroepithelial tumors, ganglioglioma, and gangliocytoma. Controversy continues over their proper classification. These neoplasms occur most often in children and young adults, and the frequency of these neoplasms in epilepsy surgical series is approximately 5% to 8% (19). Tumors are often located in the temporal lobes, where residual heterotopic neurons in the white matter are also common but can also present in other brain regions. While patients usually exhibit partial seizures that are difficult to control with medication, complete resection of the lesion may lead to seizure freedom.

MALFORMATIONS DUE TO ABNORMAL NEURONAL MIGRATION (NEURONAL MIGRATION DISORDERS)

Lissencephaly and Subcortical Band Heterotopia

LIS is characterized by absent (agyria) or decreased (pachygyria) convolutions, producing cortical thickness and a smooth cerebral surface. Several types of LIS have been recognized. The most common, classical (or type 1) LIS, features a very thick cortex (10 to 20 mm as compared to a normal thickness of 4 mm) without other brain malformations. The cytoarchitecture consists of four primitive cortical layers, rather than the normal six. From the cortical surface inward, these consist of a (i) poorly defined marginal zone with increased cellularity; (ii) superficial cortical gray zone with diffusely scattered neurons; (iii) relatively neuron-sparse zone; and (iv) deep cortical gray zone with neurons often oriented in columns (20, 21).

Subcortical band heterotopia (SBH) consists of bands of gray matter interposed in the white matter between the cortex and the lateral ventricles (Fig. 26.5) (6). LIS and SBH are MCD that manifest along the same spectrum. This conclusion is based on observations of rare patients with areas of LIS that merge into SBH and of multiple families with X-linked LIS in males and SBH in females.

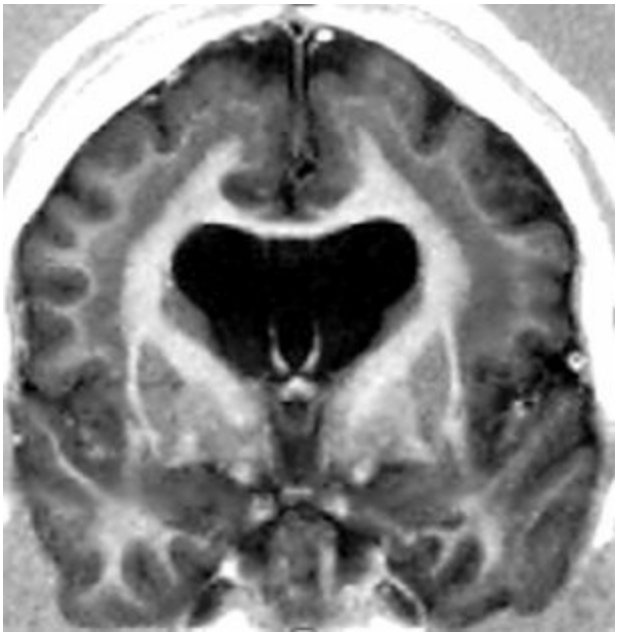

Figure 26.5. SBH. DCX mutation in a female. Coronal T1W image shows typical SBH with relative preservation of cortical anatomy.

The two most common genes associated with classic LIS and SBH are LIS1 and DCX. LIS1 (PAFAH1B1) is responsible for the autosomal form of LIS1, while the doublecortin (DCX) gene is X-linked. Although either gene can result in LIS or SBH, most cases of classic LIS are due to deletions or mutations of LIS1, whereas most cases of SBH are due to mutations of DCX. LIS1-related LIS is more severe in the posterior (p) brain regions (p > a gradient), whereas DCX-related LIS is more severe in the anterior (a) brain (a > p gradient) (Fig. 26.6).

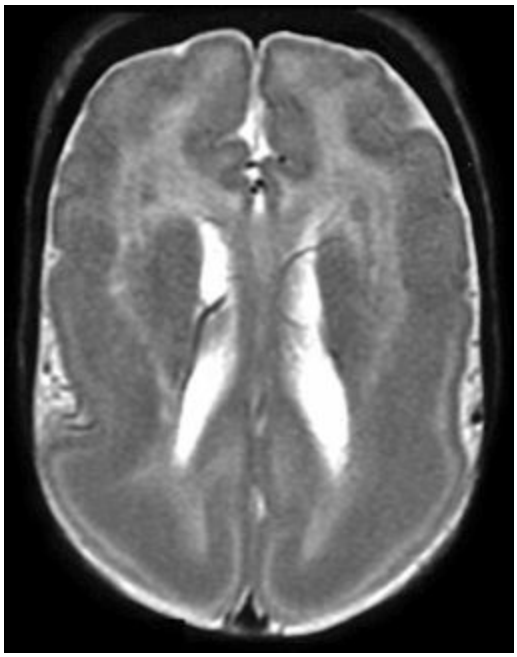

Figure 26.6. Lissencephaly. LIS1 mutation. MRI shows the typical smooth cortex predominantly affecting the posterior regions.

Children with classic LIS often appear normal as newborns but may present with apnea, poor feeding, or hypotonia. Seizures are uncommon during the first few days of life but typically begin before 6 months of age, and the clinical presentation is often similar. Infantile spasms (ISS) occur in 80% of affected children within the first year of life, often appearing initially as hypsarrhythmia on EEG. ISS respond to ACTH or other anticonvulsants in the majority of patients, but in the long term, almost all affected children have frequent seizures and many meet criteria for Lennox–Gastaut syndrome. Profound ID, hypotonia, mild spastic quadriplegia, and opisthotonus are also seen. Many patients require a gastrostomy because of poor nutrition and repeated episodes of aspiration and pneumonia.

In contrast, patients with SBH and the rare patients with partial LIS have mild to moderate ID (although normal intelligence or severe ID has been reported), minimal pyramidal signs, and dysarthria (22). Seizures usually begin during childhood but may appear later in life. Multiple seizures types may occur that can be difficult to control; however, the frequency and severity vary among affected individuals. As with other developmental syndromes, epilepsy may be an independent factor to cognitive delay and overall neurodevelopmental status. EEGs usually show generalized spike–wave discharges or multifocal abnormalities. The neurologic outcome depends on the thickness of the heterotopic band on MRI and associated malformations.

Lissencephaly Syndromes and Genes

The most common LIS syndromes include (i) isolated LIS sequence (caused by DCX in males; LIS1; and, rarely, TUBA1A, TUBB2B, TUBG1, and DYNC1H1), (ii) SBH (DCX in females and rare in males, and LIS1), (iii) Miller–Dieker syndrome (MDS) (contiguous deletion of LIS1 and YWHAE), (iv) several types of LIS with cerebellar hypoplasia (LCH) (RELN and VLDLR), (v) X-linked LIS with abnormal genitalia (XLAG) (ARX), and (vi) Baraitser–Winter syndrome (BWS) (ACTB1 and ACTG1), among others. Table 26.3 lists the frequency of mutations in these syndromes. Careful review of brain imaging and clinical features can distinguish these syndromes and helps with the identification of the causative gene.

Table 26.3 Frequency of Mutations in LIS and SBH Syndromes

	Gene or locus				
Syndrome	*ARX*	*DCX*	*LIS1*	Del 17p	*RELN*
ILS	0	12	24	40	0
LCH	Rare	25	15	0[a]	Rare
MDS	0	0	0	All[b]	0
SBH	0	80	Rare	Rare	0
XLAG	95	0	0	0	0

[a]Deletion of 17p13.3 could be seen in LIS group a (mild vermis hypoplasia).
[b]Miller–Dieker syndrome is partly defined by the deletion.
LIS, lissencephaly; SBH, subcortical band heterotopias; ILS, isolated lissencephaly sequence; LCH, lissencephaly with cerebellar hypoplasia; MDS, Miller–Dieker syndrome; XLAG, X-linked lissencephaly with abnormal genitalia. Figures represent percentages from published series.

Isolated lissencephaly sequence (ILS) consists of classic LIS with mild facial dysmorphism including mild bitemporal hallowing and small jaw (23). ILS associated with mutations of the X-linked DCX gene is characterized by either a severe LIS with no apparent gradient or an a > p gradient and normal facial appearance, whereas mutations or deletions of the LIS1 gene produce LIS with p > a gradient (see Fig. 26.6). The facial appearance may be normal or involve subtle dysmorphism similar to but milder than MDS. Mutations of the tubulin genes (TUBA1A, TUBB2B, TUBG1) are characterized by LIS in addition to other complex developmental brain abnormalities such as PMG, callosal hypoplasia or agenesis, abnormal basal ganglia, and cerebellar hypoplasia (see Table 26.2) (24-27).

MDS is the prototypic LIS syndrome associated with characteristic facial features and other birth defects such as heart malformations and omphalocele. Facial features include prominent forehead, bitemporal narrowing, short nose with upturned nares, protuberant upper lip with a thin vermilion border, and small jaw. LIS in MDS is severe with no apparent gradient or rarely a p > a gradient similar to ILS with LIS mutations. All patients have deletions of chromosome 17p13 that include LIS1 and YWHAE. About 60% to 70% of deletions are detected by karyotype, and the remainder are detectable by fluorescence in situ hybridization or chromosomal microarray (28-31).

LCH affects a small percentage of patients with LIS syndromes. Group a, the most common type, resembles isolated LIS syndrome but with mild cerebellar vermis hypoplasia. Some patients have mutations of DCX or LIS1 but much less frequently than patients with typical ILS. Group b consists of moderate LIS with an a > p gradient, moderate 8- to 10-mm cortical thickness, a globular hippocampus, and a small afoliar cerebellum. Mutations in RELN and VLDLR have been identified in individuals with LCH overall.

XLAG is a variant LIS characterized by a p > a gradient, intermediate 8 to 10 mm cortical thickness, total agenesis of the corpus callosum, often cavitated or indistinct basal ganglia, severe postnatal MIC, and ambiguous or severely hypoplastic genitalia. Affected children have profound ID, hypothalamic dysfunction with poor temperature regulation, intractable epilepsy typically beginning on the first day of life, infancy-onset dyskinesia that may be difficult to distinguish from seizures, and chronic diarrhea. Female relatives, including mothers, have isolated agenesis of the corpus callosum. Mutations of the ARX gene have been found in almost all patients with XLAG.

BWS is a rare but recognizable disorder characterized by congenital ptosis, high-arched eyebrows, hypertelorism, ocular colobomata, and anterior predominant LIS. Other typical features include postnatal short stature, MIC, ID, seizures, and hearing loss. Recently, de novo mutations in ACTB and ACTG1 have been identified in individuals with BWS (see Table 26.2) (32).

Cobblestone Brain Malformations (Cobblestone Complex)

The cobblestone complex (previously known as type 2 or cobblestone LIS) is a severe brain malformation consisting of cobblestone cortex, abnormal white matter, enlarged ventricles often with hydrocephalus, small brainstem, and small dysplastic cerebellum (Fig. 26.7). In the most severely affected patients, the brain surface is smooth, which previously led to the designation LIS, although less severe cobblestone malformations have an irregular, pebbled surface rather than a smooth surface. Severely affected individuals may have progressive hydrocephalus, large posterior fossa cysts (atypical for Dandy–Walker malformation), and occipital cephaloceles. Eye malformations are frequent, and congenital muscular dystrophy is probably always present.

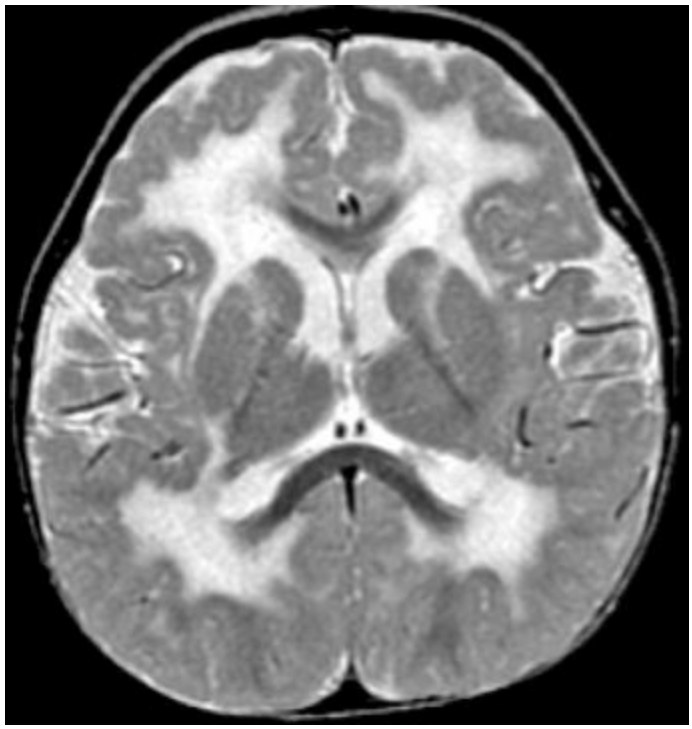

Figure 26.7. Axial T2W MRI shows extensive white matter changes and PMG typical of cobblestone malformation due to a Fukutin mutation.

The cobblestone malformation has been observed in three genetic syndromes that clearly overlap: Fukuyama congenital muscular dystrophy (FCMD), muscle–eye–brain (MEB) disease, and Walker–Warburg syndrome (WWS). All share a clinical course characterized by severe to profound ID, severe hypotonia, mild distal spasticity, and poor vision. Most classic cobblestone syndromes are autosomal recessive in inheritance (33-35).

FCMD consists of relatively mild cobblestone complex, moderate to severe ID, epilepsy, and severe congenital muscular dystrophy with progressive weakness, joint contractures, and elevated serum levels of creatine kinase (CK). Mutations in fukutin (FKTN) are the only known cause of FCMD. A common founder mutation of this gene is present in the Japanese population (36).

MEB disease consists of moderate cobblestone dysplasia with moderate to severe ID, epilepsy, congenital muscular dystrophy or myopathy with weakness, contractures, elevated serum CK levels, and complex eye abnormalities. The latter include retinal and choroidal hypoplasia, optic nerve pallor, high-grade myopia, anterior chamber angle abnormalities, glaucoma, iris hypoplasia, cataracts, and rare colobomas. Mutations of three genes, FKRP, LARGE, and POMGnT1, are primarily found in individuals with MEB. Other genes associated with MEB are listed in Table 26.2 (37, 38).

WWS is characterized by LIS and the most severe brain stem and cerebellar malformations of any of the cobblestone group. Most patients have hydrocephalus, and approximately 25% have occipital cephaloceles. All patients have profound ID, epilepsy, and eye abnormalities similar to those of MEB disease and the same congenital muscular dystrophy or myopathy with elevated serum CK levels and contractures. Mutations of POMT1, POMT2, and FKRP have been found in individuals with WWS.

Heterotopia

Heterotopias are defined as groups of cells found in inappropriate locations in the correct tissue of origin. Heterotopias are subdivided into three main groups based on location: periventricular (usually

nodular), subcortical (either nodular or laminar), and leptomeningeal. Only the first two of these are easily detectable on brain imaging. PNH is by far the most common type. Subcortical nodular heterotopia (SNH) is relatively frequent and often accompanied by irregular folding of the overlying cortex. Its etiology and genetic basis remain unknown. SBH is a mild form of LIS and is classified as such, as previously discussed. We will consider here PNH, which is by far the most frequent and best-known form of nodular heterotopia.

Periventricular Nodular Heterotopia

PNH consists of nodules of gray matter located along the lateral ventricles because of failure of migration of some neurons (3). The distribution ranges from isolated, single lesions to confluent bilateral nodules. The overlying cortex maybe abnormally disorganized, and the heterotopias may show some rudimentary lamination and a variety of neuronal types (39).

The most frequent clinical manifestation of PNH is epilepsy, occurring in 80% to 90% of patients, most of whom have various types of partial seizures that are often intractable (40). One study using depth electrodes in patients with PNH and epilepsy showed the nodules to be intrinsically epileptogenic (41) while, in other patients, the ictal-onset zone is less defined with often simultaneous onset in the cortex and nodules.

In typical PNH, MRI shows nodular masses of gray matter adjacent to the lateral ventricles that often protrude into the lumen (Fig. 26.8). Most are located along the lateral ventricular walls, although more posterior or medial locations may also occur. The nodules may be single or multiple, unilateral or bilateral, large or small, and symmetric or asymmetric. They may be contiguous or separated to resemble "pearls on a string." PNH differ from the subependymal nodules of TSC; as the latter are usually smaller, fewer, inhomogeneous, calcified and have signal intensity resembling white matter. Unilateral or focal PNH may occur in combination with SNH or in association with other MCD such as PMG. Typical bilateral PNH may be associated with mild to moderate hypoplasia of the corpus callosum or cerebellum (42-44).

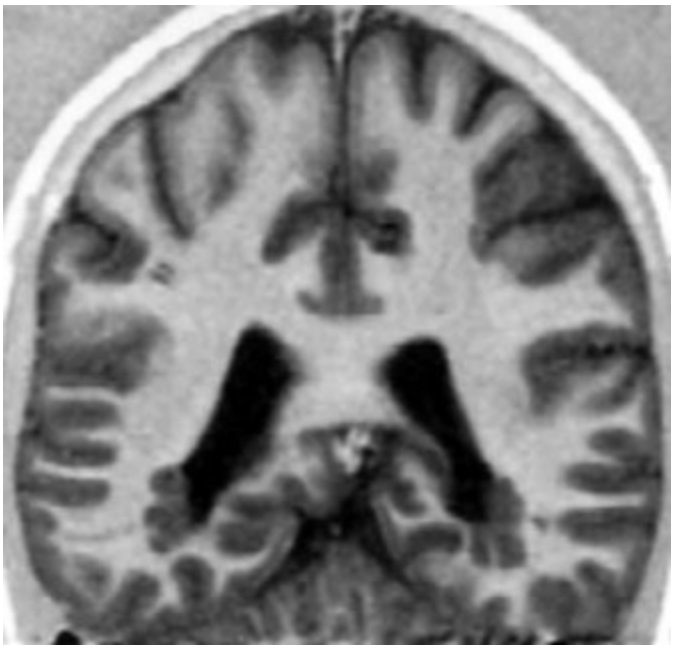

Figure 26.8. Coronal T1W MRI shows gray matter heterotopia lining the posterior ventricular system.

Mutations in the FLNA gene were identified in families of multiple affected individuals with bilateral

PNH (45). FLNA is located on the X chromosome. Mutations in males are thought to be lethal, accounting for the female predominance of PNH. Although approximately 80% of familial PNH cases have FLNA mutations, the mutation detection rate is much smaller (approximately 20%) in individuals with sporadic PNH (46). Individuals with mutations usually have typical bilateral PNH, while most patients with atypical PNH test negative for FLNA mutations. An autosomal recessive form of PNH with MIC due to mutations in ARFGEF2 is present in a small number of children from consanguineous unions. Finally, copy number changes (e.g., duplications of 5p14 and 5p15, and deletions of 6q27 and 7q11.2) have been identified in subsets of patient with focal or diffuse PNH. Therefore, PNH appears to be genetically heterogeneous secondary to abnormalities of genes involved in neuroblast proliferation or initiation of neuroblast migration.

MALFORMATIONS DUE TO ABNORMAL CORTICAL ORGANIZATION

Polymicrogyria

PMG refers to excessive microscopic gyration and is a common cortical malformation. The imaging appearance of PMG varies with the patient's age (47). In newborns and young infants, the malformed cortex is very thin with multiple, very small undulations. After myelination, PMG appears as thickened cortex with irregular cortex–white matter junction (3).

PMG is associated with a wide range of patterns and syndromes and is caused by mutations in several genes. Its pathogenesis, however, remains poorly understood. Brain pathology demonstrates abnormal development or loss of neurons in the middle and deep cortical layers, variably associated with an unlayered cortical structure.

The clinical sequelae of PMG are highly variable depending on etiology, extent, and location of the PMG; the presence of other brain malformations; and complications such as epilepsy. Furthermore, PMG is identified in different disorders such as metabolic syndromes, chromosome deletion syndromes, and multiple congenital anomaly syndromes. Therefore, affected individuals may have a wide spectrum of clinical problems other than those attributable to PMG. The most common form of PMG involves the perisylvian regions in a bilateral and rather symmetric pattern called bilateral perisylvian PMG (BPP) (Fig. 26.9). Patients with BPP typically have oromotor dysfunction including difficulties with tongue, facial, and pharyngeal motor functions resulting in problems with speech production, sucking and swallowing, excessive drooling, and facial diplegia. They may also have an expressive dysphasia in addition to dysarthria, often necessitating the use of alternative communication devices and/or sign language. Examination may show facial diplegia, limited tongue movements, brisk jaw reflex, absence of the gag reflex, and limb spasticity. Mild to moderate ID is seen in as many as 75% of patients (48). Other recurrent topographic patterns of PMG include unilateral perisylvian, bilateral frontal, bilateral frontoparietal, bilateral parasagittal, parietooccipital, bilateral parietooccipital, multilobar, and bilateral generalized PMG (Fig. 26.10). The clinical features of these rarer subtypes of PMG may vary from those seen in BPP, although epilepsy and variable ID are common accompaniments.

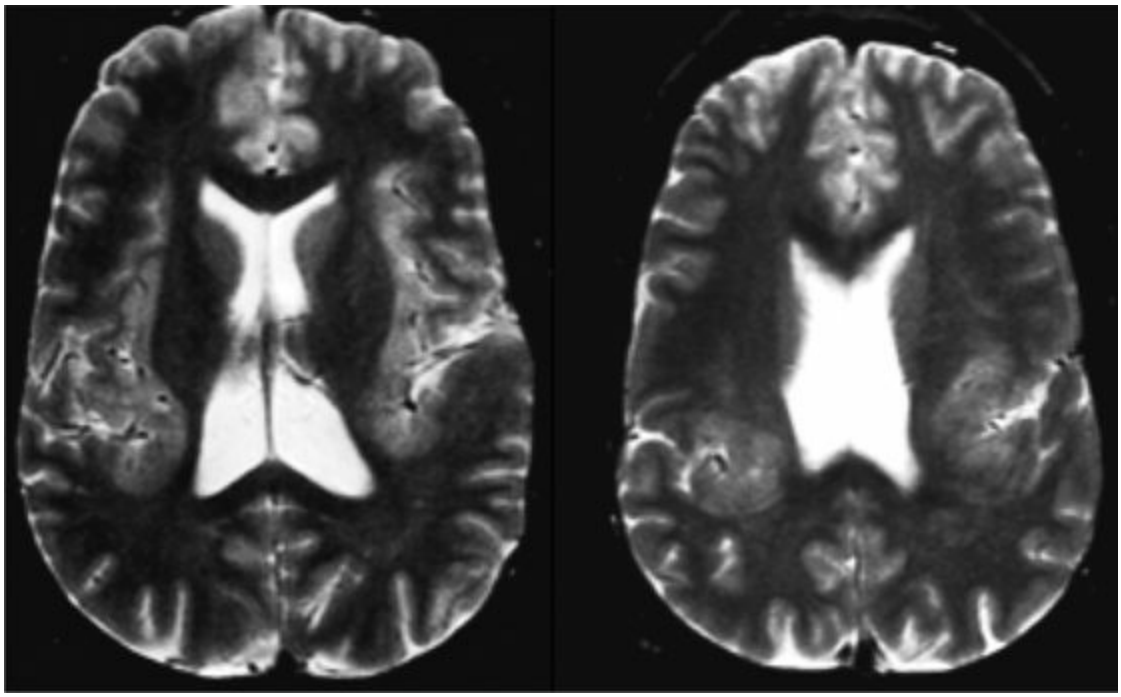

Figure 26.9. Congenital bilateral perisylvian syndrome (CBPS). The axial T2W MRI shows perisylvian PMG. The lesions are often asymmetric.

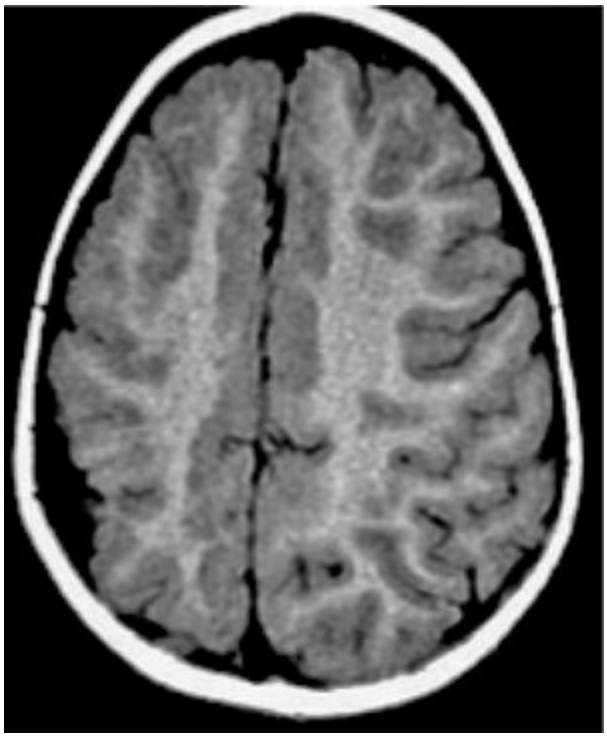

Figure 26.10. Unilateral PMG. Axial T1W image shows evidence of hemispheric atrophy and underlying PMG. Changes are most prominent in the central region.

The frequency of epilepsy in PMG is 60% to 85%. Seizure onset is variable but does not necessarily correlate with the severity of PMG. While most affected individuals present with seizures between 4 and 12 years of age, seizures may not occur until the second decade in some cases. Seizure types include atypical absence (62%), atonic and tonic drop attacks (73%), generalized tonic–clonic seizures (35%), and partial seizures (26%). A small number of patients may present with infantile spasms, in contrast to patients with LIS, TSC, or FCD in which the frequency of spasms is higher. EEG typically shows generalized spike–wave or multifocal discharges with a centroparietal

emphasis (48). Seizures may be intractable in at least 50% of patients.

Using CT and low-field strength MRI, PMG is difficult to discern and may only appear as thickened cortex. The only role for CT in the evaluation of PMG is to assess for evidence of calcification, which is seen in PMG resulting from congenital cytomegalovirus (CMV) infection. Using high-quality MRI with appropriate age-specific protocols, it is possible to reliably differentiate PMG from other MCD (3). The polymicrogyric cortex often appears mildly thickened (6 to 10 mm) on imaging due to cortical overfolding rather than true thickening (49). Using inversion recovery and thin contiguous slices, microgyri and microsulci may be appreciated. Diffusely abnormal white matter signal intensities should raise the question of an in utero infection (such as CMV) or a peroxisomal disorder. Other developmental anomalies seen with PMG include ventricular enlargement or dysmorphism, abnormalities of the corpus callosum and cerebellum, as occurs with the tubulinopathies, for example.

Numerous genetic and nongenetic etiologies have been reported in association with PMG. Nongenetic causes other than hypoxia or hypoperfusion mainly implicate congenital infections. Multiple reports suggest that congenital CMV infection is the single most common cause of BPP (50).

Among the genetic causes, deletion 22q11.2 (or DiGeorge) syndrome is most commonly associated with bilateral PMG. Further, PMG is associated with metabolic syndromes such as Zellweger syndrome due to mutations of the PEX family of genes, although the pathologic changes differ from typical PMG. BPP in association with MEG is seen in the MCAP syndrome (due to postzygotic PIK3CA mutations) and the MPPH syndrome (due to de novo germline mutations in PIK3R2 and AKT3). Furthermore, mutations in SRPX2 have been found in a single family with BPP. Besides these distinct genetic associations, all modes of inheritance have been suggested with PMG, although X-linked inheritance appears to be most frequent.

In summary, MCD are highly recognizable developmental brain disorders whose clinical delineation has improved dramatically due to advanced brain imaging techniques. In conjunction, the number of genes associated with these disorders has risen dramatically over the past decade due to significant advancements in genetic testing technologies. Most MCD are associated with epilepsy and ID and accurate diagnosis facilitates adequate clinical management, prognosis, and genetic counseling.

CHAPTER 27 BRAIN TUMORS AND EPILEPSY

LARA JEHI AND INGMAR BLUMCKE

Many epidemiologic studies established the frequent coexistence of brain tumors and epilepsy. Recently, significant insights into the mechanisms of epileptogenesis were derived from studying the intricate relationship between the two conditions. This chapter discusses the following:

1. Current data on the prevalence and incidence of epilepsy in brain tumor patients, and vice versa
2. Clinical characteristics of patients with brain tumor and epilepsy
3. Various proposed mechanisms of epileptogenesis in brain tumor patients
4. Medical as well as surgical treatment of brain tumor patients with epilepsy
5. Challenges in the pathologic classification of brain tumors in epilepsy and future directions

EPIDEMIOLOGY

Up to 38% of patients with a primary and 20% of those with a metastatic brain tumor initially seek medical attention following a seizure (1). Conversely, brain tumors cause about 10% to 15% of all adult-onset and 0.2% to 6% of all childhood-onset epilepsies (2–4) and on histopathology represent 26% of all epileptic lesions based on a large European patient series (5).

Major tumor characteristics that determine the likelihood of developing epilepsy include tumor type, grade, and location. As a general rule, the lower the grade of the tumor, the closer it is to the cortex, and the more connected it is to potentially epileptogenic structures (e.g., hippocampus, primary motor cortex, etc.), and the higher are the chances of it producing seizures. The following statistics illustrate these concepts: first, while only 30% to 60% of high-grade gliomas (6,7) and 20% of primary central nervous system (CNS) lymphomas (8) lead to epilepsy, seizures occur in up to 40% of patients with meningiomas (9) and in more than 80% of those with low-grade gliomas (10,11). Second, among patients with a low-grade glioma, cortical location and oligodendroglioma and oligoastrocytoma subtypes are significantly more often associated with epilepsy when compared to deeper midline locations and astrocytoma, respectively (11). Third, while tumors represent up to 56.3% of epilepsy etiologies in temporal lobe epilepsy (TLE) (12), they proportionally account for only half as many (27%) extratemporal lobe epilepsies (13). In one series of 147 patients with newly diagnosed brain tumors, primary location of the tumor also correlated with seizure risk: parietal (80%), temporal (74%), frontal (62%), and occipital (0%) (1). Infratentorial and sellar tumors rarely cause seizures unless they extend into the cerebral hemispheres (3). Careful consideration of these epidemiologic observations, as well as detailed analyses of clinical variables and basic science

investigations, improved our understanding of various mechanisms of epileptogenicity and facilitated the development of targeted treatments.

