Preface to the First Edition

Although in recent decades many methods have been developed to control parasitic diseases of humans and animals, chemoresistance and reduction of budgets for control have caused the problems to incease worldwide. Efforts in the "*struggle against parasites*" must be redoubled if we are not to become overwhelmed by human health problems and problems of food production. This absolute need has led to the application of various new methods to classical parasitology. Thus the different fields of parasitological research are at present expanding so rapidly that it is impossible for an individual to follow the main problems and to evaluate and recognize recent progress.

The purpose of this book is to give a comprehensive review of the facts and trends in veterinary and human parasitology, through contributions from distinguished specialists in different fields. The authors have focused their contributions on the most important and promising results, in a way which it is hoped will inform students, teachers, and researchers (zoologists, veterinarians, physicians) about those topics, which may be far from their own working fields, but knowledge of which may be necessary to develop new ideas. Thus, all chapters, the length of which will surely change in future editions, are provided with references opening the literary entrance to each field of research.

We hope that the book will be fruitful and lead to the establishment of new ideas, trends, and techniques in the struggle against parasites.

Bochum, January 1988

For the authors

Preface to the Third Edition

Globalization is the term of our time, and includes a daily constant and extremely rapid transportation of millions of humans and animals, plants, foods, and goods over often far distances from one region of the world to any other and back.

This, of course, has increased the likelihood of a broad and intensive import and export of parasites, their vectors and/or transmitted agents of diseases, which may give rise to the local endemics arising worldwide or even pandemics of considerable impact for human and animal health and all related economic factors. Thus there are no more tropical diseases, which can be avoided by not entering such countries. Today we have traveler's disease, we have local zoonoses, and we have diseases due to imported animals and plants. The latter may have severe consequences in countries where such diseases had been absent up to now since the people, animals, and plants have not had the chance to develop immunity or other means of protection. An example is the Blue-tongue-virus-disease of ruminants – transmitted by ceratopogonid bloodsuckers, which in summer 2006 was apparently imported (inside game animals) from South Africa to Central Europe and has spread within a few months in the Netherlands, Belgium, Northern France, and wide regions of Germany seriously harming the rearing of cattle and sheep.

Therefore, we are aware that the knowledge in the field of parasitology – especially in transmission, diagnosis, and treatment – must be kept at a high level and up to date in order to fight a parasitosis, from wherever, as quickly and effectively as possible.

The presentation of our third edition of the *Encyclopedia of Parasitology* contributes to these goals in several ways. The number of keywords has been increased by about 30%, their contents include important new knowledge gained since 2001, and perception of the facts has been ameliorated by adding 20% more tables, more figures, and an even closer connection by setting more links from one keyword to another. The quick and effective finding of updated information in human, veterinary, and biological aspects of parasitology is offered by more than 40 contributors, all of whom are well-known specialists in their fields of research, and who are all active in cooperation with their governments in the daily fight against the diseases deriving from parasitic infections of all kinds.

The third edition is presented as two volumes, sorted A to Z, and in an online version, both of which make it easy for all users to obtain the needed information within a minimum of time.

I am very grateful to all coauthors for their intensive, quick reviewing and serious updating of their keywords. I also wish to express my thanks to the readers of the second edition for their broad acceptance of our book, since the complete selling of this edition made it possible to publish the present edition after such a short period.

I hope that our most recent efforts are as well accepted as with the first two editions, and that the readers of our book and the users of our online version have the same benefit as the authors, when working on our parasitologic topics.

Düsseldorf, September 2007

Acknowledgements

No one could write a book such as this without the help of many people, including our close coworkers. Their material and comments were helpful while selecting and preparing the contributions to this book. We are especially grateful to those colleagues who contributed one or several micrographs:

– Prof. Dr. G. Brugerolle, Clermont-Ferrand
– Prof. Dr. J.F. DeJonckheere, Brussels
– Prof. Dr. I. Desportes, Paris
– Dr. W. Franz, Münster
– Prof. Dr. J. Grüntzig, Düsseldorf
– Prof. Dr. I. Ishii, Japan
– Prof. Dr. K. Hausmann, Berlin
– Prof. Dr. A.O. Heydorn, Berlin
– Dr. S. Klimpel, Düsseldorf
– Prof. Dr. M. Køie, Kopenhagen
– B. Mehlhorn, Neuss
– Prof. Dr. S. Palm, Düsseldorf
– Prof. Dr. S. Saem, Teheran
– Prof. Dr. E. Schein, Berlin
– PD Dr. G. Schmahl, Düsseldorf
– Dr. J. Schmidt, Düsseldorf
– Prof. Dr. J. Schrével, Paris
– Prof. Dr. Y. Yoshida, Kyoto

All other micrographs are either from the authors of the particular chapter or from the editor.

The editor and the authors would like to thank Mrs. K. Aldenhoven and Miss S. Walter for carefully typing large parts of the manuscript, Mrs. H. Horn and Mr. S. Köhler for their excellent preparation of the micrographs, and Mrs. B. Mehlhorn for correcting the proofs. The beautiful hand drawings were produced by the late Fried Theissen (Essen) and Dr. Volker Walldorf (Düsseldorf).

Furthermore we would like to thank the publishers, especially Dr. D. Czeschlik, Mrs. S. Fabiani, Dr. S. Blago and Mrs. L. Müller (at the Publisher, Springer-Verlag Heidelberg), for their cooperation and generous support of our efforts to produce an optimum outline of parasitology.

The Authors

Main Topics and Contributors

- Acanthocephala (Taraschewski)
- Antibodies (Seitz and Reiter-Owona)
- Arboviruses (Aspöck and Dobler)
- Behavior (Taraschewski)
- Cell penetration (Dubremetz)
- Chemotherapy against helminthoses (Raether and Harder)
- Chemotherapy against protozoan diseases (Raether and Hänel)
- Classification (Mehlhorn)
- Clinical and pathological signs of parasitic infections in domestic animals (Vercruysse, de Bont, and Daugschies)
- Clinical and pathological signs of parasitic infections in man (Frenkel and Mehlhorn)
- Connecting entries (Mehlhorn)
- Drug action in ectoparasites (Turberg and Londershausen)
- Drug action in protozoa and helminths (Harder)
- Drug tables (Raether)
- Ecological aspects (Combes)
- Ectoparasitizides (Londershausen and Hansen)
- Environmental aspects (Combes)
- Epidemiological aspects (Wernsdorfer)
- Eye parasites (Mehlhorn)
- Fine structure of parasites (Mehlhorn)
- Hormones (Spindler)
- Host finding mechanisms (Haas)
- Host parasite interface (Dubremetz and Mehlhorn)
- Immunodiagnostic methods (Seitz and Reiter-Owona)
- Immunological responses of the host (Gessner and Röllinghoff)
- Insects as vectors (Schaub)
- Life cycles (Mehlhorn and Walldorf)
- Lyme disease (Spielman, Armstrong, and Mehlhorn)
- Mathematical models (Freeman and Lehmacher)
- Metabolism (Köhler and Tielens)
- Molecular systematics (Mackenstedt)
- Morphology (Mehlhorn)
- Motility (Dubremetz and Mehlhorn)
- Nerves-structures and functions (Gustafsson and Maule)
- Novel drugs (Kayser and Julsing)
- Nutrition (Köhler and Tielens)
- Opportunistic agents, except *Pneumocystis* (Mehlhorn)
- Pathologic effects in animals (Vercruysse, de Bont, and Daugschies)
- Pathologic effects in humans (Frenkel and Mehlhorn)
- Pathology (Frenkel and Mehlhorn)
- Pentastomida (Walldorf)
- Phylogeny (Mackenstedt)
- Physiological aspects (Köhler and Tielens)
- Planning of control (Wernsdorfer)
- *Pneumocystis* (Kaneshiro and Smulian)

- Reproduction (Mehlhorn)
- Resistance against drugs (Harder)
- Serology (Seitz and Reiter-Owona)
- Strategy of control measurements (Wernsdorfer)
- Ticks as vectors in animals (Mehlhorn)
- Ticks as vectors in humans (Spielman, Armstrong, and Mehlhorn)
- Ultrastructure (Mehlhorn)
- Vaccination
  - Protozoa (Behr and Pereira da Silva)
  - Plathelminthes (Richter)
  - Nemathelminthes (Schnieder)
- Vector biology
  - Insects (Schaub and Mehlhorn)
  - Ticks (Spielman and Mehlhorn)

All these topics are presented in either a single, long entry, in several smaller, separate entries and/or as inserts in other longer entries. This cooperation of specialists contributes to a better understanding of the recent complex problems in parasitology.

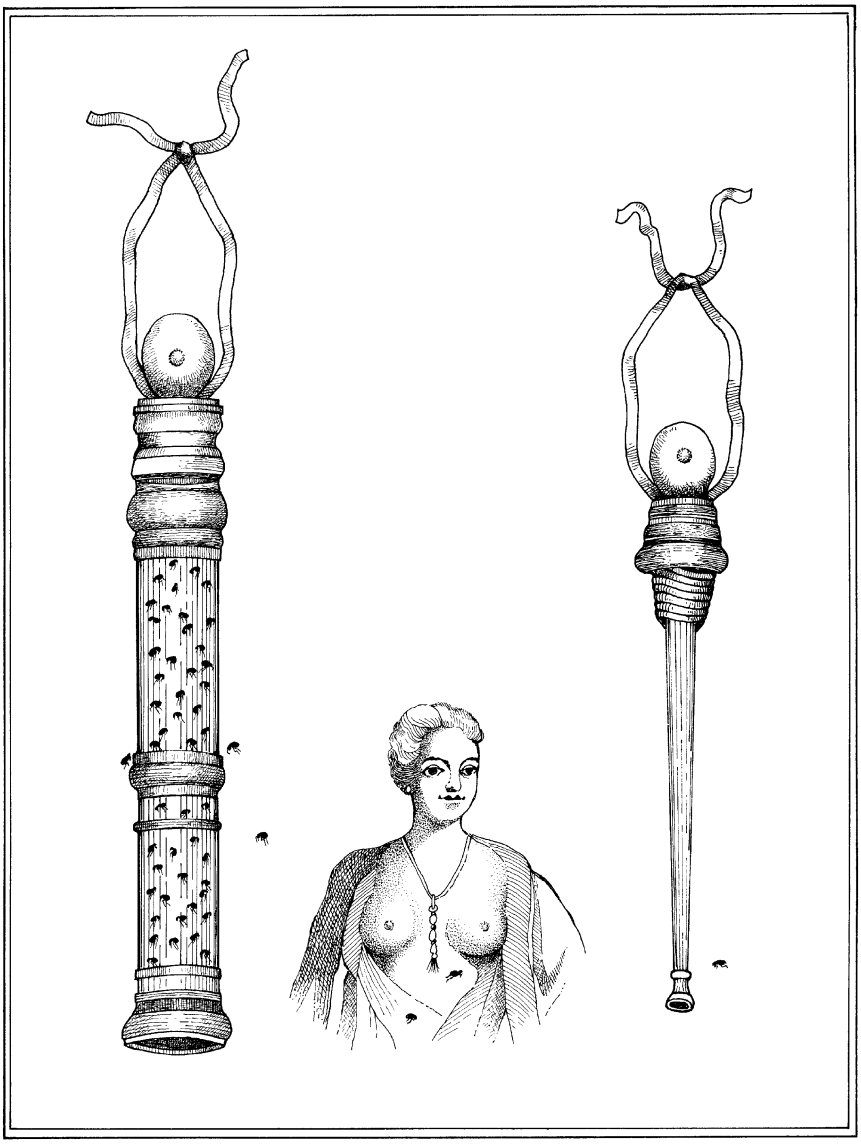
Introduction

Starting from the early beginnings of human culture, man became aware of parasites. In animals, which developed social contacts via coat-lousing, humans noted first the crucial activities of large amounts of ectoparasites such as ticks, lice, fleas, mosquitoes, and flies, as is shown in the earliest written reports of mankind. Furthermore, those endoparasitic worms that occurred in feces in larger numbers and were big enough to be seen with the naked eye were known. Thus the physicians of the Egyptians (~2000 BC), the Greek physician Hippocrates (460–370 BC), and the natural scientist Aristoteles (384–322 BC) knew ascarids, oxyurids, and of course tape-worms very well. Their knowledge was passed on to the Romans, who called the round worms *lumbrici teretes* and the plathyhelminths *lumbrici lati*, and from there it was transmitted to later human societies, especially by propagation of manuscripts in Christian cloisters or by translations of Greek books that were being used and preserved by physicians in the Near East.

However, only a few remedies were available apart from combing (Fig. 1), catching of parasites (Fig. 2), bathing in water and/or hot sand, and eating special plants or spicy food, which were felt to decrease intestinal worm populations, as, for example, pepper does (Fig. 3). Thus the highly sophisticated physicians of the ancient Egyptian kingdoms surely did know the fatal symptoms of the schistosome-derived diseases, but the transmission pathways

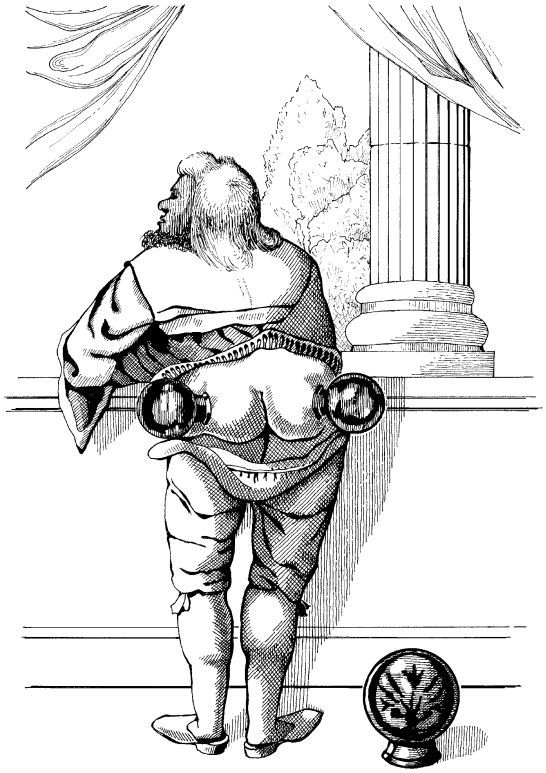
Introduction. Fig. 1. Redrawn reproduction of a medieval engraving showing a housewife delousing her husband with a comb-like instrument.



Introduction. Fig. 2. Redrawn reproduction of a figure from a German book of the 18th century showing two types of lady's necklace used as glooming flea-catcher.

and methods of treatment were as nebulous as they were 3,000 years later when the Holy Hildegard of Bingen (1098–1179) recommended that worms be treated with, for example, extracts of stinging nettles, dandelions, and walnut-tree leaves, as described in her book *Physica* (1150–1160) – chapter "*De causis et curis morborum*" (i.e. "On the causes and cures of diseases"). The treatment of dracunculosis by removal of the whole worm from human skin was, however, much more successful. The use of a wooden splinter, onto which this so-called Medina-worm was wound by physicians in the Near East, probably gave rise to the Aesculap-stick of our days – the symbol of an increasingly successful caste – although it is not long ago that cupping and/or the use of leeches were universal remedies (Figs. 4, 5). At the end of the Middle Ages, a new interest arose among educated people to study the natural world, and this newly awakened curiosity led people to make detailed investigations of plants and animals. Even human beings were a subject of investigation, provided religion did not prevent this (e.g., dissections of humans – even of executed and thus lawless people – were forbidden for centuries in Christian and Moslem countries). Thus at first, descriptions of the outer morphology of plants, animals, and humans became available and later – after the development of microscopical techniques – structural ground plans and histological insights into organisms were obtained. However, it was not until the middle of the 19th century that the theory of "de novo

Introduction. Fig. 3. Redrawn reproduction of an ambulant Renaissance pharmacist equipped with his main helper plants and therapeutical animals, including snakes and leeches.



Introduction. Fig. 4. Redrawn reproduction of a Baroque noble using cupping-glasses in order to be bled.

Introduction. Fig. 5. Redrawn reproduction of a medieval engraving demonstrating the therapeutic use of the leech, *Hirudo medicinalis*, even in middle-class households.

creation" (latin: *generatio aequivoca et spontanea*), the creation of organisms from dead or anorganic material (e.g., worms develop from intestinal slime) became replaced by the idea of cellular organization and the self-reproduction of organisms as postulated in Virchows thesis (1858): "*omnis cellula e cellula*" ("each cell derives from a cell"). This growing spirit of investigation led to the discovery of numerous species of plants and animals and to the differentiation into prokaryotic and eukaryotic organization of organisms. The knowledge derived from the cell-dependent life of viruses or prions is a fruit of our century. According to their morphology and life cycles – the study of which is not completed even today – species of bacteria, fungi, plants, and animals were characterized and ***systematical classifications*** and ***phylogenetic trees*** were established. Such investigations provided a basis for the establishment of phylogenetical theories such as those of Lamarck or Darwin.

Moreover, most of the species of parasites still valid today were described in those times (cf. ***Historical Landmarks***) and the term ***parasite*** (Greek: *parasitos* = eaters at the court = meal taster) became fixed as the word to describe those organisms that live on other animals or humans. According to the different life-cycle adaptations the latter may become:

- ***Final (definite) hosts*** lodging the sexual stages of the parasite
- ***Intermediate hosts*** lodging asexually reproducing stages of the parasite
- ***Transitory/accidental/paratenic hosts*** lodging parasitic stages without further reproduction
- ***Vectors*** representing bloodsucking parasites such as arthropods, worms or leeches which transmit other pathogens and/or parasites during their blood meal.

The constant refinement of microscopical techniques (including the establishment of electron microscopy) and the development of a broad spectrum of molecular biological methods led (especially in the last 30 years) to an explosion of the knowledge on the organization of the parasites, on the parasite–host interface, and on host immune reactions, which altogether were used to establish control measurements and to develop prophylactic strategies, drugs, and/or vaccines. Thus the third edition presented here is based on the following pillars:

- Life cycles (inclusive behavior and epidemiology)
- Morphology (up to molecular insights)
- Mechanisms of reproduction
- Metabolism and nutrition

- Host–parasite interactions
- Diseases and pathological effects
- Immune reactions
- Control measurements (including drugs, vaccines, prophylactic strategies).

The selected keywords are arranged in an encyclopedic manner and intend to outline easy interactions with many other fields of interest and importance. The simultaneously appearing online version of the book speeds up the finding of the appropriate information.

Abamectin

Chemical Class
Macrocyclic lactone (16-membered macrocyclic lactone, avermectins).

Mode of Action
Glutamate-gated chloride channel modulator →Nematocidal Drugs, →Ectoparasiticides – Antagonists and Modulators of Chloride Channels.

Abbreviata

Genus of physalopteroid nematodes in amphibians, reptiles, and a few mammals.

Abdominal Pain

Leading symptom in some parasitic infections (Angiostrongyliasis costaricensis, →Ascariasis in children, →Capillariasis, →Dipylidiasis, →Echinococciasis, →Gnathostomiasis, →Mansonelliasis, →Strongyloidiasis, →Taeniasis, →Toxocariasis, →Trichuriasis).

Abortion

Premature expulsion of an embryo or a nonviable fetus caused by parasitic infections, e.g., with →*Toxoplasma gondii*, →*Neospora caninum* (syn. →*Hammondia heydorni*), →*Trypanosoma* species, →*Tritrichomonas foetus*.

Abscess

Inflammatory reactions around foci of parasites within hosts (e.g., →Angiostrongylus, →Leishmania, →*Entamoeba histolytica*). →Pathology.

Abundance

(Latin: *abundantia*), this ecological term describes the number of individuals within a biotope with respect to a defined area or a certain space.

Acalculous Cholecystitis

Symptom due to infections of gall bladder, e.g., by →*Encephalitozoon intestinalis*, →*Opisthorchis* species.

Acanthamoeba

→Amoebae.

Acanthamoeba castellanii

Species of facultatively parasitic →amoebae; →Acanthamoebiasis, →Opportunistic Agents; →GAE.

Infectious leginonellae or other bacteria and viruses may be transported by such amoebae in biofilms. Life cycle see →Amoebae.

Acanthamoeba-Keratitis

Sight-threatening infection of the eye due to opportunistic *Acanthamoeba* spp., which excrete proteases that degrade basement membranes and induce cytolysis as well as apoptosis of corneal cells. This finally culminates in the dissolution of the collagenous corneal stroma.

Acanthamoebiasis

→*Acanthamoeba* spp. have been found in the throat; mouth pipetting of fluids into cell culture has given rise to contaminated cell cultures in numerous instances. In the throat the →amoebae appear to be nonpathogenic. However, in patients with long-standing immunosuppression tissue invasion does occur, usually leading to →encephalitis which is fatal and occasionally to focal lesions elsewhere. The inflammation is mononuclear; partially in response to →necrosis of brain tissue and is sometimes stated to be granulomatous; hemorrhage may be marked. Large amoebic →trophozoites and smaller cysts with an irregular "corrugated" wall are found in the lesions. Often the →amoebae (Figs. 1, 2) are difficult to distinguish from macrophages; the latter have intensely staining nuclei, whereas the amoebae have vesicular nuclei and a "foamy" →cytoplasm. The →inflammatory reaction is of course variable because of immunosuppression of the patients (→Pathology). The amoebae are not found in the spinal fluid. Patients with the Acquired Immunodeficiency Syndrome →(AIDS) showed invasion of the nasopharynx with →*Acanthamoeba* spp. Other sites of involvement by *Acanthamoeba* spp. are the cornea, skin, and lung; especially in the eyes *Acanthamoeba* stages are rather common in persons using plastic lenses. Thus these species are not only →opportunistic agents.

Main clinical symptoms: Chronic brain disturbances, possibly granulomatous encephalitis (→GAE); eye: →conjunctivitis, keratitis, uveitis.
Incubation period: 1 day – 2 weeks.
Prepatent period: 1 day – 2 weeks.
Patent period: Weeks to months in chronic cases.
Diagnosis: Culture techniques.
Prophylaxis: Do not swim in eutrophic lakes; change fluids for contact lenses often.
Therapy: →Treatment of Opportunistic Agents.

Acanthella

The name acanthella (Figs. 1, 2) has been attributed to the →Acanthocephalan stage between the →acanthor and the larva that is infective to the final (or paratenic) host (→Cystacanth, →Acanthocephala). Its growth begins under the serosa of the →intermediate host and continues in its body cavity. The morphological changes from the →acanthor that has survived the enclosure by the intermediate host's haemocytes and detached itself from the intestinal wall, to the late acanthella and the →"cystacanth" are considerable, e.g., organogenesis occurs as well as a rotation of the worm's axis through 90 degrees, while the →tegument of the acanthor becomes stretched to form the acanthella's tegument. First, the central nuclear mass begins to split into different bodies which become the primordia of the organs.

The acanthella's tegument shows remarkable differentiation during the development in the arthropod's haemocoel. Its outer membrane forms microvilli-like protuberances (Fig. 1, page 3) that build up a membranous sponge-like envelope around the larva. Haemocytes can be found in it (Fig. 1), especially near early acanthellae and if the intermediate host is not entirely suitable. Later on the spongy vesicular cover becomes supplemented by a thin interior and an exterior layer of amorphous matter and detaches itself from the worm body, forming a gap of different width with an electron lucent granular matrix (probably liquid), Fig. 2 (page 4). Late acanthellae show everted probosces; finally the →proboscis becomes invaginated or the entire →praesoma as well as the posterior end is retracted, so that the larva appears in a cystlike shape (→Cystacanth). This shape is common among species with definitive hosts that chew or grind their food in their upper intestinal tract (Fig. 2).

Acanthocephala

Name

Greek: *acantha* = thorn, *cephale* = head.

Classification

Phylum or lower group of →Metazoa.

General Information

Adult members of the Acanthocephala are highly specialized heterosexual, intestinal parasites that take up nutrition parenterally since they have no intestine. Vertebrates are used as final (definitive) hosts, arthropods as intermediate hosts (Table 1). The body consists of 2 major parts, the →praesoma and the →metasoma. The →praesoma comprises the →proboscis, armed with a set of specific hooks (Fig. 1, Attachment), a more or less pronounced →neck, the →proboscis receptacle, and the 2 lemnisci (Figs. 4, 16), which are cylindrical appendages of the praesomal →tegument. The tube-shaped metasoma (= trunk) is bounded by a solid body wall, enclosing the pseudocoel, which in addition to liquid is mainly filled with male or female sexual organs.

Additional morphological features as well as biological characteristics determine the affiliation to one of the classes.

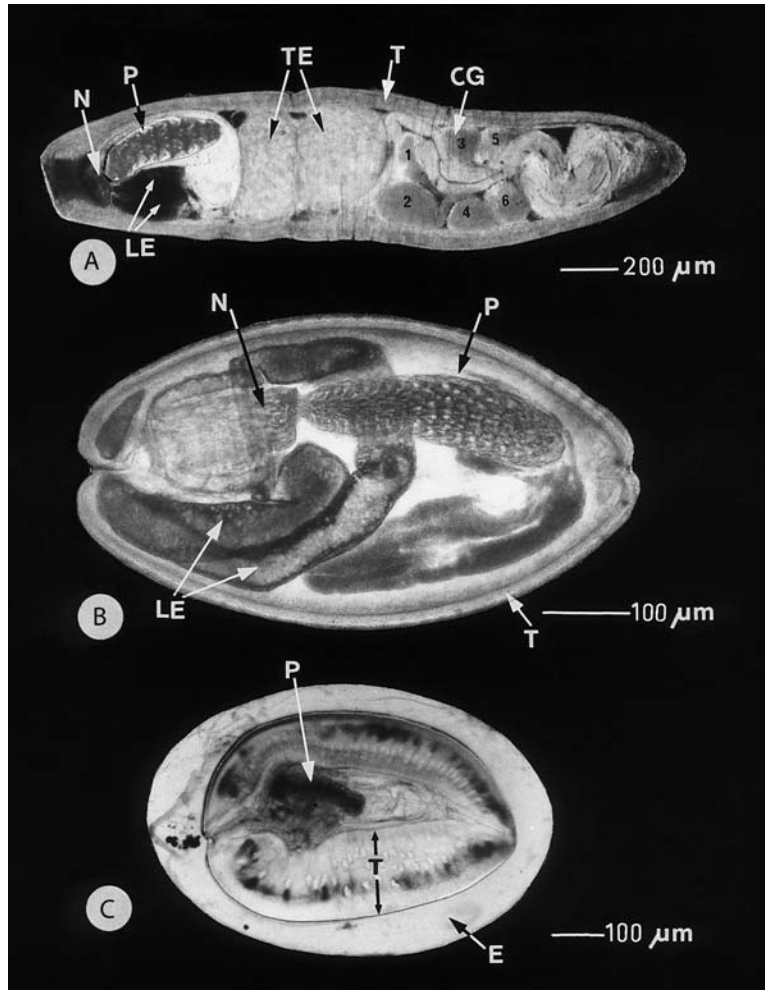
System

Class 1: Archiacanthocephala Meyer 1931: species have terrestrial life cycles; mammals or birds are final hosts, and insects (or millipedes) intermediate hosts; in addition, paratenic hosts are often involved; main longitudinal vessels of the lacunar system run dorsally and ventrally; usually there are 8 uninucleate →cement glands; few tegumental nuclei; ligament sacs inside the pseudocoel, also in adult worms (Fig. 16). The well known orders are:

Order: Apororhynchida
Order: Gigantorhynchida
Order: Moniliformida
Family: Moniliformidae
Genus: *Moniliformis*
Order: Oligacanthorhynchida
Family: Oligacanthorhynchidae
Genus: →*Macracanthorhynchus*
Genus: *Prosthenorchis*

Class 2: Palaeacanthocephala Meyer 1931: mostly aquatic life cycles; fish (waterbirds, seals) are final hosts, crustaceans intermediate hosts; main vessels of the lacunar system run laterally; 2–8 multinucleate cement glands; numerous tegumental nuclei; ligament sacs ruptured in adult worms.

Order: Echinorhynchida
Family: Echinorhynchidae
Genus: →*Acanthocephalus*
Genus: *Echinorhynchus*



Acanthella. Figure 2 Infective male larvae of **A** →*Acanthocephalus anguillae*, **B** →*Filicollis anatis*, **C** →*Moniliformis moniliformis*. Note the progressing degree of encystment (from A to C) of the larvae parallel with a reduction in size and suppression of sexual organogenesis. Encystment seems to be an adaptation to the chewing or grinding activity of the final host (see life cycles). The larval envelopes (E) have been removed in A and B. The sausage-shaped larva of *A. anguillae* (A) has a very thin, closely fitting envelope. *CG*, →cement glands (1–6); *E*, →envelope; *LE*, →lemnisci; *N*, →neck; *P*, →proboscis (retracted); *T*, tegument; *TE*, testes.

Family: Pomphorhynchidae
Genus: *Pomphorhynchus*
Order: Polymorphida
Family: Centrorhynchidae
Family: Plagiorhynchidae
Family: Polymorphidae
Genus: *Corynosoma*
Genus: *Filicollis*
Genus: *Polymorphus*

Class 3: Eoacanthocephala Van Cleave, 1936: aquatic life cycles; fish (also reptiles, amphibians) are final hosts, and small crustaceans (mostly Ostracoda) intermediate hosts; main vessels of the lacunar system run dorsally and ventrally, only a single, giant uninucleate cement gland; tegument with giant nuclei; ligament sacs generally persistent in adults.

Order: Gyracanthocephala
Order: Neoechinorhynchida
Family: Neoechinorhynchidae
Genus: →*Neoechinorhynchus*
Family: Tenuisentidae
Genus: *Paratenuisentis*

Recently, a fourth class has been erected, the Polyacanthocephala. The few known members of this group have been little studied. Fishes and crocodiles were found to be parasitized.

Important Species

Life Cycles

Figs. 2, 3.

Attachment

Concerning the attachment to the host's intestinal wall, 2 groups can be distinguished: perforating and non-perforating acanthocephalans.

Non-Perforating Acanthocephalans

Generally, acanthocephalans that have a short neck do not penetrate deeply into the host's intestinal wall with their praesoma, but display some mode of shallow attachment, i.e., they do not create lesions reaching as deep as into the muscular layers of the intestinal wall (Figs. 4–6, →Acanthocephalan Infections/Fig. 8). Accordingly, often even the posterior half of the proboscis does not become surrounded by host tissue (Fig. 5). Layers of connective tissue within the hosts' intestinal wall often appear to function as penetration obstacles. This might be the stratum compactum in salmonids retaining →*Echinorhynchus truttae* in superficial positions or a →collagen layer interiadly lining the intestinal mucosa of perch (*Perca fluviatilis*) affecting the mode of attachment of →*Acanthocephalus lucii* (Fig. 5). On the other hand, the tipped proboscis hooks seem to use the collagen layers as suitable substrates of anchorage (Fig. 6). In Fig. 6 a necrotic tissue with a slight infiltration of granulocytes and haemorrhagic involvement, typical of the attachment site of *Acanthocephalus lucii* and other non-perforating species, is shown (Fig. 4). When non-perforating species were experimentally inoculated into small specimens of fish not comprising penetration obstacles in their gut wall, 3 non-perforating species did not try or succeed in perforating either. And accordingly such species usually cannot be found *in toto* in extraintestinal locations like perforating species. →*Paratenuisentis ambiguus* and *P. lucii*, both non-perforators, do not possess colagenolytic →proteinases useful in chemical support of penetration activity. So paratenic hosts do not occur in the life cycles of non-perforating acanthocephalans, but postcyclic transmission of intraintestinal worms like *Neoechinorhynchus rutili* in sticklebacks to predatory brown trout seems to be very common.

Such species either continuously or occasionally change their point of attachment, exposing them to the posteriadly directed intestinal peristalsis. In infrapopulations of *E. truttae* in brown trout all specimens have arrived at the posterior end of the small intestine by the time the worms have matured. As has been shown for *N. cylindratus*, a species that is potentially perforating, infrapopulations with high worm densities lead to enhancement of change of the point of attachment and consequently to greater posterior shift. An interesting feature can be observed in other neoechinorhynchids. Although they occupy superficial positions, they do not seem to migrate or become shifted after an initial period of establishment, due to a firm capsule of collagen fibres enclosing their small, roundish proboscis. A negative point of the proboscis remains in the intestinal wall after deattaching a worm using forceps (→Acanthocephalan Infections/Fig. 5A). Not unlikely, this massive collagen formation is provoked by the excretion of →proline (→Amino Acids) or other substances by the praesoma.

A typical non-perforating species is the archiacanthocephalan →*Moniliformis moniliformis* displaying a deep proboscis cavity and shallow attachment (→Acanthocephalan Infections/Fig. 8).

Acanthocephala. Table 1 Some important species of the Acanthocephala

Class/Species	Size (adults, mm; egg, E, µm)	Final host	Intermediate host	Paratenic host	Geographic distribution
Archiacanthocephala					
Moniliformis moniliformis	m 30–45 f 140–270 E 90–125 × 50–62	*Rattus* spp., other rodents, occasionally humans, monkeys etc.	Cockroaches	–	Worldwide
Macracantho-rhynchus hirudinaceus	m 50–90 f 200–650 E 90–100 × 50–56	Pigs, occasionally humans, etc.	Beetles (larvae)	–	Worldwide
M. ingens	m 130–150 f 180–300 E 96–106 × 51–54	Raccoons, other mammals	Beetles	Amphibia, reptilia	North America
Prosthenorchis elegans	m 20–40 f 30–55 E 60–65 × 41–43 (78–81 × 49–53)	Monkeys, other mammals	Cockroaches, beetles	–	South America, domestic cycle worldwide

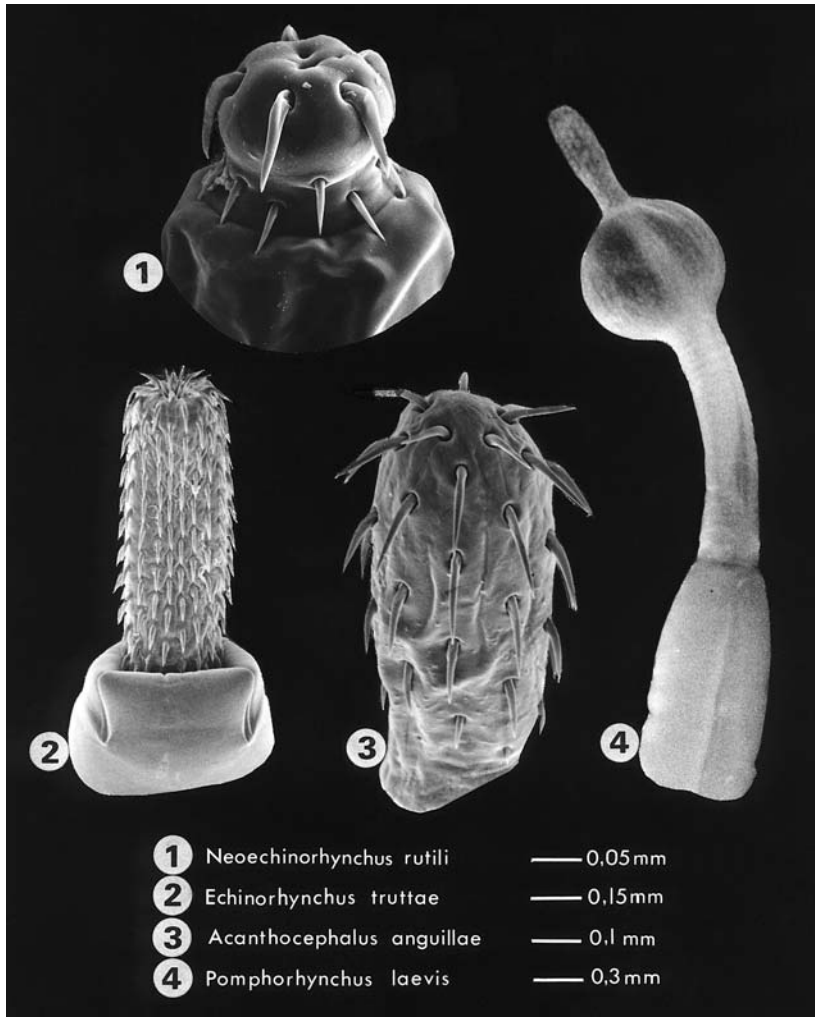
Acanthocephala. Table 1 Some important species of the Acanthocephala (Continued)

Class/Species	Size (adults, mm; egg, E, µm)	Final host	Intermediate host	Paratenic host	Geographic distribution
Palaeacanthocephala					
Acanthocephalus anguillae	m 5–7 f 10–35 E 100–125 × 12–14	Chub, barbel	*Asellus aquaticus*	Small cyprinid fish*	Europe
A. ranae	m 5–12 f 20–60 E 110–130 × 13–16	Amphibia	*Asellus aquaticus*	–	Holarctic
Echinorhynchus truttae	m 8–11 f 15–20 E 100–110 × 23–26	Salmonid fish	*Gammarus* spp.	–	Europe
Corynosoma semerme	m 3–5 f 3–5 E 79–100 × 16–29	Seals, birds, occasionally dogs, etc.	*Pontoporeia affinis* (Amphipoda)	Various marine fish	Holarctic
Pomphorhynchus laevis	m 6–16 f 10–30 E 110–121 × 12–19	Chub, barbel, trout	Gammaridae	Small Cyprinidae and other fish*	Palaearctic
Filicollis anatis	m 6–8 f 10–25 E 75–84 × 27–31	Ducks, other water birds	*Asellus aquaticus*	–	Palaearctic
Polymorphus minutus	m 2–3 f 6–10 E 100 × 11–12	Ducks, other water birds	*Gammarus* spp.	–	Holarctic
Eoacanthocephala					
Neoechinorhynchus cylindratus	m 4.5–8.5 f 10–15 E 51–61 × 17–28	Predatory fish (bass, etc.)	*Cypria globula* (Ostracoda)	Small fish (bluegills, etc.) *	North America
N. emydis	m 6–15 f 10–22 E 20–25 × 20–22	Turtles	*Cypria globula* (Ostracoda)	Water snails	North America
N. rutili	m 2–6 f 5–10 E 26–27 × 14–17	Salmonid and other fish	Ostracoda	–	Holarctic
Paratenuisentis ambiguus	m 2.5–8 f 8–14 E 62–72 × 26–31	Eels	*Gammarus tigrinus*	–	North America, Europe (introduced)

* This host category is not yet sufficiently investigated. Thus it remains doubtful whether these species are true paratenic hosts.
m = male, f = female, E = egg

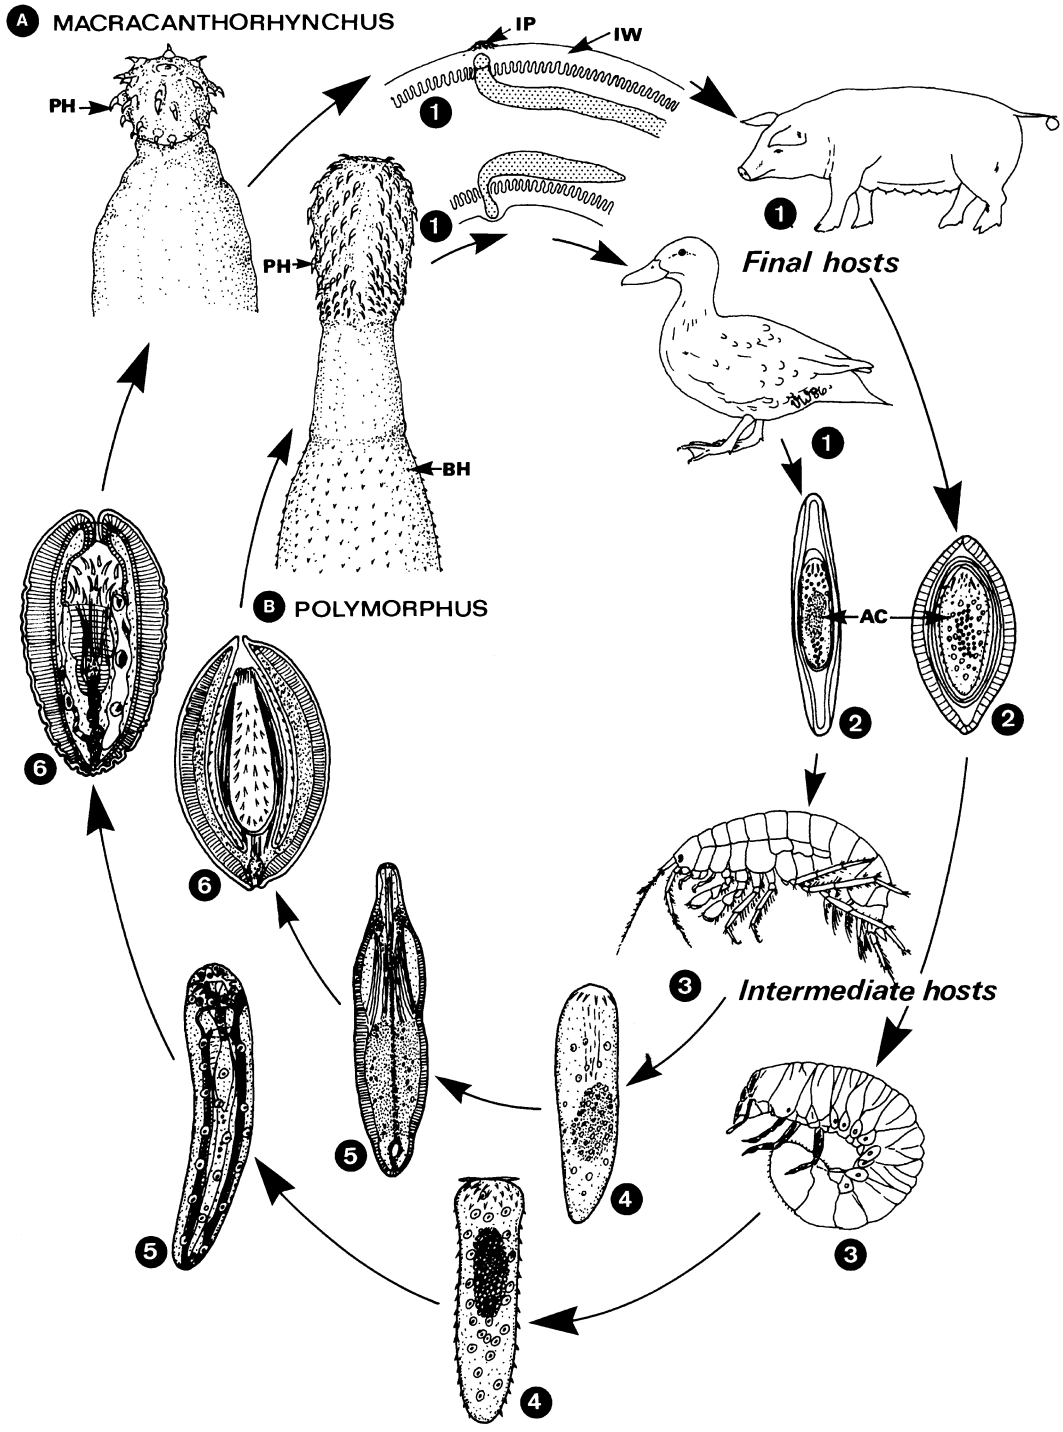
Perforating Acanthocephalans

Many Acanthocephalans possess a long neck which may comprise a bulbus such as the *Pomphorhynchus* spp. (Palaeacanthocephala) with an inflated neck region (praesoma) (Fig. 1). In the eoacanthocephalan →*Eocollis arcanus* it is the anterior part of the metasoma which forms a bulb. In both cases the bulbus functions as a dowel enabling the worm to occupy a permanent point of attachment at a specific site. The deep and quick perforation of the intestinal wall may be supported by a proteolytic enzyme as shown for →*Pomphorhynchus laevis* which excretes a trypsin-like proteinase into the

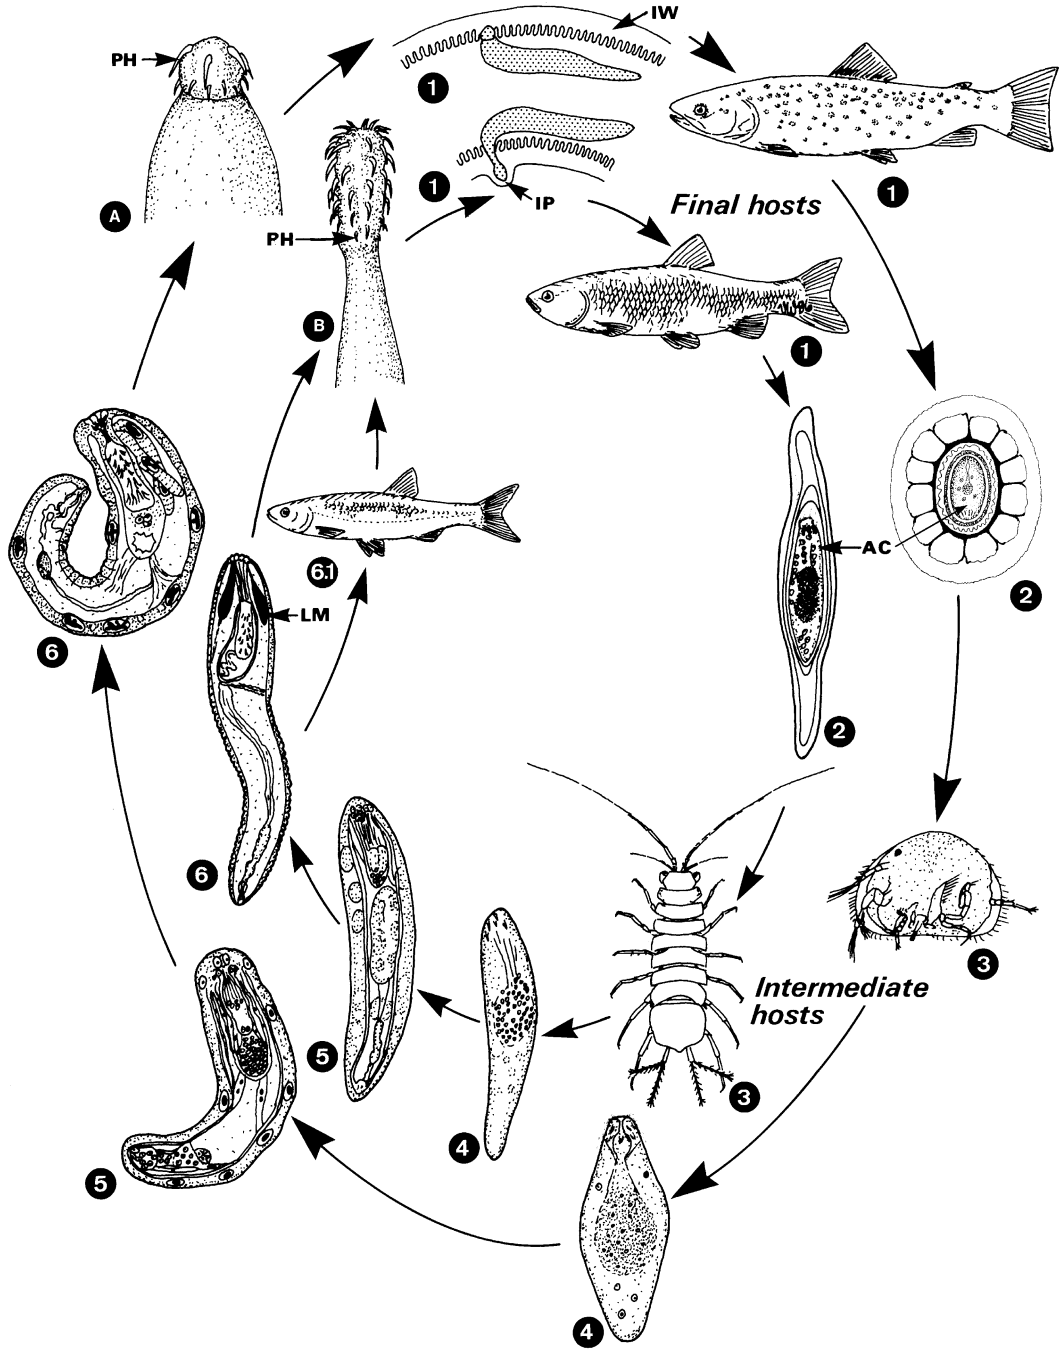


Acanthocephala. Figure 1 SEMs of acanthocephalan praesomae.

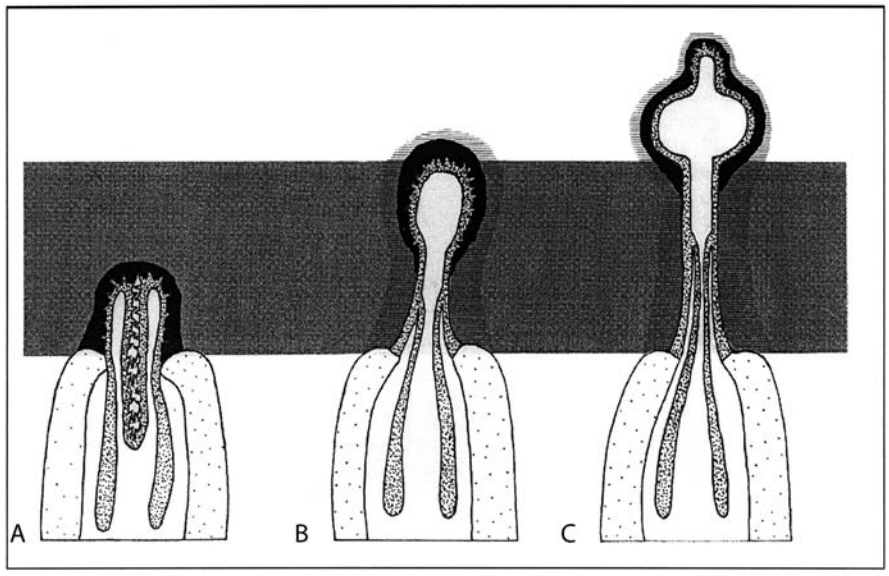
culture medium. It has a collagenolytic activity and the molecular mass differs slightly among infectious larvae and adult worms removed from fish. The long-necked species *A. anguillae* does not display such abilities in lysing collagen and accordingly the collagenic stratum compactum of salmonid fishes retains most worms in rather superficial connections with the intestinal wall. In experimental infections in adult rainbow trout the worms take about 60 days to perforate the stratum compactum, in juveniles of the same salmonid host it occurs around 20–30 d.p.i. In the long run, only those worms which succeed in penetrating seem to survive for several months in this host, while the others probably do not have the potential to withstand the intestinal drift. As shown for *P. laevis*, typical perforating species do not change their site of attachment and thus do not become backwards shifted. In natural populations of fish hosts, species like *P. laevis, Eocollis arcanus*, or *A. anguillae* are not only found in positions with a praesoma deeply inbedded inside the intestinal wall, but also partly lying *in toto* inside the peritoneal cavity or viscera, especially in small specimens or species. Obviously, in such hosts the intestinal wall or the collagen layers within it are not strong enough to withstand the worms' penetrating activity. In juveniles of goldfish experimentally infected with *A. anguillae*, the first worms started projecting into the peritoneal cavity with parts of their praesoma up from about 10 d.p.i., worms of about 20–30 d.p.i. were mostly found in various positions like lying with parts of their bodies inside one intestinal loop and projecting into another with the proboscis or anterior body (→Acanthocephalan Infections/Fig. 5). In contrast, at 50 d.p.i. all worms recovered had taken intraperitoneal positions and most of them were already degenerating. Due to this quick death of the worms in extraintestinal positions, one may conclude that they did not leave the intestine "on purpose" but slipped into the peritoneal cavity *in toto* by lack of penetration obstacles or other features. Thus, the small fishes that became infected in these experiments should not be called →paratenic hosts. However, true paratenic hosts exist in the life cycles of certain perforating



Acanthocephala. Figure 2 Life cycle of common acanthocephalan species. **A** →*Macracanthorhynchus hirudinaceus*; **B** →*Polymorphus minutus*. *1* The adults live in the intestine of their final hosts, being attached by their hooked proboscis. The penetration of the intestinal wall leads to inflamed protrusions (IP) appearing along the outer side. *2* After copulation the adult females excrete eggs for several months (patent period). These eggs are passed fully embryonated (i.e., they contain the hooked →acanthor larva) with the faeces of the host. *3-6* Intermediate hosts (*Gammarus* spp. or beetle larvae) become infected by ingesting infective eggs. Inside the intestine the acanthor is released from the egg (4), enters the body cavity, and is transformed into an →acanthella larva (5). The latter grows up within 60–95 days (in *M. hirudinaceus*) and is described as an infective larva (→Cystacanth). Infection of the final hosts occurs when they swallow infected intermediate hosts. The young worms reach sexual maturity within 60–90 days in *M. hirudinaceus* (after 20 days in *Polymorphus minutus*) and start egg production (= end of prepatent period). *AC*, acanthor; *BH*, body hooks; *IP*, inflamed protrusion of IW; *IW*, intestinal wall; *PH*, proboscis hooks; *RA*, released acanthor.



Acanthocephala. Figure 3 Life cycle of two common acanthocephalan species parasitizing fish. **A** →*Neoechinorhynchus rutili*; **B** →*Acanthocephalus anguillae*. *1* Adults are attached to the intestinal wall of their final hosts, trout (A) or chub and other fish (B). *2* Fully embryonated eggs are passed with host's faeces. *3–6* Intermediate hosts (**A** ostracod crustaceans, **B** *Asellus aquaticus*) are infected by uptake of eggs. Inside their intestine the acanthor larva (4) is released from its →eggshell, enters the body cavity and becomes transformed into the acanthella larva (5). This stage differentiates to the infective larva without →encystation in about 30–60 days (6) depending on outer conditions. Final hosts are infected by swallowing intermediate hosts. In *A. anguillae* a →paratenic host may also become involved. When bleaks and some other fish ingest intermediate hosts *(Asellus aquaticus)*, the infective larva enters the fish viscera, but there is no further development, but quick degeneration. *Neoechinorhynchus rutili* and *A. anguillae* reach sexual maturity in about 20–30 or 40–60 days, respectively (prepatent period). Adults live only for about 2–3 months (patent period). *AC*, acanthor; *IP*, inflamed protrusion of IW; *IW*, intestinal wall; *LM*, →lemniscus; *PH*, proboscis hooks.



Acanthocephala. Figure 4 A–C Schematic drawings of the acanthocephalan praesoma and the corresponding mode of attachment. Black area: tissue →necrosis, hatched area: tissue neoplasia. **A** Acanthocephalan with a short neck, and lemniscis branching away from the posterior end of the praesomal tegument. A deep proboscis cavity is formed. Necrotic host tissue (black area) can be found all around the parasite's proboscis. **B** Perforating acanthocephalan with a long neck, and lemnisci branching away from the praesomal tegument at the mid-neck. In the chronic mature stage of infection the proboscis becomes deeply embedded in the intestinal wall and is usually kept fully evaginated. Necrotic host tissue in mainly confined to the proximity of the proboscis. Tissue neoplasia is pronounced also proliferating into the peritoneal cavity. **C** Perforating acanthocephalan with a long neck, a bulbus and lemnisci branching away from the praesomal tegument at the mid-neck. In the chronic (mature) stage of infection the parasite is "doweled" in the intestinal wall with the bulbus. The proboscis is usually kept fully evaginated. Necrosis is mainly confined to the tissue close to those parts of the worm that project into or border the peritoneal cavity. Tissue neoplasia especially in the peritoneal cavity is conspicuous.

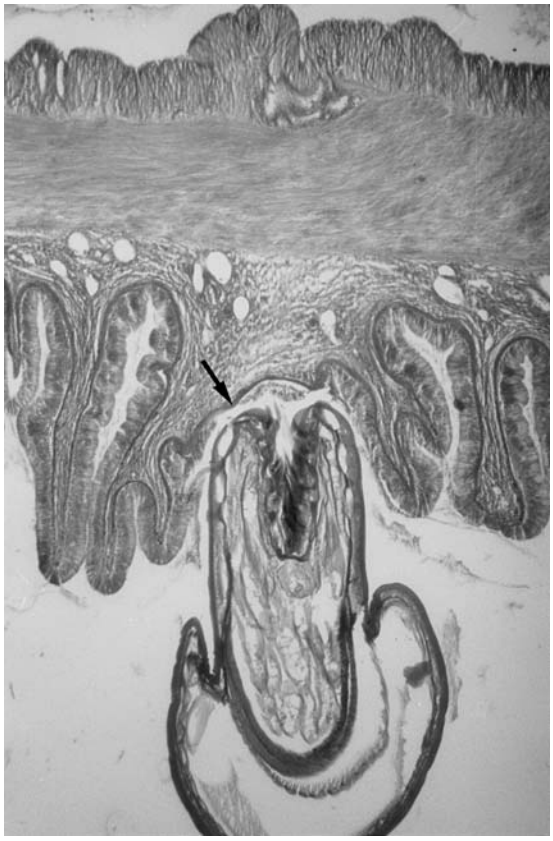
acanthocephalans. →*Oncicola pomatostomi*, for instance, is parasitic in the intestine of Felidae and Canidae in Southeast Asia and Australia while it has been found under the skin of 19 species of passerine birds where it probably has a certain longevity making the birds true paratenic hosts.

Often *Macracanthorhynchus hirudinaceus* occupies extraintestinal positions in humans. The migration of this perforating acanthocephalan through the gut wall is very painful. Such infected humans with an intraperitoneally located worm might be named accidental hosts since they do not play a role in the transmission of the acanthocephalan.

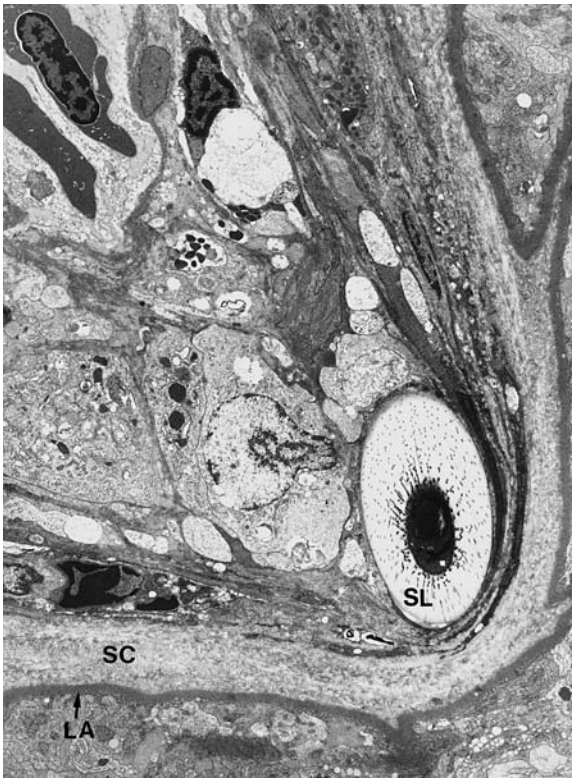
Among perforating species a proboscis cavity is formed mainly during the early phase in the final host when the worm has not yet penetrated, later on, the cavity's depth and frequency of invagination are progressively reduced (→Acanthocephalan Infections/Fig. 5).

Food Uptake

In non-perforating acanthocephalans the proboscis itself is usually kept in a more or less invaginated condition creating a deep proboscis cavity (Fig. 4A) which obviously functions as a funnel collecting remnants of cells and nutrients leaking into the lesion that has been created by the worm. In eo- and palaeacanthocephalans, especially lipid substances such as triacylglycerols are highly abundant as storage lipids in the intestinal wall of fish, ducks, or seals serving as final host. As shown in Fig. 10 lipid matter as well as, for instance, peptides deriving from the granules of eosinophilic granulocytes contribute to the efflux from the necrotic tissue. However, autoradiographic studies by Taraschewski and Mackenstedt with 2 species of eoacanthocephalans and 4 palaeacanthocephalans (2 non-perforating and 2 perforating species) show that predominantly lipid substances are absorbed at the worms' praesoma (Figs. 7, 8). The "→apical organ" of eoacanthocephalans, a structure not yet well understood at the tip of the proboscis, i.e., at the bottom of the proboscis cavity (Fig. 7), and the tegument of the anterior half of the proboscis (Fig. 8) play the most active role in lipid uptake. Interestingly, the proboscis hooks, too, can be considered organs well adapted to the task of lipid uptake (Figs. 7, 8). In accordance with their tapered and tipped construction (Fig. 7B) the hooks are in reach of lipid deposits which are not (yet) in contact with the surface of the praesoma. Behind the septum



Acanthocephala. Figure 5 Light micrograph of a longitudinally sectioned (paraffin section) anterior body of *Acanthocephalus lucii* attached to the intestinal wall of a river perch (*Perca fluviatilis*). Only the intestinal mucosa has been ruptured. A thin layer of collagen fibres (arrow) interiadly lining this epithelium was not perforated. Also note the proboscis cavity at the anterior tip of the worm showing the normal condition of the proboscis of a non-perforating species. ×20.



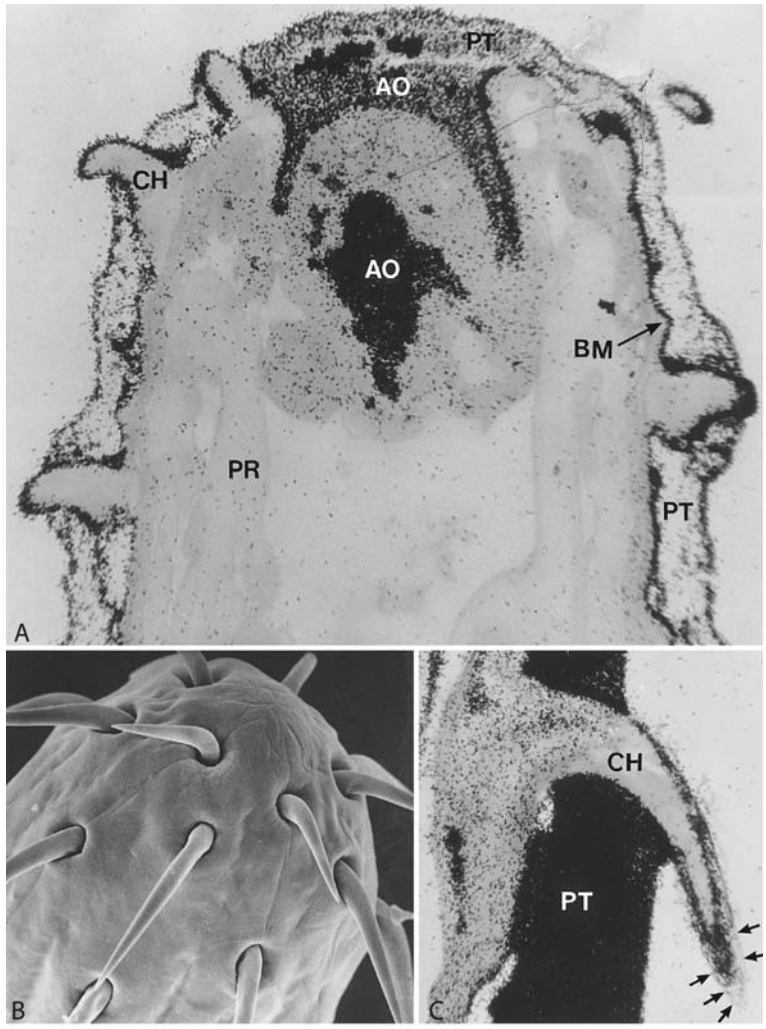
Acanthocephala. Figure 6 TEM of a transversally sectioned proboscis hook of *Acanthocephalus lucii* surrounded by necrotic and inflamed intestinal tissue of *Perca fluviatilis*. The hook: note the perforations in its →striped layer (SL); the connective tissue of the hook does not reach into the tip sectioned here. The hook has punctually perforated the layer of subepithelial connective tissue (SC) that can be seen in Fig. 5 at a lower magnification (arrow). But the proboscis *in toto* did not perforate this layer (LA: lamina of fine amorphous material lining the mucosal epithelium). The proboscis (not seen) is either in front or behind the plane of the section. × 2,000.

between praesomal and metasomal tegument the uptake of a →triacylglycerol as well as of →vitamin A was very low in *in vitro* trials. However, if "shoulders" of the metasoma were in contact with the praesomal surface during the exposition of a worm to the labelled nutrient, the shoulders too revealed a markable label (Fig. 8), suggesting that enzymes localized at the praesomal surface were involved. Uptake of amino acids as well as monosaccharides also occurs at the surface of the praesoma (Fig. 9), but the metasomal tegument seems to be the major absorptive surface for these substances.

Concerning the uptake of nutrients by adult perforating species, the mechanisms do not basically deviate from those described for non-perforating species. Since the whole praesoma is deeply embedded in the gut wall, a funnel for substances leaking into intestinal lumen is not very large. Intraintestinally attached worms that have a bulbus can be easily recognized at the gut's exterior side (→Acanthocephalan Infections/Fig. 6) but also in species without a bulbus, like *M. hirudinaceus*, a fibrous whitish →nodule with reddened annulation around it can be seen.