Table 27.1 summarizes the prevalence of tumors as an epilepsy substrate, while Table 27.2 characterizes the tumor types encountered in medically intractable, chronic epilepsy using data retrieved from the European Epilepsy Brain Bank. Table 27.3 summarizes the prevalence of seizures in various types of brain tumors.

Table 27.1 Neuropathologic Categories in Symptomatic Chronic Human Epilepsies

Category	Numbers (%)	Age OP	Onset	Duration
HS	1908 (32.7%)	33.9 + 10.4	11.3 + 7.7	22.7 + 10.0
DUAL	294 (5.0%)	25.5 + 12.8	9.5 + 7.8	15.9 + 9.9
Tumors	1551 (26.5%)	27.9 + 12.3	16.5 + 10.1	11.8 + 8.8
MCD	930 (15.9%)	18.2 + 12.0	5.9 + 5.7	12.3 + 9.1
Vascular	328 (5.6%)	36.1 + 12.3	23.4 + 11.4	12.7 + 9.0
Glial scars	284 (4.9%)	25.6 + 12.4	10.3 + 8.0	14.7 + 8.6
Encephalitis	96 (1.6%)	20.4 + 12.6	13.3 + 9.4	8.2 + 7.1
No lesion	451 (7.7%)	29.2 + 10.8	12.6 + 7.7	16.1 + 8.0
Total	**5842**	**28.6 + 12.5**	**12.4 + 8.9**	**16.5 + 10.1**

Data retrieved from the European Epilepsy Brain Bank.
HS, hippocampal sclerosis; DUAL, dual pathologies; Tumors, long-term epilepsy-associated tumors; MCD, malformations of cortical development; Age OP, age of patients at surgery (in years); Onset, age at onset of spontaneous seizure activity (in years); Duration, Duration of seizure disorder before surgical treatment (in years).

Table 27.2 Tumor Types Encountered in Medically Intractable, Chronic Epilepsy using Data Retrieved from the European Epilepsy Brain Bank

Entity	Numbers (%)	Age OP	Onset	Duration
GG I°	671 (43.3%)	24.9	12.8	12.7
GG II°/III°	77 (5.0%)	26.9	14.2	11.0
DNET I°	256 (16.5%)	25.2	14.7	10.7
PXA	38 (2.5%)	29.3	18.8	12.2
INET	29 (1.9%)	27.9	14.4	17.7
SEGA	16 (1.0%)	20.1	12.3	9.0
ANET	5 (0.3%)	19.7	2.0	13.0
ASTRO II°/III°	110 (7.1%)	36.2	29.5	6.7
OLIGO II°/III°	97 (6.33%)	38.6	24.5	12.5
PA I°	81 (5.2%)	25.1	14.8	12.1
CYSTS	31 (2.0%)	32.4	21.7	11.6
MENINGIOMA	26 (1.7%)	46.5	38.9	8.4
NOS	62 (3.2%)	29.2	16.1	13.3
OTHER	50 (4.0%)	31.5	25.0	11.3
Total	1549	27.9	16.5	11.7

The table outlines a summary of 1549 long-term epilepsy-associated tumor diagnoses collected at the European Epilepsy Brain Bank (total n = 5842). Seven hundred and nine female and 821 male patients were included. Grading according to WHO I°, II° or III° [84].
GG, ganglioglioma; DNET, dysembryoplastic neuroepithelial tumor; PXA, pleomorphic xantoastrocytoma; INET, isomorphic astrocytoma variant (analogous to WHO I°); SEGA, subependymal giant cell astrocytoma; ANET, angiocentric glioma; ASTRO, astrocytoma; OLIGO, oligodendroglioma incl. mixed gliomas; PA, pilocytic astrocytoma, CYSTS, arachnoid, dermoid, or epidermoid cysts; NOS, highly differentiated neuroepithelial tumor (not otherwise specified); Other, all other tumors with rare frequency (<1%); Age OP, age at operation (mean in years); Onset, age at epilepsy onset (mean in years); Duration, epilepsy duration (mean in years).

Table 27.3 Seizure Frequency in Various Brain Tumor Types

Tumor	Seizure frequency (%)
Dysembryoplastic neuroepithelial tumor (4)	100
Ganglioglioma (3,14)	80–90
Low-grade astrocytoma (3)	75
Meningioma (9)	27–60
Glioblastoma multiforme (3)	29–50
Primary CNS lymphoma (3,8)	10–20

CLINICAL CHARACTERISTICS

Most tumor-related seizures first appear early in the course of the disease, usually as a presenting manifestation (9,10). In 10% to 30% of brain tumor patients, epilepsy develops later in the course of the disease (4,10). In brain tumor patients presenting with seizures, age and presence of associated neurologic deficits may correlate with tumor grade: Children and adolescents usually have no associated neurologic deficits and generally have a low-grade tumor, whereas middle-aged or elderly people often have other associated neurologic deficits on presentation and frequently present with a high-grade brain neoplasm (3,15,16).

Both focal and generalized seizures occur in the setting of brain tumors (10,11,17–19). Even isolated auras have been reported as the only epileptic manifestation of temporal lobe tumors (20). Therefore, in any given patient, seizure semiology is mainly determined by the location of the tumor and its connectivity. However, certain general remarks may be noted. First, seizures that start earlier in the course of a brain tumor are more likely to be generalized: Hildebrand et al. (10) found that while 50% of "early seizures" occurring at or soon after brain tumor diagnosis were generalized and 40% were focal, the converse was true when seizures occurred during the later follow-up phases, with about 75% being focal and only 20% being generalized. Second, in certain special situations, seizure semiology carries a specific tumor-related diagnostic correlation, for example, gelastic seizures and hypothalamic hamartomas.

The observations made above are likely due to distinctly different mechanisms of epileptogenicity that are detailed later. In brief though, younger patients are statistically more likely to have small, slow-growing tumors (developmental tumors, low-grade gliomas, etc.) that take their time to develop focal and remote cellular and pathway changes sufficient to develop epileptogenicity without causing major local tissue damage. As such, patients with low-grade temporal lobe tumors, for example, might not have deficits on a traditional neurologic examination, develop seizures later in the course of the tumor progression, and have more complex partial seizures related to dysfunction of the limbic network. On the other hand, older patients with glioblastoma multiforme (GBM) usually have a larger rapidly growing tumor, causing significant local tissue damage with associated neurologic deficits and seizures starting earlier in the tumor disease course as a result of abrupt tissue necrosis.

Regardless of the tumor type, patients who present with seizures as the initial symptom of a brain tumor are at higher risk of developing epilepsy later (recurrent seizures), even with prophylactic trials of antiepileptic drug (AED) treatment (21,22). Furthermore, up to 50% of those tumor-related epilepsies may become medically intractable, and this is a higher intractability risk than in other epilepsies (10,19,23).

PROPOSED MECHANISMS OF EPILEPTOGENESIS

The development of epilepsy in a brain tumor patient is probably a multifactorial phenomenon. Therefore, even though we will discuss multiple proposed mechanisms of epileptogenicity in brain tumors, it is important to remember that those mechanisms are not mutually exclusive and that in any given patient, epilepsy is likely due to an interplay of all of those variables.

Role of Tumor Type

High-grade tumors may lead to epilepsy by abruptly damaging local tissue, causing tissue necrosis and hemosiderin deposition, and increasing excitability of local and immediately surrounding cortex (4,16,24). Chronic intractable epilepsy is, however, most often caused by lower-grade tumors, specifically low-grade gliomas and developmental tumors—mainly gangliogliomas and dysembryoplastic neuroepithelial tumors (DNET) (12,13,17,25–28). These developmental tumors are surrounded by dysplastic cortex in 25% to 70% of cases (13,28–30) which should be classified as associated Focal Cortical Dysplasia ILAE Type IIIb, or may be associated with coexistent hippocampal sclerosis (14,30,31). In such a setting of "dual pathology," seizures may be predominantly or even independently arising from the dysplasia or hippocampal sclerosis, and not necessarily the tumor. A practical and important implication of this "dual pathology" is the inability

to control seizures surgically in these patients with chronic intractable epilepsy unless both "lesions" are resected (32).

Role of Peritumoral Morphologic Changes

A brain tumor disrupts the tissue around it and causes a variety of morphologic changes that facilitate excitability and thus increase epileptogenicity. Those changes include aberrant neuronal migration, enhanced intercellular communication through increased expression of gap junctions, changes in synaptic vesicles, and increased local concentrations of glutamate and lactate (3,4,24,33). Synaptic transmission, including GABA receptor signaling, may be underexpressed in brain tumor tissues compared with control tissue, further increasing excitability (34,35).

In addition to the above microscopic and molecular changes, gross tumor-related effects include mass effect, local edema, and increased pressure. Also, local infiltrative tumor growth may cause local irritation and epileptogenicity, presumably through inducing tissue hypoxia (36).

Role of Changes to the Microenvironment

Tumors have increased metabolic requirements, and even with increased angiogenesis, eventually lead to intra- and peritumoral hypoxia. This alkalinizes the interstitial pH and causes glial cell swelling and damage, increasing neuronal excitability and facilitating epileptogenic activity (4,37). The risk of epilepsy further increases because of increased inward sodium currents at the level of the astrocytic cell membrane. This results from defective intracellular mechanisms for deoxyribonucleic acid repair and genetic instability also occurring due to tumor-related hypoxia (3). Cortical hemosiderin deposition is also a frequently considered cause for tumor-related epileptogenesis (38).

Role of Genetic Factors

Long-term epilepsy-associated tumors (LEATs) do not share those molecular oncogenes or tumor suppressor genes typically observed in diffusely infiltrating gliomas, such as IDH1 or 1p/19q deletions. In contrast, the oncofetal marker protein CD34 can be frequently identified, and developmental genes are likely to be involved (39). Mutations in B-RAF (40) or mTOR signaling (41) may also play an important role. Other studies have suggested a role for LGI-1 in tumor-related epilepsy (3,4). This is a tumor suppressor gene absent in GBM and other high-grade invasive tumors. It also happens to be responsible for the rare autosomal dominant lateral TLE. Therefore, some authors suggested that LGI-1 plays a role in both tumor progression and epileptogenesis (3,4).

Posttranscriptional and posttranslational alterations have also been implicated in the genesis of epilepsy in brain tumors. For example, LIM domain-binding 2 (LDB2) transcript, critical for brain development during embryogenesis, was one of the strongest reduced mRNAs in gangliogliomas in recent array analyses. Silencing of LDB2 resulted in substantially aberrant dendritic arborization in cultured developing primary hippocampal neurons. This characterizes yet another molecular mechanism operating in gangliogliomas, contributing to the development of dysplastic neurons and an aberrant neuronal network (42). Recent transcriptomic profiling of human peritumoral neocortex tissues revealed that several genes enriched in focal adhesion and cell adhesion molecular pathways may be involved in tumor-induced epilepsy (43). Lastly, the expression of aquaporin-4, a membrane protein implicated in peritumoral edema generation and in drug-resistant hippocampal sclerosis, was reduced in brain tissue from GBM patients without seizures as opposed to GBM patients with

seizures. The aquaporin-4m-RNA levels were identical in these two groups of GBM patients suggesting a posttranslational mechanism (44).

Role of Disruption of Functional Network Topology and Secondary Epileptogenesis

Rather than traditional views conceptualizing the brain as a conglomerate of segregated functional areas, each specifically dedicated to one function, the modern theory of brain networks proposes the presence of cortical networks composed of multiple cortical regions connected via white matter pathways controlling various mainly higher cortical functions and requiring a delicate balance between excitability and inhibition of those multiple pathways to operate correctly (3,34). A disruption of those "normal networks"—as occurs anatomically with a tumor—will disturb this balance, leading to multiple consequences, including deafferentation and release of regulatory inhibition on potentially epileptogenic structures (such as the hippocampus), and the appearance of pathologic, less stable compensatory networks that may themselves be more excitable and thus potentially epileptogenic. This hypothesis is still being investigated, and further research is needed to clarify the full extent of its impact. It might, however, partly explain, among other things, how an epileptogenic focus arises distant from a tumor (14), and why a procedure such as a simple removal of the tumor via a lesionectomy, may not achieve optimal seizure freedom (45).

It has been suggested that in almost one-third of patients with brain tumors and epilepsy, the epileptogenic focus does not correspond to the tumor location. This phenomenon is called secondary epileptogenesis, implying that an actively discharging epileptogenic region induces similar paroxysmal activity in regions distant from the original site. This process is mostly seen with low-grade brain tumors located in the temporal lobe, which frequently present with hippocampal sclerosis (20). In those cases, the "secondary focus" becomes a completely independent epileptic generator that also needs to be removed to achieve seizure freedom in intractable patients. Since young age and long disease duration have been proposed as being the main risk factors for this secondary epileptogenesis (46), early resection of the primary focus—the tumor—has been promoted to avoid the development of an irreversible secondary focus and was actually shown to correlate with better rates of seizure freedom following resective epilepsy surgery (11,17,46).

TREATMENT OF SEIZURES IN THE SETTING OF BRAIN TUMORS

With seizures occurring so frequently in patients with brain tumors, it is important to be aware of the various treatment options available. Very often, adequate treatment of seizures in such a setting requires a multidisciplinary approach, including the patient's neuro-oncologist, neurosurgeon, and epileptologist. Goals of treatment need to be clarified early on in the treatment course, as well as a clear determination of the risk–benefit ratio of various medical and surgical therapeutic options. For example, aiming at complete seizure freedom in a patient with an inoperable, rapidly growing, GBM while concomitantly using five different AEDs with their associated side effects may actually be counterproductive and worsen the patient's quality of life. On the other hand, merely aiming for reduction in seizure frequency in a patient with a developmental tumor would likely be an unacceptable treatment goal as resective epilepsy surgery has a high chance of rendering this patient

seizure free, with a relatively low risk of complications.

The following section reviews current information on medical and surgical aspects of the treatment of seizures in the setting of brain tumors.

Medical Treatment

Anticonvulsant medications are the mainstay of epilepsy treatment in any patient with seizures, including patients with brain tumors. However, little is known about the specific efficacy of different AEDs in the setting of a brain neoplasm. Many patients have recurrent seizures (60% to 70%) despite the use of AEDs, and results of specific AEDs trials are outlined in Table 27.4. First-line AEDs fail in about 60% of patients and, of the remainder, a similar proportion of second-line treatments with monotherapy or polytherapy fails (10,34). A few retrospective studies have favored the use of valproic acid when compared to phenytoin or carbamazepine. Valproic acid was preferred due to the promptness of achieving a therapeutic level, its enzyme-inhibiting properties that may increase the effectiveness of concomitant chemotherapy, and some potential inherent antitumor effects (3,36,54,55). However, it may cause significant bone marrow suppression, especially in combination with chemotherapy. On the other hand, several prospective studies have recently suggested that gabapentin (51), levetiracetam (47,48,52), topiramate (50), or lacosamide (56) may be effective options for add-on therapy. In one prospective series of 26 patients with primary brain tumors who received add-on levetiracetam, usually in combination with valproic acid, a seizure reduction of more than 50% was observed in 65% of patients (47). Similar success rates were seen with levetiracetam used both as add-on or monotherapy (52,57,58). In a small prospective series of 14 patients with intractable seizures and brain neoplasms, gabapentin was added to phenytoin, carbamazepine, or clobazam. Reduction in seizure frequency was seen in all patients, and more than 50% became seizure free (51). In another prospective observational study of 47 glioma patients, initial or add-on therapy with topiramate achieved complete seizure freedom in 56% of patients with a seizure reduction in an additional 20% after a mean follow-up of 16.5 months (59). Most recently, a prospective pilot study following 14 patients with brain tumors and epilepsy showed a 78.6% responder rate with lacosamide (56). All these prospective studies report a low incidence of side effects, although those were slightly higher with topiramate when compared to others.

Table 27.4 Summary of Studies Evaluating Effectiveness of Various AEDs in the Setting of Seizures in Brain Tumors

	Study characteristics			Tumor characteristics		AED characteristics		Outcome	
Study	*N*	Type[a]	Follow-up	Grade	Treatment	Primary drug	Add-on drug	% Seizure free (%)	% Seizure reduction (%)
Hildebrand et al. (10)	234	R	3–276	High, grade II glioma	Surgery Radiation Chemotherapy	VPA CBZ GBP LTG Others		13	NA
Wick et al. (36)	107	R		High, Low	Surgery Chemotherapy Radiotherapy	PHT VPA CBZ		30[b]

Saria et al. (53)	70	R		High, Low	Radiation Surgery Chemotherapy Corticosteroids	Multiple	LCS		66%

[a]P, prospective; R, retrospective.
[b]70% of patients on CBZ had recurrent seizures, as opposed to 51% of those on PHT and 44% of those on VPA.
CBZ, carbamazepine; PHT, phenytoin; PB, phenobarbital; VPA, valproic acid; TOP, topiramate; LTG, lamotrigine.

Few head-to-head studies compare the effectiveness of various AEDs in treating brain tumor–related epilepsy. Levetiracetam was compared to phenytoin in two retrospective series (60,61) and one prospective study (62). All showed similar efficacy in both groups, although the prospective study suggested better tolerability and response rates with levetiracetam (62). Similarly, a retrospective observational study suggested that oxcarbazepine had similar effectiveness and better tolerability when compared to traditional AEDs (63). Interestingly, one observational study comparing the use of valproic acid and levetiracetam used either alone or in combination to other AEDs found the highest percentage of responders (81.5%) in those treated with the levetiracetam plus valproic acid combination (64).

Special Issues Pertaining to Medical Treatment of Epilepsy in Brain Tumors

Medical Intractability of Epilepsy in Brain Tumors

While 20% to 25% of epilepsy patients in general continue to have frequent seizures despite the use of AEDs at adequate serum concentrations, this medical intractability occurs in up to 50% to 60% of patients with seizures and brain tumors (3,11,15,19,24,34,37). This has been attributed to a variety of possible mechanisms. Overexpression of proteins belonging to the multidrug resistance pathway is a frequently discussed mechanism of refractoriness. These proteins are members of the adenosine triphosphate–binding cassette transporter family, normally present in the apical membranes of

endothelial cells. The multidrug-resistance gene (MDR)-1 (ABCB1, P-glycoprotein) and multidrug-resistance–related protein (MRP, ABCC1) contribute to the blood–brain and blood–cerebrospinal fluid barriers by controlling the transport of various lipophilic substances in and out of the brain. Many AEDs, including phenytoin, carbamazepine, lamotrigine, felbamate, and phenobarbital, are substrates for MDR-1 products, and are therefore actively eliminated from the intracellular milieu and brain parenchyma when the MDR proteins are overexpressed. Such overexpression has been found for MDR-1 in cells of patients with gliomas and gangliogliomas (19,24,65) and for another MDR protein, the breast cancer resistance protein, in endothelial cells of brain tumor specimens from astrocytomas, anaplastic astrocytomas, and GBM (37). Gabapentin may be transported via a nonspecific transporter out of the brain. However, levetiracetam does not seem to be a substrate for either MDR-1 or other MDR proteins, while the histone deacetylase–inhibiting effects of valproic acid might reduce the expression of P-glycoprotein and MRP-1, raising interest in the potential usefulness of those AEDs in intractable patients (37). This needs to be confirmed by further studies.

Other proposed mechanisms of AED resistance in brain tumors are reduced drug receptor sensitivity, including ion channels, neurotransmitter receptors, and metabolic enzymes involved in the activity of neurotransmitters, as well as reduction in the concentration of several enzyme-inducing AEDs caused by concomitant use of chemotherapeutic agents. Figure 27.1 illustrates the interaction among various proposed mechanisms of resistance to medical therapy.

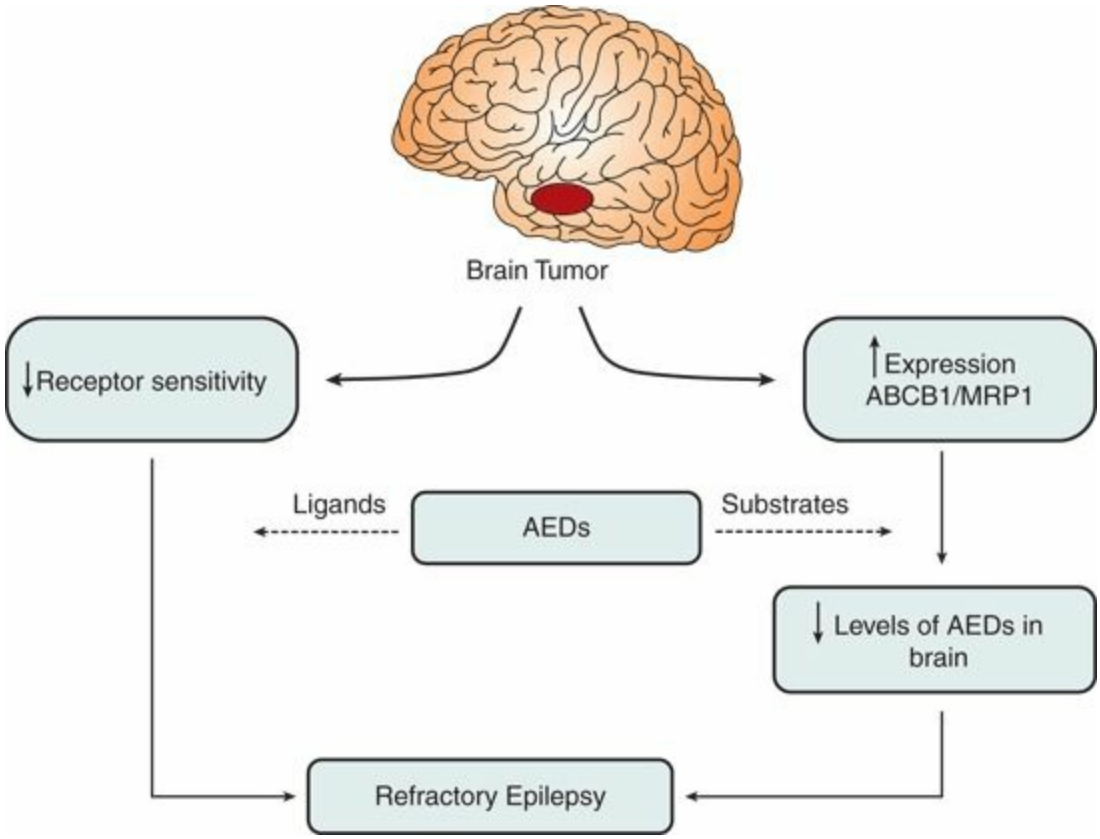

Figure 27.1. Decreased receptor sensitivity and increased expression of multidrug resistance proteins play the most important roles in medical refractoriness seen with brain tumors and epilepsy.

Issues Related to Interactions Between AEDs and Antineoplastic Agents

There is a significant risk for drug–drug interactions during concomitant use of AEDs and chemotherapeutic agents, as both are substrates for the same hepatic metabolic pathways, mainly the cytochrome P450 system. Carbamazepine, phenytoin, phenobarbital, and primidone, and to a lesser

extent lamotrigine and topiramate, have prominent cytochrome P450 enzyme–inducing effects, while valproic acid has an inhibitory effect. Induction or inhibition of these enzymes by AEDs can cause a decrease or increase in anticancer drug concentrations and thus possibly their effectiveness. Similarly, enzyme inhibition or induction by anticancer drugs can lead to toxicity or loss of seizure control (37,66). Newer AEDs such as gabapentin, levetiracetam, and pregabalin do not influence the cytochrome P450 or other metabolic pathways and theoretically only have minimal risk for drug–drug interactions with chemotherapeutic agents (4,24). Focal treatment with AEDs has been investigated in animal models to circumvent efficacy and toxicity challenges, including intraparenchymal injections, self-contained implanted devices, or convection-enhanced delivery (34). Further data are needed before definite statements can be made about the clinical applicability of these investigations.

Dexamethasone is frequently used in the treatment of tumor-associated edema and also interacts significantly with certain AEDs. It competes with phenytoin for protein binding, raising its blood concentration. Conversely, it may cause the opposite effect of lowering phenytoin's serum concentration by affecting its hepatic metabolism (24).

In summary, significant risks for reduced effectiveness and toxicity exist for both chemotherapeutic agents and enzyme-inducing and enzyme-inhibiting AEDs when used concomitantly. The patient should be cautiously observed for side effects, and serum AED blood levels need to be monitored closely.

AED Prophylaxis in Brain Tumors

The American Academy of Neurology published a consensus statement in 2000 recommending that AED prophylaxis should not be used, and current AEDs should be discontinued, in brain tumor patients who do not have a history of seizures (21). A more recent meta-analysis of controlled clinical trials evaluating the effectiveness of seizure prophylaxis in people with brain tumors, performed between 1966 and 2007, found no difference between the treatment interventions and the control groups in preventing a first seizure in participants with brain tumors concluding that the evidence is neutral, neither for nor against seizure prophylaxis, in people with brain tumors (22). The authors recognized that these conclusions apply only for the older AEDs: phenytoin, phenobarbital, and divalproex sodium (22). Therefore, based on current evidence, the decision to start prophylactic AED use in brain tumor patients should ultimately be guided by assessment of individual risk factors and careful discussion with patients, keeping in mind that there is no strong evidence that any of the currently available AEDs reliably prevent a first seizure in a brain tumor patient.

Surgical Treatment

In general, the following questions are considered when evaluating the surgical management of a patient with tumor- associated epilepsy: does this patient really need surgery now to treat his or her seizures, or is medical therapy sufficient? Should any kind of neurophysiologic testing be performed prior to surgery? What type of surgery should be offered? Will a lesionectomy be appropriate, or is a more aggressive resection required? How can this patient be counseled about his or her seizure outcome following surgery? Despite extensive literature on these topics, such decisions remain very much patient dependent, and a careful consideration of all treatment options as well as a clear and educated patient informed consent process represent the cornerstones of a successful "outcome." Although the WHO has published a classification system for brain tumors, only few prognostic and predictive tumor-specific features are available for those tumors typically associated with early-

onset epilepsy (67). Indeed, neuropathologic agreement for microscopic diagnosis is only moderate and is discussed further below. The following segments briefly address some of the questions raised above.

Timing of Surgery: Now or Later?

A critical piece of information that determines the answer to this question is the type and grade of the tumor in question. Alternatively asked, this question is equivalent to deciding whether the patient needs "tumor surgery" or "epilepsy surgery." In patients with a high-grade brain tumor, or one with a high risk of malignant transformation such as gangliogliomas, surgical removal is an essential part of the tumor treatment and should be performed regardless of whether it is believed to help with seizures or not in order to improve the patient's quality of life and chances of survival (16,17,20,24,25,68). On the other hand, most developmental tumors and many low-grade tumors may be observed for years from a tumor treatment perspective or be treated with chemotherapy or radiotherapy. "Tumor surgery" is therefore not required immediately, and the decision to operate would mainly depend on whether a patient's seizures are controlled with AEDs or not. Many epileptologists usually wait until seizures are medically intractable before pursuing surgical tumor removal. However, many studies suggest that a shorter epilepsy duration at the time of tumor resection is an important predictor of postoperative seizure freedom (69,70). In a retrospective review of 332 patients following resection of low-grade gliomas, postoperative seizure control was significantly poorer in patients with longer seizure history ($P < 0.001$) (11). In another study evaluating the seizure outcome of 26 children following resection of their DNETs, all patients with epilepsy duration of <2 years were seizure free at 12 months after surgery as opposed to 7/11 of those with longer seizure history (23). Such observations, together with the high risk of intractability in low-grade tumors (1,3,4), support early removal of low-grade brain tumors associated with epilepsy, especially when the tumor is easily surgically accessible (3). At any rate, a careful preoperative attempt at determining the nature of the tumor should be one of the initial steps in evaluating whether a patient needs immediate surgery or not.

Presurgical Neurophysiologic Evaluation

In most tumor-related epilepsy surgery patients, preoperative video-EEG evaluations confirm that seizures arise from the lobe involved with the tumor. In one study of children with DNET, all but one case had ictal onset discharges unilaterally concordant with the tumor location (23). In another series of adult tumor-related epilepsy patients, the epileptogenic focus as determined by interictal and ictal recordings agreed with the involved lobe in 72% of the cases (28). So, why do we need to perform video-EEG evaluations prior to treating the epilepsy of a brain tumor patient by simply removing the tumor? Several hypothetical and evidence-based outcome data support this practice. First, it is important to acknowledge that even though the above-mentioned studies showed seizures arising from the "same lobe" as the tumor, electrocorticographic recordings usually show that the tumors themselves are electrically inert and that epilepsy often arises from the tissue surrounding the tumor (33). Some have even suggested that seizures arise distant from the tumor in up to a third of patients with brain tumors and epilepsy (10,14). So, a preoperative video-EEG evaluation may provide evidence for the extent of epileptogenicity in the surrounding brain tissues. Figure 27.2 illustrates a case where a subdural EEG evaluation confirmed ictal onset distal from the tumor and where seizure freedom was achieved by resecting both the lesion and surrounding cortex. Second, not all brain

tumors are epileptogenic and not all "spells" are epileptic, so a video-EEG evaluation may be helpful in confirming the epileptic nature of a patient's spells and characterizing the relationship of the epileptogenic focus to the tumor itself (29). Third, some studies have reported better seizure outcomes with the use of intraoperative electrocorticography in tumor surgery and the resection of intraoperatively identified zones of interictal spiking and ictal onsets (3,25,71). In a study of 35 patients with intractable TLE related to benign mass lesions, the number of 3-year postoperative seizure-free incidences for the group that underwent lesionectomy plus additional spike-positive site resection equated to 90.9%. In contrast, in the group that underwent a lesionectomy only, 76.9% were seizure free for 3 years postoperatively (71). However, such results need to be reproduced in larger-scale randomized studies. Lastly, when tumors occur in proximity to eloquent cortex, intra- or extraoperative functional mapping is often essential in determining the extent of the surgical resection (72). For all the above reasons, it is recommended to perform a neurophysiologic evaluation, preferably at least a video-EEG evaluation with ictal recordings, prior to proceeding to surgery in a brain tumor patient with seizures.

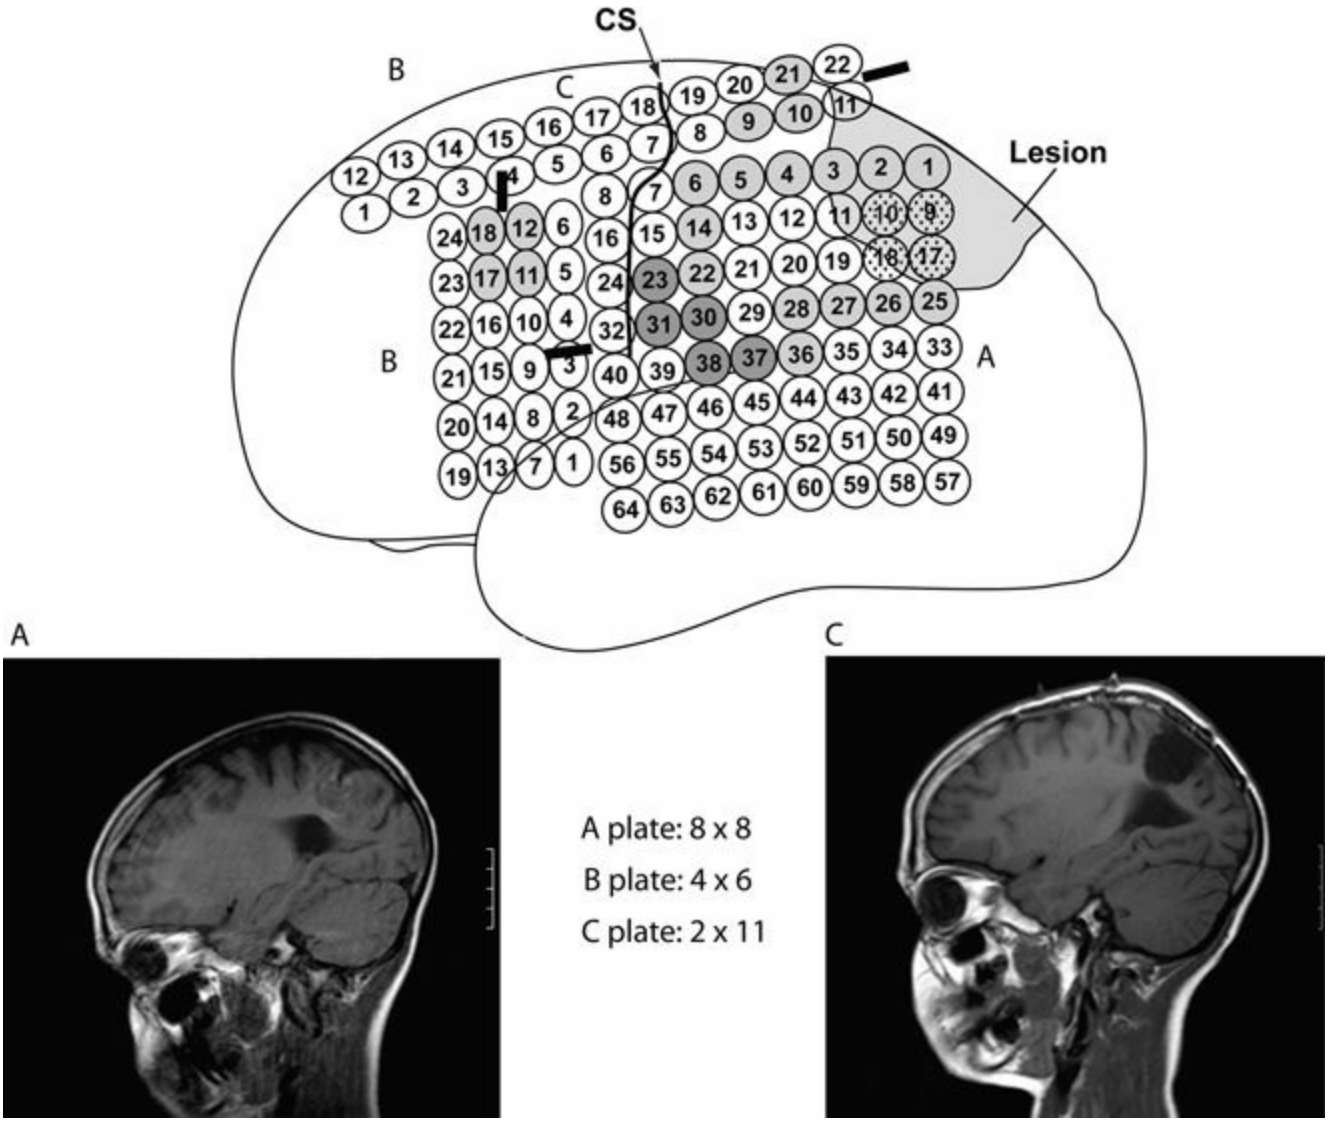

Figure 27.2. This figure illustrates the case of a 10-year-old boy with a left parietal low-grade glioma where subdural EEG recordings showed interictal activity diffusely, both proximal and distal to the lesion (light gray), and two different seizure patterns: one arising from the lesion itself (speckled gray) and one arising somewhat distally from the lesion (dark gray). Central sulcus (CS) location is also illustrated. An "extensive lesionectomy" was performed to include areas of identified epileptogenicity rendering the patient seizure free (follow-up of 2 years). **A** and **C** show the preoperative and postoperative MRI, respectively.

Type of Surgery: Lesionectomy Alone or More Aggressive Resection?

Multiple studies have reported favorable seizure outcomes with complete lesionectomies alone, with seizure freedom rates ranging from 65% to 80% (20,26,27,73). There is evidence, however, to support more aggressive resections in certain situations, most recently from a large meta-analysis evaluating predictors of seizure freedom after resection of supratentorial low-grade gliomas (70). This issue has been investigated most extensively in relation to temporal lobe tumors and epilepsy. In one study of 18 patients who underwent surgical removal of a DNET—12 via temporal lobectomy and 6 via lesionectomy—temporal lobectomy led to a better seizure outcome (Engel Class I, 83.3%; Engel Class IA, 66.7%) than lesionectomy (Engel Classes I and IA, 33.3%) after a mean follow-up of 10.8 years (74). In another study reporting 41 surgical interventions in 38 adults with dual pathology, including 10 with tumors, lesionectomy plus mesial temporal resection resulted in complete freedom from seizures in 11/15 (73%) patients, while only 2/10 (20%) patients who had mesial temporal resection alone and 2/16 (12.5%) who had a lesionectomy alone were seizure free ($P < 0.001$) (75). Such findings have been attributed to the high prevalence of dual pathology in temporal lobe tumors (29,30,76) and to the risk of associated secondary epileptogenesis. This is supported by the persistence of interictal spiking recorded with intraoperative electrocorticography in the hippocampus of 86% of cases and in the amygdala in 64% of the cases after resection of temporal lobe tumors (3). The practice of resecting the mesial temporal structures while removing the tumor is easy to accept and understand when there is preoperative evidence of dual pathology preoperatively, that is when the hippocampus looks dysmorphic or sclerosed on baseline magnetic resonance imaging (MRI). In such cases, the above-mentioned outcome data prompt most surgical centers to resect the hippocampus, especially if neuropsychological testing suggests a low risk for postoperative functional decline. The decision becomes more problematic when the hippocampus looks normal on imaging, especially if baseline neuropsychological testing is normal. Currently, it is difficult to justify resecting a dominant normally appearing hippocampus unless there is compelling evidence, such as extraoperative depth electrode recordings, for example, documenting seizures arising from the mesial structures.

Seizure Outcome

In both temporal and extratemporal epilepsy surgery, a tumoral etiology carries usually a favorable prognosis and is associated with a favorable seizure outcome in as many as 65% to 87% of the cases (11,17,20,26,27,77).

Consistently identified favorable prognostic indicators are complete tumor resection and short epilepsy duration at the time of surgery.

In one study evaluating outcomes of 44 patients with ganglioglioma following surgery, 23/23 patients with a gross total tumor removal were seizure free at last follow-up compared to 1/3 of those with subtotal resections (78). In another review of 332 adults with low-grade glioma, patients with a gross-total resection were 16 times more likely to achieve seizure freedom than after subtotal resection/biopsy alone (11). Residual tumor on postoperative MRI in a cohort of 26 children with DNETs predicted long-term seizure recurrence (23). There is currently little doubt then that a complete resection is the crucial determinant of seizure freedom. Seizure recurrence should prompt an evaluation for tumor recurrence (23,29).

Similarly, a shorter duration of epilepsy at the time of surgery seems to predict more favorable seizure outcomes (11,23,78,79). In a large European series of patients subjected to epilepsy surgery

(EEBB), epilepsy due to a brain tumor showed a mean duration of 12 years (Table 27.2). Considering young age at epilepsy onset (mean 16 years) and increased long-term risk to develop cognitive comorbidities by sustained temporal lobe seizures (77% of all tumors registered at EEBB were localized in the temporal lobe), presurgical evaluation should be envisaged at an early stage of drug refractoriness.

PATHOLOGIC TUMOR CLASSIFICATION: CHALLENGES AND FUTURE DIRECTIONS

It is difficult to describe and classify the paramount histo- and cytologic features within the LEAT spectrum (Table 27.2) using standard microscopic hematoxylin and eosin (H&E) stains, which has promoted diverse classification schemes of histomorphologic LEAT subtypes, that is, the four different variants of a DNT with diffuse and simple forms, as well as complex and nonspecific variants (Figs. 27.3 and 27.4) (80,81). Other strategies tried to incorporate rare or unusual subtypes into well-introduced WHO tumor entities, such as the ganglioglioma (82,83). Any meta-analysis of published LEAT series will be, therefore, almost impossible and generate inconsistent data, despite an existing and systematically revised WHO classification system for brain tumors (84). In a previous review of eight international LEAT series (covering a total of 2055 patients), DNT and GG were identified as most prevalent entities (67). However, reported percentages for both categories reached a huge, although similar variance between 7% and 70%. These figures suggest that the same tumors were classified either as GG or DNT, reflecting rather differences in neuropathology school and training than reliable histopathologic hallmarks. As a consequence, prognostic or predictive features reported so far are inconsistent and cannot be generalized. The enigmatic and controversially discussed risk for malignant progression in a DNT may be an important example.

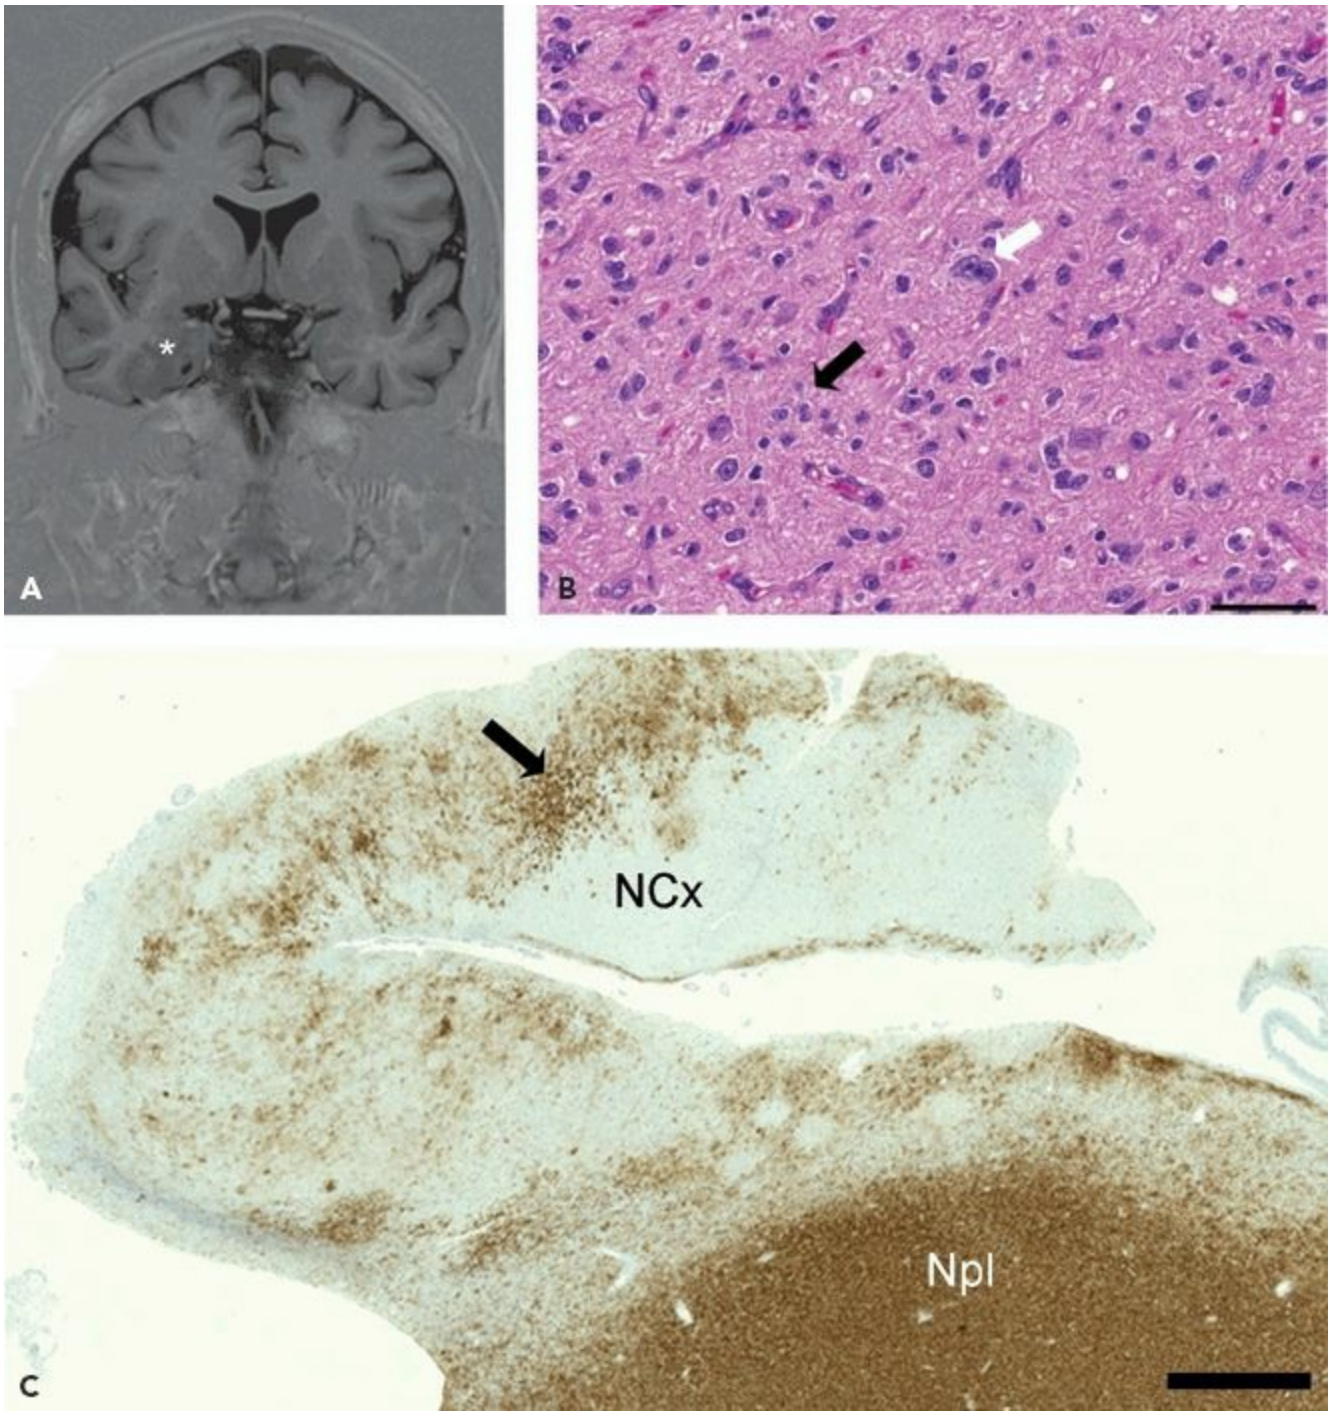

Figure 27.3. Neuropathology findings in a ganglioglioma. This is a 27-year-old male patient suffering from symptomatic epilepsy since age 13. MRI revealed a right temporal cystic lesion (asterisk in **A**), suspicious for a low-grade tumor. The microscopic inspection revealed a mixed glioneuronal tumor with dysplastic neurons (white arrow in **B**) and neoplastically transformed glial cells (black arrow in **B**). The expression of CD34 (brownish color in **C**) is a characteristic immunohistochemical hallmark of this tumor entity (33) and can be observed within the tumor mass (Npl in **C**) as well as tumor infiltration into adjacent neocortex (NCx and black arrow in **C**). The biologic behavior of this tumor corresponds to WHO Grade I without frank signs for atypia or anaplasia.

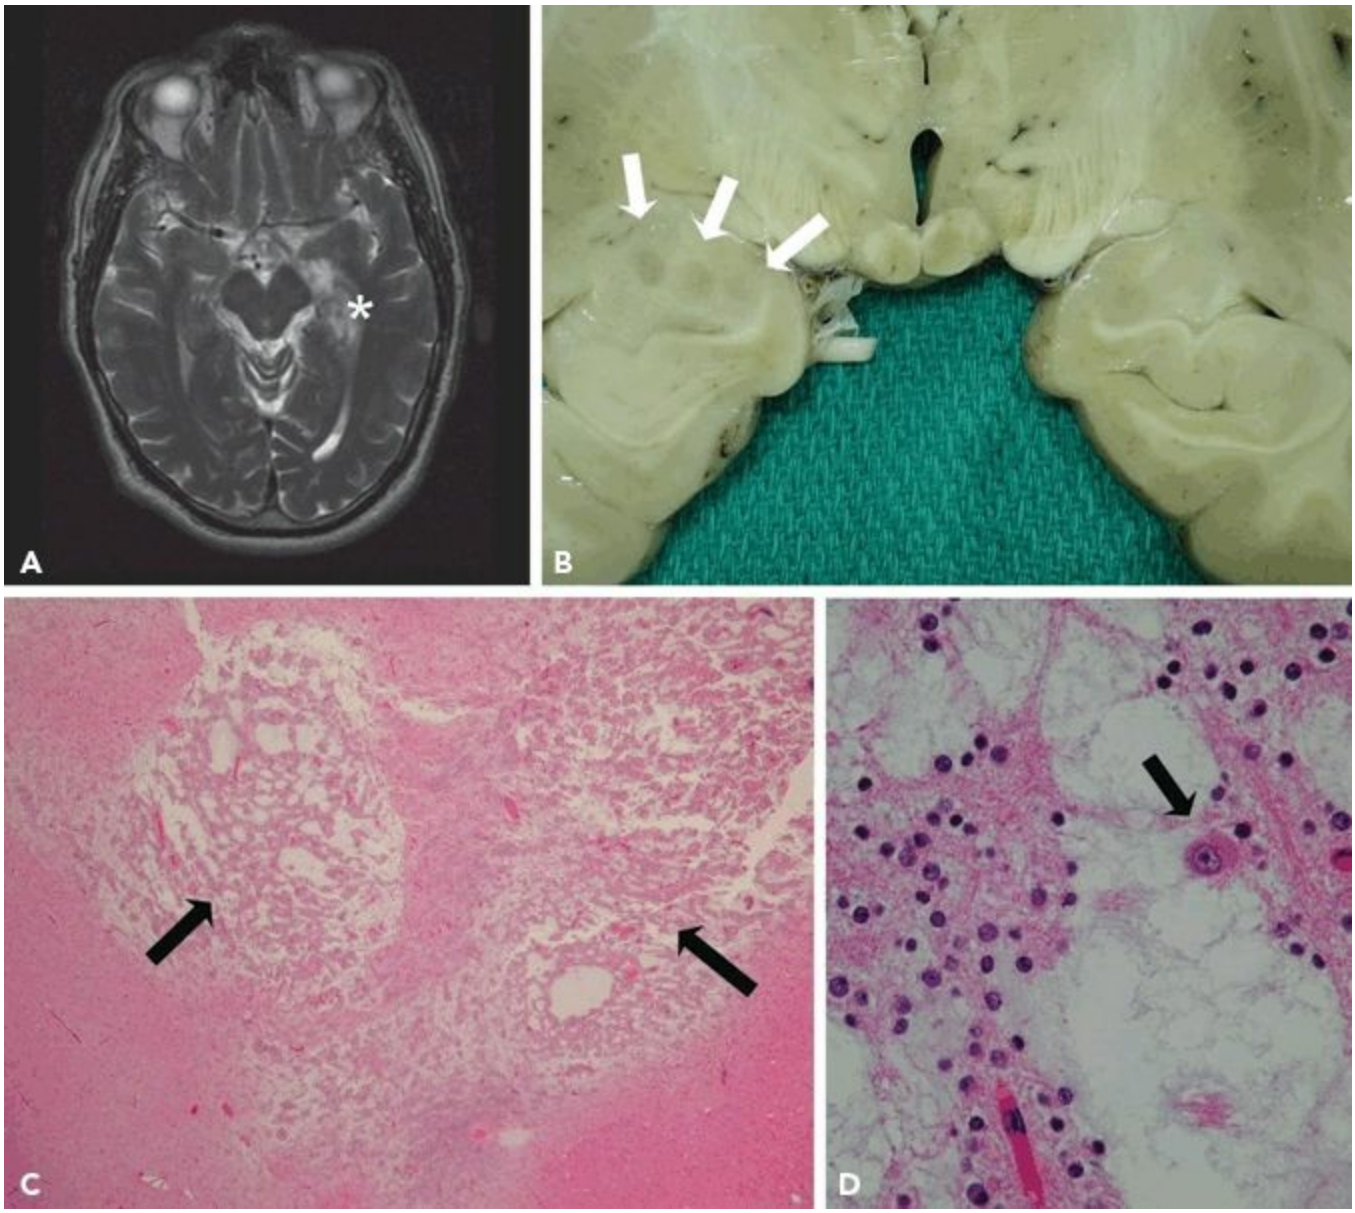

Figure 27.4. Neuropathology findings in a DNT. This 34-year-old male was found dead in his residence, and no anatomic cause of death was evident. He was known to have a seizure disorder, with a stable lesion of the left amygdala first documented 5 years before death; it was hyperintense on T2 (**A**). He was not taking an antiseizure medication. The left amygdala showed subtle enlargement with a multinodular mucinous lesion (arrows in **B**). Microscopically patchy infiltration with focal nodularity (arrows in **C**) and a specific glioneuronal element with "floating neurons" (arrow in **D**), which is characteristic for the histopathologic diagnosis of a dysembryoplastic neuroepithelial tumor (DNET). (Courtesy of Dr. R. Macaulay, Halifax, Canada.)

Increasing availability of surgical tumor specimens may provide the opportunity to clearly characterize the molecular signature of each LEAT variant as well as their molecular pathogenesis and epileptogenic potential. Notwithstanding, such studies will require a reliable terminology use and histopathologic classification that can be reproduced by any other laboratory. Uniform terminology will pave the way for a prospectively designed randomized controlled trials for LEAT treatment providing urgently needed class I evidence for potential biomarkers.

CONCLUSIONS

Tumors constitute a very important cause of chronic intractable epilepsy, and seizures represent a very frequent presenting symptom of brain tumors. Our knowledge of the mechanisms defining the relationship between the two conditions has grown exponentially over the past few years, but a lot

remains to be learned. Several medical and surgical treatment options are available, and multiple potential mechanisms of epileptogenicity in brain tumors have been proposed. So, a diagnostic or a treatment approach focused solely on one mechanistic premise will provide an incomplete view of the true disease pathophysiology and likely be unsuccessful.

CHAPTER 28 POST TRAUMATIC EPILEPSY

JAY R. GAVVALA AND STEPHAN U. SCHUELE

EPIDEMIOLOGY

Posttraumatic epilepsy (PTE) accounts for around 200 new cases of epilepsy per 100,000 persons per year (1,2). PTE is the most common cause of acquired epilepsy, comprising almost 20% of all cases, and is the leading cause of epilepsy with onset in young adulthood (3,4). Head trauma underlies 6% of all epilepsies in the general population and accounts for 5% of patients seen at specialized epilepsy centers (5,6).

The cumulative risk of late unprovoked posttraumatic seizures (seizures occurring >1 week after injury) consistent with a diagnosis of PTE varies between 2% and 20% in civilian populations suffering from closed head injuries and can be as high as 50% in military series after penetrating head injuries (5). Nearly 40% of these late seizures appear within the first 6 months after injury; 50% to 66% appear by 1 year; and more than 75% appear by 2 years after the injury (7–9). Although the risk of PTE continues to decline as the postinjury seizure-free interval lengthens, late seizures may develop over 15 years after the initial insult (10–12). The probability of PTE 5 years after traumatic brain injury (TBI) is estimated as 0.7% after mild (loss of consciousness [LOC], posttraumatic amnesia for <30 minutes, and no skull fracture), 1.2% after moderate (LOC, posttraumatic amnesia lasting for 30 minutes to 24 hours, or skull fracture), and 10% after severe TBI (brain contusion or intracranial hematoma, LOC, or posttraumatic amnesia for >24 hours) (11). After follow-up for more than 30 years, the probability increases to 2.1% for mild, 4.2% for moderate, and 16.7% for severe TBI. The relative risk (RR) of developing PTE after mild TBI increases twofold, fourfold after moderate TBI, and up to sevenfold or more after severe TBI (Table 28.1) (13,14).

Table 28.1 Risk of Posttraumatic Epilepsy

Risk factors		Cumulative incidence (10)		Relative risk/standardized incidence ratio
		5 y	30 y	
Closed head injury	Mild	0.7%	2.1%	2.22 (95% CI 2.07–2.38) (13) 1.5 (95% CI 1.0–2.2) (10)
Multivariate analysis (10)	Moderate	1.2%	4.2%	2.9 (95% CI 1.9–4.1) (10)
▪ Contusion	Severe	10.0%	16.7%	7.40 (95% CI 6.16–8.89) (13)
▪ Subdural				
▪ Skull fracture				17.0 (95% CI 12.3–23.6) (10)
▪ LOC > 1 d				
▪ Early seizure				
▪ Age ≥ 65 y				
Penetrating head injury (89)		22%–43%	50%	

Although the annual incidence of head injury in the general population has not changed in the past 30 years, the number of survivors of severe head injuries has risen, leading to a higher prevalence of patients with PTE (15). Additionally, there has been a high percentage of head injuries of soldiers from the Iraq and Afghanistan wars, with recent studies reporting 7% to 15% of veterans being diagnosed with or having symptoms of TBI (16). Considering this, one can expect a markedly increased number of veterans with posttraumatic seizures.

PATHOPHYSIOLOGY OF POSTTRAUMATIC SEIZURES

Early Seizures

Early posttraumatic seizures, defined as seizures occurring within 1 week of the initial insult, are triggered by the acute trauma or subsequent complications and have to be differentiated from late, unprovoked posttraumatic seizures defining a diagnosis of epilepsy (11). A variety of mechanisms directly related to the initial trauma can trigger symptomatic seizures: The immediate insult after a head injury leads to diffuse axonal injury due to shearing forces and focal brain damage caused by the direct impact to the skull, movement of the brain within the skull (coup and contrecoup), or penetrating wounds (17–20). Secondary axonal injury ensues caused by retraction and swelling of the injured axons with distal wallerian degeneration (21). Subsequent brain necrosis may result from cytotoxic processes such as the release of free oxygen radicals and cytokines and the influx of calcium into open ion channels (18,22). Complications during the acute recovery phase, for example, hypoxia, increased intracranial pressure, hypotension, ischemia, cerebral edema, intracranial bleeding, electrolyte imbalances, or infections, can cause symptomatic seizures several weeks after the injury (Table 28.2) (7,11,23,24). Overall, 90% of seizures within the first 4 weeks after head injury will happen during the first week and more than half of them within the first 24 hours (25,26).

Table 28.2 Definitions

Seizures	Duration after insult	Increased risk of epilepsy	Prophylaxis
Impact convulsion	At impact. Nonepileptic	–	7 d in *severe* TBI
Early seizure	<1 wk[a]	+	
Immediate seizure	<24 h		
Late seizure	>1 wk[a]	+++	After first late seizure
Posttraumatic seizures	Single or recurrent seizures after TBI, separated by early or late occurrence, not attributable to another obvious cause		
Posttraumatic epilepsy	Late-onset, recurrent, unprovoked seizures after TBI, not attributable to another obvious cause		
Degree of TBI	**LOC**	**Skull fracture**	**Structural brain damage**
Mild	<30 min	–	–
Moderate	>30 min and <24 h	+/–	–
Severe	>24 h	+	+

[a]Four weeks in patients with additional complications that may cause acute symptomatic seizures.
LOC, loss of consciousness; TBI, traumatic brain injury.

The incidence of early posttraumatic seizures depends on the severity of the injury and is seen in approximately 2.5% of head injury patients in population-based studies and in up to 16% of patients admitted after severe head trauma (7,11,27–33). Moderate to severe head injury, in particular the presence of a subdural or intracerebral hematoma, a depressed skull fracture, a penetrating brain injury, or a cortical contusion, increases the incidence of early seizures up to 30% (11,34,35). With mild head injuries, an early seizure often indicates other neurologic or systemic abnormalities and should warrant further evaluation and observation (23,36–38). A structural lesion from the acute injury—for example, an epidural or subdural hematoma—has to be excluded with imaging. On rare occasions, seizures after mild trauma are seen in the context of a preexisting brain pathology (39,40), known as pseudotraumatic epilepsy (41).

Approximately 10% of patients with early symptomatic seizures develop PTE. While early seizures are associated with an increased risk for late seizures, the increased risk for PTE is not a direct consequence of the early seizures (7,11,27–33). Multivariate analysis in a large population-based study demonstrated that the increased risk of late epilepsy can be explained by other factors, for example, the presence of a cerebral contusion or hematoma, in particular subdural hematoma, skull fracture, or age (11).

The presentation of early posttraumatic seizures is variable. Electrographic seizures without clinical correlate that are only detectable by continuous electroencephalogram (EEG) monitoring occur frequently. Based on a study of continuous EEG monitoring in the intensive care unit (ICU), which included mostly patients with severe head injury, 21 out of 94 patients (22%) had posttraumatic seizures within the first week of injury (42). Only six patients had clinically witnessed generalized tonic–clonic seizures, another four patients showed subtle myoclonic movements with an epileptiform EEG correlate, while more than half of the patients had electrographic seizure without associated clinical signs. Frequent posttraumatic electrographic seizures are associated with episodic increases in intracranial pressure and lactate/pyruvate ratio and may be a target for aggressive antiepileptic management (43).