Integument

The tegument of acanthocephalans is a →syncytium of up to 2 mm in thickness (*M. hirudinaceus*). It either contains numerous small nuclei (Fig. 13C) or specific numbers of giant nuclei in eoacanthocephalans (Table 1). The nuclei of the tegument of the metasoma (trunk) are not immersed below the tegument (Fig. 13C). In the praesoma (proboscis and neck), however, the nuclei are harboured by the lemnisci; sack-shaped outgrowths of the praesomal tegument projecting into the body cavity (Fig. 16). The tegument is supported by underlying fibres of connective tissue, partly identified as collagen, of equal thickness in all parts of the body, and by cords of circular (only in the metasoma)

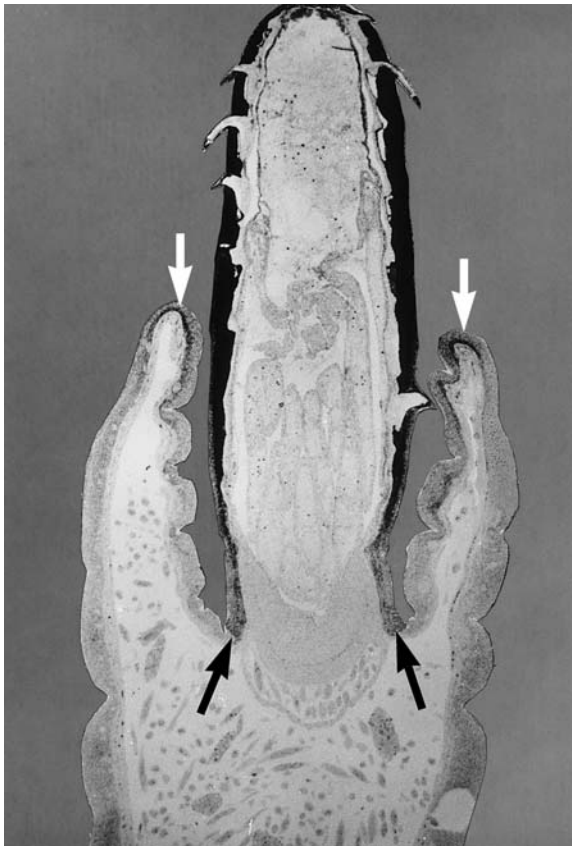


Acanthocephala. Figure 7 A–C Micrographs showing the proboscis tip and hooks of various acanthocephalans. **A** Longitudinal semithin section of *Paratenuisentis ambiguus* that had been exposed *in vitro* to [^{3}H]-glyceroltrioleate for 5 minutes. The proboscis is fully everted, which is not the normal condition *in vivo*. Note the intense label of the "apical organ" (AO). The lipid that has been taken up by the hooks and the surrounding tegument (PT) seems to be transported along the outer membrane and the basal membrane (BM) of the tegument; *CH*, connective tissue of a hook; *PR*, proboscis retractor muscle. × 3,500. **B** SEM of the tipped hooks at the anterior proboscis of *Acanthocephalus anguillae*. ×1,600. **C** Longitudinal semithin section of a proboscis hook of *A. anguillae* that has been exposed to [^{3}H]-labeled lipids. Note the labelled tegument of the hook underneath its striped layer. The proboscis tegument (PT) has already absorbed huge quantities of the lipid. × 3,000. *CH*, connective tissue of the hook.

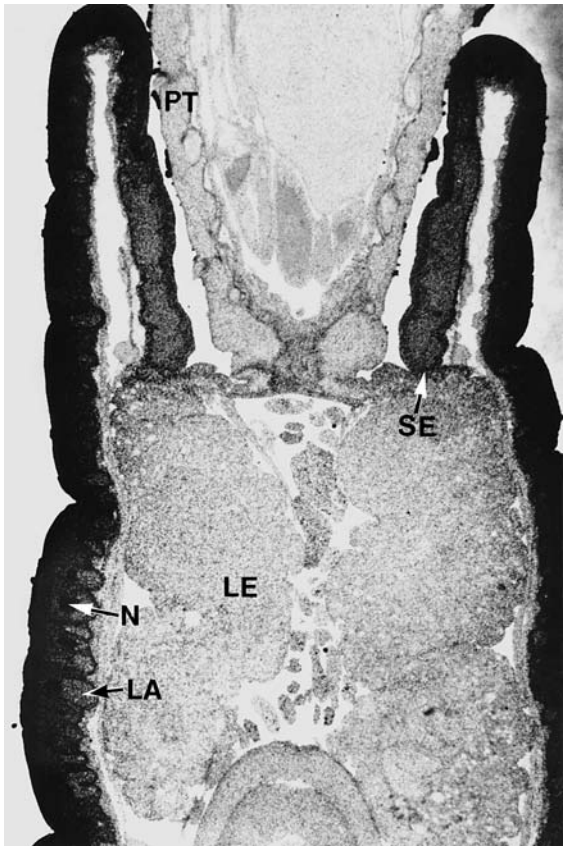
muscles and longitudinal muscles (in both parts of the body; Fig. 13C). These components together build up the body wall (Fig. 13C). The tegument shows a typical stratification and a differentiation related to the praesoma-metasoma organization of the acanthocephalan body.

Metasoma

- The syncytial tegument of the Acanthocephala is delimited by a plasma membrane carrying a filamentous →surface coat (Fig. 12A) which has a similar appearance in all systematic groups of these worms regarding the surface of the metasoma (Fig. 12, Table 1). This →glycocalyx also covers the pores (openings of the outer membrane's crypts) of the tegument. It may reach a thickness of up to one µm or more and obviously proteoglycanes are present in it. Infective larvae inside the intermediate host's hemocoel carry the most conspicuous surface coat. The plasma membrane itself forms densely set crypts projecting into the outer part of the tegument. Their greater density in the metasoma compared to the praesoma might have to do with the heavy competition pressure between the trunk surface being located inside the gut lumen, and the host's



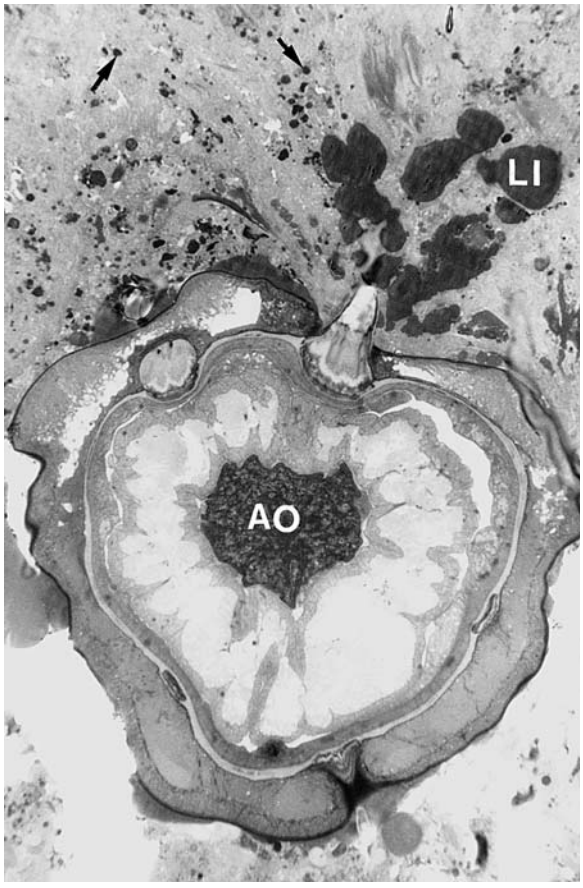
Acanthocephala. Figure 8 Longitudinally cut semithin section of the anterior body of an *Acanthocephalus lucii* that had been *in vitro* exposed to [^{3}H]-vitamin A for 15 minutes. Note the intense label of the anterior half of the proboscis tegument which lines the proboscis cavity normally formed. Behind the septum between the praesomal and the metasomal tegument (black arrows) almost no absorbance of the substance offered has taken place. However, it appears that the accidentally formed "shoulder" of the metasoma that obviously was in contact with the praesoma during the exposure has attained some label in its tegument (white arrows), suggesting that this part of the metasoma took advantage of enzymatic activity prevailing at the praesomal surface. ×60.



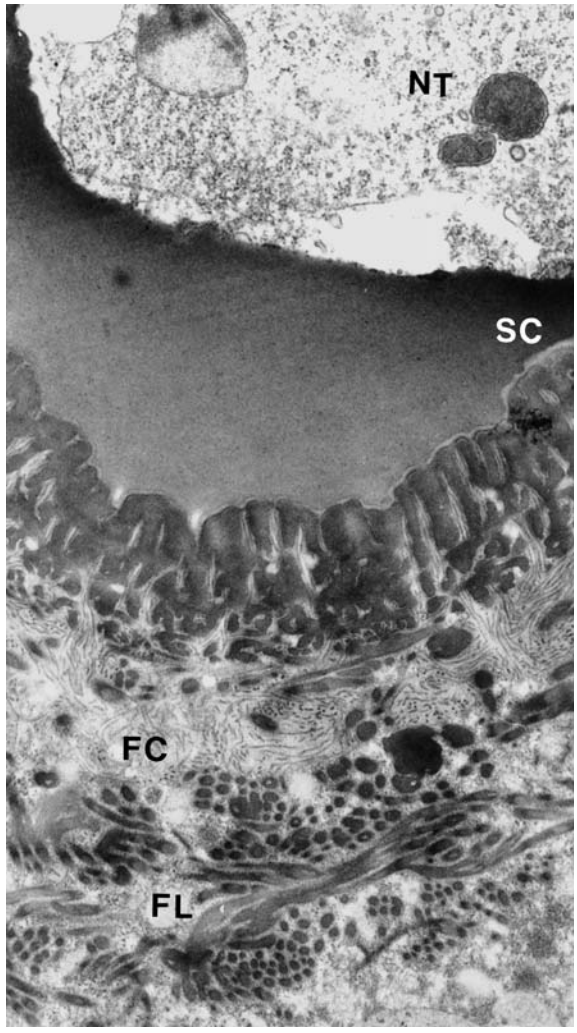
Acanthocephala. Figure 9 Autoradiographically treated longitudinal section of the anterior body of a female *Echinorhynchus truttae* that was exposed to [^{3}H]-lysine for 8 minutes. Note the less intense label of the presomal tegument (PT) compared to the metasomal tegument. ×100. *SE*, septum between the presomal and the metasomal tegument (compare Fig. 12B); *LA*, tegumental lacunar system; *LE*, lemniscus; *N*, nucleus.

intestinal mucosa for the absorbance of nutrients. The crypts have been calculated to increase the worm's "outer" surface 20- to 80-fold. The crypts have slender necks with electron-dense annulations underneath their outer openings (seen as pores by SEM) and they form branches directly underneath the pores or further inside the tegument. The crypts are considered extracytoplasmic digestive organelles which under the influence of surface hydrolytic enzymes maximize the opportunities of food absorption by these gutless worms. So it might be a point of debate whether the membrane limiting the lumen of the crypts really is an "outer" surface (Fig. 12).

- Interiadly, the outer membrane is supported by an electron-dense layer of about 5 μm in thickness. Due to perforations of this "→cuticle" by the crypts, this layer obviously having stabilizing functions is seen as a striped layer in TEM micrographs (Fig. 12). Usually the longitudinal extension of the membrane-crypts considerably exceeds the diameter of the striped layer, forming a spongy belt rich in pinocytotic activity (Fig. 12). This layer is considered a "→vesicular layer" by a few authors.
- The →feltwork layer adjoining underneath again seems to contribute to the skeletal task of the tegument but its diameter is about 5 times larger than that of the striped layer (→Acanthella/Fig. 1, showing this feature in the praesoma). It is characterized by fibres displaying no particular order, and normally it contains large amounts of →glycogen. Metasomal spines, present in many palae- and eoacanthocephalans (Table 1),



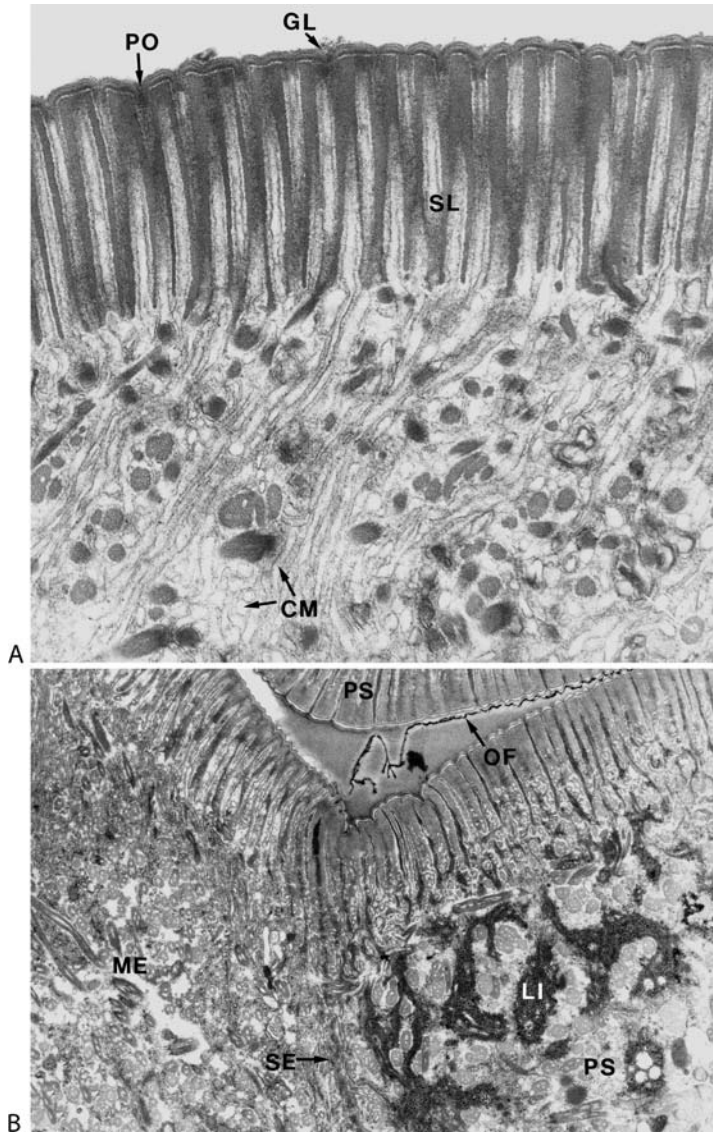
Acanthocephala. Figure 10 Semithin section of the proboscis of a specimen of *Neoechinorhynchus rutili* attached to the gut wall of a naturally infected juvenile rainbow trout. Note the conspicuous quantities of lipid (LI) accumulating at the worm's proboscis. They seem to derive from the surrounding necrotic tissue. Also, fused granules from degranulated eosinophilic granulocytes (arrow) are abundant, fusing with the lipid drops. In such a methylene-blue-stained section the lipid attains a greenish-golden colour while the fused granules are a deep blue. Thus both substances can be distinguished well. ×100. *AO*, apical organ.



Acanthocephala. Figure 11 Transmission electron micrograph of a section through the distal part of the praesomal tegument of *Acanthocephalus anguillae* (in a rainbow trout, 90 dpi). Note the thick lipoid surface coat (SC) between the tegument and the necrotic tissue (NT) at the point of attachment, also the fused crypts of the outer membrane (FC) with supporting microfibres in it and the underlying feltwork layer (FL). A section with little osmiophilic content of the fused crypts was chosen in order to show the microfibres in it. ×25,000.

have been described as outgrowths of the feltwork layer and are thus invested by a thin cover of a somewhat condensed striped layer. These trunk spines, often ornamenting a wider part of the ventral surface than of the dorsal side, are thought to act as additional →holdfast organs.

- The more proximal radial layer (Fig. 13C) occupies more than 70% of the tegumental diameter. This layer is considered to be the main metabolic centre of the acanthocephalan body. During the (allometric) growth of the worms it is mainly the increase in diameter of the radial layer which leads to a thicker tegument. This layer is characterized by radially arranged fibres connected to the basal membrane. Electron-dense matter accumulates around the spokes (Fig. 13C). This layer harbours the tegumental nuclei (Fig. 13C) and the major canals of the lacunar system (Fig. 14C). The lumen of this system is poor in organelles and electron-dense matter (Fig. 14C) and in autoradiographic trials it takes up and/or retains less nutrients than the surrounding →cytoplasm. Also its →glycogen content is low in contrast to the true radial layer, which usually stores plenty of this →carbohydrate. Apparently contractions



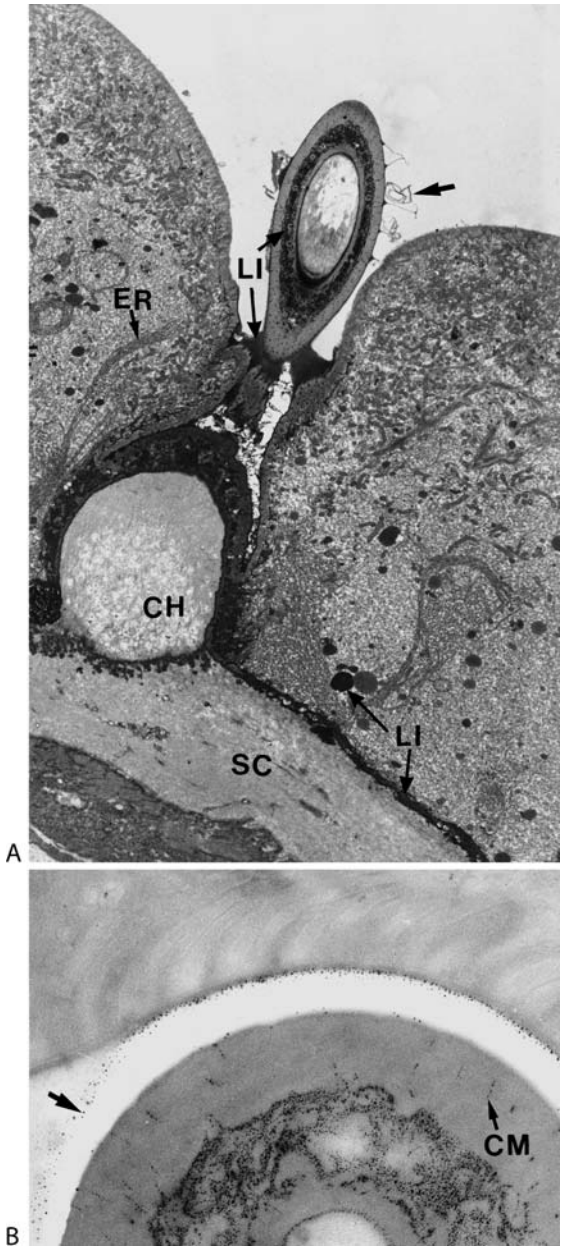
Acanthocephala. Figure 12 A, B TEMs of the distal part of the adult acanthocephalans' tegument. **A** Section through the metasomal tegument of *Acanthocephalus lucii*. Note the striped layer (SL) functioning as a cuticle. It is perforated by densely set crypts of the outer membrane (CM). *PO*, pore of a crypt; *GL*, glycocalyx (which is thin on the specimen shown here). **B** Section through the area around the septum (SE) separating the praesomal tegument (PS) (which is folded in this worm shown *in vivo*) from the metasomal tegument (ME) of *Acanthocephalus anguillae*. Note the abundance of lipid (LI) in the praesoma and the osmiophilic film (OF) obviously shed from the praesomal surface into the thick, apparently liquid surface coat of the praesoma. ×28,000.

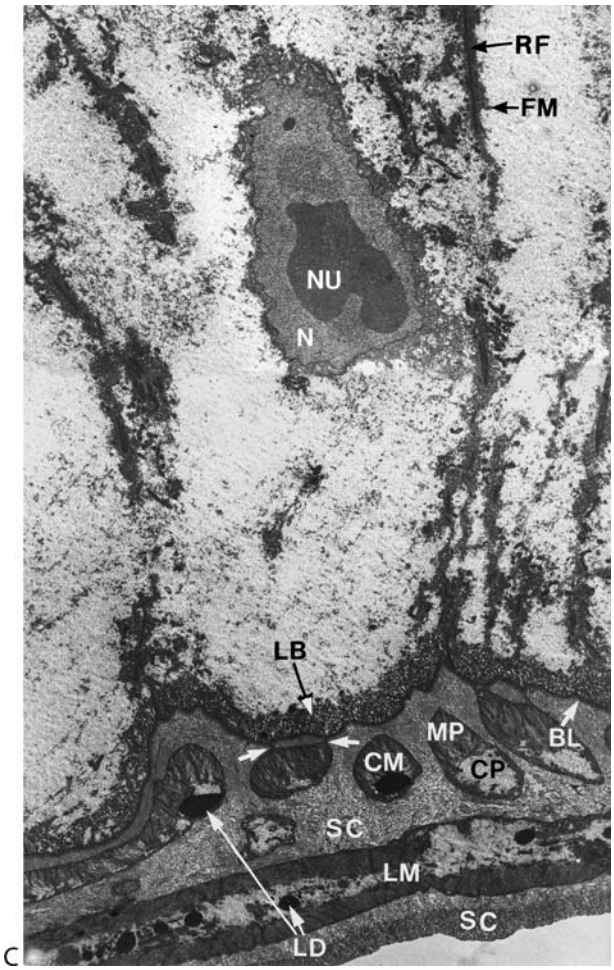
of the subtegumental musculature (Fig. 13C) act as the motive force for fluid flow inside the lacunas. However, it remains unclear whether these caverns fulfil functions of a circulatory system.

- The basal membrane, interiadly bounding the tegumental syncytium, shows a typical labyrinthine structure. Along its distal surface it is supported by amorphic matter, whereas a thin lamina of a fine matrix lines the proximal side of the membrane (Fig. 13C).

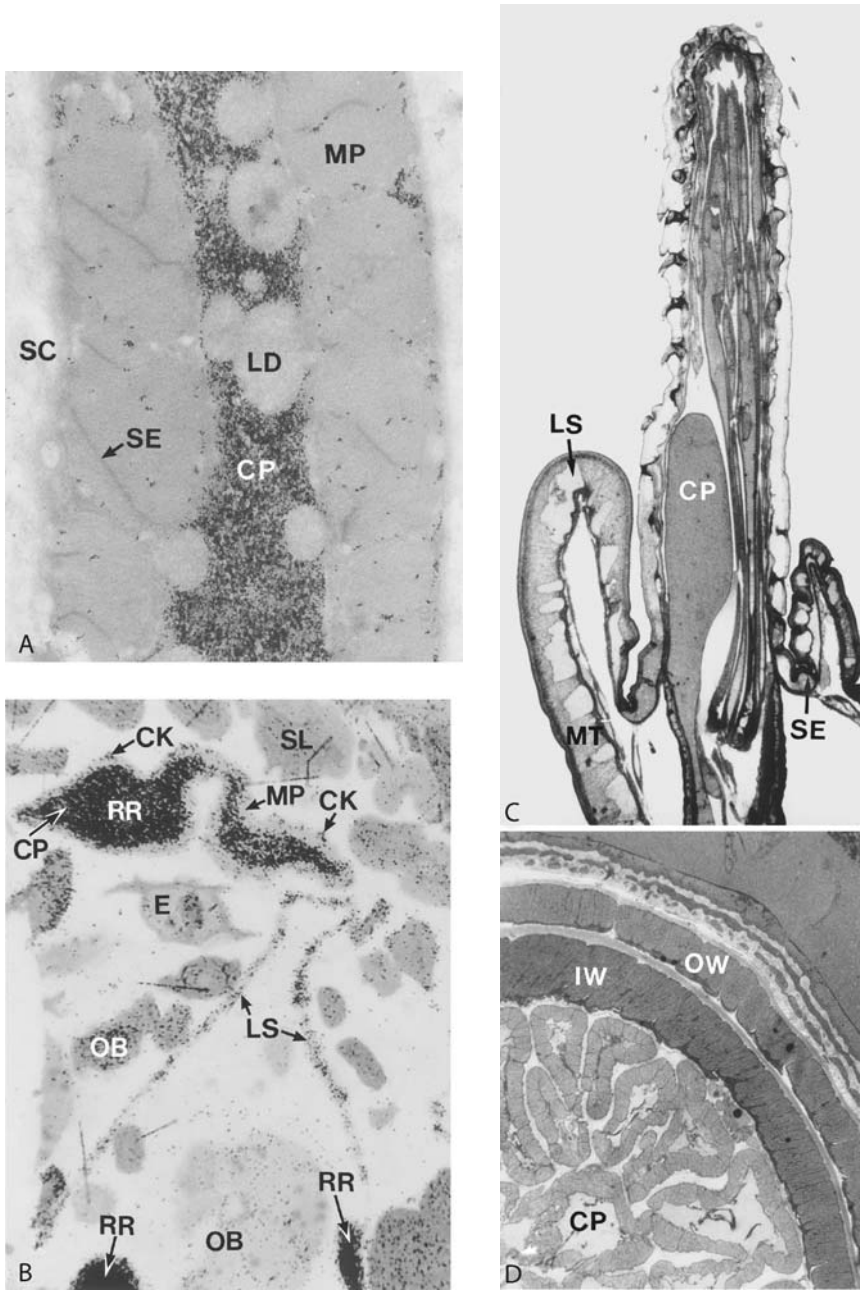
Praesoma

The tegument of the praesoma is separated from that of the trunk by a septum composed of fibres and adherent amorphic matter (Fig. 12B). So even the lacunar cavities are part of 2 different systems, which might make sense considering the assumed involvement of hydrostatic pressures in the protrusion, invagination, and retraction of the proboscis or the entire praesoma. Within the praesoma mainly the neck possesses lacunar cavities. The praesomal tegument reveals major differences compared to

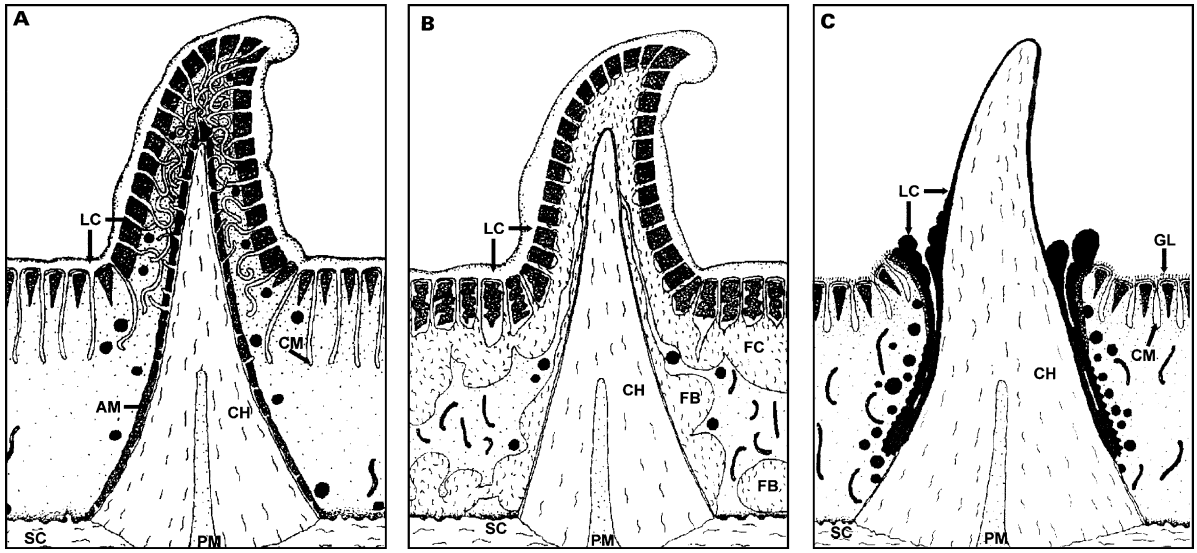




Acanthocephala. Figure 13 A–C TEMs of sections through the proboscis tegument and hooks of the eoacanthocephalan *Paratenuisentis ambiguus*. **A** The curved hook which is retracted in this micrograph is sectioned twice, at its connection with the subtegumental connective tissue (*CH*, connective tissue of the hook) and at its tipped outer portion. Note the lipoid substance (LI) being excreted through the pores in the hook, which (or a similar substance) is also abundant in the surrounding tegument; *SC*, connective tissue of the presomal tegument; *ER*, rough endoplasmic reticulum. ×10,000. **B** Cross section through a retracted hook and neighbouring proboscis tegument. The section has been treated according to the electron microscopical PAS-staining method by Thiéry. Note the mucus-like carbohydrates inside (*CM*, crypt of the hook's outer membrane) and outside the hook (arrow). × 56,000. **C** TEM of the basal part (radial layer) of the metasomal tegument of an adult *Acanthocephalus anguillae*. Note the radially arranged fibres (RF) with fibrous, electron-dense material (FM) attached to them, the labyrinthine basal membrane (LB) and the cords of subtegumental musculature (*CM*, circular muscle, *LM*, longitudinal muscle) consisting of an outer myogenic portion (MP) and an inner non-contractile portion (CP); *BL*, basal lamina, *LD*, lipid drop, *N*, nucleus, *NU*, →nucleolus, *SC*, subtegumental connective tissue. ×50,000.



Acanthocephala. Figure 14 A, B Micrographs of acanthocephalan muscles of *Paratenuisentis ambiguus* showing their bi-component construction comprising an outer myogenic belt (MP) and an enclosed cytoplasmic portion (CP). **A** Longitudinally ultrathin-sectioned subtegumental muscle of an infectious larva. The section has been treated according to the electron microscopical PAS method of Thiéry in a mode to visualize glycogen. Note the intense Thiéry label in the core of the muscle; *LD*, lipid drop, *SC*, subtegumental connective tissue, *SE*, septum. ×260. **B** Transversally semithin sectioned body cavity of an adult worm that was exposed to ^{3}H-glucose and then autoradiographically treated. The intense label in the cytoplasmic portion of the receptacle retractor muscles (RR) seems to be due to glucose-metabolites (probably mainly glycogen) incorporated in these muscles; *CK*, knobs on the muscle's surface also showing the bi-portion structure, *E*, egg, *LS*, ligament strand, *OB*, ovarian ball, *SL*, subtegumental longitudinal muscle. ×300. **C, D** Semithin sections of the praesoma (and partly the metasoma: C) of adult acanthocephalans. **C** Longitudinal section showing the cytoplasmic "finger" (CP) of the (inner) receptacle wall projecting into the proboscis. Also note the lacunar system (LS) inside the metasomal tegument (MT); *SE*, septum between praesomal and metasomal tegument. × 30. **D** Transverse section through the receptacle wall musculature (*IW*, inner wall, *OW*, outer wall) of *Acanthocephalus lucii*; note the tubular structure of the proboscis retractor musculature with its cytoplasmic cores (CP) of low density. × 150.

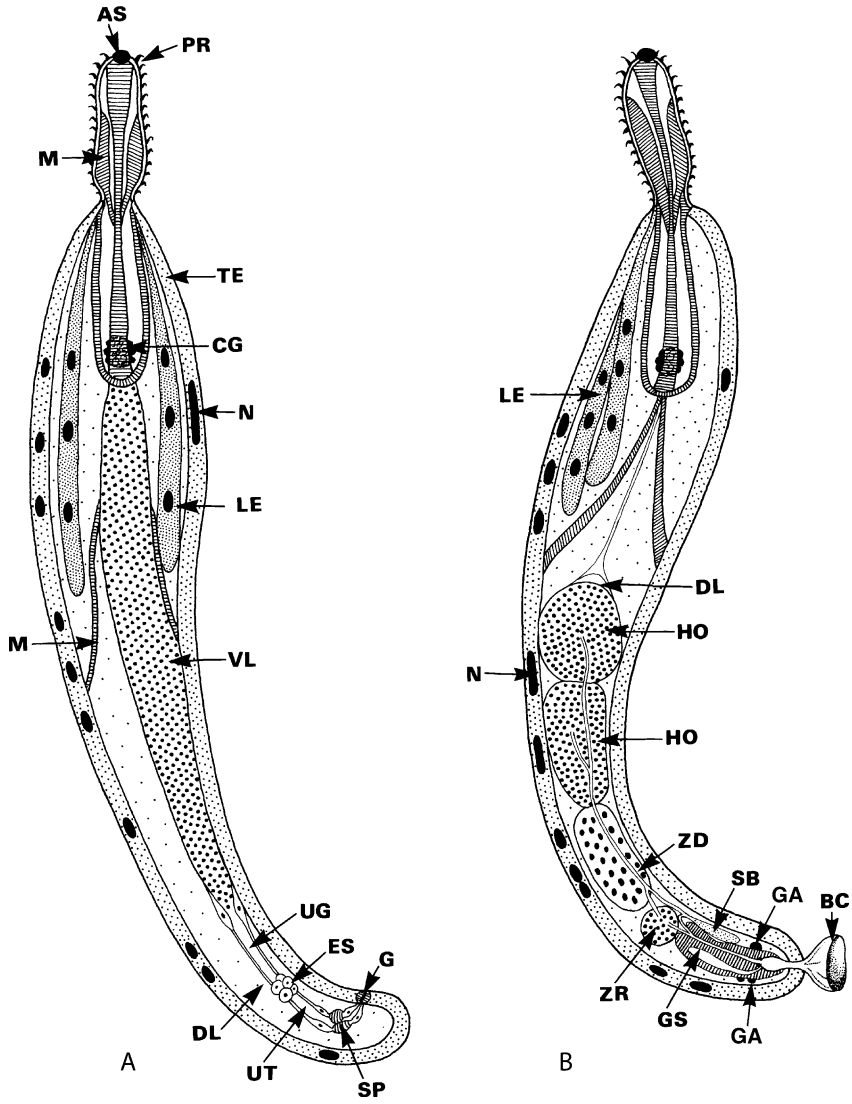


Acanthocephala. Figure 15 A–C **A** Schematic drawing of an eoacanthocephalan proboscis hook and surrounding tegument. Note the tegumental cover of the hook's connective tissue (CH), and the crypts of the outer membrane (CM) entangling with "crypts" of the tegument's basal membrane externally lining the connective tissue of the hook. These crypts perforate a layer of amorphic matter (AM) covering the connective tissue of the hook's tegument. *LC*, lipoid coat on the hooks and on the tegument; *PM*, finger-shaped protuberance of the subtegumental musculature; *SC*, subtegumental connective tissue. **B** Schematic drawing of a palaeacanthocephalan proboscis hook and surrounding tegument. Note the tegumental cover of the hook's connective tissue (CH), the lipoid coat (LC) on the tegument and the hook, the fused crypts of the outer membrane (FC) supported by fibres, and the fused crypts of the basal labyrinth (FB) which possibly are continuous with the latter fused crypts. *PM*, finger-shaped protuberance of the subtegumental musculature; *SC*, subtegumental connective tissue. **C** Schematic drawing of an archiacanthocephalan proboscis hook and surrounding tegument. Note that the connective tissue of the hook (CH) has no tegumental cover and is invested only by alipoid coat (LC) which is discharged by the tegument into the pouch surrounding the hook. The proboscis tegument carries a fuzzy →glycocalyx (GL), and the crypts of the outer membrane (CM) are not fused. *PM*, finger-shaped protube ance of the tegumental musculature; *SC*, subtegumental connective tissue.

that of the metasoma and these features become more prominent towards the anterior part of the proboscis. Generally, the praesomal tegument contains more amorphous, electron-dense matter, more →mitochondria, and rough and smooth endoplasmic reticulum (Fig. 13A) as well as lipid (especially in eo- and palaeacanthocephalans, Figs. 13A, 15) than the metasomal tegument. Interestingly, a submersion of the tegumental nuclei only occurs in the praesoma. The lemnisci harbouring the nuclei (Fig. 16) do not show a specific stratification like the tegument they branch away from. They too contain lacunar spaces, and are very rich in lipid.

The surface coat of the praesomal tegument reveals systematics-related specificities (Fig. 15) and shows interesting links with the host–parasite interactions (→Acanthocephalan Infections). The fine structure and obviously also the chemical composition of the surface coat vary among the classes. Regarding archicacanthocephalans the optical impression of the praesomal glycocalyx resembles that of the metasoma, although it is more coarsely structured and more osmiophilic than the latter. Shedding of the surface coat frequently or often occurs and seems to follow a complexation of host's anti-parasitic enzymes or antibodies with the surface coat (→Acanthocephalan Infections/Fig. 5A). Eoacanthocephalans and palaeacanthocephalans reveal a lipoid, non-fuzzy surface coat which may reach a thickness of several microns (Fig. 11) and shows a matrix which suggests a liquid or semiliquid condition. In addition to lipid, mucus-like carbohydrates are also present in it. Often osmiophilic films, perhaps representing a "glycocalyx," can be seen in it, and it is rather likely that these films are shed into the voluminous coat once the outer membrane has become loaded with anti-parasitic →peptides of the host's defense system (Fig. 12B). Unfortunately, the chemical properties of the acanthocephalan →surface coat have not been extensively studied to date.

The (pores of the) praesomal crypts are less densely set and the striped layer measures half or less in diameter than the trunk surface. In Palaeacanthocephala the single crypts are fused underneath the striped layer, forming large caverns with stabilizing fibres in them (Fig. 15B). The other systematic groups have retained their individual crypts (Fig. 15A, C). Generally, the strata of the tegument as described from the trunk cannot be well distinguished: due to the abundance of fibres



Acanthocephala. Figure 16 A DR of a female acanthocephalan (*Paratenuisentis ambiguus*, Eoacanthocephala) with emphasis on the sexual organs (most muscles omitted). lt has been reduced in size (length) compared with the male worm. The ventral ligament sac leading into the uterine bell is specific to eoacanthocephalans. Note the lack of genital ganglia (GA) in the female worm. For the inscriptions of the non-sexual organs see **B**. Eggs and floating ovaries inside the ligament sacs are not shown (Fig. 18A). **B** DR of a male acanthocephalan (*Paratenuisentis ambiguus*, Eoacanthocephala) with emphasis on the sexual organs. Most muscles are omitted. The single polynucleate cement gland and the presence of a cement reservoir and a seminal vesicle are specific to eoacanthocephalans. *AS*, apical sensory organ; *BC*, bursa copulatrix (evaginated); *CG*, cerebral ganglion; *DL*, "dorsal" ligament sac; *ES*, egg-sorting apparatus; *G*, genital opening; *GS*, Saefftigen's pouch; *HO*, testes; *LE*, lemnisk; *M*, muscle; *N*, giant nucleus; *PR*, proboscis with hooks (evaginated); *SB*, seminal vesicle; *SP*, sphincter; *TE*, tegument; *UG*, uterine bell; *UT*, uterus; *VL*, "ventral" ligament sac; *ZD*, cement gland; *ZR*, cement reservoir.

they often all together appear like a feltwork layer. The metasomal labyrinthine structure of the basal membrane is considerably reduced and instead its coating with amorphous material is more pronounced.

Proboscis Hooks

Irrespective of the systematic affiliation of the worms the hooks (Figs. 7B, 13A, B, 15) possess a central cone of connective tissue which partly has been demonstrated to contain collagen and/or →chitin. This major part of the hook arises from the subtegumental connective tissue. In its proximal part it encircles a finger-like projection of the subtegumental longitudinal musculature (Fig. 15). But this musculature tie is not present in all hooks of all species, implying that not all hooks can be individually retracted.

In eo- and palaeacanthocephalans the fibrous core of the hooks carries a condensed tegumental cover making these holdfast organs pointed (Figs. 13, 15A, B). The striped layer does not markably differ between eo- and palaeacanthocephalans but in eoacanthocephalans the crypts are not fused but entangle with finger-form protrusions of the tegument's basal membrane inside the hooks (Fig. 15A). In both of these subclasses the tipped hooks are capable of discharging lipid substances through their pores (Fig. 13A). Mucus-like carbohydrates also contribute to the excreted matter (Fig. 13B) and, rather likely, enzymes are also contained in it which thus far can only be hypothesized. The grease-like surface coat of the hooks may be very voluminous (Fig. 15). Amazingly, however, the hooks are also capable of absorbing nutrients from the host tissue surrounding them (see Food Uptake).

In archiacanthocephalans the hooks do not bear a tegumental vestment and the naked cone of the connective tissue, thus piercing the tegument, is less pointed than the hooks of the 2 other systematic groups (Fig. 15C). Obviously, the hooks attain their slippery surface cover by dipping into a pit encircling them; this annular cleft filled with a highly osmiophilic lipoid paste deriving from the surrounding tegument (Fig. 15C).

Uniformly in all systematic groups of the Acanthocephala, the close tegumetal surrounding of the hooks is rich in lipid droplets, mitochondria, and rough (Fig. 13A) as well as smooth endoplasmic reticulum, indicating elevated metabolic activity.

Proboscis Cavity

Contrary to the way in which acanthocephalans are usually shown in drawings made from dead worms (Fig. 16), *in vivo* and *in situ* the acanthocephalan proboscis is normally kept in a semi-invaginated position, especially among species with superficial attachment (Fig. 4). Thus a proboscis exhibiting a more or less deep anterior cavity resembling a mouth opening should be part of our idea of these gutless worms. Among eo- and palaeacanthocephalans inside the proboscis cavity the tegumental surface including the hooks appears as a labyrinth with remnants of host cells and tissue between its curves and with grease occupying all external niches of the labyrinth at its bottom plane.

In Archiacanthocephala the proboscis cavity is not filled with grease in its inner part and the labyrinth is lined by the fuzzy →glycocalyx described under →praesoma.

Musculature

Relatively few investigations have dealt with the fine structure of the acanthocephalan musculature. Some muscles, such as the receptacle retractor muscles, appear obliquely striated, e.g., fibres are connected to Z-line-like structures.

The basic feature of the acanthocephalan musculature is its 2-component structure composed of an outer myogenic, contractile belt and a cytoplasmic core enclosed by it (Figs. 13C, 14). The interior part seems to have a function in energy storage.

Usually glycogen is very abundant in it (Fig. 14A) and in autoradiographic experiments with labelled glucose, the glucose, or more likely metabolites of it like glycogen, accumulates in the cytoplasmic core (Fig. 14B). The cords of subtegumental musculature follow this bi-component composition (Fig. 13C), as do the retractor muscles (Figs. 14B–D). In addition the receptacle retractor muscles also carry small knobs on their surface which have non-contractile cores (Fig. 14B). In all these muscles the central non-contractile portion may contain plenty of organelles, mainly mitochondria, or may be rather electron-lucent, suggesting a higher fluidity than the latter cytoplasm. Inside the proboscis retractor musculature a low viscosity core should enable a quick directional shift of the enclosed cytoplasm when the proboscis cavity is formed or discontinued. An interesting differentiation is shown by the proboscis receptacle musculature enclosing and thus forming the hollow into which the proboscis can be retracted. In palaeacanthocephalans it consists of a double wall which has almost no non-contractile portion (Fig. 14D). In eoacanthocephalans it is considered single-walled but the "receptacle protrusor musculature" exteriadly surrounding the receptacle without being firmly connected to it probably represents the outer wall of the receptacle. It reveals the described 2-portion structure. The inner wall basically consists of a firm, contractile wall but on its dorsal inner side a conspicuous sack-shaped cytoplasmic outgrowth with a very narrow contractile outer cover projects into the posterior half of the proboscis (Fig. 14C). The cytoplasmic finger seems to function as the major glycogen deposit of the praesoma. In archiacanthocephalans the inner wall consists of plane myogenic tissue whereas the outer wall is formed by spirally arranged single muscle cords with non-contractile cores. Due to this spiral arrangement the retraction and protrusion of the praesoma (not only the proboscis can be invaginated) are performed in a torsion-like, screwing fashion.

Excretory System

Excretory products of most acanthocephalans seem to be released exclusively through the body wall, but it is not known whether this takes place through the whole tegument or through special regions. In addition,

oligacanthorhynchids and probably other archiacanthocephalans have protonephridia. Their efferent canals either lead into the vas deferens (male) or into the uterine bell (female). Two types of protonephridia are known:

- Dendric type: numerous flame cells drain into branched canals which lead into a central canal;
- Saccular type: the flame cells drain into an encapsulated bowl and a subsequent central canal.

Excretory products of acanthocephalans seem to be similar to other helminths, containing lactate, succinate, etc. Ethanol, however, has been described as the main excretory product of →*Moniliformis moniliformis*. There is still controversy over whether acanthocephalans are osmoconformers or not, but most species seem to have little osmoregulatory ability.

Reproduction

Acanthocephalan reproduction as well as the fine structure and genesis of the →oocytes and spermatocytes show some unique features.

Reproductive Organs

Acanthocephalans are →dioecious. Male worms are usually smaller than females, and in addition →sexual dimorphism may affect other features such as trunk spination. Only males have a pair of genital ganglia (and a bursal ganglion, so far only described for *M. moniliformis*), whereas both sexes have a →cerebral ganglion. Sensory papillae of the genital region are confined to males. And indeed only males seem to be active in finding a sexual mate and copulation. In female worms the sexual organs lie within 2 ligament sacs (Fig. 16A) which rupture in palaeacanthocephalans and some eoacanthocephalans. The male sexual organs are located within only one ligament sac (Fig. 16B).

The **male** gonads and accessory organs are enclosed by the dorsal ligament sac (the ventral sac does not persist in males), and further posteriadly, by the muscular genital sheath (Fig. 16B). The organs are attached to the ligament strand which keeps them in position. Males normally have 2 testes, but →monorchidism is rather frequent. A seminal vesicle may be present (Eoacanthocephala). The vasa efferentia fuse to form a vas deferens, which fuses with one or several ducts of the cement gland(s) to form a genital canal. Cement glands are significant accessory organs (1–8 in number), and eoacanthocephalans have a separate cement reservoir. The cement locks the female vagina after copulation until the first embryonated eggs are released, and forms typical copulatory caps on the posterior tips of inseminated females. But dominant males may also use this secretion to prevent inferior male competitors from fertilizing females of the respective infrapopulation. If protonephridia are present, the genital canal is joined by the (ciliated) excretory canal. The genital (or urogenital) canal leads into the →bursa copulatrix (Fig. 16B). The muscular terminal part of the genital canal inside the bursa is considered a penis. Additional accessory organs are the →Saefftigen's pouch and a few glandular structures associated with the bursa that are not yet well known. The fluid-filled muscular Saefftigen's pouch is connected with the lacunar system of the bursa tegument. By its contraction it regulates the hydrostatic pressure of the bursa and thus its protrusion or invagination (Fig. 16B).

The **female** reproductive system consists of 2 major tubes:

- The ligament sacs (or the pseudocoel if the sacs are ruptured) that contain the →floating ovaries (ovarian balls).
- An efferent duct system including a complex →egg-sorting apparatus which is unique among helminths.

The 2 ligament sacs are interconnected at their anterior end. Posteriad, one sac leads into the uterine bell while the other is connected to a lateral opening of the subsequent apparatus (Fig. 16A).

The muscular efferent duct consists of the uterine bell, the egg-sorting apparatus, the uterus, and the vagina which is enclosed by 1 or 2 genital sphincters (Fig. 16A). Eggs from the dorsal (Archiacanthocephala) or ventral (Eoacanthocephala) ligament sac are "sucked" into the funnel-shaped bell which leads into a narrow duct. The subsequent egg-sorting apparatus of *M. moniliformis* consists of 2 lateral pockets, 2 dorsal median cells, 2 anterior ventral median cells, 2 posterior ventral median cells, and 2 lappet cells. It ensures that normally only embryonated eggs are found in the host's faeces. By a complex interaction between the muscular activity of the bell wall and the cells and pockets of the apparatus, only embryonated eggs are allowed to enter the uterus, while immature ones are forced back into the ventral (Archiacanthocephala) or dorsal (Eoacanthocephala) ligament sac. The egg-sorting mechanism is not fully understood. The uterus is surrounded by layers of muscles and fibrous material. The vagina is a narrow duct which connects the uterus with the gonopore (Fig. 16A) and was found to carry glandular appendages in some species. The gonopore of a few species is surrounded by genital spines, and after insemination is generally blocked by a copulatory cap imposed on it by the male until eggs are released.

Gametogenesis

Acanthocephalan reproduction as well as the fine structure and genesis of the oocytes and spermatocytes show some unique features. Acanthocephalan

→spermatozoa are filiform (Fig. 17) and consist of a nucleocytoplasmic spermatozoan body rich in glycogen, and a flagellum. They measure 20–80 μm in length depending on the species, and obviously do not posses mitochondria or acrosomes. They contain a longitudinal chromatin strand (which is not membrane bound), 2 lateral rows of "dense inclusions" of unknown function and a →centriole which gives rise to the flagellum. The →axoneme of the free flagellum consists of →microtubules which in most species are arranged in a (9 × 2) + 2 pattern, but also either 1 or 3 central tubuli have been found even within one species. The microtubules may show typical dynein arms, but the pattern is not consistent (Fig. 17). Among the phases of →spermatogenesis the spermiogenesis is best described. It is characterized by several events:

- The centriole of the flagellum migrates from the posterior to the anterior region of the spermatid while the spermatids are still connected in clusters (Fig. 17B) by cytophoral stalks. The flagellum then extends slightly posteriorly (while the nucleus becomes elongated) and finally it extends greatly anteriorly (Fig. 17C). Thus, as a result of this extension the spermatozoan body becomes reversed in relation to the free flagellum.
- The nuclear membranes disintegrate to form the nucleocytoplasmic body (Fig. 17A, C). Only a remnant of the nuclear envelope remains.
- The mitochondria disappear from the spermatozoan body.
- The spermatozoan body detaches from the spermatid's residual body containing the mitochondria.

Several species of acanthocephalans have been found to be precocious, e.g., mature spermatozoa have been found in male larvae.

Mature oocytes are spherical cells that lie below the surface of the free-floating ovaries (ovarian balls) and show typical electron-dense inclusions (Fig. 18A, C). The floating ovaries derive from the ovarian primordium of some larval stage. Immature floating ovaries have a thick surface coat and lack microvilli-like structures of their outer membrane. Mature ones consist of 2 syncytia, i.e., the central oogonial syncytium and the peripheral supporting syncytium. Furthermore they contain developing oocytes which seem to derive from the oogonial syncytium. The superficial supporting syncytium reveals microvilli-like outgrowths of its surface which absorb nutrients from the body cavity, as can be demonstrated by autoradiographic experiments. Fertilized ovaries (and unfertilized mature ovaries of a few species) apparently lose their →microvilli (Fig. 18C). The actual process of oogenesis from oogonia to mature oocytes is not yet well known.

Fertilization

Acanthocephalan females may become inseminated subsequently several times. But little is known about how the worms attract each other – if they do so – prior to copulation and insemination. According to observations by Richardson et al. in the palaeacanthocephalan →*Leptorhynchoides thecatus*, parasitizing in green sunfish, mate finding follows a very simple pattern. Individuals of both sexes are usually positioned inside the pyloric ceca in a mode such that their posterior ends extend into the intestinal lumen within the small area from which the ceca orginate. So emigration to find a mate is unnecessary (see also →Behavior). There is still a lack of evidence about the function of the copulatory cap which locks the vagina of inseminated females during the prepatent period. Some philosophical debate has been held about the applicability of the "→selfish gene theory" preventing males with inferior genes from reproduction. There are still open questions on acanthocephalan copulation and fertilization.

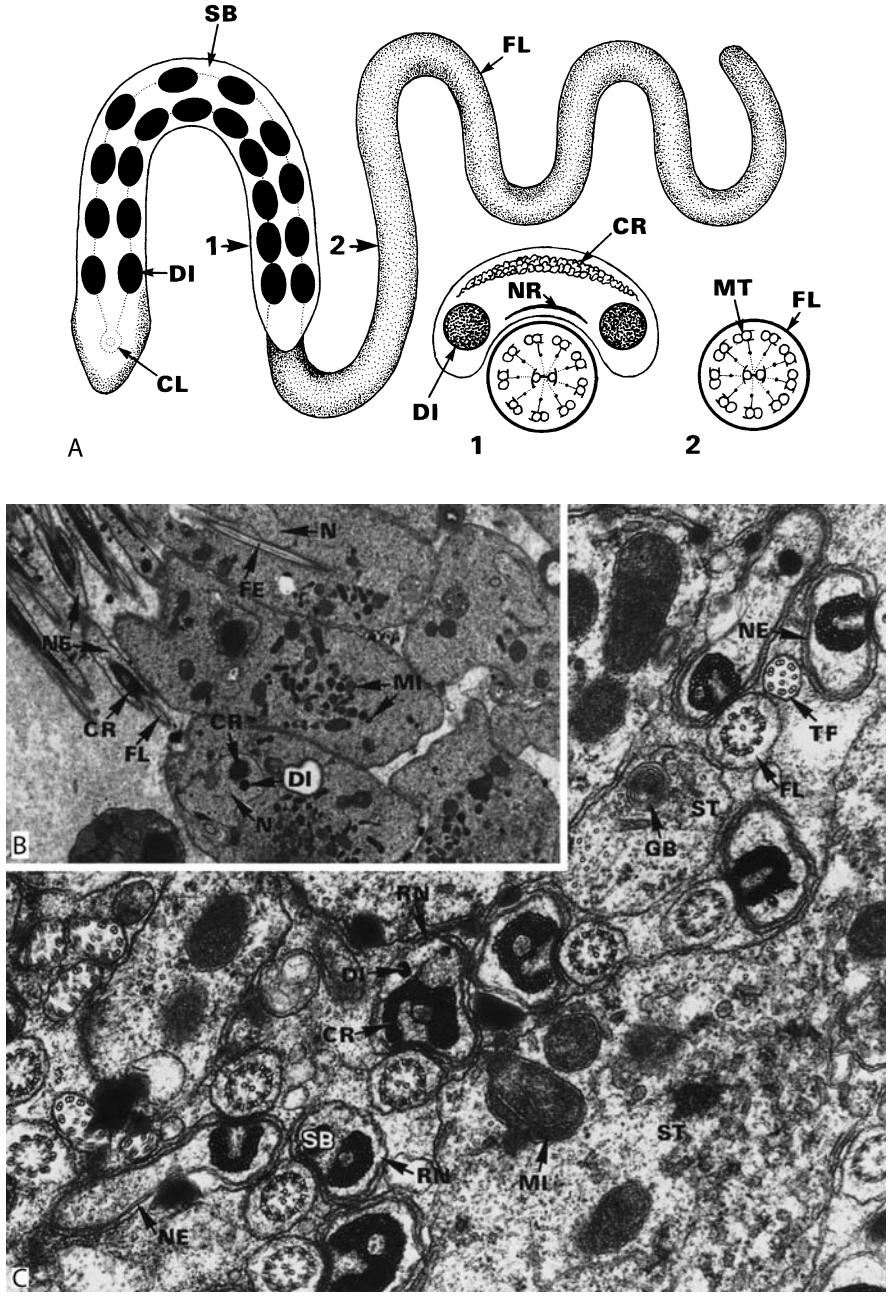
The following steps of fertilization have been documented: oocysts become fertilized whilst lying underneath the surface (syncytium) of an ovary. The flagellum of the sperm attaches to the surface of the ovary (Fig. 18B), which leads to an inflation of the flagellar apex. The subsequent penetration of the spermatozoan through the supporting syncytium into the oocyte (Fig. 18C) apparently initiates meiosis and the formation of polar bodies. The electron-dense inclusions of the mature oocyte move to the periphery and initiate the formation of a →fertilization membrane around the →zygote. The zygote now becomes ovoid and gives rise to a fertilization gap between its surface and the supporting syncytium of the ovary.

Postzygotic Development

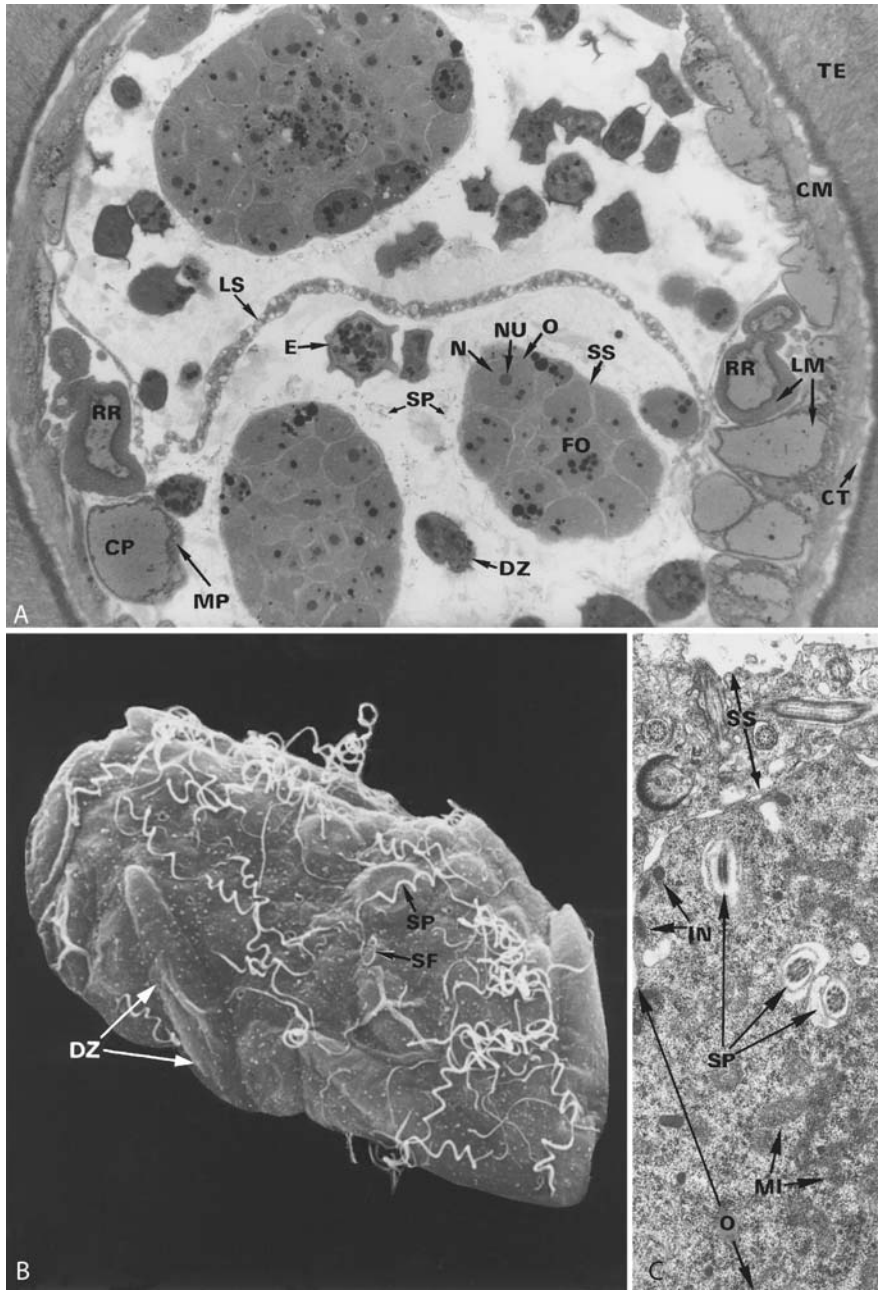
The first step of postzygotic development is the formation of the first larva, the →acanthor.

Females of all acanthocephalans release fully embryonated eggs. Prepatent periods of worms from homoiothermic hosts last between 22 days (*Polymorphus minutus*) and 70 days (*Macracanthorhynchus hirudinaceus*); in poikilothermic hosts development depends on the temperature. These same 2 species may remain patent for a maximum of only 25 days (*P. minutus*) or for up to 10 months (*M. hirudinaceus*).

After being taken up by the →intermediate host the acanthor changes its morphology and becomes an →Acanthella – the stage between the acanthor and the larva that is infective to the final (or paratenic) host.



Acanthocephala. Figure 17 A–C Acanthocephalan spermatozoan and spermatid morphology. **A** DR of an acanthocephalan spermatozoan. *1, 2* Transverse sections through the spermatozoan body (× 2) and through the flagellum (×3). **B** Transmission electron micrograph of a cluster of spermatids of *Echinorhynchus truttae* in the process of nuclear and flagellar elongation, i.e., spermiogenesis. Note the numerous mitochondria (MI) inside the spermatids. × 6,840. **C** TEM of a transverse section through spermatids (ST) and early spermatozoans (SB) of *E. truttae*. Note the apparent lack of mitochondria in the spermatozoan body and the rupturing nuclear envelopes (RN) in some spermatozoans. ×39,900. *CL*, centriole; *CR*, chromatin; *DI*, electron-dense inclusions; *FE*, flagellum extending from the anterior part of a spermatid posteriad; *FL*, flagellum; *GB*, Golgi body; *MI*, mitochondrion; *MT*, microtubules with dynein arms; *N*, nucleus; *NE*, nuclear envelope; *NR*, remnant of nuclear envelope; *RN*, rupturing nuclear envelope; *SR*, spermatozoan body; *ST*, spermatid; *TF*, terminal flagellum.



Acanthocephala. Figure 18 A–C Micrographs of acanthocephalan floating ovaries and fertilization of the enclosed oocytes. **A** LM. Floating ovaries (FO) are contained within the 2 ligament sacs which are separated by the fibrous ligament strand (LS) (*Paratenuisentis ambiguus*, Eoacanthocephala). Note the oocytes (O) lying underneath the surface syncytium (SS) of the ovaries, adhering sperms (SP), the detached zygotes (DZ), and the shell-coated developing eggs (E). × 260. **B** SEM. A floating ovary from the body cavity of *Acanthocephalus anguillae* (Palaeacanthocephala) shows numerous sperm at its surface. The flagellum is visible as a slender prolongation of the spermatozoan body. Note the detaching zygotes (DZ) which already resemble the spindle shape of the mature eggs. × 4,560. **C** TEM. Sperm have penetrated the surface syncytium and the underlying oocyte (zygote?) of a floating ovary of *Neoechinorhynchus rutili*. The accumulation of "inclusions" (IN) at the oocyte's margin seems to follow fertilization and possibly initiates the formation of the eggshell. × 16,450. *CM*, circular musculature; *CP*, cytoplasmatic part of muscle; *CT*, connective tissue; *DZ (black)*, detached zygote; *DZ (white)*, detaching zygote; *E*, shell-coated developing egg; *FO*, floating ovaries; *IN*, inclusion; *LM*, longitudinal musculature; *LS*, ligament strand; *MI*, mitochondria; *MP*, myogenic part of muscle; *N*, nucleus of oocyte; *NU*, nucleolus of oocyte; *O*, oocyte; *RR*, receptacle retractor muscle; *SP*, spermatozoa; *SS*, surface syncytium of floating ovary; *TE*, worm's tegument.

Acanthocephalacidal Drugs

General Information

The large to medium-sized →acanthocephalans are thorny (spiny)-headed worms with an elongated →proboscis armed with recurved hooks parasitizing the digestive tract of a wide range of vertebrate animals throughout the world, and occasionally found in humans. They have been placed in their own phylum since their affinities to other parasites are not well defined. The sexes are separate, males being much smaller than females. The life cycle of acanthocephalans infecting mammals involves intermediate hosts. There are a number of genera in the dung beetle family Scarabaeidae and cockroaches containing the infective stage of worm (→Cystacanth, which is really a young adult) or vertebrates, which act as paratenic hosts (e.g., mice, and frogs) harboring re-encysted cystacanths. No acanthocephalans are primarily human parasites.

Two species of these worms may infrequently infect humans more often than others. One species is →*Moniliformis moniliformis*, which commonly parasitized rats and other **rodent hosts**, the other *Macracanthorhynchus hirudinaceus* (adults resemble *Ascaris suum*), a common parasite of pigs and wild boars, ubiquitous in areas where **pigs** are kept free. The final host (swine, occasionally man) becomes infected by ingesting either the infected grubs or the adult beetles and rarely the infected vertebrate. Infections may frequently occur in China and Indonesia and other parts of Southeast Asia, but also in most other countries of the world though *M. hirudinaceus* is absent from Western Europe. In **humans**, the adult worms, which are attached to the wall of the small intestine, cause diarrhea, GI disturbances, and →vomiting but also serious complications, such as severe ulcerative enteritis or perforation of the bowel resulting in peritonitis. The pathogenic significance of *M. hirudinaceus* is similar for pigs causing →granuloma formation at the site of attachment in the small intestine, →weight loss and, rarely in heavy infections, penetration of the intestinal wall resulting in fatal peritonitis.

Very important parasites of Central and South American **monkeys** are →*Prosthenorchis elegans* (very common), and *P. spicula* (less common). These acanthocephalans are now found throughout the world where primates are kept in zoos or elsewhere in captivity and where they have introduced the parasites. In heavy infections there is diarrhea, →anorexia, and debilitation often associated with death caused by perforation of the intestinal wall by adult worms.

There are 2 genera which may cause enteritis in **aquatic birds**, e.g., *Filicollis* (*F. anatis*) and *Polymorphus* (*P. minutus*). The intermediate hosts in both cases are crustaceans. Pathogenic effects produced by adult worms attached to the intestinal wall resemble those that are seen in mammals.

Pathogenicity of numerous **fish** acanthocephalans is species-specific and varies considerably. There are species which penetrate through the intestinal wall, thereby entering the body cavity of fish. Other species remain in the lumen of intestine, showing frequent or less frequent change of attachment site. Intermediate hosts are crustaceans, and various fishes may serve as paratenic hosts. In the fish industry disastrous economic losses may be due to acanthocephalans, especially when fish farming is practiced with overcrowded fish populations.

Prevention and Treatment

Prevention and treatment of →Acanthocephala infections can be seen in Table 1, which are in general problematic. In man, usually Acanthocephala eggs are not passed with the feces since worms may not mature to adults. Diagnosis is made by x-ray examination or endoscopy. Serological tests are not available.