Approximately 10% to 20% of early seizures evolve into status epilepticus, more commonly seen in children (25,44). Generalized convulsive status epilepticus often accompanies underlying secondary complications, such as ischemia or metabolic imbalance. Focal motor status is most common with subdural hematomas or depressed skull fractures and can be refractory to treatment. Patients with early status epilepticus may have a higher risk for late seizures than patients with self-limited early seizures according to one study (45). Patients with early status epilepticus had a 41% 10-year cumulative risk to develop late seizures compared to a 13% risk after brief symptomatic seizures. It remains unclear if this is related to the underlying lesion, the effect of status epilepticus, or a shared susceptibility for prolonged early seizures and epilepsy in some patients.

Late Seizures and Epileptogenesis

“Through trauma, the brain may be injured by contusion, laceration, compression, and it is well known that these insults may result in epilepsy after a ‘silent period of strange ripening.’ That period lasts for months or years, but these insults produce epilepsy in the case of one individual and not in the case of another… Our attention should therefore be directed toward the discovery of this mysterious difference” (46,47).

The development of PTE after a latent period has been an intriguing observation and challenge for more than half a century. The “strange ripening” in PTE is a rare example of human epileptogenesis,

the transformation process of a nonepileptic brain into a brain able to generate recurrent, unprovoked seizures (48). The window between insult and occurrence of these unprovoked seizures offers a unique opportunity to investigate the potential mechanisms leading to epileptogenesis, to identify biomarkers, and to implement therapeutic interventions, which are able to prevent the development of the disease rather than merely suppress the seizures. Most of our understanding of the cellular and molecular mechanisms of epileptogenesis derives from experimental animal models, which are not specifically related to traumatic injury. These studies have shown immediate neuronal and glial responses following an injury, usually leading to significant cell loss in areas of the injured brain and over time. Additional changes involve long-term reorganization of neural circuits including disinhibition and selective loss of inhibitory γ-aminobutyric acid (GABA)ergic neurons and increased glutamatergic excitation. Ultimately, these changes lead to an imbalance between excitatory and inhibitory neurotransmission and increased risk for spontaneous seizures (49–51).

A better understanding of the processes between initial insult and development of epilepsy may provide potential treatment targets to prevent epilepsy. Example of a potentially treatable process are early symptomatic seizures or status after head trauma that could cause progressive changes in neural networks and lead to spontaneous and recurrent late seizures (52). Another example is the highly epileptogenic process of hemosiderin deposition and formation of free iron radicals typical for head trauma (53,54).

Several animal models of PTE—including the fluid percussion model, controlled cortical impact injury model, weight drop injury model, neocortical undercut model, and more recently the blast injury model—have been widely used to investigate epileptogenicity after TBI (33,51,55–57). Based on the fluid percussion model, either a selective loss of hilar interneurons in the dentate gyrus or a relative survival of irritable mossy fibers may lead to persistent granule cell hyperexcitability (58–60). More recent studies have shown that focal brain damage after a single episode of severe fluid percussion injury is able to trigger spontaneous seizures (51,61), which originate from the site of the lesion and become clinically and electrographically more severe over time (62,63).

The controlled cortical impact model utilizes an electronically controlled impactor to apply a focal contusion injury to the cortical surface, allowing for consistent and reproducible results without risk of secondary rebound injuries. Studies have shown that injury to the dentate gyrus leads to mossy fiber sprouting with structural reorganization leading to increased spontaneous excitability (64,65). Recently, a new model of penetrating TBI in rats was developed to more closely mimic wartime TBI. However, it is unclear if this model results in long-term spontaneous seizures (51).

Isolation of a small cortical region by transecting the white matter with a needle leads to epileptiform activity of the pyramidal cell layer in slice recordings in the “cortical undercut” model. Axonal sprouting of the isolated pyramidal cells is associated with an increased number of excitatory connections (66). Furthermore, recent studies have shown a decrease in the GABA output of neocortical fast spiking interneurons that synapse on excitatory postsynaptic targets (67). Early application of tetrodotoxin after the injury blocks action potentials and prevents the development of evoked and spontaneous epileptiform activity in the neocortical slices (68), suggesting that posttraumatic epileptogenesis may be an activity-dependent process. Tetrodotoxin given within 3 days of injury prevented the occurrence of late seizures in an animal model of PTE (69). Several seizure medications have also shown antiepileptic properties in both kindling and posttraumatic animal models of epilepsy including valproate and topiramate with levetiracetam showing antiepileptic properties in a kindling model only (70,71).

The process of epileptogenesis and postinjury recovery overlaps in time and seems to share some

basic mechanisms, including neurogenesis, axonal sprouting, and activity dependence (49). Disease-modifying agents and antiepileptic drugs may, therefore, have a positive (or negative) effect on recovery or epileptogenicity. TBI drug trials aimed to improve injury recovery have not looked at late seizures as an outcome measure or as an adverse effect. There are at least data that seizure medications—including remacemide, topiramate, talampanel, lacosamide, and carisbamate—seem to cause no major benefit nor harm on posttraumatic recovery in animal models (49). Additionally, a recent phase II study of levetiracetam in children suffering severe TBI showed it to be safe and well tolerated (72). Effective prevention of epileptogenicity after trauma will require a clear target, appropriate timing, and should not interfere with adaptive processes necessary for functional recovery (50).

TREATMENT OF EARLY AND LATE SEIZURES

A meta-analysis (70) demonstrated effectiveness of phenytoin (RR 0.33; confidence interval [CI], 0.19 to 0.59) and carbamazepine (RR 0.39; CI 0.17 to 0.92) in the prevention of early seizures after head trauma. A Cochrane Database Review of six trials also concluded a beneficial effect of antiepileptic drugs (RR 0.34; 95% CI 0.21 to 0.54) for prevention of early seizures. Based on the Cochrane estimate, for every 100 patients treated, 10 would be kept seizure free in the first week after TBI (73,74). However, seizure control was not associated with a reduction in mortality, neurologic disability, or diminished occurrence of late seizures (pooled RR 1.28; 95% CI 0.90 to 1.81).

On the basis of an analysis of prospective studies (16,75), the American Academy of Neurology has published recommendations on the use of antiepileptic drug prophylaxis in adults with TBI. Their current recommendation is to use short-term phenytoin prophylaxis in adults only with severe brain injury with the goal to prevent early posttraumatic seizures. Phenytoin may be initiated as an intravenous loading dose as soon as possible after the injury. Data on newer antiepileptic medications for the prophylaxis of early seizures after severe head trauma are limited. Levetiracetam has been used for this indication, and several studies have shown similar effectiveness as phenytoin, with fewer side effects (74,76,77). There are limited data to make definite recommendations on the use of antiepileptic drugs to prevent seizures in children. However, there is level III evidence suggesting that prophylactic phenytoin may be considered in children with severe TBI to reduce the risk of early posttraumatic seizures (78–82). There are no data to support the routine use of antiepileptic drugs beyond the first 7 days after the injury (16). Administration of glucocorticoids after brain injury does not prevent late posttraumatic seizures, and early treatment with steroids has been shown to actually increase seizure activity (83).

Medical prophylaxis of late posttraumatic seizures is currently not recommended. For a long time, phenytoin and phenobarbital were thought to be useful in the prevention of late seizures based on observational studies (84,85). Therefore, these medications were routinely prescribed as prophylactic treatment for the most severely injured patients or those experiencing early posttraumatic seizures for 6 months or more (86). However, more recent randomized, double-blind, prospective evaluations of antiseizure prophylaxis with phenytoin, phenobarbital, carbamazepine, and valproic acid consistently found no benefit (75,87–89), irrespective of the choice of antiepileptic drug (89,90). On the contrary, phenytoin can impair cognition in posttraumatic patients (91), and benzodiazepines and barbiturates may interfere with injury recovery (92).

Late posttraumatic seizures beyond the period of the acute insult reflect permanent changes in the

brain and signal the onset of PTE (27,93–95). After a first late unprovoked posttraumatic seizure, the vast majority of patients (86%) experienced a second seizure within the following 2 years, with the highest risk after a focal injury or coma for over 7 days (95). Treatment initiation in patients after a first late posttraumatic seizure seems appropriate, even if the traditional diagnostic criteria for epilepsy requiring at least two unprovoked epileptic seizures have not been met (16), and the recent move toward a broader epilepsy definition by the International League Against Epilepsy can be interpreted in support of this approach.

POSTTRAUMATIC EPILEPSY RISK FACTORS

Severity of Head Trauma

The risk of developing PTE depends on the severity of the head trauma and the presence of a penetrating injury. The most commonly used criterion for the severity of closed head trauma employed by epidemiologic studies examining civilian populations is based on the duration of LOC or amnesia and the presence of structural brain damage. The extent of the structural brain damage can be assessed by focal features on the neurologic examination, x-rays showing a depressed skull fracture, or findings on computed tomography (CT) scan (11,13). Correlating with the severity of the TBI and an increased risk of PTE are prolonged coma or amnesia (longer than 24 hours), brain contusion, and intracranial hematoma, in particular subdural hematoma, depressed skull fracture, and dural penetration, and, to a lesser extent, linear skull fractures (93,96,97).

The incidence of late posttraumatic seizures after closed head injury depends on the study population and varies between 1.9% and 25.3% (7,11,27–32). In the series reported by Annegers and Coan (see Table 28.1) (11,98), the RR of seizures was 1.5 (95% CI 1.0 to 2.2) after mild injuries with no increase after 5 years, 2.9 (95% CI 1.9 to 4.1) after moderate injuries, and 17.2 (95% CI 12.3 to 23.6) after severe injuries. In this study, mild trauma was defined by the presence of coma or amnesia for <30 minutes and the absence of a skull fracture; moderate head trauma was classified as coma or amnesia lasting between 30 minutes and 24 hours and the presence of a skull fracture in patients without contusion or intracranial hemorrhage; and severe trauma was classified as coma or amnesia for more than 24 hours and/or brain contusion or intracranial hemorrhage (see Table 28.2). According to a recent multicenter study, the highest cumulative probability for PTE after a 2-year follow-up is seen with biparietal contusions (66%), dural penetration with bone and metal fragments (63%), multiple intracranial operations (37%), multiple subcortical contusions (33%), subdural hematoma (28%), midline shift >5 mm (26%), and multiple or bilateral contusions (25%) (32).

In military personnel who survive high-velocity penetrating head injuries during warfare, the long-term risk of PTE is consistently estimated at 50% in series examining the major wars of the 20th century (99,100). The most recent wars in Iraq and Afghanistan have seen an increase in the numbers of head and neck injuries compared to prior conflicts. However, there has been a lower percentage of penetrating head injuries with an increased number of closed head injuries (101). In combination with the better injury survival to death ratio (7.0 compared to 1.6 for World War II and 2.8 for the Vietnam War), the high percentage of patients with head injury will likely amount to a significant incidence of posttraumatic seizures.

Early Seizures

An early seizure increases the risk to develop late epilepsy by more than 25% after moderate and severe head injury (30,35,93,94,97). Mild TBI with early seizures may not carry an increased risk for late epilepsy (98). Late seizures are more likely to begin early (within the first year) if there has been an early seizure.

Age

The influence of age on the development of early seizures is well documented (2,31,93,94). Children younger than age 5 years are more likely than adults to have seizures within the first hour after mild head injury (28,29,44,102). However, in children, unlike adults, early seizures are less predictive of late seizures (7,94).

Patients older than age 65 years are highly vulnerable to more severe brain damage and late PTE from any type of head injury (11,103). Earlier reports suggested an increased vulnerability for the development of late seizures associated with posttraumatic hippocampal sclerosis in children younger than 5 years of age (104,105). These findings have not been confirmed in more recent case series (106–108).

Genetic Factors

The evidence for genetic influences on posttraumatic seizures is conflicting. Some studies (109) reported a higher incidence of seizures in family members of patients with posttraumatic seizures. Other research has failed to demonstrate a similar relationship (12,110). According to a recent report, a family history of epilepsy and mild brain injury independently contributed to the risk of epilepsy (14), which supports the concept that genetic factors play a role even in symptomatic focal epilepsies (111,112). Additionally, specific polymorphisms in the glutamic acid decarboxylase genes were associated with an increased risk of posttraumatic seizures, both during the early and late phases, further implicating genetics in the development of posttraumatic seizures (113).

DIAGNOSIS

Clinical Seizures

The full spectrum of seizure semiology can be seen after head trauma. The site of injury and the underlying structural damage determine the type of focal manifestations (9,12,114,115). Early posttraumatic seizures are likely to present as generalized tonic–clonic convulsions even in the presence of focal brain damage (28,36,116). Late seizures mostly have a focal onset (9,114,115) and may develop subsequent to early generalized seizures (12). An interaction between the site of injury and the time when seizures are first noticed has been described. Seizures appear earliest after lesions of the motor area, followed by temporal lobe and those in the frontal or occipital areas (117).

Diagnostic Pitfalls

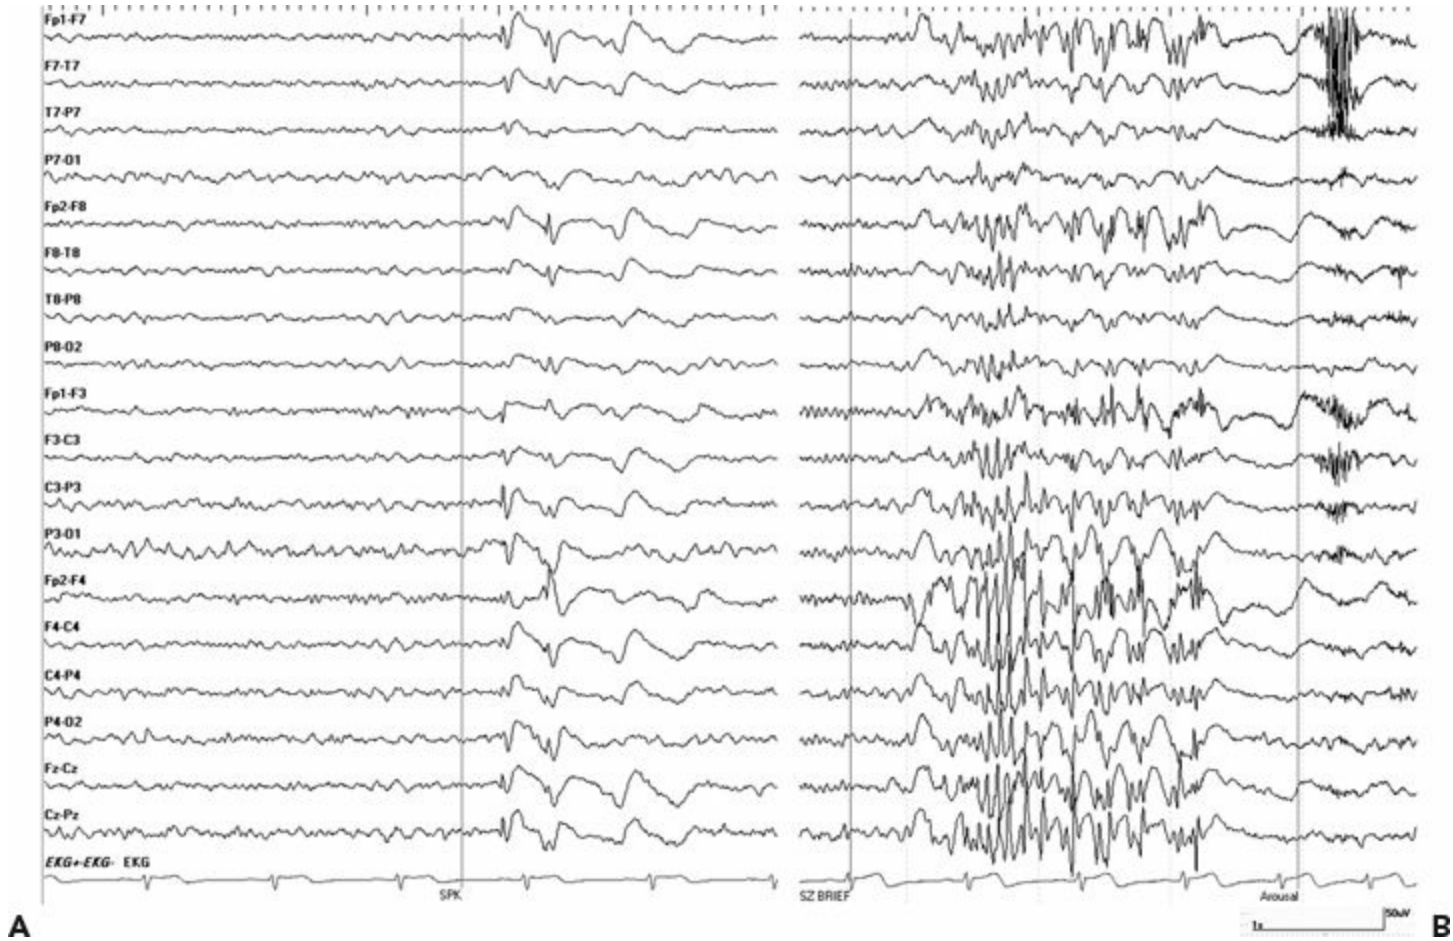
Nonepileptic Posttraumatic Seizures

Head trauma is a risk factor for epilepsy but is also strongly associated with nonepileptic seizure

disorders—presenting in the setting of a somatoform disorder, factitious disorder, or malingering (118,119). The diagnosis can be challenging, particularly in patients with mild head injury and normal routine EEG and magnetic resonance imaging (MRI).

A series of 127 adults diagnosed with intractable posttraumatic seizures who underwent video-EEG (VEEG) monitoring (107,108) had typical events captured in 104 patients (82%) during an average length of stay of 4.6 days (standard deviation [SD] 2.4, median 4). Thirty-six out of the 104 patients (35%) were found to have nonepileptic seizures. There was no difference in the mean duration (19.2 years; SD 11.06, median 18) between onset of seizure-like events and diagnostic referral of patients with epileptic and nonepileptic events. Trauma is a shared risk factor for epileptic and nonepileptic events, but only two patients (1.9%) had both epileptic and nonepileptic seizures. A similar study of 72 children who suffered TBI had paroxysmal events captured with VEEG monitoring, with 17% of children having nonepileptic seizures. Nonepileptic seizures were much more common in the mild TBI group with epileptic seizures more likely in the moderate to severe TBI group (120).

The majority of patients had focal-onset epilepsy: 54% presenting with temporal, 33% with frontal, 5% with parietal, and 3% with occipital lobe epilepsy. Secondary generalized convulsions were more common for extratemporal compared to temporal lobe–onset epilepsy (19% vs. 33%, RR 1.25, P = 0.01). Half of the patients with temporal lobe epilepsy had mesial temporal lobe sclerosis, most of them with a head injury after the age of 5 years. Interestingly, six patients who were initially thought to have symptomatic focal epilepsy for many years were subsequently diagnosed with generalized epilepsy, and four out of five had features of idiopathic generalized epilepsy. This illustrates that the onset of idiopathic generalized epilepsy during teenage years and the high frequency of minor head injuries during the same age can easily delay the diagnosis of the underlying epilepsy syndrome with significant impact on the medical management and outcome (Fig. 28.1).



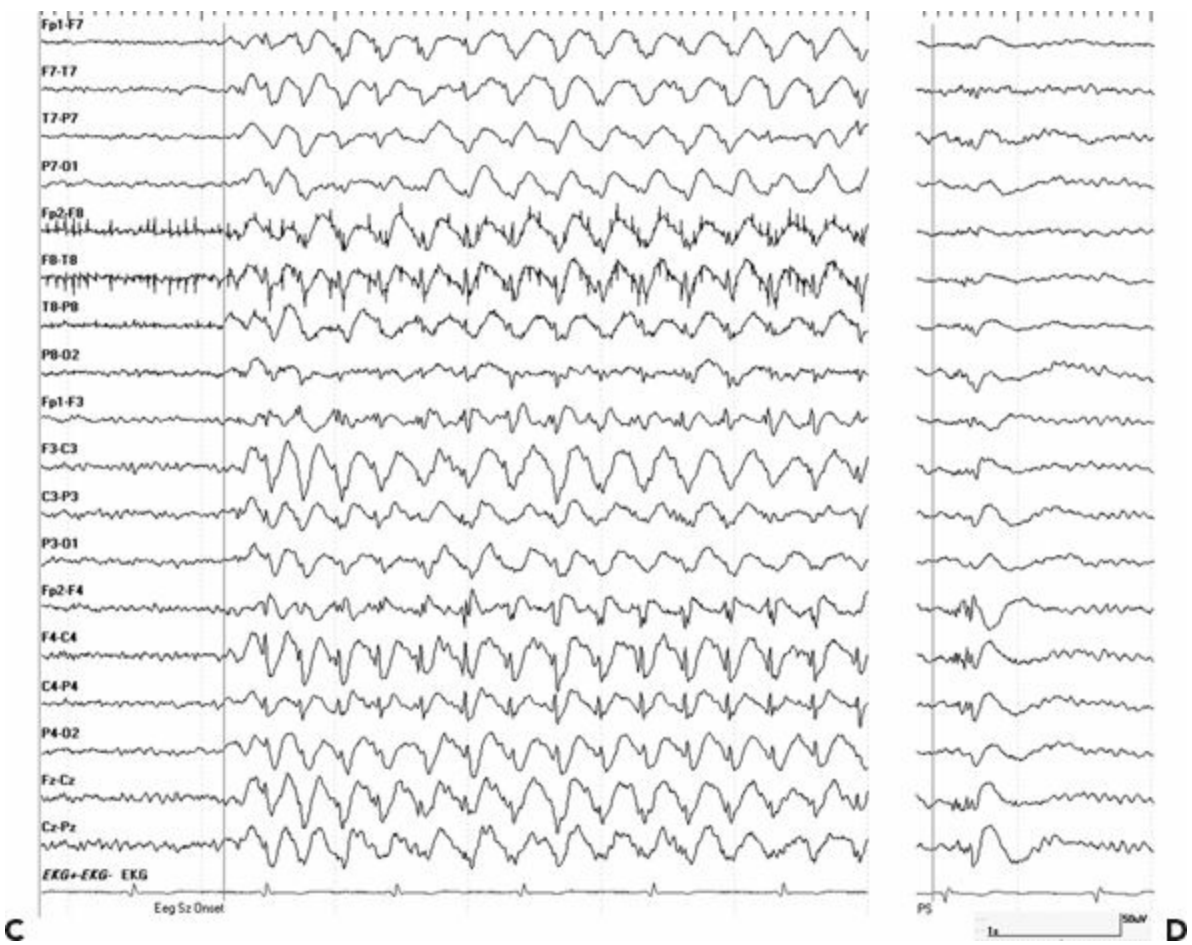


Figure 28.1. A–D: Idiopathic generalized epilepsy versus secondary bilateral hypersynchrony. **A and B (upper panel):** A 39-year-old male diagnosed with PTE after he was hit with baseball bat at age of 13 years. This patient started to have seizures 1 year later and was diagnosed with PTE. He continued to have sporadic generalized convulsions throughout his life and was treated with phenobarbital and phenytoin and later switched to carbamazepine. After starting pregabalin, he developed concentration difficulties, stuttering speech,

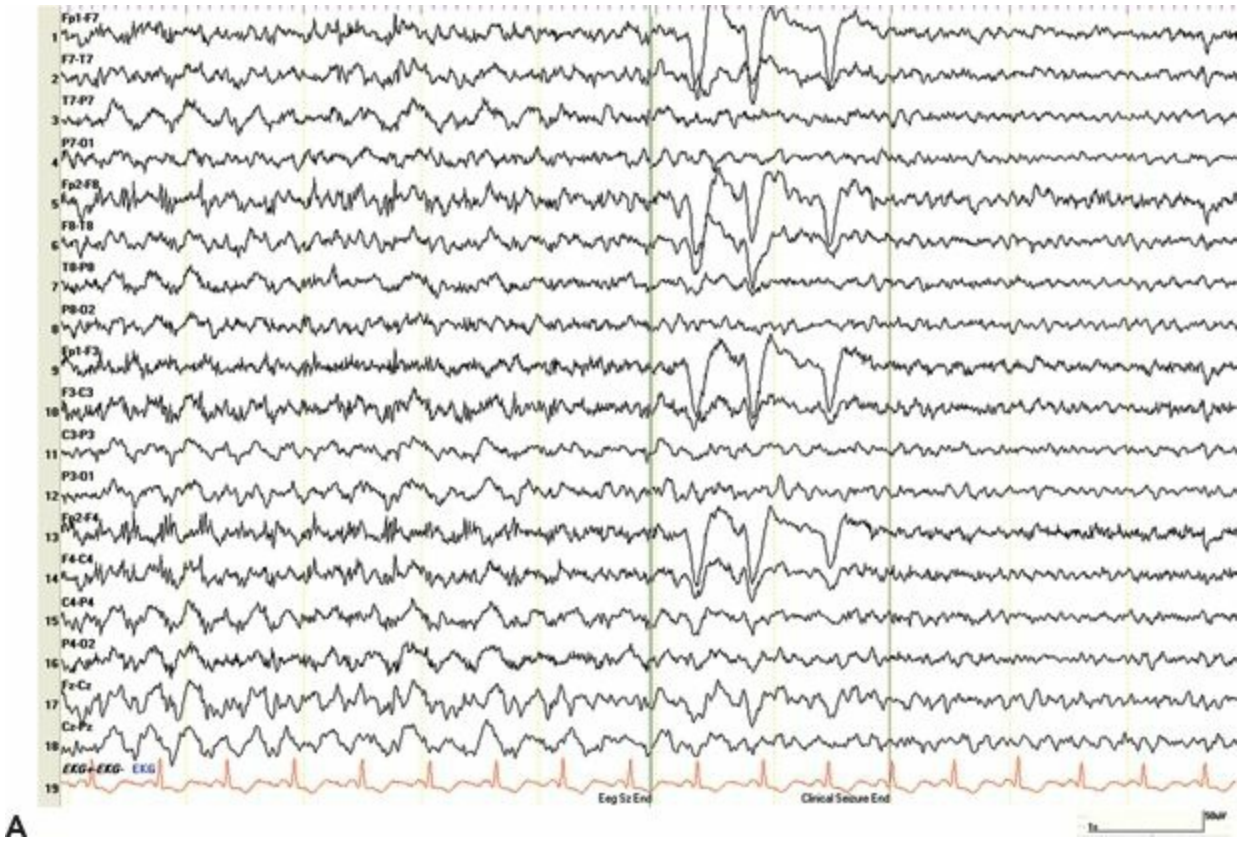
and poor concentration and was referred for presurgical workup. VEEG showed interictal generalized spike and waves (A) and polyspikes (B). Myoclonic jerks associated with generalized EEG pattern were recorded. After initiation of valproic acid, he became seizure free. Impression: juvenile myoclonic epilepsy. **C and D (lower panels):**A 29-year-old female with minor head trauma at age 13 years when she fell on ice and briefly lost consciousness. Onset of epilepsy was at age 14. Outside EEG were reported as generalized spike-and-wave discharges consistent with idiopathic generalized epilepsy. She remained seizure free on carbamazepine for many years. As part of pregnancy planning, she was switched to levetiracetam, and this lead to subacute onset of frequent staring and confusion. EEG showed a generalized spike-and-wave pattern more prominent over the right hemisphere (C) consistent nonconvulsive epileptic stupor, and this nonconvulsive status persisted despite loading her with Valproic acid and levetiracetam, with only transient improvement with Ativan. EEG status eventually resolved after carbamazepine was resumed. Interictal EEG showed generalized and right frontal spikes and polyspikes (D). Impression: posttraumatic focal epilepsy with secondary bilateral hypersynchrony on EEG.

Nonepileptic seizures after head trauma pose a particular challenge to the medical community. The risk of developing epilepsy after a mild head injury is low, and even patients with a normal interictal EEG and MRI may develop epilepsy (Fig. 28.2A). Additionally, nonepileptic seizures are not uncommon after minor head injuries, and a delay in diagnosis and antiepileptic therapy not only interferes with rational treatment but also negatively affects long-term prognosis (121). Similar rates of nonepileptic events were found in both civilian and military veterans undergoing VEEG monitoring over a 10-year period. Interestingly, there was a 5-year delay to diagnosis in veterans compared to 1 year for civilians, resulting in veterans receiving more frequent and prolonged unwarranted antiepileptic drug therapy than do civilians (122).