Acanthocephalacidal Drugs. Table 1 Control and treatment of acanthocephala infections in humans and animals

Host (other information)	**Parasite** (other information)	**Control and treatment** (nonproprietary name, miscellaneous comments)
Humans acquire the parasite by ingesting beetles as food	*Macracanthorhynchus hirudinaceus* (pig), *Moniliformis moniliformis* (rodents)	Prevention can be effected by rodent control and keeping of food intended to be eaten cold in beetle-proof containers may help to prevent accidental infection; treatment is not well established; **niclosamide** (→Cestodocidal Drugs) has been successfully used in Nigeria, loperamid hydrochloride, an antidiarrheal agent, proved very active in *M. hirudinaceus* infected pigs (see below); in China, surgery is often practiced to remove adult worms from heavily infected patients

Acanthocephalacidal Drugs. Table 1 Control and treatment of acanthocephala infections in humans and animals (Continued)

Host (other information)	**Parasite** (other information)	**Control and treatment** (nonproprietary name, miscellaneous comments)
Pig, wild boar (other occurring in carnivores like wolf, domestic dog, badger, fox), others are *M. catalinum*, and *M. ingens*, *Oncicola canis*	*M. hirudinaceus* **egg** containing the acanthor larva with rostellar hooks is large, ovoid and has a thick, dark brown, textured shell **egg** of *O. canis* is relatively small, ovoid, brownish, and has a smooth, thick shell	Where pigs are kept in small sties or runs regular removal and suitable disposal of feces containing eggs will help in reducing the infection; older drugs such as carbon tetrachloride, tetrachlor-ethylene, and nicotine sulphate have been used; the drug of choice appears to be **loperamid** hydrochloride which at 1.5 mg/kg twice daily × 3 days kills 100% adult and pre-adult worms without showing side effects; **fenbendazole** (→ Nematocidal Drugs, Animals) at 20 mg/kg × 5 days and levamisole may also be effective; a single intramuscular dose of 0.3 mg/kg **doramectin** reduced *M. hirudinaceus* worm burden in naturally infected pigs by 62%
Monkeys infection may be common in zoos	*Prosthenorchis elegans* *P. specula* **eggs** in feces are smaller than those of *M. moniliformis*	Insecticides and good sanitation will control the intermediate hosts (cockroaches, *Blattella germanica);* dithiazinine iodide has been effective; other drugs (see pig) may also affect adult worms and may be used by way of trial
Hedgehog adult worms of different species measure 0.5– 12 cm in length	*Prosthenorchis rosai* *Nephridiorhynchus major* and others **eggs** in feces have a thick shell	Pathogenic effects of adult worms may be ulcerative enteritis, GI disturbance and peritonitis caused by perforation of intestinal wall; intermediate hosts are insects; prevention is not possible; treatment with fenbendazole (20–50 mg/kg × 5 days in feed), other benzimidazole carbamates (→Nematocidal Drugs, Animals), loperamid or levamisole may be used by way of trials
Rodents (mice, rats) parasite has a worldwide distribution	*M. moniliformis* **egg** is larger than that of *M. hirudinaceus*, elongated oval, has a thick, smooth, clear shell	Strategic use of insecticides may control intermediate host (cockroaches) in laboratories; treatment of rodents is similar to that used with *M. hirudinaceus* (see hedgehog, above); infections have been reported on rare occasions in humans and are acquired by accidentally ingesting of beetles with food; adult worm has a pseudosegmentation of the body; adult female worm can reach >20 cm in length
Aquatic birds parasite has minor veterinary importance	*Filicollis anatis* *Polymorphus minutus* (syn. *P. boschadis*) **eggs** in feces are relatively small and spindle-shaped	Worldwide distribution; prevention is impossible because of the ubiquitously occurring freshwater isopods and other crustacean intermediate hosts; treatment is unknown but fenbendazole (20–50 mg/kg × 5 days in feed), other benzimidazole carbamates (→Nematocidal Drugs, Animals), and loperamid may be used by way of trial; acanthocephalan infections

Acanthocephalan Infections

Attachment

Generally, acanthocephalans that have a short →neck do not deeply penetrate into the host's intestinal wall with their →praesoma, i.e., they do not create lesions reaching as deep as the muscular layers of the intestinal wall (→Acanthocephala/Fig. 4). In contrast, many acanthocephalans possess a long neck which may comprise a bulbus as an inflated part of the neck (Figs. 1, 6). The bulbus functions as a dowel enabling the worm to occupy a permanent point of attachment at one site. Long-necked species perforate the tunica muscularis or the whole intestinal wall of the hosts with their praesoma (Fig. 1). In small hosts with thin intestinal wall parts of the metasoma (Fig. 2) or entire worms may be found in extraintestinal positions. The perforation of the intestinal wall may be supported by proteolytic enzymes.

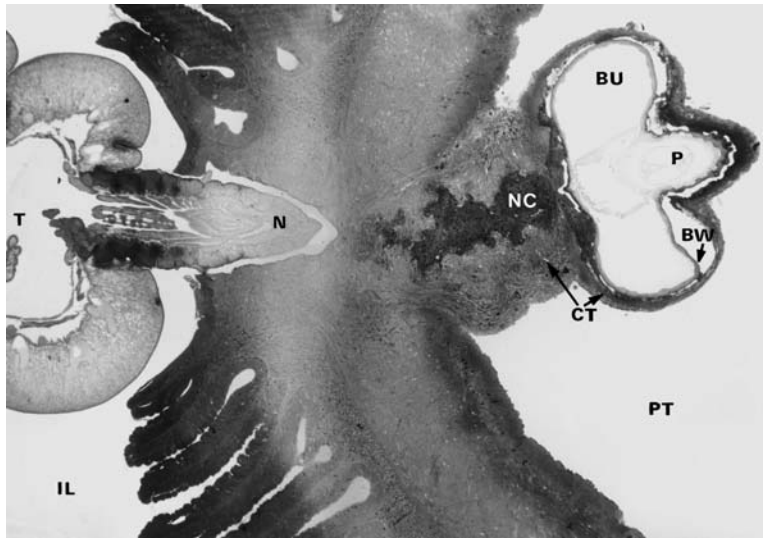
Cellular Host Responses

Successive Cell Assemblages

The specific composition of host cells accumulating at the worm's praesoma follows a certain sequence which is related to the worm's mode of attachment. During the first days p.i. only necrotic tissue surrounding the praesoma can be found. After about 3–5 days p.i. a belt of inflammatory tissue with haemorrhagic involvement starts forming (Fig. 7). From about 10 days p.i. onwards the further succession of cell assemblages depends on the type of attachment. At the praesoma of perforating species the inflammatory tissue becomes dominated by macrophages maturing into epitheloid cells and another belt of connective tissue which attains a blue colour in Azan-stained paraffin sections, starts forming (Fig. 2). Later on, this belt may become considerably reinforced and interspersed with fibroblasts and →collagen fibres and an outer belt of connective tissue (Fig. 3B, C) sometimes consisting of plane collagen fibres (Fig. 3C) is built up. The attachment site of the eoacanthocephalan →*Neoechinorhynchus rutili*, although non-perforating, is characterised by a pronounced accumulation of collagen fibres (Fig. 3A). In contrast, species with shallow attachment seem to change their point of attachment prior to the formation of connective tissue at the site of the temporary anchorage, and a concentric zonation of neoplasic tissue around the parasite's praesoma does not emerge. Haemorrhagic spots (Fig. 7B) may occur in all the tissue belts mentioned here.

Longitudinal Zonation of Defence Cells

Among perforating species like →*Pomphorhynchus laevis* the chronic stage of infection not only reveals concentrically arranged belts of necrotic, inflammatory, and connective tissue (Fig. 1) but also a longitudinal zonation can be figured out. Near or inside the peritoneal cavity the necrotic belt is very conspicuous. It is very



Acanthocephalan Infections. Figure 1 Micrograph of a semithin section of *Pomphorhynchus laevis* (penetrating species) in a naturally infected adult chub (*Leuciscus cephalus*). The upper praesoma (e.g., *P*, proboscis; *BU*, bulbus; upper neck not visible) has penetrated the host's peritoneal cavity (*PT*). The praesoma has become encapsulated by connective tissue (*CT*) which degenerates in close contact to the worm's anterior neck and its bulbus. ×40 *BW*, bulbus wall; *IL*, intestinal lumen; *N*, neck; *NC*, →necrosis; *T*, trunk (metasoma).

rich in lipids that seem to become absorbed by the worm's →tegument. In contrast, at the lumen side of the intestinal tube the necrotic belt almost does not exist and defence cells form a closely fitting belt of solid compensatory tissue (Fig. 1). The question arises whether this zonation is host-or parasite-induced. Taking also the histopathology of *N. rutili* into consideration (Fig. 3A) it appears that the described zonation of the host's tissue is largely brought about by the parasite.

Proboscis Hooks

Irrespective of the type of construction, i.e., whether a tegumental outer cover exists (compare →Acanthocephala/ Fig. 15) the hooks always provoke the most pronounced accumulation of granulocytes. In *N. rutili* the small roundish →proboscis with its large hooks the attracting of granulocytes towards the hooks, and the surrounding tegument is very severe in salmonids and other fish during the acute initial phase of the infection and it has been suspected that this is induced by the parasite benefiting from it in aspects related to nutrition or attachment (Fig. 4B).

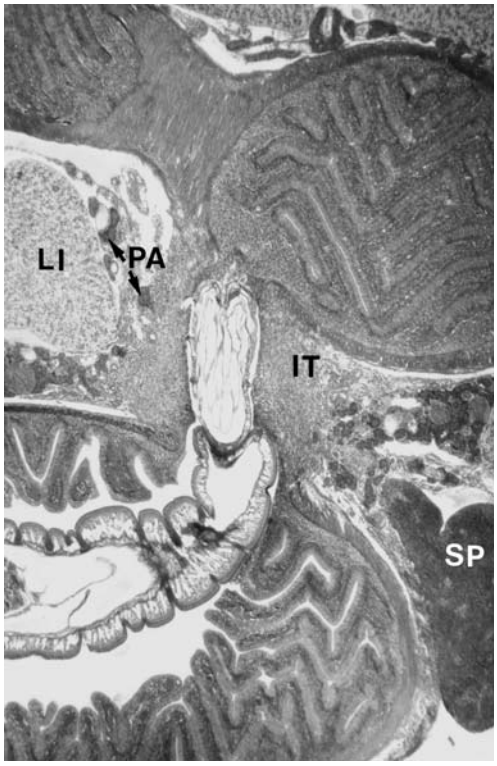
Infections in Fish, Birds, and Mammals

In contrast to the paucity of information available on many aspects of host–parasite interactions of acanthocephalans, these worms are very common in many wild-living vertebrates as well as cultured fish. Species like →*Moniliformis moniliformis* can be easily kept in a laboratory in cockroaches and rats. It offers huge quantities of tissue and Surface Coat. So it would be very useful for physiological and molecular studies.

In fish hosts the inflammatory response is dominated by granulocytes (Fig. 7) and marcrophages/epitheloid cells depending on the conditions described above. Usually eosinophils are the most abundant granulocytes (Fig. 7A) but in eels, for instance, eosinophilic granulocytes rarely occur and thus heterophilic granulocytes dominate in the tissue near the praesoma of →Paratenuisentis ambiguus or other parasites of eel. Fish-specific melano-macrophages, also may occur near the acanthocephalan praesoma. Plasma cells, however, (documented from fish) also may occur but do not seem to play the same role as, for instance, in mammals. In fish immunoglobulins develop relatively slowly during the course of an infection, precipitms are rare, and the only immunoglobulin class produced is IgM being better at agglutination and complement activation than precipitation. Very little is known about the use of antibodies of fish against acanthocephalans.

In birds (ducks infected with →*Filicollis anatis*, Fig. 6) heterophils represent the major granulocyte fraction (Fig. 7B). Macrophage giant cells frequently occur in the tissue near the parasite's praesoma, and also plasma cells are contained in it depending on the stage of infection.

In mammals a progressed stage of infection is accompanied by the abundance of plasma cells near the worm surface (Fig. 5B) after having passed through an acute phase of infection associated with a mass occurrence of eosinophilic and heterophilic granulocytes (Fig. 5A, C). In rats infected with *M. moniliformis* the occurrence of plasma cells up from about 10 d.p.i. (Fig. 5B) corresponds with the increase of worm-specific IgE-antibodies as described elsewhere.



Acanthocephalan Infections. Figure 2 LM of a paraffin section showing a longitudinally sectioned male →*Acanthocephalus anguillae* in an experimentally infected goldfish fingerling, 18 d.p.i. The worm has perforated the intestinal wall of one loop with its praesoma and the anterior portion of its metasoma and now has ruptured the outer part of another loop's wall. The extraintestinal part of the worm is enclosed by inflammatory tissue (IT). ×80. *LI*, liver; *SP*, spleen; *PA*, pancreas.

Several fish researchers have often been amazed by the high intensities, often exceeding 100 specimens per gut, with acanthocephalans like the perforating species *Pomphorhynchus laevis*, being tolerated without showing external signs of disease.

In birds and mammals, however, different species of perforating acanthocephalans have been involved in →morbidity and mortality, especially under elevated worm intensities as shown by a domestic duck infected with *F. anatis* (Fig. 6). This polymorphid palaeacanthocephalan also causes →weight loss, →anaemia, debility, apathy, and somnolence among infected ducks.

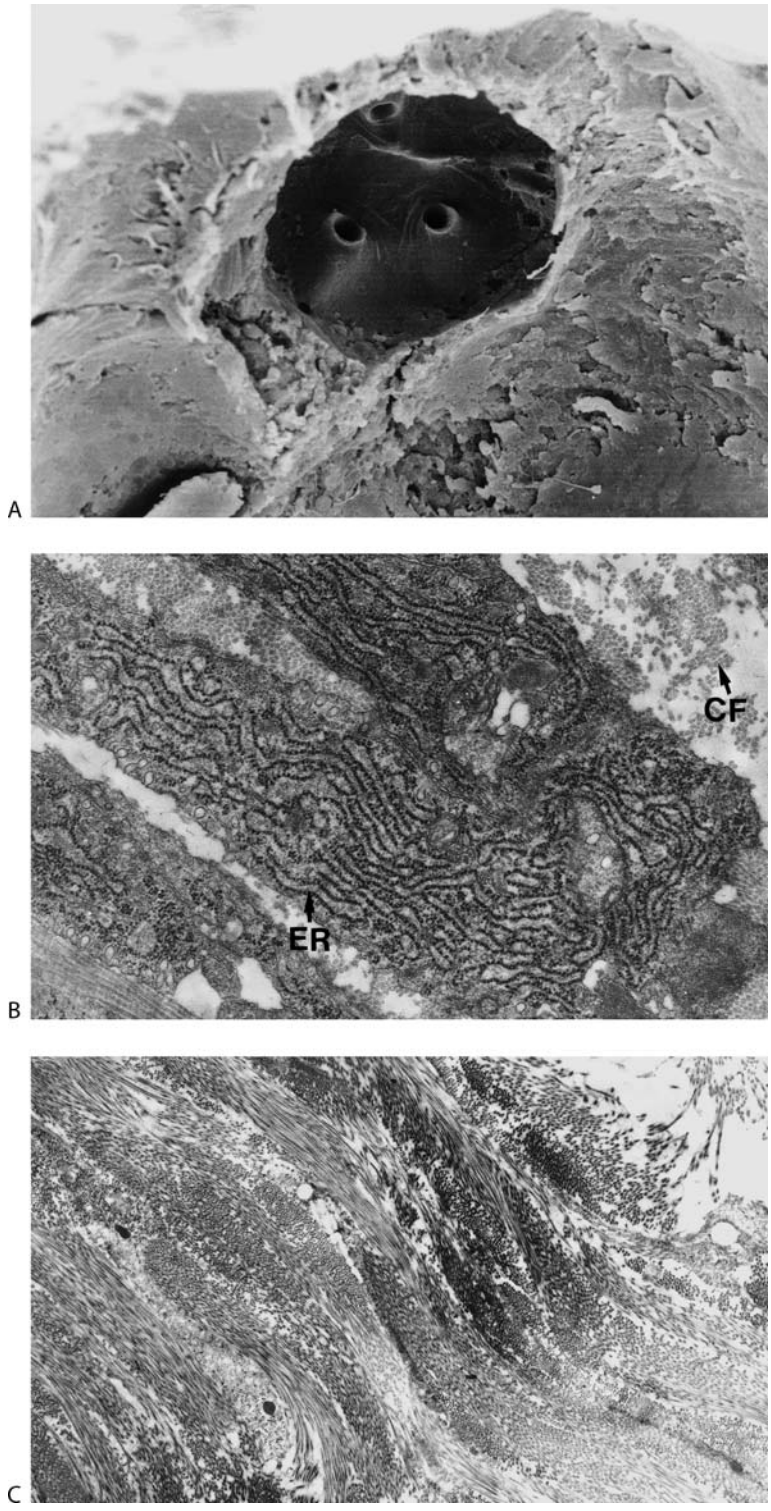
In mammals and birds the involvement of secondary infections and the infiltration of bacteria from the deep lesions into the peritoneal cavity seem to contribute to this pronounced pathology. In swine the sites of attachment of the perforating archiacanthocephalan *Macracanthorhynchus hirudinaceus* are marked on the outer surface by a caseous →nodule with a reddened annulation around it. It frequently abscesses with bacterial involvement, which may lead to perforation of the gut wall. Human patients in China and Southeast Asia have suffered unbearable →abdominal pain during the passage of the entire worm or parts of it into the peritoneal cavity which is accompanied by infiltration of eosinophils and neutrophils, massive →oedema, and large quantities of serosanguineous exudate in the body cavity near the site of perforation. Prior to 1980 perforating acanthocephalans (mainly →*Prosthenorchis elegans* and occasionally *Oncicola spirula*) infecting primates held in zoos were the cause of numerous fatal cases among these hosts. But since then no further cases have been published, probably due to the resulting growing awareness of this threat in zoological gardens since then. The perforation canal through the intestinal wall harbouring the parasite was filled with inflammatory exudate enriched with scattered masses of bacteria and acute peritonitis was diagnosed to be the cause of death in many cases reported by several authors. Less than 15 specimens of *P. elegans* are considered sufficient to cause mortality in squirrel monkeys.

In contrast to these descriptions from 3 perforating acanthocephalans, *M. moniliformis* with its superficial attachment (Fig. 8) does not create mortality among rats, and in these hosts as well as in accidental human cases where a worm had been measured to be 26.5 cm in length, the symptoms of morbidity are much less pronounced. All these findings suggest that the depth of penetration of an acanthocephalan species is an important criterion influencing the course of pathology at least in host–parasite associations involving mammals or birds as final hosts.

Praesoma Morphology Influencing the Host-Parasite Interface

The praesoma of eo- and palaeacanthocephalans is invested by a lipoid surface cover (→Acanthocephala/Integument/Fig. 11). It probably fulfills defence functions but obviously also incorporates lipids from necrotic host tissue which then becomes absorbed by the parasite (→Acanthocephala/Fig. 10). Within this coat, osmiophilic films seem to be shed from the parasite's surface (→Acanthocephala/Fig. 12B). Whether these are loaded with peptides or substances deriving from defence mechanisms of the host will have to be proven in experiments.

The phenomenon of shedding (→Capping) of surface coat can be commonly observed from *M. moniliformis* in rats (Fig. 5A, C). Large patches of the fuzzy surface coat detach from the praesomal worm surface into the surrounding necrotic inflammatory tissue/exudate. It happens during the acute phase of infection associated with a granulocyte response as well as later on when plasma cells accumulate at the praesoma. One may conclude that host's enzymes and/or antibodies bind to this coat until it is shed by the parasites. In transmission electron micrographs patches of detached coat attain a more coarsely structured and more electron



Acanthocephalan Infections. Figure 3 A–C Micrographs of connective tissue in the intestinal wall of fishes infected with acanthocephalans. **A** SEM showing the former point of attachment of a proboscis of *Neoechinorhynchus rutili* in the intestinal wall of a naturally infected rainbow trout. Collagen fibres have formed a firm capsule appearing as a "print" of the proboscis. **B** TEM of fibroblasts (ER: rough →endoplasmatic reticulum) and excreted collagen fibres (CF) in the outer connective tissue belt encapsulating the proboscis of the perforating species *Acanthocephalus anguillae* in an experimentally infected rainbow trout 30 d.p.i. **C** TEM of firm connective tissue consisting of plane collagen fibres near the outer margin of the neoplasic tissue encircling the bulbus of a large specimen of the perforating species *Pomphorhynchus laevis* in a chub.

Acanthocephalan Infections. The worm is surrounded by a "cloud" of cells and liquids leaking from the intestinal wall into the gut lumen. Also note the densely set, hyperplastic goblet cells in the mucosa (arrow). **B** Paraffin longitudinal section through the anterior third of a *Neoechinorhynchus rutili* in a naturally infected grayling (*Thymallus thymallus*). Note the huge inflammatory reaction around the worm's praesoma. *SC*, collagenous stratum compactum.

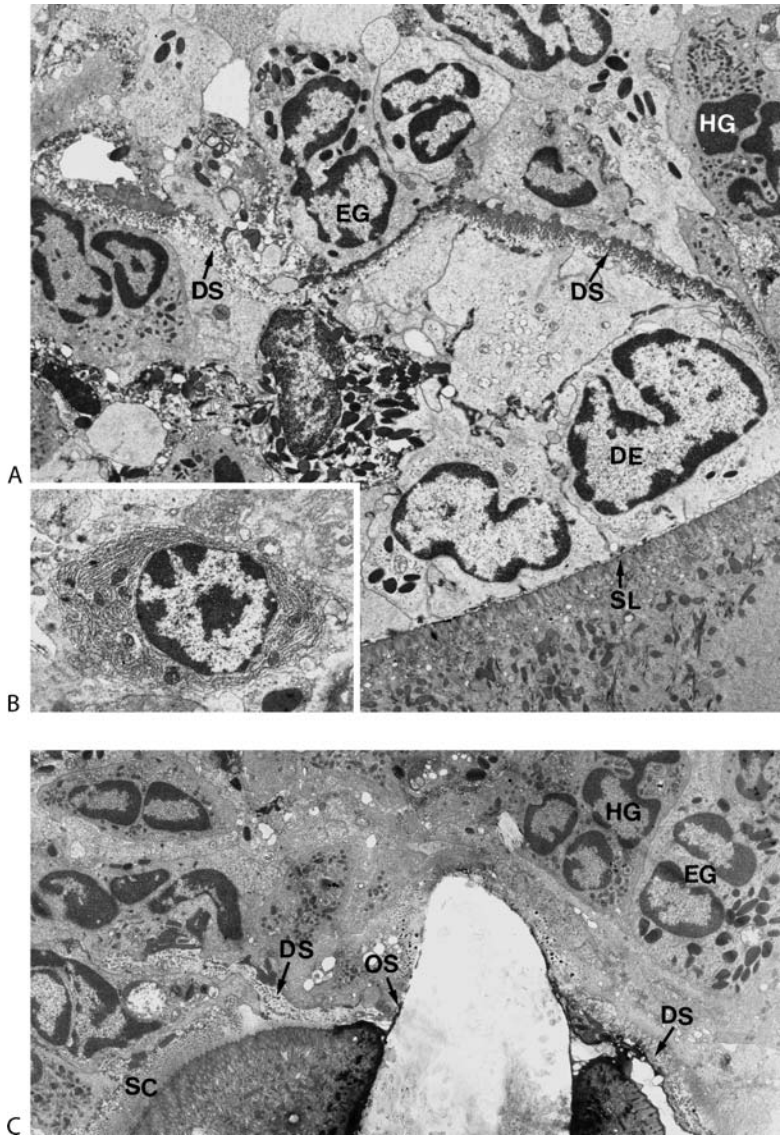
lucent appearance compared to the →glycocalyx still lining the surface (Fig. 5A, C).

Leakage of Liquids, Cells, and Debris from the Lesion

The phenomenon of leakage from the lesion created by a worm into the intestinal lumen has been documented in many acanthocephalans (Figs. 4A, 8). It seems to be most pronounced at the climax of the acute phase of infection at the point of attachment of perforating species (Fig. 4A). Having reached a progressed chronic stage, the opening of the lesion heading towards the intestinal lumen almost tightens up by the host so that the leakage decreases (Fig. 1). Most non-perforating species, on the other hand, seem to switch their site of attachment prior to a severe →inflammatory reaction with an accompanying leakage.

Abrasion, Erosion, Compression

Usually the mucosal surface within the range of an acanthocephalan →metasoma, also becomes mechanically affected by movements and the body pressure of the worms, especially close to the lesion. Also, many acanthocephalans possess body spines which support a burrlike affiliation of parts of the metasoma



Acanthocephalan Infections. Figure 5 A–C TEM of the proboscis surface and of surrounding host tissue of *Moniliformis moniliformis* in rats. *DS*, detached surface coat; *DE*, degranulated eosinophilic granulocyte; *EG*, eosinophilic granulocyte; *HG*, heterophilic granulocyte; *SC*, surface coat; *SL*, →striped layer of the tegument; *OS*, osmiophilic substance deriving from the annular cleft around the "naked" hook. **A** Acute phase of infection, 10 d.p.i. Eosinophilic and heterophilic granulocytes form dense populations near the praesoma. Large patches of the surface coat have detached from the worm. **B** Plasma cell out of a dense association of such cells near the surface of a worm, 60 d.p.i. **C** 10 d.p.i. infection. Note the fine fuzzy structure of the surface coat still adhering to the worm's praesomal surface while other portions of it have detached.

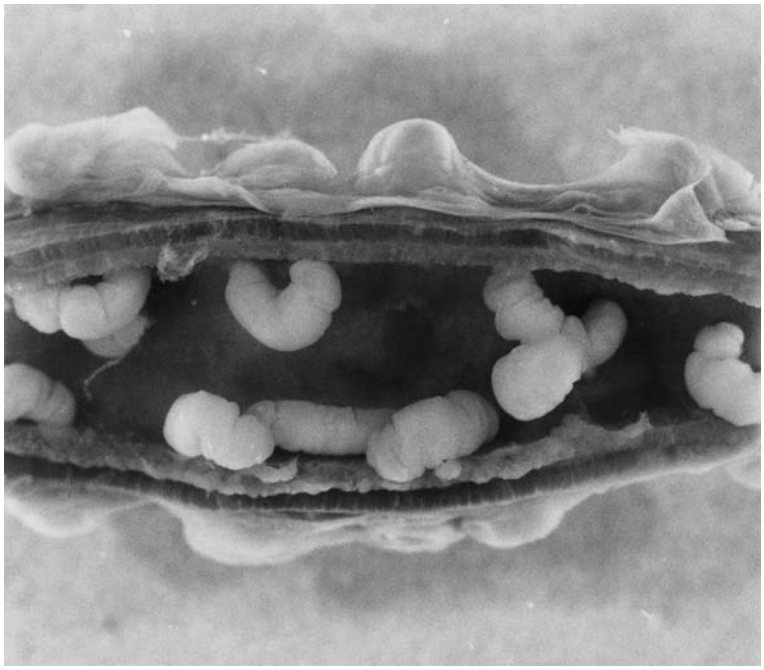
with the mucosal surface which should have some scratching effect.

Increased Diameter of the Intestinal Wall

A local increase in thickness of the intestinal wall at the site of anchorage is well described in acanthocephalans. In addition also other parts of the host's gut which are not in contact with the worms may be enlarged in diameter.

Distention of the Intestine

The rat intestine in its length may be extended due to a single specimen of *M. moniliformis*. Also certain appendages like pyloric caeca were found to become almost doubled in diameter due to the acanthocephalans (→Leptorhynchoides thecatus) inhabiting the caeca. Interestingly intestinal caeca seem to be a preferred environment of several intestinal helminths, and one acanthocephalan has been found to create its own caecal microhabitat. This species, *N. carpiodi*, also exhibits



Acanthocephalan Infections. Figure 6 LM of an opened intestine of a domestic duck naturally infected with *Filicollis anatis*. The trunks (metasoma) of the worms can be inside the gut lumen whereas the praesomal bulb encapsulated by neoplasic tissue is seen at the outer side of the intestinal wall; The worm density of *Filicollis anatis* shown here potentially creates mortality among ducks.

that social clustering exists among acanthocephalans. Up to 20 or more worms can be found together inside deep caverns surrounded by collagen capsules seen as expansions at the outer intestinal wall.

Occlusion of the Intestine

A few acanthocephalans such as *Macracanthorhynchus hirudinaceus* reach considerable size, i.e., more than half a meter in length. High worm burdens have been mentioned to have occluded the intestinal tube leading to mortality among piglets.

Negative Influence on Metabolic Parameters

As in other helminths which are better investigated than acanthocephalans one should expect that various physiological parameters of the hosts become negatively influenced by an acanthocephalan infection, especially under the influence of a co-stressor like insufficient energy supply or unsuitable temperatures. Indeed, growth, weight gain, and blood sugar concentrations of rats infected with *Moniliformis moniliformis* were most conspicuously altered when diets with low amounts of carbohydrates were offered. Among starlings experimentally infected with moderate numbers of *Plagiorhynchus cylindraceus* only negative effects (on the weight of male host individuals) could be observed under deficient temperatures.

Fever

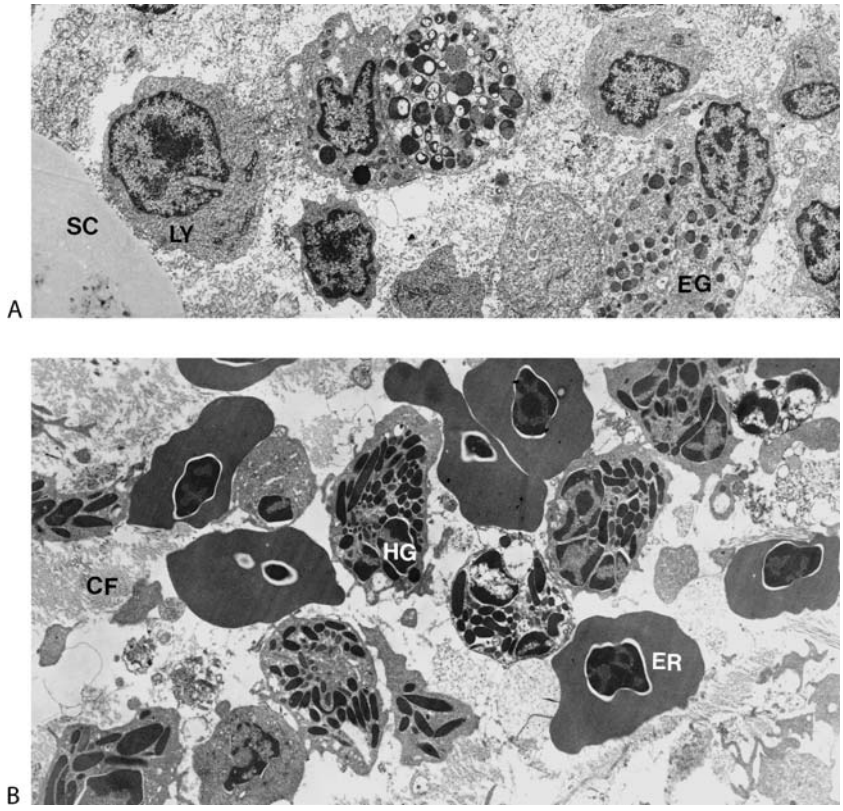
Elevated body temperatures due to acanthocephalan infections have been reported in domestic ducks as well as in primates and humans.

Goblet Cell Hyperplasia

Several authors have reported inflated goblet cells along the intestinal mucosa in hosts (fish, rats) infected with acanthocephalans, also their density was found to – increase due to acanthocephalan infections (Figs. 4A, 8). Concerning primary infections of perforating acanthocephalans permanently remaining at one point of attachment, this defence measure might be ineffective. But young worms supplementing an established infrapopulation as well as specimens of non-perforating acanthocephalans showing a non-sessile behavior, should be affected by an excess of mucins deriving from goblet cells.

Skeletal Deformations

Notes exist, that describe brown trout, heavily infected with different acanthocephalan species, to show deformed backbones and/or shortened gill operculae or fins. This may have to do with the recently detected very high absorptive capacity of acanthocephalans for calcium and other minerals.



Acanthocephalan Infections. Figure 7 A, B TEM of granulocytes and erythrocytes near the praesoma of acanthocephalan species. **A** Acute infection of *Acanthocephalus anguillae* in a carp, 14 d.p.i. Infections in Humans

Two species of archiacanthocephalans and three species of palaeacanthocephalans (→Acanthocephala) have been found in humans. Cases of *Macracanthorhynchus hirudinaceus* have been reported mainly in China and Thailand, of *Moniliformis moniliformis* in many tropical and subtropical countries. Specimens of *M. moniliformis* are located inside the intestine, where they reach sexual maturity. All other acanthocephalans recovered from humans do not reproduce in this accidental host. *Acanthocephalus rauschii*, *A. bufonis*, and *Corynosoma strumosum* (parasites of fish, amphibians, and seals, respectively) have been obtained from human patients in Alaska (*A. rauschii* and *C. strumosum*) and Indonesia (*A. bufonis*). *A. rauschii* was located in the peritoneum, and the other two palaeacanthocephalans in the gut.

Infections with *M. hirudinaceus* and *M. moniliformis* usually occur among small children who, willingly or accidentally, ingest insects. In parts of Asia, however, where raw or undercooked insects are customarily eaten, adult humans also become infected; symptoms of infection such as weight loss, intermittent fever, bulging abdomen, diarrhea, and severe pain are well described. In a hospital in China 115 cases of acute abdominal colic due to *M. hirudinaceus* were reported over a period of only 3 years. Often *M. hirudinaceus* in humans occupies extraintestinal positions. The migration of this perforating acanthocephalan through the gut wall is very painful. An adult volunteer who swallowed infective larvae of *M. moniliformis* suffered from abdominal pain beginning from the 20th day after infection. It seems that *M. moniliformis* does not lead to a great inflammatory reaction; however, abdominal surgery on patients infected with *M. hirudinaceus* revealed a serosanguinous exudate in the peritoneum, inflamed parts of the intestine with →nodules of up to 3 cm in diameter, and/or intestinal perforations. Thus, in humans both species show a pathogenicity similar to that in their major hosts, i.e., rats and swine (*M. hirudinaceus*) respectively.

Therapy

Acanthocheilonema

Genus of the family →Filariidae, →Nematodes. New genus name for →*Dipetalonema*.

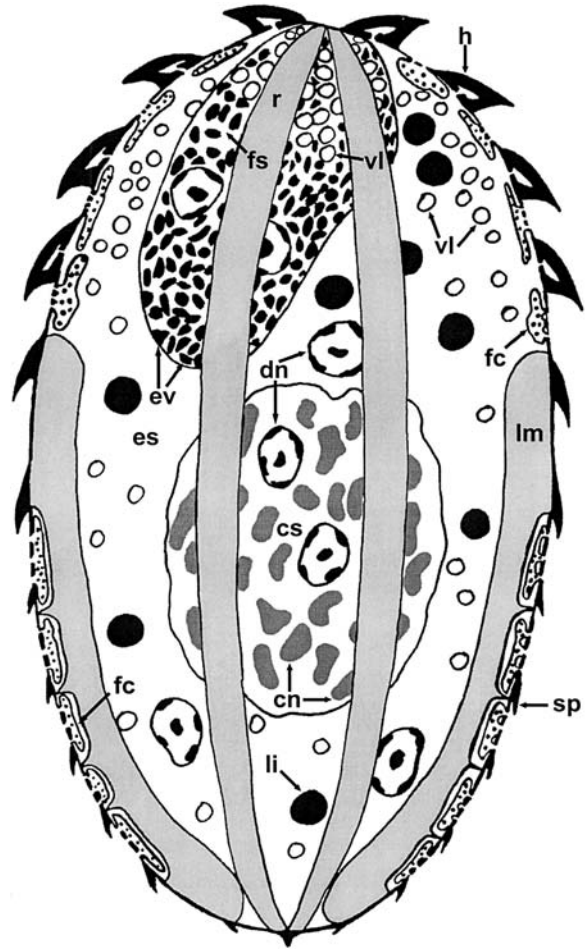
Acanthocheilonema viteae

→Nematodes, →*Dipetalonema*.

Acanthor

The first larva of →Acanthocephala (→Acanthocephala/Reproduction, →Acanthocephala/Figs. 2,3). During the first equal cell divisions after fertilisation 2 polar bodies usually appear at the end of the embryo that will become the anterior end of the acanthor. Further equal and unequal divisions show a kind of spiral cleavage resulting in micromeres and macromeres. In a later stage, the central nuclear mass (inside the central syncytium) appears. However, there is no formation of a digestive tract at any phase of development. In addition, the very early embryo attains a syncytial organisation. Thus, it is difficult to decide what is ectoderm, endoderm, or mesoderm. During the course of development the embryo detaches from the floating ovary and the single →eggshell differentiates into the different envelopes.

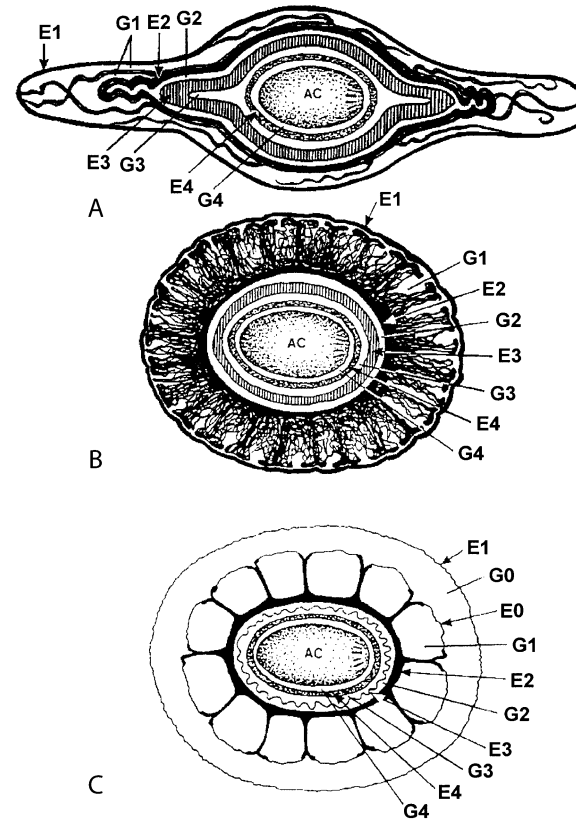
Mature acanthors consist of 3 syncytia. The central →syncytium (median), the epidermal syncytium (caudal), and the frontal syncytium (Fig. 1). Within the central syncytium there are 10 subepidermal longitudinal muscles and 2 more centrally located retractor muscles. According to descriptions of Albrecht et al. from acanthors (of 3 species) that were still inside the mother's body cavity and enclosed by eggshell-envelopes, the subepidermal muscles are connected via



Acanthor. Figure 1 Schematic drawing of a hatched acanthor of the eoacanthocephalan *Paratenuisentis ambiguus*. The frontal syncytium (fs) is rich in electron-dense vesicles (ev) as well as vacuoles containing electron-lucent mucus-like matter (vl). The central syncytium (cs) harbours condensed nuclei (cn) and a few decondensed nuclei (dn). The epidermal syncytium (es) forms most of the body including fused crypts of the outer membrane which contain round electron-dense granula. The surface of the larva is armed with hooks (h) and body spines (sp). The 2 retractor muscles (r) enable the larva to perform invaginations of the anterior body. The hind body may contract itself by the action of the 10 longitudinal muscle cords (*lm*, only 2 are drawn); *li*, lipid drop. (Reitze and Taraschewski unpubl.)

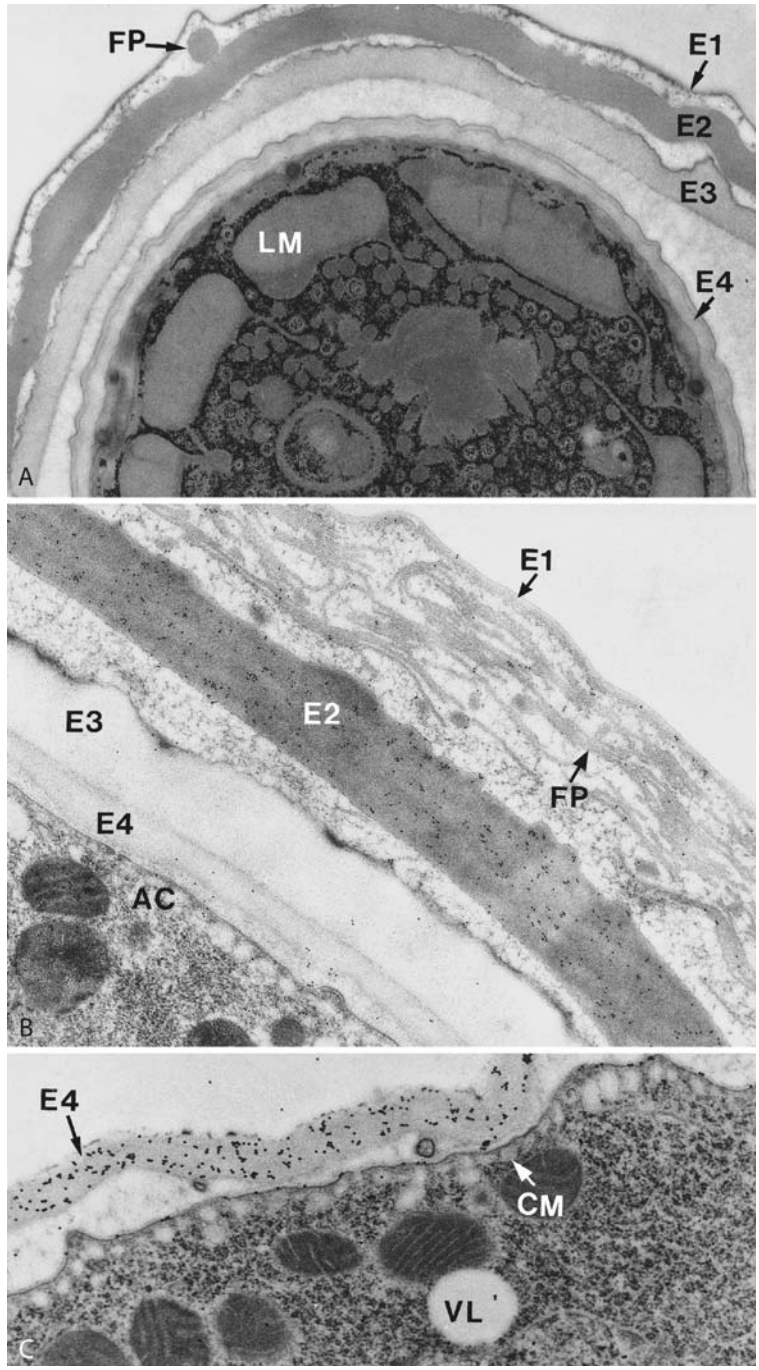
cytoplasmic bridges with the central nuclear mass. However, in hatched acanthors of →*Paratenuisentis ambiguus* collected from the gut of its crustacean →intermediate host, no connections between the central syncytium and the subepidermal muscles could be found; the muscles were part of the epidermal syncytium (Fig. 1). So probably the bridges described may get lost during the final maturation of the acanthor or the hatching process. The central nuclear mass contains condensed as well as decondensed nuclei. The latter are also found in the epidermal and the frontal syncytium (Fig. 1). The epidermal syncytium forms the outer surface and most of the larva's body. It contains numerous →vacuoles with mucus-like electron-lucent content which are concentrated near the surface of the anterior half (Fig. 1). In acanthors of →*P. ambiguus* the crypts of the outer membrane are fused underneath the larva's surface and harbour electron-dense granules which may have a function during the penetration of the larva into the haemocoel of the intermediate host. The electron-dense vesicles as well as the vacuoles with electron-lucent content inside the frontal syncytium could probably also be involved in the task of penetration, chemically supporting the action of the hooks. Stimulated acanthors of *Moniliformis moniliformis* have been found to discharge chitinase, but this enzymatic activity has not been localised at the acanthor's body. Hooks are most prominent at the anterior surface and decline in size towards the larva's posterior end (Fig. 1). Acanthors are rich in →glycogen in the →cytoplasm between the muscles, nuclei →mitochondria, and inclusions (Fig. 3A).

Mature acanthors of acanthocephalans are enclosed by 4 eggshells separated by interstices containing granular electron-lucent material (Figs. 2, 3, 4A). However, eggs of →*Neoechinorhynchus* species become complemented by a fifth envelope (E0) creating a fifth voluminous outer interstice (Fig. 2C). The outermost, first envelope seems to derive from the "→fertilisation membrane". Usually it is thin but can be reinforced by outgrowths of the underlying eggshell (Figs. 3B, 4A). This envelope (E2) was found to contain keratin in all 3 groups of the Acanthocephala. In palaeacanthocephalans it forms more or less filiform outgrowths (Figs. 2A, 3A, 3B) entangling with algae or leaves (the food substrates of the intermediate hosts) once the outermost envelope has disintegrated in the water. In archiacanthocephalans, the second eggshell is interspersed with the respective outermost interstice and seems to function in protecting the egg from dissication and other negative outer influences (Figs. 2B, 4A). Among archiacanthocephalans the underlying tripartite third envelope also comprises keratin, while eo- and palaeacanthocephalans do not have keratin in this eggshell. The fourth, innermost eggshell contains →chitin among palae- and archiacanthocephalans (Fig. 3C). In eoacanthocephalans, however, this innermost eggshell lacks chitin. The interstices contain carbohydrates which together with the envelopes seem to have different functions.

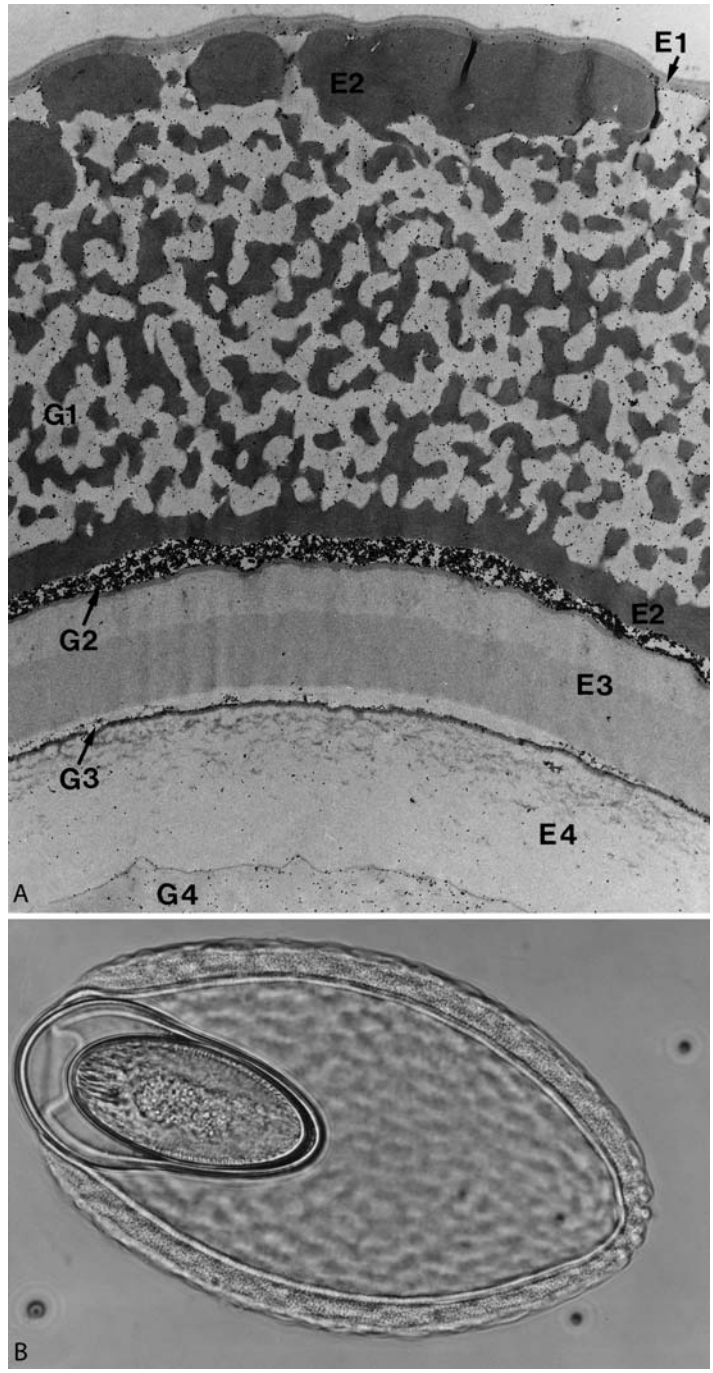


Acanthor. Figure 2 Schematic drawings of the eggshells of Palaeacanthocephala (**A**), Archiacanthocephala (**B**), and a neoechinorhynchid eoacanthocephalan of the genus *Neoechinorhynchus* (**C**). *E*, eggshells (envelopes); *G*, granular interstices; *AC*, Acanthor. **A**. Note the filiform outgrowth of the second eggshell. **B**. The second eggshell creates a thick mesh of amorphic matter intermingling with the first interstice. **C**. Note the existence of 5 eggshells and 5 interstices, respectively. The 2 outermost interstices are loaded with carbohydrates. The eggshell E2 seems to keep the E0 eggshell in position. The E3 eggshell is just a membrane.

As a general rule, the outer envelopes and interstices appear to be ecologically related, accomplishing functions in parasite transmission, etc. In archiacanthocephalan eggs the outer part of the eggshell swells when exposed to digestive influences so that the inner part containing the acanthor is passively released (Fig. 4B). The interior envelopes (Figs. 2, 3, 4A) seem to be systematics related and obviously fulfil tasks belonging to the principle requirements of the acanthor.



Acanthor. Figure 3 TEMs of sections through eggshell envelopes and interstices enclosing acanthors of palaeacanthocephalans treated in different fashions. **A** Egg of →*Acanthocephalus anguillae* incubated according to the electron microscopical PAS-method of Thiéry in a mode to visualise glycogen (dark granules in the acanthor). Also note the 4 eggshells (E1–E4) and the transversally sectioned subepidermal longitudinal muscles (LM); *FP*, filiform protuberance of E2. **B** Egg of →*Polymorphus minutus* incubated with anti-keratin and subsequently with a second antibody labelled with colloidal gold. Note the gold granules on eggshell E2 and its outer filiform protuberances indicating keratin in the second envelope. This section does not show the granular interstice between the 3rd and the 4th envelope. As can be seen under **A**, the width of the interstices is different. *AC*, acanthor. **C**. Innermost envelope (E4) and acanthor of *P. minutus* after incubation with lectin wheatgerm agglutinin (coupled with colloidal gold granules) in a mode that chitin is visualized. Note the gold label on E4, also the crypts of the acanthor's outer membrane (CM) and the glycogen granulation between the mitochondria and the vacuole of electron-lucent content (VL) (probably mucus).



Acanthor. Figure 4 Micrographs showing envelopes, interstices and an acanthor (B) of the archiacanthocephalan *Macracanthorhynchus hirudinaceus*. **A** The ultrathin section has been incubated with chitinase and subsequently with lectin wheatgerm agglutinin coupled with gold granules. The innermost envelope E4 therefore does not show a chitin-gold-label as it would without the enzyme treatment. According to competition experiments with *N*-acetylglucosamine and triacetyl chitotriose it becomes evident that the partly intense label in the granular interstices is due to different carbohydrates but not chitin. The acanthor is not seen. Note that E1 and E3 are tripartite; G1–G4: granular interstices separating the envelopes; E1–E4: envelopes. **B** Light microscopical micrograph of an egg that has been incubated in sodium docecyl sulfate (SDS) and dithiothreitol (DTE) to extract proteins including keratin. Consequently, the outer 2 envelopes swell considerably and eventually rupture due to an increase of the osmotic pressure. Therefore the acanthor seen still enclosed by the keratin containing E3 envelope and the E4 envelope that has chitin, "shoots" out of its enclosure, suggesting that the digestive activity in the gut of the intermediate host largely contributes to the hatching process of the acanthor.

Acanthosis

Symptom in →onchocerciasis, with thickening of the epidermis and increased melanin in the upper dermis; skin thickening in Scabies →*Sarcoptes*.

Acanthostomum

→Digenea.

Acarapis woodi

→Mite of honey bees that lives in the tracheoles and thus blocks oxygen transport (Fig. 1). The female mite reaches a size of 180 × 100 µm. The disease has to be announced to government. Treatment by chlorfenson or dimeform.

Acarapis woodi. Figure 1 Adult male miteset free from bee tracheole.

Acari

Name

Greek: *acari* = mite.

Acaridae

→Acarina.

Acarina

Classification

Order of →Arthropoda.

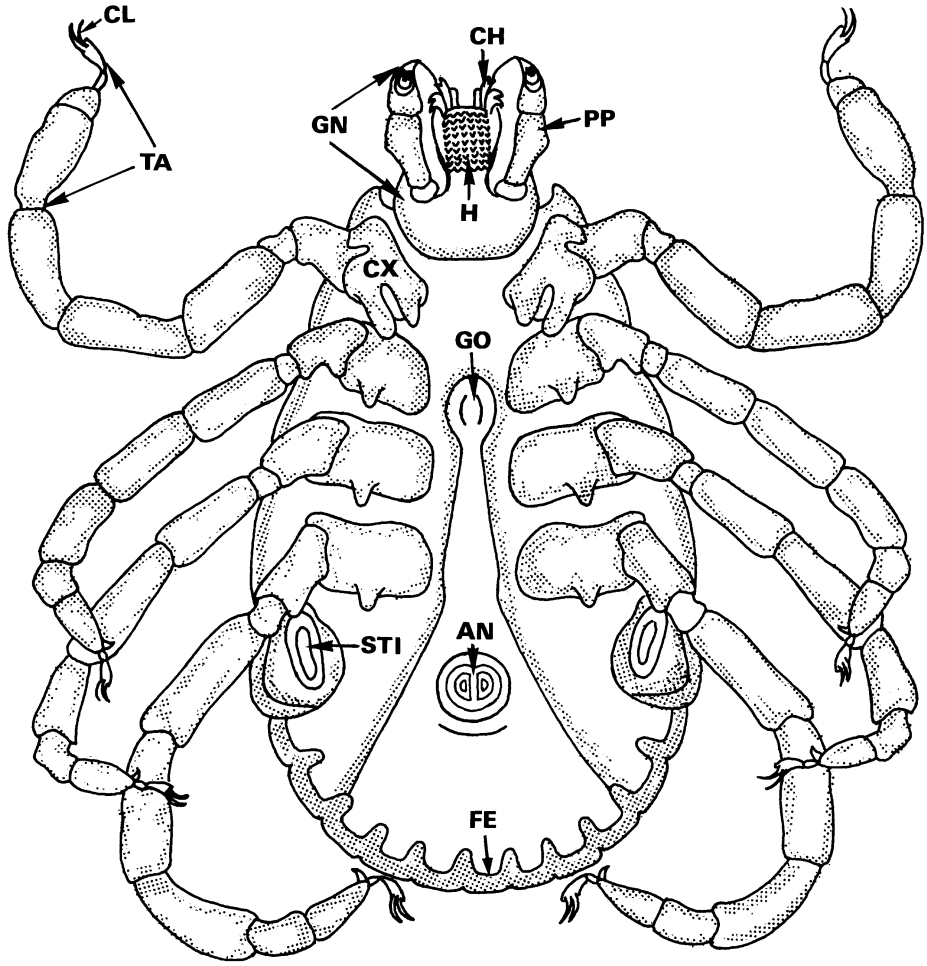
General Information

The order Acarina, including →mites and →ticks, contains numerous economically and medically important species that are parasitic on humans, domesticated or hunted animals, and crops, food, etc. Unlike other chelicerates, members of the Acarina lack a visible body division. Thus, the abdominal segmentation has disappeared and the abdomen has fused with the praesoma; the portion of the body on which the legs are inserted (the →podosoma) is broadly joined to the portion of the body behind the legs (the →opisthosoma) to form the →idiosoma (Fig. 1). Another general feature of the group is the appearance of the anterior (head) region carrying the mouth parts (a pair of →chelicerae and of →pedipalps), this region being called the capitulum or gnathosoma. The chelicerae and pedipalps are variable in structure, depending on their function in the different groups (→Argas/Fig. 1, →*Ixodes*/Fig. 1, →Mites/Fig. 1, →*Neotrombicula autumnalis*/Fig. 1). Chelicerae may appear needle-like for piercing the skin of hosts or toothed (as in →ticks) for anchoring to the →integument of the host.

System

The classification of the Acarina, which as adults have four pairs of legs, is still a matter of controversy; with respect to the parasitic stages, the following system, which is based on the location of the openings of the tracheal system (stigma or spiracle), covers all parasitic species:

Subphylum: →Chelicerata.
Class: Arachnida.
Order: Acarina.
Suborder: →Metastigmata (ticks; large species with recurved teeth, a pair of tracheal →spiracles is located behind third or fourth coxae).
Family: →Argasidae (→Argas).
Family: →Ixodidae (→*Ixodes*).
Suborder: →Notostigmata (large leathery primitive free-living →mites; four pairs of spiracles behind the fourth coxae).



Acarina. Figure 1 Diagrammatic representation of an ixodid tick (e.g., *Dermacentor* sp.) from its ventral side. *AN*, anus; *CH*, chelicera; *CL*, claw; *CS*, sheath of chelicera; *CX*, coxa; *E*, esophagus; EM, pulvillus; *FE*, festoon; *GN*, gnathosoma (capitulum); *GO*, genital opening; *H*, →hypostome; *PP*, pedipalpus; *SA*, salivary duct; *SC*, →scutum; *STI*, stigma; *TA*, tarsus.

Suborder: →Tetrastigmata (large predatory mites, two pairs of spiracles: one pair by the third coxae, the other behind the fourth coxae).
Suborder: Mesostigma (parasitic and free-living mites; a pair of spiracles behind third or fourth coxae).
Family: →Dermanyssidae (→Mites).
Family: →Liponyssidae (→Mites).
Suborder: →Prostigmata (trombidiform mites with a pair of spiracles located anteriorly near mouth region; many free-living predatory species and some parasitic families).
Family: →Demodicidae (→Mites).
Family: →Trombiculidae (→*Neotrombicula autumnalis*).
Suborder: →Astigmata (mites without spiracles, including storage-, scabies-, mange-, and itch-mites).
Family: →Acaridae
Family: →Glyciphagidae
Family: →Sarcoptidae (→Mites).
Suborder: →Cryptostigmata (oribatid or beetle mites; typical spiracles absent, but the tracheal system is usually associated with the basis of the first and third pairs of legs).

Acariosis, Animals

Several →mites infest animals and cause significant dermatologic diseases. These may be occasional parasites e.g., harvest mites (*Trombicula*) or obligatory parasites like →*Sarcoptes* and →*Demodex* genera. Mites may be free-living on the surface of the skin

(*Cheyletiella*, →*Chorioptes*), superficial burrowers (→*Sarcoptes*) or may penetrate more deeply (*Demodex*). The parasitic mites of the families →Sarcoptidae and Psoroptidae, known as "→mange mites", generally give rise to well-defined dermatoses. The lesions are the result of mechanical damage to the skin and probably also of →hypersensitivity reactions to toxic secretions (→Pathology/Fig. 30).

→*Sarcoptes scabiei* (→**Sarcoptic Mange**) occurs commonly in pigs, dogs and cattle; and more rarely in horses, sheep, goats and cats. The so-called feline →scabies is caused by →*Notoedres cati*. The several varieties of →Sarcoptes scabiei may represent strains of the same mite which have become more adapted to particular hosts. The mites burrow into the skin. It has long been suspected that antigens from the mites themselves, their faeces, or their moulting and hatching fluids are responsible for the allergic reactions observed. Clinical signs are similar in all species and consist of a papillar eruption accompanied by severe →pruritus. The intense scratching caused by the pruritus may lead to →alopecia, secondary bacterial infections, lichens and hyperpigmentation. The skin becomes thickened in severe cases. Clinically affected animals may become debilitated and lose weight or fail to properly gain weight. Feed efficiency is reduced and the hide may suffer considerable damage. Severely affected pigs may also become anaemic. The distribution of the lesions is characteristic in the various hosts.

→**Psoroptic mange** is a serious disease in cattle and sheep, less so in horse and goats. The causative mites are species of →*Psoroptes* and are host-specific. Mites penetrate the epidermis to suck body fluids, and cause a local reaction with formation of vesicles. The exudate from the vesicles coagulates and dries on the skin surface, resulting in the formation of a →crust or scab of varying thickness. The mites move to the edge of the scab, and the lesion increases in size. There is marked pruritus, and scratching results in alopecia, erosions and →lichenification. Lesions usually begin in areas thickly covered by hair or wool. Debilitation, reduced productivity and occasionally death may follow severe infestations. In goats *Psoroptes cuniculi* is known as the "earcanker" mite because of its predilection for the ear (causing otitis).

→**Chorioptic mange** occurs commonly in cattle, sheep and horses, and more rarely in goats. The *Chorioptes* mites are host-specific and live on the surface of the skin. Generally, it is a less severe condition than psoroptic or sarcoptic mange. Lesions consist of alopecia, erythrema, excoriations and (small) crusts associated with pruritus. The mites have a predilection for the perineum, udder, caudal areas of thigh, rump and feet. Lesions caused by *Chorioptes equi* start as a pruritic dermatitis affecting the distal limbs around the foot and fetlock. A moist dermatitis of the fetlocks develops in chronic cases.

→*Otodectes cynotis* is an obligate parasite of the external skin surface, mainly the external ear canal of cats and sometimes dogs. The major lesion is thus otitis externa.

Demodex spp. lives in the hair follicles and sebaceous glands of dogs, cats, cattle and goats. Demodicosis is of clinical importance in dogs. It is less common in cats and other animals. Mites are often present on healthy animals without causing obvious lesions, but heavier infestations produce mechanical damage to the skin. As the mites multiply in hair follicles and sebaceous glands, the hairs fall out. Enlargement and rupture of adjacent follicles and glands leads to cyst formation. Secondary pyoderma associated with staphylococcal infection is a common complication in the dog. Skin lesions in this animal may range from small localised patches of alopecia, in which the skin may appear normal, to more generalised dermatitis with loss of hair, thickening and discoloration of the skin. In the pustular form of the condition, small pustules are formed in the hair follicles. Dogs with generalised demodicosis may have a concurrent pododemodicosis, which is characterised by interdigital →erythema and alopecia or interdigital furunculosis with associated →oedema and pain. Pododemodicosis may be the only manifestation of the disease. In cattle and goats *Demodex* lesions consist of small elevated →nodules of varying size. Most lesions appear on the shoulder, head and →neck region. Nodular demodicosis is characterised by the permanent formation of new nodules when the older ones disappear. Nodules arise when granulomatous inflammation is complicated by secondary bacterial infection.

Other ectoparasitic mites include →*Dermanyssus gallinae*, *Lynxacarus radovsky*, →*Trombiculidae* (chiggers) and *Cheyletiella yasguri*, *C. blakei* in dogs and cats, and *Psorogates ovis* in sheep. Clinical signs include erythrema and pruritic papulocrustous eruptions. →Cheyletiellosis in dogs and cats is typically more severe in young animals, with the primary lesion being scaling over the dorsal medline. Pruritus is variable.

Therapy

→Acarizides, →Nematocidal Drugs, Animals, →Arthropodicidal Drugs.

Acariosis, Humans

→Scabies, →*Sarcoptes*, →*Demodex*, →*Neotrombicula*, →Arthropodicidal Drugs, →Ectoparasiticidal Drugs.

Acarizides

→Ectoparasitocidal Drugs, →Arthropodicidal Drugs.

Acarodermatitis

Skin symptom (straw itch) due to bites of mites, e.g., of →*Pyemotes ventricosus*, which lives as larva and nymphs at the cost of various insect pests.

Acarus siro

→Mites.

Acceptable Daily Intake

Synonym

→ADI.

Definition

Dose of a drug residue in edible tissues, such as meat, various organs and fat, which during the entire lifetime of a person seems to be without obvious risk to health based on all toxicological data known at the time.

General Information

The ADI for humans may be determined by applying a safety factor of 1:100, or a safety factor of at least 1:1000 in case of a teratogenic drug. Therapeutic claims made by the manufacturer must coincide with safety and tissue residue data for the drug approved by government regulatory agencies (→Chemotherapy).

Acephal

Greek: *a* = not, *kephale* = head; term means without head, e.g., describes appearance of the larvae of flies (→Brachycera).

Acetabulum

Holdfast organ in →tapeworms, ventral sucker in →trematodes and attachment point of *os ileum*, *os pubicum* and *os ischium* in the human skeleton.

Acetylcholine (ACh)

→Nervous System of Platyhelminthes.

Acetylcholine-Neurotransmission-Affecting Drugs

Mode of Action

Fig. 1.

Structures

Fig. 2.

Organophosphates

Important Compounds

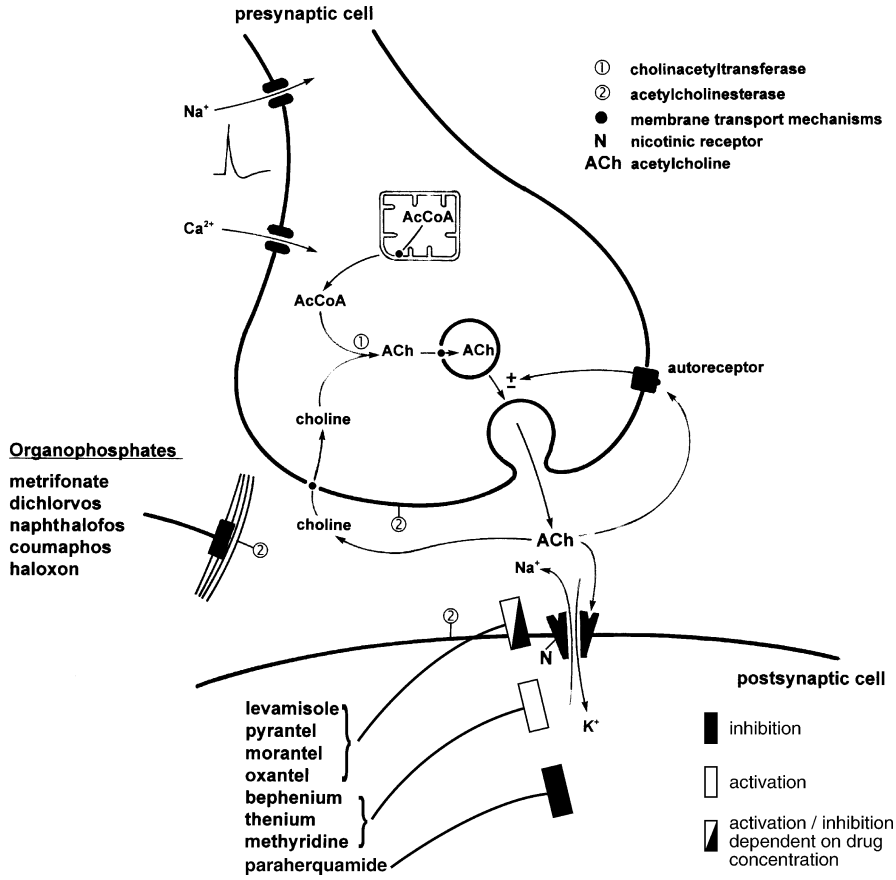
Dichlorvos, Diuredosan, Frento, Metrifonate, Coumaphos, Haloxon, Naphthalophos, Vapona.