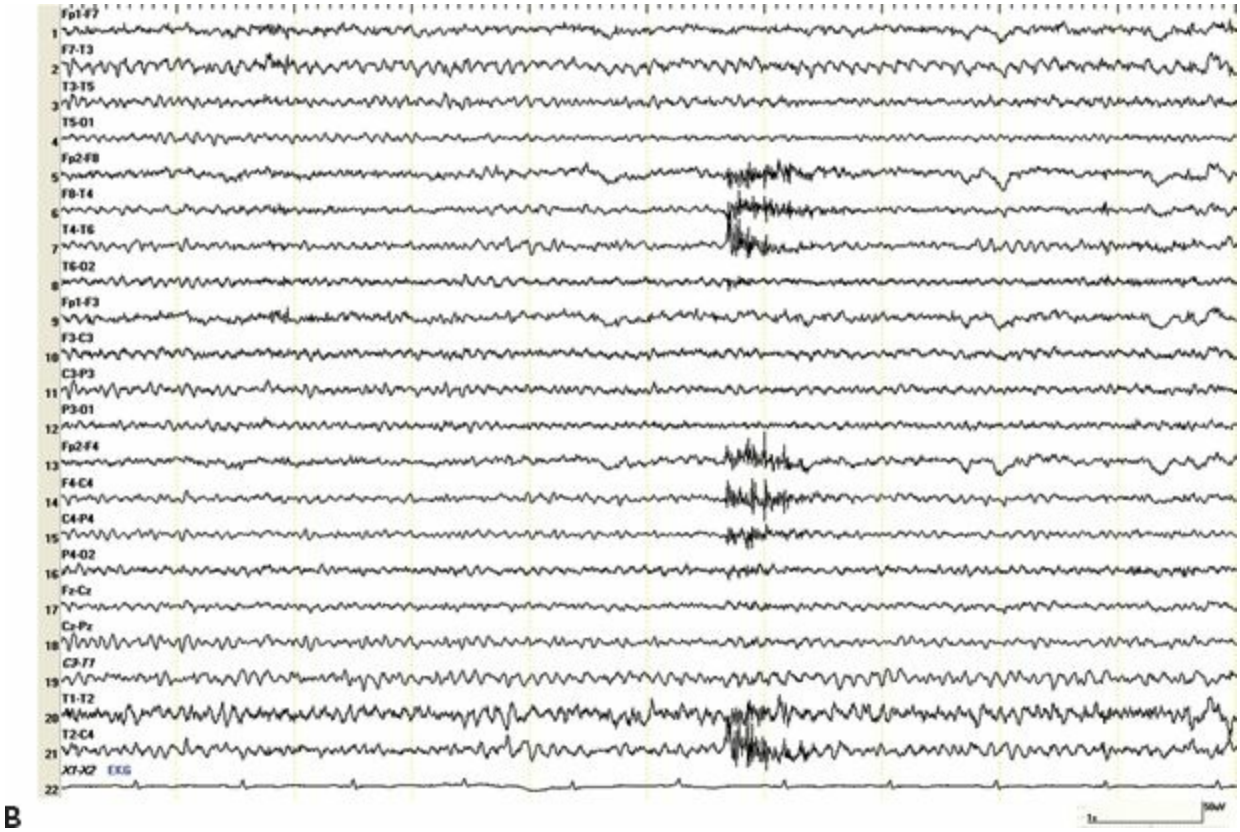


Figure 28.2. A and B: Epilepsy after minor head trauma. **A:** A 50-year-old right-handed male presented with a mild head injury in 2002 when he hit his head on an iron beam at work. There was no LOC. He suffered from a first seizure 6 days later and a second event 10 months later. Both were described as generalized convulsions without warning. Three MRI studies including gradient echo sequences for trauma were normal. Several routine EEGs and prior VEEG monitoring (on medication, no events recorded) were normal, and the concern of nonepileptic seizures was raised. The patient was admitted for a second VEEG monitoring assessment. Within 1 day of discontinuing his medications, carbamazepine and phenobarbital, he developed nonconvulsive status epilepticus. The EEG shows prolonged episodes of generalized slowing with superimposed paroxysmal fast activity in the bifrontal region, clinically associated with staring, occasional lip smacking, and diffuse myoclonic jerks. EEG and clinical seizure activity resolved after administration of Ativan. Impression: PTE after concussion without LOC. **B:** A 50-year-old male with a first seizure 25 years after a mild head trauma. Subsequent CT scan of the brain showed remote left inferior frontal and bilateral temporal contusions. He was treated with antiepileptic medications for 3 years. Two years after stopping the medication, the patient presented with difficulty speaking, brief episodes of unresponsiveness, and ongoing headaches for several days. Routine EEG showed left temporal electrographic seizures lasting around 30 seconds, seen twice during a 30-minute recording, without noticeable clinical changes. Subsequent VEEG showed 6 to 12 seizures per hour, which subsided after temporary burst suppression with midazolam. Impression: late PTE after minor head trauma presenting with nonconvulsive status epilepticus.

There is no clear relationship between the presence of preinjury mental disorders and posttraumatic nonepileptic seizures. However, a high incidence of new psychiatric conditions including posttraumatic stress disorder (PTSD), depression, and anxiety in up to 75% of patients can be noted, often associated with dissociative symptoms and complaints. In some cases, symptoms are not be related to a dissociative problem but may occur in the context of a factitious disorder or due to malingering.

Up to one-third of patients with nonepileptic seizures have a history of head injury, including 78% to 91% having mild injuries (118,119). In the setting of workman's compensation, a diagnostic distinction between epileptic and nonepileptic events is paramount to establish a likely causal relationship between seizures and injury. Secondary gain from disability or workman's compensation has a tendency to perpetuate nonepileptic seizure disorders. In regard to disability estimation, dissociative nonepileptic seizures can be as disabling as epileptic events. However, the disability claim is based on a completely different diagnostic entity, which may influence the chance of approval.

Differentiating epileptic and nonepileptic seizures poses a diagnostic challenge in veterans of the wars in Iraq and Afghanistan. The high number of mild head injuries is associated with a small but definitive risk for PTE and also bears a high risk of PTSD, which is often combined with somatic complaints including seizure-like episodes (123,124).

Nonconvulsive Seizures and Status Epilepticus

There is limited information on the incidence of late posttraumatic nonconvulsive seizures and status (Fig. 28.2B). Particularly, patients with persistent cognitive impairment after head injuries are at risk of subclinical seizures, for a variety of reasons. These patients have a 20% risk to develop epilepsy and may not be able to communicate clinical manifestations of seizures. The caregivers may confuse seizure activity with other causes of impaired or fluctuating cognition and consciousness (23). Even patients who are not cognitively impaired do not recognize more than half of their seizures. The accuracy of a seizure account is even lower in patients with focal seizures with impaired consciousness and with nocturnal seizures. These aspects raise further concerns about the accuracy of seizure reporting in the high-risk patient population with cognitive impairment (125).

Testing

Imaging

Imaging of the brain has been extremely helpful to predict the risk of seizures after head injury. CT and MRI of the brain aid in the determination of the underlying etiology, support the diagnosis in patients presenting with seizure-like events, and may delineate a focal lesion amenable to surgery.

The presence of a focal brain lesion is a risk factor for the development of early seizures as well as late seizures (94,126). The odds ratio of PTE with a focal lesion on CT or MRI scan lies between 2 and 6 (30,31). However, the severity and localization of traumatic brain lesions on MRI do not correlate with the risk for late seizures (127). The presence of cortical or subcortical hemosiderin alone was also not associated with an increased risk of late seizures (30). Only more detailed characteristics of the lesion itself, for example, the relation of hemosiderin deposition to surrounding gliosis or a history of a surgical intervention, may provide additional information regarding epileptogenesis and risk of PTE (128). Functional studies, either with diffusion-weighted MRI or with tomography using radioactive tracers may be more specific in predicting the epileptogenic potential of a structural abnormality (129,130). Recent studies have shown the utility of using quantitative diffusion MRI in detecting hippocampal abnormalities ipsilateral to the site of TBI in animal models that correlate with increased seizure risk (131). Additionally, high-field MRI and diffusion tensor imaging may offer a higher sensitivity to detect diffuse axonal injury in patients with mild head trauma (132,133). Furthermore, longitudinal disease evolution in patients with mild TBI is important. A recent study followed 28 patients with mild TBI with interval MRI scans 1 year later and found statistically significant degrees in atrophy in patients with TBI. The changes were most prominent in the anterior cingulate white matter bilaterally, left cingulate gyrus, and right precuneal gray matter (134).

In spite of a diffuse injury to the closed skull, the epileptogenic process manifested itself more often in a vulnerable brain region such as the hippocampus (135). Surgical series of anterior temporal resections report that 10% of their patients presented with trauma as the major risk factor for epilepsy

(104–106,136). Approximately half of the patients with PTE undergoing epilepsy surgery present with hippocampal sclerosis, and in one-third of these, additional focal neocortical abnormalities are presents (106,107). However, diffuse abnormalities, often global cerebral atrophy, are common in the cases with hippocampal sclerosis. In surgical patients with PTE, there is always the concern that the obvious MRI lesion only represents the "tip of the iceberg" and that neighboring or remote sites, not visible on MRI, are the actual or future culprit for focal epileptogenicity (137). Patients with a neocortical temporal and extratemporal posttraumatic encephalomalacia who are thought to have surgically amenable focal epilepsy based on surface VEEG recording usually require an invasive evaluation to define the precise focus and extent of the epileptogenic lesion. Orbital frontal and anterior temporal–polar cortices are predisposed to neocortical injury after closed head injuries and seem to represent areas particularly susceptible to epileptogenic brain injury.

Diagnostic EEG and Video-EEG Monitoring

EEG patterns during the acute phase of head injury are usually nonspecific and reflect systemic factors in addition to the effects of the acute brain damage (138). In that stage, routine EEG might be helpful to predict recovery from coma (139). Interictal epileptiform abnormalities may appear as early as a week after injury (140). Focal EEG activity seen 1 month after head trauma may predict an increased risk of seizures at 1 year after head injury (30). However, in most studies, the EEG during the early phase after injury proved unhelpful in predicting the development of PTE and does not seem to be an adequate tool to select patients for prophylactic treatment to prevent epileptogenesis and late seizures (115,141,142). The available evidence does not support the use of early EEG changes to predict long-term seizure risk (73). However, the high risk of subclinical seizures acutely after TBI may warrant continuous VEEG monitoring to detect early electrographic seizure activity and initiate treatment (42,143).

After the acute recovery phase, routine EEG can be useful to support the diagnosis of epilepsy in patients with late posttraumatic seizures and to distinguish between focal and generalized epilepsy syndromes (115,144). However, overinterpretation of EEG findings can lead to an erroneous diagnosis of epilepsy in patients with nonepileptic seizures and delay the diagnosis and adequate treatment. Additionally, routine EEGs may capture evidence of nonepileptic events as well. In a retrospective study of outpatient EEGs performed at a veterans hospital for all indications, only 3% of all EEGs had clear epileptiform abnormalities, much lower than previous literature. Of note, almost 6% captured psychogenic nonepileptic events and proved helpful this way to facilitate the diagnosis (145).

Diagnostic VEEG is the gold standard to confirm the clinical diagnosis in patients with pharmacoresistant seizures for more than a year. Monitoring should be done in a setting where antiepileptic medications can safely be withheld. A study in patients with intractable seizures and a history of moderate to severe TBI was able to deliver a definitive diagnosis in 82% of patients during an average length of stay of 4.6 days (SD 2.4, median 4) while off antiepileptic medications (106,107). Unfortunately, referral for monitoring was delayed by an average of 19 years after onset of seizures, irrespective if the seizures proved to be epileptic or nonepileptic. Diagnostic VEEG evaluations not only are helpful to differentiate between epileptic and nonepileptic events but can also influence the choice of medication. Over 5% of patients diagnosed with focal epilepsy may turn out to have an unrecognized generalized epilepsy syndrome (106,107).

TREATMENT

Medical

Seizure remission with medical treatment in patients with posttraumatic seizures ranges from 25% to 40%, but there remains a high risk for seizure recurrence when medications are discontinued. Seizures that develop within the first year after injury are more likely to remit with medication than those that appear later (96). However, the prevailing evidence suggests no significant relation between the occurrence of the first seizure and responsiveness to medication (12,146). Similar to symptomatic epilepsies, a high seizure frequency in the first year of onset predicts future seizure severity and medical intractability (12,147). Seizures that occur after severe head injury and seizures that do not controlled by early treatment tend to persist (95). The chance for spontaneous remission is low, but a medication taper can be justified in selected patients with normal EEG and imaging findings and good response to initial treatment, who have been seizure free for at least 2 years.

Surgical

The selective vulnerability of the hippocampus after blunt head trauma has been well demonstrated in animal models and described in patients with PTE (60). Histopathologic examination in a series of temporal lobectomies and trauma as the major risk factor for epilepsy showed neocortical gliosis in all specimens and hippocampal neuronal loss in 94% of the cases. These findings confirm that a blunt head trauma is able to induce hippocampal epilepsy in the absence of other known risk factors (135). The length of the latent period until the onset of recurrent seizures was inversely related to the age at the time of trauma, which is consistent with prior reports suggesting a particular predilection for posttraumatic hippocampal sclerosis below the age of 5 years (103). However, other studies have demonstrated that trauma may lead to hippocampal sclerosis even at a later age (104,106).

Patients with a history of head trauma who undergo temporal resection are less likely to become seizure free than patients without a history of trauma (55% vs. 40% Engel class Ia) (105). However, these patients may still achieve significant seizure reduction beyond what they can expect from medical management. In a series of 102 patients, 59% of patients with PTE reported a class I outcome with resection after a mean follow-up close to 4 years compared to a 70% class I outcome in all patients undergoing resection. The presence of an isolated focal MRI abnormality—mesial temporal or neocortical—seems critical for a chance of a successful surgical intervention in patients with PTE (104). In a more recent study looking at all epilepsy surgery cases secondary to PTE, 82% had an improvement in seizure frequency with 28% having Engel class I outcomes. Similar to previous studies, patients with focal areas of encephalomalacia on imaging were more likely to have a better outcome (148).

FUTURE DIRECTIONS

The study of PTE yields valuable insights into the complex process of epileptogenesis. The role of neuroprotective agents in TBI and prospective trials with new antiepileptic medications may eventually lead to a reduction in the incidence of PTE. The delayed onset of PTE months or years after the injury offers a unique window for antiepileptic prevention. However, a better understanding of the mechanisms specific to the epileptogenic process after head injuries is required.

The diagnosis of PTE remains a challenge and contributes significantly to treatment failure. More than one-third of patients diagnosed with posttraumatic seizures may have nonepileptic events. Early and late posttraumatic epileptic seizures may go unrecognized, particularly in patients with cognitive impairment and altered level of consciousness. Correct determination of the epilepsy syndrome and appropriate choice of medical and surgical management is crucial to improve treatment outcome.

CHAPTER 29 EPILEPSY IN THE SETTING OF CEREBROVASCULAR DISEASE

STEPHEN HANTUS, NEIL FRIEDMAN, AND BERND POHLMANN-EDEN

Cerebrovascular disease (CVD) is a significant cause of seizures and a risk factor for the development of epilepsy in all age groups. Stroke is a common cause of morbidity and mortality in the elderly population and is the leading cause of epilepsy in patients older than 60 years. Seizures occur in 7% to 11% of adult patients who survive strokes, while poststroke epilepsy develops in 2% to 4% (1,2). CVD is less common in the pediatric population, but early vascular insults are associated with an increased incidence of epilepsy as compared to adult patients. Understanding the prevalence, etiology, and risk factors associated with poststroke seizures and epilepsy is of vital clinical importance, and multiple studies have attempted to address these issues (2–5). The management, prognosis, and treatment of seizures and epilepsy associated with CVD are less well known and will remain an important area for investigation (6). Seizures and stroke can co-occur in rare conditions, such as mitochondrial encephalomyopathy (7). Patients with Takayasu arteritis and hyperhomocysteinemia are at high risk for ischemic events in young adults, with an increased susceptibility for seizures (8).

EPILEPSY IN PEDIATRIC CEREBROVASCULAR DISEASE

The past two decades have seen a renewed interest and focus in pediatric stroke. Although relatively uncommon, the reported incidence has increased with better data collection, improved imaging modalities, and better recognition and awareness among physicians. An incidence rate of 2.52/100,000 children per year (0.63/100,000 children per year for ischemic stroke) was found in the first North American population–based study of pediatric stroke from 1965 to 1974 (9). Since then, data from the largest cohort of pediatric stroke patients from the prospective Canadian Ischemic Stroke Registry have shown an incidence of 6/100,000 children per year (3.3/100,000 for arterial ischemic stroke [AIS]) (10). The highest incidence occurs in the neonatal period with estimates as high as 20 to 30/100,000 newborns per year, although a recent population- based epidemiologic study from Switzerland using magnetic resonance imaging (MRI) confirmation of neonatal AIS showed a higher incidence of just over 40/100,000 per year or 1 in 2300 live births per year (11).

Perinatal AIS occurs primarily in term infants and constitutes approximately 25% to 30% of all AISs in children (12,13). Two-thirds have large vessel cortical infarcts (14) compared with childhood stroke in which more than 50% of strokes involve small vessel territories. The anterior circulation is five times more commonly involved than the posterior circulation, and 60% to 65% involve the left middle cerebral artery territory (14–17). Multiple infarcts are seen in 15% to 20% of cases.

Childhood AIS is more common in males (13) and blacks (18), with the mean age of presentation being 4 to 6 years (12,19–21). Ischemic stroke is only slightly more common than is hemorrhagic stroke in the pediatric population (22). Stroke remains one of the top 10 causes of death in children (23) with a mortality rate of approximately 10% (24). Outcome, in general, is better than that seen in adults, mostly due to brain plasticity and the absence of ubiquitous underlying degenerative vascular disease such as atherosclerosis. Morbidity, however, remains a serious complication of pediatric stroke, and a majority of survivors will have residual and persistent neurologic and/or cognitive impairment. Neurologic impairment includes residual hemiparesis in about two-thirds of children, visual field deficits, cognitive and behavioral difficulties, and/or epilepsy (25). The recurrence risk for stroke is variable, depends on the underlying etiology, and has been estimated to be 15% to 20% (25). The etiologies of stroke in childhood vary considerably from those seen in adults, with approximately 20% to 30% of cases remaining unresolved.

Seizures are more commonly seen as a heralding symptom in childhood stroke than in adult stroke. However, even in childhood stroke, as compared to neonatal stroke, motor deficits are more commonly the presenting neurologic symptom than are seizures. Among motor deficits, hemiparesis is a frequent clinical presentation. The reported incidence of stroke-associated seizures and subsequent epilepsy in children with stroke has been highly variable, partly based on few prospective studies, selection bias, small sample size, lack of long-term follow-up, and differing definitions and terminology in the classification of epilepsy. Acute symptomatic seizures at stroke onset occur in approximately 20% to 30% of childhood AIS (reported incidence of 19% to 54%) with epilepsy as a sequela in approximately 25% (reported incidence of 7% to 58%) (21,26–36). In a large retrospective study of remote seizures and epilepsy within a population-based cohort of children with nonperinatal stroke enrolled in the Kaiser Permanente Northern California database, the average annual incidence rate of first remote seizure was 4.4% with a cumulative risk of 16% at 5 years and 33% at 10 years poststroke. The cumulative risk of active epilepsy was 13% at 5 years and 30% at 10 years, and the presence of acute seizures at the time of stroke onset predicted development of active epilepsy (36). Data regarding seizure presentation and subsequent epilepsy risk for hemorrhagic stroke in childhood are much less clear, with only a few descriptive series. Seizures at onset are minimally more common in childhood AIS occurring in approximately 40% (28,29), with the subsequent risk of epilepsy varying between 10% and 39% (28–30).

The situation is different in perinatal AIS where seizures are the most frequent presenting neurologic symptom, occurring in over 80%. Focal neurologic deficits, such as hemiplegia, or generalized symptoms, such as hypotonia or encephalopathy, are uncommon. In a large prospective series (37), 62 of 90 (69%) term infants who presented only with seizures (and without evidence of a more diffuse neonatal encephalopathy) showed MRI evidence of acute focal ischemia (35/62) or hemorrhagic brain injury (27/62). Similarly, in an autopsy series of 592 infants (38), 5.4% were found to have AIS and none showed focal neurologic features during the newborn period; however, 17% had neonatal seizures. Twelve to eighteen percent of all neonatal seizures are associated with perinatal arterial ischemic infarcts (39–42), tend to be focal (75%), and typically present within the first 72 hours of stroke onset. Generalized and subtle seizures, including apnea, and electrographic seizures (43,44) in the absence of clinical findings may occur. The seizures usually last 3 to 5 days (45,46) in duration and tend to be easy to control medically (45,47,48). Acute symptomatic neonatal seizures have been reported in 57% to 70% of cases of cerebral sinus vein thrombosis (CSVT) (49,50). The presence of seizures in perinatal AIS and neonatal CSVT is associated with adverse neurologic and neurocognitive outcome (49–52). Seizure semiology is variable and frequently

includes infantile spasms (50,53,54). In two large series of infantile spasms, perinatal stroke accounted for 5% and 6%, respectively, of symptomatic spasms, and 4.5% and 8%, respectively, of all cases of infantile spasm (53,55). Spasms secondary to perinatal AIS were associated with high rates of subsequent epilepsy and chronic neurologic morbidity, similar to other etiologies of symptomatic spasms (53). In the Canadian pediatric ischemic stroke registry, the risk of epilepsy was 20% following an infarct due to CSVT versus 15% when the stroke was due to an AIS. The data, however, of subsequent epilepsy risk following perinatal AIS have been very inconsistent and have varied considerable from 0% to 50% depending on the nature of the study. The overall "mean" from these studies would suggest a risk of about 22% for the subsequent development of epilepsy (25). In one of the few prospective studies, Wusthoff et al. (56) showed late seizure (LH) occurrence (median age of 8 months) following perinatal AIS in 24% (with 3 of 11 children not having neonatal seizures), with just over half of these patients (13%) subsequently developing epilepsy. Follow-up was, however, just over 2½ years. An Australian study in 2010, on the other hand, showed that the estimated cumulative incidence of epilepsy following perinatal AIS was 55% by 10 years of age (54). Interestingly, in their study, a history of neonatal seizures was not predictive of subsequent epilepsy. Fetal stroke appears to predict the earlier onset of epilepsy in one recent large cohort (57).

The electroencephalogram (EEG) in perinatal stroke is highly variable and frequently normal. Abnormalities include focal or generalized slowing; focal, multifocal, or bilateral spike or spike-and-wave discharges; low-voltage rhythms; and burst suppression. Focal repetitive seizures, including focal status epilepticus, with a normal background EEG should raise the suspicion for a perinatal AIS. Periodic lateralized epileptiform discharges (PLEDs) have also been reported in perinatal AIS in the term infant (58). Thalamic hemorrhage due to suspected or proven neonatal CSVT appears to carry a high risk for subsequent development of an electrical status epilepticus in slow-wave sleep spectrum (59). The presence of an abnormal background on EEG (25) independent of EEG seizures or epileptiform discharges has been associated with hemiplegia on follow-up (14).

For childhood AIS, cortical involvement and stroke size has, not surprisingly, been associated with a subsequent risk for epilepsy (28,56,60). Subcortical infarcts (basal ganglia, thalamus) have also been associated with seizures either as an isolated presenting feature or in combination with hemiplegia (61). The semiology of seizures is variable, and often patients have more than one seizure type including focal motor, complex partial seizures, with or without secondary generalization, and, occasionally, primary generalized seizures. Clinical and subclinical status epilepticus has variably been reported (35,62,63). The occurrence of seizures and/or altered level of consciousness at the initial presentation of childhood AIS has been associated with increased mortality at 6 months or with unfavorable neurologic outcome (32).

> Infantile hemiplegia offers some of the most typical instances of cortical epilepsy, and it may be well to consider how far it is likely that surgical interference can here be successful—Sir William Osler (64).

Surgical intervention for intractable epilepsy as a consequence of perinatal stroke dates back to the latter part of the 19th century (64,65). The first detailed series of hemispherectomy in children as a treatment option for intractable epilepsy, however, can be traced back to Krynauw in 1950. Histopathology of the resected specimens documented infarcts due to vascular ischemia/stroke as the etiology in a number of his cases (66). Seizure freedom with surgical intervention for refractory epilepsy secondary to AIS is good (67).

EPILEPSY IN ADULT CEREBROVASCULAR DISEASE

Epidemiology

The reported incidence of poststroke seizure and epilepsy has varied in the literature from 3.3% to 13%, although heterogeneous study designs, inconsistent use of terminology, and variable follow-up periods have made them difficult to interpret (68). The Oxfordshire Community Stroke Project prospectively followed 675 patients with a first stroke for a minimum of 2 years and found a 7.7% prevalence of poststroke seizures (1). The Seizures After Stroke Study prospectively followed 1897 patients for a mean follow-up time of 9 months and found 168 patients with poststroke seizures (8.9%) (2). Multiple studies have also differentiated early, late, and recurrent seizures as having different clinical characteristics and prognoses (69–71). A study by Berges et al. retrospectively evaluated 3205 patients and identified 57 patients with early-onset seizures (within 2 weeks of the stroke in the study) and 102 patients with late-onset seizures (>2 weeks from the stroke). They found that the later-onset seizures were significantly more likely to recur (and develop into poststroke epilepsy) than were the early seizures (70). In a retrospective study of Rochester Minnesota residents, 192 patients were identified with poststroke seizures, including 91 patients with acute symptomatic seizures and 101 patients with unprovoked seizures (3). Two key points were made by this study: The acute symptomatic seizures had a much higher 30-day mortality (41.9%) versus the unprovoked seizures (5%), and the recurrence rate was 33% for the acute symptomatic seizure group and 71.5% for the unprovoked seizure group.

The International League Against Epilepsy has developed definitions for early and late poststroke seizures that have been variably defined in the past:

- Acute symptomatic seizure: Epileptic seizure within the first 24 hours after onset of stroke
- Early poststroke seizure: One or more seizures within the first week after the stroke
- Late poststroke seizure: One unprovoked epileptic seizure at least 1 week after the stroke
- Poststroke epilepsy: Two or more unprovoked epileptic seizures at least 1 week after the stroke

The prevalence of poststroke epilepsy has been reported variably from 2% to 4.1% with follow-up periods ranging from 9 months to 7 years (1,2,69–74). A large prospective study followed 1195 patients for 7 years and found 38 patients (3.2%) with poststroke epilepsy (74).

Status epilepticus also occurs in poststroke patients with an overall prevalence reported at 1.5% of all new-onset strokes, which represents 10% of the patients presenting with poststroke seizures (75–77). The number of the patients is small, but these patients tend to have early-onset status, nonconvulsive seizures with no apparent clinical signs, and increased mortality.

In conclusion, poststroke seizures occur in 7% to 11% of new-onset strokes. Approximately one-third of these occur as acute symptomatic or early-onset seizures. Based on the extensive Dijon Stroke Registry of 4411 stroke patients, and in contradiction to previous studies, early epileptic seizures were not associated with higher risks of mortality at 1 month and 1 year or with unfavorable functional outcome after acute stroke (78). Contrarily, the unprovoked or LHs are predicted to have 50% to 70% recurrence rates and thus frequently develop into poststroke epilepsy. The prevalence of poststroke epilepsy is 2% to 4% in patients with new-onset strokes. Status epilepticus occurs after

stroke in a smaller portion of patients (1.5%) but is associated with an early onset and high mortality. A high incidence of 4% to 26% of seizures after subarachnoid hemorrhage was recently reported (79), and it is likely that this is overestimated as a result of inclusion of misdiagnosed decerebrate posturing as seizure activity (8).

An increasing practical problem is that poststroke seizure activity may result in Todd paresis mimicking acute stroke occurrence. Twenty out of 648 patients (3.3%) enrolled in a monocentric stroke registry actually had Todd paresis (80). Eleven out of 539 patients in another study who all underwent thrombolysis turned out to have postictal paresis (81). However, thrombolysis with rt-PA itself was rarely an independent risk factor for seizure occurrence in the acute phase of ischemic stroke (82).

New-onset seizures in the elderly of no obvious cause are often indicators for underlying subtle CVD. These patients have been found to be at significantly increased risk for subsequent stroke (83,84). Accordingly, a sophisticated and comprehensive workup including high-resolution MRI is necessary in these patients to detect otherwise unknown CVD.

The magnitude of seizure risk and the major risk factors were similar to older ischemic stroke patients. However, young patients using anxiolytic medication at the time of stroke onset and psychiatric comorbidity were at high risk for acute symptomatic seizures, and antidepressant use was a significant risk factor for LHs (85).

Pathophysiology

Much of the pathophysiology of poststroke seizures requires further investigation. Based on animal models, acute symptomatic seizures are thought to arise from the penumbra surrounding the infarction (86). Occlusion of middle cerebral artery blood flow in rats is associated with epileptic spiking over the region of proposed penumbra. The ischemia is hypothesized to release glutamate, causing excitotoxicity and early seizures. Other factors proposed to effect early seizures are deposits of hemosiderin-causing focal cerebral irritability, fluctuations in cerebral ions concentrations, and loss of inhibitory GABAergic circuits (87,88). The pathogenesis of LHs and poststroke epilepsy is even less clear. Etiologic factors include the formation of a gliotic scar with reorganization of axonal connections, loss of GABAergic pathways, the presence of hemosiderin in cortical neurons, and free radical formation and membrane peroxidation. Another possible trigger of LHs is recurrent ischemia at the site of the previous stroke. This mechanism was proposed after a series of positron emission tomography studies (77,89).

Advanced epigenetic studies suggest that disruption of chromatin modifications play a role in both stroke and seizures. The gene repressor element-1 silencing transcription factor (REST) is activated in adult neurons in response to ischemia and seizures orchestrating epigenetic remodeling and silencing of subsets of transcriptionally responsive target genes implicated in neuronal death (90,91).

Predictors of Poststroke Epilepsy

A number of clinical factors have been proposed to predict which patients would develop poststroke seizures and epilepsy. Cortical location, stroke severity, and hemorrhagic stroke all were shown to be independent risk factors on multivariate analysis (1,2,69,73,74,92). In addition to the cortical localization, an island of spared cortex, infarct with irregular borders, temporal–parietal location, and posterior cerebral artery infarcts have all been hypothesized to increase the risk of poststroke

epilepsy (93). A recent review of intracerebral hemorrhage (ICH) found that 8% of all patients had clinically detectable seizures, with 90% occurring in the first 3 days (94). In a prospective study in ICH, the median delay between ICH and LS was 9 months, and cortical involvement was the only factor associated with the occurrence of LS (95).

One out of 100 unprovoked first seizures is caused by brain arteriovenous malformations (BAVMs). BAVM patients experience seizures in 20% to 30% of cases (96). BAVMs are considered to be models for epileptogenic lesions as a result of perilesional gliosis, hemorrhage, steal phenomena, and iron deposits.

The analysis of the angioarchitecture of unruptured BAVMs in a huge data set of 1299 BAVMs identified location, fistulous component in the nidus, venous outflow stenosis, and the presence of a long pial course of the draining vein as the strongest predictors of seizures (97). A small study (98) revealed further evidence for the importance of venous infarcts in ictogenesis, and in these patients, the risk for seizure recurrence was 10-fold (26.6%) as compared to patients with ischemic strokes (2.7%).

Cerebral cavernous malformations (CCMs) are associated with seizures as the initial presentation in 25% of cases. After a single seizure associated with a CCM, there is a 94% chance of recurrence. Thus, once CCMs are found in association with a seizure, they require treatment with antiepileptic medications and possibly surgery if they become medically intractable. Factors that have been shown to increase the likelihood of seizures include supratentorial location, cortical involvement and archicortical/mesiotemporal locations (99). Lobar localization, the number of cavernomas, and the size of the lesion/hemosiderin rim have been more controversial (100).

Diagnostic Studies in Poststroke Epilepsy

The value of EEG in predicting poststroke seizures and epilepsy has been controversial (101). In a retrospective study of 110 patients who developed poststroke seizures (12 early seizures, 98 LHs), EEGs were compared in patients who had a first seizure after stroke as compared to a control group of stroke patients without seizures. PLEDs have been associated with increased risk of seizures in prior studies and were also predictive in this study. However, PLEDs were only recorded in 5.8% of patients who would later develop seizures and none in the control group without seizures. Thus, PLEDs were predictive (more often with early seizures) but were rarely observed. Frontal intermittent rhythmic delta (FIRDA) was observed in 24.6% of the seizure group compared to 1.1% of the control group. Diffuse slowing also occurred more frequently in the seizure group (21.7%) than in the control group (5.1%). Focal slowing was equally represented in both groups. Normal EEGs were seen in only 8.5% of the seizure group, while 53.8% of the control group was normal. The authors concluded that PLEDs, FIRDA, and diffuse slowing are the typical EEG findings of early seizures, while FIRDA and diffuse slowing may suggest an increased risk to develop late-onset seizures. The findings of a normal EEG poststroke would suggest decreased risk of developing late-onset seizures (101). In a prospective study of 100 patients who received continuous EEG (CEEG) after acute stroke, 17% were found to have epileptiform discharges or seizures (102). Stroke severity (measured by National Institute of Health Stroke Scale [NIHSS]) was the only independent predictor of epileptiform discharges and/or seizures on CEEG. In a study of 102 patients with nontraumatic ICH who underwent CEEG monitoring, 32% were found to be having seizures (103). In addition, patients who expanded their hemorrhage by 30% or more were twice as likely to have electrographic seizures. Many of the seizures recorded were without clinical signs. Cortical location and severity of

the ICH were related to increased seizure risk. PLEDs were associated with increased mortality. Twenty-eight percent of the seizures were recorded after 24 hours, but only 5% were recorded after 48 hours. In conclusion, poststroke EEG may be useful in prediction of future seizures if PLEDs, FIRDA, or diffuse slowing are noted, and CEEG may be of value in high-risk patients with severe ischemic stroke and ICHs.

Emergency imaging after acute stroke, including perfusion studies, suggests that a large area of postictal hypoperfusion without a corresponding arterial lesion is more likely the correlate of a postictal paresis rather than a stroke and therefore would contraindicate thrombolysis (104). Seizures can lead to additional harm to the infarcted area as demonstrated by magnetic resonance diffusion-weighted imaging findings (105).

Treatment

The treatment of poststroke seizures and epilepsy has been controversial (6). In animal models of ischemia, antiepileptic medications had a neuroprotective effect; however, the same has not been demonstrated in humans (106). First-generation antiepileptics (phenytoin, phenobarbital, and benzodiazepines) were shown to worsen functional recovery in animal models of stroke (107). Unfortunately, there are no randomized controlled trials of treatment for patients with poststroke seizures or epilepsy. The risk of seizure recurrence after an early seizure ranges from 13% to 43%. This is similar to the recurrence risk of 24% that is quoted to patients with a single seizure and normal imaging and EEG studies. However, the risk of recurrent seizures after a single late-onset seizure is in the range of 54% to 66%; thus, some have advocated treatment with antiepileptic drugs (AEDs) after even a single late-onset seizure, while others prefer to treat after a second unprovoked seizure (68,77,108). When medications are used, these seizures tend to respond to monotherapy, with relatively rare recurrence (most notably due to noncompliance). As most of the patients with stroke-associated seizures are elderly, the specific aspects of reduced liver and renal metabolism, higher sensitivity to drug side effects, and potential interactions through liver enzyme–inducing antiepileptic agents due to intrinsic factors as well as comedication have to be considered. The new generation of AEDs seems to have significantly fewer interactions. Though no studies have been conducted in poststroke epilepsy patients per se, a study compared lamotrigine, gabapentin, and carbamazepine in the elderly (with stroke the most likely etiology of the majority of seizures) (109). Seizure control was similar among all three drugs, but tolerability favored lamotrigine and gabapentin. The ultimate goal to prevent poststroke epilepsy has never been successfully demonstrated in humans due to lack of statistical power and methodological pitfalls (110).

With regard to surgical treatment strategies, the role of intervention and modality for seizure outcome in BAVM patients is currently not certain. It has been reported that complete obliteration of BAVMs correlates with good seizure outcome in multimodality therapy (111). Outcome data on the surgical therapy of CCM-associated epilepsy are also scarce: in a small series seizure of a highly specialized epilepsy center, seizure freedom in drug-resistant CCM patients was accomplished in 80%, and outcome in patients with sporadic seizures was 91% after a mean follow-up of 107 to 137 months (112). Extensive resections and complete removal of hemosiderin fringe brain tissue surrounding CCMs (112,113) and early intervention (114) were found to improve short-term and long-term seizure outcome.

CHAPTER 30 EPILEPSY IN THE SETTING OF NEUROCUTANEOUS SYNDROMES

AJAY GUPTA

Neurocutaneous syndromes are genetically and clinically heterogeneous congenital diseases with common characteristics of distinct cutaneous stigmata in association with neurologic disease, and involvement of various organs and systems. Cutaneous findings, noted by the patient, the family, or a family physician, are usually the tip-off for suspecting a neurocutaneous disease. In a few neurocutaneous syndromes, epilepsy is the most common presenting symptom. Identification and chronic management of these patients with complex epilepsy issues often fall into the hands of neurologists and epileptologists, who sometimes lead a team of various specialists in a multidisciplinary clinic model to provide disease-based clinical care. Recognition of neurocutaneous syndromes associated with epilepsy is therefore of critical importance for neurologists and epileptologists. Accurate early diagnosis is vital to counsel the patient and the family regarding chronicity of the condition, choose appropriate antiepileptic drugs for epilepsy, ensure timely selection of candidates for epilepsy surgery, guide testing and consulting for coexisting morbidities, and, when appropriate, refer for genetic testing and counseling. In this chapter, we discuss diagnosis and treatment of such conditions. While our focus is on the diagnosis and treatment of epilepsy in these conditions, we touch upon important aspects of comorbid neuropsychiatric conditions, and other organ system involvement that impact decision making for medical and surgical treatment of epilepsy. Clinical, radiographic, and pathologic findings are presented in the pictorial atlas (Chapter 5).

TUBEROUS SCLEROSIS COMPLEX

Tuberous sclerosis complex (TSC) is a multisystem genetic disease with an autosomal dominant pattern of inheritance. The prevalence is reported to be 1 in 6000 to 10,000 (1). Seizures are one of the most common presenting symptoms in TSC, and most patients with TSC develop lifelong refractory epilepsy. The classic Vogt triad of mental retardation, seizures, and adenoma sebaceum that was used to diagnose TSC in the pre–magnetic resonance imaging (MRI) and gene testing era is found in only 29% of TSC patients (2,3). Diagnostic criteria for clinical diagnosis of TSC have been developed and are clinically useful (4). However, TSC remains a disease with extremely variable expression, and approximately 7% of the patients with TSC1 or TSC2 mutation may not meet diagnostic criteria for TSC, and 15% of patients who meet the criteria for TSC may not have a detectable mutation or deletion in TSC1 or TSC2 (5). Approximately 60% of the patients are the only family member affected, suggesting a new spontaneous mutation (6). Mutations in two genes have been identified in patients with TSC. TSC1 is located at chromosome 9q34 and encodes a protein called hamartin. TSC2 is located at chromosome 16p13.3 and encodes a protein called tuberin. Although located on different chromosomes, the two genes code two proteins that work in the same biochemical pathway, the mTOR (mammalian target of rapamycin) pathway that is critical to cell

cycle regulation. Although most patients have mutations localizable to either TSC1 or TSC2 by currently available testing, 15% of patients may not have a detectable known mutation (7). Such patients should be screened for TSC 1 and 2 gene deletions. Sporadic mutations are more common in the TSC2 gene. TSC1 seems to have less severe phenotypic expression. Specifically TSC1 patients appear to have fewer seizures, fewer intracranial lesions, and less severe mental retardation (7). Both parents of a child who has TSC should be examined for evidence of the disease. When the index case has an identified pathogenic mutation, family members at risk could be screened by looking for that specific mutation. In a case with no identifiable mutations, the family screening could begin by testing of the biologic parents including a complete physical examination including a Wood lamp inspection of the skin, dilated eye examination, MRI of the head, and renal ultrasonography. If the biologic parents have no evidence of TSC, the recurrence risk for their next child is low due to a remote possibility of gonadal mosaicism; if either parent has the disease, the risk for another affected child is 50%.

Pathogenic mutations in TSC 1 or TSC 2 genes activate the mTOR cascade, resulting in abnormal growth and proliferation in various organs and systems. An understanding of this mechanism provided a unique opportunity to test already available mTOR inhibitor drugs such as rapamycin as a potential therapeutic agent targeting TSC-related tumoral diseases in the brain, kidneys, and lungs (8–10). Later, clinical trials led to the FDA approval of mTOR inhibitor everolimus as a treatment option in selected TSC patients with subependymal giant cell astrocytomas (SEGA) and renal angiomyolipomas (9,11–13).

Epilepsy and Neurologic Manifestations in TSC

Seizures are one of the most common presentations in TSC and occur in up to 80% patients with TSC. Most TSC patients with seizures tend to present early in life, and 70% of TSC patients develop epilepsy by the age of 1 year (3,14). A typical patient is an infant who presents with infantile spasms with no prenatal and perinatal adverse events (15–17). Lifelong neurologic morbidity of TSC is usually defined early in life by intractable epilepsy and global cognitive delay that typically go hand in hand. Early onset of epilepsy is one of the most important risk factors for continuing seizures and cognitive disability later in life (18). Most infants with epileptic spasms, despite going into remission with antiepileptic treatment (vigabatrin, ACTH, or other medications), develop complex partial, focal motor, tonic, or generalized tonic–clonic seizures later in life. It is generally accepted that most seizures in TSC are partial-onset seizures from one or more cortical tubers. Infrequently, a TSC patient may present with seizures later during teenage years or adulthood with exclusively partial seizures (3,18,19).

Electroencephalography (EEG) has no specificity to the diagnosis of TSC. A variety of abnormal findings could be seen during the interictal period including a picture of hypsarrhythmia during infancy and Lennox–Gastaut syndrome in older children and adults. Westmoreland found that 88% of TSC patients had abnormal recordings; 75% had epileptiform discharges, and focal slowing occurred in 13%. The epileptiform discharges were multifocal in 25% and focal in 23%; hypsarrhythmia occurred in 19% and generalized spike–wave discharges in 8% (19). Approximately 70% of focal spikes were in the temporal lobe. A variety of seizure onsets (ictal EEG) could be observed ranging from exclusively well-localized focal seizures with partial semiology to generalized or nonlocalized ictal EEG onset with generalized motor or bland seizures. It remains unclear if the threshold of epileptogenicity from the tuber(s) changes throughout the patient's lifetime. It is also not known if and

how multiple epileptogenic tubers interact with each other (or kindle each other), leading to an unpredictable course of epilepsy. Cusmai et al. (20) reported that during follow-up EEG, although some epileptic foci disappeared (usually occipital foci), others became evident, especially in the frontal regions (consistent with posterior–anterior migration of epileptic foci in childhood). The study also found that, although there was no correlation between the number of EEG foci and the number of cortical tubers, in 25 of 26 patients in this series, there was an EEG and MRI topographic correlation between at least one large tuber (larger than 10 mm in the axial plane and larger than 30 mm in the coronal plane) and an EEG focus. Secondary bilateral synchrony appeared in 35% of children with tuberous sclerosis after the age of 2 years, especially during drowsiness and sleep (20,21).

Fifty to sixty-five percent of TSC patients have mild to moderate mental retardation. IQ appears to be bimodally distributed in patients with tuberous sclerosis. On the good side of the spectrum are the few patients who have no or infrequent seizures beginning after early childhood with no or mild learning disabilities and an IQ that is lower than that of siblings without TSC. On the guarded side of the spectrum are TSC patients who present with infantile spasms or catastrophic epilepsy with onset before 12 months of age and who end up with moderate to severe mental retardation, limited or no speech, and inability to ambulate (22). Autism is commonly described in TSC patients and is reported in 25% to 50% of patients. Between 26% and 58% of children with tuberous sclerosis and infantile spasms have autism, compared with 13% of patients with infantile spasms who do not have tuberous sclerosis (22–24). The association between autism and tuberous sclerosis therefore appears to be more than coincidental. Both the number of tubers and their topography seem to play an important role in the cognitive outcome. The persistence of epileptic foci in anterior and posterior areas is thought to be important in the development of autistic traits, such as severe disability in verbal and nonverbal communication, stereotypies, and complete indifference to social interaction. Patients with multiple cortical lesions are likely to have developmental delay and intractable seizures. However, it is not possible to predict neurocognitive function or burden of epilepsy in an individual TSC patient by brain MRI alone. Patients with TSC also have other neuropsychiatric morbidity in the form of high frequency of hyperactive and aggressive behavior, and rarely self-mutilation (23). SEGA may grow and obstruct the CSF flow presenting with symptoms and signs of hydrocephalus requiring tumor excision with or without placement of a ventriculoperitoneal shunt.

Nonneurologic Lesions in TSC

TSC patients have a multitude of cutaneous lesions such as hypomelanic macules (ash leaf spots), adenoma sebaceum (facial angiofibromas), forehead plaques, shagreen patches, and ungual or subungual fibromas. In Gomez's series of 300 tuberous sclerosis patients, skin lesions were seen in 96%, followed by seizures in 84%, retinal hamartomas in 47%, and mental impairment in 45% (3). Patients with TSC may have many visceral lesions including cardiac rhabdomyomas, retinal astrocytomas (hamartoma) in the eyes, renal cysts and angiomyolipomas, hepatic cysts, and pulmonary leioangiomyomatosis.

Brain Involvement and Neuroimaging in TSC

TSC is associated with a variety of brain lesions, and these are cortical tubers, white matter lesions, subependymal nodules (SEN), and SEGA (25,26). Histologically, each of the four types of intracranial lesions is composed of clusters of giant cells with varying degrees of neuronal and

astrocytic differentiation, and the presence of cells that are transitional forms between these two types. On an unenhanced brain CT, cortical and subcortical white matter lesions in TSC appear hypodense and may be mistaken for a remote insult; however, the presence of multiple lesions and associated calcified SEN usually clarify the diagnosis. Many unsuspecting patients are identified to have TSC for the first time by a brain CT done as a part of workup for unrelated questions (e.g., in the emergency room after a head trauma).

While brain CT is helpful in noticing calcified lesions in TSC, brain MRI is the neuroimaging procedure of choice to elicit the extent of all lesions. Age is an important factor in the interpretation of brain MRI in TSC. Cortical tubers are hyperintense on T2 and FLAIR sequences, and hypointense on T1 sequences in patients with mature myelination. In newborns and infants with immature myelination, the tubers are hyperintense to unmyelinated white matter on T1 sequences and appear hypointense on T2-weighted images. This effect of immature myelination on the brain MRI findings in infants with TSC is felt to be secondary to the increased water content in unmyelinated regions of the brain. There is evidence to suggest that cortical tuber count and location are associated with increased risk of infantile spasms (27). There also appears to be a correlation between increased number of tubers, development of early seizures, and developmental delay.

There are three types of white matter lesions in TSC (25,26). These are, in the order of common occurrence, thin linear bands extending radially from the ventricular surface to cortical tubers, wedge-shaped bands with apices near ventricles, and amorphous lesions in the deep white matter. The white matters lesions tend to be predominant in frontal lobes.SEN are often near the caudate head or caudothalamic groove. They are variable in appearance and signal intensity. SEN do not usually obstruct CSF flow, but may uncommonly do so by mechanical pressure against the foramen of Monro. SEN may rarely enhance on gadolinium administration in a nodular or ring-like fashion, and enhancement is better appreciated at higher signal strengths. When small, SEN are better seen on CT than MR because of the presence of calcification. SEGA are slow-growing tumors. They are typically located near the foramen of Monro and are believed to originate from SEN. However, rarely SEGA may also appear in other locations in the brain. Typically, there is no edema in brain parenchyma adjacent to the SEGA. Most SEGA are benign, although there are rare cases of malignant degeneration. The symptoms of SEGA are mainly due to their location. TSC patients with SEGA often present with acute or chronic increased intracranial pressure suggesting chronic or intermittent obstruction at the level of the foramen of Monro. Incidence of SEGA in various studies on TSC is reported to be 1.7% to 26%. A series in a moderate-sized group of patients reported 8.2% (28). SEGA are generally iso- to hypointense to brain parenchyma on T1 and hyperintense on T2-weighted images. SEGA are heterogeneous in appearance. Flow voids may be identified within these lesions. They often have internal susceptibility artifact reflecting hemorrhage or calcification. SEGA usually show contrast enhancement. SEGA should be suspected and periodic screening scans are indicated if SEN show increased size and contrast enhancement.

Medical Treatment of Epilepsy

The first-line treatment for seizures is antiepileptic medications. Many case series and randomized clinical trials show that vigabatrin is particularly effective in the treatment for infantile spasms and partial seizures during infancy in TSC (29–31). Vigabatrin may cause irreversible peripheral field visual defects after long-term use, and most experts agree not to use vigabatrin beyond 6 to 12 months of treatment. Corticotropin (ACTH) provides an alternative treatment; the response of children with

tuberous sclerosis and infantile spasms to corticotropin is similar to the response of children with cryptogenic infantile spasms; however, those with tuberous sclerosis have a higher relapse rate. Vigabatrin may be superior compared to ACTH considering the similar or marginally better rate and rapidity of seizure remission, ease of oral administration, lack of serious side effects in the short term, and significantly lower cost of treatment (29–31). Many experts use Vigabatrin as the first-line drug in infantile seizures in the setting of TSC. Other antiepileptic treatments could be used in TSC following the general guidelines of partial versus generalized seizures. However, one should keep in mind that most seizures in patients with TSC are partial in origin despite an overwhelming electroclinical picture of generalized epileptic encephalopathy and, therefore, not contraindicating antiepileptic drugs that are effective only for partial epilepsy. Coexisting renal morbidity in TSC warrants cautious use of topiramate and zonisamide, and ketogenic diet. Extra caution is required for monitoring preexisting neuropsychiatric and behavior issues that may paradoxically show worsening with antiepileptic drug(s). Recently, mTOR inhibitors have been proposed as an option for treatment of epilepsy in TSC. However, it remains controversial, and at the time of writing this chapter mTOR inhibitors are not approved by the FDA (USA) for treatment of epilepsy in patients with TSC, but treatment trials are ongoing, suggesting encouraging preliminary results (32).

Surgical Treatment and Outcome of Epilepsy in TSC

Like in any other refractory partial epilepsy, when medical treatment fails, evaluation for the possibility of epilepsy surgery should be considered early in every patient with TSC (33). Frequency of medical intractability of seizures is higher in TSC and reported to be approximately 50% in patients with tuberous sclerosis and partial epilepsy (18). Seizure freedom or effective control of debilitating seizures after epilepsy surgery would likely improve quality of life in patients and families with TSC. However, two key rules for planning surgical strategy, localization of the epileptogenic zone (EZ) and minimizing risk of a permanent new postoperative deficit(s), pose additional challenges unique to TSC. These challenges emanate from multiple factors, often age related, and in complex interaction with each other. First, the presence of multiple bilateral tubers, sometimes partially or nearly confluent, on the brain MRI portrays a possibility of multiple epileptogenic lesions. The tubers often intermingle with white matter abnormalities and defy accurate identification of margins even on a high-resolution brain MRI making anatomical delineation for surgery inaccurate. Second, the patient is frequently a child or a cognitively disabled young adult with stereotypic nonfocal seizure semiology (epileptic spasms, bland seizures with behavior arrest, tonic or atonic seizures with falls) and a scalp video-EEG that often shows overwhelming generalized or multiregional interictal abnormalities and nonlocalizable ictal onset. Considering recent reports of a single epileptogenic lesion on the brain MRI leading to generalized and multiregional interictal and ictal abnormalities on scalp EEG, a scenario of multiple epileptogenic lesions with such an EEG appears to be an insurmountable condition for epilepsy surgery (Chapter 88). Third, young age along with cognitive delay and behavior issues renders cooperation for noninvasive mapping of eloquent functions, whenever necessary, challenging or even impractical. And lastly, lack of long-term longitudinal postoperative outcome studies makes family counseling before surgery imprecise as there is always a potential concern for emergence of epileptogenicity from the nonresected tubers. It is therefore no wonder that in the quest for a successful surgical strategy in TSC, multiple presurgical investigative tools in various combinations and recipes have been reported in the published case series from various centers (33).

Multimodal presurgical tools such as 18F fluorodeoxyglucose–positron emission tomography (PET), alpha-[(11)C] methyl-L-tryptophan (AMT)-PET, ictal single photon emission computed tomography, and magnetoencephalogram (MEG) coregistered to the brain MRI have been used in varying combinations with claims of success; however, there is no perfect formula for identification of the epileptogenic tuber, and neither have any tools, alone or in combination, been shown to improve the rate of seizure freedom after surgery (33–40). A logical step-by-step by investigation tailored to each patient remains the cornerstone of presurgical evaluation in TSC. Recently, in patients with unidentifiable EZ (epileptogenic tuber(s)) on multimodal noninvasive investigations, bilateral subdural and depth electrode implantation encompassing wide regions of brain bilaterally followed by a focused search for the epileptogenic tuber(s) with staged resection(s) has been reported from one center (41). Palliative procedures, such as corpus callosotomy or partial or complete resection of the "most" epileptogenic tuber (cause of most frequent or most severe seizures), could also help in some patients with TSC where surgery is done to minimize injuries, abolish the most disabling seizures with falls and loss of consciousness, and prevent episodes of life-threatening status epilepticus.

Published series on epilepsy surgery in TSC have reported high rates of success in alleviating or significantly improving seizures in most patients who undergo surgery. In a systematic review of literature published between 1960 and 2006, Jansen et al. (42) reviewed a sample of 177 TSC patients who underwent epilepsy surgery and were subjects in 25 published articles in peer-reviewed journals. Not surprisingly, authors found these observational case series incomparable due to extreme variability in the collection and reporting of data (42). However, in a composite analysis, 75% TSC patients were either seizure free (57%; 0.1 to 47 [mean 3.7] years follow-up) or >90% improved in seizure frequency (18%; 0.5 to 20 [mean 4.2] years follow-up). Also of interest was the finding that a large number of TSC patients who underwent surgery had generalized and multiregional interictal scalp EEG abnormalities (48%) and nonlocalizable ictal onset (46%) findings; however, the presence of focal versus nonfocal scalp EEG abnormalities had no statistically significant relationship to seizure remission after surgery (42). Obviously, these patients were selected for epilepsy surgery based on other (not studied in the paper) criteria(s) such as semiology, functional deficits, dominant tuber(s) on the brain MRI, nuclear imaging studies, or MEG, again highlighting the point that generalized and multiregional EEG abnormalities on the scalp video-EEG does not preclude surgical candidacy in a child with a solitary or multiple lesions (such as in TSC). In a recent series of 33 TSC patients who underwent epilepsy surgery, complete removal of epileptogenic tissue detected by MRI and intracranial EEG, regional scalp interictal EEG patterns, and agreement of interictal and ictal EEG localization were the most powerful predictors of seizure-free outcome (43). Other significant predictors included occurrence of regional scalp ictal EEG patterns, fewer brain regions affected by tubers, presence of preoperative hemiparesis, and one-stage surgery. Remaining factors such as age at seizure onset, incidence of infantile spasms or other seizure types, duration of epilepsy, seizure frequency, mental retardation, as well as types and extent of resections did not influence outcome (43).

Overall, despite additional challenges of epilepsy surgery in TSC, the findings from the published TSC series are quite similar to the proven principles and practice of epilepsy surgery in children with extratemporal epilepsy substrates (Chapter 89). The investigation to find the culprit tuber and perituberal regions (and define the EZ) is, therefore, best individualized to each patient considering all aspects of his or her clinical condition and goals of epilepsy surgery. No formula fits all TSC patients. Every TSC patient with refractory epilepsy should undergo presurgical evaluation using a

customized approach. In a few refractory patients who were not candidates for resective surgery or did not benefit from resection, vagus nerve stimulator implantation may offer some palliative benefit (44–46).

STURGE–WEBER SYNDROME

Sturge–Weber syndrome (SWS) or Sturge–Weber–Dimitri syndrome is also known as encephalotrigeminal angiomatosis or encephalofacial angiomatosis. SWS was first described in 1879 by Sturge, who thought that the neurologic features of the syndrome resulted from a nevoid condition of the brain similar to that affecting the face. Volland in 1912 and Weber in 1922 described the intracranial calcifications, and Dimitri was the first to report a case with calcifications seen on skull roentgenogram. SWS is a sporadic disease presumed to be caused by somatic mutation. Prevalence of SWS is estimated in one study to be 1 in 50,000. In a recent tissue-based study, SWS (brain tissue) and port-wine stains (PWSs) (cutaneous tissue) were shown to be caused by somatic mosaic mutations in the GNAQ gene leading to disruption of normal vascular development (47). The study group identified a nonsynonymous single-nucleotide variant (c.548G-->A, p.Arg183Gln) in GNAQ in samples of affected tissue from 88% of the participants (23 of 26) with the SWS and from 92% of the participants (12 of 13) with apparently nonsyndromic PWSs, but not in any of the samples of affected tissue from 4 participants with an unrelated cerebrovascular malformation or in any of the samples from the 6 controls (47).

Characteristic clinical features of SWS are unilateral facial PWS, ipsilateral pial angiomatosis, epilepsy, stroke-like episodes and glaucoma. Neurologic manifestations include seizures, varying degrees of mental retardation, migraine-like headaches, intermittent or progressive stroke-like episodes with focal deficits such as hemiparesis, hemiatrophy, aphasia, and hemianopsia (26,48,49).

Chronic cortical ischemia from angiomatous malformation leading to calcification and laminar cortical necrosis have been proposed as likely mechanisms of brain injury. During the sixth week of intrauterine life, the primitive embryonal vascular plexus develops around the cephalic portion of the neural tube and under the ectoderm in the region destined to be the facial skin. In SWS, it is hypothesized that the vascular plexus fails to regress, as it should in the embryo in the ninth week, resulting in angiomatosis of related tissues (50). The intracranial lesion is thought to be related to proliferation of leptomeningeal vessels in the subarachnoid space, which causes shunting of blood away from the brain tissue resulting in decreased blood flow, decreased venous return (venous stasis), and consequent focal hypoxia leading to cellular death. This is seen radiographically as gliosis, volume loss, and calcification.

Epilepsy and Neurologic Manifestations in SWS

Seizures are the most common neurologic presentation, and occur in 75% to 80% of children with SWS. Only 10% to 20% of children with unilateral port-wine nevus of the forehead have a leptomeningeal angioma. Typically, SWS involves occipital and posterior parietal lobes ipsilateral to the port wine nevus, but it can affect other cranial regions and both cerebral hemispheres. Bilateral brain lesions occur in 15% of children. Bilateral hemispheric involvement increases the risk of seizure. The age range of seizure onset varies between birth and 23 years with a median age of 6 months (51). The risk of developing seizures is highest in the first 2 years of life and occurs earlier in patients with bilateral disease. The most common type of seizure is a partial seizure, usually a focal

motor with hemitonic, hemiclonic semiology. Secondary generalized seizures are also uncommonly seen, usually later in childhood and adolescence. There is also an increased incidence of prolonged seizures or status epilepticus in SWS patients. In many SWS patients, seizures tend to cycle with relapsing clusters over a few days, and then remit for many days to weeks. Fever and infection may trigger the onset of seizure clusters in many children. Seizures frequently accompany stroke-like episodes. Onset of a motor deficit may precede a cluster or prolonged seizures rather than seizures followed by Todd paralysis; however, this distinction could be difficult in children. Hemiparesis is often discovered for the first time around the seizure clusters before it becomes an obvious permanent deficit. It remains unclear if fixed hemiparesis is a stuttering progressive hemiparesis that occurs due to acute (seizures, stroke-like episodes) over chronic (hypoxia from leptomeningeal angiomatosis) injury, raising the question of SWS being a progressive disease. Fixed hemiparesis contralateral to the facial angioma eventually occurs in 50% of children. Transient episodes of hemiplegia, not related to clinical or EEG evidence of seizure activity, may also occur. As a general rule, children with SWS do not exhibit significant mental retardation in the absence of seizures. Hemiparesis and hemisensory loss increase in frequency with age. Hemianopsia is often present by the time hemiparesis is manifested. SWS patients may also have associated migraine-like headache, attention deficit disorder, and mild to severe cognitive impairment (51,52). Sixty to eighty percent of SWS patients have some degree of mental retardation, and 47% to 60% are reported to have moderate to severe mental retardation in two studies. Bilateral hemispheric involvement usually shows increased severity of mental retardation (53). Intensity of seizures rather than age of onset or hemiparesis were correlated with the presence and severity of mental retardation (54).

EEG could serve as a noninvasive tool for diagnosis of brain involvement in newborns and young infants who have not yet developed neurologic symptoms and signs. Commonly seen EEG abnormalities are slowing and attenuation of background activity on one (ipsilateral to the disease) or both (likely bilateral disease) sides, epileptiform spikes coexisting with background abnormalities, and only epileptiform spikes without background abnormalities. A few patients may have bilateral independent or generalized spike discharges. Quantitative EEG (qEEG) has been claimed to provide an objective measure of EEG asymmetry that correlates with clinical status and brain asymmetry seen on MRI (55).

Nonneurologic Lesion in SWS

The hallmark cutaneous lesion of SWS is the unilateral facial capillary angioma (i.e., port-wine stain or nevus flammeus) in the distribution of cranial nerve V. The dermatologic lesion of a facial PWS is usually present during birth. It is a flat lesion of variable size, involving the upper eyelid and forehead. The size of the cutaneous angioma does not predict the size of the intracranial angioma. It is unilateral in 70% cases, almost always ipsilateral to the brain involvement. Usually it is in the V1 distribution with variable V2 and V3 involvement. Patients with V1 involvement are at risk for neurooocular lesions. Some experts feel that facial angioma is not a sine qua non, and up to 5% of patients with SWS do not have facial angiomas. Nevi may be found on the nape of the neck above or below the hairline, the upper trunk, or even the extremities and hence may escape recognition on a cursory examination. Even when facial angiomas are bilateral, intracranial involvement tends to be unilateral or dominant (asymmetric) on one side (26,49,53). Glaucoma is diagnosed in 15% of SWS patients at birth, 61% in the first year of life, and 72% by the age of 5 years (56). Presence of vascular malformation in the distribution of the V1 segment increases the probability of glaucoma.

The presence of buphthalmos and amblyopia in newborns with SWS may suggest glaucoma. There may be associated vascular abnormalities in the conjunctiva, sclera, retina, and choroid. In SWS, glaucoma is usually found with ipsilateral choroidal angiomas. This elevated intraocular pressure may be due to elevated episcleral venous pressure (57). Dilated episcleral and retinal vessels are present with V1 involvement. There is increased incidence of retinal detachment secondary to hemorrhages from the choroidal hemangiomas. Eye involvement may result in acute or chronic visual loss that may not be readily apparent in a young infant without an ophthalmologic examination by an expert.