Synonyms

Dichlorvos: Atgard, Dichlorman, DDVP, Equigard, Equigel, Task.
Diuredosan: Uredofos, Sansalid.
Metrifonate: Trichlorphon, Anthon, Bilarcil, Combot, Dipterex, Difrifon, Dylox, Dyrex, Mastotem, Neguvon, Tugon; in: Bubulin, Combotel, Dyrex T.F., Equizole, Neguvon A, Telmin B.
Coumaphos: Asuntol, Baymix, Co-Ral, Meldane, Muskatox.
Haloxon: Eustidil, Halox, Loxon; in: Haloxil.
Naphthalophos: Amdax, Maretin.

Clinical Relevance

Metrifonate was introduced as insecticide in 1955. It exerts activity in →*Taenia solium* →neurocysticercosis. Diuredosan is active against *Taenia* spp., →*Dipylidium caninum*, *Mesocestoides corti* and is only slightly active against *Echinococcus granulosus*. Fospirate is active against *T. hydatigena*.

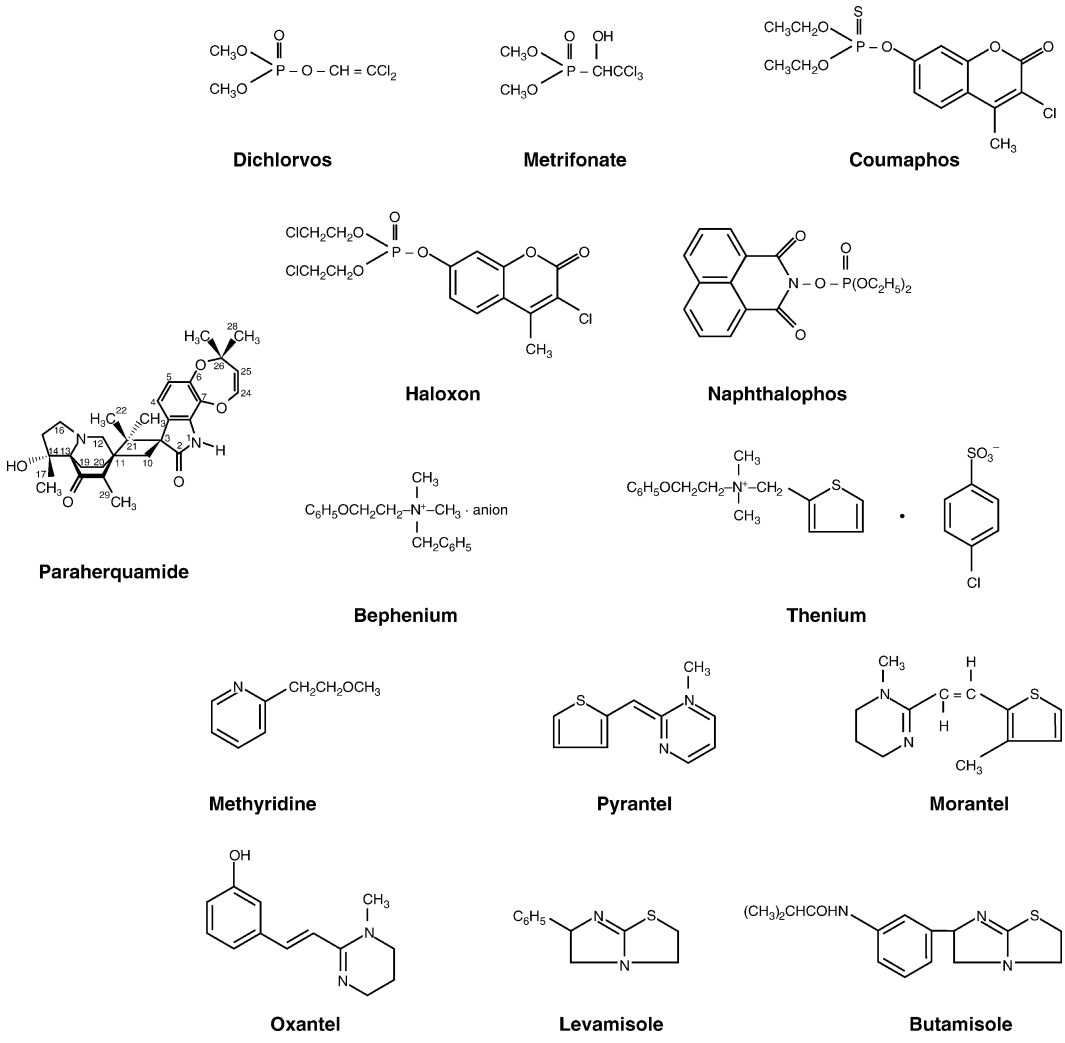


Acetylcholine-Neurotransmission-Affecting Drugs. Figure 1 Model of the action of drugs interfering with acetylcholine-mediated neurotransmission.

The antitrematodal activity of metrifonate is directed against →*Schistosoma haematobium*, and is only slightly active against →*S. mansoni* and →*S. japonicum*. Metrifonate is one of the drugs recommended by the WHO for the treatment of urinary schistosomiasis and present in the current Model List of Essential Drugs. For use in ruminants organophosphates had been available only in a limited number of countries. They are generally not as effective as the broad-spectrum anthelmintics and also have a lower therapeutic index. Haloxon, trichlorphon, coumaphos, naphthalophos and crufomate had been used in cattle, haloxon in sheep, dichlorvos in pigs, dichlorvos and trichlorphon in horses, and coumaphos in poultry.

Molecular Interactions

Metrifonate is unstable in aqueous solutions, and a spontaneous, nonenzymatic transformation into various compounds takes place. One of the degradation products is dichlorvos, which exerts high biological activity. Acetylcholinesterase (AChesterase) from helminths as target for organophosphates was first explored in the late 1950s. Metrifonate has *in vitro* activity against →*Ascaris lumbricoides* by the inhibition of AChesterases and cholinesterases resulting in an impairment of the action of the neurotransmitter acetylcholine (Fig. 1). AChesterase in →nematodes is inhibited at very low concentrations of 10^{-13} M. This leads to an indirect permanent stimulation of excitatory neuromuscular transmission mediated by acetylcholine, followed by a continuous depolarization of the postsynaptic junction resulting in a spastic paralysis. In general, a complete paralysis of the oral sucker is induced at lower metrifonate concentrations than those required to produce complete paralysis of the body musculature. The prolonged paralysis of the intestinal musculature leads to an interruption of peristaltic movements and a starvation of the parasite. The differences in metrifonate susceptibility among schistosome species are explained by differences in the amount of AChesterase located on the surface of adult schistosomes. Thus, *Schistosoma haematobium* teguments contain up to 20 times, and *S. bovis* teguments up to 6.9 times, higher AChesterase activity than *S. mansoni* teguments. These quantitative differences correlate well with the relative sensitivities of these species to metrifonate. There is presumably an association of the



Acetylcholine-Neurotransmission-Affecting Drugs. Figure 2 Structures of drugs affecting nicotinergic neurotransmission.

tegumental AChesterase and nACh receptors located on the dorsal surface of the adult males which may be responsible for the glucose import into schistosomes. Thus, the surface and not the muscle AChesterase functions as the primary target of the metrifonate action.

The antinematodal activity of metrifonate is low. It has little activity against *Trichuris vulpis* and some activity against →roundworms and →hookworms.

Metrifonate also has antifilarial activity, which is directed against microfilariae (→Inhibitory-Neurotransmission-Affecting Drugs/Table 1) and only to a minor degree against adult worms. Some organophosphates exert strong activity against *Litomosoides carinii* microfilariae. Metrifonate and fenthion are effective against microfilariae of →*Dirofilaria immitis*. There is no effect on developing stages of *D. immitis*, *L. carinii*, and →*Acanthocheilonema viteae* by organophosphates. In cats metrifonate has adulticidal effects. In addition, metrifonate has been used in combination with different antinematodal drugs because of its activity against *Gasterophilus* spp. (→Microtubule-Function-Affecting Drugs/Table 2).

The action of organophosphates against *L. carinii* microfilariae is complicated. The inhibition of AChesterase which is important for effect against gastrointestinal nematodes and *S. haematobium* is presumably not the →mode of action of these compounds against microfilariae. Microfilariae do not become primarily immobilized *in vivo* by haloxon or metrifonate. Instead, there is an induction of organophosphate-mediated adherence of phagocytic cells to the microfilariae observable resulting in a final killing of larvae. This effect looks similar but not identical to that of DEC (Inhibitory-Neurotransmission-Affecting Drugs/Table 1; Membrane-Function-Disturbing Drugs/Fig. 1).

Furthermore metrifonate possesses insecticidal activity. In this indication metrifonate is known as trichlorphon (=Dipterex or Dylox).

Resistance

Until now resistance against metrifonate is not known. However, against coumaphos and naphthalophos there are resistant →*Haemonchus contortus* strains in sheep and goats which lead to the ineffectivity of these organophosphates.

Ethanolamines

Important Compounds

Bephenium, thenium, methyridine.

Synonyms

Bephenium: Alcopar, Francin.
Thenium: Bancaris, Canopar; in: Ancaris, Thenatol.
Methyridine: Dekelmin, Mintic, Promintic.

Clinical Relevance

The antinematodal activity of bephenium is directed against *Ascaris lumbricoides*, →*Ancylostoma duodenale*, →*Trichostrongylus*.

Molecular Interactions

Several drugs belong to the class of ethanolamines such as bephenium, thenium, and methyridine. They have structural similarity to acetylcholine or nicotine and act as agonists of the acetylcholine receptor (Fig. 1) by binding to the acetylcholine receptors in the nerve cords of the nematodes. The compounds are not inactivated by AChesterase. The result of the agonistic activity is the induction of depolarization and a permanent muscle contraction or spastic paralysis in the worms. The specific toxicity of these compounds is explained by the greater affinity to the parasite's receptors compared to the host receptors. At high concentrations they are also toxic for the host.

Pyrantel, Morantel, Oxantel, Levamisole, Tetramisole

Synonyms

Pyrantel pamoate: in Antiminth, Banminth, Cobantril, Combantrin, Felex, Helmex, Imathal, Nemex, Piranver, Pyraminth, Strongid T; in: Dosalid, Trivexan, Welpan.
Pyrantel tartrate: in Banminth, Exhelm, Nemex, Pyreguan, Strongid.
Morantel: in Banminth II, Ibantic, Paratec; rumatel; in: Banminth D, Equiban.
Oxantel pamoate in: Quantrel.
Levamisole: Anthelpor, Aviverm, Bionem, Cevasol, Chronomintic, Citarin-L, Cyverm, Dilarvon, Duphamisole, Ketrax, Levadin, Levamisol "Virbac" 10%, Levipor, Levacide, Levasole, Narpenol 5, Nemacide, Nilvern, Ripercol L, Solaskil; in: Ambex, Nilvax, Nilzan, Spectril.
Tetramisole: Anthelvet, Ascaridil, Citarin, Nemicide, Ripercol, Spartakon.

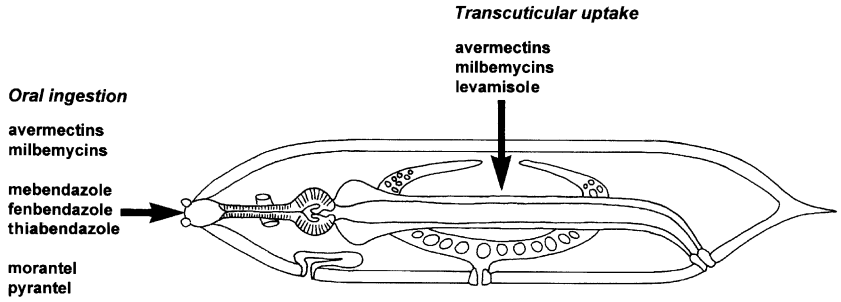
Clinical Relevance

Pyrantel has some anticestodal activity. It is effective against →tapeworms in horses in field trials, but the efficacy against Anoplocephala perfoliata is uncertain. However, pyrantel and levamisole are mainly used in the treatment of nematode infections in human and veterinary medicine (→Microtubule-Function-Affecting Drugs/Table 1). In addition, levamisole has microfilaricidal activity as shown in *Litomosoides carinii* infected *Mastomys coucha*. There is also microfilaricidal efficacy against →*Wuchereria bancrofti* and →*Brugia malayi* in man (→Inhibitory-Neurotransmission-Affecting Drugs/Table 1). Of interest is the topical application (eye drops) of levamisole. Levamisole has no effect against microfilariae of →*Onchocerca volvulus*. The side effects are similar to that of DEC treatment. Embryotoxic activity is observed in different filarial infections.

Molecular Interactions

The mode of action of these drugs relies on their anticholinergic activity. Levamisole is chemically an imidazothiazole, while pyrantel, morantel, and oxantel are tetrahydropyrimidine derivatives. They are simultaneously agonists and antagonists of the nematode ACh-receptors. Pyrantel acts as a nicotinic agonist on the acetylcholine receptor in the nematode *Ascaris suum* (Fig. 1). It induces a depolarization and an increase in input conductance of the muscle membrane due to sodium and potassium. Pyrantel leads to a spastic paralysis of →*Angiostrongylus cantonensis*. Levamisole is taken up by the nematodes via the cuticula, whereas the uptake of pyrantel and morantel occurs via the oral route (Fig. 3). In patch-clamp studies these nicotinic anthelmintics open cation channels nonselectively. Each channel has a characteristic conductance. There are variations of conductance between channels recorded from different patches in the range 19–60 pS. The mean open time of the channels varies with the anthelmintic in the range of 0.5–2.5 ms. These nicotinic anthelmintics act on the receptor with properties similar to, but not identical with, the nicotinic receptors in mammalian and vertebrate hosts because of pharmacological differences. Indeed, there is no significant action of levamisole on host muscle.

The antagonistic effects of levamisole, pyrantel, morantel, and oxantel may be explained by the fact that these molecules are too large to pass through the nicotinic acetylcholine receptor channel. However, they pass through the extracellular opening of the channel and lead to a blockage at the so-called middle ring of the channels. Thus, the middle ring of ACh-channel acts as a bottleneck for passing molecules. Thus levamisole, pyrantel, oxantel, and morantel induce a voltage-sensitive channel block at the nicotinic receptors in *A. suum* at higher concentrations.



Acetylcholine-Neurotransmission-Affecting Drugs. Figure 3 Route of uptake of anthelmintics by nematodes (representation of the morphology of a sexually mature female worm according to Cox (1996) In: Cox FEG (ed) Modern Parasitology, Blackwell Science, 2nd edition).

The antifilaricidal action of levamisole relies presumably on an immunomodulatory effect. Thereby, cell-mediated immunity is stimulated, resulting in a generally depressed cellular response in microfilariaemic hosts. The levamisole-dependent immunostimulation is observed at low doses. So far there are no experimental data on enhanced →immune reactions after levamisole treatment. There is only one report on enhanced filarial antigen-induced inhibition of the migration of macrophages in *B. malayi* infected *Mastomys coucha*.

Besides antiparasitic activities levamisole exerts antitumor activity.

Resistance Against Levamisole

Resistance against levamisole occurs in a variety of nematodes in sheep, goats, cattle, and swine. The mode of resistance against levamisole is yet unclear. The heterogeneity in the types of nicotinic receptors are thought to facilitate the development of anthelmintic resistance against nicotinic drugs and perhaps to other anthelmintics that act on membrane ion channels. Thus, in *Oesophagostomum dendatum* up to four nicotinic receptor types are present. The α-chains of the nicotinic ACh-receptor from susceptible and resistant *Trichostrongylus colubriformis* and *H. contortus* show no difference in amino acid sequence. There are different effects on the hatching of eggs between levamisole/morantel-susceptible, levamisole/morantel-resistant and morantel-resistant strains of *H. contortus* and *T. colubriformis* in the presence of levamisole, morantel, or pyrantel. Compared to adult susceptible *H. contortus*, five- to sixfold higher concentrations of ACh and other nicotinic agonists are necessary to cause equivalent contractions in levamisole/morantel-resistant worms. It is assumed that levamisole/morantel resistance is due to a reduced number or sensitivity of cholinergic receptors in resistant *H. contortus*. Levamisole-resistant mutants of →*Caenorhabditis elegans* lack ACh-receptors and there is no response to the nicotinic agonists acetylcholine, nicotine, carbamyl chloride, or levamisole, which in susceptible *C. elegans* cause contractions. The binding of cholinergic agonists varies between levamisole-susceptible and levamisole-resistant *C. elegans*.

Paraherquamide

Clinical Relevance

Paraherquamide is an oxindol alkaloid metabolite of *Penicillium paraherquei*. It has antiparasitic activity and was first reported in rodent models. It is highly efficaceous at a single oral treatment at dosages above 0.5 mg/kg against adult trichostrongylides in sheep and in addition against L4 larvae of *Cooperia* spp. Moreover, it is effective against ivermectin- and benzimidazole resistant *Haemonchus* and *Trichostrongylus* strains. In calves paraherquamide is effective against adult stages of nine common gastrointestinal and lung nematodes at single oral dosages of 0.5, 1.0, 2.0 or 4.0 mg/kg. However, *Cooperia punctata*, the dose-limiting species, was affected only at the highest dosage of 4.0 mg/kg to 89%. The compound is not toxic in ruminants up to a dosage of 10 mg/kg, but three dogs given an oral dose of 10 mg/kg had severe intoxications within 30 minutes of dosing and two animals died within 2 hours. On the basis of available data, for a broad-spectrum therapeutic paraherquamide has a therapeutic index of less than 3 at the dosage of 4 mg/kg and is thus inferior to ivermectin. As a narrow spectrum therapeutic used at a dosage of 0.3 mg/kg paraherquamide has a therapeutic index of 33 and could be thus useful as an antiparasitic agent if used in combination with an integrated approach to control resistant parasites.

Molecular Interactions

Paraherquamide is an extremely potent competitor at the α-bungarotoxin binding site at the nicotinic acetylcholine receptor in insects. It is also a competitor at the phenothiazine binding site. However, the real mode of action in nematodes has to be elucidated.

Acetyl-CoA

→Energy Metabolism.

Achroia grisella

Small species of the butterfly group moths, that parasitize in stocks of bees.

Achteres

Genus of ectoparasitic crustaceans attached to fish skin, e.g., *A. percarum* on perch.

Achtheinus

Genus of caligoid ectoparasites (crustaceans) on fish.

Acidocalcisomes

Acidic Ca^{2+} storage compartment in trypanosomatids, e.g., *Leishmania mexicana*, *Trypanosoma cruzi*, and →Apicomplexa (→*Toxoplasma gondii*). They are also rich in phosphorous, Ca^{2+}, Mg^{2+}, and Zn^{2+} and have a number of pumps and exchangers involved in their homeostasis.

Acini

Grape-like arranged salivary glands of →Ticks.

Acquired Immune Deficiency Syndrome

→AIDS.

Acquired Immunity

→Immune Responses, see, e.g., →Malaria, →Schistosomiasis, →Trichomoniasis.

Acquired Immunodeficiency Syndrome (AIDS)

Disease due to infection with HI-virus, which supports development of →opportunistic agents.

Acridinorange

Fluorescent stain for nucleic acids.

Acrodermatitis

A. chronica atrophicans is a symptom of phase three of the tick-transmitted →lyme disease or borreliosis.

Acrosom

Anterior peak of some →spermatozoa (e.g., →microgametes of →Coccidia have a perforatorium, that is lacking in →Platyhelminthes, →Nematodes and →Acanthocephala).

Actin

→Cytoskeleton, motility in →Apicomplexa, muscles of metazoans.

Actinocephalus

→Gregarines.

Actinomycin

Compound to block nuclear spindle apparatus.

Actinopilin

The setae of one progressive group of →mites (Actinotrichida) possess an axis of this light-breaking material.

Actions of Drugs

→Drugs.

Activation Factors

→Cytokines.

Acuaria

Nematodes in the esophagus of the dove.

Acute Dermatolymphangitis

→Lymphatic filariosis, →*Wuchereria bancrofti*, →*Brugia malayi*.

Adaptation

→Local Adaptation.

ADCC

Antibody-dependent cytotoxicity (→Immune Responses).

ADCL

→Anergic Diffuse Cutaneous Leishmaniasis, a syndrome of the New World, →Leishmaniasis.

Adeleidea

Systematic group of the →Coccidia now containing the genera *Klossia* (e.g., →*K. helicina*) and →*Klossiella* (e.g., *K. equi*).

Adelina cryptocerci

→Adeleidea, →Chromosomes.

Adelina deronis

→Coccidia.

Adenolymphangitis

→Lymphatic filariosis.

Adenophorea

Synonym

→Asphasmidea.

Classification

Class of →Nematodes.

General Information

→Phasmids are generally absent; →amphids are postlabial and variable in shape, cephalic organs

setiform to papilloid; setae and hypodermal glands usually present, hypodermal cells uninucleate; excretory organ, if present, single-celled; caudal glands mostly present; usually two testes in males; →cuticle four-layered.

Adhesion Proteins

→Knobs, →Coccidia, penetration.

ADI

Synonym

→Acceptable Daily Intake.

Adjuvant

To increase the immunogenicity of an antigen, various adjuvants are available. Freund's adjuvant, an oil emulsion of heat-killed *Mycobacterium tuberculosis*, saponins and various other formulations have commonly been used in experimental animal models. Because of possibly severe local and systemic reactions, they are considered unsafe for use in people and their use in animals is now restricted. Solely aluminium hydroxides and aluminium phosphate are registered for use in people.

Aedeagus

Copulatory apparatus in →Mites for injecting sperms.

Aedes

→Diptera, →Filariidae, →Mosquitoes, →Insects.

Aedes albopictus

Asian species of mosquitoes - so-called tiger mosquitoe – actually spreading worldwide (vector of dengue fever virus, West Nile virus). →Diptera.

Aega

→Crustacea.

Aegyptianella pullorum

Bacterium transmitted by the fowl tick →*Argas persicus* to chicken.

Aelurostrongylus abstrusus

Name

Greek: *ailouros* = cat, *strongylos* = cylindric.

Metastrongylid nematode (up to 14 mm long as females) that parasitizes worldwide in the branchioles and alveoles of cat lung (high prevalence rates: up to 90%). Intermediate hosts are snails; larvae become also transported by rodents, frogs, reptiles. →Respiratory Diseases, Animals, →Nematocidal Drugs.

Aerobic Metabolism

→Energy Metabolism.

Aeromonas hirudinis

→Leeches.

Aeropyls

Pores in the eggs of →Lice.

Aerotolerant Anaerobism

→Trichomonadida.

AFC

Antibody-forming cell (e.g., plasma cell, B-lymphocyte).

African Horse Sickness

Disease due to a virus (AHSV), which becomes transmitted by →*Culicoides* spp. (e.g., *C. imicola*) in South Africa.

African Swine Fever

Caused by the →ASF virus (ungrouped), African swine fever is an acute, contagious disease leading to high mortality in domestic pigs. It is maintained in wild pigs, particularly warthogs (*Phacochoerus* spp.), and in the tick *Ornithodorus porcinus*. It has been reported that infected male *O. porcinus* can infect uninfected females during mating. Warthogs are usually not severely affected, but it can be considered one of the most serious diseases of domestic swine, where it can be transmitted by contact alone and has caused severe economic losses after introduction into European countries.

African Trypanosomiasis

Unstained wet blood preparations, chancre fluid, CSF or lymph node aspirate can be used for the demonstration of motile trypanosomes. Giemsa-stained slides should also be prepared from the same material. With native blood samples it will be usually possible to demonstrate trypanosomes of *Trypanosoma brucei rhodesiense*, but less frequently those of *T. b. gambiense* since parasitaemia is usually much lower with this parasite. Here, concentration techniques may be successful, such as blood centrifugation and subsequent examination of the buffy coat, also in the form of the quantitative buffy coat technique (QBC). Mini anion-exchange and centrifugation is another useful method.

Antibody detection methods proved to be too insensitive or unspecific for a reliable diagnosis of African trypanosomiasis.

Agamermis decaudata

Species of free-living nematodes, the larvae of which are parasitic in grasshoppers and thus become transported to other biotopes.

Agamodistomum suis

Diplostomal trematode species of pigs, which are thought to represent mesocercaria of →*Alaria allata*. They are also described as →Duncker's muscle fluke.

Agamogony

Asexual reproduction (e.g., →Schizogony and →Sporogony in →Coccidia).

Age Related Prevalence

Prevalence rate of parasites in a host is mostly dependent on its age, i.e., it increases with the time of exposition e.g., in →*Clonorchis sinensis* and hookworms. In soil-transmitted nematodes, however, the prevalence is high beginning after the first year of host's life. In other parasites (e.g., in coccidians), infections occur mainly in the first weeks of life.

Agents of Disease

→Prions, viruses, bacteria, →fungi, parasites (plants, animals).

Aggregata eberthi

Classification
Species of →Coccidia.

Life Cycle
Fig. 1 (page 53).

Aggregation-Attachment Pheromones

Type of →pheromones, e.g., produced by the males of the metastriate genus →*Amblyomma* during the course of feeding. →Ticks/Reproduction, →Ticks/Host Finding.

AHSV

→African Horse Sickness virus.

AIDS

Immuno-suppression in AIDS patients or other reasons lead to an increase in the growth rate of so-called →opportunistic agents.

Airport Malaria

Malaria due to bites of imported, infected *Anopheles* females at airports (in aircraft, suitcases, containers, etc.). Also named: baggage – or taxi malaria.

ALA

Amoebic liver abscess; →*Entamoeba histolytica*.

Alae

Modification of the →cuticle in →Nematodes: keel-like thickenings which follow the lateral lines and support undulating locomotion (→Nematodes/Fig. 14C, →Nematodes/Integument).

Alaria allata

Trematode species (2.5–6 × 0.5–2 mm) of wild canids, lives in the small intestine and reaches prevalence rates of up to 30%. First intermediate hosts: snails (production of cercariae), paratenic hosts (e.g., pigs, amphibia, reptiles with formation of mesocercariae), final hosts harbour metacercariae in lung, adults in intestine (→Alaria canis).

Alaria canis

Synonym
Alaria americana.

Classification
Species of →Digenea.

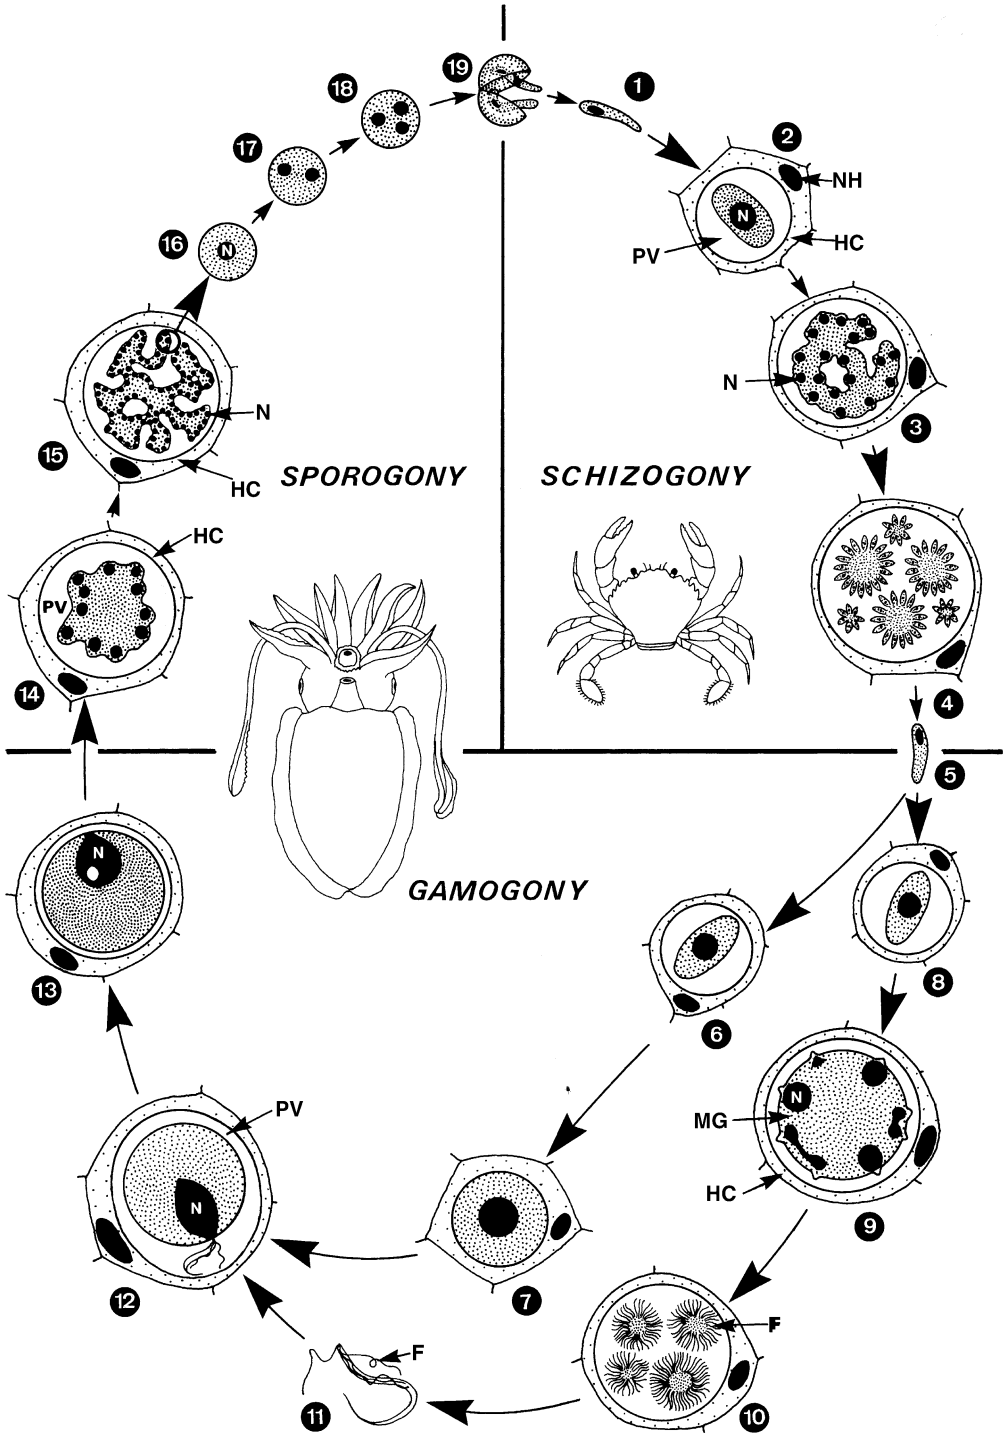
Life Cycle
Fig. 1 (page 54).

Albendazole

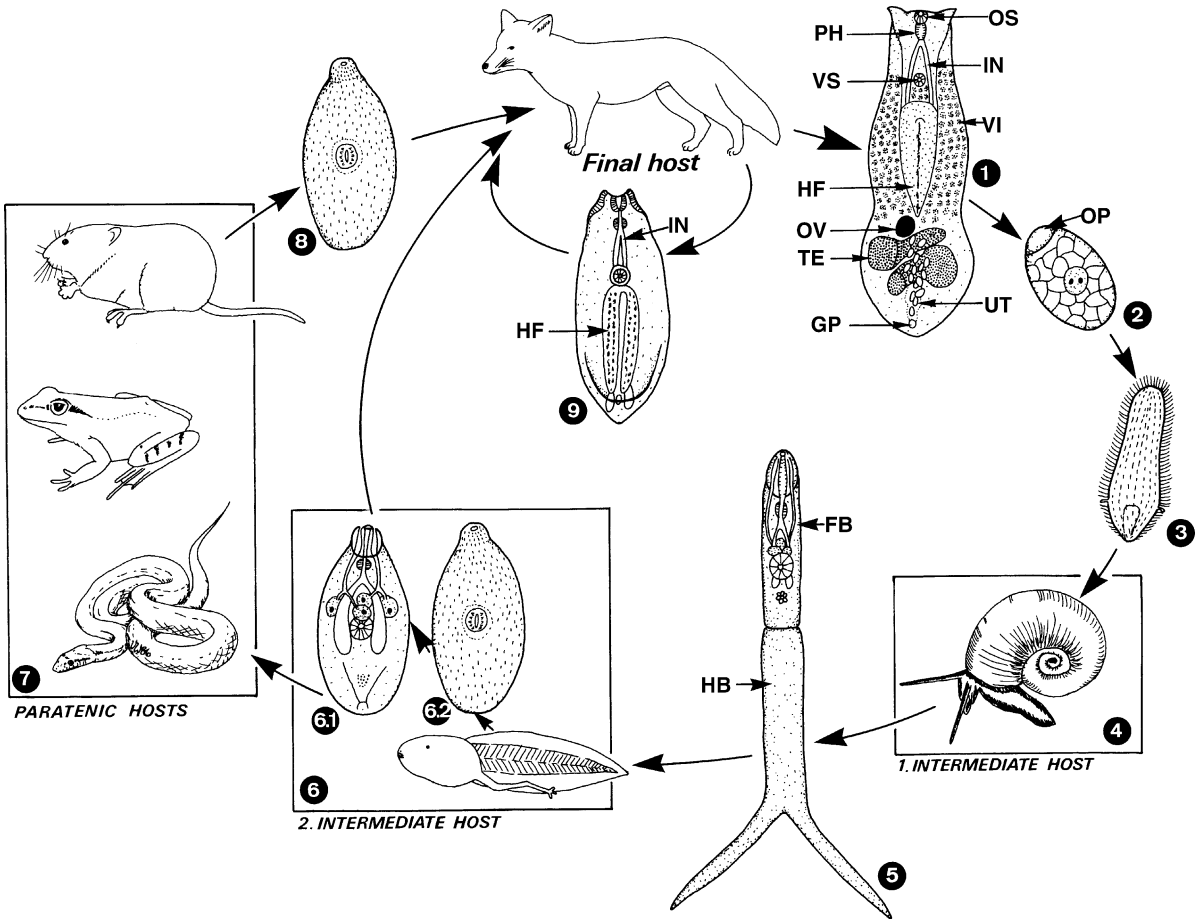
Macrocyclic lactone, →Nematocidal Drugs.

Aleppo Button

Badly healing skin lesion: a symptom of cutaneous →leishmaniasis, named after Aleppo, a town in the Middle East (Syria).



Aggregata eberthi. Figure 1 Life cycle of *Aggregata eberthi* in its hosts. *1–5* After oral uptake of sporocysts (19) by the crab (*Portunus* sp.) the sporozoites (*1*) are set free, leave the intestine, and enter cells of the connective tissues surrounding the gut; inside a →parasitophorous vacuole (*PV*) schizonts (*3*) produce 7–9 µm long, motile merozoites (*4, 5*). *6–11* As soon as the crab has been eaten by the cuttlefish *Sepia officinalis* (final host), the merozoites penetrate through the gut wall into cells of the submucosa. There they grow into macrogamonts (*6, 7*) or →microgamonts (*9*). The latter produce numerous biflagellate →microgametes (*10, 11*), which are about 30 µm in length and have an additional →recurrent flagellum. *12* Fertilization of the →macrogamete (200 µm in diameter). *13* →Zygote, surrounded by a very smooth →oocyst wall. *14–19* During →sporogony many globular sporocysts (*16*) are formed inside the smooth-walled oocyst. Each →sporocyst produces three sporozoites: large numbers of sporocysts are found within the feces of the cuttlefish (or within necrotic pieces of its gut). Crabs are again infected when ingesting such sporocysts. *F*, flagellum of microgamete; *HC*, host cell; *MG*, microgamont; *N*, nucleus; *NH*, nucleus of the host cell; *PV*, parasitophorous vacuole.



Alaria canis. Figure 1 Life cycle of *Alaria canis* (*A. americana*). *1* The adults (2.5–4.2 mm long) live in the anterior third of the small intestine of the final hosts (canids). *2* The operculate eggs are unembryonated when laid. *3* Larvae (miracidia) hatch in about 2 weeks after reaching water. *4* Miracidia swim actively and enter several species of helisomid snail (first →intermediate host), inside which mother →sporocyst and daughter sporocyst are produced. The latter give rise to →cercariae. *5* The →furcocercous cercariae leave the snail during daylight hours and swim to the water surface, where they hang upside down. *6* If tadpoles (as intermediate hosts of the second type) pass by, the cercariae penetrate the skin. In about 2 weeks the cercariae become transformed into →mesocercariae (*6.1, 6.2* show surface view). *7–9* Two weeks after infection the mesocercariae are infectious for a series of paratenic hosts, or directly for the final host (canids) if this eats an infected tadpole (or an adult frog after its →metamorphosis). Inside the →paratenic host, the mesocercariae are accumulated (8) in various tissues without further development. Large numbers of mesocercariae are very pathogenic for their hosts. If humans become accidentally infected, severe damage or death may occur. Mesocercariae which have reached the intestine of the final host penetrate into the body cavity and pass through the diaphragm into the lungs by the end of 2–3 weeks. Here, they transform into →diplostomulae (→metacercariae) in about 5–6 weeks. The diplostomulae migrate up the trachea and are finally swallowed. Inside the intestine they mature in about 4 weeks and cause severe enteritis. *FB*, forebody; *FT*, forked tail; *GP*, genital pore; *HB*, hindbody; *HF*, holdfast organ; *IN*, intestine; *OP*, →operculum; *OS*, oral sucker; *OV*, ovary; *PH*, pharynx; *TE*, →testis; *UT*, uterus with eggs; *VI*, →vitellarium; *VS*, ventral sucker.

Algid Malaria

Patent →malaria also possible in →*Plasmodium falciparum* with progressing multiplication of parasites but without fever. Thus this form of disease is often misdiagnosed.

Alimentary System Diseases, Animals

Gastrointestinal parasites affect their hosts, both directly and indirectly, through a wide variety of mechanisms. The diseases are associated mainly with →anorexia, loss of productivity, and →diarrhoea (→Clinical Pathology,

Animals). The characteristic changes in blood constituents are →hypoalbuminaemia and →anaemia – for parasites inducing loss of blood. Abomasal parasitism is associated with characteristic increases in the concentration of plasma pepsinogen and liver parasitism with increases in the levels of liver enzymes.

The lesions caused by important parasites of domestic animals have been described many times and will not be dealt with in detail. Briefly, lesions may be almost negligible, e.g., in *Moniezia* infections in ruminants. They may also be confined to the point of attachment of the parasite, as with the tapeworm *Anoplocephala* in horses or the acantocaphalan *Macracanthorynchus hirudinaceus* in the pig. At the other extreme, lesions caused by some parasites may cover entire parts of the gastrointestinal tract such as during infections with →*Ostertagia* in the abomasum, →*Strongyloides* in the small intestine, or →*Trichuris* in the large bowel. Finally, the liver fluke →*Fasciola hepatica* causes hepatic →necrosis and haemorrhages during migration, and erosions of the biliary mucosa when it reaches the bile duct.

It is not always possible to establish a link between the severity of the lesions and either the impaired physiology of an organ, or the secondary manifestations of disease, such as anorexia, →productivity loss, diarrhoea, or haematological changes. For example, lambs infected with →*Haemonchus contortus* and given a low-protein diet show more severe clinical signs of →weight loss, anaemia, and loss of appetite than others given a normal diet, despite similar levels of blood loss. Dietary protein supplementation may not, however, be successful in animals with concurrent abomasal and intestinal infections in which compensatory digestion and an increase in intestinal absorption of nutrients depend upon the integrity of the latter organ. On the other hand, larval challenge of immune animals may cause impaired production despite low parasite burdens. It is important to consider these nutritional and immunological factors during any field observations. They may well account for some of the conflicting reports on the effect of parasitism. A genetically determined variation in the susceptibility of cattle and sheep to certain →helminth infections has also been demonstrated. Inherited resistance, as assessed by faecal egg output, worm burdens, or clinical symptoms of disease, has been described, e.g., in sheep or cattle infected with *Ostertagia* spp., *Haemonchus contortus*, *Cooperia* spp. and →*Trichostrongylus* spp. Finally, the interaction between parasitism and the physiological condition of the ewe is well documented: the postparturient rise in worm egg output is attributed to a loss of resistance associated with late pregnancy and lactation. The common clinical signs and pathology of the parasitic diseases of the alimentary tract are summarized in: →Alimentary System Diseases, Ruminants, →Alimentary System Diseases, Horses, →Alimentary System Diseases, Swine, →Alimentary System Diseases, Carnivores.

Therapy and other measurements are presented in the chapters on control and disease control and under →Drugs.

Alimentary System Diseases, Carnivores

The common clinical signs and pathology of the parasitic diseases of the gastrointestinal tract of carnivores are summarized in Table 1.

Protozoal Enteritis

Coccidiosis (*Coccidiosis, animals*) and cryptosporidiosis have been reported in dogs and cats. *Giardia* spp. occurs in dogs and cats, and giardiosis may represent an important problem in these hosts. It causes →anorexia, depression, and a mild recurring →diarrhoea consisting of soft, light-coloured stools with a characteristic "oatmeal" texture, frequently containing mucus. Growth retardation and cachexia may occur. The mechanism by which giardial →malabsorption and diarrhoea occurs is unclear. Epithelial damage, increased turnover of epithelial cells, villous shortening, and disaccharidase deficiency have all been reported as manifestations of giardiosis. →*Entamoeba histolytica* is the cause of →entamoebiasis in humans and among domestic animals. The disease which occurs rarely in dogs is characterized by diarrhoea.

Gastrointestinal Helminthosis

Oesophagus

→*Spirocerca lupi*, the oesophageal worm, is a parasite usually associated with the formation of →nodules in the oesophageal wall. Occasionally, however, it may be found in gastric nodules in cats. Most infected dogs are not clinically affected and the infection is only detected at necropsy. Signs of oesophageal involvement include anorexia, →vomiting, dysphagia, and bloodstained regurgitus. There is a strong evidence of a causal relationship between *Spirocerca* and oesophageal fibrosarcomas or osteosarcomas. Ventral spondylitis of caudal thoracic vertebrae is also observed, the cause might be migrating worms inducing periosteal irritation.

Stomach

The presence of parasites in the stomach of dogs and cats does not commonly produce signs, except in severe infestations. The overall incidence of these parasites is low. Several →nematodes have been identified in the stomachs of dogs, cats, and wild carnivora:

Alimentary System Diseases, Carnivores. Table 1 Gastrointestinal parasitic diseases of carnivores (according to Vercruysse and De Bont)

Parasite	Host	Clinical signs and pathology[a]

[a] Clinical signs and pathology: 1, →Weight Loss; 2, →Anorexia; 3, →Vomiting; 4, →Diarrhoea; 5, →Dehydration; 6, →Unthriftiness; 7, →Anaemia; 8, →Abdominal pain; 9, →Hypoalbuminaemia; 10, Others

Occurrence of signs: ±, rare; +, common; ++, very common

* Probably identical with →*Neospora caninum*

Cylicospirura, *Cyathospirura*, *Spirura*, *Physaloptera* spp., →*Gnathostoma spinigerum*, and *Ollulanus tricuspis*. Only the latter three parasites are likely to cause signs of gastric parasitism. *Physaloptera* spp. inhabit the stomach and proximal duodenum of many carnivores and may be a cause of vomiting and chronic gastritis. Regurgitation may occur, presumably because of the oesophagitis induced by vomiting. Adults of *G. spinigerum* are found in groups up to 10 in cysts within the gastric mucosa of cats and dogs. The cysts may be 2 cm in diameter, and communicate with the gastric lumen by small openings. Gnathostomosis has been associated with illness and death. Symptoms include anophagia, occasional vomiting, →abdominal pain, and loss of weight.

Ollulanus tricuspis inhabits the stomach of cats. Although most infections are asymptomatic, *O. tricuspis* should be included in the differential diagnosis for vomiting in cats, especially when vomiting is postprandial.

Small Intestine

Several →trematodes cause infections in carnivores. →Schistosoma japonicum live within the mesenteric and hepatic portal veins of dogs (→Schistosomiasis, Animals Ruminants).

Many genera of trematodes (*Apophallus*, *Heterophyes*, *Alaria*, *Nanophyetus*, and others) are parasitic in dogs and cats throughout the world, but they are only rarely of any clinical consequence. →*Nanophyetus*

salmincola is important as a vector of the highly pathogenic *Neorickettsia helminthoeca*, the cause of "→salmon poisoning" in dogs, a disease with a high mortality rate.

Dogs may be parasitized by a great number of →cestodes. Some common species are *Taenia hydatigena, T. pisiformis, T. ovis,* →*Taenia multiceps, T. serialis,* →*Dipylidium caninum*, →*Echinococcus* spp., →*Mesocestoides* spp., and *Spirometra* spp. Two species occur frequently in cats: →*Taenia taeniaeformis* and *Dipylidium caninum*.

In most cases there are few, if any, clinical symptoms. Infections have been associated with diarrhoea and failure to thrive, but concomitant gastrointestinal nematode parasitism may often be of greater significance. The passage through the rectum and anus of the gravid segments of *Taenia* and *Dipylidium caninum* produces irritation in dogs, but not in cats. The proglottides passing through the rectum, or lodging in the anal glands, frequently cause the dog to scoot.

Strongyloidosis in dogs is caused by →*Strongyloides stercoralis*. Though not common, infection in young animals may have severe consequences. There is enteritis with erosion of the mucosa of the small intestine and haemorrhages. Bloody diarrhoea occurs in heavy infections. →Dehydration develops rapidly, and death may occur.

There are four hookworm species that commonly affect dogs and cats. →*Ancylostoma caninum* and *A. tubaeforme* are the most pathogenic species of dogs and cats, respectively. *A. braziliense* is another hookworm parasite of dogs and cats and is not very pathogenic. *Uncinaria stenocephala* is mainly a hookworm of dogs; in cats it is much less common. *U. stenocephala* is the least pathogenic of the →hookworms that affect dogs and cats. With *A. caninum*, disease results from blood loss into the bowel which leads to iron deficiency, →anaemia (hypochromic, microcytic). In →chronic infections there is emaciation, poor appetite, and pica and the animals are frail. There is some diarrhoea and the faeces are dark and sometimes blood-streaked.

With respect to ascarid infections →*Toxocara canis* is by far the commonest roundworm of dogs. It is not highly pathogenic and the effects of infection are often overstated. During larval migration various tissues (liver, lung, heart, kidney) may show granulomatous lesions. The pulmonary phase may be lethal in pups infected heavily before birth; death occurring within a week after birth. This is the most severe effect of *T. canis* infection. Once the worms have become adults in the small intestine the only clincal signs are those of pot-bellied abdomen, light diarrhoea, and failure to thrive. Adult worms are often passed in the faeces or vomited. The other ascarid of the dog, and rarely the cat, *Toxascaris leonina*, is non-migratory and of little pathological importance.

→*Toxocara cati*, the ascarid of cats, is endemic in all countries. As for infections with *T. canis*, many cases remain asymptomatic.

The Acanthocephalan *Onicola canis* occurs in the small intestine of wild carnivores and occasionally of dogs and cats. The lesions are the same as those described for *Macrocanthorynchus hirudinaceus* in swine (→Alimentary System Diseases, Swine), although clinical manifestations are rare.

Caecum, Colon, Rectum, Anus

The most important species are *T. vulpis* in dogs, and *T. campanula* and *T. serrata* in cats. →*Trichuris* is highly prevalent in all parts of the world but rarely causes clinical signs. Heavy infections associated with severe and often haemorrhagic typhlitis or typhlocolitis has been reported in dogs. Clinical manifestations include failure to thrive, →weight loss, abdominal pain, diarrhoea, dehydration, and terminal anaemia. In severe cases the faeces may be speckled with fresh blood. The lesions are caused by the adult worms boring tunnels into the mucosa of the large intestine.

Liver

The commonest parasite of the liver of cats, and less frequently in dogs, is *Opisthorchis felineus*. The signs of infection are emaciation, jaundice, and ascites.

Capillaria hepatica occurs only rarely in the liver of cats and dogs, and infection remains inapparent.

Therapy

→Chemotherapy, →Drugs.

Alimentary System Diseases, Horses

The common clinical signs and pathology of the parasitic diseases of the gastrointestinal tract of horses are summarized in Table 1.

Protozoal Enteritis

The only →*Eimeria* sp. occurring in horses, *Eimeria leuckarti* (→Coccidiosis, Animals) has been only sporadically reported to cause diarrhoea in young horses. *Cryptosporidium* has been reported in all domestic animals (→Cryptosporidiosis, Animals) including horses. In horses, symptoms have been particularly observed in animals with inherited or acquired immunodeficiency. *Giardia* spp. are usually non-pathogenic inhabitants of the small intestine of horses. However, they may cause

Alimentary System Diseases, Horses. Table 1 Gastrointestinal parasitic diseases of horses (according to Vercruysse and De Bont)

Parasite	Clinical signs and pathology[a]

[a] Clinical signs and pathology: 1, →Loss in performance, →Weight Loss; 2, →Anorexia; 3, →Diarrhoea; 4, →Constipation; 5, →Abdominal Pain; 6, →Hypoalbuminaemia; 7, Others

Occurrence of signs: ±, rare; +, common; ++, very common

diseases under certain circumstances, such as in animals which are immunocompromised, malnourished, or very young.

Gastrointestinal Infections

Stomach

→*Trichostrongylus axei* occurs in the stomach of horses. The worm is rarely a pathogen on its own, most infections are chronic and mild. However, *T. axei* induces typical lesions in horses. The condition has been described as a *gastritis chronica hyperplastica et erosiva circumscripta* for the main lesion is a pad- or cushion-like thickening in the glandular part of the stomach.

The most common parasites of the equine stomach are larvae of botflies of the genus →*Gasterophilus*. The most common species which pass to the stomach and settle on the gastric mucosa are *G. intestinalis* followed by *G. haemorrhoïdalis*. Despite the dramatic appearance of a heavy bot infestation, its true veterinary significance is unclear. The parasites may produce significant gastric lesions, but primarily in the non-glandular part of the stomach which plays little role in digestion. This is possibly the reason why the vast majority of infections remain asymptomatic. Yawning and unsatisfactory performance are described as common signs. Erratic movements of the larvae into the abdomen (with or without peritonitis) are described.

The spiruroid →nematodes *Habronema majus, H. muscae*, and *Draschia megastoma* are also parasitic in the stomach of equidae. →*Habronema* species lie on the mucosal surface while *Draschia* burrows in the submucosa to produce large, tumour-like →nodules. *D. megastoma* is therefore the most pathogenic of the →stomach worms, although clinical signs remain inapparent in most cases. The parasite is often incorrectly blamed for the disease and death of the host because of the very impressive character of the lesions it produces.

Small Intestine

The →cestodes found in the small intestine are →*Anoplocephala magna* and *Paranoplocephala mamillana*. In most cases they induce few, if any, clinical symptoms. The only →*Strongyloides* spp. in horses is *Strongyloides westeri* (→Strongyloidosis, Animals/Ruminants). Clinical outbreaks principally affect young suckling foals. Signs include →anorexia, loss of weight, coughing, →diarrhoea (rarely haemorrhagic), →dehydration, and slight to moderate →anaemia. Severe infections may be fatal. The ascarid →*Parascaris equorum* is a common parasite in young horses. Both the parasitic migration through the lungs and the intestinal phase of the life cycle may be associated with clinical signs. Symptoms include lethargy, loss of appetite, coughing, nasal discharge, and decreased weight gain. In the rare severe infections the intestinal phase may cause impaction, rupture, peritonitis, intussusception, and formation of abscesses.

Caecum, Colon, Rectum, Anus

Members of the trematode genus *Gastrodiscus* may be found in the colon of horses and swine, but they are of little clinical significance. However, the immature trematode has been reported to cause a severe and hyperacute, possibly fatal colitis in horses.

The cestode *Anoplocephala perfoliata* is commonly found in the distal small intestine, caecum, and proximal large intestine. A significant number of the parasites often accumulates at the ileocaecal junction and may produce marked lesions there. *A. perfoliata* is a significant risk factor for spasmodic colic and ileal impaction colic in the horse. The risk of spasmodic colic increases with infection intensity.

Members of the Strongylidae are abundant and common nematode parasites of the caecum and colon in Equidae. There are 55 species of strongyles, with fewer than 20 commonly found in horses, usually as mixed infections. Therefore, the clinical signs can be considered to be caused by all the worm species collectively. Specific clinical signs may arise due to the larval stages of the *Strongylus* spp. These are described in the section on the cardiovascular system. Adult large strongyles are inhabitants of the large intestine. They feed by attaching to the glandular epithelium and drawing a plug of mucosa into the buccal capsule. Incidental damage to blood vessels in the plug results in bleeding. Some, as seen with clusters of *Triodontophorus* spp., cause deep ulcers. The damage thus caused results in the formation of crater-like ulcers which may extend deep into the gut wall. These lesions are believed to be the cause of anaemia, failure to thrive, and poor performance. The colitis and typhlitis do not often lead to diarrhoea. The adults of the Cyathostominae feed mainly on intestinal contents and are of little pathogenic significance. *Cyathostoma*-associated clinical disease is attributed to the synchronous emergence of large numbers of previously inhibited third- and fourth-stage larvae from the large intestinal wall, resulting in physical disruption of the mucosa and typhlitis/colitis. Animals sometimes develop a fatal syndrome (winter cyathostominosis) characterized by sudden onset of diarrhoea, mild colic signs, failure to thrive or cachexia, and →hypoalbuminaemia. Emaciation possibly results from the anorexia, the reduction of absorptive function, and the loss of protein through the disrupted intestine. A reduced level of ileocaeco-colic motility was recorded in ponies experimentally infected with a mixture of strongyles, predominantly cyathostomes. It was argued that this would reduce propulsion of ingesta, and cause loss of appetite and weight. Additional mechanisms which may contribute to the occurrence of cyathostome-associated colic include intestinal mucosal →oedema and/or vasoconstriction induced by the local production of vasoactive substances in response to the presence of cyathostome mucosal stages.

The only oxyurid of importance is *Oxyuris equi*, the large →pinworm of horses. It is never regarded as a serious pathogen. The chief feature of oxyuriosis in equines is the →anal pruritus produced by the egg-laying females. The irritation caused by the anal pruritus produces restlessness and improper feeding. The animal rubs the base of its tail against any suitable object, causing the hairs to break off and the tail to acquire an ungroomed "rat-tailed" appearance.

Liver

A variety of cestodes, nematodes, and →trematodes produce inflammation of the liver and bile ducts, but they are of minor importance in horses. *Parascaris equorum, Strongylus equinus*, and *S. edentatus* migrate through the liver, but only *S. edentatus* has been associated with transient colic. *Echinococcus granulosus* is commonly found in the liver. Although they may involve a large amount of tissue, hydatid infections appear to be well tolerated. →*Fasciola hepatica* is occasionally found in the equine liver. Heavy infections are rare and are usually discovered only during post-mortem examination.

Abdominal Cavity

Most of the parasites found in the peritoneal cavity have their final habitat elsewhere and passage through the peritoneum occurs in the normal course of migration, or by accident. Parasites normally migrating through the peritoneal cavity are the immature *Fasciola hepatica, Strongylus edentatus*, and *Strongylus equinus*. They can cause acute and chronic peritonitis.

Examples of accidental passages are those of *Parascaris equorum* and *Gasterophilus*, which enter the cavity through intestinal or gastric perforations.

Therapy

→Chemotherapy, →Nematocidal Drugs, →Cestodocidal Drugs.

Alimentary System Diseases, Ruminants

The common clinical signs and pathology of the parasitic diseases of the gastrointestinal tract of ruminants are summarized in Table 1.

Protozoal Enteritis

Coccidiosis (→Coccidiosis, Animals) and Cryptosporidiosis (→Cryptosporidiosis, Animals) are very common diseases in young ruminants. *Cryptosporidium parvum* is frequently observed in calves and lambs of 1–4 weeks of age. Watery diarrhoea, sometimes with blood, is very typical and animals may dehydrate and show retarded growth. Morbidity is high but mortality is low in most cases. However, lethal cryptosporidiosis has been reported, possibly related to strain-specific virulence. *C. parvum* is not host specific and may also infect humans where severe disease may occur in immune-comprised individuals. Other *Cryptosporidium* spp. have been described in ruminants; however, these appear to be of no or very limited clinical significance.

Many *Eimeria* spp. have been identified in ruminants; however, only few are of clinical importance. Depending on the infection pressure *Eimeria bovis* or *E. zuernii* may induce subclinical disease or moderate to severe, sometimes haemorrhagic, diarrhoea in calves. Lesions are mainly found in the large intestine. Watery diarrhoea related to infection of the small intestine with *E. alabamensis* has been repeatedly reported in grazing calves. In sheep, *E. ovinoidalis*, *E. bakuensis,* and *E. ahsata* are considered particularly pathogenic; in goats, *E. ninakohlyakimovae* and *E. arloingi* are the most pathogenic species. Dehydration and hypoproteinaemia are typical signs of coccidiosis; fever and anorexia may be observed in severe cases. Disease symptoms are generally seen before oocysts are shed which makes specific diagnosis difficult. Coccidiosis-related mortality is variable but usually low. Recovering calves may show retarded growth. Cryptosporidiosis and coccidiosis are self-limiting diseases and generally disappear after 2–14 days. Drugs for therapy are available (toltrazuril, diclazuril), but effective control depends on strategic measures (improvement of hygiene, disinfection, and metaphylactic/prophylactic treatment). *Giardia* spp. are usually non-pathogenic inhabitants of the intestine of cattle, sheep, and goats. However, they may cause diseases under certain circumstances, such as in animals which are immunocompromised, malnourished, or very young.

Gastrointestinal Helminthosis

Abomasum

Various infections of the abomasum have been reported of which →Ostertagiosis is probably the most important disease in grazing sheep and cattle in temperate climatic zones throughout the world. It causes subclinical losses of production and disease. The clinical disease is characterized by →diarrhoea, →weight loss, decreased production, rough hair coats, partial →anorexia, mild →anaemia, →hypoalbuminaemia, →dehydration, and in some cases death. →*Ostertagia ostertagi* in cattle and *O. (Teledorsagia) circumcincta* in sheep and goats are the most important species.

→Haemonchosis is a common and severe disease of the ruminant abomasum in many parts of the world. →*Haemonchus contortus* infects mainly sheep and goats, while *H. placei* occurs mainly in cattle. The pathogenesis of *Haemonchus* infection is the results of anaemia and hypoproteinaemia caused by the blood-sucking activity of the parasite.

→*Trichostrongylus axei* lives in the abomasum of cattle, sheep, and goats. In ruminants, *T. axei* infections are usually part of a mixed abomasal helminthosis and its effects cannot be dissociated from those of other worm species. The worm is rarely a pathogen on its own, as most infections are mild. Animals experimentally infected with large numbers of *T. axei* show a decrease of blood albumin, haemoconcentration, and a rise in serum pepsinogen. The clinical signs include diarrhoea, anorexia, progressive emaciation, listlessness, and weakness.

The pathogenesis of *M. digitatus* resembles that of *H. placei*. A drop in haematocrit to less than 20% has been reported in cattle infected with more than 1000 worms.

Small Intestine

Paramphistome infections may cause significant intestinal problems in ruminants (→Paramphistomosis). The adult worms live in the rumen, but the pathological effects of infection are caused by the immature stages within the small intestine. The most pathogenic species are thought to be *Paramphistomum microbothrium*, *P. ichikawai*, →*P. cervi*, *Cotylophoron cotylophoron*, and various species of *Gastrothylax*, *Fishoederius*, and *Calicophoron* (→Digenea).

Schistosomes live within the mesenteric and hepatic portal veins of ruminants. Although →*Schistosoma* infections in ruminants are highly prevalent in certain regions, the general level of infestation is often too low to cause clinical disease or losses in productivity. Levels sufficiently high to cause outbreaks of clinical schistosomosis do occur occasionally and infestation

Occurrence of signs: ±, rare; +, common; ++, very common

becomes manifest either as an intestinal syndrome which is usually self-limiting, or as a chronic hepatic syndrome, which is usually progressive (Schistosomiasis, Animals). The intestinal syndrome is caused by the deposition of large numbers of eggs in the intestinal wall and usually follows a heavy infestation in a susceptible animal, i.e., an animal in which the capacity of the host to suppress the egg laying of the parasite has not been stimulated by previous infestations. This has been reported among cattle, sheep, and goats infected with either *S. bovis* or by *S. mattheei*. As the faecal egg counts rise sharply with the onset of egg production the animal develops a mucoid and then haemorrhagic diarrhoea, accompanied by anorexia, loss of condition, general weakness and dullness, roughness of coat, hypoalbuminaemia, and paleness of mucous membranes. Death may occur 1 or 2 months after the onset of clinical signs. In most cases, the animal makes a spontaneous but slow recovery. The primary cause of the diarrhoea is the passage of large numbers of eggs through the wall of the intestine. The anaemia is usually due to an increased rate of red cell removal from the circulation; while haemodilution and the inability to mount a sufficiently effective erythropoietic response are of secondary importance. The underlying cause of the hypoalbuminaemia is hypercatabolism of albumin due to substantial loss of protein in the gastrointestinal tract.

In ruminants the more common and widely distributed intestinal →Cestodes are →*Moniezia expansa*, *M. benedeni*, *Thyzaniezia* (*Helicometra*) *giardi*, *Stilesia globipunctata*, and →*Avitellina* spp. These →tapeworms live in the middle third of the small intestine. They are generally of minor pathological importance and only produce harmful effects on the host in rare circumstances. The host–parasite relationship is so well adjusted that there is a surprising absence of apparent pathogenicity, even in such heavy infestations that the passage of intestinal contents may be impeded by the worms and, in most cases there are few, if any, clinical symptoms. Infections have been associated with diarrhoea and ill thriving, but concomitant gastrointestinal nematode parasitism may often be of greater significance. In sheep *S. globipunctata* infections may cause signs of enteritis. The pathogenesis of this parasite is associated with the immature stages, which enter the mucosa of the intestine and induce the formation of →nodules.

Several nematode species cause severe gastrointestinal diseases such as →Strongyloidosis, →Trichostrongylosis, →Cooperiosis, and →Nematodirosis. Hookworm infections are caused by the two ancylostomatids occurring in cattle *Bunostomum phlebotomum*, and the little known *Agriostomum vryburgi*. Two species occur in sheep and goats: *Bunostomum trigonocephalum* and *Gaigeria pachyscelis*. Apart from the little damage to the mucosa of the small intestine caused by the bites, the entire pathogenesis of these worms is attributable to blood-sucking, which begins when larvae enter the adult stage. In addition to the withdrawal of great quantities of blood by the parasites, the feeding sites continue to bleed for several minutes after the worms have moved to another area. The signs are those of a rapid loss of blood: pale mucosae, hydraemia, sometimes →oedema, lassitude, and loss of weight. The faeces are often diarrhoeic and contain bloody mucus, or may be tarry in character.

The anaemia that develops is first normocytic and normochromic, but later becomes microcytic hypochromic as the animal becomes iron deficient. Other pathological changes recorded are hypoproteinaemia, hypocalcaemia, hyperglycemia, and →eosinophilia. The lowered plasma protein levels may be caused by both a compensatory replacement of haemoglobin at the expense of circulating plasma proteins and the loss of blood taken by the parasites. The non-specific loss of body fluid by leakage would account for the lowered plasma calcium values; the calcium associated with plasma albumin being lost with the protein.

Toxocara vitulorum, the pathogenic ascarid of large ruminants, is most commonly found in buffalo and cattle calves of less than 4 months of age. Infection occurs through ingestion of larvae with the milk from the mother. The clinical signs in calves relate primarily

to the bulk of parasites in the small intestine, which impedes the passage of ingesta and impairs the assimilation of food. The clinical signs include anorexia, diarrhoea or →constipation, dehydration, steatorrhoea, →abdominal pain, and a butyric odour of the breath.

Caecum, Colon, Rectum, Anus

→*Trichuris* spp., the whipworms, inhabit the caecum and occasionally the colon of ruminants (→Trichuriasis, Animals). Members of the genus →*Oesophagostomum* infect cattle, sheep, and goats (→Oesophagostomosis).

→*Chabertia ovina* is found in the colon of sheep, cattle, goats, and deer throughout the world. Infections are usually light in intensity, and outbreaks of clinical disease are sporadic. Disease in sheep is associated with the presence of fifth stage and adult worms in the colon. Affected animals have a severe diarrhoea, sometimes blackened by blood. Ill thriving has been reported. The adults penetrate the muscularis mucosae and take a plug of mucosa into the buccal capsule; minor haemorrhage may be related to physical trauma to the mucosa but this blood loss is insufficient to induce anaemia in natural infections. More significant is the loss of plasma protein from the mucosa, which may cause hypoalbuminaemia and weight loss.

Liver

The common clinical signs and pathology of the parasitic diseases of the liver of ruminants are summarized in Table 2.

A variety of →cestodes, →nematodes, and →trematodes produce inflammation of the liver and the bile ducts. Some of the parasites produce hepatic lesions in the course of their natural or accidental migration to their final habitat in the guts. The traumatic lesions produced by such larvae rarely cause disease, and are mostly found incidentally during post-mortem examination. Very heavy infections in sheep with the oncospheres of *Cysticercus tenuicollis* may induce severe haemorrhagic migration tracts in the liver. Animals are weak, show abdominal pain, and have an enlarged, often palpable liver. Death may occur.