Brain Involvement and Neuroimaging in SWS

Characteristic brain MRI findings in SWS are enhancement of the leptomeningeal angioma, enlarged transmedullary veins, choroid plexus hypertrophy, white matter abnormalities, calcification, and patchy parenchymal gliosis (neuronal loss) (Chapter 5). However, the brain MRI may only show subtle or no abnormalities in young infants who are, at a later date, shown to have SWS. Unenhanced CT scan of the brain, although routinely not done, may show cortical calcification typically described as "tram track" or "gyriform" appearance. Calcification may be absent or minimal in neonates and infants. On brain MRI, calcified lesions are best visualized on gradient or susceptibility sequences where they exhibit gyriform susceptibility artifact (low signal areas). Contrary to what might be anticipated intuitively, neither MR venography nor MR angiography are generally helpful in the diagnosis and severity of SWS (26).

Medical Treatment of Epilepsy in SWS

Broad-spectrum antiepileptic medications that are effective in partial seizures may control seizures. Onset of epilepsy before 2 years of age increases the risk of mental retardation and refractory epilepsy. Clinical progression may have a stuttering course with unpredictable periods of rapid worsening, episodes of intense seizure clusters and status epilepticus, and stroke-like episodes as discussed in the previous section (49,51,55). There is a higher risk for neurologic complications in widespread or bihemispheric disease. Aspirin 3 to 5 mg/kg/day is often recommended with SWS as primary prevention or secondary prevention (after first stroke-like episode), but its efficacy is controversial, and there have been no randomized controlled clinical trials. In one case series, patients who received prophylactic aspirin were found to have 65% fewer strokes than those who did not (58). In another series, 58 SWS patients who took aspirin were analyzed in a retrospective chart review (59). The majority of SWS patients on aspirin had neurologic outcomes reflecting reasonable seizure control (91%), no or mild hemiparesis (57%), no vision impairment (71%), and no or mild cognitive impairment (80%). Forty-nine patients reported no significant side effects, and nine reported either allergic reaction or minimal to significant bleeding on aspirin. This study's clinical observations provide support for a low-dose aspirin use under clinical supervision in SWS (59). Regular evaluation by an ophthalmologist is recommended, particularly in those patients with choroidal lesions. Medical and surgical treatment of glaucoma includes beta-blockers, carbonic anhydrase ophthalmic drops, and surgery. Salvaging (or preventing) visual loss by aggressive glaucoma management has important implications for future epilepsy surgery that likely involves ipsilateral posterior quadrant resection with permanent postoperative contralateral hemianopsia (48).

Surgical Treatment and Outcome of Epilepsy in SWS

About 50% of patients with SWS may have medically refractory epilepsy. Epilepsy in SWS is amenable to surgical treatment in most refractory patients with SWS (48). Peterman et al. (52) followed 25 patients with SWS for more than 5 years and reported spontaneous remission or controlled epilepsy in nearly half. In medically refractory patients, presurgical evaluation should be promptly considered. General principles of pediatric epilepsy surgery apply to SWS children (Chapter 89). The timing of surgery is important. Considering that the disease may be progressive in some SWS patients, some experts argue that early resective surgery may be useful in halting the progressive brain involvement, neurologic deficits, and cognitive impairment. Visually guided complete excision of the angiomatous cortex with or without the guidance of intraoperative electrocorticography is generally considered the primary surgical strategy. Extensive hemispheric resection and hemispherectomy could be considered in children with extensive unilateral brain involvement and a fixed hemiparesis. The completeness of resection or disconnection of diseased tissue is an important factor in achieving epilepsy control. 70% to 80% patients may be seizure free or significantly improved (>75% to 90% seizure reduction) after surgery, and early surgery may improve developmental outcome in refractory patients. The prognosis for intellectual outcome is better in patients who underwent surgery earlier (preferably before the age of 3 years) compared with those who were operated on later (48,60–64). In patients with bihemispheric disease and intractable generalized seizures, corpus callosotomy could be considered. However, very few patients with SWS have undergone this procedure (65).

LESS COMMON NEUROCUTANEOUS SYNDROMES

Epidermal Nevus Syndrome

Epidermal Nevus syndrome (ENS) is a sporadic neurocutaneous disorder without any known familial cases. Somatic mutation is postulated as the underlying genetic mechanism. The defining cutaneous feature of ENS is congenital epidermal nevi that are usually raised (palpable), and may be band-like, round, oval, or linear in configuration. Cutaneous lesions may be subtle to detect due to their skin-like color and velvety appearance in infancy; however, they may become verrucous orange or brown later in life. A wide variety of epidermal congenital lesions have been linked to ENS, such as linear sebaceous nevus (of Jadassohn), nevus verrucosus, ichthyosis hystrix, nevus unius lateris, and inflammatory linear verrucous epidermal nevus. The cutaneous lesions may differ somewhat in histology. Characteristically, the dermis is not involved, and there is thickening and hyperkeratosis of the epidermis with hyperplasia of the sebaceous glands. Some investigators prefer to group the cutaneous lesions together, whereas others maintain that these are separate entities on the basis of histologic differences (66). The potential for malignant transformation exists after puberty. Heterogeneity of cutaneous findings in ENS is not just limited to the skin. Brain involvement also tends to be variable ranging from focal cortical dysplasia to hemispheric dysplasia and hemimegalencephaly (67). In this chapter, we use the term epidermal nevus syndrome to encompass all these entities. Besides cutaneous manifestations, there is a wide spectrum of clinical presentation involving multiple organs and systems. Ocular, dental, and skeletal abnormalities, as well as

malignancies, have been reported. Ocular involvement reported in approximately 25% of cases includes microphthalmia, proptosis, choristomas (including dermoids and epidermoids), cataracts, and colobomas (68).

Brain Involvement, Epilepsy, and Its Treatment in ENS

Pathogenesis of brain involvement is postulated to be vascular dysplasia and migrational anomalies. Brain involvement is usually ipsilateral or asymmetric bilateral (worse ipsilateral) to the cutaneous findings. However, there is no consistent relationship between the side of the nevus and CNS abnormality. Various types of brain malformations and migration abnormalities are reported; however, classical involvement of the brain presents as hemimegalencephaly (including 17 out of 60 patients in Pavone's study) (67,69–71). In a series of 60 patients, Solomon and Esterly (66) reported moderate to severe CNS involvement in 30 (50%). Reported clinical, EEG, and imaging findings include mental retardation, seizures, hyperkinesis, hydrocephalus, porencephaly, cortical atrophy, nonfunctioning cerebral venous sinuses, hemimacrocephaly or macrocephaly, hemimegalencephaly, infantile spasms with hypsarrhythmia or hemihypsarrhythmia, and other seizure types such as myoclonic, complex partial, partial motor, and generalized seizures (67,69–72). In other words, ENS has a wide spectrum of findings; however, in general, the neurologic involvement is severe. Seizure onset is usually within the first year of life. Seizures are usually daily, are catastrophic, and fail to respond to medical treatment. Pediatric epilepsy surgery (Chapter 89) principles should again guide the testing, timing, and surgical strategy. Anatomic or functional hemispherectomy is the treatment of choice in patients with hemimegalencephaly (73). Important considerations before epilepsy surgery in ENS patients include careful examination and investigations to elicit the clinical severity of other organ/system involvement in the patient. Counseling of parents is critical as the long-term outlook for neurocognitive development is guarded in ENS. Histopathologic examination of the brain resected in epilepsy surgery cases has shown a spectrum of dysplastic abnormalities, including diffuse cortical dysplasia, gyral fusion, pial glioneuronal hamartomas, cortical astrocytosis, and foci of microcalcification.

Neurofibromatosis 1

In neurofibromatosis type 1 (NF1), seizures occur in 3% to 5% of individuals, a rate that is slightly higher than in the general population. Korf et al. (74) found that 21 (5.4%) of 359 children with neurofibromatosis had seizures. In a recent retrospective cross-sectional review of 536 individuals with NF1, 9.5% had a history of at least one unprovoked seizure, and 6.5% had documented epilepsy (75). Age of presentation varied from 4 days to over 20 years. Cognitive impairment is often present in those NF1 patients who have seizures. A variety of seizure types, including infantile spasms, absence, generalized convulsions, and complex partial seizures, have been reported (74,76,77). Seizures were due to tumors (hamartomas), cortical malformations, and mesial temporal sclerosis. Complex partial seizures or other types of focal seizures appear to be the most common type, and have been reported in the absence of obvious structural lesions. Reports of epilepsy surgery in NF1 are scant. In a recent published survey of epilepsy surgery in NF1, data from 25 European epilepsy surgery centers identified only 12 patients from 8 centers who underwent resections (78). MRI abnormalities were present in all patients but one, with unilateral temporal in eight, bilateral temporal in one, and multilobar or hemispheric in two. One year after surgery, eight patients were seizure free, one had worthwhile improvement, and the remaining three had experienced no benefit.

Histology revealed dysembryoplastic neuroepithelial tumors in five, hippocampal sclerosis in four, mixed pathology in one, polymicrogyria in one, and no histologic abnormality in the remaining patient (78).

These observations suggest that all individuals with NF1 and a new seizure should undergo MRI despite previous normal neuroimaging. In addition, epilepsy in NF1 patients typically requires more aggressive therapy than that in those without NF1, and selected NF1 patients are candidates for epilepsy surgery and surgery should be investigated as an option in a timely manner.

RARE NEUROCUTANEOUS CONDITIONS WITH EPILEPSY

Incontinentia Pigmenti

Incontinentia pigmenti, which occurs almost exclusively in females (X-linked dominant condition), presents in the neonatal period with erythematous bullous lesions that become crusted and pigmented. Children with this disorder may develop seizures (13.3%), mental retardation (12.3%), or spasticity (11.4%) (79). A variety of dysplastic brain MRI findings may be seen (79).

Hypomelanosis of Ito

Seizures and mental retardation are also seen in approximately two-thirds of children with hypomelanosis of Ito, in which irregular, hypopigmented skin lesions along the embryonal lines of dermatologic fusion are seen. Seizures are more severe in early-onset cases and consist of infantile spasms or myoclonic seizures. Choroidal atrophy, corneal opacities, deafness, dental anomalies, hemihypertrophy, hypotonia, and macrocephaly may also be seen (80,81). Reported CT and brain MRI findings include cerebral atrophy, porencephaly, and low-density areas in the white matter. Autopsy showed gray matter heterotopias and abnormal cortical lamination in a patient in one series indicative of abnormalities in neuronal migration (81).

Neurocutaneous Melanosis

This is a rare disorder in which patients have congenital cutaneous nevi and leptomeningeal melanosis leading to CNS manifestations (82–85). Patients have multiple congenital cutaneous nevi, the largest of which typically measure more than 5 cm. A 2.5% risk of developing neurocutaneous melanosis (NM) with CNS involvement is quoted in patients with large congenital melanocytic nevi (82). This disease may be lethal early in life, but some patients survive into their 20s. NM patients usually present with seizures or increased intracranial pressure. Cranial nerve palsy, hemiparesis, myelopathy, or psychiatric disorders may coexist. NM is believed to be a sporadic neurocutaneous disorder and is not transmitted as a single gene disorder. Most common brain MR findings in NM patients is T1 shortening (increased signal) in temporal lobe and infratentorial brain areas on noncontrast exams. There is variable ventriculomegaly. There may be thickening of leptomeninges of brain and spine as demonstrated on contrast enhancement. Leptomeninges may appear to be normal on T1- and T2-weighted sequences. Usually there is leptomeningeal enhancement. However, cases have been described without the leptomeningeal involvement. There may also be pachymeningeal (dural)

involvement (83–85).

CHAPTER 31 EPILEPSY IN THE SETTING OF INHERITED METABOLIC AND MITOCHONDRIAL DISORDERS

SUMIT PARIKH, DOUGLAS R. NORDLI, JR., AND DARRYL C. DE VIVO

INTRODUCTION

There are more than 11,000 well-recognized and well-characterized inherited disorders in humans, with many of them associated with seizures and epilepsy. The daunting task for the clinician is to recognize these important diagnoses in the patient with epilepsy so that optimal medical treatment, family counseling, and prognosis can be provided. The presentation is often not distinct enough to allow precise identification of the disorder on the basis of clinical criteria alone. Instead, the physician must observe a patient over a period of time and begin screening tests to detect abnormalities suggestive of the underlying disorder. These abnormalities point the way toward further diagnostic evaluations, which may culminate in the definitive diagnosis of the inherited disorder and actual detection of the defective gene. In other circumstances, important clues are present when a child is first seen, but these features can be easily overlooked if the clinical data are not synthesized and analyzed in an orderly way. Advances in genomics and genetic testing methodologies have transformed diagnosis as well. With the availability of next-generation sequencing gene panels and whole exome sequencing, patients are now at times diagnosed rapidly without the need for extensive metabolic testing.

In general, the scalp electroencephalogram (EEG) has low specificity but high sensitivity for diagnosing, determining severity, and monitoring brain dysfunction over a period of time in children of all ages. Although various EEG patterns are reported in the literature as being typical of an inborn error of metabolism, rarity of metabolic disorders, ascertainment bias, and limited repertoire of possible EEG findings in the face of enormous variability in spectrum and severity of metabolic disorders reduce the usefulness of EEG in suggesting a specific diagnosis. EEG may, however, supplement clinical assessment and other test results in shortening the list of possible diagnoses.

How can clinicians mentally organize this wealth of material? One method is to group diseases according to categories on the basis of the subcellular organelle involved: mitochondrial, lysosomal, peroxisomal, and so on. Another method is to group diseases according to metabolic or catabolic pathways, such as organic aciduria, aminoaciduria, and fatty acid oxidation. However, the clinical presentation within these groups may be diverse and dissimilar. Another method of grouping is to organize diseases according to their clinical presentation. This can be performed by age, but many different disorders are responsible for seizures and epilepsy within any defined age group. Diseases may also be organized on the basis of specific characteristics of the seizures and the epilepsy syndromes. As each metabolic and mitochondrial disorder may present along a biologic spectrum, with more severe involvement presenting earlier and in a more devastating fashion, various epilepsy

syndrome presentations can occur due to the same disorder. Early myoclonic epilepsy (EME), West syndrome, and progressive myoclonus epilepsy are three well-recognized epilepsy syndromes in which there is a high likelihood of an inborn error of metabolism. In other instances, metabolic and mitochondrial diseases can masquerade as forms of cryptogenic epilepsy.

In the organization of this chapter, we group the various disorders first by their age at onset (early infancy or later infancy and childhood onset) followed by the metabolic process or organelle affected. We also list, in tabular form (Table 31.1), the various cryptogenic or symptomatic epilepsy syndromes that might be mistaken for these disorders. In addition, we discuss clinical and EEG features of certain disorders that may provide clues to the underlying etiology. Additionally, we also review the appropriate screening tests that may be performed, where applicable, followed by more definitive diagnostic procedures. Genetic information is listed for each condition when known.

Table 31.1 Metabolic Diseases Masquerading as Epilepsy Syndromes

Neonatal seizures

- Organic acidurias
- Urea cycle defects
- Peroxisomal disorders: Zellweger syndrome
- Molybdenum cofactor deficiency/sulfite oxidase deficiency
- Pyridoxine-, pyridoxal phosphate–, or folinic acid–responsive epilepsy
- Mitochondrial disorders
- Disorders of biotin metabolism
- Glucose transporter defect (Glut-1 deficiency)
- Disorders of fructose metabolism

Early myoclonic encephalopathy/early infantile epileptic encephalopathy

- Glycine encephalopathy (nonketotic hyperglycinemia)
- Serine deficiency (3-phosphoglycerate dehydrogenase deficiency)
- Creatine synthesis or transport disorders
- Organic acidurias, especially propionic academia
- Mitochondrial disorders, especially those leading to Leigh syndrome
- D-glycine acidemia

Cryptogenic epilepsies with progressive neurologic decline

- GM1 and GM2 gangliosidoses
- Neuronal ceroid lipofuscinosis
- Infantile neuroaxonal dystrophy
- Glut-1 deficiency
- Late-onset multiple carboxylase deficiency
- Disorders of cerebral and peripheral folate metabolism
- Disorders of neurotransmitter synthesis
- Arginase deficiency (urea cycle defect)
- Amino and organic acidurias (variant phenotypes)
- Sialidoses

West syndrome, generalized

- Pyruvate dehydrogenase deficiency
- Pyruvate carboxylase deficiency
- Congenital disorder of glycosylation type III
- Organic and amino acidurias

Progressive myoclonus epilepsies

- Lafora disease (EPM2A/B gene mutations)
- Unverricht–Lundborg disease (EPM1 gene mutations)
- Mitochondrial diseases including MERRF/MELAS, and POLG1 gene mutations
- Dentatorubral–pallidoluysian atrophy
- Neuronal ceroid lipofuscinosis
- GM1 and GM2 gangliosidoses
- Sialidoses

MERRF, myoclonic epilepsy with ragged-red fibers; MELAS, mitochondrial encephalomyopathy with lactic acidosis and stroke-like episodes.

For an up-to-date review of an individual metabolic disease or to find a lab where an analyte or gene test can be sent, we recommend visiting the NIH GeneReviews site at http://www.genetests.org.

METABOLIC DISORDERS IN THE NEWBORN AND YOUNG INFANT

Disorders of Neurotransmitter Synthesis and Removal

Tetrahydrobiopterin and Guanine Triphosphate Cyclohydrolase Deficiency

Tetrahydrobiopterin (BH4) is a cofactor for the enzymes involved in converting tyrosine and tryptophan to levodopa and serotonin. Deficiencies in BH4 lead to disruptions in the neurotransmitter amines, levodopa, and serotonin. It is one of several disorders of neurotransmitter production. Defects most commonly occur due to abnormalities of guanine triphosphate cyclohydrolase (GTPCH), the first enzyme involved in the multistep process of converting guanine triphosphate to BH4. However, defects in other enzymes in the pathway have also been identified.

GCH1 is the gene involved in GTPCH enzyme formation. Autosomal dominant mutations lead to early onset dopa-responsive dystonia (Segawa disease), and autosomal recessive mutations lead to a neonatal onset encephalopathy. Genetic testing for GCH1 mutations and several other enzyme deficiencies in the BH4 synthesis pathway is available as are gene panels to screen for mutations in many of the genes involved in neurotransmitter synthesis.

Symptoms typically involve variable and fluctuating levels of psychomotor retardation, convulsions, microcephaly, swallowing difficulties, truncal hypotonia, limb hypertonia, involuntary movements, and oculogyric crises. Some of these symptoms begin shortly after infancy. A diurnal pattern of worsening of symptoms may be described. Of clinical note, other enzyme abnormalities both before and after BH4 production (including α-amino decarboxylase [AADC] deficiency involved in converting levodopa to active dopamine) can lead to identical symptoms (1).

Diagnosis of many of the neurotransmitter disorders is typically made by measuring levels of spinal fluid neurotransmitter metabolites (5-hydroxyindoleacetic acid and homovanillic acid) and precursors (biopterin, neopterin, and 3-methyl-dopa). Elevations in plasma and cerebrospinal fluid (CSF) phenylalanine may be seen in the amino acid profile of some patients, but this finding is frequently not present (1). Urine pterin concentrations can aid in differentiation between the various defects of biopterin synthesis, though this testing is not readily available in North America at this time.

Treatment includes tetrahydrobiopterin supplementation, pharmacotherapy with levodopa–carbidopa, and 5-hydroxytryptophan. Pyridoxine is an important cofactor, and supplementation may benefit patients. In AADC deficiency a dopamine agonist and monoamine oxidase inhibitor are used. Treatment is beneficial to varying degrees (2).

Glycine Encephalopathy (Formerly Nonketotic Hyperglycinemia)

In this autosomal recessive inborn error of amino acid metabolism, large amounts of glycine accumulate in the body, especially the brain, because of a defect in the multienzyme complex for glycine cleavage. The enzyme system is confined to the mitochondria and is composed of four protein

components (designated P, H, T, and L), three of which have a gene identified. GLDC, localized to 9p22, is the most common gene affected, with mutations leading to abnormal functioning of the P protein (3).

The pathophysiology of nonketotic hyperglycinemia (NKH) has not been fully elucidated, but the elevated glycine is believed to impact the central nervous system (CNS) via its role as an inhibitory transmitter in the brainstem and spinal cord, and an excitatory transmitter in the cortex. The majority of cases present within the first 48 hours of life with lethargy, respiratory difficulties, apnea, and seizures that are often myoclonic or characterized as infantile spasms. Cortical malformations or corpus callosum defects may be present. A burst-suppression EEG pattern with variable intervals between the bursts alternating with epochs of greater continuity is characteristic. The combination of early-onset seizures with prominent myoclonus and variable burst-suppression EEG is also called EME, as described by Aicardi. Glycine encephalopathy is an important cause of EME evolving to hypsarrhythmia, although this is more commonly observed in Ohtahara syndrome. Ohtahara syndrome is thought by some authorities to be more commonly associated with structural abnormalities and not as highly associated with errors of metabolism (1).

Later-onset forms of this disease have also been described, with patients having varying degrees of epilepsy, retardation, and movement abnormalities. An adolescent/adult-onset form presents with associated spastic paraparesis and optic atrophy (4).

Laboratory testing reveals elevations of glycine in the plasma, urine, and CSF amino acid profile. The absence of excess ketones in the blood and urine, and of abnormal organic acids in the urine, helps to differentiate NKH from other conditions associated with hyperglycinemia, such as propionic and methylmalonic acidemias. The ratio of CSF to serum glycine is also helpful, as it is significantly elevated in patients with NKH. Genetic sequencing for the three known loci is clinically available (5).

There is no effective long-term treatment for this disorder. High doses of benzoate may reduce CSF glycine and improve seizure control, but it does not appear to stop the development of mental retardation (6,7). Because benzoate treatment may deplete carnitine levels, carnitine supplementation is recommended when benzoate is used (8). Dextromethorphan, an NMDA antagonist, has been tried for this condition as well. Valproic acid should be avoided because it induces hyperglycinemia. Strychnine, a glycine antagonist, and diazepam have been reported to blunt seizures, but have not influenced the long-term outcome (9). Prognosis is poor, with progressive microcephaly and intractable epilepsy. Even when treated, death often occurs within the first few months to years of life (10).

A transient form of NKH exists with similar early clinical and biochemical findings. In this condition, glycine concentrations normalize between 2 and 8 weeks of life, and prognosis is favorable (11).

Serine and 3-Phosphoglycerate Dehydrogenase Deficiency

3-Phosphoglycerate dehydrogenase (PHGDH) deficiency is an autosomal recessive condition that results in impaired L-serine biosynthesis due to a mutation in the PHGDH gene (1p12). Serine is the precursor of D-serine and glycine, both potent neurotransmitters. Serine also has a role in myelin production (12).

Typically there is a pre- or perinatal onset of symptoms including congenital microcephaly, intractable seizures, spastic quadriparesis, and profound cognitive delays. The magnetic resonance

imaging (MRI) may show white matter lesions. The condition is often misdiagnosed as cerebral palsy. Reduced serine levels are found in CSF amino acid specimens though glycine levels are not always low. Plasma serine and glycine levels may only be low in fasting specimens but are not reliable indicators as they may also be normal (13).

Enzyme activity can be measured in skin fibroblasts. Genetic testing is clinically available. Treatment involves supportive care and L-serine supplementation (14).

Succinic Semialdehyde Dehydrogenase Deficiency

Succinic semialdehyde dehydrogenase (SSADH) deficiency is an autosomal recessive disorder impairing γ-aminobutyric acid (GABA) catabolism. The enzyme is involved in the second and final step of GABA degradation. GABA, an inhibitory neurotransmitter, accumulates (15). The ALDH5A1 (6p22) gene encodes this enzyme, and mutations here account for over 97% of cases (16).

The disorder is slowly progressive with infancy to childhood onset. Seizures occur in more than 50% of patients. Other symptoms include varying degrees of ataxia, hypotonia, speech delay, and mental retardation. A movement disorder with hyperkinetic movements, choreoathetosis, dystonia, and myoclonus can be seen with earlier onset, and presenting as a more severe form of this disease. Aggressive behaviors and self-injury may also occur (17).

Diagnosis is initially made by finding elevations of 4-hydroxybutyric (4HB) acid in urine organic acids, plasma, or CSF. Of clinical note, the 4HB peak can be easily missed on routine organic acid analysis due to its coeluting with a large urea peak. Thus, one must ensure that the lab processing the specimen is monitoring for this ion. Variable elevations of glycine can be seen in the amino acid profile. Confirmatory gene sequencing is clinically available. The EEG may show generalized background slowing and spike discharges (18).

Treatment of this disorder is symptom based. Vigabatrin, an irreversible inhibitor of GABA transaminase, has been used in some individuals with positive responses (including increased socialization, behavioral improvement, increased alertness, and reduced ataxia), but treatment with this agent has worsened symptoms in others. Valproate use is contraindicated as it may inhibit residual SSADH enzyme activity (19–21).

Vitamin and Mineral Metabolism–Related Diseases

Pyridoxine- (and Folinic Acid–) Responsive Epilepsy

In pyridoxine-responsive epilepsy, refractory seizures typically develop within the first several days of life. These may be characterized by infantile spasms or have a variety of partial, myoclonic, and atonic features. Atypical presentations include a later onset of seizures, seizures that initially respond to treatment and then become intractable, and seizures with only a partial initial response to pyridoxine.

The disorder occurs due to a mutation in the ALDH7A1 gene (5q31). The ALDH7A1 gene encodes for the protein antiquitin, which is involved in lysine catabolism. While it is not directly involved in pyridoxine metabolism, disruptions of antiquitin function secondarily deplete pyridoxine (22). Pyridoxine plays several critical roles in the brain, including the conversion of levodopa to dopamine and glutamate inactivation via glutamic acid decarboxylase.

Diagnosis has typically been made clinically, with seizures abating after a high dose of

intravenous (IV) pyridoxine (100 to 500 mg). The initial EEG is characterized by generalized bursts of high-voltage delta activity interspersed with spike and sharp waves and periods of asynchronous attenuation. After treatment there is conversion of the EEG to a burst-suppression pattern, and later normalization with subsequent doses. This change occurs within minutes and may persist for hours, or even a day (23). Confirmatory testing is via spinal fluid analysis, as described below. Testing for ALDH7A1 mutations is clinically available.

A clinical and genetic link has been made between folinic acid–responsive epilepsy, pyridoxine-responsive epilepsy, and ALDH7A1 mutations, thus leading one to conclude that folinic acid– and pyridoxine-responsive seizures are one and the same. Previously it was believed that folinic acid–responsive epilepsy was a rare yet separate metabolic epileptic encephalopathy with a diagnosis made by identifying a characteristic peak of a yet unknown compound in spinal fluid neurotransmitter analysis (24).

More recently, a patient with folinic acid–responsive epilepsy was found to respond to pyridoxine supplementation (25). Eventually, individuals with folinic acid–responsive epilepsy were identified as having ALDH7A1 mutations and patients identified as having pyridoxine-dependent epilepsy (mutation confirmed cases) were found to have the characteristic folinic acid–responsive epilepsy peak identified in their CSF (26).

In evaluating these patients, plasma, urine, and spinal fluid levels of pipecolic acid may also be elevated though this chemical is not a sensitive biomarker (27). A link also exists to elevated urinary and CSF concentration of α-aminoadipic semialdehyde (α-AASA), and clinical testing for this compound is available. The characteristic peak of this yet unidentified compound is found when spinal fluid neurotransmitter testing is run. Spinal fluid folate levels are normal in this condition. As the link between folinic acid– and pyridoxine-responsive epilepsy is secure, routine CSF analysis for diagnosis is crucial. Early treatment is also critical, as it improves developmental outcome. Maintenance therapy with pyridoxine and folinic acid is necessary. Onset of disease may extend beyond the newborn period, making this disorder a consideration in older infants with refractory seizures as well (28,29). Due to pyridoxine and folic acid's relatively decreased ability to cross the blood–brain barrier, treatment with pyridoxal 5-phosphate and folinic acid is recommended.

Pyridoxal-L-Phosphate-Responsive Epilepsy

Some neonates and children with an epileptic encephalopathy seemed to respond to pyridoxal-L-phosphate (PLP) supplementation as opposed to pyridoxine. Further research showed that some of these individuals had a defect in an enzyme pyridoxal/PLP—pyridox(am)ine 5′-phosphate oxidase (PNPO) required for the synthesis of intracellular PLP from dietary pyridoxine. Eventually, the PNPO gene (17q21.2) was identified and these mutations were confirmed as the cause of this relatively rare condition. The clinical presentation in these children is similar to those with pyridoxine-dependent epilepsy and disorders of neurotransmitter metabolism as described above. Treatment, however, requires PLP as opposed to pyridoxine (30). Diagnosis is aided by measuring pyridoxal 5-phosphate levels in spinal fluid.

Molybdenum Cofactor Deficiency and Sulfite Oxidase Deficiency

The rare conditions of molybdenum cofactor deficiency (MOCOD) and sulfite oxidase deficiency present shortly after birth, also with a progressive encephalopathy, feeding difficulties, hypotonia, and refractory partial, myoclonic, or apparently generalized seizures. Dysmorphic features, lens

dislocation, and hepatomegaly are all characteristic findings (31). The two conditions have an essentially identical clinical phenotype, likely due to both conditions leading to the loss of sulfite oxidase function. As typical of all of these diseases, later-onset and relatively milder and varying phenotypes have been described in the literature.

Molybdenum cofactor is critically needed for the proper function of three enzymes: sulfite oxidase, xanthine dehydrogenase, and aldehyde oxidase. Sulfite oxidase converts sulfite to sulfate. Xanthine dehydrogenase converts xanthine to hypoxanthine to eventually form uric acid. Aldehyde dehydrogenase is involved in the reverse reaction of hypoxanthine to xanthine (32).

MOCOD is due to mutations in one of two genes, MOCS1, at 6p21.3 or MOCS2, at 5q11 (33). Sulfite oxidase deficiency is typically due to mutations in the SUOX gene on chromosome 12 (34).