The most important parasites of the liver are those which have their final habitat in this organ.

Trematodes

A variety of trematodes are very important parasites of the liver of animals. They belong to the families Fasciolidae (→*Fasciola hepatica*, →*F. gigantica*, and →*Fascioloides magna*), Dicrocoeliidae (→*Dicrocoelium dendriticum*, *D. hospes*), and Paramphistomatidae (*Gigantocotyle explanatum*).

Fasciola hepatica, the common liver fluke, is the most widespread and important of the group. *F. gigantica* occurs in the tropics. It occurs mainly in sheep and cattle, but a patent infection can develop in horses, pigs, wild animals, and in humans. The pathogenesis of fasciolosis is attributable in part to the invasive stages in the liver and in part to the blood feeding by the adults in the bile ducts. The process in all hosts shows close similarities, but considerable variation in severity occurs (→Fasciolosis, Animals).

The host range of *Fascioloides magna* includes cattle, bison, sheep, goat, and horse but it is only recognized as a pathogen of sheep. In sheep this parasite wanders continuously in the liver and causes extensive parenchymal destruction. Even a few →flukes may kill a sheep. *Dicrocoelium*, as with many →liver flukes, has a wide host range including both sheep and cattle. The pathological changes in the liver are less severe than those seen in *F. hepatica* infection (→Fasciolosis, Animals) and even in heavy infections there may be no clinical signs.

A chronic hepatic syndrome has been described in cattle infected with *Schistosoma mattheei*. This syndrome is less common than the intestinal syndrome (see above). It is characterized by progressive hepatic fibrosis and may be manifested clinically as chronic hepatic insufficiency, with loss of condition, or as acute terminal hepatic failure, which often provokes nervous signs as ataxia or mania. The established condition is

Alimentary System Diseases, Ruminants. Table 2 Parasitic diseases of the liver (ruminants) (according to Vercruysse and De Bont)

Parasite	Clinical signs
Dicrocoelium spp.	Loss of condition
Fasciola hepatica, F. gigantica	Acute (sheep): anorexia, distended abdomen pain, death. Mild: hypoalbuminaemia, hyperglobulinaemia eosinophilia, light anaemia. Chronic: loss of appetite, pale mucosae, oedema, productivity loss, Hypoalbumiunaemia, anaemia, SGOT, γ-GT rise
Fascioloides magna	Sheep: weakness, death
Gigantocotyle explanatum	Decreased production, enlargement of bile ducts, inflammatory reactions
Schistosoma spp.	Loss of condition, diarrhoea

invariably fatal. The syndrome is of immunological origin and apparently depends on the ability of the ox to limit the infestations by destruction of adult parasites. It is probably initiated by an immunological reaction in the hepatic portal veins to antigen released by dead or dying worms in the portal system. The lesion is analogous to Symmer's pipestem fibrosis in man.

Gygantocotyle explanatum occurs in the bile ducts of ruminants in Asia. Heavy infections induce inflammatory reactions, with enlargement of the bile ducts. Decreased production has been reported.

Cestodes

Thysanosoma actinoides and *Stilesia hepatica* are parasites of the bile ducts of ruminants. They are both practically non-pathogenic.

Abdominal Cavity

Most of the parasites found in the peritoneal cavity have their final habitat elsewhere and passage through the peritoneum occurs in the normal course of migration, or by accident. The only parasite of importance is *Fasciola hepatica* as it can cause acute and chronic peritonitis.

Other parasites, such as the commonly seen →*Setaria*, use the peritoneal cavity as their final habitat. All members of this genus live as well-adjusted parasites in their normal host and do not cause peritoneal lesions.

Therapy

→Chemotherapy, →Trematocidal Drugs, →Cestodocidal Drugs, →Nematocidal Drugs.

Alimentary System Diseases, Swine

The common clinical signs and pathology of the parasitic diseases of the gastrointestinal tract of swine are summarized in Table 1.

Protozoal Enteritis

Coccidiosis (→Coccidiosis, Animals) and Cryptosporidiosis (→Cryptosporidiosis, Animals) have been reported in pigs. Although it is possible to experimentally induce clinical cryptosporidiosis in piglets this pathogen appears to be of little significance under natural conditions. Pigs serve as hosts for a number of coccidia species of the genus *Eimeria*. Oocysts of *Eimeria* are frequently found in adult pigs, particularly sows, but are only rarely associated with clinical disease or reduced performance. In contrast, *Isospora suis* is now widely accepted as a major cause of enteritis in suckling piglets. Prevalence is very high in young piglets and generally peaks in the second or third week after birth. Even moderate infection levels can induce diarrhoea in suckling pigs. Due to the short prepatency of around 5 days, rapid sporulation in the environment and high reproductive potential *I. suis* spreads rapidly within a litter and across farrowing crates. Faeces is of pasty to watery consistency, gray to yellow, and has a typical odour. Although mortality is low the economic loss may be considerable due to impairment of piglet performance which may continue after weaning in recovered animals. →*Balantidium coli* occurs in the large bowel in pigs and sometimes other mammals. It is normally present as a commensal in the lumen but is capable of invasion of tissues injured by other diseases (e.g., →*Trichuris* infection, see below).

Gastrointestinal Helminthosis

Stomach

There are several helminths that possibly live in the stomach of swine. In contrast to ruminants, →*Trichostrongylus axei* occurs rarely in pigs (→Trichostrongylosis). →*Hyostrongylus rubidus* is the most important parasite of the stomach of swine but very rare under conventional keeping conditions. This trichostrongylid nematode produces lesions resembling those caused by →*Ostertagia* in ruminants, but with less severe consequences. Listlessness, thirst, →anorexia, →anaemia, →diarrhoea, and reduced weight gains may occur. Under field conditions hyostrongylosis is associated with the "thin-sow syndrome." Parasite or host strain differences may account for some of the variations recorded in the literature regarding the effects of experimental *H. rubidus* infections on swine health and performance.

Gnathostoma hispidum live deep in the gastric mucosa where they may cause severe ulceration. Migrating larvae may be found in the liver where they leave necrotic tracks. *Physocephalus sexalatus* and *Ascarops strongylina* may be found free in the lumen or partly embedded in the mucosa. *Simondsia paradoxa* female worms form palpable →nodules in mucosal crypts. Clinical signs of acute or chronic gastritis, and occasional ulceration have only been observed in the rare heavy infections.

Small Intestine

The trematode →*Schistosoma japonicum* lives within the mesenteric and hepatic portal veins of pigs (→Schistosomiasis, Animals).

Strongyloidosis caused by →*Strongyloides ransomi* occurs in swine. Clinical outbreaks principally affect piglets. Signs include anorexia, loss of weight, diarrhoea (rarely haemorrhagic), →dehydration, and slight to moderate anaemia. Severe infections may be fatal.

Alimentary System Diseases, Swine. Table 1 Gastrointestinal parasitic diseases of swine (according to Vercruysse and De Bont)

Parasite	Clinical signs and pathology[a]

Oesophagostomum dentatum	+	+	+			+	+
O. quadrispinulatum							
Trichuris suis	+	+	+		+	+	+

[a] Clinical signs and pathology: 1, →Loss in performance, →Weight Loss; 2, →Anorexia; 3, →Diarrhoea; 4, →Constipation; 5, →Abdominal Pain; 6, →Hypoalbuminaemia; 7, Others

Occurrence of signs: ±, rare; +, common; ++, very common

→Hookworms of the genus →*Globocephalus* appear to be of little significance in swine (→Alimentary System Diseases, Ruminants).

Ascaris suum is a very common parasite of pigs. Its importance is related both to the sometimes very significant lesions caused by larvae during migration through the liver and lungs, and to the effects of adult worms in the small intestine. In the liver, the travelling larva causes intralobular →necrosis and a granulation reaction known as "milk spots." However, these lesions are not associated with symptoms. In the ordinary moderate infections, adults have no defined pathogenesis. In heavy infection, there is experimental evidence of reduction in growth rate, diarrhoea, and ill thriving. Intestinal obstruction is rare.

The Acanthocephalan *Macrocanthorynchus hirudinaceus* is the thorny-headed worm of swine, which infects the small intestine. The worm causes trauma at the site of attachment with its thorny →proboscis. The proboscis may penetrate as far as the serous coat, and nodules of up to 1 cm in diameter may be visible on the serosal surface of the gut. They occasionally perforate, causing peritonitis. Severely infected pigs may suffer ill thriving and anaemia. The latter is probably related to the loss of plasma protein and to the haemorrhages from numerous ulcerative lesions. The pigs often show signs of acute →abdominal pain during these infections.

Caecum, Colon, Rectum, Anus

The →whipworm *Trichuris* suis inhabits the caecum of pigs. Heavy infections associated with severe and often haemorrhagic typhlitis or typhlocolitis has been reported. Clinical manifestations include anorexia, dysentery, dehydration, →weight loss, and terminal anaemia. In severe cases the faeces may be markedly haemorrhagic or even all blood. The lesions are caused by the adult worms boring tunnels into the mucosa of the large intestine. Penetration of the mucosa by the parasites produce nodules in the intestinal wall (→Alimentary System Diseases, Carnivores). It has been shown that concurrent infections with *T. suis* enhances the ability of opportunistic bacteria to multiply and cause disease and pathology.

→Oesophagostomosis has been reported in pigs. The two common species found in pigs are *O. quadrispinulatum* and *O. dentatum*. Although the parasites themselves are generally highly prevalent, clinical →oesophagostomosis is not common in pigs. The "thin-sow-syndrome" has been associated with oesophagostomosis. At necropsy distinct nodules caused by the histotropic larvae are a common observation.

Liver

The most important parasitic condition affecting the liver of pigs is the "milk spots" caused by the passage

of ascarid larvae (see supra). The pathogenesis of →*Stephanurus dentatus* infections (→Urinary System Diseases, Animals) is primarily related to the damage caused by the larvae during their migration through the liver. Hepatitis cysticercosa, resulting from the migration of *Cysticercus tenuicollis*, may be rarely observed in pigs (→Alimentary System Diseases, Ruminants).

→*Fasciola hepatica* has been found in pigs, but infections are very rare. Hepatic schistosomosis occur in swine infected with *S. japonicum*. The lesions resemble those observed in cattle (→Alimentary System Diseases, Ruminants).

The opisthorchid →flukes (*Opisthorchis felineus*, →*Clonorchis sinensis*) are normally parasitic in the bile ducts of carnivores. However, they may also occur in swine and humans. The signs of heavy infection are emaciation, jaundice, and ascites.

Abdominal Cavity

Most of the parasites found in the peritoneal cavity have their final habitat elsewhere and passage through the peritoneum occurs in the normal course of migration, or by accident. Parasites normally migrating through the peritoneal cavity are the immature *Fasciola hepatica* and *Stephanurus dentatus*. Both can cause acute and chronic peritonitis.

Therapy

→Chemotherapy, →Trematocidal Drugs, →Cestodocidal Drugs, →Nematocidal Drugs.

Allantosoma

Genus of suctorian ciliates attached to the intestinal wall of horses.

Allergen

Substance (e.g., house dust) or portions of an animal (e.g., mite), that cause an increased immune-reaction in humans.

Allergy

Increased immune reactivity of humans on repeated contact with allergenic substances.

Allethrin

Chemical Class

Pyrethroid (type I). →Arthropodicidal Drugs.

Mode of Action

Open state voltage-gated sodium channel blocker. →Ectoparasiticides – Blockers/Modulators of Voltage-Gated Sodium Channels.

Allochthony

The Greek terms *allos* = foreign and *cthonos* = home/place are used to characterize species which invade a new region/new hosts and often do not stay.

Alloiozona

Genus of symbiontic ciliates in the caecum and colon of horses.

Allopathy

→Speciation.

Allopatric Speciation

From Greek: *allos* = alien, Latin: *patria* = homeland. This term describes the formation/occurrence of related species in different regions/biotopes. →Speciation.

Allopurinol

→Leishmaniacidal drugs, agent against Leishmaniasis (dogs).

Alloscutum

Dorsal region posterior to the →scutum in ixodid ticks.

Alloxenic Speciation

→Speciation.

Alopecia

Clinical and pathological symptoms (e.g., loss of hair) of infections with skin parasites (→Skin Diseases, Animals, →Demodicosis, Man, →Acariosis, Animals, →Lice).

Alphamethrin (Alpha-Cypermethrin, A-Cypermethrin)

Chemical Class

Pyrethroid (type II, α-CN-pyrethroids).

Mode of Action

Open state voltage-gated sodium channel blocker. →Ectoparasiticides – Blockers/Modulators of Voltage-Gated Sodium Channels, →Arthropodicidal Drugs.

Aluminium Hydroxide

The only adjuvant for vaccines licensed for use in humans.

Alveococcosis

→Echinococcosis due to infection with →*Echinococcus multilocularis*.

Alveococcus

→*Echinococcus*.

Alveolar Cyst

→Echinococcus/Fig. 1. Formation and growth see →Echinococcus/Fig. 5.

Alveolata

New phylum of protozoans comprising the subphyla Apicomplexa (Sporozoa), Dinoflagellata and Ciliophora. →Classification/New System.

AMA

Apical membrane antigen.

Amandibulata

Synonym

→Chelicerata.

Classification

Subphylum of →Arthropoda. Arthropods (e.g., →Spiders, →Scorpions, →Ticks, →Mites) that lack antennae and mandibles and are commonly placed in the subphylum Amandibulata. Others prefer the term Chelicerata, thus named because the first postoral appendages become feeding organs called →chelicerae (→Arthropoda/System).

Amastigotes

Intracellularly parasitic developmental stage of, e.g., →*Leishmania* species, the very short flagellum (invisible

in light microscopy), does not rise above the surface of the parasite (→Flagella). These amastigotes are also called →micromastigotes.

Ambiphrya

Sessil ciliates on skin and gills of fish.

Amblyomma

Name
Greek: *amblys* = not sharp rounded, *omma* = eye.

Classification
Genus of ixodid →ticks; see also →Aggregation-Attachment Pheromones.

General Information
Genus of hard →ticks, which comprises about 100 species, the most important of which are found in Africa south of the Sahara and in the New World in tropical and subtropical humid regions (not in Europe). Important species are the Bont tick *A. hebraeum* (nicely coloured) in South Africa, *A. variegatum* (Tropical bont tick) in East Central Africa, *A. pomposum* (Highland bont tick) in western Central Africa, *A. americanum* (Lone star tick) in the USA, Eastern Coast until Central Texas, *A. maculatum* (Gulf Coast tick) in the southern states of the USA, and *A. cajennense* (Cayenne tick) from Texas to Argentinia. All *Amblyomma* spp. involve 3 hosts. Their sucking always induces painful skin lesions, necroses, itching, ulcera, granulomas (e.g., *A. cajennense* in horses). Also humans are attacked by larvae and nymphs when walking on cattle meadows. Loss of weight is enormous, if large amounts of ticks suck at cattle. *A. hebraeum* needs at least 171 days for one generation, it produces nearly 20,000 eggs per female and each stage may starve for more than 6 months. Thus they are absolute competitive ectoparasites. As vectors they are known to transmit stages of *Ehrlichia* spp., *Rickettsia rickettsii, Cowdria ruminantium, Coxiella burneti, Hepatozoon americanum (A. americanum), Theileria mutans (A. variegatum, A. hebraeum), Cytauzoon felis = Theileria (A. variabilis).*

Disease
→Heartwater, →Tularemia.

Amblyospora

Classification
Genus of →Microsporidia.

Life Cycle
Fig. 1 (page 69).

Amebae

→Amoebae.

American Trypanosomiasis (Chagas Disease)

In the acute stage of →Chagas Disease, the direct examination of anticoagulated blood or its buffy coat will usually reveal the presence of motile trypanosomes. Giemsa-stained thin or thick blood films are useful for confirmation. Direct visualization of trypanosomes is much more difficult in the chronic stage of the disease, where culture in NNN medium, blood inoculation into mice or xenodiagnosis with uninfected reduviid bugs are used to propagate the causative parasite which then becomes detectable by microscopic examination. Where appropriate facilities are available, PCR may be useful for detecting *T. cruzi* in blood.

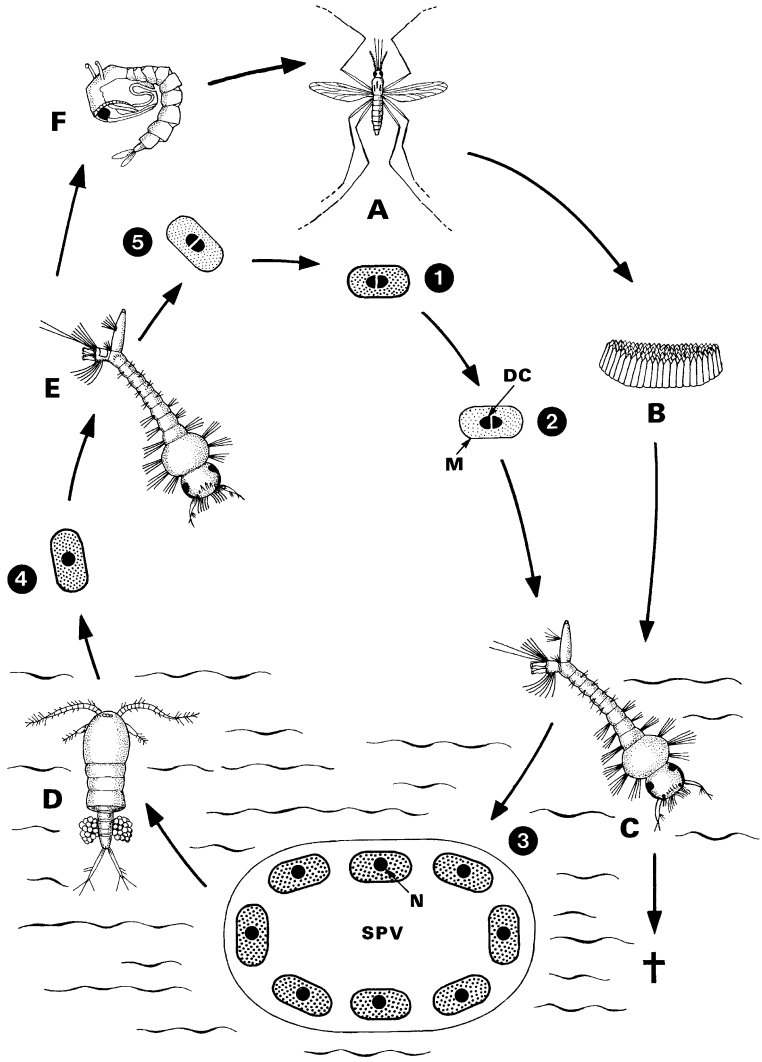
For epidemiological or individual screening, the indirect fluorescent antibody test (IFAT) proved to be highly sensitive. However, cross-reactivity with *Leishmania* spp. co-endemic with *T. cruzi* in various areas of Latin America limits the usefulness of the IFAT.

Amidines

Used as →arthropodicidal drugs and agents against Babesiosis.

Amidostomum

Genus of trichostrongylid, →nematodes of birds.



Amblyospora. Figure 1 Life cycle of *Amblyospora* species using different →*Culex* stages (A, B, C, E, F) and copepods (D) as hosts. *1* Inside adult female →mosquitoes (A) diplocaryotic →spores are formed (dense wall) which are transovarially transmitted to the eggs (B) and to the developing larvae (C) of the insect. *2, 3* Inside the larvae diplocaryotic →meronts (DC, M) reproduce and finally give rise to unicaryotic (N) →meiospores – eight within a sporophorous vesicle. During this process most larvae die, thus setting free the meiospores which are ingested by another host, i.e., by a copepod (D). *4* Within the copepod, finally, uninucleate spores are formed from meronts. *5* When such uninucleate spores are swallowed by larvae of mosquitoes, various generations of diplocaryotic meronts are formed and persist in the pupae and adults of the insect. In the adult →mosquitoes, finally, new diplocaryotic spores are produced (1). *DC*, →diplocaryon; *M*, meront; *MS*, meiospore; *N*, nucleus; *SPV*, →sporophorous vacuole.

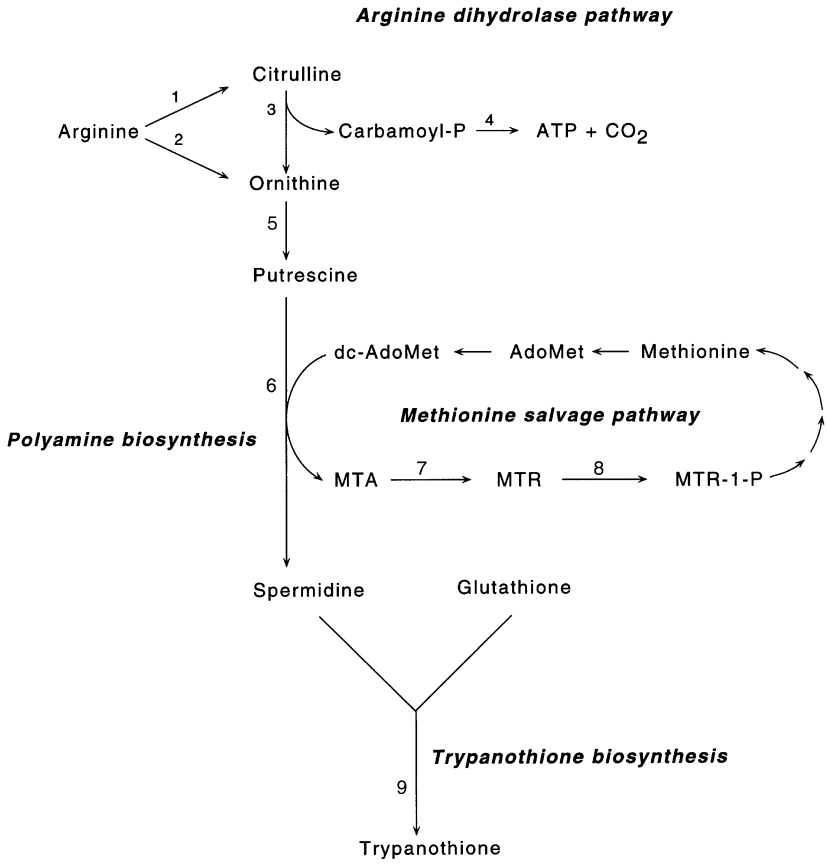
Amino Acids

Like all other organisms, parasitic protozoa and helminths require the basic set of 20 amino acids for their protein synthesis, formation of other biomolecules, and, to a lesser extent, for energy production. The majority of these amino acids are essential for the parasite and have to be obtained from the diet or from exogenous proteins. Ingested proteins are hydrolyzed within specialized organelles (lysosomes, lysosome-like organelles, and other specialized vacuoles) into their constituent amino acids by the concerted action of specific proteinases and peptidases. In nematodes and trematodes, protein digestion is accomplished in the gut lumen. The amino acid metabolism of parasites resembles that of higher animals, but there are differences regarding the properties of the enzymes involved, the relative importance of the various pathways and the occurrence of a variety of unusual metabolic routes. The unique properties of amino acid metabolism found in protozoan parasites are often

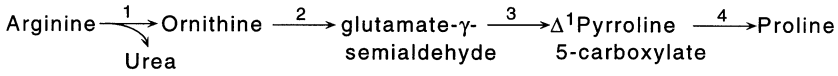
determined by secondary gene loss and lateral gene transfer, primarily from bacterial lineages.

Biosyntheses and Interconversions

The carbon skeletons of glycine, alanine, serine, aspartate, and cysteine are derived primarily from glycolytic or Krebs cycle intermediates, while the α-amino groups are usually furnished by transamination reactions from glutamate. The latter amino acid is formed from ammonia and the Krebs cycle intermediate, α-ketoglutarate. Other amino acids are produced by amino acid interconversions, a capacity in which parasites can differ greatly from their hosts. An unusual metabolic feature of some protozoa is the conversion of arginine to ornithine, ammonia, and CO_2 by a route called arginine dihydrolase pathway (Fig. 1). In eukaryotic organisms, this pathway has been reported to be present only in *Giardia*, trichomonads, and a green alga, in which it may serve as an energy source but also for ornithine production for further biosynthesis of polyamines (Fig. 1). Cysteine can be synthesized in most parasites from methionine, with the exception of *Giardia* which is absolutely dependent on an exogenous supply of this amino acid for survival and growth. Examples for more profound differences in sulphur compound metabolism between parasites and their mammalian hosts are the exclusively bacterial enzyme methionine γ-lyase catabolizing methionine and cystathionine in certain anaerobic protozoa, and the novel type of cystathionine β-synthases of trichomonads and nematodes involved in cysteine synthesis from



Amino Acids. Figure 1 Interrelationships between the arginine dihydrolase pathway, methionine recycling and biosynthetic routes for polyamines and trypanothione in protozoan parasites. The arginine dihydrolase pathway is unique to *Giardia* and trichomonads and is used for energy generation and polyamine biosynthesis. Certain protozoa utilize a mechanism for methionine recycling during polyamine biosynthesis that is modified from that present in other eukaryotes. In this pathways, the intermediate MTA is converted in a 2-step reaction to MRT-1-P involving the mocrobial enzymes MTA nucleosidase and MTR kinase. In other eukaryotes, MTA is converted to MTR-1-P in one step by a phosphorylase. Trypanothione biosynthesis occurs only in trypanosomatids. *1*, Arginine deiminase; *2*, arginase; *3*, ornithine carbamoyltransferase; *4*, carbamoylphosphate kinase; *5*, ornithine decarboxylase; *6*, spermidine synthase; *7*, 5′methythioadenosine (MTA) nucleosidase; *8*, 5-decarboxylated AdoMet; MTA, methylthioadenosine; MTR, methylthioribose; MTR-1-P, methylthioribose-1-phosphate.



Amino Acids. Figure 2 The proline biosynthetic pathway in trematodes. *1*, Arginase; *2*, ornithine aminotransferase; *3*, spontaneous reaction; *4*, pyrroline *5*-carboxylate reductase.

homocysteine and in cysteine degradation. *Giardia*, *Entamoeba histolytica*, and *Plasmodium falciparum* possess a unique pathway for methionine recycling from methylthioadenosine produced from decarboxylated S-adenosylmethionine (Fig. 1). This process serves to conserve the essential amino acid for polyamine and other biosyntheses and involves enzymes, which are otherwise only found in prokaryotes. A unique feature of *Plasmodium* and other apicomplexan parasites is their ability to synthesize chorismate (shikimate pathway), the pivotal precursor in bacteria, fungi, and plants for the biosynthesis of aromatic amino acids. However, on the basis of gene similarity searches, no evidence was found for a role of chorismate in the synthesis of phenylalanine, tyrosine, and tryptophan in the malaria parasite. Other unusual routes of amino acid interconversions can occur during catabolism. Examples are procyclic *Trypanosoma brucei*, *T. cruzi* epimastigotes and *Leishmania* promastigotes which possess high rates of proline oxidation resulting in the formation of succinate mainly (Energy Metabolism). *T. brucei* procyclic culture forms catabolize threonine to form equimolar amounts of glycine and acetyl-CoA. The latter compound can be excreted as free acetate or used as a carbon source for lipid synthesis.

The large quantities of proline produced by *Fasciola hepatica*, schistosomes, and other trematodes correlate with an extremely active proline pathway in these helminths. In contrast to higher organisms, in which glutamate serves as the precursor for proline synthesis, the liver fluke and schistosomes use host-derived arginine as preferred substrate for the production of this amino acid (Fig. 2). The enzymes involved in the proline pathway of helminths are several times more active than in mammalian tissues. This, together with the absence of proline oxidase, aids in explaining the excessive levels of proline produced by certain helminths that have been implicated in the pathogenesis of trematode infections, including bile duct hyperplasia in fasciolosis and fibrosis in schistosomiasis.

Catabolism

Like higher animals, the first step in amino acid catabolism in parasites is often the removal of the α-amino nitrogen mediated primarily by transamination and deamination reactions. The ammonia arising from these reactions constitutes a major portion of the total excretory nitrogen in endoparasites. While in most terrestrial vertebrates the α-amino nitrogen is finally converted into urea by the urea cycle, the presence of this pathway in parasites appears doubtful. The small amounts of urea produced by helminths possibly derive from the cleavage of dietary arginine. In addition to ammonia, many parasites excrete a substantial amount of their amino nitrogen in the form of amino acids, primarily as alanine and proline. This metabolic strategy is also common in free-living protozoa and invertebrates but is unusual in higher animals, where oxidative degradation with associated energy production is the preferred strategy for amino acid breakdown. Larval and adult helminths were also found to excrete amines as end products of amino acid metabolism. The formation of these compounds, which includes various alkylamines and ethanolamine, appears to be catalyzed by unusual and as yet unknown enzymatic mechanisms. Certain amino acids can serve as important energy sources for parasites, including proline for insect stage trypanosomatids, arginine for anaerobic protozoa, and glutamine for filarial parasites (see above). In all these processes, substrate oxidation is incomplete and results, besides some CO_2, in the formation of partially oxidized end products.

Precursor Function

Except in being the building blocks for protein synthesis, the capability of parasites to use amino acids as precursors for synthetic purposes is rather limited. An example is the absence of the pathways for the *de novo* synthesis of purines in parasites for which glycine and aspartate are major precursors. Although amino acid-derived neurotransmitters and neurohormones are widely distributed among helminths, little is known about their synthesis in these organisms. Most of the neurophysiologically active substances found in worm tissues, such as histamine, serotonin (5-hydroxytryptamine), and catecholamines may be primarily of host origin.

Aminosidine

Compound, →Leishmaniacidal Drugs.

Amitraz

Chemical Class
Amidine (formamitdine) →Arthropodicidal Drugs.

Mode of Action
Octopamine receptor agonist →Ectoparasiticides – Modulators/Agonists of Aminergic Transmission.

Ammonia

→Amino Acids.

Amocarzine

→Nematocidal Drugs, agents against nematodes.

Amodiaquine

→Coccidiocidal drugs, →Anticoccidial Drugs.

Amoebae

Synonym
Amoebida.

Classification
Order of →Protozoa (new phylum Amoebozoa).

General Information
Among the →Sarcodina (→Rhizopoda), only the amoebae are of parasitological interest. Amoebae are characterized by the presence of an endo- and ectocytoplasm, and by their locomotion and reeding as consequences of the formation of →pseudopodia (→Trichomonadida/Fig. 2). These family-specific formations originate from the outward flow of →cytoplasm and push the →cell membrane ahead in the direction of flow; amoebic stages cannot swim, but creep around the substratum or the intestine (or vessels) of a parasitized host. Some of the amoebae, however, may become flagellated during their life cycles (Fig. 1, page 73).

Most members of the order Amoebida are free-living, although some are facultative (Table 1, page 74) or accidental (Figs. 1–8) pathogens; others live regularly as parasites. Reproduction of the parasitic species occurs by asexual binary or multiple division (→Cell Multiplication); sexual stages have not been described. **Transmission** occurs by oral uptake of fresh →trophozoites or by ingestion of cysts (if present), the wall of which is excreted by the trophozoites (Figs. 1–8, see pages 73, 75–77).

Systematics
Order: Amoebida.
- Family: Entamoebidae.

- Family: Hartmannellidae
  - Genus: →*Acanthamoeba* (Figs. 1, 2, 4)
  - Genus: *Hartmannella*.
- Family: Amoebidae.
  - Genus: *Amoeba* (Fig. 3).
  - Genus: *Chaos*.

Order: Schizopyrenida.
- Family: Vahlkampfiidae.
  - Genus: *Naegleria* (Fig. 1)
  - Genus: →*Vahlkampfia*.

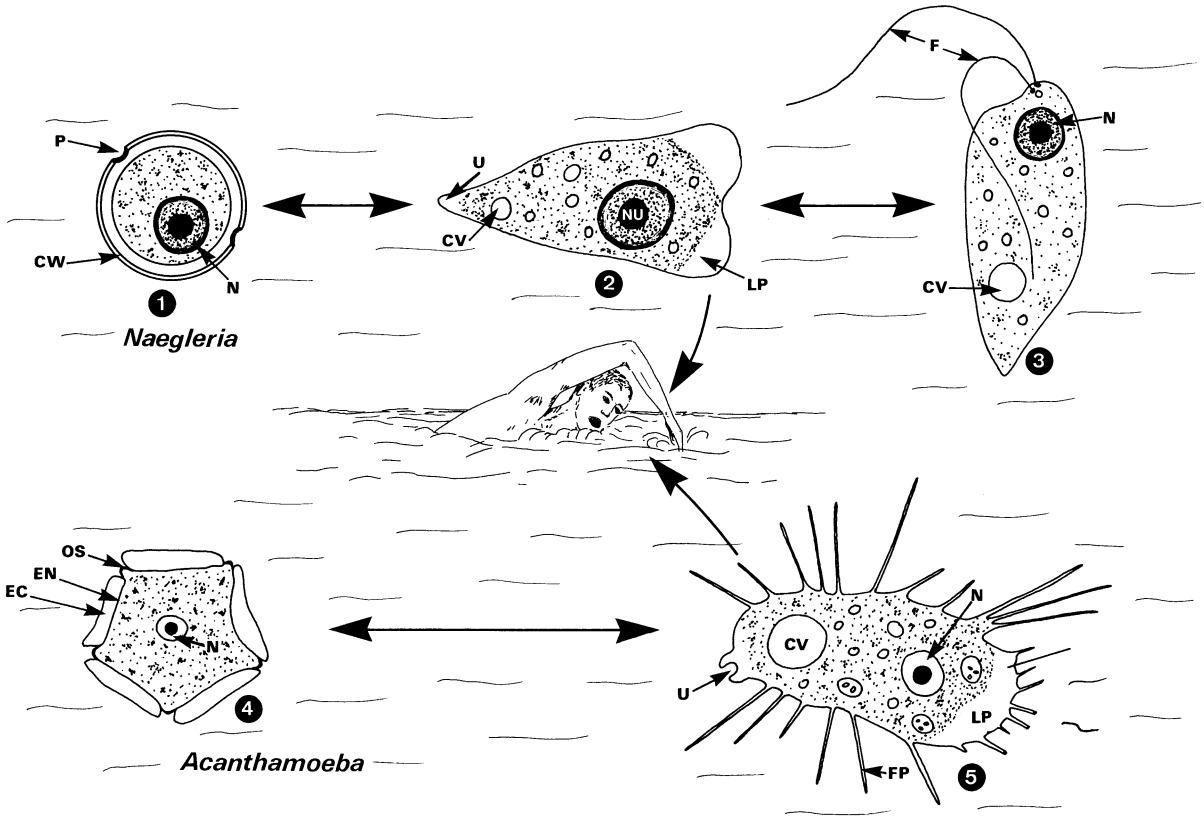
Important Species
Table 1 (page 74).

Life Cycle
Fig. 1 (page 73).

Diseases
→Naegleriasis, →Amoebiasis, →Acanthamoebiasis, →PAME, →GAE.

Amoebapora A

This is a protein of *Entamoeba histolytica*, which may initiate openings in membranes of endothelial cells of the host. Its structure belongs to the archetypes of saposin-like proteins. Similar proteins have been found in porcine and human cytotoxic lymphocytes and have been described as “natural killer lysine” and “granulolysin”, respectively.



Amoebae. Figure 1 Developmental stages of two species from →soil amoeba which (under undefined conditions) may become pathogenic to man. ***1–3*** *Naegleria* spp. (e.g., *N. gruberi*). ***1*** Cyst. ***2*** Amoeboid stage (probably infectious for man via the olfactory pathways) is able to produce a cyst wall. ***3*** Flagellated stage: under certain physiological conditions, the amoeboid form undergoes transformation into flagellated stages, which do not feed or divide. ***4, 5*** →*Acanthamoeba castellanii* (syn. some *Hartmannella* species). The life cycle comprises cysts (**4**) and free amoeboid stages (**5**), which may become pathogenic to man. *CV*, →contractile vacuole; *CW*, cyst wall; *EC*, ectocyst; *EN*, endocyst; *F*, flagellum; *FP*, filopodium; *LP*, lobopodium; *N*, nucleus; *NU*, →nucleolus; *OS*, ostiole; *P*, plug of CW; *U*, uroid (for size see Table 1, page 74).

Amoebapore

A polypeptid that is excreted by →trophozoites of →*Entamoeba histolytica*. It comes in contact with host cell membranes and initiates the formation of ion channels. This introduces the lysis of these cells and thus opens the entry of the amoeba into the intestinal wall. Recently, it was also found in →*Acanthamoeba* and →*Naegleria*.

Amoebiasis

Synonyms

Amoebic dysentery; →*Entamoeba histolytica* infection.

Distribution

Fig. 1 (page 78).

Pathology

Infectious disease caused by the amoeba →*Entamoeba histolytica* which may be commensal in the gut for long periods of time, or it may invade the mucosa soon after infection. The dose of infection, the strain of →amoebae, the nutritional state of the patient, and the nature of the intestinal flora are likely to be determinants of the development of disease. Axenic animals with an intestine free of bacteria do not appear to develop invasive amoebic infection. Some strains of amoebae are more pathogenic and appear to share isoenzyme or genomic patterns, described as zymodemes or →schizodemes. Although multiple pathogenic mechanisms of *E. histolytica* have been described, none have been definitively linked with pathogenicity. The amoebic →trophozoites are best demonstrated with

Amoebae. Table 1 Important amoebes

[a] Some authors keep them for synonyms

the periodic acid Schiff (PAS) technique (→Pathology/Fig. 4C,D) because most trophozoites contain →glycogen. Also, their →cytoplasm stains more distinctly with →Giemsa or eosin than the smaller macrophages. They adhere to the intestinal epithelium and generally invade in areas where the intestinal mucus appears depleted. The amoebae fan out in the lamina propria and submucosa, giving rise to "flask-shaped" ulcers (→Pathology/Fig. 4A). The histiolytic nature of the amoebae is suggested by the lysis of the surrounding cells, seen light microscopically by lysis of the nuclei and by ultrastructural changes in the cytoplasm. However, the clear space around individual amoebae is largely a fixation artifact. Neutrophils are attracted by the amoebae and are degranulated and lysed (→Pathology/Fig. 4B). This release of neutrophil granules may contribute to tissue destruction. The absence of neutrophils around the ulcers is notable. The absence of fecal leukocytes with positive results of a guaiac test for blood is a useful diagnostic finding. However, eosinophilic leukocytes are often seen histologically and →Charcot-Leyden crystals may be found in the stool. The magna-stages phagocytose red blood cells and cell debris which distinguishes *E. histolytica* from nonpathogenic amoebae. Intestinal ulcers may extend through the muscularis (→Pathology/Fig. 4C) and lead to intestinal perforations. This complication is made more likely by the administration of anti-inflammatory corticosteroids which can occur if an erroneous diagnosis of inflammatory bowel disease has been made. However →AIDS patients do not appear to be especially susceptible to recrudescenses.

The amoebae often invade the veins in the submucosa of the gut (→Pathology/Fig. 21B) and are transported to the liver and rarely other organs (lung, brain, skin), where they may set up foci of infection. Liver abscesses may reach a size of several centimeters. They usually develop in the right side according to the laminar flow of the portal vein drainage from the colon. The amoebae colonize, lyse, and digest the liver cells, giving rise first to amoebic hepatitis (→Pathology/Fig. 4D). Only when the focus of destroyed liver →parenchyma is too large for the lysed debris to be absorbed into the lymphatic and venous circulation will an →abscess result. The center of the abscess is formed by brownish, semiliquid fluid which is said to resemble "anchovy paste". A liver abscess may extend through the diaphragm into pleura and lung with the abscess

material being coughed up. Older abscesses are surrounded by fibrinous chronic →inflammatory-reaction products or by fibrosis. The amoebic trophozoites are found in the periphery of the abscess between the liver cells, best identified in PAS-stained sections (→Pathology/Fig. 4D). The delicate nuclei of the trophozoites are shown with hematoxylin and eosin, but they stain less intensely than the nuclei of macrophages from which they need to be distinguished. Amoebic cysts are found only in the stools and not in the tissues. Invasive

Amoebae. Figure 8 Magna-form of *Entamoeba histolytica*.

amoebiasis is enhanced by immunosuppression of whatever cause, e.g., by corticosteroid administration, as mentioned above, and in patients with AIDS. Entamoeba histolytica infections also occur in extraintestinal sites, penile infections following anal intercourse, infections of the cervix uteri, and the buccal mucosa.

Immune Responses

Intestinal amoebiasis is characterized by fulminant diarrhea and intestinal hemorrhage. The associated disruption of the intestinal epithelium allows hematogenous dissemination of the parasite leading to →granuloma formation most commonly found in the liver. Survival of amoebic trophozoites may be favored by a transient immunosuppression associated with hepatic infections. The downregulation of the host's immune response involves macrophage effector and accessory cell functions as well as T cell functions (→Immune Responses).

Innate Immunity

SCID mice infected with *E. histolytica* were used as a model of amoebic liver abscess formation and to study the functional role of neutrophils *in vivo*. Neutrophil-depleted animals developed significantly larger liver abscesses at early stages of infection, which lacked the prominent inflammatory cell ring observed in control SCID mice. These findings suggest a protective role of neutrophils in the early →host response to amoebic infection in the liver (→Innate Immunity). *E. histolytica* lipopeptidophosphoglycan initiates an innate immune response by interacting with TLR2 and TLR4 and that, through NF-κB activation, it can regulate an early proinflammatory response followed by an anti-inflammatory response.

B Cells and Antibodies

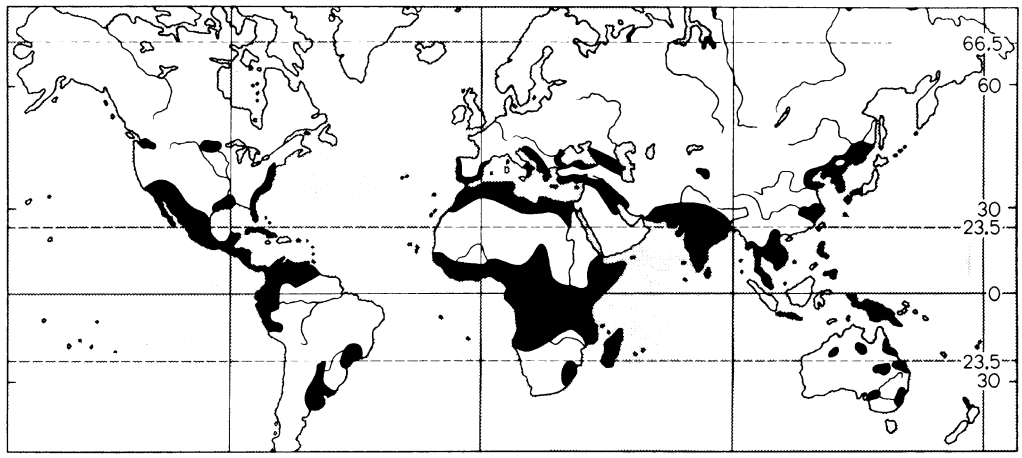
A majority of *E. histolytica* isolates were found to be lysed by the alternative complement pathway *in vitro* in the absence of specific antibodies. A protective role of specific antibodies is suggested by experiments using passive immunization protocols of SCID mice. It could be shown that serum or purified antibodies from patients with amoebic liver abscesses were able to significantly reduce the mean abscess size in the experimental animals when applied 24 hours before intrahepatic infection with *E. histolytica*. In addition, specific antibodies against the serine-rich *E. histolytica* protein (SREHP) prevented amoebic liver abscesses in SCID mice. Furthermore, →vaccination with the immunodominant galactose/N-acetylgalactosamine-inhibitable lectin of *E. histolytica* induced protective immunity to amoebic liver abscesses at least in some animals, while in others of the same species exacerbation of disease was observed after vaccination. Lotter et al. recently showed that protective immunity is due to the development of an antibody response to a region of 25 amino acid residues of the lectin, while exacerbation of the disease is caused by antibodies against the NH2-terminal region of the lectin. These findings might be of clinical relevance, since individuals who are colonized with *E. histolytica* but resistant to invasive disease have a high prevalence of antibodies to the protective epitope.

T Cells

There is good evidence suggesting that cell mediated immunity is centrally involved in the defense against *E. histolytica*. Human and mouse macrophages activated with IFN-γ are able to kill trophozoites in a contact-dependent manner. This killing involves both oxidative and nonoxidative mechanisms. With mouse macrophages it has been demonstrated that one of the principal effector molecules is →nitric oxide (NO). The responsible induction of iNOS is enhanced by →TNF produced in an autocrine fashion by stimulated macrophages. The requirement for macrophage activation suggests that a Th1-type immune response might be necessary for an efficient immune response against amoebae. In line with this, T cells from patients with treated amoebic liver abscesses secreted macrophage activating cytokines leading to amoebic killing. IL-2 and IFN-γ production of T cells can be induced by galaxies/N-acetylgalactosamine-inhibitable lectin, an immunodominant molecule of *E. histolytica*. The analysis of cytokine production patterns in gerbils infected with *E. histolytica* showed that resistance to reinfection correlated with a Th1-like response.

Evasion Mechanisms

Patients infected with *E. histolytica* generate specific IgGs that often do not prevent invasive or recurrent infection. One mechanism by which the



Amoebiasis. Figure 1 Distribution map of amoebic dysentery.

parasite might avoid binding of the specific antibodies is the production of extracellular cysteine proteases. It has been shown that these proteases cleave IgGs near their hinge region resulting in fragments binding less efficiently to *E. histolytica* trophozoites (→Evasion Mechanisms).

The invasion and disease associated with *E. histolytica* has long been connected with suppression of host cellular immunity. Several studies have begun to clarify, at the cellular level, the dampening effects which *E. histolytica* exerts on immune cell and effector cell functions. Although, as discussed above, macrophages are potent cells for amoebicidal activity, the cytotoxic activity of abscess-derived macrophages is reduced during acute hepatic amoebiasis, while macrophages distal from the site of infection are in a heightened state of activity. Obviously, macrophage suppression is a local event, most likely mediated by direct exposure to the parasite or its products. It has been shown that soluble amoebic proteins (SAP) decreased the IFN-γ-induced upregulation of MHC class II molecules on murine macrophages. This inhibitory effect, which is mediated at the transcriptional level, involves the production of prostaglandin E2 (PGE2). The fact that inhibition of PGE2 synthesis by indomethacin reversed SAP-mediated suppression of MHC class II expression by 60%, establishes that PGE2 induction is the main but not the only mechanism involved. Thus, PGE2 and related products, which may also be produced by *E. histolytica* trophozoites themselves, could indirectly inhibit T cell receptor recognition of parasite antigens. In addition, pretreatment of macrophages with SAP results in suppression of TNF and →nitric oxide synthesis. While addition of indomethacin restored TNF production, it had no effect on iNOS mRNA levels or NO production. Thus, *E. histolytica* appears to have the ability to inhibit different macrophage functions by separate pathways.

To date, T cell deficiencies in amoebiasis are less well characterized. However, the reduced delayed-type →hypersensitivity reaction during acute amoebiasis seen in patients as well as the reduced mitogenic response of purified T cells *in vitro* argue for a relative paucity of T cells mediating defensive responses against amoebae. A major phosphorylated, lipid-containing glycoconjugate surface molecule of *E. histolytica* may function similarly to →lipophosphoglycan (LPG) of →*Leishmania* by inhibiting PKC signal transduction. Other amoebic molecules with potential suppressive roles include a 220 kDa lectin, which induces the production of IL–4 and IL–10.

Main clinical symptoms: →Abdominal pain, bloody-slimy →diarrhoea, liver dysfunction in case of liver abscess (Fig. 2).
Incubation period: 2–21 days.
Prepatent period: 2–7 days.
Patent period: Years.

Amoebiasis. Figure 2 Human liver with *Entamoeba*-abscesses (amoebomas).

Diagnosis: Microscopical determination of cysts in fecal samples, →Serology.
Prophylaxis: Avoidance of uncooked food/water in endemic regions.
Therapy: Treatment see →Antidiarrhoeal and Antitrichomoniasis Drugs.

Amoebic Colitis

The process develops as follows:

1. Magna forms of →*Entamoeba histolytica* adhere to colonic mucus via Gal/GalNAc lectin (Galactose/N-acetyl-D-galactosamine).
2. Cysteine that is excreted by the amoebae degrades the colonic mucus.
3. The amoebae excrete the protein amoebapore initiating contact dependent apoptotic and necrotic killing of host cells.
4. Amoebic cysteine proteinases activate pre-interleucin 1-ß inside the intestinal cells resulting in the occurrence of inflammatory cytokines, which contribute to tissue damage and thus production of hollows.
5. Amoebic invasion in the hollows and lateral spreading produces flask-shaped ulcers with rather low inflammation.

Amoebic Infections

Several species of →amoebae (e.g., →*Entamoeba histolytica* causing →Amoebiasis) give rise to infections of the intestinal lumen (→Protozoan Infections, Man/Table 1). Most are commensal, feeding on bacteria, and producing neither lesions nor functional abnormalities. However, *Dientamoeba fragilis* does give rise to diarrhea often accompanied by →eosinophilia in both the stool and blood but without apparent tissue invasion. Its transmission in the absence of a cyst has been linked circumstantially to the nematode →*Enterobius vermicularis*.

Therapy

→Antidiarrhoeal and Antitrichomoniasis Drugs.

Amoebocides

→Antidiarrhoeal and antitrichomoniasis drugs, agents against Amoebiosis.

Amoeboflagellates

Group of protozoan parasites, that show a flagellum in some developmental stages, e.g., →*Histomonas meleagridis*, →*Naegleria gruberi*, →Amoebae, →*Dientamoeba*.

Amoeboma

→Abscess caused by →amoebae (→*Entamoeba histolytica*/Life Cycle).

Amoebotaenia

Genus of cyclophyllid →tapeworms of birds.

Amoebotaenia cuneata

Tapeworm (2–4 mm long) in chicken and other birds with earthworms as intermediate hosts; it belongs to the family Dilepididae.

Amoebozoa

Name

From Greek: *amoibos* = changing, *animan* = soon. New phylum of protozoans.

Amphids

→Adenophorea.

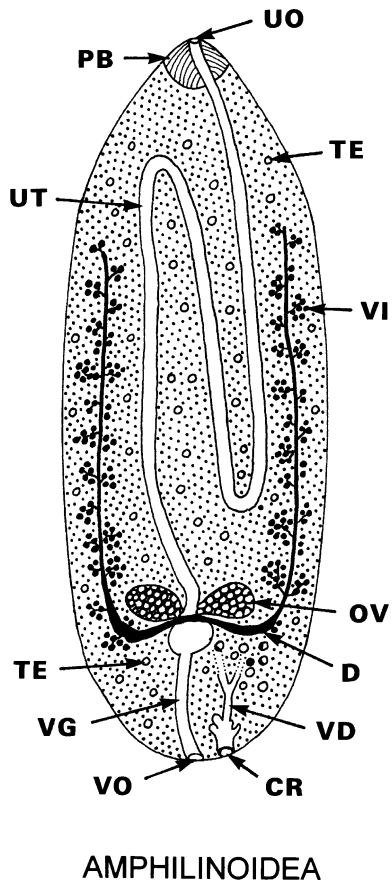
Amphilina foliacea

Classification

Species of →cestodes.

Life Cycle

Fig. 1.



Amphilina foliacea. Figure 1 Diagrammatic representation of different groups of adult monozoic →tapeworms. *Amphilina foliacea* (about 2 cm long) from the body cavity of sturgeons (*Acipenser* sp.); eggs are swallowed by small crustaceans, where the →procercoid is formed. When the →intermediate host is ingested by the final hosts, the pleorcercoid develops, reaching maturity in a few days (=→neoteny). *AH*, adhesion zone; *CR*, →cirrus; *D*, duct of →vitelline glands; *DB*, →dense bodies in the vitelline system; *GA*, genital atrium (joint pore of UT and VE); *OV*, ovary; *PB*, →proboscis; *SU*, sucker; *TE*, testes; *UO*, opening of the uterus; *UT*, uterus; *VD*, vas deferens; *VG*, vagina; *VI*, vitelline glands; *VO*, opening of vagina; *Z*, interruption (animals are longer).

Amphilinidea

→Cestodaria.

Amphistoma

Name

Greek: *amphi* = at both sides, *stoma* = mouth (= 2 suckers).

Amphistostomida

Order of trematodes, with suckers at both poles, e.g., →*Paramphistomum cervi* of ruminants.

Amphotericin

→Leishmaniacidal drugs, agents against Leishmaniasis.

Amprolium

Thiamin analogue drug, blocking the thiamin transport in chicken-coccidia (*Eimeria*), →Coccidiocidal Drugs.

Amyloodinium

Genus of flagellated protozoans, which after attachment to skin redraw the flagella and form root-like pseudopodia that penetrate deep into the skin and gills of salt water fish thus introducing openings for bacterial superinfections, which may lead to death (Fig. 1).

Amyloodinium. Figure 1 LM of a sessile *A. ocellatum* – stage from a coral fish.

Amylopectin

→Reserve Granules, e.g. in →Coccidia, →Energy Metabolism.

Anaemia

Clinical symptom due to infections with e.g., →Hookworms, →*Babesia* and *Plasmodium* species, →*Gastrodiscus aegyptiacus* (→trematodes in horses), →Fascioliasis, Man, →Fasciolosis, Animals, →Schistosomiasis, Man, →Schistosomiasis, Animals, →Diphyllobothriasis, →*Ascaridia galli*, blood sucking of →fleas, →mites (e.g., *Dermanyssus*).

Anaerobic Glycolysis

→Energy Metabolism.

Anaerobic Respiration

→Energy Metabolism.

Anal Pruritus

Skin reaction in humans and horses due to infections with pinworms (→*Enterobius vermicularis*, →*Oxyuris equi*) (→Alimentary System Diseases, Horses).

Analgidae

Family of skin and feather mites of birds.

Anamnesis

Phenomenon (also called memory response) in animals that have the capacity to synthesize immunoglobulins (e.g., mammals).

Anaphylactic Shock

Hypersensitivity-shock-reaction due to repeated setting free of masses of parasitic antigens inside a host (→Echinococcosis), fly larvae (→Myiasis, Animals, →Myiasis, Man).

Anaphylaxis

Type 1 of immediate hypersensitivity (occurs within minutes after the introduction of an antigen into a previously sensitized host).

Anaplasma marginale

Bacterium transmitted by *Boophilus*-, *Rhipicephalus*-, and *Dermacentor*-ticks introducing the anaplasmosis of cattle.

Anaplasmosis

Disease in bovines or dogs due to tick-transmitted *Anaplasma*-stages (→Tick Bites: Effects in Animals).

Anapolytic

Mode of detachment of proglottids. →Eucestoda.

Anaticola

Genus of mallophaga (→Lice).

Anatoecus

Genus of →mallophaga on feathers of birds.

Anautogeny

Inability of female →mosquitoes (e.g., most →Culicidae) to produce eggs without preceding blood meal.

Ancylostoma caninum

→Nematodes. Hookworm of dogs, may cause →larva migrans in human skin (Figs. 1–5).

Ancylostoma duodenale

→Hookworms of humans.

Ancylostoma Species

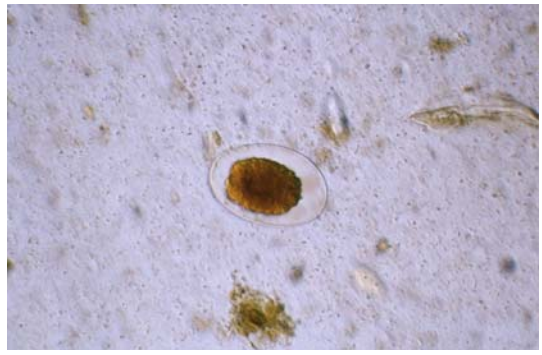
Name

Greek: *ancylos* = hook, *stoma* = mouth.

Intestinal nematodes of man and animals, →Hookworms, →*Necator*, →Uncinaria, →*Bunostomum*, →*Globocephalus*.

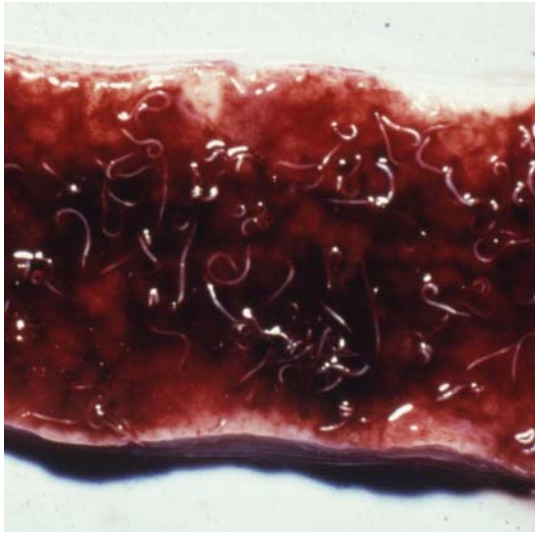
Ancylostoma caninum. Figure 1 Mouth of *Ancyclostoma caninum*.

Ancylostoma caninum. Figure 2 Mouth of *Ancylostoma duodenale* of humans.



Ancylostoma caninum. Figure 3 Egg of *Ancylostoma* sp.

Ancylostoma caninum. Figure 4 Infectious larva 3 of *Ancylostoma duodenale*.



Ancylostoma caninum. Figure 5 Section of a dog's intestine filled with adult hookworms and masses of blood that passed through their guts.

Ancylostomiasis

Synonym

→Hookworm infection (→Hookworm/Disease). Soil-transmitted helminthic infection (→Nematocidal Drugs, Man/Table 1).

Ancyrin

Protein to connect proteins of the →cytoskeleton and →cell membrane in red blood cells.

Ancyrocephalus paradoxus

Monogenean species parasitic on gills of perch.

Anderson and May Model

→Mathematical Models of Vector-Borne Diseases.

Androgyny

→Hermaphroditism. The stages look like females but the genital systems are male.

Anemia

→Anaemia.

Anepitheliocystidia

→Digenea.

Anergic Diffuse Cutaneous Leishmaniasis (ADCL)

Syndrome of the New World, →Leishmaniasis.

Angiostrongylosis

Abdominal Angiostrongylosis is an accidental parasitosis of man by *Angiostrongylus costaricensis* – a species usually found in rats, acquired by eating third stage larvae from slugs or their mucus left on unwashed vegetables. Most of the cases have been found in the Americas, and only a few in Africa. The larvae enter the intestinal wall and migrate to the arteries of the ileocolic region where they become adult (→Pathology/Fig. 23B). The eggs are deposited in the vessel; and are propelled into the intestinal mucosa where they give rise to an intense granulomatous inflammation with eosinophils and fibrosis. Most of the eggs degenerate; although larvae are occasionally seen in the tissues, they have not been found in the stool where they are shed by the natural host (→Pathology/Fig. 29A–D). Many of the arterioles containing adults become thrombosed after the worms die. The lesions may simulate appendicitis or give rise to large inflammatory ileocolic masses which can cause intestinal obstruction and must be resected surgically. **Cerebral angiostrongylosis** is due to infection with →*Angiostrongylus cantonensis* (see Fig. 1). showing the following-signs:

Main clinical symptoms: →Eosinophilic meningoencephalitis, paralysis.
Incubation period: 2–3 weeks.
Prepatent period: Larvae are found within 2 days in the brain.
Patent period: Months until the larvae die.
Diagnosis: Serodiagnostic methods.
Prophylaxis: Avoid eating raw food (meat, snails, crabs).
Therapy: Treatment see →Nematocidal Drugs, Man.

Angiostrongylus cantonensis

Synonym

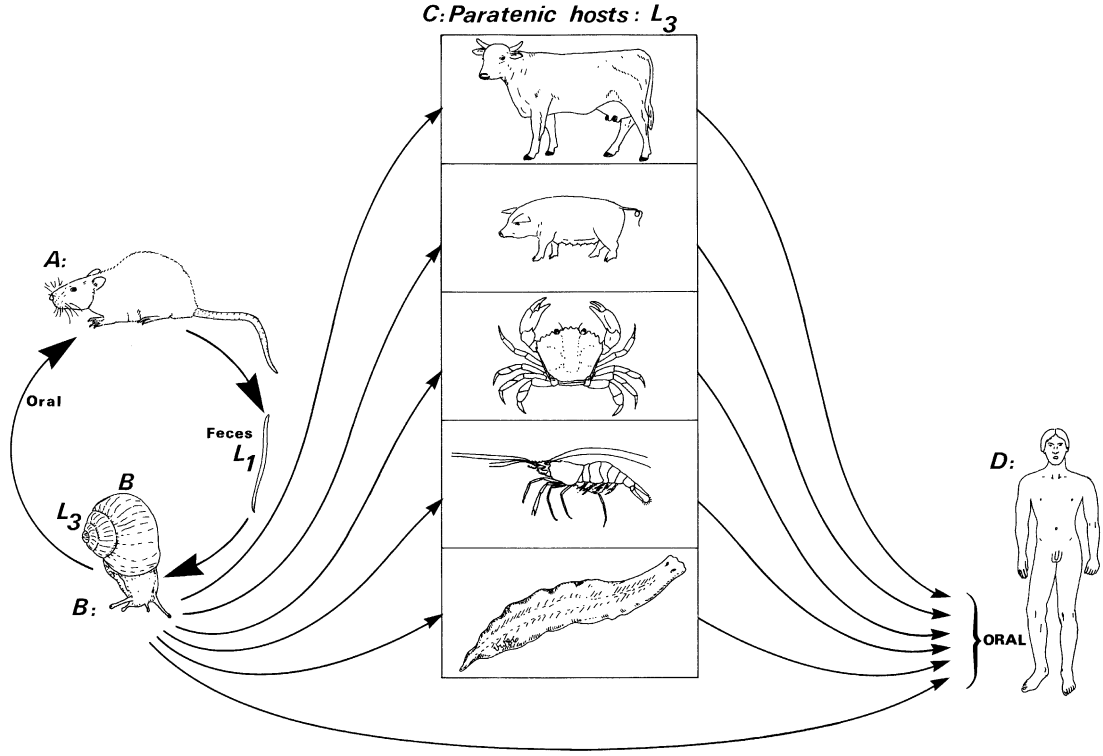
→*Parastrongylus cantonensis*.

Classification

Species of →Nematodes.

General Information

A. cantonensis is an accidental human parasite, normally found in rats (Fig. 1). The worm is acquired by eating undercooked snails or freshwater →crustacea, the intermediate hosts, or fresh vegetables contaminated with larvae in the slime of snails, slugs, or land planaria. The larvae migrate to the meninges and may be found in the spinal fluid. They wander through the brain and occasionally the eye, where they give rise to an acute →inflammatory reaction rich in eosinophils. The meninges may show the main lesions, or the cerebral cortex may be involved with worm tracks, hemorrhages, and large eosinophilic abscesses containing Charcot-Leyden crystals around dead worms.



Angiostrongylus cantonensis. Figure 1 Life cycle of *Parastrongylus (=→Angiostrongylus) cantonensis*. **A** Final hosts are rats, where the adult worms (male 19 mm, female 25 mm long) live mainly in the pulmonary arteries. There, the eggs are laid and carried to the pulmonary capillaries, where the first-stage larvae develop within 6 days; these break into the air spaces, migrate up the trachea, are swallowed, and finally passed with the feces. **B** A number of molluscs serve as intermediate hosts, within which the infectious third larval stage (L_3) is formed after two molts. If a rat swallows such intermediate hosts containing infectious L_3 (after about 4 weeks), the larvae migrate to the rat's brain, which they leave 4 weeks after ingestion, having undergone another →molt. About 6 weeks after infection (prepatent period) maturation finally occurs in the pulmonary arteries. **C** A number of animals are involved in the life cycle as paratenic hosts bearing accumulations of infectious larvae. **D** Humans become infected when eating intermediate (B) or →paratenic host tissues (C) containing third-stage larvae. In man these larvae migrate to the capillaries of the meninges, there inducing an →*eosinophilic meningoencephalitis*. The larvae never become mature worms in man, but eventually die within eosinophilic *granulomas*.

When the worms are near adulthood, they migrate to the branches of the pulmonary artery. In rats, the natural host, eggs and larvae are produced with little inflammation, but in humans the cycle ends as the worms die in the pulmonary arteries.

Life Cycle

Fig. 1.

Angiostrongylus costaricensis

Synonym

Morerastrongylus costaricensis.

Geographic Distribution

South from Texas to Brazil.

Classification

Species of nematodes.

General Information

This roundworm has domestic rats (*Rattus rattus*) and cotton rats (*Sigmodon hispidus*) as final hosts, which become infected by feeding smooth snails (e.g., *Vaginulus plebeius*). In rats the worms (reaching as females a size of 28–42 mm × 0.35 mm) live in the mesenteric arteries in the caecal region. Their eggs and larvae are found in the wall of the intestine (without inflammatory reaction); the larvae leave the intestine within the faeces. The intermediate hosts (snails) feed these larvae, which develop into the infectious larvae 3.

Humans (especially children) become infected when in contact (eating, playing) with such snails. The mesenteric arteries are the places of development of the worms (until maturity). Inflammation reactions are common. →Angiostrongylosis.

Similar reactions are produced by related worms, e.g., by *A. malaysiensis* in monkeys, by *A. mackerrase* (leading to eosinophilic meningitis) in rodents and humans in Australia or by *A. vasorum* (about 25 mm long, living in the arteria pulmonalis of dogs and foxes) in Europe (with a prevalence rate of 40% in foxes), Asia, Africa and South America. →*Aelurostrongylus abstrusus* is found in the bronchioles of cats.

Treatment

→Nematocidal Drugs.

Angiostrongylus Species

Name

Greek: *angeion* = bottle, *strongylos* = round, cylindric.

→*A. cantonensis*, →*A. costaricensis*, with *A. mackerrase* in Australia, *A. malaysiense* in Asia or *A. vasorum* (foxes, dogs – worldwide).

Angiostrongylus vasorum

The adults of these worms live in the pulmonary arteries of dogs, foxes, and other canids. The females excrete eggs which give rise to the larva 1, that leaves the final host by means of a penetration of the lung blood capillaries. Thus they reach the trachea, pass to the pharynx, and when arriving in the mouth, they are swallowed and leave the host via faeces.

If molluscs (e.g., snails) take up such faeces the larva 3 develops within 16 days. Frogs (e.g., *Rana temporaria*) may become paratenic hosts when feeding such infected intermediate hosts. As soon as the final hosts have taken up L_3-containing hosts, the L_3 is set free in the intestine, enters the gut wall, and moults twice inside the abdominal lymph nodes. The preadult worms reach via liver the right ventricle and settle finally inside the pulmonary artery, where maturity is reached within 40–60 days. The **disease** is associated with coughing, dyspnoea, exercise intolerance, vomiting, abdominal pain, weight loss, neurological signs, heart failure, sudden death →Nematocidal Drugs.

Anguillicola crassus

Blood-sucking →Nematode in the swim bladder of, e.g., eels and other fish (Fig. 1, page 86).

Anilocra

→Crustacea.

Anguillicola crassus. Figure 1 Male and female of *A. crassus* in the swim bladder of an eel.

Animal Reservoirs

Animals containing identical stages of parasites as found in humans, but symptoms of disease are mostly less strong, so that these animals are often the source for human infections.

Anisakiasis

Anisakiasis comprises accidental human infection; with a variety of →nematodes normally infecting marine fish (salmon, herring), which was consumed raw, marinated, or undercooked (→Anisakis). The worms are often expelled or vomited. Occasionally they penetrate the gastric or intestinal wall where they give rise to an eosinophilic →abscess, or in the omentum, or peritoneal lining associated with an adult nematode that may still be alive or dead (→Pathology/Fig. 28D). The specimens are often recovered surgically after an abrupt onset of severe abdominal discomfort. The structures of the worm may be well preserved in acute cases or may have degenerated after an illness of a few days.

Main clinical symptoms: →Abdominal pain, intermittent →diarrhoea, loss of weight.
Incubation period: 1 hour–1 week.
Prepatent period: Larvae are present from the moment of oral uptake.
Patent period: Weeks until the worms have been killed within granulomas.
Diagnosis: Gastroscopical methods.
Prophylaxis: Avoid eating raw fish (saltwater).
Therapy: Treatment see →Nematocidal Drugs, Man.

Anisakis

Genus of roundworms (→Nematodes; Figs. 1–3, pages 87, 88).

Disease

→Anisakiasis.

Anisogametes

→Gametes of different sexes that vary in size and shape occurring, e.g., in →Apicomplexa (e.g., →Gregarines/Fig. 1) while →Coccidia (e.g., →*Plasmodium*, →*Eimeria*) have macro- and →microgametes.

Anisus

Genus of snails, intermediate hosts of →*Paramphistomum.*

Annelida

Classification

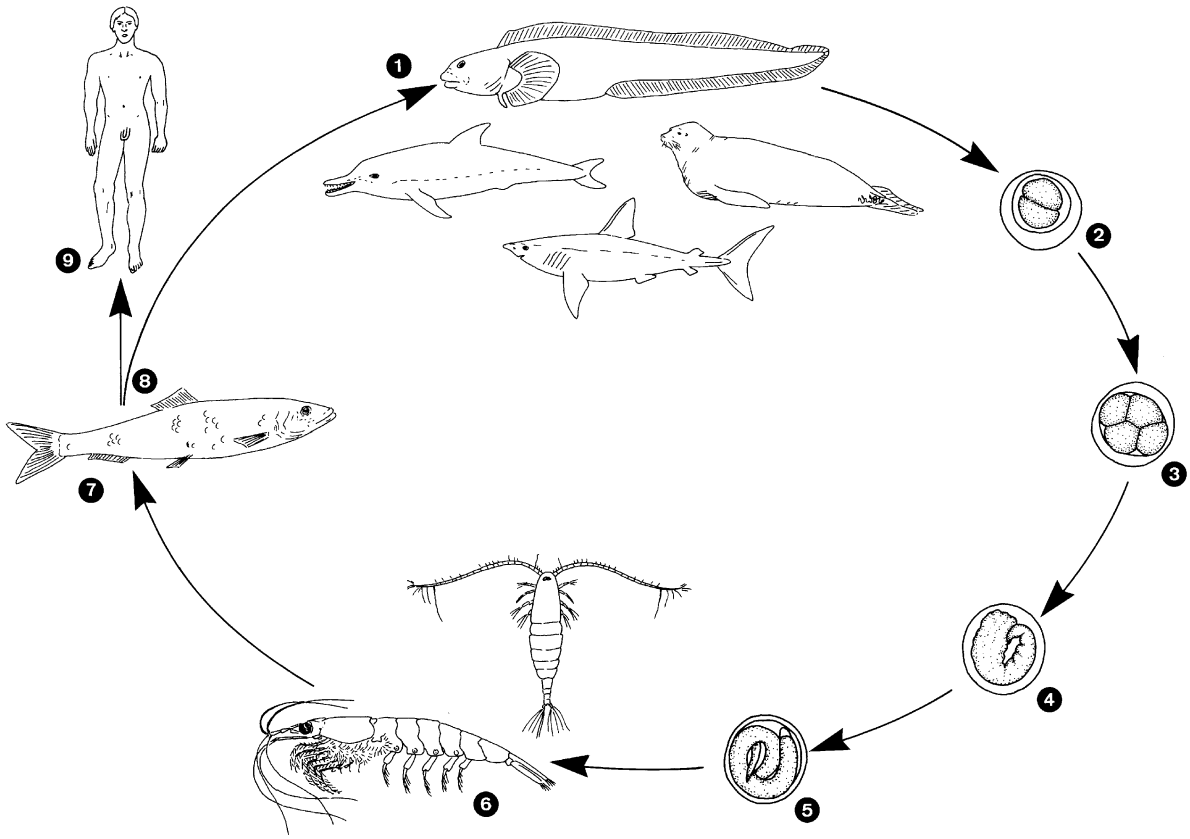
Phylum of →Metazoa.

General Information

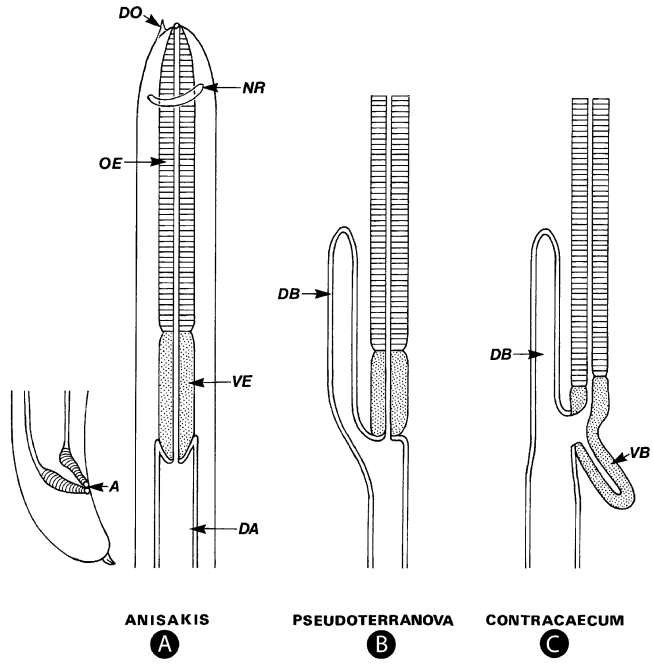
The annelids were named with respect to their outer annulated appearance, which apart from Hirudinea corresponds to an inner, more or less homonomous segmentation. Most of the annelids are free-living species; blood-sucking ectoparasites are mainly found among the members of the subclass Hirudinea (→Leeches).

System

The classification of the Annelida is still in discussion, however, the following groups are widely accepted:
Phylum: Annelida.
Class: Polychaeta (mainly free-living).
Class: →Myzostomida (parasites of Crinoidea).
Class: Clitellata.
Subclass: Oligochaeta (mostly free-living).
Subclass: Hirudinea (some parasitic species).



Anisakis. Figure 1 Life cycle of marine ascarids (e.g., →*Contracaecum* spp., *Phocanema* sp. = *Terranova*, →*Pseudoterranova* sp., *Anisakis* sp.). *1* Adult worms live in the intestine of fishes or sea mammals, respectively (final hosts). *2* Eggs are unembryonated when fecally excreted. *3–5* Formation of L_1 and L_2 apparently occurs inside the eggs floating in the water. *6* Apparently a wide range of small marine crustaceans may act as intermediate hosts when ingesting infectious eggs. Inside the →intermediate host the L_3 is formed (in some species free L_3 have also been suggested). *7* When these L_3-bearing crustaceans are swallowed by a wide range of fish, the third-stage larvae are spirally encapsulated and thus accumulated inside various organs, including muscles, without further development. Some authors believe that development to L_4 occurs. When there is no further →molt, these fish must be considered as transport- or paratenic hosts. In addition, accumulation of L_3 often occurs in carnivorous fish species. *8* Infection of final hosts occurs by oral uptake of infected fish. Inside the stomach and intestine, ulcerations (by embedded groups of larvae and preadults) and even perforation of the intestinal wall have been described. *9* Humans who can be accidentally infected by eating raw or insufficiently cooked meat of infected fish (e.g., green herring) may become some sort of →paratenic host and suffer from an acute →anisakiasis as a result of the penetration of larvae into the walls of the stomach and/or intestine; this can lead to death. Over the last 50 years, the specific name of "codworm" or "sealworm" has changed several times. Once it was called *Ascaris decipiens* (decipiens means deceiving); it later became →*Porrocaecum decipiens*, then *Terranova decipiens*. Myers created a new genus for this worm, proposing the name *Phocanema decipiens*, but reexamination of the concept and validity of anisakid in general led to the conclusion that *Phocanema* was a synonym of *Pseudoterranova* Mosgovoi, 1951. This criterion has been gradually accepted and *Pseudoterranova decipiens* is found in current literature. *Terranova* sp. larva Type A, as referred to in Japanese literature, is definitely the third-stage larva of this *P. decipiens*, which is commonly called →codworm. Similarly, various names have been applied to the human disease caused by codworm. Margolis suggested restriction of 'anisakiasis'to denote infection with anisakid larvae of the genus *Anisakis*, using "nonspecific anisakiasis" when the larva has not been identified to genus or as a collective term for infection with anisakid larva, and "phocanemal (or terranoval) anisakiasis" for infections with larvae of genus *Phocanema*. But the genus *Terranova* is now restricted to the parasites of elasmobranchs, teleosts, and aquatic reptiles, and the genus *Phocanema* has been abandoned. However, "pseudoterranoval anisakiasis" would be an impractical name for clinicians, so the term "codworm anisakiasis" is preferred.



Anisakis. Figure 2 Schematic representation of diagnostically useful intestinal features of human pathogenic marine anisakids (A–C). *A*, anus; *DA*, intestine; *DB*, intestinal enlargement; *DO*, thorn; *NR*, nerve ring; *OE*, esophagus; *VB*, enlargement of →ventriculus; *VE*, ventriculus.

Anisakis. Figure 3 Ice fish (*Macrourus* sp.) from the Antarctic sea, the liver of which is filled with anisakid larvae.

Annual Transmission Potential (ATP)

A factor that determines the burden of infection in a human community (e.g., in →onchocerciasis it is determined by the number of infectious larvae 3 transmitted per year by the biting black fly vector (→*Simulium* species).

Anocentor

Genus of hard →ticks. *Anocentor* (syn. *Dermacentor*) *nitens* (the tropical horse tick) is found in Latin America. It is a one-host tick, e.g., all stages stay on its first host.

Anopheles

→Diptera, →Filariidae, →Mosquitoes.

Anoplocephala magna, A. perfoliata

Tapeworm of horses, →Eucestoda, →Alimentary System Diseases, Horses.

Anoplocephaloides mamillana

Syn. *Paranoplacephala mamillana/is*, a 1–4 cm × 4–6 mm tapeworm of horses, which has its seat in the anterior small intestine (occasionally in the stomach).

Anoplura

From Greek: *anoplos* = unarmed, *ura* = tail. Blood-sucking →lice.

Anopluridosis

Disease due to infestation with →lice; see Table 1 (page 90).

Anorexia

Clinical symptom (=reduction in voluntary food intake) in animals due to parasitic infections (→Alimentary System Diseases, →Clinical Pathology, Animals).

Antarctophthirus ogmorhini

Louse from the Weddell-seal *Leptonychotes weddelli* reaching a size of about 4 mm in length (Fig. 1, page 91). The eggs, which have a single opening (spiraculum) in the cover (operculum) of the egg (Fig. 2, page 91).

Anthelminthic Drugs

→Nematocidal Drugs, →Trematocidal Drugs, →Cestodocidal Drugs.

Anthelmintic, Anthelminthic

Describes a reaction or compound that acts against worms (Greek: *anti* = against, *helminthes* = worms).

Anthroponoses

Diseases affecting only humans. The major representatives of parasitic anthroponoses are listed in Table 1 (page 92).

Therapy

→Chemotherapy, →Drugs.

Anthroponosis

Disease, the agents of which are transmitted by man or vectors exclusively from man to man (e.g., →malaria, →louseborne spotted fever) see below (Table 1, page 92).

Anthropophagic

→Mosquitoes that feed predominantly on humans (e.g., several →*Anopheles* species) are referred to as anthropophagic. However, hungry females also choose other hosts in case of absence of their favourites.

Anthropozoonoses

Synonym

→Zooanthroponoses (see also Table 1, pages 92–94).

General Information

Diseases affecting both man and other animals. The major representatives of parasitic →zoonoses are listed in Table 1 (see pages 92–94).

Therapy

→Chemotherapy, →Drugs.

Anti Parasitic Sexual Mate Choice

→Behavior.

Anti Parasitic Social Mate Choice

Anthroponoses. Table 1 Important parasitoses which are usually restricted to humans as vertebrate hosts

Parasite species	Infective stage	Mode of infection	Other obligatory hosts	Disease
Protozoa				
Trypanosoma gambiense	Metacyclic trypanosome	Bite of *Glossina* spp.	*Glossina* spp.	Sleeping sickness (Gambian)
Trichomonas vaginalis	Trophozoite	Mainly sexual intercourse	None	Human trichomoniasis
Hartmanella spp.	Vegetative forms (cysts?)	Entry through nasal mucosa	None	Amoebic meningoencephalitis
Acanthamoeba spp.				
Naegleria spp.				
Plasmodium falciparum	Sporozoite	Bite of *Anopheles* spp.	*Anopheles* spp.	Falciparum malaria
Plasmodium ovale	Sporozoite	Bite of *Anopheles* spp.	*Anopheles* spp.	Ovale malaria
Plasmodium vivax	Sporozoite	Bite of *Anopheles* spp.	*Anopheles* spp.	Vivax malaria
Trematodes				
Schistosoma haematobium	Cercaria	Transdermal invasion	*Bulinus* spp.	Urinary schistosomiasis (bilharzia)
Schistosoma intercalatum	Cercaria	Transdermal invasion	*Bulinus* spp.	Schistosomiasis intercalatum
Schistosoma mansoni	Cercaria	Transdermal invasion	*Biomphalaria* spp.	Mansonian schistosomiasis
Nematodes				
Ascaris lumbricoides	Eggs containing 2nd-stage larva	Ingestion	None	Human ascaridiasis
Enterobius vermicularis	Eggs, larvae entering anus	Ingestion	None	Human pinworm infection
Trichuris trichiura	Embryonated egg	Ingestion	None	Human trichuriasis
Ancylostoma duodenale	Strongyliform larva	Transdermal invasion	None	Human ancylostomiasis
Necator americanus				
Wuchereria bancrofti	Filariform 3rd-stage larva	Mosquito bite	Mosquitos (*Culex, Aedes, Anopheles, Mansonia* spp.)	Lymphatic (bancroftian) filariasis
Onchocerca volvulus	Filariform 3rd-stage larva	Blackfly bite	*Simulium* spp.	Onchocerciasis

Anthropozoonoses. Table 1 Important zooanthroponotic and anthropozoonotic parasitoses (according to Wernsdorfer)

Parasite species	Principal hosts (besides humans)	Infective stage	Mode of infection	Other obligatory hosts	Disease
Protozoa					
Leishmania donovani	Various domestic animals	Promastigote	Sand fly bite	*Phlebotomus* spp.	Visceral leishmaniasis (Kala-azar)
Leishmania tropica	Dogs	Promastigote	Sand fly bite	*Phlebotomus* spp.	Oriental sore
Leishmania brasiliensis	Dogs	Promastigote	Sand fly bite	*Phlebotomus* spp.	Mucocutaneous leishmaniasis (Espundia)

Anthropozoonoses. Table 1 Important zooanthroponotic and anthropozoonotic parasitoses (according to Wernsdorfer) (Continued)

Parasite species	Principal hosts (besides humans)	Infective stage	Mode of infection	Other obligatory hosts	Disease
Trypanosoma rhodesiense	Wild and domestic mammalians	Metacyclic trypanosome	*Glossina* bite	*Glossina* spp.	Sleeping sickness (Rhodesian)
Trypanosoma cruzi	Wild and domestic mammalians	Metacyclic trypanosome	Invasion through bite wound from reduviid feces	Reduviid bugs (*Triatoma, Panstrongylus, Rhodnius* spp.)	Chagas disease
Giardia duodenalis	Wild and domestic mammalians	Cyst	Ingestion	None	Lambliasis (Giardiasis)
Balantidium coli	Pigs	Cyst	Ingestion	None	Balantidiosis (dysentery)
Entamoeba histolytica	Various mammalians	Cyst	Ingestion	None	Amoebiasis (dysentery and amoebic abscesses)
Toxoplasma gondii	Domestic mammalians	Oocyst, bradyzoite	Ingestion and transplacental	None	Toxoplasmosis
Babesia bigemina	Cattle	Sporozoite	Tick bite	Ticks (especially *Boophilus* spp.)	Texas cattle fever, babesiosis
Babesia canis	Dogs	Sporozoite	Tick bite	Ticks (various spp.)	Canine babesiosis
Plasmodium malariae	*Pan troglodytes*	Sporozoite	Bite of *Anopheles* spp.	*Anopheles* spp.	Quartan malaria
Trematodes					
Fasciola hepatica	Sheep, cattle	Metacercaria	Ingestion	Aquatic snails (*Lymnaea, Succinea, Fossaria, Practicolella* spp.)	Fascioliasis (liver rot of sheep and cattle)
Fasciolopsis buski	Pigs	Metacercaria	Ingestion	Aquatic snails (*Planorbis* and *Segmentina* spp.)	Fasciolopsiasis
Dicrocoelium dendriticum	Various domestic mammalians	Xiphidiocercaria	Ingestion with ants	Land snails (mainly *Cionella* spp.) followed by ants (mainly *Formica fusca*)	Dicrocoeliasis
Opisthorchis felineus	Felines	Cercaria	Ingestion	Aquatic snails *(Bithynia* spp.) followed by cyprinid fish	Opisthorchiasis
Clonorchis sinensis	Canines, felines	Cercaria	Ingestion	Various aquatic snail species, followed by cyprinid fish	Clonorchiasis
Paragonimus westermanni	Cats	Metacercaria	Ingestion	Molluscs (*Semisulcospira, Tarebia, Brotia* spp.), followed by crustaceans (mainly freshwater crabs)	Paragonimiasis
Paragonimus kellikotti	Canines, felines and other mammalians	Metacercaria	Ingestion	Aquatic snails followed by crayfish	Paragonimiasis
Schistosoma japonicum	Wild and domestic mammalians	Cercaria	Transdermal invasion	*Oncomelania* spp.	Japanese schistosomiasis

Anthropozoonoses. Table 1 Important zooanthroponotic and anthropozoonotic parasitoses (according to Wernsdorfer) (Continued)

Parasite species	Principal hosts (besides humans)	Infective stage	Mode of infection	Other obligatory hosts	Disease
Cestodes					
Diphyllobothrium spp.	Canines, felines and other fish eaters	Procercoid	Ingestion	Copepods (e.g., *Diaptomus* spp.), followed by fish	Fish tapeworm infection
Taenia solium	Pigs (adult worm), cysticercus also in other animals	Egg and cysticercus	Ingestion	No obligatory host species alternation	Cysticercosis cellulosae and pig tapeworm infection
Taenia saginata	Cattle (cysticercus), humans (adult worm)	Cysticercus	Ingestion	Humans (adult worm), cattle (cysticercus)	Taeniasis saginata (cattle tapeworm infection)
Echinococcus granulosus	Canines (adult worm), various mammalians (hydatid cysts)	Egg and hydatid larva	Ingestion	Canines (adult worm), various mammalians (hydatid cysts)	Hydatid disease
E. multilocularis	Fox, dogs, mice	Egg for man, alveolar cyst for fox	Ingestion	Mice, many animals	Alveolar disease
Hymenolepis nana	Rodents	Egg	Ingestion	None	Hymenolepiasis nana
Hymenolepis diminuta	Rodents	Cysticercoid larva	Ingestion with infected roach	Roaches (*Tembrio, Pyralis, Anisolobis* spp., etc.)	Hymenolepiasis diminuta
Nematodes					
Angiostrongylus cantonensis	Rats	3rd-stage ensheathed larva	Ingestion with infected slug or snail	Slugs and aquatic snails	Human angylostrongyliasis (eosinophil meningoencephalitis)
Ascaris lumbricoides	Various vertebrates	Egg with 2nd-stage larva	Ingestion	None	Ascariasis
Toxocara canis *Toxocara cati*	Canines Felines	Embryonated egg or 2nd-stage larva	Ingestion	None	Human visceral larva migrans
Anisakis spp.	Marine mammalians and birds	3rd-stage larva	Ingestion of fishmeat	Insufficiently known, mostly fish	Human anisakis infection (due to 3rd-stage larvae)
Trichinella spiralis	Various mammalians	Infective larva	Ingestion	None	Trichinellosis
Gnathostoma spinigerum	Canines and felines	3rd-stage larva	Ingestion	*Cyclops* spp., followed by fish, frogs or snakes	Gnathostomiasis
Capillaria hepatica	Various mammalians	Embryonated egg, after passage through "transport" host	Ingestion	Only "transport" host	Capillariosis, human visceral larva migrans
Strongyloides stercoralis	Various mammalians	Filariform larva	Transdermal penetration	None	Strongyloidosis of humans and sheep
Dracunculus medinensis	Canines, felines, equines, monkeys	3rd-stage larva	Ingestion (with *Cyclops*)	*Cyclops* spp.	Guinea worm disease
Brugia malayi	Felines and non-human primates	Filiariform 3rd-stage larva	Mosquito bite	Mosquitos (usually *Anopheles* and *Mansonia* spp.)	Lymphatic (Brugian) filariasis
Loa loa	Baboons	3rd-stage larva	Tabanid bite	Tabanids (*Chrysops* spp.)	Loiasis

Antibiotica

General term to describe drugs acting in various ways on bacteria (e.g., they may have bacteriostatic (tetracyclines) or bacteriocidic (e.g., penicillines) activities. See →Lyme Disease, →Streptothricosis, →Borreliosis, →Rickettsiae.

Antibody

Synonym

Immunoglobulin (Ig).

General Information

The function of antibodies is to remove antigen from the system and to support an effective immune response. Circulating antibodies which are detected in serodiagnostic systems are secreted by antibody-forming cells (plasma cells) after contact between B cells and antigen. They circulate freely throughout the blood and lymph. Antibodies are bifunctional molecules with antigen-binding sites (Fab fragment) and a region which is involved in other aspects of the immune regulation (Fc fragment). In most higher mammals and man, four of the five immunoglobulin classes of molecules are involved in the humoral immune response to parasites: IgG, IgM, IgA, and IgE.

Classes

Each immunoglobulin class differs in the heavy-chain polypeptides which determine its function at particular stages of the maturation of the immune response. IgM class antibodies are predominately antibodies of the early immune response and are distributed to a high degree intravascularly. A specific IgM class antibody response is indicative for an acute infection mainly with protozoan parasites. IgM serodiagnostic tests are used to discriminate between acute/recent and latent infections with *Toxoplasma*, *Trypanosoma cruzi*, and →*Babesia*. In contrast, during the early phase of West →African trypanosomiasis specific IgM antibodies may be undetectable in spite of a rising total serum IgM concentration. In helminthic infections diagnostic IgM class antibodies do not necessarily proceed an IgG response. This may be due either to a "diagnostic window" as seen 4–6 weeks after *Trichinella*-infection or, e.g., to the late onset and long-term persistence of gut-associated IgM antibodies after →*Schistosoma*-infection. The human IgG, which can be subdivided into the four subclasses IgG1–IgG4, is the major antibody of the primary and secondary immune response and the major serum immunoglobulin. In chronic →helminth infections elevated IgG and IgE specific responses develop. The prominent IgG subclasses recognizing parasite-specific antigens are IgG4 > IgG1 > IgG3, rarely IgG2. A high IgG4 response may indicate a successful parasite infection. The detection of parasite-specific IgG4 is essential for a species specific diagnosis of →*Onchocerca volvulus*, →*Wuchereria bancrofti*, →*Strongyloides*, →*Ascaris*, and →*Echinococcus*. IgG molecules of all subclasses can cross the placenta. Only the detection of specific IgM and/or IgA in the serum of the fetus or newborn is of relevance for the serological diagnosis of congenital infection with *Toxoplasma*, *Trypanosoma cruzi*, or →*Leishmania*. IgM and IgG1-3 antibody classes are able to activate the complement cascade, but not IgG4, IgA, and IgE. IgA is the predominant immunoglobulin in seromucous secretion, IgA1 being the predominant subclass in the serum. IgA antibodies are of additional value as markers for an acute infection as documented for toxoplasmosis. An elevation of total serum IgE, but not necessarily specific IgE class antibodies, is often related to infections with helminth parasites and may indicate an active disease. In contrast, protozoan parasites do not induce a significant IgE class antibody response. Specific IgE is not a reliable diagnostic marker for acute *Toxoplasma*-infection due to many non- or low-responders within the population.

Molecular Weights

IgM app. 970 000 daltons; IgG app. 146 000 daltons, IgA app. 160 000 daltons, IgE app. 188 000 daltons, IgD app. 184 000 daltons.

Binding Sites and Affinity

Antibodies are highly specialized in recognizing small regions of antigens but occasionally recognize similar epitopes on other related or unrelated molecules (cross-reaction). The binding between the antibody and the epitope of the antigen is non-covalent. The strength of bond between an antibody-combining site with an antigen is characterized as antibody affinity, the strength with which a multivalent antibody binds a multivalent antigen as antibody avidity. The antibody affinity/avidity to many antigens increases during an immune response and determines the biological effectiveness of the antibody. High-affinity antibodies are superior to low-affinity antibodies in respect to many biological reactions (e.g., haemagglutination, complementfixation) and in achieving antigen-binding more effective even at low antigen concentration. Today, this immunological mechanism is utilized for the differential diagnosis of a recent and latent *Toxoplasma*-infection in man.

Half Lives

The half-life of antibodies differs according to the antibody classes. It is high for IgG (21 days), medium for IgM (10 days) and low for IgA, and IgE (6–2 days). The complexed antibody is catabolized before clearance.

Biological Activity

In general, a primary antibody response can be divided into four phases: a first period when no antibodies are detectable, followed by an immune response of primarily IgM antibodies with a progressive change to IgG antibodies and an increasing antibody titer. The plateau phase with stable antibody titers is followed by an antibody decline. During →chronic infections, when the parasite is established at its permanent habitat, antibody production is mainly stimulated by circulating (excretory-secretory) antigens. The antibody secretion by B cells continues as long as the antigen(s) persists. Persisting antigen may increase the strength of the immune response. The primary antibody response is not only influenced by the nature of the antigen, its dose and infection route but also by the genetic background of a host. The time of antibody maturation and the final antibody concentration can vary considerably in individuals. Especially low responders or people with a recently contracted infection or patients from low endemic areas may not be detected in all serological test systems. Seroepidemiological studies in *L. infantum*-infected dogs indicate that a high sensitivity of the IFAT is reached only after an →incubation period of 8–9 months when first clinical symptoms occur. A complete antibody clearance is only possible after a complete elimination of the parasite (blood parasites after therapy) or its antigenic epitopes. Also, antigenic epitopes may be hidden by "walling off" in the host tissue (*Echinococcus*, →*Cysticercus*). However, after elimination of the antigen specific lymphocytes remain in circulation and may respond to a subsequent challenge (immunological memory). A challenge by antigens released after surgical or therapeutical measures (*Echinococcus*, *Cysticercus*) or reinfection induces a →secondary antibody production with a steep increase of mainly IgG class antibodies.

Clinical Relevance

Generally, the presence of circulating antibodies indicates the recognition of a foreign antigen. In parasitic infections →antibody detection does not correlate with disease, protective immunity or the parasite load. The serum antibodies are the most important defence mechanism of the host against extracellular parasitic forms in blood and body fluids like →*Trypanosoma*, *Toxoplasma*, →*Plasmodium*, or *Babesia* during acute infection. Symptomatic individuals normally present high antibody levels whereas asymptomatic carriers show a low antibody concentration. Antibodies in individuals without clinical symptoms may indicate an abortive infection as described for *E. multilocularis* or an infection with a long latency/incubation period. A correlation between cyst burden and antibody detection is known for porcine and human →cysticercosis (→*Taenia solium*). →Cysticercosis or →echinococcosis in asymptomatic or symtomatic patients is not excluded by negative test results. An assessment of the parasite load is not possible by conventional serological test systems. Recent developments indicate that specific antibody assays are useful for the determination of the egg-load after *Schistosoma*-infection. However, a better quantitation is by direct and indirect immunoassays which measure circulating parasitic antigens in body fluids. The quality of antibodies induced after natural infection or vaccination may differ in many aspects. It has to be considered that post-vaccination antibodies may not be detectable in conventional test systems. An evaluation of parasitic treatment is difficult by →serology. Only a complete parasitological cure is confirmed by negative serological results. Antibody disappearance is described for hepatic fascioliasis in humans 6–12 months after specific therapy and goats 1–5 months after therapy. In patients with Chagas' disease humoral response may persist for years after a negative result in direct parasite examination. This is also true for schistosomiasis, echinococcosis, cysticercosis, and filariosis. However, there are promising results that a follow-up of the antibody response to selected antigen(s) may be efficient in post-therapeutic monitoring.

In parasitic infections the antibody isotype profiles may vary with time and the clinical manifestation. Differences in the IgG isotype pattern of the paired sera from motherand newborn add to the diagnosis of congenital toxoplasmosis. Congenital toxoplasmosis or congenital infection with *Trypanosoma cruzi* is proven by the demonstration of specific IgM and/or IgA antibodies in the newborn serum.

Antibody-Dependent Cellular Cytotoxicity (ADCC)

Destruction of the target cell by release of toxic molecules by the effector cell.

Antibody-Dependent Cellular Inhibition (ADCI)

An assay measuring (e.g., in malaria) the cooperation between antibodies and monocytes.

Antibody Detection

→Serology.

Anticoccidial Drugs

→Coccidiocidal Drugs.

Antidiarrhoeal and Antitrichomoniasis Drugs

Drugs Acting on Giardiasis

→*Giardia lamblia* (syn. *G. intestinalis, G. duodenalis*) is distributed worldwide and has been identified in humans and domestic livestock, particularly in young animals such as calves, lambs, piglets, and foals and birds. The flagellate (with four pairs of →flagella) living in the small intestine may produce acute or chronic enteritis with profuse and heavy diarrhea and growth rate reduction in mammals and birds. *Giardia* spp. infections in animals may pose a serious zoonotic threat to humans. Humans may acquire infection either through waterborne transmission by *Giardia* cysts occurring in the drinking water contaminated with infectious feces or by direct contact with contaminated feces. Although quinacrine and furazolidone resistance have been induced in *G. duodenalis* →trophozoites, the substituted acridine dye derivative quinacrine can be of value in humans suffering from giardiasis, mainly in patients showing reduced response to 5-nitroimidazoles. However, quinacrine may cause exacerbation of psoriasis, ocular toxicity, and toxic psychoses, or distinctly enhance toxicity of 8-aminoqunolines, e.g., primaquine (→Malariacidal Drugs).

Benzimidazole carbamates such as mebendazole, fenbendazole, or albendazole may exhibit the most pronounced activity against *Giardia* infections in man, farm animals, and dogs; however, repeat treatments may be necessary to eliminate parasites in reinfected farm animals. Currently used drugs in *Giardia*-infected humans are summarized in Table 1. The **control** and **prevention** of *Giardia* should be directed at young animals. They are highly susceptible to the parasite and show a markedly higher output of cysts than adult animals. Control measures for humans should be centered on environmental and personal →hygiene issues such as routine hand-washing, control of insects to prevent their contact with infected stools. **Iodine** seems to be an effective disinfectant for drinking water; filtration systems are also recommended (drawbacks may be clogging and safe removal of contaminated filters); killing of *Giardia* cysts by boiling the water is most effective but will cost energy. The chances of a protective vaccine against giardiasis are poor.

Drugs Acting on Trichomoniasis in Humans and Cattle

→*Trichomonas vaginalis* (motile trophozoite) is a common pathogen of the urogenital system in men and women but is uncommon in preadolescent girls. A frequent transfer of this flagellate is due to sexual intercourse, which explains the need for a therapy of both partners. In childbearing women, there may be an overall prevalence of 30%, which is significantly higher than that in men (5% or more). Very frequently *T. vaginalis* infection is asymptomatic, especially so in the male. Clinical signs may develop if parasites cause degeneration and desquamation of the vaginal epithelium followed by inflammation of the vagina and vulva and a leucocytic discharge may be evident. Topical treatment can be tried with clotrimazole or pimaricin but appears to be of little value because these drugs lack systemic action, which is essential in cryptic infection of men. Current **therapeutic drugs** with good systemic activity against *T. vaginalis* infections, are the well-tolerated **5-nitroimidazoles** metronidazole, ornidazole, tinidazole, and others showing high cure rates even after a single dosing (Table 1). These drugs may differ somewhat in their pharmacologic properties but not so in efficacy or toxicity. They have a wide spectrum of activity, including →*Entamoeba histolytica*, *G. lamblia, Balantidium coli*, and anaerobic bacterial infections. Drug resistance of *T. vaginalis* strains has been reported infrequently. This step forward in the 5-nitroimidazole-therapy becomes apparent when comparing the list of more than 170 different treatment regimens with exotic compounds like picric acid and mercuric

Antidiarrhoeal and Antitrichomoniasis Drugs. Table 1 Drugs acting on *Giardia, Trichomonas*, Amoebae, and *Balantidium* in humans

DISEASE **Nonproprietary name** (chemical group)	**Brand name** other information	**Adult dosage/*pediatric dosage** (mg/kg b.w., or total dose/individual, oral route), miscellaneous comments
GIARDIASIS *Giardia lamblia* may contaminate drinking water, which is a common source of infection for humans and mammals; flagellated trophozoites attach by their 'suckers' to the surface of mucosa of small intestine, producing partial villous atrophy of the duodenum or jejunum; the ovoid cyst is passed in feces and has a very distinctive form; although *G. lamblia* is commensal in many individuals, it may be particularly pathogenic in debilitated and immunosuppressed patients, and is a common cause of diarrhea and a malabsorption syndrome characterized by excessive amounts of fat in the stool (steatorrhea) in travellers.		
metronidazole (5-nitroimidazole)	Flagyl, Clont, others	250 mg tid ×5d; *15 mg/kg/d in 3 doses × 5d (not licensed in the USA but considered investigational for this condition by the FDA)
nitazoxanide	Alinia	500 mg bid × 3; *1–3 yrs: 100 mg q12 × 3d; 4–11 yrs: 200 mg q12 × 3d
tinidazole (5-nitroimidazole)	Fasigyn, others	2 gr once; *50 mg/kg once (max. 2 g) treatment should be followed by administration of iodoquinol or paromomycin in doses as used to treat asymptomatic amoebiasis (see below)
furazolidone (nitrofuran)	Furoxone, others	100 mg qid × 7–10d; *6 mg/kg/d in 4 doses × 7–10d toxic effects may be serious and common, hypersensitivity reactions (urticaria)
paromomycin (aminoglycoside)	Humatin	25–35 mg/kg/d in 3 doses × 7d (use of drug may be suitable in pregnancy as it is not absorbed)
TRICHOMONIASIS Motile trophozoites of *Trichomonas vaginalis* can be found in the foamy vaginal discharge of trichomonal vaginitis; the creamy discharge is often secondarily infected with the yeast *Candida albicans*; infection is transmitted by sexual intercourse; asymptomatic infection in the male (and therefore not treated) may be often a source of trichomonal infection in the female partner; for this reason sexual partners should be treated simultaneously; metronidazole-resistant strains have been reported, and enhanced doses of the drug for longer periods or use of tinidazole may be effective against these strains In cattle the *Tritrichomonas foetus* infection of the cow often leads to an abortion and sterility; infection is transmitted by coitus; in birds, particularly in pigeons, heavy *Trichomonas gallinae* infections may lead to high mortality caused by necrotic lesions in the mouth, crop, and the esophagus with extension to the bones of the skull, the liver, and elsewhere		
metronidazole (5-nitroimidazole)	Flagyl, Clont, others	2 g once; or 250 tid or 375 mg bid × 7d; *15 mg/kg/d in 3 doses × 7d
tinidazole (5-nitroimidazole)	Fasigyn, others	2 g once; *50 mg/kg once (max. 2 g) (the drug seems to be better tolerated than metronidazole, it is not marketed in USA)
AMOEBIASIS *Entamoeba histolytica* infection occurs by oral uptake of cysts, which are quite refractory to environment; the cysts are ingested with drinking water or food, which is not readily prepared or thoroughly cooked; as the disease is not characterized by a certain incubation time it is difficult to determine the onset of the amoebiasis; fever and feces containing blood and foamy fluid may be indications for acute amoebiasis; treatment should be started immediately after diagnosis has been made to avoid colonization of the liver by so-called "magna-forms" (tissue stages causing necrosis of liver parenchyma followed by formation of an abscess); large liver abscesses should be aspirated prior to treatment; there is no drug resistance in amoebiasis		
ASYMPTOMATIC CASES Asymptomatic carriers extruding cysts (quadrinucleate form) in the feces are an important source of infection; there are no therapeutic drugs, which may affect cysts; **luminal drugs** act directly (by contact) on (uninucleated) trophozoites of *E. histolytica* living in the lumen of large intestine; paromomycin may also act by modifying intestinal bacterial flora.		
diiodohydroxyquinoline (8-hydroxyquinoline)	Iodoxin, others (drug of choice)	650 mg tid × 20 d; *30–40 mg/kg/d (max. 2 g) in 3 doses × 20 d; toxic effect maybe SMNO (= subacute myelooptic neuropathy) after high doses and for long periods
paromomycin (aminoglucoside)	Humatin (drug choice)	25–35 mg/kg/d in 3 doses × 7d (may be useful in pregnancy as it is not absorbed); *25–35 mg/kg/d in 3 doses
diloxanide furoate (dichloroacetamide)	Furamide (alternative drug)	500 mg tid × 10d; *20mg/kg/d in 3 doses × 10d remarkably safe drug for treatment of carriers
MILD TO MODERATE INTESTINAL DISEASE Uninucleated trophozoites of *E. histolytica* invade the intestinal epithelium, principally in the cecum and the ascending colon causing lytic necrosis of tissues; 5-nitroimidazoles are well absorbed from the intestine and exhibit a marked systemic effect on extraintestinal amoebiasis		

Antidiarrhoeal and Antitrichomoniasis Drugs. Table 1 Drugs acting on *Giardia, Trichomonas*, Amoebae, and *Balantidium* in humans (Continued)

DISEASE **Nonproprietary name** (chemical group)	**Brand name** other information	**Adult dosage/*pediatric dosage** (mg/kg b.w., or total dose/individual, oral route), miscellaneous comments
metronidazole (5-nitroimidazole)	Flagyl, Clont, others (drug of choice)	500–750 mg tid × 10d; *35–50 mg/kg/d in 3 doses × 10d
tinidazole (5-nitroimidazole)	Fasigyn (drug of choice)	2 g/d × 3 d; *50 mg/kg (max. 2 g) qd × 3 d (drug may be better tolerated than metronidazole; it is not marketed in the USA
ornidazole	Tiberal	2 g once a day × 3d; amoebicidal activity of ornidazole is similar to that of other 5-nitroimidazole, not licensed in the USA
SEVERE INTESTINAL DISEASE, EXTRAINTESTINAL AMOEBIASIS (HEPATIC ABSCESS) In fulminating amoebic dysentery with loose feces, containing mucus and blood, the ameba penetrate more deeply into the intestinal wall thereby damaging all layers of the intestinal wall resulting in confluent ulceration; ameba may pass into the lymphatics or mesenteric venules and invade other tissues of the body, especially the liver, but also skin or genital organs; the most common form is a large single abscess in the right lobe of liver		
metronidazole	Flagyl (drug of choice)	750 mg tid × 10d; *35–50 mg/kg/d in 3 doses × 10d
tinidazole	Flasigyn	2g once daily × 5d; *50 mg/kg/day (max. 2g) × 5d
ornidazole (5-nitroimidazole)	Tiberal	2 g once a day × 3d; amebicidal activity of ornidazole is similar to that other 5-nitroimidazole; (not licensed in the USA)
AMOEBIC INFECTIONS OF CENTRAL NERVOUS SYSTEM (CNS) AND THE EYE Free-living aquatic amoeba such as *Naegleria* spp. *Acanthamoeba* spp., and *Balamuthia mandrillaris* may cause various CN disorders, which may be fatal; *N. fowleri* causes a rapidly fatal infection known as 'primary amoebic meningoencephalitis' (PAM); most patients with naeglerial infection have had a history of recent swimming in fresh water during hot summer weather; a number of *Acanthamoeba* species may produce a chronic CNS infection called 'granulomatous amoebic encephalitis' (GAE) or an eye infection characterized by a chronic progressive ulcerative keratitis; *B. mandrillaris* also causes GAE; unlike naeglerial infection, GAE does not appear to be associated with swimming; infections are often seen in individuals debilitated or immunocompromized including patients with AIDS; diagnosis is made by microscopic identification of living or stained amoeba trophozoites in CSF (Giemsa stained spinal fluid smears) or corneal scrapings, and motile amoeba (trophozoites) can be readily seen in wet-mount preparations; **chemotherapy** of PAM and GAE is problematic; almost all cases of PAM and GAE have been fatal because of the foudroyant course of PAM and lack of an effective causative treatment; considerable toxic amphotericin B seems to be the only drug with clinical efficacy		
amphotericin B (polyene antibiotic)	Amphotericin B powder	there are some known survivors of **PAM**, children from Australia, the UK, India, and the USA treated with amphotericin B: 1–(1.5) mg/kg/d × 3 d i.v. followed by 1mg/kg/d × 6 d i.v. or longer (additional amphotericin B given intrathecally plus miconazole or rifampicim i.v.)
miconazole	Daktar, solution for injection	**GAE** caused by *Acanthamoeba* has been successfully treated by total excision granulomatous brain tumor and administration of ketoconazole, *Acanthamoeba* meningitis with penicillin and chloramphenicol; *Acanthamoeba* and *Balamuthia* form cysts in tissues; thus, a potential effective drug for GAE must be capable of damaging cysts and trophozoites to prevent relapse after course of treatment; strains of *Acanthamoeba*isolated from fatal GAE cases were susceptible to pentamidine, ketoconazole, flucytosine *in vitro*; today, *Acanthamoeba* **keratitis** can be managed by medical treatment alone, if diagnosis has been made soon enough; successful regimens may be topical propamidine, miconazole, and neosporin with epithelial debridement (removal of infected tissue from the lesion to expose intact tissue) or clotrimazole, systemic ketoconazole or itraconazole with topical miconazole and surgical debridement
ketoconazole (azoles)	Nizoral	
flucytosine (pyrimidinone analog) various topical formulations of azoles and other drugs for *Acanthamoeba* keratitis	Ancobon	
BALANTIDIASIS *Balantidium coli* (a ciliate) is a common commensal of the large intestine of wild and domestic pigs, but it can be pathogenic to humans and primates in which it produces various clinical forms (asymptomatic carrier condition, acute cases with fulminant diarrhea or chronic cases: diarrhea changes with constipation); however human infections are infrequent and pigs act as the main reservoir for human infections; motile flagellated trophozoites can invade the submucosa of large intestine		

Antidiarrhoeal and Antitrichomoniasis Drugs. Table 1 Drugs acting on *Giardia, Trichomonas*, Amoebae, and *Balantidium* in humans (Continued)

DISEASE **Nonproprietary name** (chemical group)	**Brand name** other information	**Adult dosage/*pediatric dosage** (mg/kg b.w., or total dose/individual, oral route), miscellaneous comments
causing an ulcerative enteritis in severe cases; trophozoites and cysts are passed in the feces and can readily be found in fresh wet-mount preparations; the main endemic areas are in the tropical and subtropical areas and where there is close contact between humans and pigs; humans become infected by ingestion of cyst-contaminated food and water		
tetracycline (tetracyclines)	various	500 mg qid × 10 d; *40mg/kg/d (max. 2 g) in 4 doses × 10 d; use of tetracyclines is contraindicated in pregnancy and children <8 years of age; they discolor teeth in growing children; (not licensed in the USA but considered investigational for this condition by the FDA)
metronidazole (5-nitroimidazole)	Flagyl (drug of choice)	750 mg tid × 5 d; *35–50 mg/kg/d in 3 doses × 5 d (not licensed in the USA but considered investigational for this condition by the FDA)
diiodohydroxyquinoline (8-hydroxyquinoline)	Iodoxin alternative drug	650 mg tid × 20 d; *40 mg/kg/d in 3 doses × 20 d (not licensed in the USA but considered investigational for this condition by the FDA)

Abbreviations: the letter d stands for day (days); qd = daily (quaque die); bid = twice daily; tid = three times per day; qid = four times per day (quarter in die); p.c. (post cibum) = after meals

Dosages listed in the table refer to information from manufacturer or literature (e.g., Medical Letter 46, 2004)

Data given in this Table have no claim to full information

chloride cited in a book on trichomoniasis published about 50 years ago.

Also other flagellates may occur in the digestive tract or in the reproductive system being potential pathogens for diseases in mammals (monkeys, dogs, cats, zoo animals, or ruminants), and birds. →*Tritrichomonas foetus* with three anterior flagella may be of significance in the veterinary medicine causing an →abortion in cows followed by prolonged, and at times permanent, sterility or a closed pyometra (purulent endometritis). In the bull, the principal infection site is the preputial cavity. *A T. foetus* infection is transmitted during coitus or by artificial insemination, and by gynecological examination of cows. The major control measure for trichomoniasis in cattle is the use of artificial insemination. The administration of **5-nitroimidazoles** like metronidazole or tinidazole is probably the most effective and expensive therapy for most of these protozoan infections. However, in some countries the use of 5-nitroimidazols in food animals is now subject to regulatory actions of government agencies. The aim is to remove drugs of this chemical group from the market because of potentially cancerogenic action in rodents. Benign epithelial tumors (adenoma) have been observed in mice after being treated with high daily doses of metronidazole and others 5-nitroimidazoles administered for prolonged periods such as 6 months or so.

Drugs Acting on Histomoniasis (Blackhead Disease) of Birds

Histomonas meleagridis is found in the ceca and liver of various birds (turkey, chicken, peafowl, guinea fowl, pheasant, partridge). The organism is probably transmitted by ingestion of cysts and/or anal contact to fresh feces. The amoeboid stage of the flagellate may cause enterohepatitis in turkeys (or chickens) under range or yard management and thus high economic losses in the turkey industry. Control of enterohepatitis consists of good husbandry and preventive medication; contact between turkeys and chickens must be avoided, and regular treatment of all birds with anthelmintics should be performed to reduce the incidence of *H. gallinarum*, which apparently suppresses the immune system. Drugs used as additives in-feed and/or therapeutic drugs in-water belong to different chemical groups. Various **5-nitroimidazoles** such as dimetridazole, ronidazole, carnidazole, or ipronidazole may be used in-feed (the latter drug at dose levels between 50–85 ppm, withdrawal time 6 days, EC directives, 1999). Nifursol (use level in-feed, 50–75 ppm, withdrawal time 5 days, EC directives, 1999) or furazolidone, and others belong to the group of **5-nitrofuranes.** However, in various countries there are increasingly legislative restrictions concerning the use of additives in-feed for the prevention of histomoniasis because of potential cancerogenicity of these drugs in rodents.

Drugs Acting on Intestinal and Extraintestinal Amoebiasis of Humans

Entamoeba histolytica in humans, monkeys, dogs, cats, and zoo-animals may produce acute or chronic enteritis associated with profuse and heavy diarrhea. Acute →amoebiasis must be differentiated from the chronic form. The use of amoebicidal drugs in the treatment of patients with various clinical forms of amoebiasis (Table 1) has contributed to reduction of →morbidity and mortality of the disease. Luminal drugs are used to treat asymptomatic carriers passing cysts of

E. histolytica in stool being an important source of infection. Various drugs are available for patients with invasive intestinal amoebiasis associated with ulceration of deep layers of the intestinal wall of cecum and colon (Table 1). The same agents (e.g., 5-nitroimidazoles) can be used in treating invasive extraintestinal amoebiasis, involving liver, skin, and other organs. Systemic amoebicides currently seldom used because of their high toxicity or only limited action (e.g., chloroquine) are emitine and dehydroemitine (alkaloids), which act in the liver, and intestinal wall (other tissues), and chloroquine, which acts in the liver only. Emitine and dehydroemitine administered intramuscularly are fairly toxic drugs producing cardiac arrhythmia, and asystole, but also adverse effects of the central nervous system (CNS).

Drugs Acting on Amoebic CNS Diseases and Amoebic Keratitis

A number of free-living opportunistic →amoebae are known to be potential pathogens for humans. →*Acanthamoeba* spp., →*Balamuthia mandrillaris*, and →*Naegleria fowleri* can cause lethal infections particularly in children having close contact with water. Their distribution is worldwide in fresh water and soil. The protozoans live preferably in aquatic habitats where they feed on bacteria (e.g., in warm lakes or swimming pools). Infection by *N. fowleri* is acquired by intranasal absorption of amoebae (flagellates or cysts); trophozoites invade the nasal mucosa, cribriform plate, and olfactory bulbs of the brain (cysts are absent in infected tissues). *Acanthamoeba* spp., and *B. mandrillaris* may infect man via nasal mucosa causing fatal CNS disease or by direct invasion of the cornea through lesions of the eye or the wearing of contaminated contact lenses of healthy persons producing *Acanthamoeba* keratitis. Primary amoebic →meningoencephalitis (PAM) due to *N. fowleri* is usually diagnosed after death of patient and is characterized by an acute, hemorrhagic, necrosing meningoencephalitis. *Acanthamoeba* spp. and *B. mandrillaris* cause focal granulomatous amoebic →encephalitis (→GAE) and trophozoites and cysts occur in most infected tissues. **Chemotherapy** of PAM and GAE is problematic and only a few cases have been treated successfully with the highly toxic polyene antibiotic amphotericin B (Table 1). *Acanthamoeba* keratitis, which increasingly occurs in immunocompromized patients, can be treated with success if it is diagnosed at an early stage. Various drugs (dibromopropamidine, neomycin azoles, alone or in combination) have been administered topically as ointments and drops (see Table 1).

Drugs Acting on Balantidiasis

→*Balantidium coli*, which possesses →cilia for locomotion, is a natural inhabitant of the digestive tract of mammals and widespread in swine; the vegetative forms of *Balantidium* (man, monkeys and pigs) may produce acute or chronic enteritis with profuse and heavy diarrhea. Good hygiene and sanitation may prevent infections, which are associated with close contact to pigs. Acute *B. coli* infections may be treated with **tetracycline**. Alternative drugs may be the 5-nitroimidazole **metronidazole** (Table 1). In many countries its use in food animals is now subject to regulatory actions of government agencies; the aim is to remove drugs of this chemical group from the market because of their potentially cancerogenic action in rodents after prolonged administration.

Antifolates

Drugs acting against folata production, e.g., in malaria parasites, →Malariacidal Drugs.

Antigen Presentation

→Immune Responses.

Antigenic Variation

→Surface Coat/Antigenic Variation.

Antigens

Synonym

Immunogens.

Introduction

Antigens are molecules – proteins, peptides, carbohydrates, nucleic acids, lipids, or any other compound - that induce the production of antibodies and bind to antibodies. Parasites may present a great quantity and variety of antigens to the host that change with time as a consequence of maturation through different life-cycle stages. Parasitic antigens may be divided into several categories: diagnostic, protective, pathologic. An antigen acts as immunogen when it is able to induce

an immune response (immunogenicity). In general, different antibodies are produced to an antigen which bind to different epitopes. The hosts' immune response depends on the presentation, quantity, and kind, of →circulating antigen. Cross-reacting epitopes exist between the different stages of the same species, and between different species of the same genus. In →helminth infections there is a high degree of cross-reactivity between species and genus. The antigens of helminths commonly exposed to the immune system are excretory and/or secretory (E/S) antigens or surface molecules (somatic antigen). Antigens of →Protozoa have a lower degree of variability between species and their immunogens are mainly surface antigens. For each parasite the diagnostic potency of surface, E/S, and somatic antigens has to be evaluated in regard to their effectiveness in a specific test system.

Antigen Processing

Due to the often complicated life cycle of parasites, including vector transmission, it may be difficult to maintain helminth parasites in laboratory animals or *in vitro*. In practice it is impossible to recover large quantities of antigen from each pathogen species. It is a common laboratory practice to select one single, highly cross-reacting species for antibody screening within a whole genus (→*Brugia malayi* for filariasis, →*Schistosoma mansoni* for schistosomiasis, *Leishmania donovani/infantum* for leishmaniasis, →*Plasmodium falciparum* for →malaria). Until recently the primary source of antigen for most of the serological assays was parasite maintained *in vivo* (helminths) or in continuous *in vitro* culture systems (Protozoa). Complete cells, fragments, or cryosections of parasites (cellular antigens) are used as antigen in IFAT, DT, and agglutination test. Crude or purified soluble extract antigens or culture-derived E/S antigens are utilized in other test systems like →ELISA, IHAT, CFT, CIEP, and gel precipitation. Today, new technologies which allow the construction of synthetic peptides, recombinant proteins, or DNA-based immunization have opened up the possibility for large-scale production of defined antigens or specific antibodies. However, for each preparation the diagnostic potency must be proven. It could be shown that a single antigen or a monoclonal antibody may be satisfactory for individual diagnosis but not for screening purposes. A combination of several defined antigens may improve the sensitivity, a polyclonal antibody, the binding capacity of a test system.

Antigen Assays

→Immunoassays for antigen detection are increasingly developed. Urinary antigen detection is of diagnostic interest for parasites with developing stages associated to the genito-urinary tract (→*Schistosoma haematobium*, →*Trichomonas vaginalis*) or parasitic antigens excreted during the acute or →chronic infection stage in urine (→*Wuchereria bancrofti*, *Trypanosoma cruzi*). Circulating antigen detection is useful for a quantification of blood parasites (→*Trypanosoma* spp., microfilariae) or detection of E/S antigens (→*Schistosoma* spp.). It may provide information on the presence and/or activity of the parasite. Antigen detection in stool specimens enables a species-specific diagnosis which is impossible after microscopic examination (→*Entamoeba histolytica/dispar*, →*Echinococcus* spp.).

Clinical Relevance

Many stage-specific antigens of different parasites have been characterized so far and some of them are already applied in serodiagnostic test systems. A tachyzoite-specific, recombinant surface antigen (P30) is of proven diagnostic value for the detection of *Toxoplasma* antibodies. Species-specific antigens of *Echinococcus multilocularis* like Em18 or the recombinant antigen Em2 are in use for the serological differentiation of infection with the alveolar or cystic form. ELISAs with improved specificity by use of recombinant antigens were developed for parasitic infections like Chagas' disease, leishmaniasis, →*Strongyloides*, and many others. Defined glycoproteins of the cyst fluid from →*Taenia solium* are highly specific and allow the identification of patients with →cysticercosis by use of the WB. The seroreactivity to a specific antigen as indication for active infection was described for →visceral leishmaniasis and amoebiasis. The detection of one or both genus-specific *Schistosoma*-antigens (circulating anodic, CAA, and cathodic, CCA, antigens) indicate an active schistosomiasis. A positive correlation between *Schistosoma haematobium* egg excretion and levels of CAAs was reported. The level of complexed antigen in serum is a good indication for the microfilarial load in →Bancroftian filariasis.

Not only a quantification of the parasite load but also a discrimination between recent and past infection is possible by urinary antigen detection. A better discrimination between acute and congenital-infected patients was reported for Chagas' disease. The →immunodiagnosis of intestinal parasitic infection has advanced significantly through the development of coproantigen detection methods. Commercial ELISA systems which use monoclonal antibodies for the detection of fecal parasitic antigens like *E. histolytica/dispar*, *Giardia lamblia/G. intestinalis* and/or *Cryptosporidium* spp. are now available and are going to replace microscopic examination in many laboratories. However, the specificity, sensitivity, and clinical value of the available tests are still under investigation.

The detection of *Echinococcus*-antigen in fecal samples of the dog (*E. granulosus*) or fox (*E. multilocularis*) by use of polyclonal antibodies may become an important diagnostic tool in veterinary medicine.

Antimony Compounds

Drugs acting, e.g., against trypanosomiasis (e.g., antimony potassium tartrate), →Trypanocidal Drugs.

Antiparasitics

Compounds (natural or chemical) acting against parasites, e.g., →Nematocidal Drugs = agents against nematodes.

Antricola

Genus of →argasid ticks (e.g., *A. coprophilus, A. marginatus*), which feed on bats in Central America and in USA.

Aonchotheca

Synonym for the genus name →*Capillaria*.

Apanteles

Genus of Ichneumonoidea (e.g., *A. melanoscelus*), which are used in the USA as biocontrol of gypsy moth larvae.

Apatemon gracilis

2 mm-sized trematode (syn. *Strigea gracilis*) living in the small intestine of geese, ducks, etc. →Digenea.

APC

Antigen-presenting cell.

Aphaniptera

The term means animals with hidden/lost wings, see →Fleas.

Aphanipteridosis

Disease due to →flea bites.

Aphanipteriosis

→Fleas, →Siphonapteridosis.

Apical Cap

→Apicomplexa.

Apical Complex

→Apicomplexa, organelles at the apical cell pole.

Apical Organ

→Acanthocephala.

Apicomplexa

Synonym

→Sporozoa.

Classification

Subphylum of →Alveolata (new system), Phylum of →Protozoa (old system).

General Information

Members of this phylum are characterized by the occurrence of the name-giving sporocysts (and/or oocysts) which produce the infectious sporozoites. The life cycles comprise a regular alternation of different sexual and/or asexual generations (→Coccidia). Although several multinucleate stages occur during the reproduction of individuals of the different species (→Plasmodium/Fig. 2), the typical sporozoan cell is uninucleate. With respect to fine structure the Sporozoa are a relatively uniform group, being provided with a typical →apical complex (→Pellicle/Figs. 3–5).

System

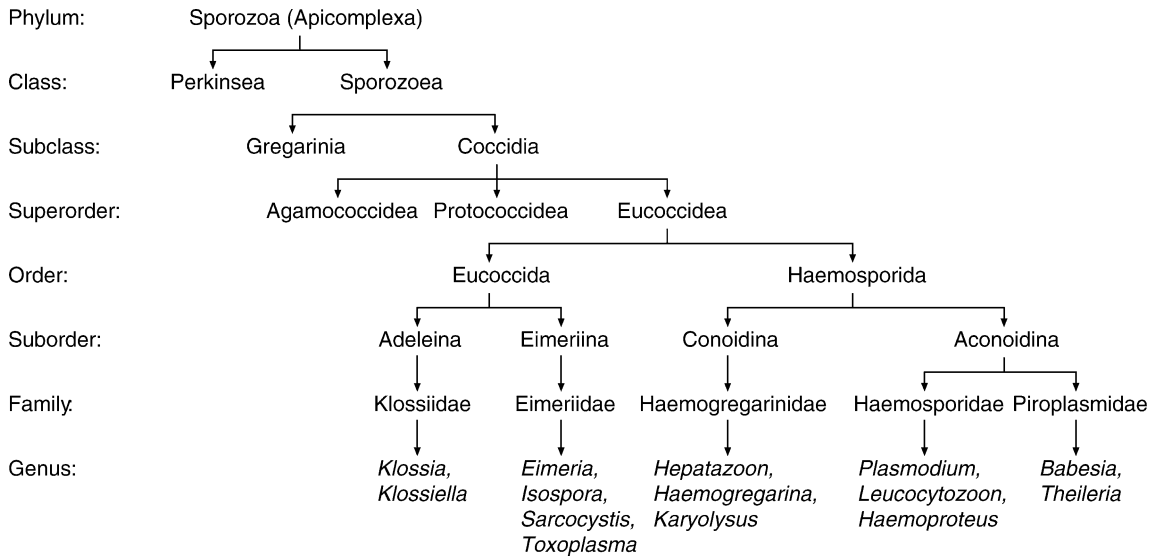
Due to these fine structural features, several groups of parasites have been added to, or excluded from, the Sporozoa. This led to the systematic concept of Levine et al., which is, however, not generally accepted. Thus, the authors of this chapter do not support the addition of the class →Perkinsea, since the fine structure is not identical with that of other sporozoans. Furthermore, we find it necessary to include the →Piroplasmea (→*Babesia*/Fig. 1, →*Theileria*/Fig. 1) and all blood-parasitizing members of the →Adeleidea (genera →*Karyolysus*, →*Hepatozoon*, →*Haemogregarina*, →*Leucocytozoon simondi*/Fig. 1, →*Karyolysus lacertae*/Fig. 1, →*Hepatozoon*/Fig. 1) in the Haemosporida. Thus, in our opinion the following system better reflects the biological and morphological relations among the members of the Sporozoa (Fig. 1).

Surface Coat

The major surface proteins of →*Plasmodium* merozoites or →*Toxoplasma gondii* →tachyzoites have been shown to be GPI-anchored (→Glycosylphosphatidylinositols). The Circumsporozoite protein (→CSP) of sporozoites and the →ookinete surface proteins have the primary sequence requirements for →GPI anchoring, although the latter has not been formally demonstrated due to the low amount of material available for study. Although the trimannosyl-glucosaminyl core is common with kinetoplastids, the structure of the GPI anchors differs from the trypanosomes, and among apicomplexans, by the sugar ornamentation of the glycannic core, and it does not undergo remodeling after addition to the protein.

The GPI anchor of *Plasmodium* has been shown to be a strong immunomodulator responsible for signal transduction in cells of the vertebrate host.

The →MSP1 of *Plasmodium* merozoites undergoes proteolytic processing before reinvasion, and shedding of the cell coat described during invasion coincides with the removal of most of the protein except the C-terminal 19 kDa that is internalized with the parasite inside the red blood cell. In sporozoites, the CSP is deposited on the substrate during motility on serum albumin-coated surfaces, or is capped and shed when bound to specific antibodies. The mechanism of



Apicomplexa. Figure 1 Overview of groups among Sporozoa (Apicomplexa/Alveolata) (according to Mehlhorn and Schein). Recent molecular biologically obtained data indicate that it is necessary to exclude →*Toxoplasma*, →*Sarcocystis*, and →*Isospora* from Eimeriidae and to include them into a newly created sister family (Sarcocystidae). Furthermore Perkinsea are surely no longer Apicomplexa but dinoflagellates. The genus *Cryptosporidium* probably belongs to the group of Gregarines.

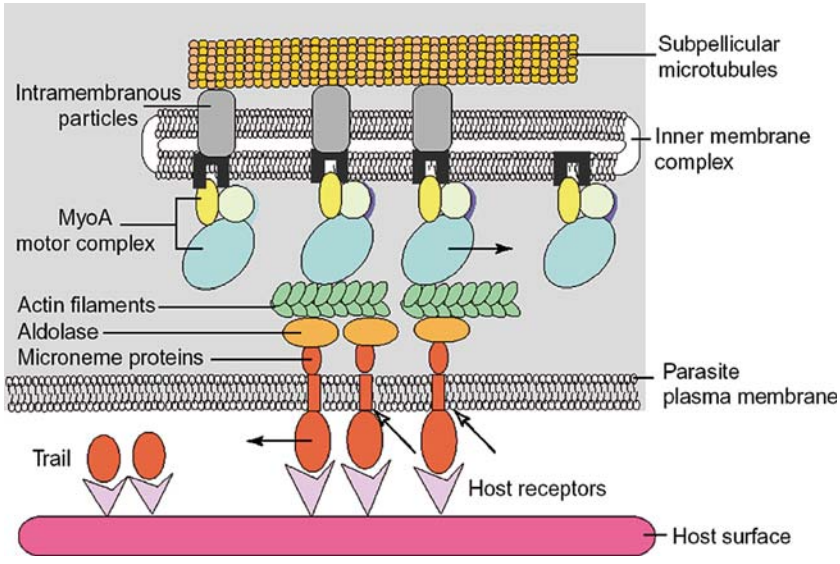
shedding (release of proteins, cleavage of the anchor, or removal of lipids associated with the coat) is not elucidated. As described below, the contribution of GPI-anchored proteins to Apicomplexan motility is not known; in addition, exocytosed microneme protein are transiently inserted into the →plasmalemma of the parasites during motility and at the invasion stage and may therefore be part of the glycocalix during a short period of the parasite cycle.

Motility

As described by many investigators, motility of Apicomplexan zoites can be subdivided into 3 types which are, respectively, gliding, twisting, and bending. Only the first type leads to active displacement of the →zoite, the 2 others being involved in changing the direction of motion. →Gliding motility is very uncommon among eukaryotic cells; it is clearly different from amoeboid locomotion and involves a unique molecular assembly of proteins originating from several compartments of the zoite.