Patients typically present with a metabolic crisis, developing irritability, opisthotonic posturing, and seizures. The EEG in these patients may show multifocal paroxysms and a burst-suppression pattern. Neuroimaging may show poor differentiation between the gray and white matter, severe cerebral and cerebellar atrophy, and multiple cystic cavities in the white matter. Diagnosis is made by a variety of methods. Since MOCOD and isolated sulfite oxidase deficiency both result in high levels of urinary sulfites, a sulfite dipstick on a fresh urine sample may detect abnormalities, though this test has a high false-negative rate (35,36). Plasma uric acid levels may be low in MOCOD, but not in sulfite oxidase deficiency. Both disorders will lead to an accumulation of urine S-sulfocysteine. The two disorders can be distinguished on laboratory testing as elevations of urine purines and pyrimidines (xanthine and hypoxanthine) occur in MOCOD but not in sulfite oxidase deficiency. The enzyme deficiencies can be demonstrated in cultured fibroblasts and liver tissue. Genetic testing is clinically available. No effective treatment has yet been identified and prognosis is poor, with death occurring within the first days to weeks of life (37). Clinical trials with cyclic pyranopterin monophosphate, an intermediary precursor of molybdenum cofactor, are planned after they showed potential benefit in slowing disease progression in several patients with MOCOD (38).

Cerebral Folate Deficiency

Folate is concentrated in the nervous system, and the CSF concentrations of folate are higher than the serum concentrations. Deficiencies in cerebral folate lead to a slowly progressive encephalopathy, with intractable seizures. If it occurs in conjunction with systemic folate deficiency, megaloblastic anemia, mouth ulceration, diarrhea, and failure to thrive may also be seen. Neuroimaging may reveal calcifications in the occipital lobes and basal ganglia (39).

Reductions in cerebral folate can occur primarily due to a mutation in the gene encoding the folate transporter (FOLR1) or secondarily due to systemic disease, gut malabsorption syndromes such as colitis, primary mitochondrial disorders (40), many other metabolic diseases (see section Methylenetetrahydrofolate Reductase Deficiency), and certain genetic syndromes (Rett syndrome) (41). Most patients with cerebral folate deficiency do not have a defect in the FOLR1 gene (42). This condition is different from folinic acid–responsive epilepsy described above.

There is also an association of lactose autoantibodies cross reacting with and blocking the folate receptor, potentially leading to a secondary cerebral folate deficiency (43). A lactose-free diet has been considered as a treatment in these situations (44). However, testing for folate autoantibodies is not clinically available and this association needs further study.

The disorder is typically diagnosed by finding low levels of methyltetrahydrofolate (MTHF) in CSF. Normal amino and organic acids analysis and normal plasma folate levels help exclude other

potentially treatable causes. If another syndromic, metabolic, or systemic cause of low cerebral folate is not identified, specialized testing for folate autoantibodies is available on a research basis (43).

Treatment involves supplementation with IV and oral folate. Folinic acid may be used since it has better blood–brain barrier penetration than does folic acid. If lactose-mediated autoantibodies are identified, a lactose-free diet might be considered (44). Outcome is still poor.

Methylenetetrahydrofolate Reductase Deficiency

Methylenetetrahydrofolate reductase deficiency (1p36.3) is the most common inborn error of folate metabolism (45). The metabolic defect results from insufficient production of 5-MTHF, which is needed for the remethylation of homocysteine to methionine, because of a deficiency in methylenetetrahydrofolate reductase. In affected individuals, a progressive neurologic syndrome develops in infancy. Children with this disorder have acquired microcephaly and seizures characterized by intractable infantile spasms, generalized atonic and myoclonic seizures, and focal motor seizures. EEG findings vary from diffuse slowing of background activity to continuous spike–wave complexes or multifocal spikes. The early-onset form differs from the late-onset form. The latter presents with progressive motor deterioration, schizophrenia-like psychiatric symptoms, and recurrent strokes; seizures are uncommon. Homocystinuria and elevated serum concentrations of homocysteine with reduced or normal serum methionine are the main biochemical features. These findings can be caused by several other amino acid disorders as well. Dietary supplementation with folic acid, betaine, and methionine has proven beneficial. In the acute setting, high-dose methionine has been effective in stopping seizures (46).

Defects in methionine biosynthesis are also associated with seizures. Convulsions are frequent and are predominantly generalized, although myoclonic seizures with hypsarrhythmia have been reported. Diagnostic laboratory findings are megaloblastic anemia, homocystinuria, decreased methionine, and normal folate and cobalamin concentrations in the absence of methylmalonic aciduria (46). These conditions are typically diagnosed via extended newborn screening (NBS) in North America and treated presymptomatically. Thus patients presenting with new-onset epilepsy who have obtained extended NBS are less likely to have this condition.

Inborn Errors of Creatine Metabolism

Creatine represents a storage depot of adenosine triphosphate (ATP) for various tissues including the brain. Depletion of cerebral creatine due to inborn errors in synthesis or transport leads to a progressive encephalopathy and epilepsy. Creatine forms via a two-step enzymatic path, with arginine converted to guanidinoacetate via arginine:glycine amidinotransferase (AGAT) and then to creatine via guanidinoacetate N-methyltransferase (GAMT). Deficiencies in both enzymes have been identified, and the genetic loci for AGAT and GAMT are known. Creatine, once formed, is transported into the cell via a specific transporter, and abnormalities in creatine transport can also occur due to defects in the SLC6A8 gene at Xq28 (47).

Development can be delayed from the beginning or after a regression beginning between 3 months and 2 years of age. Seizures may present in the first months of life with generalized tonic–clonic, astatic, absence, myoclonic, or partial events. Multifocal epileptiform discharges have been reported on the EEGs of affected individuals (48). Other clinical features may include dystonia, dyskinesias, microcephaly, and autistic behaviors (49). A mild form presenting with severe speech delay, mild autism, and infrequent seizures has also been identified (50).

Diagnosis is typically via quantifying urine, plasma, and/or spinal fluid guanidinoacetate and creatine. Low creatinine is not a reliable marker of the condition. Brain magnetic resonance spectroscopy (MRS) shows a reduced creatine peak (51).

Supplementation with creatine monohydrate (350 mg/kg/day to 2 g/kg/day) has led to improvement in affected individuals though not in patients with creatine transporter disorders (47).

Early-Onset Multiple Carboxylase Deficiency (Holocarboxylase Synthetase Deficiency)

Early-onset multiple carboxylase deficiency presents in the first week of life with lethargy, respiratory abnormalities, irritability, poor feeding, and emesis. A skin rash is present in more than 50% of patients. Generalized tonic convulsions, partial motor seizures, and multifocal myoclonic jerks develop in 25% to 50% of cases. This disease is tested for in the neonate in certain states via expanded NBS and can often be treated prior to symptom onset.

A deficiency in the enzyme holocarboxylase synthetase (HLCS) leads to a decrease in holocarboxylase. As this enzyme links biotin to four carboxylases in the mitochondria and one in the cytosol, an inactivity of all carboxylases results. The HLCS gene locus is 21q22.1. Although rare, this condition is very important to recognize because prompt treatment with biotin may result in dramatic improvement. Laboratory findings demonstrate ketoacidosis and a characteristic pattern on organic acid analysis. Hyperammonemia may be seen with acute episodes. Electrographically, a burst-suppression pattern or multifocal spikes are observed. Definitive diagnosis can be made by enzyme assays, and gene sequencing. Treatment with biotin (10 mg/day) produces clinical improvement (52).

Late-Onset Multiple Carboxylase Deficiency (Biotinidase Deficiency)

This disease is also screened for in certain states via expanded NBS. The disorder involves the body's ability to recycle biotin via biotinidase. The BTD gene has been identified at the 3p25 locus (53).

When not diagnosed early, seizures are a prominent feature occurring in 50% to 75% of affected children. In fact, seizures are the presenting feature in 38% of patients and may be generalized tonic–clonic, partial, myoclonic, or infantile spasms. Symptoms often begin at 3 to 6 months of age, with hypotonia and developmental delay. Seborrheic or atopic dermatitis and alopecia are common. As the disease progresses, ataxia, optic atrophy, and sensorineural hearing loss develop. Later-onset and/or milder phenotypes exist due to partial enzyme deficiency. EEG findings may include a suppression-burst pattern, absence of physiologic sleep patterns, poorly organized and slow waking background activity, and frequent spike and spike-slow-wave discharges (54).

Diagnosis is typically made via abnormalities in urine organic acid and plasma acylcarnitine analysis. Biotinidase enzyme activity can be measured in leukocytes and cultured fibroblasts. Genetic sequencing is clinically available. When this condition is considered as a differential diagnosis, a therapeutic trial with high-dose oral biotin should be started while awaiting test results.

Menkes Disease (Kinky-Hair Disease)

An X-linked disorder of copper absorption, Menkes disease was first described by Menkes et al. in 1962. Defects in the copper transporting ATPase gene (ATP7A, Xq12–q13) impairs intestinal copper absorption, reduces copper export from tissues, and decreases the activity of copper-dependent

enzymes, including dopamine β-hydroxylase (55).

A characteristic twisting of the hair shaft, resulting in "kinky hair" of the head and eyebrows, is noted on microscopic examination of the poorly pigmented hairs. Affected boys may be premature and may have neonatal hyperbilirubinemia or hypothermia. Progressive neurologic deterioration with spasticity is present by 3 months of age, and children may have associated bone and urinary tract abnormalities as well. The disease has a rapidly fatal course (1).

Seizures are a prominent feature in Menkes disease, with intractable generalized or focal convulsions. Infantile spasms have also been reported (56). Stimulation-induced myoclonic jerks may be present. Multifocal spike and slow-wave activity can be seen on the EEG, sometimes resembling hypsarrhythmia (57).

Laboratory testing reveals extremely low serum copper and ceruloplasmin levels. Elevations in CSF lactate may be seen, and there is low total copper content in the brain. Neuroimaging may show brain atrophy, focal areas of necrosis, and subdural collections. Brain magnetic resonance angiography (MRA) shows dilated and tortuous intracranial blood vessels. Genetic testing of the ATP7A gene via sequencing and deletion analysis identifies almost all patients with Menkes (55).

There is no fully effective treatment. Daily copper injections may be beneficial if administered early in the course of the disease.

Overlap exists between Menkes disease and occipital horn syndrome (58). It is now known that both Menkes and occipital horn syndrome conditions are allelic due to mutations in the same gene (58).

Disorders of Carbohydrate Metabolism

Glut-1 Transporter Deficiency Syndrome

The Glut-1 transporter deficiency syndrome was first described in 1991 (59). This autosomal dominant condition results from a loss of functional glucose transporters, encoded by the SLC2A1 gene, that mediate glucose transport across the blood–brain barrier (60). Clinical features include developmental delay, ataxia, hypotonia, infantile seizures, and acquired microcephaly. There is a reduction in the CSF-to-blood glucose ratio to half of normal (typically, CSF glucose is <40 mg/dL). In addition, a low lactate concentration might be seen. Additional confirmation of impaired glucose transport can be performed through assays in erythrocytes (61), and clinical genetic testing is available.

Seizures, specifically neonatal ones, are often the first identified feature of this syndrome though patients with later onset and mild epilepsy have been described. Typical seizure types include absence, myoclonic, astatic, generalized tonic–clonic, and partial–complex. About 10% of patients have no clinical seizures. A normal EEG is commonly seen between seizures, although generalized 2.5- to 4-Hz spike–wave discharges are observed in more than one-third of children older than 2 years of age (62).

Affected individuals without early-onset refractory epilepsy have been identified, and a screening for lumbar puncture should be considered in those individuals as well (63). Early initiation of the ketogenic diet is effective in the treatment of seizures as well as overall disease progression, as it provides an alternative cerebral energy source (64).

More recently, patients with Glut-1 diseases presenting with early-onset atypical absence epilepsy and, less frequently, idiopathic generalized epilepsy have been identified (65,66). Some

patients may present with isolated movement disorders. Paroxysmal exertional dyskinesia (PED) is now recognized as an allelic variant of Glut-1 deficiency (67,68). Some patients with PED also have epilepsy. In patients without the classic presentation, hypoglycorrhachia may be milder. Genetic testing is often needed for diagnosis (69).

Other Disorders

Fructose 1,6-bisphosphatase deficiency, a rare, potentially life-threatening disorder of gluconeogenesis, presents within the first few days of life with respiratory abnormalities, hypotonia, lethargy, hepatomegaly, irritability, and convulsions. Laboratory findings reveal lactic acidosis, ketosis, hypoglycemia, elevated plasma concentrations of alanine, and the presence of abnormal urinary organic acids with glycerol and glycerol-3-phosphate (70). The FBP1 gene is located at 9q22.2–q22.3 (71). Neurologic sequelae can be prevented by avoidance of hypoglycemia.

Hereditary fructose intolerance (fructose 1,6-biphosphate aldolase deficiency) may be seen in the neonatal period in infants who are formula fed and given fructose or sucrose early in life. Symptoms include profound hypoglycemia, emesis, and convulsions. If the disease is readily diagnosed, fructose and sucrose can be eliminated from the diet before significant cerebral injury occurs (70).

Mitochondrial Disorders

Disorders of energy metabolism typically present with later-onset epilepsy outside of the immediate newborn period. However there are exceptions to the rule, especially when discussing the ever-growing array of mitochondrial phenotypes.

Mitochondria are the cell's energy factories, though they also have a key role in initiating apoptosis, and reactive oxygen species formation and removal. When not functioning properly, organs most dependent on cellular energy show symptoms—especially the brain. While multi-organ involvement and lactic acidosis were initially described as sine qua nons of the disease, these findings are not reliably present and the vast majority of patients do not present with the classically described syndromes. These phenotypes, such as MELAS, myoclonic epilepsy with ragged-red fibers (MERRF) and at least 10 others, created order to a set of novel and often unrelated symptoms prior to our current knowledge of the disease. We now know that almost any unexplained neurologic symptom can be due to mitochondrial dysfunction, especially refractory epilepsy. The epilepsy may occur in isolation, or with other neurologic problems including optic nerve disease, retinal pigmentary changes, hearing loss, developmental delays, neuropathy, and myopathy. Myoclonic epilepsy has been associated with mitochondrial disease, but patients with almost any seizure type, including generalized epilepsy, are seen (72).

These conditions typically occur due to genetic abnormalities leading to aberrant mitochondrial function. Over 1500 nuclear DNA (nDNA) genes are involved in mitochondrial formation and function, along with maternally inherited mitochondrial DNA (mtDNA) providing an additional 37 genes. Thus, most cases of mitochondrial disease are autosomal recessive in inheritance, and <20% have a maternal mtDNA-based inheritance pattern. Diagnostic testing initially involves looking for a combination of biochemical abnormalities in plasma amino acids, acylcarnitines, lactate, pyruvate, and urine organic acids (73).

While biochemical and pathologic studies of mitochondria in muscle and other tissue are at times needed to provide a diagnosis, advances in genomic medicine has led to the availability of a wide array of next-generation sequencing testing for mitochondrial disease. For some patients, diagnosis is

routinely made using DNA testing, circumventing the need for invasive studies.

Treatment varies and includes preventing worsening during metabolic or physiologic stresses, avoiding mitochondrial toxins and poisons, use of select cofactors and supplements, and providing symptomatic care (74).

Pyruvate Dehydrogenase Deficiency

The mitochondrial pyruvate dehydrogenase (PDH) complex is composed of three enzymes: pyruvate decarboxylase (E1), dihydrolipoyl transacetylase (E2), and dihydrolipoyl dehydrogenase (E3). The E1 enzyme is itself a complex structure, a heterotetramer of two α and two β-subunits. The E1 α-subunit is particularly important, as it contains the E1 active site. Mutations in the PDHA1 gene (Xp22.2–p22.1) encoding for this region are the most common cause of PDH deficiency (75).

PDH deficiency has a wide variety of clinical presentations, ranging from acute lactic acidosis in infancy with severe neurologic impairment in affected males to a slowly progressive neurodegenerative disorder in some males and more commonly females. Structural abnormalities, such as agenesis of the corpus callosum, are often present on neuroimaging (76). Epilepsy frequently occurs and includes infantile spasms and myoclonic seizures. EEG findings include multifocal slow spike–wave discharges (77). The ketogenic diet may benefit these patients.

Pyruvate Carboxylase Deficiency

Pyruvate carboxylase is a biotin-responsive enzyme that converts pyruvate to oxaloacetate in the citric acid cycle. Two predominant clinical presentations occur with pyruvate carboxylase deficiency. The neonatal type (type B) manifests with severe lactic acidemia and death in the first few months of life. The infantile and juvenile type (type A) begins in the first 6 months of life with episodes of lactic acidemia precipitated by an infection. Developmental delay, failure to thrive, hypotonia, and seizures, including infantile spasms with hypsarrhythmia, may be seen (78). A benign form (type C) also has been described with recurrent metabolic acidosis and normal neurologic development (79).

Seizures are related to the energy dysfunction that occurs secondary to Krebs cycle dysfunction. Treatment with the ketogenic diet or corticotropins may markedly exacerbate the disorder and should be avoided (80,81).

Leigh Syndrome

Leigh syndrome (subacute necrotizing encephalomyopathy) is both a clinical and radiologic phenotype and may be related to various metabolic defects, including syndromic and nonsyndromic mitochondrial disease, and PDH deficiency. Biochemical defects in both nuclear and mitochondrially encoded genes have been identified with this condition. It is genetically heterogeneous, and depending on the etiology, may be autosomal recessive or dominant, X-linked, or maternally inherited (82).

The clinical presentation is often acute to subacute, involving regression, cranial nerve and bulbar dysfunction, progressive hypotonia, lactic acidosis, and failure to thrive. The disease progresses with spasticity and central respiratory failure. Neuroimaging shows bilateral, fairly symmetric, basal ganglia, thalamic, and midbrain lesions that can fluctuate in severity. Varying degrees of white matter lesions may also be present along with cortical and cerebellar atrophy (83).

A variety of different seizures, including focal and generalized seizures, have been described (84). Infantile spasms and hypsarrhythmia may occur (85,86). In addition, there have been cases of epilepsia partialis continua (EPC) (87). EEG features do not appear to be distinctive enough to contribute to the clinical diagnosis of Leigh syndrome (88).

Disorders of Amino and Organic Acids Metabolism

Amino and organic acids predominantly form from the catabolism of proteins and carbohydrates. Any enzymatic defect in these metabolic pathways leads to an accumulation of potentially acidic compounds, and partial inhibition of the citric acid and urea cycles. Acidosis and hyperammonemia ensue leading to encephalopathy and, at times, seizures. These disorders, when most severe (a severe enzyme deficiency), typically present in the newborn period, especially after an infant is exposed to a protein or carbohydrate challenge in the diet. For some, this means after feeding in the first week of life, while for others it is after the introduction of solid foods. Regardless of the type of amino or organic acid disorder, the acute presentation is often the same. Milder enzyme deficiencies may present with a later sudden-onset epileptic encephalopathy (later infancy, childhood, or in the adult years) in the midst of a physiologic stressor (illness, surgery, fasting) that leads to accelerated catabolism. Thus, many of these metabolic disorders should be considered in a patient with an acute to subacute epileptic encephalopathy of later onset as well when an etiology for the problem remains unknown. With the advent and increased utilization of expanded NBS in states across this country, and internationally, many “classic” inborn errors of metabolism are now diagnosed and treated before they lead to neurologic symptoms. Conditions such as phenylketonuria (PKU), propionic or methylmalonic acidemia, and other relatively well-known amino or organic acid and fat metabolism disorders have become chronic conditions with improved neurologic outcomes due to early diagnosis and preventative care. However, there is no “standardized” NBS protocol, and the diseases screened for may vary from state to state and country to country. Thus, while many inborn errors of metabolism may now be excluded by the extended newborn screen, familiarity with the diseases screened for in one’s area is useful. As genetic knowledge of these conditions has evolved, we have moved from making an analyte-based diagnosis from blood and urine testing to confirmatory molecular genetic diagnostic studies. The treatment for all of these diseases is often very similar in the acute encephalopathy period—correct any metabolic derangements (acidosis/hyperammonemia), stop the introduction of the toxic substance by making the patient NPO, stop catabolism with dextrose-containing fluids, and prescribe any metabolic scavengers if needed. Below we discuss a few of the disorders where seizures are a prominent feature.

Phenylketonuria

One of the most frequent autosomal inborn errors of metabolism, occurring in 1 in 10,000 to 15,000 live births, PKU is caused by a deficiency in hepatic phenylalanine hydroxylase (89). As a consequence of the metabolic defect, toxic levels of the essential amino acid phenylalanine accumulate.

Currently, diagnosis is typically made with NBS, and in fact, this was the condition that led to the advent of NBS by Dr. Robert Guthrie in the 1960s. NBS is able to diagnose 100% of these patients. If the patient has not received NBS, routine amino acid analysis in plasma will identify elevated phenylalanine (90).

PKU occurs due to mutations in the PAH gene (12q23.2). Mutations in this gene account for more

than 99% of cases (91).

If untreated, severe mental retardation, behavioral disturbances, psychosis, and acquired microcephaly can result. Seizures are present in 25% of affected children. The majority of children with PKU (80% to 95%) are also found to have abnormalities on the EEG. An age-related distribution of EEG findings and seizure types has been observed since a 1957 report by Low et al. (92). Infantile spasms and hypsarrhythmia predominate in the young infant. As children mature, tonic–clonic and myoclonic seizures become more frequent, and the EEG evolves to mild diffuse background slowing, focal sharp waves, and irregular generalized spike and slow waves (93,94). Donker et al. (95) showed proportionate increases in delta activity as levels rose during phenylalanine loading.

Primary treatment is a phenylalanine-free diet. With early detection and institution of this diet, the neurologic sequelae of hyperphenylalaninemia can be prevented or significantly minimized (96).

Maple Syrup Urine Disease

Maple syrup urine disease (MSUD) is an autosomal recessive condition due to a defect in the branched-chain α-keto acid dehydrogenase complex (BCKAD), and was first reported by Menkes et al. in 1954 (97).

The enzyme defect leads to accumulation of the branched-chain amino acids—valine, leucine, isoleucine—and their keto acids in body tissues and fluids. This disease is now tested for in most extended NBS panels and diagnosed prior to the onset of symptoms.

The BCKAD enzyme complex has four components, and three genes (BCKDHA/19q13.1–q13.2, BCKDHB/6p22–p21, and DBT/1p31) have been identified and mutations in these genes make up over 95% of cases (98).

Feeding difficulties, irritability, and lethargy are observed during the first few weeks of life. If left untreated, these signs may progress to stupor, apnea, opisthotonos, myoclonic jerks, and partial and generalized seizures. A characteristic odor can be detected in the urine and cerumen, but this may not be detectable until several weeks after birth. Milder variants of MSUD present with poor growth, irritability, or developmental delays later in infancy or childhood (1).

Laboratory testing reveals a metabolic acidosis and elevated blood and urine ketones. Hypoglycemia and hyperammonemia are rarely present in this disease. Ferric chloride testing of the urine causes a gray-green reaction, and the 2,4-dinitrophenylhydrazine test is positive. A marked elevation in branched-chain amino acids/branched-chain keto acids in the plasma, urine, and CSF amino acid profile is observed, and the presence of L-alloisoleucine is pathognomonic for this condition. Definitive testing can be performed by enzyme assay and molecular genetic studies (99).

The EEG shows diffuse slowing and a loss of reactivity to auditory stimuli. The "comb-like rhythm" characteristic of MSUD was initially reported by Trottier et al. in 1975, when bursts of a central mu-like rhythm were observed in four affected patients (100). Tharp described resolution of this pattern in an affected infant when dietary therapy was initiated (101). Korein et al. (100) observed a paroxysmal spike and spike–wave response to photic stimulation in 7 of 15 affected patients.

Pathologic studies reveal diffuse myelin loss and increased total brain lipid content. Cystic degeneration of the white matter associated with gliosis is observed. Disordered neuronal migration may occur with heterotopias and disrupted cortical lamination.

Acute treatment is aimed at counteracting the effects of hypoglycemia, acidosis, and ending

catabolism. Dialysis or exchange transfusion rarely is necessary. Dietary therapy with protein restriction, thiamine supplementation, and elimination of branched-chain amino acids from the diet is the mainstay of treatment (99).

Histidinemia

Histidinemia or histidase deficiency is also associated with infantile spasms and myoclonic seizures. Other features include developmental delay and an exaggerated startle response. A diet low in histidine may be partially beneficial.

Isovaleric Acidemia

This condition is screened for by extended NBS. Symptoms develop during the neonatal period in half of the children with isovaleric aciduria (gene locus 15q14–q15). The presentation typically involves poor feeding, vomiting, dehydration, and a progressive encephalopathy manifested by lethargy, tremors, seizures, and coma. Depressed platelets and leukocytes may be seen, and the urine odor has been described as similar to that of "sweaty feet." Cerebral edema is present, and seizures are most often partial motor or generalized tonic. The EEG shows dysmature features during sleep. Distinctive biochemical findings include metabolic acidosis, ketosis, lactic acidosis, and hyperammonemia. High urine concentrations of isovalerylglycine in urine organic acids and isovalerylcarnitine in acylcarnitine analysis are diagnostic. Genetic testing is clinically available (102).

Propionic Acidemia

This condition is screened for by extended NBS. The symptoms of propionic acidemia also appear during the neonatal period, with 20% of affected newborns having seizures as the first symptom. Characteristic features include vomiting, lethargy, ketosis, neutropenia, periodic thrombocytopenia, hypogammaglobulinemia, developmental retardation, and intolerance to protein. Patients may have very puffy cheeks and an exaggerated cupid bow upper lip. Mutations have been identified in both the α-subunit (13q32) and β-subunit (3q21–q22) of propionyl coenzyme A (CoA) carboxylase (103). Generalized seizures are typical, although partial seizures have also been reported. The EEG shows background disorganization, with marked frontotemporal and occipital slow-wave activity. In 40% of children, myoclonic seizures develop later in infancy, and older children may have atypical absence seizures. Biochemical findings include metabolic acidosis, ketosis, and elevation of branched-chain amino acids and propionic acid (104).

Methylmalonic Acidemia

This condition is screened for by extended NBS. Methylmalonic acidemia may be caused by deficiencies of the enzyme methylmalonyl-CoA mutase or adenosylcobalamin synthetic enzymes. Methylmalonic acidemia occurs in association with homocystinuria in the combined deficiency of methylmalonic-CoA mutase and MTHF: homocysteine methyltransferase (105,106). Forms responsive to vitamin B_{12} have been reported (107). Stomatitis, glossitis, developmental delay, failure to thrive, and seizures are the major features. Lesions of the globus pallidus on computed tomography or MRI are characteristic.

Diffuse tonic seizures and partial seizures with secondary generalization are the most frequent seizure types. Seizures may be characterized by eyelid clonus with simultaneous upward deviation of the eyes. In a review of 22 patients, Stigsby et al. (104) described abnormalities on the EEG in seven patients, consisting of multifocal spike discharges and depressed background activity in two, excessive generalized slowing in two, and mild background slowing with lack of sleep spindles in three. Two children were reported to have myoclonus and a hypsarrhythmic EEG pattern (108).

3-Methylglutaconic Aciduria

This condition is screened for by extended NBS. Severe developmental delay, progressive encephalopathy, and seizures are features of 3-methylglutaconic aciduria with normal 3-methylglutaconyl-CoA hydratase. This disorder results from a mutation on chromosome 9 in the gene encoding the enzyme 3-methylglutaconyl-CoA hydratase. Seizures occur in one-third of cases, and infantile spasms have been reported early in the course of the disorder. The typical organic acid abnormality includes marked elevations in 3-methylglutaconic acid and 3-methylglutaric acid in the urine (109).

3-Hydroxy-3-Methylglutaric Aciduria

This condition is screened for by extended NBS. Seizures are the presenting symptom in 10% of patients with 3-hydroxy-3-methylglutaric aciduria, a disorder caused by a deficiency in the enzyme that mediates the final step of leucine degradation and plays a pivotal role in hepatic ketone body production. The odor of the urine may resemble that of a cat. The chromosome location for this disorder is 1pter-p33 (110).

Glutaric Acidemia Type I

This condition is screened for by extended NBS. Glutaric acidemia type I is a more common autosomal recessive disorder of lysine metabolism that is caused by a deficiency in glutaryl-CoA dehydrogenase (19p13.2). Seizures are often the first clinical sign of metabolic decompensation after a febrile illness. Vigabatrin, L-carnitine, baclofen, and riboflavin supplementation have been suggested (111).

Urea Cycle Disorders

Urea cycle disorders (UCDs) occur due to partial or complete deficiencies of enzymes involved in the body's attempt to remove waste nitrogen that forms from protein and carbohydrate catabolism. The incidence of these disorders is as high as 1:25,000, though later-onset diseases from partial defects are often underdiagnosed. All of these disorders are autosomal recessive except for ornithine transcarbamylase (OTC) deficiency which is X-linked dominant, but can present in both males and females. OTC is the most common of these disorders, accounting for over 50% of patients with UCDs (112).

The clinical manifestations of most of these disorders are similar and result, at least in part, from hyperammonemia. Typically, affected newborns present with poor feeding, emesis, hyperventilation, lethargy, or convulsions 1 to 5 days after birth. These signs lead to deepening coma, with decorticate and decerebrate posturing and progressive loss of brainstem function. Brain imaging and pathology

reveal cerebral edema with pronounced astrocytic swelling (113). Later onset disease due to partial enzyme deficiencies can present with progressive spasticity of the lower extremity, episodic vomiting, or episodic fluctuating encephalopathy with or without seizures. Some individuals may be symptom free until in the midst of a physiologic stressor that leads to an acute metabolic decompensation (114).

The clinical diagnosis is confirmed by elevations in serum ammonia, absence of urine ketones, and respiratory alkalosis. In contrast, metabolic acidosis and ketosis frequently occur with disorders of organic acid or pyruvate metabolism. Characteristic findings in plasma amino and urine organic acids, along with measurements of urine orotic acid can help differentiate among the various enzymatic defects. Measurements of plasma citrulline and argininosuccinic acid may also be helpful. Definitive diagnosis is established via gene sequencing if the enzymatic defect is identified by screening biochemical tests in blood and urine. If the enzyme defect needs further defining or confirmation, biochemical analysis in skin fibroblasts or liver can be performed (115).

The EEG may show a low-voltage pattern, with diffuse slowing and multifocal epileptiform discharges (116). Two patients studied by Verma et al. (117) in 1984 demonstrated episodes of sustained monorhythmic theta activity. In patients with acute neonatal citrullinemia, a burst-suppression pattern has been described (118).

In the acute setting, hemodialysis, ammonia scavengers and protein restriction have been used to reduce serum ammonia and can be lifesaving. Protein restriction and medical therapy aimed at lowering serum ammonia are recommended in the long-term management of these children. Liver transplantation has been successful in correcting the enzyme deficiency, reducing ammonia levels, and reversing neurologic deficits in select patients (119,120).

Fatty Acid Oxidation Defects