In all cases, gliding motility has been described as the backward translocation of a "junction" between a substrate and the zoite surface along the latter's longitudinal axis. The substrate could be detected by small latex beads which, in the case of the gregarine, were translocated and accumulated at the posterior extremity of the organism. The experiments clearly demonstrated that the gliding motility of Apicomplexan zoites was a relative phenomenon in which the moving partner could be the zoite or the substrate depending on their respective size. Physiological studies of these models and others have shown that gliding was temperature- and cytochalasin D-sensitive, this last property being interpreted as a clue to the participation of →actin in zoite motility. Indeed, in *T. gondii*, the direct involvement of actin in motility has been demonstrated and →myosin is also implicated, both molecules being found between the plasmalemma and the inner complex of zoites.

The parasite surface molecules involved in motility are essentially derived from the exocytosis of micronemes. Indeed, the resident surface proteins being GPI-anchored, they cannot transduce directly a mechanical force originating from the acto-myosin motor located below the plasma membrane. Instead, transmembrane proteins initially located in micronemes are translocated on the parasited surface by exocytosis at the parasite apical area and operate this transduction. Very elegant genetic studies in *P. berghei* have demonstrated the critical role of a highly conserved microneme protein TRAP in the gliding motility of sporozoites. These findings, together with other investigations in *T. gondii* have led to the description of the molecular assembly responsible for gliding motility. The TRAP family proteins are inserted into the plasma membrane and their cytoplasmic C-terminus sequence interact via an aldolase and triggers the polymerization of short actin filaments that are propelled by resident myosin molecules that are attached to underlying inner membrane complex. This antero-posterior translocation of a transmembrane protein intracting with the substrate via its N-terminus is responsible for the gliding motility (Fig. 2).



Apicomplexa. Figure 2 Schematic drawing of the mechanism of zoite motility in Apicomplexa. The myosin motor (myoA motor complex) is associated with the inner membrane complex, oriented by the subpellicular microtubules. Microneme proteins become inserted in the plasmalemma and associate with short actin filaments through an aldolase. The actin-aldolase-microneme protein complexes are translocated by the myosin motor while interacting with the substrate, resulting in gliding motility. (After Soldati and Meissner, *Current Opinion in Cell Biology*, 16, 32–40, 2004, modified).

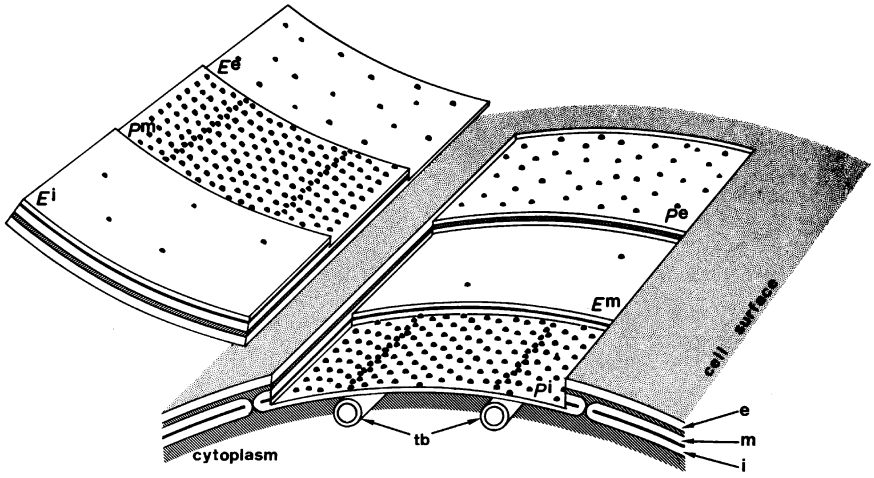
The nature of the interaction between the zoite and the substrate is entirely unknown. A classical →receptor-ligand interaction is unlikely since gliding motility has also been observed on glass or on liquid–liquid interfaces and it thus appears that zoites may use physical properties of interfaces and surface tension to interact with substrates.

The →orientation of motility, along the zoite axis, and its exclusive forward directionality can be related to morphological characteristics of zoites, although no experimental demonstration of a relation between structures and motility has yet been obtained. Indeed, freeze fracture has demonstrated highly organized structures within the →pellicle of Apicomplexan zoites: although the outer layer (cytoplasmic membrane) shows little differentiation, the inner membrane complex, which is made of 2 closely apposed membranes underlying the plasmalemma, is highly organized. This inner complex is in fact a continuous layer of rectangular flattened vesicles (plates) arranged in longitudinal rows except at the anterior extremity where a truncated conical plate (→Apical Cap) is found (Fig. 3). The intramembranous particles of both membranes of the inner complex are arranged in a dense array of parallel longitudinal lines. Lines of higher particle density are found over the subpellicular microtubules which extend longitudinally under the inner complex (Fig. 4). Similar structures have been observed in all Apicomplexan zoites described so far. This highly organized longitudinal pattern is likely to provide the template for the translocation of the TRAP Proteins. A correlation between these morphological features and the actomyosin motor of motility remains to be established.

Another phenomenon has been described on apicomplexan zoites which also concerns the surface interactions between these organisms and their surroundings. When zoites are presented with a variety of ligands interacting with their surface (cationized ferritin, surface antigen-specific antibodies), they are at first entirely covered with the ligand but they are able to cap it on their posterior extremity and shed it into the medium. This →capping phenomenon shares many common features with gliding motility (polarity, temperature, and cytochalasin D sensitivity) although, as mentioned above, the way GPI-anchored proteins can be moved by the actomyosin motor is unknown.

If one considers motility of parasites as the way of homing to their host (host cell in the present case), one would then wonder whether any signal or tropism guides the zoite to its definitive location, which is usually extremely specific. No such phenomenon has been described so far concerning Apicomplexans and in most cases, homing to the vicinity of the target cell seems to be passive; the zoites being driven either by the digestive or the circulatory route depending on the inoculation site. Gliding motility seems to be operational within a short range and to allow accidental contact between zoite and host cell when the organism has been passively carried close to the site of interaction. In the case of malaria sporozoites, the high specificity of recognition between hepatocyte surface proteoglycans and parasite surface proteins seems to be a major cause of organ targeting, probably by inducing binding of sporozoites to the hepatocytes when they are carried in the vicinity of these cells by the bloodstream.

Apicomplexa. Figure 3 Freeze fracture replica of second generation merozoites of the chicken →Coccidia *Eimeria necatrix*. Three fracture planes are found in the →pellicle, corresponding to the 3 membranes (*e*, plasmalemma; *m* and *i*, inner membrane complex). The inner membrane complex is made of continuous rows of longitudinal plates containing longitudinal arrays of intramembrane particles. (bar = 1 μm; Dubremetz and Torpier, original).



Apicomplexa. Figure 4 Schematic diagram of the organization of the →pellicle of Apicomplexan zoites as revealed by freeze fracture.Three fracture planes lead to three pairs of complementary fracture faces named according to the conventional nomenclature (*E*, external face; *P*, protoplasmic face). Longitudinal arrays of intramembrane particles are found in the P faces of the inner membrane complex; lines of higher particle density overlay →subpellicular microtubules (*e*, plasmalemma; *m* and *i*, inner complex; *t*, microtubule).

Host Cell Recognition

Regarding the host cell recognition process, 2 groups seem to exist among Sporozoa: one in which a highly specific recognition step occurs which concerns the blood parasites (Hemosporidia, →Piroplasms), and another in which little if any specific recognition of the host cell concerning the Coccidia can be demonstrated. This difference is better understood when one realizes that a *Plasmodium*→merozoite is only able to invade the red blood cells of an extremely narrow range of hosts whereas a *T. gondii* tachyzoite readily invades almost any type of cells it gets in contact with. The difference between the 2 groups could also be interpreted as the need for receptor-ligand-mediated adhesion as a prerequisite to invasion by blood parasites whereas this step would be unnecessary to Coccidia whose host cell and tissue specificity *in situ* could be due to other mechanisms. However, another possibility is that binding always occurs before invasion but its specificity varies depending on the parasite and allows a variable range of invasion that may or may not need further specific interaction to determine development or escape and search for a more suitable host cell. Although the surface proteins of the invasive stages seem to be involved in the recognition binding to the host cell, the →micronemes proteins which are translocated on the surface of the parasite appear to be essential in parasite–host cell interaction in all Apicomplexa. The present status of knowledge does not clearly differentiate between recognition binding and motility of Apicomplexan zoites.

In the case of blood parasites (*Plasmodium*, →*Babesia*), receptor–ligand types of interaction have been shown to occur between zoites and erythrocytes. These events seem to be involved in the adhesion of the parasite to its target cell which holds the partners together after accidental contact and allows invasion to proceed. Phase contrast microscopic observations of red blood cell invasion by merozoites of *P. knowlesi* or →*P. falciparum* have shown that initial contact could occur between any 2 points of the surfaces of the 2 cells. Then the merozoite reorients itself in such a way that its apical end faces the erythrocyte membrane. →Moving junction formation and invasion then occur. Reorientation has been suggested to be effected by a gradient of receptors directed towards the apical end of the zoite. The respective part of receptor-mediated interaction in initial contact, reorientation, and moving junction formation is still unclear because of the difficulty of manipulating these different events *in vitro*. Thus the following applies to these interactions as a whole and we will only describe the *P. falciparum* model.

Recognition events concern interactions between merozoite receptors and erythrocytic ligands. Soluble molecules acting as bridges between both surfaces may also be involved. Most of the data obtained on these interactions come from *in vitro* experiments in which a *P. falciparum* culture was subjected to various treatments (use of variant red cell phenotypes, enzymatic alteration of erythrocyte surface, competition with soluble molecules) or from affinity of parasite molecules for erythrocytes (erythrocyte-binding antigens) or erythrocyte fractions (Glycophorin).

Concerning the erythrocyte, →Glycophorin A (major sialoglycoprotein) is the major ligand in interaction with merozoites. More precisely, O-linked sialylated polysaccharides of the molecule seem to be directly involved in recognition. However, in addition, sialic

acid-independent recognition and invasion can occur in certain strains, which suggests the existence of alternate pathways allowing the parasite to survive if one way fails to operate.

The main merozoite receptors described so far are molecules having affinity for the erythrocyte surface that were initially described as →erythrocyte-binding antigens (EBA). These molecules are located in micronemes and are translocated in a transmembrane orientation on the merozoite surface where they play a major role in host cell recognition-invasion. A highly conserved family of →EBA proteins expressed in the merozoite stages of various *Plasmodium* has been characterized; they all contain a conserved N-terminal cystein-rich domain that is involved in recognition. As for most microneme proteins, the way these proteins stored in the lumen of an organelle become transmembrane in the parasite surface is unknown.

Although *P. knowlesi* shares a part of its erythrocyte host range with *P. falciparum*, the recognition events seem to be distinct from the ones involved for the latter species. The →Duffy blood group antigen has been described to play a key role in *P. knowlesi* invasion, in association with the DBL, which is a member of the erythrocyte-binding ligands EBL. The Duffy antigen is also involved in *P. vivax* invasion.

The role of →merozoite surface proteins in erythrocyte invasion is unclear; the major merozoite surface protein (MSP1) may participate in initial binding, and antibodies that inhibit its proteolytic cleavage occurring during invasion block cell entry, but the receptor for this interaction is unknown. This surface protein may be acting as an early ligand of low affinity that allows close contact between both partners and is then strengthened by the EBL–glycophorin interaction.

Whether the receptor-ligand recognition that precedes invasion is maintained in the moving junction that powers invasion is unknown; however, observations on the interaction between *P. knowlesi* and Duffy negative red cells where the junction does not form suggest that the DBL protein may be involved in the junction.

In the →sporozoite stage of the malarial parasite life cycle, receptor-ligand recognition has been postulated to drive the interaction with the target cell, which is the hepatocyte. Although *Plasmodium* sporozoites have been shown to invade a rather large range of cells *in vitro*, their very efficient homing to the hepatocytes *in vivo* is probably driven by the affinity between the circumsporozoite surface protein CSP and the hepatocyte surface heparan sulfate proteoglycans.

Another system of recognition, which is found in *Plasmodium* sporozoites and is conserved in many Apicomplexa is the →TRAP microneme protein family. In *Plasmodium* sporozoites, this protein also binds sulfated sugar-containing domains on the hepatocyte surface. *Toxoplasma gondii* and *Eimeria tenella* contain TRAP-like proteins in their micronemes, but their putative receptors have not been identified.

Micronemes of *T. gondii*, *Cryptosporidium*, and *Sarcocystis* also contain proteins with cell-binding properties, some of which with lectin features, that probably play a role in host cell recognition, although yet unidentified.

Host Cell Invasion

Due to their medical significance, →host cell invasion by Apicomplexan zoites has mainly been studied with malaria parasites and *T. gondii* to a lesser extent with the Coccidia and *Eimeria, Sarcocystis* or with piroplasms.

In all cases in which invasion has been described in detail, Apicomplexan zoites enter the host cell apical end first, i.e., the area where the so-called apical complex is located and especially where the rhoptry ducts reach the zoite membrane. The zoite then gains access into an intracellular compartment surrounded by a membrane which is continuous with the host cell plasmalemma during invasion. The fate of that membrane has long been controversial since some authors have described its disintegration during the invasion, arguing that the →parasitophorous vacuole appeared later around the cytoplasmic parasite. These conclusions were based on preparation artifacts due to the peculiar nature of the developing parasitophorous vacuole membrane which is poorly stabilized by the electron microscope preparation.

A very precise description of invasion has been given for *P. knowlesi*, this species being more amenable to experimental study of invasion than any other malarial parasite because of the relatively long shelf life of its merozoites. The initial step of internalization is a close contact between the apical end of the merozoite and the red blood cell plasmalemma. This latter becomes thicker on its inner side under this contact. Initiated as a segment of a sphere, this "junction" turns into a ring which moves backward on the zoite surface, whereas the host membrane area previously involved in the junction becomes the developing parasitophorous vacuole. The ring travels along the zoite to its posterior end where the junction ends up as a segment of a sphere, at which level the vacuole closes and separates from the host plasmalemma. The →surface coat of the merozoite has been shown to be "shaved off" at the level of the junction as this latter went along the zoite surface.

Associated with this process are the formation of vesicles facing the zoite apex on the cytoplasmic side of the developing parasitophorous vacuole, and a clear decrease in the electron density of the rhoptry contents. The →rhoptries open at the tip of the zoite and their contents are in contact with the parasitophorous vacuole membrane. Freeze fracture electron microscopy has shown a total depletion of intramembranous particles

of the developing parasitophorous vacuole compared to the erythrocyte plasmalemma, which indicated a very low proteinic content for this membrane. A second observation was that the moving junction had a peculiar freeze fracture structure as a rhomboedric network of "particles" in the erythrocytic side, which indicated that the junction was more than a close apposition of membranes but that the internal structure of the host →cell membrane was altered at this level.

From a physiological point of view, the major finding was that cytochalasin D inhibited the invasion, although the junction was initiated at the apex of the zoite and some vesicles appeared on the cytoplasmic side of the junction indicating that the actin motor was not needed for junction formation and rhoptry exocytosis, but essential for entry. Protease inhibitors were also found to block the phenomenon, which suggests that proteases may be involved in the process.

→Host cell invasion by Coccidia has been studied both *in vitro* and *in vivo*. Because of the larger size of the zoites and the more complex organization of the host cells, the results obtained by electron microscopy were not as clear as for *Plasmodium*. Moreover, the host cells chosen for experimental studies were in some cases professional phagocytes (monocytes, macrophages), which raised additional questions concerning the active part played by zoites in entry. It is now clearly demonstrated that host cell invasion by Coccidia proceeds as described for *Plasmodium*, i.e., by a moving junction gliding backward on the zoite which enters a parasitophorous vacuole, the membrane of which is continuous with the plasmalemma of the host cell but depleted of intramembranous particles (Figs. 5–7). The freeze fracture features of the moving junction are identical to the ones found on red blood cell membranes in *Plasmodium*.

Abundant membrane whorls are found in the parasitophorous vacuole or in "empty rhoptries" and vesicles are found on the cytoplasmic side of the parasitophorous vacuole, especially when invasion is blocked by cytochalasin, these vesicles contain rhoptry proteins.

Thus, the invasion process is conserved in all intracellular Apicomplexa, characterized by a moving junction and the development of the parasitophorous vacuole. The moving junction components have been recently identified in *T. gondii*: it contains proteins exocytosed from both the micronemes (AMA1) and from the anterior part of the rhoptries (rhoptry neck, RON proteins). These proteins are associated in a transmembrane complex at the junction level. This complex is believed to be moved by the parasite actomyosin motor on the parasite side, and to attach to host cell receptors or cytoskeleton. Another possibility is that the complex itself is anchored in the host cell membrane, avoiding the need for a specific receptor. A schematic view of the invasion process is shown in Fig. 8 (page 111).

The origin of the parasitophorous vacuole membrane is still controversial. The respective contributions (qualitative and quantitative) of the host cell plasma membrane and of rhoptry products are not fully determined, although both are probably involved. Ward et al., using fluorescent lipids or electrophysiological

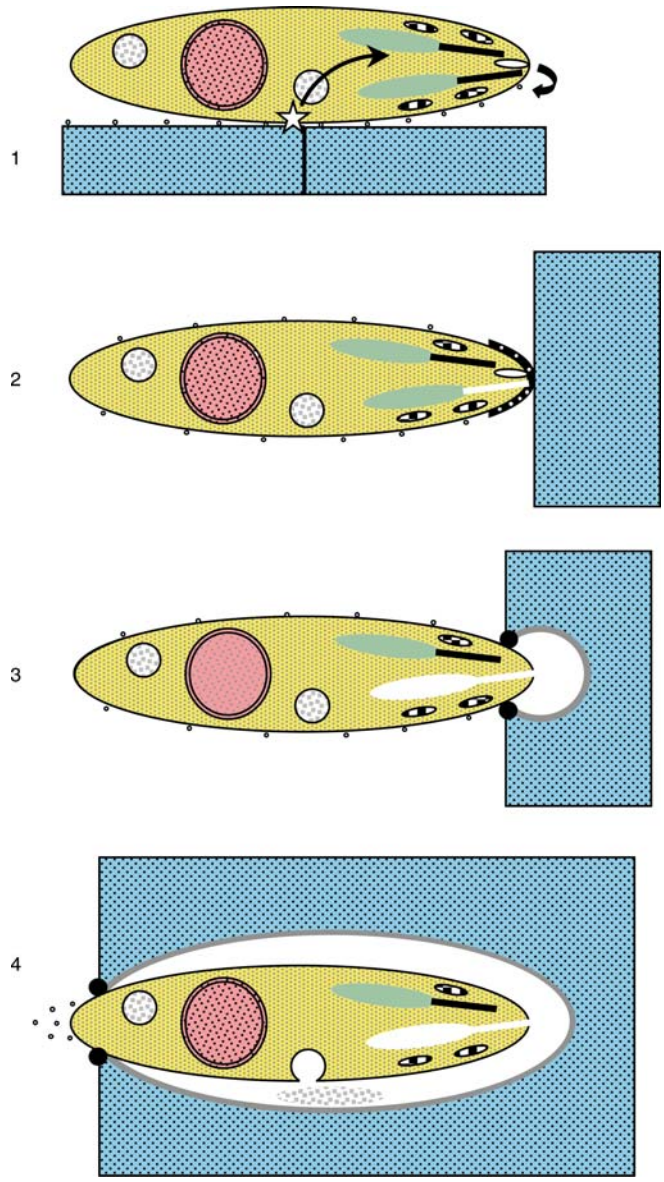
procedures, have shown in both *P. knowlesi* and *T. gondii* that host cell membrane components (essentially lipids) contribute a major part of the early parasitophorous membrane.

The contribution of the apical secretory organelles to invasion is essential. They undergo sequential exocytosis during the process. Micronemes release proteins involved in motility recognition adhesion, at an early stage of interaction. Rhoptries then contribute components of the moving junction (RON proteins, exclusively located in the neck of the organelle) followed by proteins (and lipids) which are integrated into the parasitophorous vacuole membrane (ROP proteins, derived from the posterior part of the organelle). They contribute enzymes such as proteases or phospholipases that can modify the host cell plasmalemma and facilitate vacuole formation (e.g., the cleavage of the eythrocyte protein band 3 by a serine protease of *Plasmodium* is believed to lead to disorganization of the spectrin network of the red blood cell as a prerequisite to red cell invasion). In addition, some rhoptry proteins are released in the host cell and at least



Apicomplexa. Figure 8 Schematic drawing of the successive steps of Apicomplexa invasion. *1* A zoite glides on a host-cell surface using microneme proteins exocytosed apically (curved arrow); a signal is transduced from the surface (star, arrow) to the apex. *2* The signal induces reorientation, apical binding to the host cell, rhoptry neck exocytosis, formation of the moving junction from microneme and rhoptry neck proteins. The bulk of micronemal material is capped behind the moving junction. *3* Rhoptries are exocytosed while the moving junction glides backward and the parasitophorous vacuole starts expanding. Rhoptry material is integrated in the vacuole membrane. *4* The vacuole keeps expanding, getting most of its lipids from the host cell plasmalemma. The junction reaches the posterior end of the parasite and eventually seals the vacuole. Dense granules are exocytosed in the vacuolar space. (After Dubremetz et al., *Int J Parasitol*, 28, 1009–1011, 1998, modified).

2 of them in *T. gondii* are targeted to the host nucleus where they modulate the host cell transcription. Dense granules are exocytozed into the vacuole after invasion and their role is not well understood, yet they are probably involved in rendering the vacuole contents and membrane efficient to sustain parasite metabolic needs. In *P. falciparum*, a →dense granule protein (RESA) is translocated under the erythrocyte membrane and associates with spectrin.

A peculiar process has been described for the piroplasm →*Theileria*: invasion of mononuclear lymphocytes by sporozoites seems to involve a zipper mechanism in a receptor-mediated →endocytosis due to specific receptors on the zoite surface. These

findings are very unique among Apicomplexa and may represent an exception to the moving junction process. In addition, in this model, as in the other piroplasm *Babesia* (which invades red cells in a manner very similar to *Plasmodium*), the vacuole membrane is disintegrated after invasion and the parasite develops in the cytoplasm of the host cell.

Apicoplast

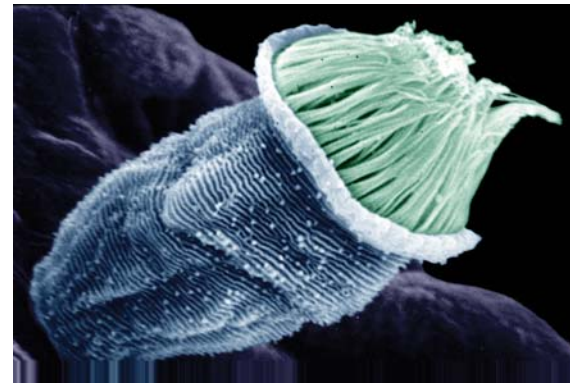
The putative origin of this characteristic organelle now called apicoplast, was and is, still highly disputed. The original description of two membranes as border of the organelle led to the former name "double-walled organelle or vesicle". However, recently authors described 3 and 4 membranes as limiting system of the apicoplast in different coccidian species.

Since the number of wall membranes is a strong indicator to distinguish primary (with two membranes) from secondary (with 3–4 membranes) plastids, the exact clarification of the apicopast's border is essential.

The appearance of membranes on electron micrographs is, however, a tricky thing. Only long series of serial sections elucidate, whether infoldings of the inner membrane of a double-walled organelle would let appear – erroneously – 3 or even 4 membranes. Recent serial sections done by Köhler (2005/2006) in the editor's laboratory clearly indicate at least in *Toxoplasma gondii*, that there are in several apicoplasts only 2 membranes, the inner of which undergoes a variety of infoldings. Whether the described triple-membrane arrangement in malarial parasites is consistant, whether it is the result of an artificial ultra-thin sectioning or whether it is due to a reduction of a further membrane during evolution, remains unclear. In any case, however, the apicoplast contains besides its activities in protein translation, fatty acid and isoprenoid synthesis as well as in iron-sulfur biogenesis typical plant-specific metabolic pathways, which are not found in mammalian cells. This gives a hint that there might be ancestors of the apicoplast in the group of small unicellular algae.

Apiosoma

Genus of about 0.1–1.0 mm sized ciliates (syn. *Glossatella*), which parasitize at inflamed skin of fish (Fig. 1). → Ciliophora.



Apiosoma. Figure 1 SEM of a sessile stage of *Apiosoma* sp.

Apolysis

Detachment of →proglottids from the →strobila of →Cestodes, →Eucestoda, or cuticle from →arthropoda.

Apomorphic Character

→Phylogeny.

Apomorphy

A derived character state.

Aponomma

Genus of hard →ticks, the species of which feed in warmer countries at the surface of reptiles.

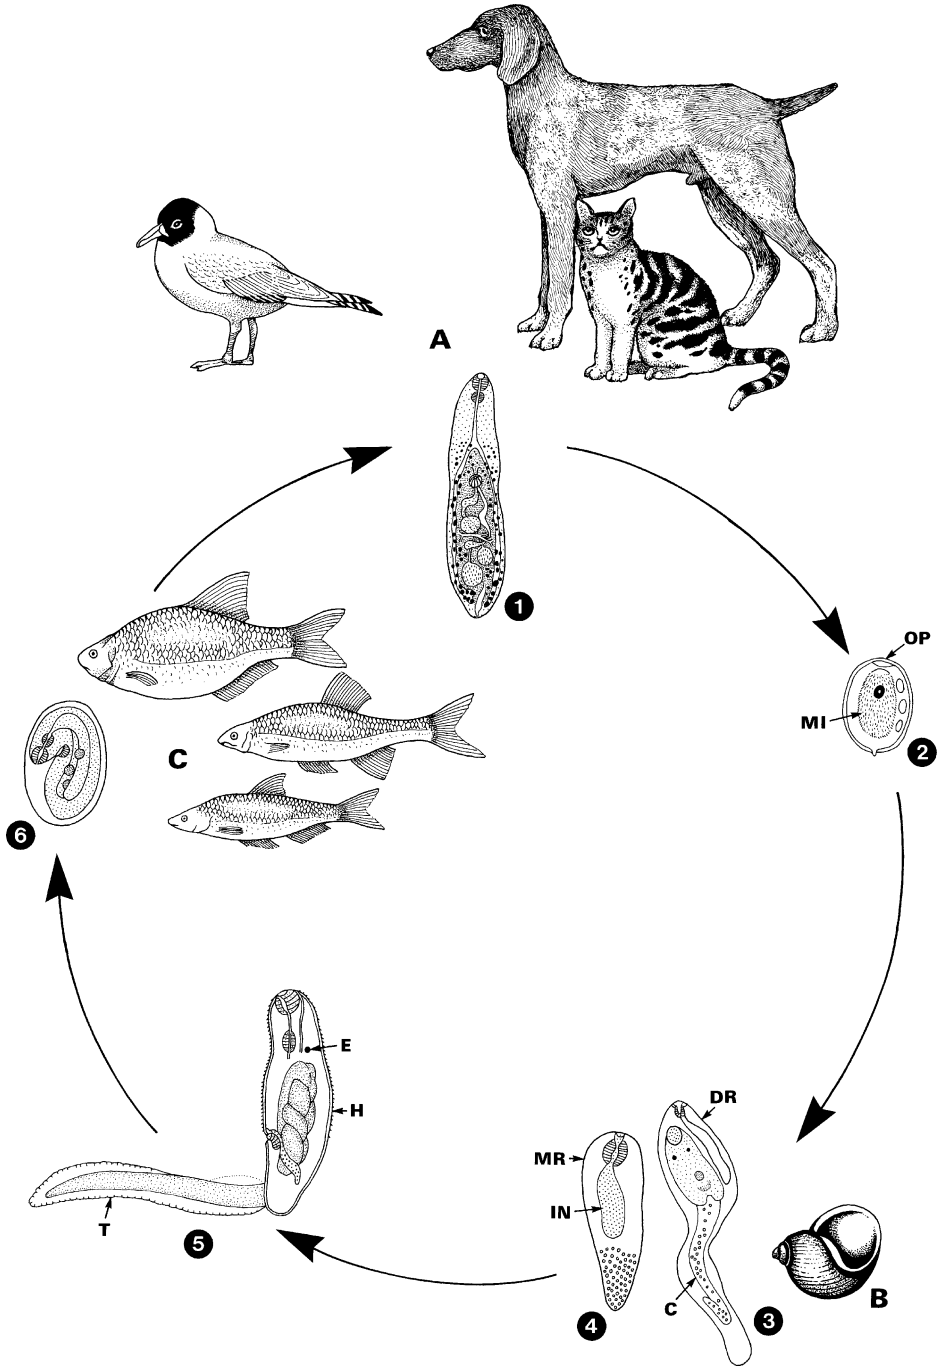
Apophallus muehlingi

Classification

Species of →Digenea.

Life Cycle

Fig. 1.



Apophallus muehlingi. Figure 1 Life cycle of the digenean *Apophallus muehlingi* that parasitizes in the intestine of several fish-eating animals (**A**) according to Odening 1970 (especially in the region of the Eastern Sea and Black Sea). ***1*** Adult worm (about 0.8 mm long). ***2*** Operculated and fully embryonated eggs (34 µm × 28 µm) are set free with the feces of the hosts. The →miracidium does not leave the egg until it is eaten by fresh water or brackish water snails (**B**, →*Lithoglyphus naticoides*). ***3-6*** Inside the snails reproduction occurs via 650 µm × 140 µm-sized →rediae (3, 4), within which tailed →cercariae (5) with eyespots are formed. These stages including tails up to 700 µm in size leave the snails and penetrate into cyprinid fish (**C**), in whose fins they become encysted as →metacercariae (6). When such infected fish are eaten by the final hosts, the metacercariae leave the cysts in their intestine and mature to adult worms within 7 days, e.g., in *Larus*-sea birds. *C*, cercaria; *DR*, redia with 6–12 cercarial embryos; *E*, eyespot; *H*, head of cercaria; *IN*, intestine; *MI*, miracidium; *MR*, mother redia; *OP*, →operculum; *T*, tail of →cercaria.

Apoptosis

Metazoa are known to possess a sophisticated machinery of programmed cell death (PCD), which limits the life span of cells and prohibits cell exaggeration leading to tumors. Recently PCD has also been found in parasitic protozoans, e.g., in trypanosomes, malaria parasites, leishmanian species, trichomonads. As apoptotic markers had been described: chromatin condensation, DNA fragmentation, externalization of phosphatidylserine, and caspase-like activities. This way of self-limitation in protozoans is much less complex than in metazoan. It brings the advantage to these parasites, that they do not lose their hosts by killing them, before a small part of the population has been transferred to the next host. Thus the parasite density in a host does not rely exclusively on the host's immune system. Since the apoptosis of protozoans is different from that of metazoans, it might be used as target for new chemotherapeutics.

However, intracellular parasites have also developed methods to survive by maintaining their host cell, if the natural response of the infected cells is leading to the reaction to commit apoptosis and thus to deprive the invader of the opportunity to multiply and to disseminate. Such protection from apoptosis is found, e.g., in cells parasitized, e.g., by →*Toxoplasma gondii*, →*Leishmania* spp. or →*Theileria* stages. The latter even stimulate their host cells (lymphocytes) to constantly repeated divisions like that of tumor cells.

Apparent Infection

Infection followed by symptoms of disease.

Application

Mode of treatment or mode of experimental infection, e.g., orally, intramuscularly, subcutaneously, intraperitoneally, etc.

Apterygota

Subclass of →insects characterized by the absence of wings.

Arachnology

Comprises the knowledge of spiders (Greek: *arachne*), mites, ticks, scorpions which are united in the systematic unit Chelicerata within the phylum Arthropoda.

Araneidae

Family of spiders: the bites of some of them are poisonous for humans: e.g., *Latrodectes mactans* (Black widow of the Americas, Europe), *Loxosceles* species (Brown recluse spider (Americas), Australian red back funnel spider (*Latrodectus hasselti*), etc.).

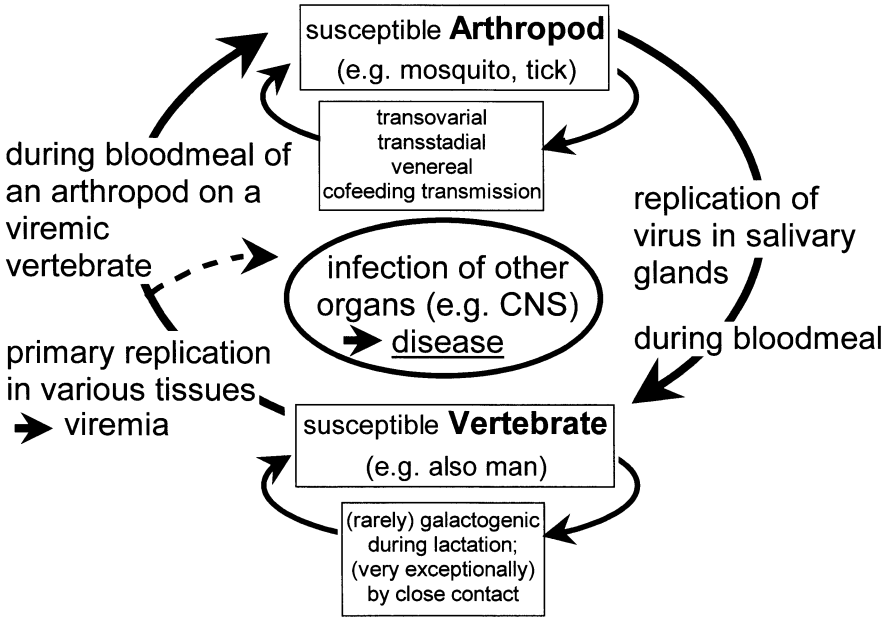
Arboviruses

General Information

Arboviruses (=arthropod-borne) is a collective name for those viruses which (1) replicate in certain arthropods as well as (2) in certain vertebrates and which are (3) transmitted by bloodsucking arthropods between their vertebrate hosts with the saliva during their blood meals. The biological (=cyclic) transmission with replication of the virus in the arthropod is a crucial criterion. A virus adhering to the mouthparts of a bloodsucking arthropod and transmitted mechanically without prior replication in the salivary glands is not an arbovirus. Thus, arbovirus is only an ecological and biological term without any phylogenetic relevance (Fig. 1).

System

Arboviruses are to be found in different virus families: among double-stranded DNA viruses (Asfarviridae →African swine fever virus), among double-stranded →RNA viruses (→Reoviridae: Orbivirus, Coltivirus, Seadornavirus), among negative-sense single-stranded RNA viruses (→Rhabdoviridae: Vesiculovirus, Ephemerovirus; →Orthomyxoviridae: Thogoto-like viruses; →Bunyaviridae: Bunyavirus, Nairovirus, Phlebovirus), and among positive-sense single-stranded RNA viruses →Flaviviridae →Flavivirus; →Togaviridae: Alphavirus). Altogether about 600 viruses have been assigned to the arboviruses, some of them were withdrawn later, but in most of them the above-mentioned criteria could be proved, in some (which have been isolated either from arthropods or from vertebrates only) the arbovirus nature has been concluded from close antigenic relationships to other confirmed arboviruses. Most arboviruses



Arboviruses. Figure 1 Arbovirus cycles.

are to be found among the →Reoviridae (about 150 species), Bunyaviridae (about 200 species), →Flaviviridae (about 60 species) and →Togaviridae (about 30 species). Among the other families (apart from the family Asfarviridae) arboviruses are more or less exceptional. Table 1 gives an overview of the genera of those virus families (also) comprising arboviruses.

Some of the viruses called "species" have turned out or will turn out to represent only slightly different strains of other "species," on the other hand, there is no doubt that a large number of arboviruses still remains to be detected. Moreover, one can hardly doubt that – besides many arboviruses without any medical significance – viruses causing (known or unknown) diseases in man and/or animals will also be discovered. It is difficult to estimate how many arboviruses may exist – possibly several thousand. Thus arboviruses will continue to form an important challenge to virologists as well as to parasitologists. The tables →Arboviruses L-X (→ASF Viruses, →Asfarviridae, →Bunyaviridae, →Flavivirus, →Orthomyxoviridae, →Reoviridae, →Rhabdoviridae, →Togaviridae) list selected species of arboviruses with indication of hosts, distribution, and diseases in man and animals. These tables include all arboviruses causing diseases of major significance and/or prevalence and representatives of all families. Most remaining species are poorly known. Some of them apparently cause febrile illness in man (and animals), but many have so far (under natural conditions) not yet been correlated to any symptoms in man or animals (which does not necessarily mean that they are strictly apathogenic, of course).

It should be noted that the concept of species, genera, and families in virology is quite different from that in other biological disciplines and that a real phylogenetic system of viruses does not and will not exist for principal reasons. Viruses derive from living organisms, thus similar viruses may have quite different and independent origins, although evolution, following the well-known factors of mutation, selection, isolation, etc., does occur to a certain extent within certain taxonomic entities, of course, so that monophyla do also exist at various levels among viruses. Most virus families and at least many virus genera are, however, not monophyla but assemblies of members with a high degree of (genomic) similarities and, in many cases, of similar, but independent origins. It has been suggested that at least most arboviruses derive from their arthropod hosts. This assumption is supported by the fact that arboviruses usually do not cause disease or life-threatening damage in their arthropod hosts (exceptions exist, particularly among Togaviridae), but often cause more or less serious harm in their vertebrate hosts.

Important Families

Table 1.

Distribution

Arboviruses occur in all continents, even in high latitudes where →mosquitoes may develop large populations. Moreover, seabirds flying far into the north may act as hosts of tick-borne viruses. It is, however, striking that the number of arboviruses endemic to a

Arboviruses. Table 1 Virus families containing arboviruses

Family	Characterization	Genera representing Arboviruses	Main arthropod hosts	Genera other than arboviruses (hosts in brackets)
Asfarviridae	ds-DNA viruses, spherical, with envelope, 175–15 nm	Asfivirus	Ceratopogonidae	
Reoviridae	ds-RNA viruses, icosahedral, without envelope, 60–80 nm	Orbivirus	Ceratopogonidae Phlebotominae Culicidae Ixodidae	Orthoreovirus (vertebrates) Rotavirus (vertebrates) Aquareovirus (vertebrates) Cypovirus (invertebrates) Phytoreovirus (plants) Fijivirus (plants) Oryzavirus (plants) Idoreovirus (invertebrates) Mycoreovirus (fungi)
		Coltivirus	Ixodidae	
		Seadornavirus	Culicidae	
Rhabdoviridae	negative-sense, non-segmented, ss-RNA viruses, rod-shaped, with envelope, 100–430 × 45–100 nm	Vesiculovirus	Culicidae Phlebotominae	Lyssavirus (vertebrates) Cytorhabdovirus (plants) Nucleorhabdovirus (plants)
		Ephemerovirus	Culicidae Phlebotominae	
Orthomyxoviridae	negative-sense, segmented, ss-RNA, spherical or filamentous, with envelope, 80–120 nm	Thogotovirus	Ixodidae	Influenzavirus A (vertebrates) Influenzavirus B (vertebrates) Influenzavirus C (vertebrates) Isavirus (vertebrates)
Bunyaviridae	negative-sense, segmented, ss-RNA, spherical, with envelope, 80–120 nm	Orthobunyavirus	Culicidae Ixodidae	Hantavirus (vertebrates) Tospovirus (plants)
		Nairovirus	Ixodidae Argasidae	
		Phlebovirus	Phlebotominae Culicidae Ixodidae	
Flaviviridae	positive-sense non-segmented ss-RNA, spherical, with envelope, 40–50 nm	Flavivirus	Ixodidae Culicidae	Pestivirus (vertebrates) Hepacivirus (vertebrates)
Togaviridae	positive-sense non-segmented ss-RNA, spherical, with envelope, 70 nm	Alphavirus	Culicidae	Rubivirus (vertebrates)

certain geographic region increases towards the equator, and the subtropical and particularly tropical regions harbour by far the largest number of arboviruses.

In Europe more than 60 arboviruses have been isolated, among these there are also 6 phleboviruses which are transmitted by sand flies; they cause Papataci fevers or reningitis which occur in Southern Europe. Even on a Europe-wide scale the →tick-borne encephalitis virus remains the most important arbovirus, but a few others may also lead to diseases of the Central nervous system.

Central Europe harbours (at least during certain periods in certain years) 11 arboviruses. Of these 6 are tick-borne: Tribec, Lipovnik, Eyach, Uukuniemi, Bhanja, and Tick-borne Encephalitis (→TBE); all of them are transmitted by ixodid →ticks, mainly Ixodes ricinus. Four viruses are transmitted by mosquitoes: Calovo, Tahyna, Lednice, West Nile. Calovo is transmitted by Anophelinae, the others by Culicinae. Tribeé, Lipovnik, Eyach, Uukuniemi, TBE, Calovo, Tahyna, and (at least partially) Lednice are probably endemic to Central Europe and also hibernate in this part of Europe. Some arboviruses, (e.g., Usutu virus) are most probably more or less regularly introduced by migrating birds to Central Europe and may get established for longer periods. Although at least Tahyna and Calovo viruses are endemic (in the sense of occurring in the area throughout the year), it has to be questioned whether Central Europe harbours autochthonous mosquito-borne viruses in the strict biogeographic sense. Of these 11 viruses 9 may cause diseases in man, the most important of them being tick-borne encephalitis virus which claims many severe cases every year, sometimes sporadically even deaths. (Before the

development of a vaccine and the broad application in the human population in some parts (particularly Austria the importance of TBE in Central Europe was much higher.) The other viruses cause febrile illnesses of various clinical symptoms (Tables →Bunyaviridae, →Flavivirus, →Reoviridae, →Togaviridae).

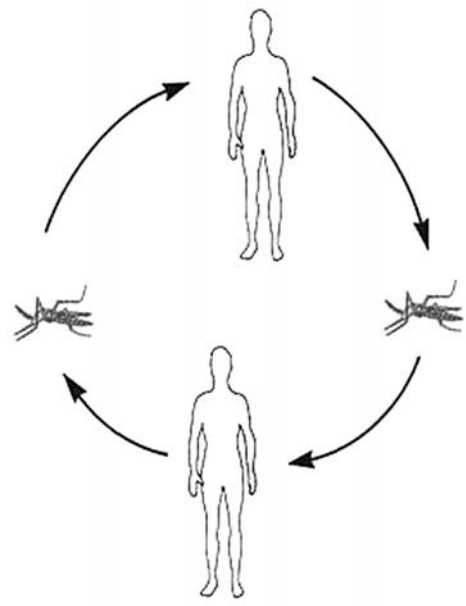
Due to the complexity of the synecological systems in which arboviruses circulate (see below) preconditions for the maintenance of the virus cycle are usually fulfilled in limited areas only. These areas are called foci to which the viruses are endemic. (The terms "endemic" and "endemisms" have different meanings in biology and medicine. In biology "endemic" means "restricted to a certain biotop or region, mountain range, island, etc." In medicine "endemic" is more or less a synonym of "autochthonous"). Thus, amplification of a focus is usually difficult. Formation of new foci requires suitable ecological conditions. New and dispersed foci may be established by introduction of virus into a suitable biocoenosis by migrating viremic birds or by larger mammals, in particular man may also act as an amplifier host. →Dengue and →Yellow fever are impressive examples of how the migrating species Homo sapiens has established numerous new foci of these arbovirus infections in many tropical and subtropical parts of the world. During the 18th and 19th centuries Yellow fever virus was introduced to several towns in the South of Europe (Spain, Portugal, Italy, France) and was established for shorter periods. In the 20th century Dengue I virus was introduced to Greece where it led to a major epidemic in 1928. Bluetongue viruses were introduced and caused heavy epidemics among livestock in Southern and Central Europe. Principally, this anthropogenic dispersal of arbovirus infections plays an important role in all arbovirus cycles in which man is the main vertebrate host (see below Fig. 2).

Vectors

The following arthropod families comprise vectors of arboviruses: →Ixodidae (hard →ticks), →Argasidae (soft ticks), Culicidae/Culicinae, →Culicidae/ Anophelinae (→Mosquitoes), Psychodidae/Phlebotominae (→Sand Flies), and →Ceratopogonidae (gnats). Moreover, arboviruses have been isolated from some other arthropod-families (→Mites, →Bugs, →Fleas, →Blackflies, Horseflies); it is, however, not clear whether (some of) these may (additionally) act as (natural) hosts and biological vectors.

Life Cycle

Fig. 1 shows the basic structure of an arbovirus cycle. Principally 2 ways can be differentiated: usually the virus is transmitted by bloodsucking arthropods (the vector and arthropod host) to a vertebrate in which it leads to viremia. During this period, which usually lasts



Arboviruses. Figure 2 Arbovirus transmission cycle involving human as naturals hosts (e.g., urban transmission cycle of yellow fever).

only a few days, the virus may be taken up by another bloodsucking arthropod. The vertebrate may or may not become ill shortly before, during, or (particularly) after the viremia. Also, man may be integrated into this form of an arbovirus cycle and may develop disease. In several arbovirus cycles man is even the only vertebrate host maintaining the virus cycle (e.g., dengue, urban yellow fever, Chikungunya), in others man is a dead end of the virus cycle regardless of whether he may develop disease or not. Besides this typical form of an arbovirus cycle there is another one in which the virus may "remain" in its arthropod host being transmitted vertically - transovarially - to the next generation and then transstadially throughout the larval (and pupal) stages to the adults. Moreover, a sexual ("venereal") transmission from male to female and vice versa during copulation has also been found in some arboviruses and may occur more often. →Transovarial transmission has been established only in a comparatively small number of arboviruses; one may, however, assume that it will principally occur in most (if not all) arboviruses, regardless of whether they are transmitted by ticks, mosquitoes, →sand flies, or gnats.

An unusual mode of infection has been described in ticks: uninfected ticks feeding simultaneously with infected ticks on the same host may become infected, despite the absence of a true viremia of the host, by uptake of virus released by the infected ticks, most probably after replication in certain cells of the skin. This mechanism, which is not yet fully understood, might possibly be of greater significance in arboviruses.

Virus ingested during a blood meal first infects epithelial cells lining the midgut; subsequently it is released into the hematocoel from where the salivary glands as well as the ovaries can be infected. The susceptibility of the midgut epithelium is the primary determinant for the vector competence of an arthropod. Infection of the salivary glands may take place after secondary amplification in other cells (tissues) or without secondary amplification. The period between the ingestion of virus during a blood meal and the salivary secretion is called extrinsic →incubation period (EIP). This interval must not exceed the lifespan of an arthropod acting as a potential vector. In some alphavirus species the tissue of the midgut is damaged so heavily by the infection that it becomes "perforated," which enables the virus to enter the haematocoel and thus to rapidly infect the salivary glands. This leads to an unusually short extrinsic incubation period.

Temperature is of great influence on the length of the EIP, which usually lasts a few days; increased temperature may lead to ashortening of EIP and/or to an increase of viral replication and in this way to an increase in transmission rates. Co-infections with other pathogens may also have an influence, e.g., microfilariae penetrating the midgut epithelium cause lesions which facilitate the virus transfer to the haematocoel. Virus transfer from a mosquito to the vertebrate mainly occurs during probing of the host tissues with the mouthparts in order to find a small vessel. Therefore the first replication takes place in extravascular tissues. In viruses transmitted by ticks, which are →pool feeders, there is a comparable situation. Other factors influencing the capacity of a given arthropod species for the virus cycle are virus amount in salivary glands, number of generations, population densities and population dynamics, frequency and duration of blood meal, horizontal and vertical distribution, →circadian rhythms, and host spectrum. From all these factors the number of individuals capable of transmission in a given biocoenosis results as a key parameter.

Vertebrate hosts of arboviruses comprise numerous mammals on the one hand and birds on the other hand; moreover in a few cases reptiles or amphibians are (or may be) of importance. The suitability of a given vertebrate species to act as a host significant to the maintenance of the cycle depends on several factors, the most important being virus concentrations reached during viremia and length of viremia as a crucial prerequisite to successfully infect a sufficiently high number of vectors. Other parameters are population density, population dynamics, reproduction rates and life expectation, degree of (homologous and heterologous) immunisation in a population, horizontal and vertical activity, circadian rhythm, and spectrum of bloodsucking parasites; from these parameters the number of susceptible and finally the number of viremic vertebrate hosts results.

Taking all these factors into consideration from the perspective of the arthropods on the one hand and of the vertebrates on the other hand, a very complex and rather vulnerable synecological system results.

In arboviruses occurring in temperate zones an important ecological problem in the virus cycle results from winter and thus →hibernation. This can be overcome by several mechanisms: →vertical transmission in the arthropod host, survival in hibernating (larval or adult) stages of arthropods, →chronic infection in vertebrate hosts with persisting or recrudescent viremia (e.g., in heterothermic mammals like →bats and hedgehogs), or regular introduction by migrating birds (with a prolonged viremia) from tropical regions. Hibernation of tick-borne viruses is usually easily achieved by persistence of the virus in the larvae or nymphs and by →transstadial transmission. In some mosquito-borne viruses overwintering is also possible in adult mosquitoes (e.g., →*Anopheles* spp., *Culiseta* spp., →*Culex* spp. hibernating as adults).

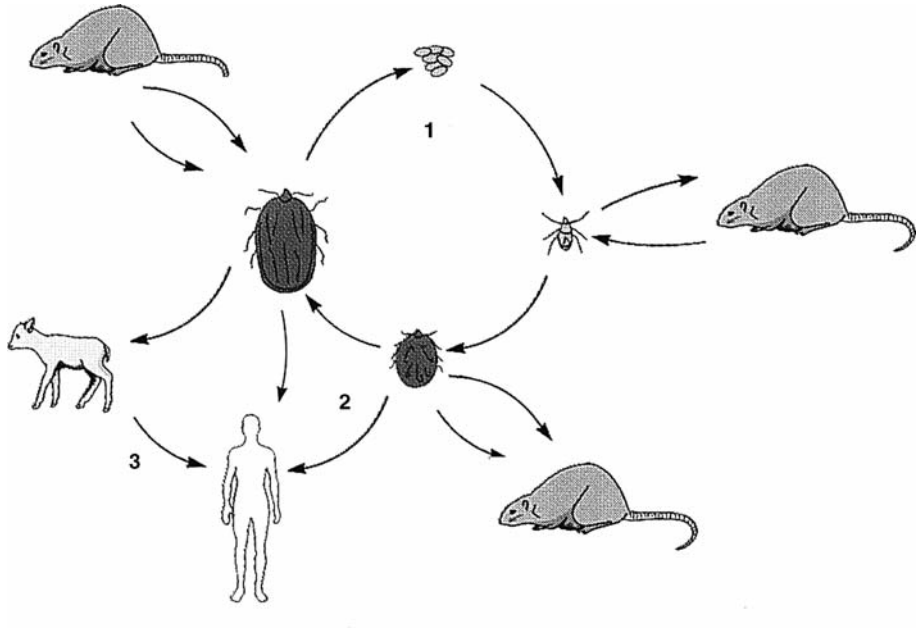
Although vertical, transovarial (and sexual) transmission are biologically remarkable phenomena and important mechanisms, it seems, unlikely that maintenance of virus in a certain biocoenosis can be achieved by such modes without regular participation of mammals in the virus circulation.

Under certain circumstances an arbovirus can also be transmitted from one vertebrate to another. A natural way is the →galactogenic transmission during lactation to the progeny or (in case of animals whose milk is used) to man (Fig. 3). In tick-borne encephalitis smaller outbreaks in the human population due to consumption of raw, infective milk have been described. Virus in the milk is found only during the viremic stage of the lactating animal.

Contact with injured (living or killed) animals can also lead to infection as it has been known from arboviruses with vertebrate hosts which are hunted or slaughtered. This is of particular importance in the transmission of Rift Valley fever, Crimean Congo hemorrhagic fever, or Alkhumra hemorrhagic fever to man.

Finally there are also a few viruses which have never been isolated from an arthropod and which are apparently transmitted between their vertebrate hosts by close contact only (e.g., Modoc, Rio Bravo). These viruses are not arboviruses by definition; they have, however, been included due to their close antigenic relationship to other viruses which present all characters of a real arbovirus.

From the viewpoint of host capacity for arbovirus circulation, vertebrates can be assigned to 3 groups: (1) species which are not susceptible (natural resistance; e.g., due to the lack of receptors) at all and in which, therefore, no virus replication will take place; (2) species which are susceptible but will develop only



Arboviruses. Figure 3 Transmission cycle of an arbovirus (tick-borne encephalitis virus) with humans as dead-end hosts. **1.** natural transmission cycle between rodents and ticks; **2.** natural transmission from vector (ticks) to humans; **3.** unusual transmission from one dead-end host (goat) to humans by milk.

a low (and/or short) viremia which is not sufficient for a successful infection of arthropod dead-end hosts. These species are therefore of no significance for the maintenance of the virus cycle; (3) species which are susceptible and will develop a viremia sufficiently high and long to infect arthropods (natural vertebrate hosts). These are the species maintaining the virus cycle. Apart from the intensity and duration of viremia, species of groups (2) and (3) may, but need not necessarily, develop a disease. Usually those vertebrates which are essential for the maintenance of the cycle will not develop (a life-threatening) disease; in many cases they do not even show any symptoms. This seems to be in good agreement with general considerations on parasites; one must, however, take into consideration that a vertebrate infected with a virus will develop immunity which prevents reinfection. Thus a vertebrate host can contribute to the virus cycle directly during its viremic stage only for a very short period. After that (apart from very rare →Chronic infections with persisting or relapsing viremia) the vertebrate will not be a source of infection. Nevertheless, it may contribute indirectly to the virus circulation by acting as a host for arthropods which maintain the circulation (e.g., ticks will reach higher populations if hosts are abundant). Therefore vertebrate species developing severe disease with a high mortality may also act as maintaining hosts, particularly if they have high population densities with a sufficient percentage of non-immune individuals. Dengue and Yellow fever are good examples; in urban areas with circulation between Culicidae (*Aedes aegypti*) on the one hand and man on the otherhand, man will develop serious disease. In many cases those vertebrate species which suffer from life-threatening arbovirus infections (e.g., horses infected with EEE or WEE) do not develop sufficiently high viremia to be of any importance for the virus cycle.

Syndromes

Out of the 600 arboviruses described so far about 150 have proved to be pathogenic for man. In some infections only antibodies, but no symptoms were found thus at least indicating that man is susceptible. The syndromes caused by arbovirus infections can be roughly divided into (1) febrile illnesses, usually with headache, rash, with or without arthralgia and polyarthritis (Dengue, West Nile, Chikungunya, Mayaro, Ockelbo, O'nyong-nyong, Ross River, Semliki, Sindbis, and many others), sometimes, however, also with neurological symptoms (e.g., in recent outbreaks of West Nile infections); (2) haemorrhagic fever (→Crimean-Congo hemorrhagic fever, →Omsk haemorrhagic fever, →Kyasanur Forest disease, Dengue, Yellow fever, Rift Valley fever, Alkhumra fever, garissa fever); (3) neurological disorders with meningitis and →encephalitis (Kyasanur Forest disease, Powassan, tick-borne encephalitis, →Eastern equine encephalitis, Venezuelan equine encephalitis, Western equine encephalitis, and others).

Arbovirus infections have a tremendous impact on human health throughout the world. Every year millions

of people become infected by arboviruses, many hundreds of thousands of whom develop diseases. Every year smaller or larger epidemics – e.g., due to Dengue viruses, Yellow fever virus, Chikungunya virus, Japanese encephalitis virus, Rift Valley virus, etc., with a varying number of deaths – are reported. Also the economic loss in livestock due to arbovirus infections is serious. Several arbovirus infections have been of considerable influence on human history. Yellow fever (which was most likely introduced to America during the dark era of transports of slaves from Africa) led to a defeat of the French army on the Caribees at the beginning of the 19th century so that Napoleon was forced to sell Louisiana to the USA, thus putting an end to French colonial strategies and influence in North America. Later in the 1880s, Yellow fever thwarted the construction of the Panama canal and led to a financial disaster and condemnation and the sentencing of the famous French engineers A.G. Eiffel and F. Lesseps. Only at the beginning of the 20th century, after it had generally been accepted that Yellow fever is transmitted by mosquitoes, mainly *Aedes aegypti*, and that mosquito control is crucial for fighting against Yellow fever, the Panama canal could be built.

Therapy

There are no specific drugs for treatment of any arbovirus infection, only symptomatic treatment is possible.

Vaccines

There are only three arboviruses against which vaccines are available and in general use: Tick-borne encephalitis virus (inactivated virus propagated in chicken cells), Japanese encephalitis virus (inactivated virus propagated in mouse CNS or in hamster kidneys or – in China – a living attenuated strain) and Yellow fever virus (attenuated strains). In addition, several "noncommercial" vaccines against a few arboviruses have been in use to protect laboratory and veterinary workers (e.g., against Rift Valley fever, Eastern, Western and Venezuelan equine encephalitis). These are usually inactivated vaccines, but also living vaccines (e.g., VEE) are in use. Moreover, a vaccine (attenuated strain) against Dengue has been developed and is now tested in field trials.

Archaeopsylla erinacei

Flea of hedgehog, →Fleas.

Archezoa

Subkingdom 1 according to 2000's classification being characterized by unicellular eukaryotic, phagotrophic, nonphotosynthetic organisms without cell walls. It includes the phylum Metamonada with its families Diplomonadidae, Enteromonadidae, and Retortamonadidae.

Archiacanthocephala

→Acanthocephala.

Archigetes Species

Classification

Genus of →Eucestoda.

Life Cycle

Fig. 1 (page 121).

Argas

Classification

Genus of →Ticks.

Important Species

Table 1 (page 121).

Life Cycle

Figs. 1–3 (pages 122–123).

Argasidae

Synonym

Soft →ticks, leather ticks.

Classification

Archigetes Species. Figure 1 A, B Life cycles of *Archigetes iowensis* (A) and *A. sieboldi* (B) according to Mackiewicz and others. ***1*** The monoecious sexually mature stages live in the intestine of many fish species (A) or in the body cavity of oligochaetes (=annelids; *Limnodrilus, Tubifex*). According to some authors, *A. sieboldi* should also form fertile stages in fish hosts. ***2*** Unembryonated eggs enter the water with the feces (A) or after death of the oligochaete (B). ***3*** Embryonation is completed after about 14–16 days in water of about 18–22 °C, leading to the formation of an →oncosphaera (ON). These eggs are infective for the next host. In *A. sieboldi* the development (1–3) is repeated in another oligochaete (i.e., indirect development). Since the sexually mature stages are procercoids, this development is progenetic. ***4–6*** In *A. iowensis* an →intermediate host is obligatorily involved; this may also occur (according to recent articles) in *A. sieboldi* if fish are used as final hosts. When oligochaetes swallow infective eggs, the oncosphere escapes from the egg and penetrates into the body cavity. Each oncosphere develops into a →procercoid larva at this site. Each procercoid forms complete reproductive organs within 60 days (6). When such procercoids are eaten by a final host, the larva loses its →cercomer, becomes adult, and starts production of sperms and →oocytes. After copulation eggs are passed with the host feces. *BO*, →bothrium (acetabular sucker); *E*, egg cell; *HO*, hooks of oncosphaera; *N*, nucleus; *ON*, oncosphaera; *OP*, →operculum; *OV*, ovary; *TA*, tail; *TE*, →testis; *UE*, uterus (gravid) filled with eggs; *UT*, uterus; *VC*, vitellary cell; *VI*, vitellary glands (→Vitellarium).

Argas. Table 1 Important species of the genus *Argas*

Species	Length (mm) of unfed adults	Hosts during development	Main hosts	Disease (pathogens)	Type of bite-transmitted pathogens

Artemisinine

→Malariacidal Drugs = agents against protozoal diseases.

Arteritis

→Cardiovascular System Diseases, Animals.

Artesunate

→Malariacidal Drugs = agents against protozoal diseases.

Arthemether

A methyl ether derivative of artemisinin that is active against malaria and schistosomiasis, →Malariacidal Drugs.

Arthropoda

Name

Greek: *arthron* = segment, *pus*, *podos* = foot.

Classification

Phylum of →Metazoa.

General Information

The metameric arthropods are named with respect to their segmented legs (→Acarina, →Mites) which probably derive from locomotory appendages similar to the parapodia of recent polychaetes. The chitin-protein exoskeleton is common to all groups of arthropods, is secreted by chitogenous cells of the epidermis (hypodermis) beneath it, and not only covers the external surface, but also passes through the mouth into the anterior part of the intestine (→Stomodaeum) and through the anus into the rectal part of the alimentary system (→Proctodaeum). The exoskeleton in the form of chitinous plates (sclerites) covers the metamerically arranged segments of the animal. The single plates are connected by fine membranous elements, thus allowing movements and body flexing by means of the strong inner muscular systems and the hydrostatic pressure of the body fluid. The chitinous cover would hinder growth of the arthropods; thus, it is cast off periodically and a new larger exoskeleton is formed during →molt (→Ecdysis). Most arthropods are monoecious; copulation and internal fertilization are characteristic of the majority of species. Ontogenesis proceeds in all parasitic forms as →metamorphosis involving at least one and sometimes several larval (nymphal) stages. The circulatory system is open with a primitive dorsal heart; respiratory systems of various kinds (gills, trachea, lungs, etc.) may occur, just as different forms of the excretory tract (Malpighian tubules, coxal and antennal glands, etc., →Insects/Fig. 6, →Mites/Fig. 7).

Arthropods have traditionally been divided into two subphyla. Those with antennae have been placed within the subphylum →Mandibulata, thus named because the first postoral appendages are mandibles. Those that lack antennae and mandibles are commonly placed in the subphylum →Amandibulata (others prefer the term →Chelicerata, thus named because the first postoral appendages become feeding organs called →chelicerae).

System

Recent classifications of the arthropods are under discussion (especially the rank of different taxonomic groups). However, the following groups are accepted *in toto*:

Phylum: Arthropoda.
Subphylum: Trilobitomorpha (the fossil trilobites).
Subphylum: →Chelicerata.
Class: Merostomata (horseshoe crabs and fossil erypterids).
Class: Arachnida (including orders Araneae = →spiders, →scorpions, →Acarina = →ticks, →mites, etc.).
Class: Pycnogonida (= Pantopoda, sea spiders).
Subphylum: Tracheata.
Class: Chilopoda.
Class: Progoneata.
Class: Insecta (Hexapoda).
Subphylum: Diantennata (Branchiata).
Class: →Crustacea.

Intestine and Food Uptake

The structure of the intestine and its appendages varies considerably among the various arthropod taxa, depending on their different ways of living and feeding. Even when they feed in the same way (e.g., blood-sucking), different (though convergent) structures, methods, and strategies have developed in →insects, →mites and →ticks.

Arthropodicidal Drugs

General Information

Much of the increase in animal productivity as well as prevention and treatment of parasitic diseases over the past half century has been due to more efficacious and economical control of arthropods through the use of synthetical chemical compounds.

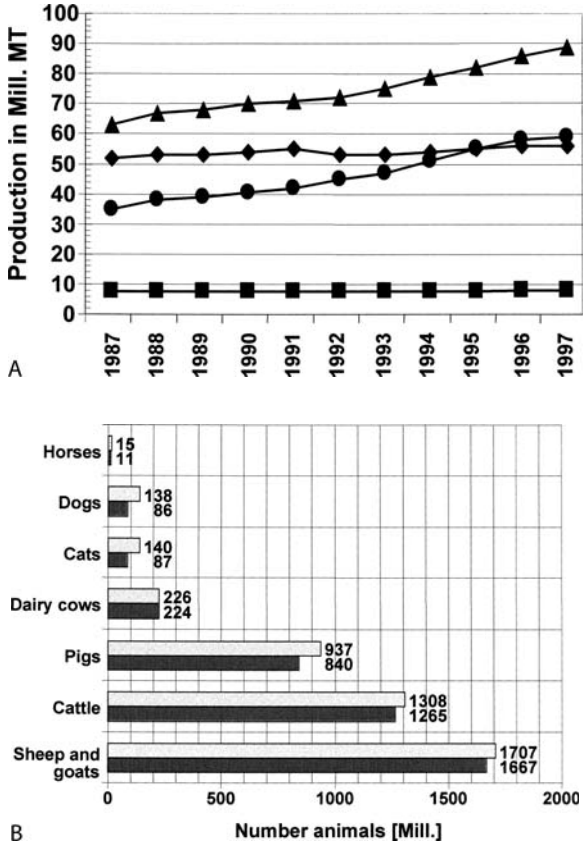
Chemical control of parasitic arthropods is a critical resource for worldwide food production as well as human or animal health. There is little doubt that it will remain so for the foreseeable future, but it is also important that progress be made to sustain and enhance its contribution. Achieving this progress depends to a great extent on the synthesis of new parasiticides, a field in research-orientated life science companies that is still highly dynamic.

In the livestock- and companion animal field the demand for chemical control measures has grown with increasing animal numbers and the world wide increase in consumption of meat (Fig. 1).

Arthropod attack causes a variety of damaging effects including reduction in feed efficiency, growth rate, milk and wool production. In addition to lower quantities of finished products, their quality is also impaired and parasite infestation contributes to a loss of general condition and an increase in susceptibility to secondary infections or further parasite attack.

While the level of parasite infestation is generally less severe in pets than in livestock species, the main health concern with dogs and cats is the danger of transmission of →fleas, worms, and tick borne diseases to human beings.

The importance of drugs to control arthropods is reflected by the market development for →insecticides, acaricides and endectocidals displaying activity against some arthropods, and various helminths (avermectinoid drugs).



Arthropodicidal Drugs. Figure 1 A Development of worldwide production capacities of meat between 1986 and 1997. (◆) Beef and veal; (■) mutton and lamb; (▲) pork; (●) poultry. **B** Standing animal populations between 1987 and 1997.

Arthropodicidal products currently account for around 14% the world animal health market, which has a value of about US$ 17 billion (including feed additives). The performance of arthropodicidal drugs has been notable in recent years, while others have been static or declining. This sector has continually expanded world wide. An amount of US$ 1,600 Million was spent in 1993 for livestock- and companion animal drugs useful for the treatment of parasitic arthropods (insecticides, acaricides and endectocides without environmental health insecticides). In 1998 the corresponding value increased by about 40% to US$ 2,300 Million. This trend looks yet to continue and it is expected that the market may increase by 12% until 2002.

In terms of volume the growth rate for livestock arthropodicides is expected to be low. In context, however, with the introduction of new highly innovative drugs against ectoparasiticides of dogs and cats, such as advantage® (imidacloprid), program® (lufenuron), and frontline® (fipronil), a significant expansion is expected in the field of pets.

Resistance

The spectrum of parasite resistance is one of the major problems affecting the usage of arthropodicidal drugs.

In some regions the development of this trait has rendered compounds practically useless. One solution is to put more effort into careful promotion of the proper use and rotation or combination of compound used in parasite control in order to prolong the life cycle of the products on the market.

Another possibility, and probably the best long term strategy is to increase the search for drugs displaying an alternative →mode of action not interfering with the resistance mechanisms already developed in relevant arthropod pests. Good examples in the area of pets are again imidacloprid, lufenuron and fipronil which act on the nicotinic acetycholin receptor, chitinbiosynthesis and y-aminobutyric acid receptor, respectively.

Improvement of Chemical Product Quality

Particularly in livestock the world trend has now moved firmly away from purely quantitative considerations towards quality of products. Concerns about critical side effects of arthropodicidal compounds which affect the classical targets (acylcholinesterase: organophosphates, carbamates; sodium channel: DDT, pyrethroids; GABA-aminobutyric acid gated chloride channel: chlorinated hydrocarbons) have led the regulatory agencies to demand additionally information and studies in order to define more clearly product efficacy, safety, residue profile and quality. Accompanied by the increasing levels of funding used for regulatory compliance the improvement and innovation in delivery formulations of existing chemical classes was and will be a preferable method for expanding product ranges. Good examples are the development of easy to apply pyrethroid pour on's and spot on's (application of an arthropodicidal drug along the backbone of an animal, or as a spot on in one place) which have considerably infringed the share of environmentally less favourable dips and sprays.

Increasing expenditure on development have led to a tendency to exploit drug properties also by combining different compounds in one product, thereby providing a broader range of activity within one treatment. In particular the combination of anthelmintic with arthropodicidal drugs such as levamisole and famphur to "produce" activity against →stomach worms, →lung worms, cattle grubs and →lice or the combination of insect growth regulators with avermectinoid drugs against intestinal worms and flea larvae are of significant interest in this context (Table 1).

Formulation and Delivery Systems

The ease of delivering an arthropodicidal drug has become almost as important in terms of it's consumer acceptance as is it's activity against parasites. With the

increasing levels of funding needed to develop new drugs, the improvement in formulation of existing drugs is fast becoming an important method to expand product ranges.

The future trend of innovative delivery systems will probably focus on stress reduction and improvement of convenience. Losses in weight gain and growth performance as well as costs for handling of livestock species can almost reach the spending on medication. Therefore systems which extend the delivery time such as tablets, boluses or other controlled release devices, will reduce handling frequency and may open up possibilities for new administration technologies (Table 2).

As miniaturisation of electronic devices continues to advance one innovative example might be the development of new bolus types that will release ectoparasiticides, for example insect growth regulators, self- or externally triggered over a long period of time. By eliminating larval development in the pasture and reducing re-infestation such products might play an important role in the strategic management of fly control programs.

Another step forward could be the development of more advanced topical applications such as pour ons or spot ons involving for example micro-encapsulation technology for livestock and pets.

Wash-off resistance and decreased dermal penetration of adulticidal drugs such as pyrethroids or others will further stimulate the usage of this easy and stress minimising application.

Arthropodicidal Drugs. Table 1 Combination products with arthropodicidal drugs (according to Hansen and Londershausen)

Example of combination	Main indications	Formulation/ Application
Large animal use		
Abamectin/Praziquantel	Control of round- and tapeworms as wells as bots in horses	Paste
Amitraz/Diazinon	Sheep ectoparasites: flies, keds, lice, ticks	Dip
Cypermethrin/Chlorfenvinphos	Broad tick activity for various host animals, catt lice and flies	Dip/Spray
Cypermethrin/Rotenone	Longterm protection for sheep against itchmite and lice	Dip
Small animal use		
Lufenuron/Milbemycin-oxime	Canine helminths and immature flea stages	Tablet
Permethrin/Pyriproxyfen	Larval development stages and adult fleas	Spray
Propoxur/Flumethrin	Control of adult fleas and ticks	Collar
Propoxur/Methoprene	Environmental control of flea development stages	Spray
Pyrethrin/S-Methoprene	Control of fleas and ticks	Spray

Arthropodicidal Drugs. Table 2 Delivery systems of arthropodicidal drugs (according to Turberg and Londershausen)

Method of application	Typical examples of actives or chemical classes used
Major topical formulations	
Collar	Propoxur, Amitraz, Permethrin, Flumethrin, Diazinon, Deltamethrin,
Dips	Methoprene
Pour-ons	Organophosphates, Pyrethroids
Spot-ons	Avermectins, Milbemycins, Pyrethroids, Metaflumizone, Amitraz
Sprays/Jetting fluids/Mist sprays	Fenthion, Fipronil, Imidacloprid, Permethrin Amitraz, Carbamates, Organophosphates, Pyrethroids
Other topical formulations	
Aerosols	Organophosphates, Pyrethroids, Carbamates
Dust bags/Back-rubbers/Dusts	
Eartags/Strips	
Foams/Shampoos	
Ointments	
Powders	
Washes	
Oral formulations	
Boluses	Methoprene, Avermectins, Milbemycins
Tablets	
Injection	Avermectins, Milbemycins

Classes of Chemical Compounds

A wide variety of ectoparasites are relevant for livestock and pets. These resolve into a relatively small number of major problems with a wide variety of products, ingredients and formulation for their control. For information on →repellents and →synergists please refer to the respective entries.

Arthropodicidal drugs can be divided into different groups according to their structure and mode of action (Table 3) assuming that similar chemical structure leads to the same basic mode of action. This certainly is a much too simplified view which doesn't reflect realistically an overall biological activity. Biological effects result from the superimposement of primary mode of action, pharmakocinetic behavior, degradation and excretion driven by the physiochemical parameters of drugs. Chemical compounds may display significantly different properties in this respect, even if they basically belong to the same chemical class.

Organochlorides

Important Compounds

Bromocyclen, chlordane, DDT, lindane (gamma benzene hexachloride), methoxychlor.

General Information

Lindane and several cyclodienes were demonstrated to stimulate the central nervous system by influencing synaptic transmission and causing hyperexcitation. In the 1980s it was shown that these compounds block the (GABA)-influenced Cl^- current in neurons by binding to the GABA receptor chloride channel. In a set of elegant experiments this theory has been confirmed by showing that target site insensitivity to cyclodienes was associated with a resistance gene (Rdl = resistance to dieldrin) which codes for a GABA receptor subunit in Drosophila melanogaster. The responsible point mutation in the membrane spanning region M2 could be identified by cloning of the M2 region with degenerated PCR primers amongst others in a variety of resistant dipteran flies.

Chlorinated hydrocarbons applicated in sprays or dips once were common products for example in the treatment of myiasis and lice infestation in cattle and other species. Nowadays organochlorides such as chlordane, lindane are no longer approved for veterinary use in many countries, particularly because of their long persistence in the environment. Occasionally compounds like bromocyclen or methoxychlor are used against →mange mites biting and sucking lice and flies such as Melophagus or Hippobosca species.

Organophosphates/Carbamates

Important Compounds

Azamethiphos, bendiocarb, bromopropylate, carbaryl, chlorfenvinphos, chlorpyrifos, coumaphos, cythioate, diazinon, dichlorvos, dicrotophos, dioxathion, ethion, famphur, fenchlorphos, fenitrothion, fenthion, heptenophos, iodofenphos, malathion, methomyl, phosmet, phoxim, pirimiphos, promacyl, propetamphos, propoxur, temephos, tetrachlorvinphos, trichlorfon.

General Information

The concept that toxicity to insects and →ticks by organophosphates and carbamates results from inhibition

Arthropodicidal Drugs. Table 3 Major arthropodicidal chemical classes used in veterinary medicine (according to Turberg and Londershausen)

Chemical class/examples	Mode of action	Chronology of discovery for veterinary use*
Chlorinated hydrocarbons		
DDT	Voltage dependent sodium channel	1943
Cyclodiens, Lindane	GABA–gated chloride channel	~1945–1959
Organophosphates	Acetylcholinesterase	~1950–1965
Carbamates	Acetylcholinesterase	~1960–1970
Pyrethroids	Voltage dependent sodium channel	~1970–1985
Amidines	Sites responsive to biogenic amines (Octopamine receptors, monoamine oxidases)	~1975–1980
Avermectins / Milbemycins	Glu-gated chloride channel	~1981–1998**
Insect growth regulators		
Cyromazine	Interference with cuticle sclerotization	1979
Benzoylphenylureas	Inhibit cuticle deposition/chitin biosynthesis	~1985–1995
Juvenoids	Mimic juvenile hormone effects	~1988–1996
Arylpyrazole (Fipronil)	GABA–gated chloride channel	1994**
Chloronicotinyles (Imidacloprid)	Nicotinic acetylcholin receptor	1996**

* Area of entry date based on the introduction of important actives of the respective chemical class into veterinary market

** The discovery and development of further products can be expected due to intensive research efforts in various veterinary companies

of acetylcholinesterase (AChE) was proven to be useful in correlating structure with activity for various compounds from both chemical classes, although some disagreement exists as to the exact mode by which AChE-inhibitors kill ectoparasites.

Organophosphates and carbamates have a wide range of activities against various arthropods, involving blowfly larvae, →keds, lice, fleas, →mites and ticks in companion and livestock animals. Products with almost any application type have been developed ranging from dips, sprays and pour on's to ear tags and collars. Organophosphates in particular have been popular due to their rapid onset of activity, but in recent years concerns have been raised regarding environmental effects and some adverse reactions. In contrast to organophosphates the carbamylation of AChE by carbaryl and propoxur results in a reversible inhibition of AChE whereas organophosphates inhibit AChE almost irreversibly. The somewhat lower safety level compared to other insecticides has limited their use on older animals (>3 months) and the development of resistance nowadays restricts their applicability significantly. This problem is especially important in such sectors as the ear tag application.

Pyrethroids and DDT

Important Compounds

Alphamethrin, bioallethrin, cyfluthrin, (beta-)cyfluthrin, cyhalothrin, cypermethrin, deltamethrin, fenvalerate, flucythrinate, flumethrin, (tau-)fluvalinate, permethrin, phenothrin, resmethrin, tetramethrin.

General Information

The symptoms of pyrethroid and DDT poisoning in insects are characterised by different forms of hyperexcitation caused by repetitive discharge of the nervous systems. In patch clamp investigations of single sodium channel currents it has been demonstrated, that under the influence of pyrethroids and DDT individual channels are modified to remain open for an unphysiological long period of time. The symptoms of intoxication differ somewhat between type II and type I pyrethroids based on the presence or absence of a cyano group at the á-position. Taking into account this structural as well as pharmacokinetic differences between various pyrethroids, the basic mechanism of action at the channel and cellular level is the modulation of the gating kinetics of individual sodium channels.

Since natural pyrethroids are not stable enough under atmospheric influences, the use of synthetic pyrethroids in animal health has become an important method to control arthropod pests such as flies and ticks. Various pyrethroids have been developed for animal health indications expressing more or less pronounced broad spectrum activity against ectoparasites. In this context the relation between dosage and occurrence of adverse drug reactions of the host animal became relevant in differentiating the range of optimal use for these pyrethroids.

Amidines

Important Compounds

Amitraz, cymiazole.

General Information

The formamidines are structurally related to octopamine. Since they mimic the action of this phenolamine in a number of insect preparations it was concluded that these compounds act via effects on octopamine sensitive adenylate cyclase (octopamine-receptors). In addition formamidines are reasonable potent inhibitors of monoamine oxidase (MAO) in cattle ticks and mammals. However MAO activity in insect nervous tissue is low and no consistent similarities or structure activity relationship have been observed between the biological effects of known MAO inhibitors and those caused by amidines in insects and ticks. It still remains to be established whether this action is causative of any of the various responses of veterinary or agricultural important insects and acarines.

Numerous biochemical targets have been suggested for formamidines, however on the basis of current knowledge the action on sites responsive to biogenic amines seem to be most likely. In animal health formamidines, in particular amitraz, displays a high acaricidal activity and offers an alternative to control organophosphorus and/or organochlorine and/or pyrethroid resistant ticks and mange mites of cattle, sheep and pigs.

Amitraz causes ticks to withdraw their mouthparts rapidly and fall off the host animal, which from the viewpoint of practical control of tick-born diseases is highly desirable.

Avermectins/Milbemycins

Important Compounds

Abamectin, doramectin, eprinomectin, ivermectin, selamectin, moxidectin, milbemycin-oxime.

General Information

Avermectins, milbemycins and their active derivatives inactivate →nematodes, arachnids and some insects by disrupting their nerve transmission. Most of the studies have been performed with ivermectin.

In GABA sensitive fibres from insect skeletal muscles ivermectin induced increased chloride conductance which was reversible at low concentrations (nM range) but irreversible in μM range. GABA insensitive muscle fibres produced only irreversible responses to ivermectin, particularly the drug inhibited chloride conductance gated by →glutamate receptors in locust muscle fibres. These and other investigations led to the conclusion that this class of compounds act through their effects on glutamate gated chloride channels.

The activity against arthropods varies to some extent depending on the milbemycin or avermectin type of drug and the delivery method.

Insect Growth Regulators

Insect or acarid growth regulators may provide a complementary method to parasite control relying on adulticide drugs. Growth regulators often have a favourable safety margin which enables them to be used also in systemic applications either as in-feed products, boluses or tablets.

After uptake their presence in manure, body fluid or skin interrupts the life cycle of various ectoparasites. Growth regulators display their mode of action either by preventing development of eggs, larvae or nymphs (e.g., tick →*Boophilus microplus*) directly on contact or by interfering with egg development and hatching after being ingested during feeding of adult females (e.g., flea: →Ctenocephalides felis).

Since growth regulators only operate on a specific part of the →ectoparasite life cycle they usually have little direct effect on the adult parasite population and achieve control after a longer period of time when compared to fast acting neuroactive compounds.

Growth regulators provide a valuable tool for long term control when used in conjunction with other arthropodicides which clear the host from adult parasite and final larval stages.

Triazine

The drug Cyromazine is an insect growth regulator which is still used to control blow fly strike and fly development in poultry manure. Cyromazine interferes with moulting and pupation and causes reduced growth of treated larvae. A direct effect on →chitin biosynthesis has not been confirmed, but evidence has been presented that interference with →cuticle sclerotisation and elasticity might be responsible for the antiparasitic effect of this substance.

Benzoylphenylureas

Important drugs are diflubenzuron, fluazuron, lufenuron, and triflumuron.

The exoskeleton of arthropods consists of different layers, of which typically the procuticle contains the amino sugar polysaccharide chitin, a major component of insect cuticle.

Nucleoside peptide antibiotics and benzoylphenylureas (BPUs) are the major groups of compounds acting primarily at chitin synthesis as target site.

For animal health indications only BPUs have been developed and commercialised internationally. Original studies of the mode of action of BPUs have implicated that synthesis and deposition of chitin are disturbed after application of BPUs.

Since these findings several hypotheses for their mode of action have been proposed, but the underlying biochemical mechanism still remains unclear. So far inhibition of precursor transport, proteolytic activation of chitin synthase zymogen, direct inhibition of chitin synthase, indirect hormonal effects and effects on cell membranes in combination with vesicle transport have been discussed as the primary mode of action.

The inhibition of cuticle deposition after BPU treatment results in death of larvae, pupae and non viable adults. In addition egg development and hatching are interrupted if particular systemically active BPUs are ingested during feeding of female ticks (fluazuron) or fleas (lufenuron). Even if growth regulators require more time to reduce ectoparasite populations they are useful tools, particularly in combination with compounds displaying an alternative mode of action, to control different life stages of ectoparasites.

Juvenoids

Important drugs are fenoxycarb, hydroprene, methoprene, and pyriproxyfen.

The development of arthropod parasites comprises an orderly series of stages in the course of which they become transformed from larval stages into an adult. This process involves a series of moults and a →metamorphosis which can be disturbed with drugs which act similarly to insect →juvenile hormones.

The main effects contributing to insect control often depend on the target pest and the timing of application.

In the veterinary field juvenoids are particularly useful in controlling flea development either used in topical on-animal applications or in sprays to prevent hatching of fleas from companion animal surroundings.

→Hygiene pests such as various species of →mosquitoes, house flies and to a lesser extent cockroaches can be controlled with juvenoids, too. Due to their improved stability particularly fenoxycarb and pyriproxyfen are useful for these indications.

The exact mode of action of juvenoids has not been resolved so far. A number of factors other than receptor binding may influence the activity of a juvenoid significantly when applied at a sensitive stage in growth. Penetration through the cuticle and transport to the target tissue, rates of degradation and excretion, inhibition of the juvenile hormone (JH) degradation system as well as competitive binding to JH carrier proteins are still under evaluation.

Arylpyrazoles

Important Compound

Fipronil.

General Information

γ-Aminobutyric acid (GABA) is a major inhibitory transmitter at the neuromuscular junction not only in nematodes but also in insects and most likely in acarines, too. Upon binding of GABA to its receptor a rapid influx of chloride into the cell is induced which results in a hyperpolarisation of the membrane potential. In most cases an inhibitory effect on the respective cell is the consequence of this GABA activity. In vertebrates two subtypes have been identified. $GABA_A$ receptors which form a ligand gated chloride channel as well as contain modulatory sites for various drugs; and $GABA_B$ receptors, G-proteins which display various effects on calcium and potassium channels.

Most GABA receptors in insects resemble $GABA_A$ subtype, but they are clearly distinct from the vertebrate $GABA_A$ receptors. The GABA receptor is an important target for some older arthropodicides such as lindane cyclodiens but is also affected by fipronil, a new insecticide and acaricide which belongs to the chemical class of arylpyrazoles. This has been recently confirmed by cloning of a Drosophila GABA-gated chloride channel subunit using genetic mapping of a mutation which causes resistance against dieldrin (RdI). Fipronil was developed as an agrochemical and veterinary arthropodicide. In the veterinary field the compound is used for the treatment of fleas in dog and cats and ticks in dogs.

Chloronicotinyles

Important Compound

Imidacloprid.

General Information

Cholinergic →synapses play a critical role in transmission in arthropods and nematodes. Recently a new drug, imidacloprid, was discovered displaying a new mode of action. Insecticides of this type act as agonists at the nicotinic acetylcholin receptor (nAChR) as was demonstrated by electrophysiological techniques and biochemical competition assays. The compound is highly effective against target insects, such as fleas or cockroaches but has virtually no effect on the mammalian nervous system. This might be explained by the fact that imidacloprid is not absorbed into the host animal bloodstream or internal organs and nAChRs from mammalian sources are much less or not at all sensitive to the agonistic action of insecticidal chloronicotinyles. In this context the fast killing of adult fleas on dogs and cats on contact not only prevents re-infestation for a long period of time (at least 4 weeks) but also significantly reduces the occurrence of flea →allergy dermatitis caused by flea saliva allergens.

Rotenone

Rotenone is a natural product derived from plant roots of Derris and Lonchocarpus. This drug is a highly effective inhibitor of complex I of the →mitochondrial respiratory chain and inhibits NADH cytochrome c-reductase in nmole per mg protein range. The drug has largely been replaced by modern compounds, but is still used in combination products against ear mites and demodectic mange.

Benzylbenzoate

Benzylbenzoate is an old acaricidal drug which is useful for the treatment of sarcoptic mites in dogs.

Sulphur

Due to the availability of new and safer products nowadays the use of sulphur for mite treatment has been largely banned not only because of toxicological but also pollution concerns.

Arthur's Phenomenon

→Gametes.

Arthus Reaction

Allergic immediate reaction with severe tissue inflammation, →oedema, hemorrhages and →necrosis named after the Swiss microbiologist M. Arthus (1862–1935).

Articles

Segments of the legs or palps in ticks and mites.

Articulation Pain

Leading symptom in vector – transmitted diseases: →Borreliosis, →Chikungunya, →Dengue Fever.

Ascariasis, Man

Pathology

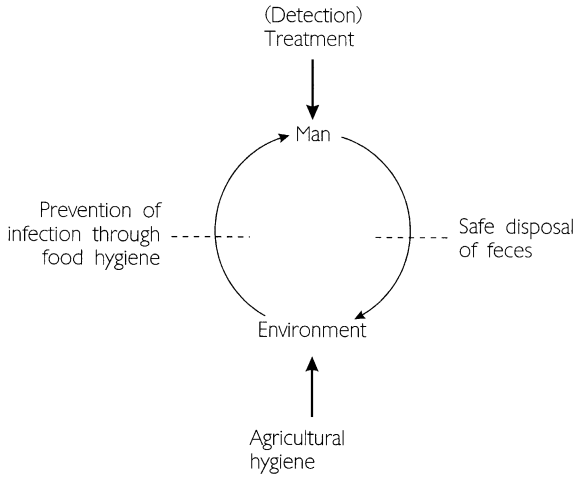
Ascariasis is an infection with →*Ascaris lumbricoides*, a large, lumen-dwelling nematode contracted by the ingestion of its larva via eggs (→Ascaris/Fig. 1). The larvae penetrate the small intestine wall and migrate through the lymphatics and blood stream to the liver, and then to the lungs where they enter the alveoli. There they pause for at least 2–3 weeks and →molt, giving rise to allergic bronchopneumonia in previously infected and sensitized individuals. Later, they wander up the bronchi and trachea, giving rise to bronchitis with bronchospasm, →urticaria, and occasionally, larvae in the sputum. Most larvae are swallowed and grow to adulthood in the small intestine. The adult worms are up to 30 cm long and 4 mm wide, and give rise to mechanical problems because of their size and, especially in children to a severe nutritional drain, because of the worm number and mass. A temperature elevation to 39 °C, certain drugs, and some unknown influences may cause the worms to congregate, sometimes resulting in intestinal obstruction and migration out of the gut into the bile duct, esophagus, mouth, pancreatic duct or appendix, and occasionally

the liver. The migration leaves necrotic tracts in the liver with hypersensitive inflammation produced by adults and eggs (→Pathology/Fig. 27A). Adult worms may perforate the intestine and pass out of the gut, leading to peritonitis.

Targets for Intervention

Eggs of *Ascaris lumbricoides* are not immediately infective after leaving the infected host. They require a holding period in a suitable environment and become infective once second-stage larvae have developed in the eggs. Fig. 1 shows the carrier and the infection cycle as targets of intervention. Control may be achieved by the detection and treatment of infected persons, safe disposal of feces, and improving agricultural →hygiene and food hygiene.

Main clinical symptoms: →Eosinophilia, →abdominal pain, →vomiting, enteritis, ileus verminosus
Incubation period: Lung: 7 days, intestine: 3 weeks (however 85% of the patients remain symptomless)
Prepatent period: 2 months
Patent period: 9–15 months



Ascariasis, Man. Figure 1 Targets and approaches for the control of ascariasis.

Diagnosis: Microscopic determination of eggs in fecal samples (→Ascaris/Fig. 1)
Prophylaxis: Avoid eating uncooked vegetables and avoid human feces.
Therapy: Treatment see →Nematocidal Drugs, Man

Ascaridia galli

Classification

→Nematodes.

General Information

Specimens of this and related species grow up as females to a length of up to 12 cm inside the intestine of chicken and doves. A related species in turkeys leads to necrosis of the intestinal wall. The life cycle is monoxenous, i.e., the infection runs from bird to bird by ingestion of the 80 µm × 50 µm-sized eggs. Each of which develops an infectious larva within 8–10 days after being excreted with the feces. The larvae – when hatched from the egg inside the intestine – enter the intestine wall for 3 weeks. After a total of 5–8 weeks maturity is reached and egg production starts. Pathogenesis is considerable, since bacteria superinfect the intestinal wall lesions. Anemia is common.

Treatment

→Nematocidal Drugs.

Ascaris

Classification

Genus of →Nematodes.

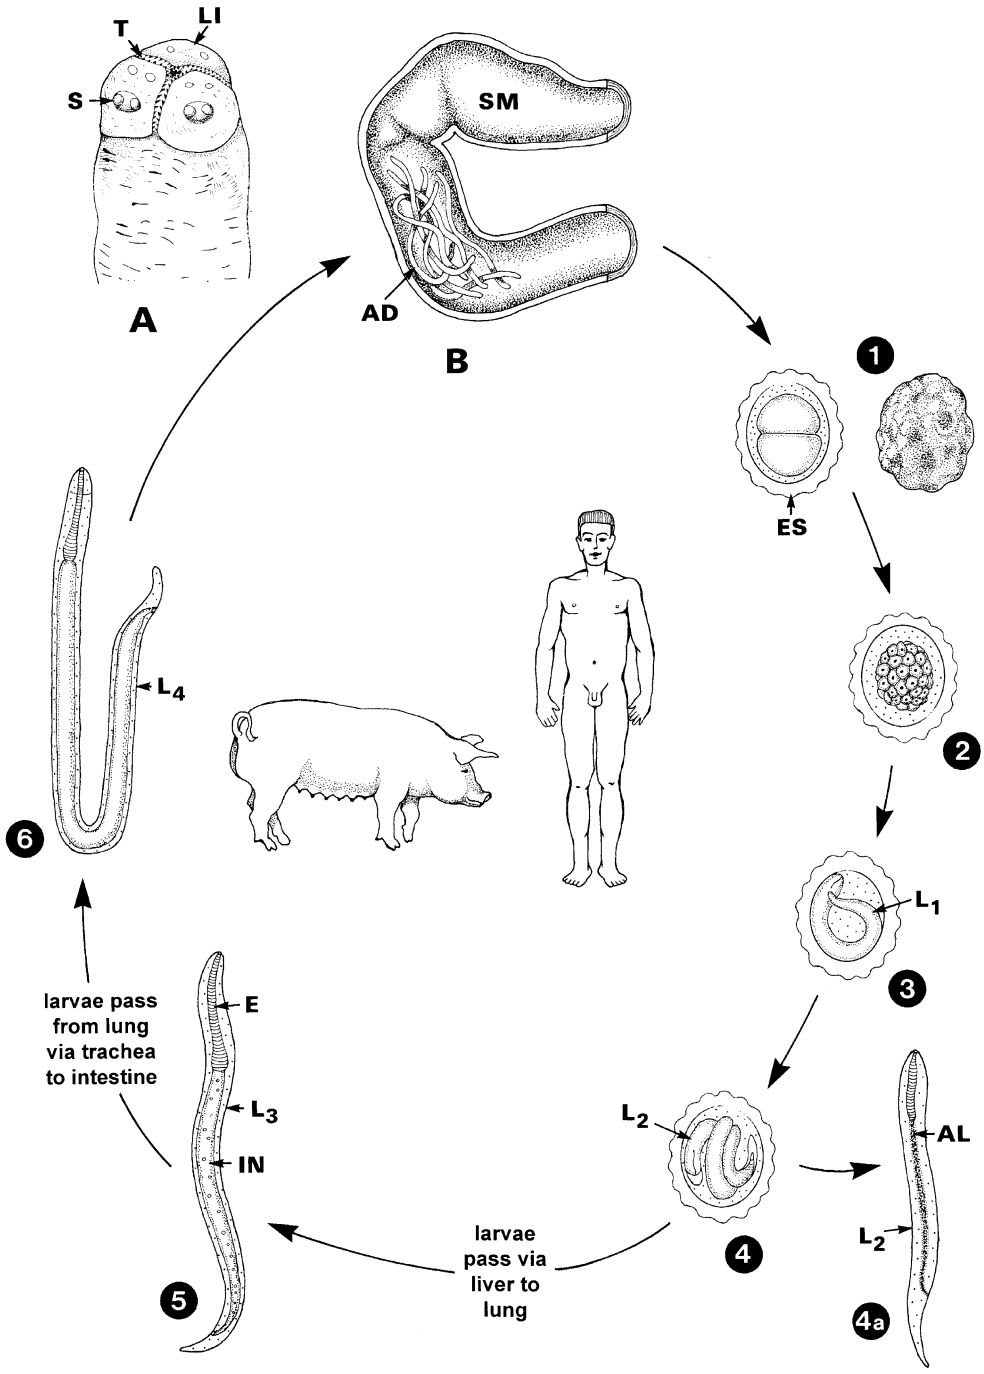
Important Species

Table 1.

Ascaris. Table 1 Important species of the genus *Ascaris*

Species	Length of adult worms (mm)		Size of eggs (or larvae) (µm)	Final host/Habitat	Intermediate host	Prepatent period in final host (weeks)
	f	m				
Ascaris lumbricoides	200–410	150–250	50–75 × 40–50	**Humans**, pigs/Small intestine	–	6–11
A. suum	200–300	150–250	65–85 × 40–60	Pigs, **Humans**/Small intestine	–	6–11

f = female, m = male



Ascaris. Figure 1 Life cycle of ascarid worms (e.g., →*Ascaris lumbricoides*, *A. suum)* of man and swine. ***1–2*** Adult worms (male 15–25 × 0.3 cm; female 25–40 × 0.5 cm) live in the small intestine of their hosts and feed (in general) on the liquid contents of the gut. Fertilized eggs are ovoid to spherical (45–75 × 35–50 µm), are surrounded by a thick, lumpy, mammilated shell and are usually uncleaved when passed in the feces (2). The shells of unfertilized eggs are thinner. ***3–6*** On the soil a period of about 10–40 days (dependent on the temperature) is needed to develop the second larval stage (L_2) inside the egg (some authors describe development until L_3). ***7–8*** After oral uptake of infectious eggs, the larvae hatch in the intestine (in 3–4 h), enter the intestinal wall, pass through the liver and via heart to the lung, where finally the L_3 is formed. These third larval stages break into the air spaces of the lung and move up the trachea to the pharynx, where they are swallowed. In the intestine (reached around the 8th day after infection) the worms →molt twice and mature, starting eight weeks after infection (prepatent period). This peculiar migration is considered as →phylogenetic reminiscence. **A** anterior end; **B** intestine; *AD*, adult worm; *AL*, anlage of intestine; *E*, esophagus; *ES*, egg shell; *IN*, intestine; L_{1-4}, larval stages; *LI*, lip; *S*, sensory organ; *SM*, small intestine.

Life Cycle
Fig. 1.

Disease
→Ascariasis, Man, →Respiratory System Diseases, Animals.

Ascaris lumbricoides

Ascaris was recently shown to possess hemoglobin. While the hemoglobin of the body wall resembles vertebrate myoglobin (~40.6 kDa), that of the perienteric fluid is an octomer (328 kDa) and has the highest affinity for oxygen of any known hemoglobins.

Life Cycle
Ascaris/Fig. 1. Human round worm, →*Ascaris*, →Nematodes.

Ascaris suum

Name
Greek: *ascaris* = worm; latin: *sus* = pig.

Important roundworm of pigs, →Alimentary System Diseases, Swine; eggs are used to settle symptoms of Morbus-Crohn.

Ascarops

Genus of the worldwide occuring nematode family Spirocercidae. The species (e.g., *Ascarops strongylina*) lives in the stomach of their hosts, suck their blood, lead to weight loss, anaemia, and bloody diarrhoea. The larvae 3 are found inside beetles, which are taken up with the food.

Incubation period: 10–13 days.
Prepatent period: 6 weeks.
Therapy: →Nematocidal Drugs.

Ascarops strongylina

Spirocercid nematode (thick stomach worm) of swine reaching as female a size of up to 20 cm. Copraphagic beetles are intermediate hosts. The larvae 3 may also become included into transport hosts such as small mammals, birds, etc. The female and male worms live on the surface of the mucocutaneous layer of the stomach and may introduce haemorrhagic inflammations.

Treatment
→Doramectin, →Ivermectin, →Nematocidal Drugs.

Ascetospora

Phylum of intracellular protozoan organisms that parasitize in Turbellaria, annelids, molluscs, and crustaceans. They include two classes (Haplosporea and Paramyxea) and do not possess polar capsules or polar filaments. The sporoplasms leave the capsule via pores of after bursting of the shell. Genera: e.g., *Haplosporidium, Marteilia, Bonamia*.

Ascogregarina taiwanensis

This species (syn. *Ascocystis, Monocystis, Lankesteria*) is an aseptate gregarine species which parasitizes in *Aedes* and *Phlebotomus* spp. (among other insects), where it is always found in the midgut and →Malpighian tubes.

ASF Viruses

General Information
Among the →arboviruses there is a group containing double-stranded DNA. These spherical viruses with an envelope are also called African swine fever-like (ASF) viruses.

Important Species
Table 1 (page 135).

Asfarviridae

Classification
Family of double-stranded DNA viruses with one genus with one species: Table 1.

ASF Viruses. Table 1 Arboviruses I. Double-stranded DNA viruses: African Swine Fever-like viruses (unnamed family) (spherical, with envelope)

Genus (group)	Species (selected)	Arthropod host	(Main) Vertebrate hosts	Distribution	Disease in man	Disease in animals
African swine fever-like viruses	African swine fever viruses	Argasidae (*Ornithodoros*)	Domestic and wild swine, wart hogs, bush pigs, grant forest hogs	Africa	–	+ (depending on strain)

Asphasmidea

Synonym
→Adenophorea.

Classification
Group of →nematodes.

Aspiculuris

Genus of oxyurid nematodes of rodents in laboratories, e.g., *A. tetraptera*, which (like *Syphacia muris* and *S. obvelata*) lives in the colon and caecum. In contrast to the quick development of the larvae in the human oxyurid →*Enterobius vermicularis*, *Syphacia* and in *Aspiculuris,* the development of the *Aspiculuris* – larvae inside the excreted eggs is slow and needs 5–7 days.

Aspidobothrea

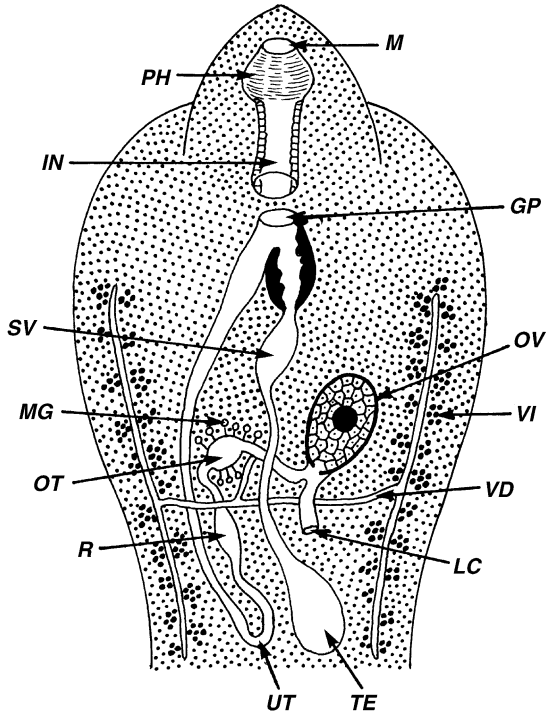
Synonym
→Aspidogastrea.

Classification
Group of →Platyhelminthes.

Morphology
Fig. 1.

Aspidogaster conchicola

→Aspidogastrea.



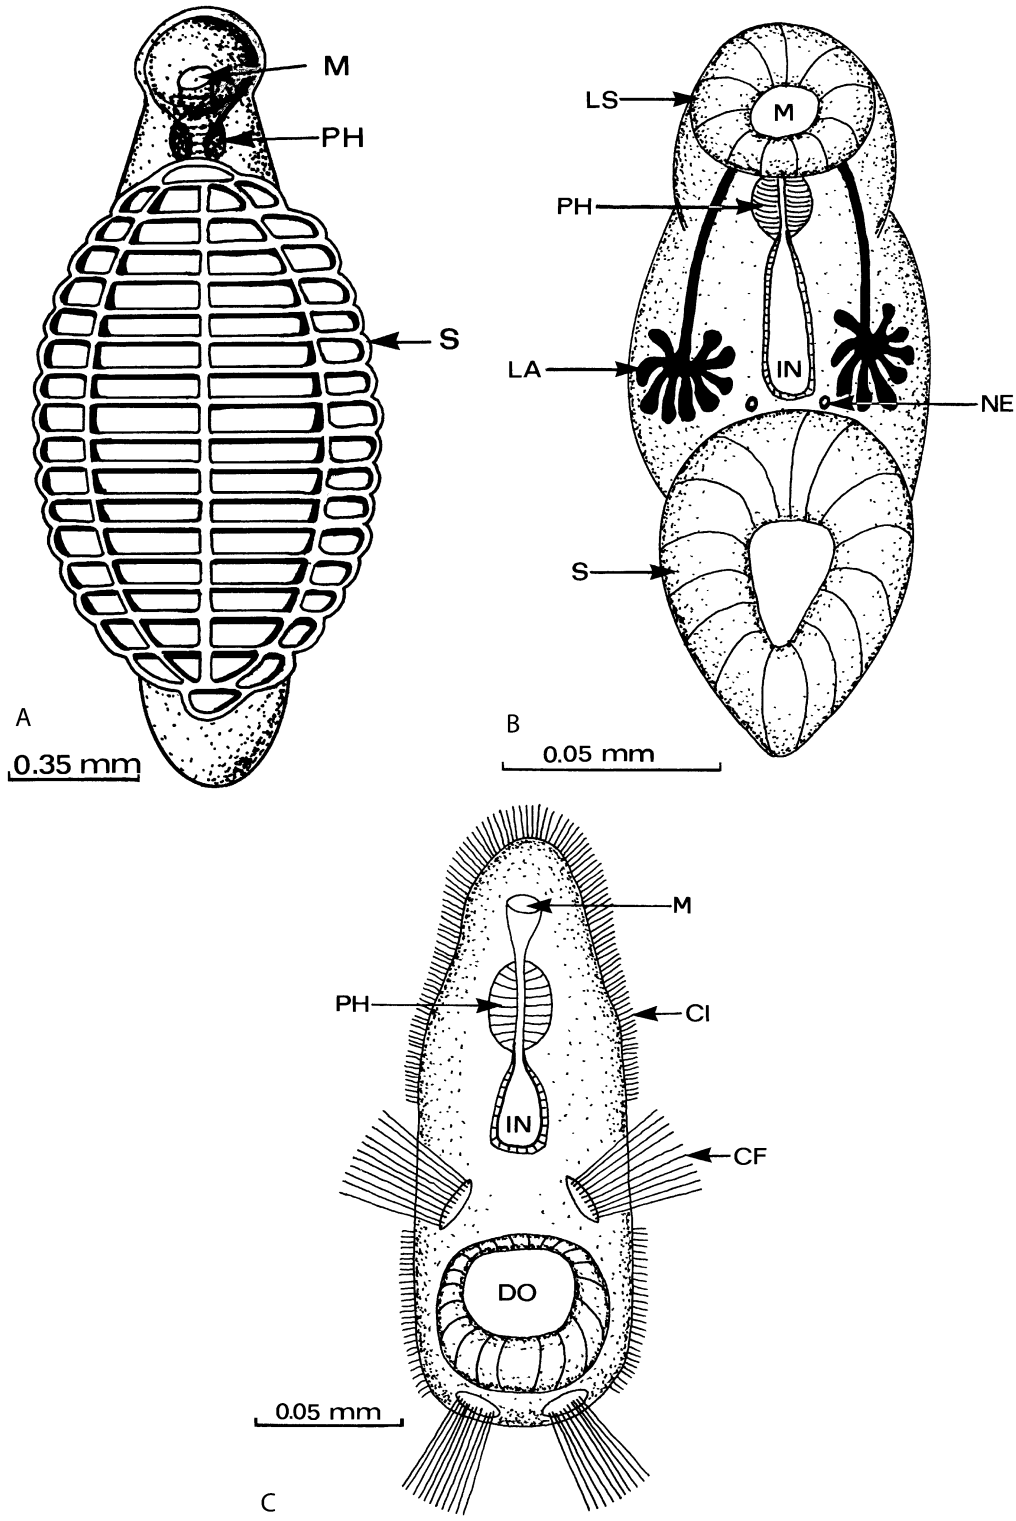
Aspidobothrea. Figure 1 Diagrammatic representations of reproductive systems (after Rohde). *GP*, genital pore; *IN*, intestine (digrammatically interrupted); *LC*, Laurer's channel; *U*, mouth; *MG*, →Mehlis' glands; *OT*, →ootype; *OV*, ovary; *PH*, pharynx; *R*, →receptaculum seminis; *SV*, seminal vesicle; *TE*, →testis; *UT*, uterus; *VD*, vitelloduct; *VI*, →vitellarium.

Aspidogastrea

Synonym
→Aspidobothrea.

Classification
Class of →Platyhelminthes.

General Information
The Aspidogastrea is a relatively small group, which is characterized by a very large hookless holdfast organ



Aspidogastrea. Figure 1 A–C Life cycle stages of Aspidogastrea (seen from ventral side). **A, B.** →*Aspidogaster conchicola*. **A.** Adult worm (2–3 mm long) from kidney of clams (Lamellibranchiata, Unionidae) or from the intestine of snails, fish, and reptiles. Excreted operculated eggs are embryonated and contain a creeping, nonciliated larva (B), which grows to the adult stage by gradual transformation. **C.** →*Multicotyle purvisi*, ciliated free-swimming larva; adults reach 10 mm in length and occur inside the pallial complex of snails (*Pila*) or in the intestine of snail-eating turtles. *CF*, ciliated field; *CI*, →cilia; *DO*, development of →opisthaptor; *IN*, intestine; *LA*, lateral larval glands; *LS*, larval anterior sucker; *M*, mouth; *NE*, nephridioporus (seen from ventral side since it opens dorsally); *S*, ventral sucker (= Baer's disc).

Aspidogastrea. Table 1 Some common species of the Aspidogastrea (syn. Aspidobothrea)

Species	Length (mm)	Host	Habitat
Aspidogaster conchicola	3	Freshwater clams Reptiles Fish Snails	Pericardial cavity Intestine Intestine Visceral mass
Lophotaspis vallei	5	Marine turtles Snails Clams	Esophagus, stomach Mantle cavity Pericardial cavity
Multicotyle purvisi	10	Snails Turtles	Pallial complex Intestine
Stichocotyle nephropis	115	Lobsters Rays	Wall of intestine Bile bladder
Macraspis elegans	15	Ratfish	Bile bladder
Cotylaspis insignis	2	Freshwater clams	Kidney, mantle cavity
Cotylogasteroides occidentalis	2	Freshwater clams Snails Fish	Gill cavity Mantle cavity Intestine
Rugogaster hydrolagi	15	Ratfish	Rectal gland

(ventral or Baer's disc, →opisthaptor), which, in adult worms, covers nearly the whole ventral side (Fig. 1A). The Aspidogastrea are typically endoparasites of many molluscs, elasmobranchs, teleosts, turtles, or decapod crustaceans (Table 1) and are not host-specific. Their development occurs as →metamorphosis via larval stages (Fig. 1B, C); in general no →intermediate host is needed; however, larvae may continue their development in different hosts. With respect to host specificity, their parasitism is apparently not very specialized, since it is not uncommon to find an aspidogastrean in the gut of a fish, although it may normally parasitize a mollusc.

Important Species

Table 1.

Life Cycle

Fig. 1A–C.

Morphology

In the →cotylocidium larva as well as the adult worms the external surface of the tegumental membrane shows a PAS-positive, filamentous surface coat, e.g., in adult *Aspidogaster conchicola* – a parasite of freshwater clams of the genera *Unio*, *Anodonta* and *Gonidea* – it has a thickness between 100 and 300 nm. The sexual organs are diagrammatically depicted in Fig. 1 of →Aspidobothrea (syn. Aspidogastrea).

Astigmata

→Acarina.

Atopic Reactions

Clinical symptoms of allergic →hypersensitivity reactions of type 1 (e.g., rhinitis, asthmatic symptoms, eczema) due to contacts e.g., with dust →mites.

Atovaquone

Compound for babesiosis, toxoplasmosis, malaria treatment, see →Malariacidal Drugs, agents against protozoal diseases.

ATP Synthesis

→Energy Metabolism.

Atractis

Genus of oxyurid nematodes in lizards and tortoises.

Attached Flagellum

→Undulating membrane of →trichomonads and →trypanosomes.

Attractans

Compounds or odour that attract blood-sucking or mating arthropods respectively eyeless species (e.g. some ticks, termites).

Auchmeromyia

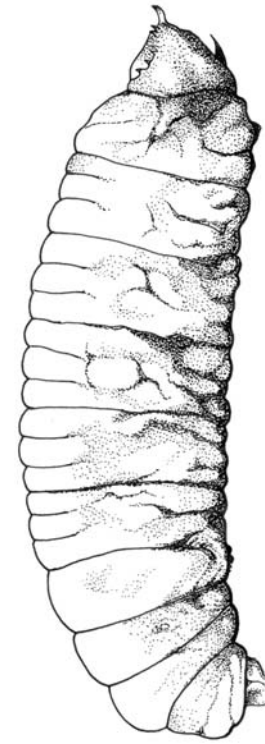
The calliphorid fly *A. senegalensis* (syn. *A. luteola*) belongs to those flies introducing →myiasis (Figs. 1, 2, page 139). Its common name is Congo floormaggot; it does not burrow in the skin, but it sucks blood at sleeping humans or animals. This activity is referred to as "sanguinivorous myiasis."

Auditory Ability

The males of many →Culicidae are able to "hear" the wing beat of females (about 250–350 Hz) via the scolopids of the Johnston organ at the 2nd segment of the antennae and are thus attracted. Females are unable to percept the wing beat of males (250–500 Hz) and thus unable to avoid them, as is claimed by producers of piping apparatures to repel biting females.

Australamphilina elongata

Species of →Cestodaria within the body cavity of the Australian tortoise *Chelodina longicollis*.



Auchmeromyia. Figure 1 *Auchmeromyia senegalenis*; blood sucking larva.

Austrobilharzia

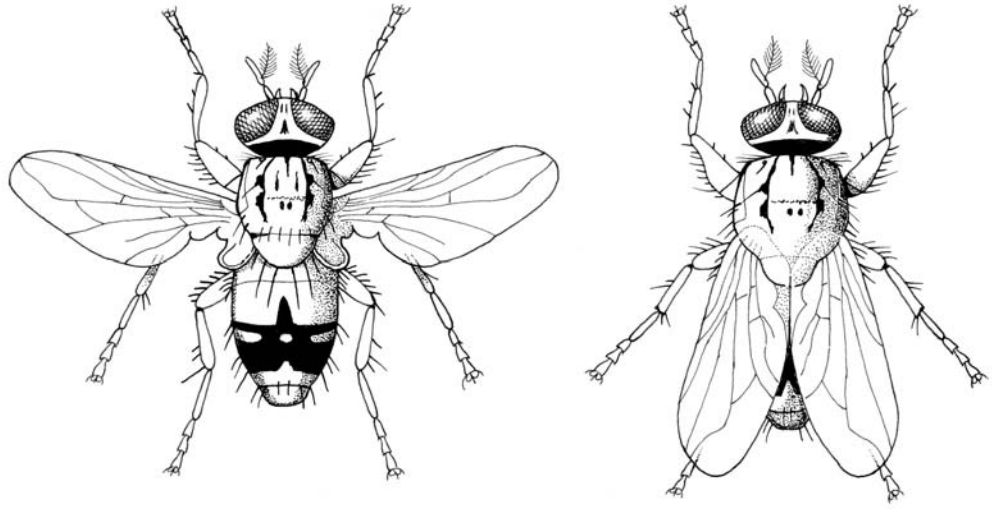
Genus of schistosomatid trematodes, →Digenea.

Austroconops

Genus of →Ceratopogonidae. The only species of this genus (*A. macmillanii*) bites during daytime in Western Australian humans and animals.

Austrosimulium

Genus of blood-sucking simuliid Nematocera in Australia and New Zealand, vectors of onchocerciasis (e.g., *Onchocerca* of cattle).



Auchmeromyia. Figure 2 *Auchmeromyia senegalenis*; adult fly with folded and unfolded wings.

Autochthony

Name derives from the Greek terms *chtono* = place and *autos* = self. It means that a plant/animal/parasite develops at a given place since long and has not been imported recently from another region. For example, the tick *Ixodes ricinus* is autochthonous in Germany, *Dermacentor reticulatus* is allochthonous (→Allochthony).

Autocid Method

→Sterile Male Technique.

Autoclavation

→Sterilization of equipment by hot steam at 121 °C.

Autogamy

Fusion of gametes originating from one individual (e.g., in *Taenia* – tapeworms).

Autogeny

Egg production in some female →Culicidae (e.g., genus *Toxorhynchites*) without preceding blood meal.

Autoimmunity

→Chagas' Disease, Man/Immune Responses.

Autoinfection

Reinfection of the same host, within which the parasite had grown up. →*Cryptosporidium* Species, →*Strongyloides*, →Hymenolepidae, →*Taenia solium*, →*Enterobius vermicularis*.

Autolysosome

Type of secondary →lysosome which is involved in the disintegration of cellular waste material, thus providing the function of disposal of debris.

Avarita

Subgenus of the genus →*Culicoides*, e.g., with the species *C. imicola* and *C. brevitarsis*, *C. actoni, C. obsoletus*, which are all proven vectors of bluetongue virus.

Avermectines

→Nematocidal Drugs, →Arthropodicidal Drugs.

Avian Spirochaetosis

Disease due to spirochaetan bacteria transmitted by the bite of →*Argas* →ticks (→Tick Bites: Effects in Animals).

Avicenna

Abu Ali El-Hosein Ben Abdullah Ibn Sina (870–1037), Arabian physician and philosopher. His famous books *Canon medicinae* and *De animalibus* describe diseases of humans, respectively of animals. He is honoured by the French name "Fil d'Avicenne" for →*Dracunculus medinensis*.

Avioserpens

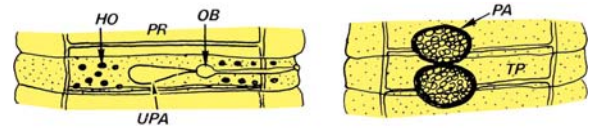
Genus of dracunculid nematodes.

Avitellina

Genus of →Eucestoda.

Morphology

Fig. 1.



Avitellina. Figure 1 Diagrammatic representations of young (left) and terminal proglottids (TP) of *Avitellina* sp.; *HO*, testis; *OB*, oogenotop; *PA*, paruterine organ; *PR*, cross running excretory channel; *TP*, terminal proglottis; *UPA*, anlagen of PA.

AVL

American visceral →leishmaniasis.

Avoidance of Parasitized Prey

→Behavior.

Axenic Cultures

In vitro cultures of parasites without addition of any feeder cells (Greek: *a* = not, *xenos* = foreign).

Axon

Efferent protrusion of a nerve cell, see →Platyhelminthes/Nervous System.

Axoneme

Microtubular elements inside flagellum or running through the →cytoplasm, e.g., of →Giardia and →*Trypanosoma* stages.

Axostylata

New phylum of protozoans comprising the class is Parabasalea with the families Trichomonadidae (→*Trichomonas*) and Monocercomonadidae (→*Histomonas*).

Axostyle

Element for stabilization consisting of one or more rows of mictrotubuli (e.g., →*Trichomonas*, →Oxymonadida).

Azamethiphos

Chemical Class

Organophosphorous compounds (monothiophosphate).

Mode of Action

Acetylcholine esterase inhibitor. →Ectoparasiticides – Agonists and Antagonists of Cholinergic Transmission.

Azanidazole

→Antidiarrhoeal and antitrichomoniasis drugs = agents against protozoal diseases.

Azathioprine

→Trypanocidal Drugs.

Azithromycin

Agent against protozoal diseases.

Azygia lucii

Trematode in the oesophagus and stomach of fresh water fish (5.5 cm × 1–5 mm), miracidium without cilia; intermediate hosts are *Lymnaea*-snails.

Babès, Victor (1854–1926)

Rumanian pathologist, 1888 discoverer of →*Babesia* spp.

Babesia

Classification
Genus of →Piroplasms (Alveolata, Apicomplexa).

General Information
The tickborne protozoans of the genus *Babesia* are unpigmented protozoans that multiply in the red blood cells of many vertebrate hosts. Several species of *Babesia* give rise to natural infections in humans, cattle, other domestic animals, and field mice, on which one stage of the ixodid →tick normally feeds.

Important Species
Table 1 (page 144).

Life Cycle
Fig. 1 (page 145).

Morphology
→Pellicle/Fig. 1; Figs. 2, 3 (page 146).

Reproduction
→Gametes/Fig. 5, →Cell Multiplication.

Disease
→Babesiacidal Drugs, →Babesiosis, Animals, →Babesiosis, Man, →Texas Fever, →Tick Fever.

Babesiacidal Drugs

See Table 1 (page 147–149).

Economic Importance
Members of the genus →*Babesia* occur throughout the world and may cause a wide range of clinical syndromes in most domestic animals and humans due to differences in virulence within each *Babesia* species. They are transmitted by hard →ticks (→Ixodidae) during blood meals, and may produce diseases in their hosts, which are characterized by an acute febrile reaction, jaundice, hemolytic anemia, hemoglobinuria, and variable mortality. The babesiosis is of major economic importance in cattle because the majority of about 1.2 billion cattle in the world are potentially exposed to *Babesia* spp. because of the extensive husbandry methods employed in raising these animals. *Babesia* spp. infections may also occur by the frequent introduction of *Babesia*-free animals into *Babesia*-enzootic areas, and by introduction of tick vectors and *Babesia* spp. into clean zones. The greatest economic loss is due to *Babesia* spp. infections in cattle, particularly in the USA, Australia (State of Queensland), South Africa, and South America. Indigenous animals are normally protected from babesiosis in early life by premunition resulting from continuous reinfection. In regions with enzootic stability babesiasis is not a disease problem, and control measures are not necessary. In these zones calves are still protected by maternal antibodies which they had received through the colostrum. Subsequently the animals remain carriers by repeated natural infections.

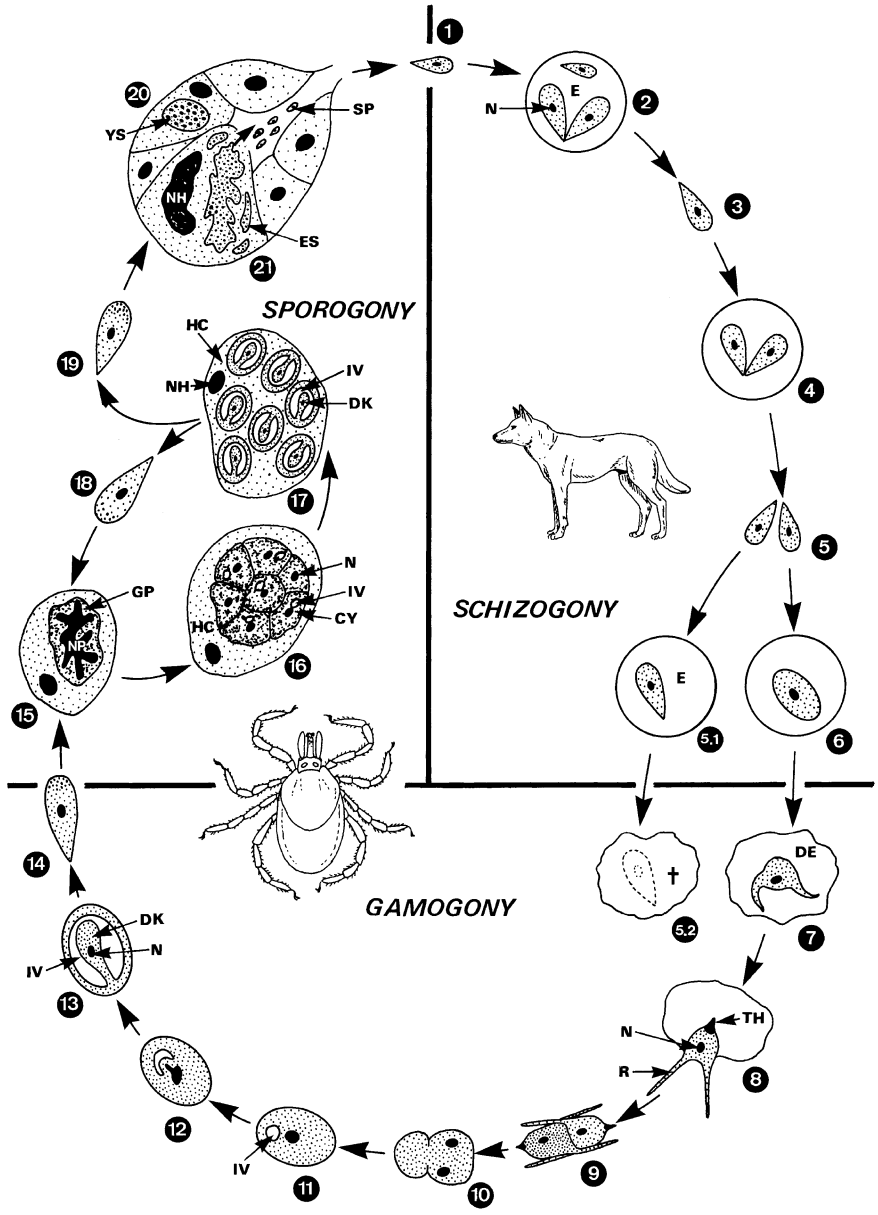
Epizootiology and Enzootic Stability of Bovine Babesiasis
The idea of maintaining enzootic stability is to allow limited challenge of the parasite and the tick to cattle without producing disease or loss of production. The immune status of a herd can be monitored serologically, and in cases where more than 50% of cattle show no antibabesial serum titres the whole herd should be vaccinated. Thus, the efficient application of vaccination procedures depends considerably on the →epizootiology of babesiasis, and involves knowledge of the complex interaction of the host, *Babesia* parasite, and vector. The aim of premunization [see Premunization and Use of Antibabesial Drugs (Chemoimmunization)] or immunization with live blood-derived vaccines of attenuated strains of *B. bovis* and *B. bigemina* is to maintain herd

Babesia. Table 1 Important species of the genus *Babesia*

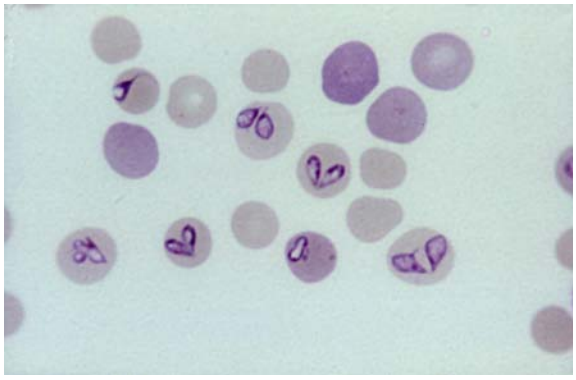
Species	Vector		Vertebrate host	Size in erythrocytes (μm)	Geographic distribution
	Species	Stage			
Significant large *Babesia* species					
B. bigemina	*Boophilus* spp.	Nymphs, adults	Cattle, water buffaloe, wild ruminants	5 × 2	Southern Europe, America, Africa, Asia, Australia
B. bovis	*Boophilus* spp., *Ixodes* spp., *Rhipicephalus bursa*	Larvae	Cattle, water buffaloe, wild ruminants	2.5 × 1.5	Southern Europe, America, Africa, Asia, Australia
B. divergens	*Ixodes ricinus*	Larvae	Cattle, wild ruminants, **humans**	1.5 × 0.5	Europe
B. major	*Haemaphysalis punctata*	Adults	Cattle	3 × 1.5	Western and Southern Europe, Great Britain, Northwestern Africa
B. motasi	*Haemaphysalis* spp., *Rhipicephalus bursa*	Adults	Sheep, goats	4 × 2.5	Southern Europe, Middle East, Southern Russia, Africa, Asia
B. ovis	*Rhipicephalus bursa*	Adults	Sheep, goats	2 × 1	Southern Europe, Middle East, Southern Russia, Africa, Asia
B. caballi[2]	*Hyalomma* spp., *Dermacentor* spp., *Rhipicephalus* spp.	Adults	Horses, mules, donkeys, *Equus burchelli*	4 × 2.5	Europe, Asia, Africa, America, Australia
B. canis[1]	*Rhipicephalus sanguineus, Haemaphysalis leachi, Dermacentor reticulatus*	Nymphs, adults	Dogs, other wild canines, fox	5 × 2.5	Europe, Asia, Africa, America, Australia
B. trautmanni	*Rhipicephalus* spp.	?	Pigs	4 × 2.5	Southern Europe, Africa
B. herpailuri	?	?	*Felis sylvestris*	3 × 2.2	Southern America
B. pantherae	?	?	*F. sylvestris, Panthera leo*	2.5 × 1.5	Africa
Small *Babesia* species of doubtful systematic position[2]					
B. (syn. *Microbabesia*) *gibsoni*	*Haemaphysalis bispinosa, Rhipicephalus sanguineus*	All stages	Canidae including dogs, fox, and other wild canines	1.2–2.1	Asia, Africa, India, Japan
B. microti group	*Dermacentor* spp., *Rhipicephalus* spp., *Ixodes* spp.	Larvae to nymphs	Rodents, **humans**	1.5–2	Europe, North America
B. felis (syn. *Achromaticus felis*)	*Haemaphysalis leachi*	?	Felidae including *Panthera leo, Felis sylvestris*	1.5–2	Africa
B. (syn. *Achromaticus*) *rodhaini* = *B. quadrigemina*	?	?	Mice	1.5–2	Europe

[1] *Babesia canis* is now subdivided into 3 subspecies: *B. canis canis* (in Europe; transmitted by *Dermacentor reticulatus*), *B. canis vogeli* (transmitted by *Rhipicephalus sanguineus* in the tropics and the subtropics), and *B. canis rossi* (very pathogenous in South Africa; transmitted by *Haemaphysalis leachi*)

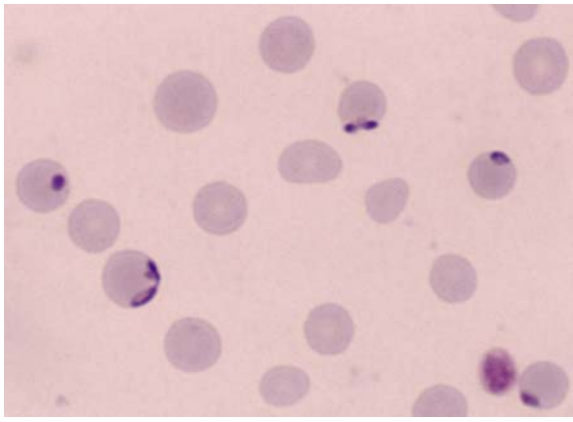
[2] *B. equi* of horses was transferred to the theilerians



Babesia. Figure 1 Life cycle of *Babesia canis* (for other species see Table 1). *1* Sporozoites in saliva of feeding tick. *2–5* Asexual reproduction in erythrocytes of vertebrate host (dog) by →binary fission, producing merozoites (**5**) which enter other erythrocytes. When merozoites are ingested by a tick (**5.1**), they become digested inside the gut (**5.2**). *6* Some merozoites become ovoid gamonts. *7, 8* After ingestion into the tick's intestinal cells the ovoid gamonts form protrusions and thus appear as →ray-bodies (**8**). Fusion of 2 uninucleate ray-bodies (gametes). *10* Formation of a →zygote. *11–14* Formation of a single →kinete from a zygote inside the inner vacuole. The kinete leaves the intestinal cell and enters cells of various organs (including the eggs) of the vector ticks. *15–18* Formation of several kinetes (sporokinetes). This process is repeated (**15–18**) and also proceeds in eggs of ticks. The infection is thus transmitted to the next generation of ticks (i.e., transovarial transmission). *19–21* Some of the kinetes penetrate cells of the salivary glands, where a large multinuclear sporont (YS, ES) is formed (inside hypertrophic host cells) finally giving rise to thousands of small sporozoites (SP), which are injected during the feeding act (i.e., →transstadial transmission). *CY*, →cytomere (uninucleate); *DE*, digested erythrocyte; *DK*, developing kinete; *E*, erythrocyte; *ES*, enlarged sporont (forming sporozoites); *GP*, growing parasite (polymorphic stage); *HC*, nucleus of host cell; *IV*, inner vacuole; *N*, nucleus; *NH*, nucleus of host cell; *R*, ray-like protrusion; *SP*, →sporozoite; *T*, thorn-like apial structure; *YS*, young sporont.



Babesia. Figure 2 Bloodsmear of dog showing *Babesia canis* stages (type of large babesias).



Babesia. Figure 3 Bloodsmear of a jird showing *Babesia divergens* stages at the periphery of red blood cells (type of small babesias).

immunity, and thus the balance between host and vector. In various countries the idea of reestablishing areas of enzootic stability has strongly been supported, particularly after the introduction of "tick-resistant" cattle, and the occurrence of increasing failures of chemical control measures.

Strategic Tick Control in Areas with Enzootic Instability of Babesiasis

Attempts at controlling babesiasis in districts with enzootic instability (i.e., where less than 90% of cattle show premunition) can be directed against the tick vector (for more details see control of →ticks, and application techniques). There are one-host ticks (e.g., →*Boophilus* spp.), two-host ticks, and three-host ticks (e.g., →*Rhipicephalus* spp., →*Haemaphysalis* spp.; *Ixodes ricinus*) which can be controlled by aggressive or strategic dipping (this latter method may involve three dippings in the dry season and is used for example in Australia) plus pasture improvement and/or pasture spelling at intervals of 8–10 weeks in summer or early autumn. Aggressive dipping is still imperative in areas where, in addition to babesiosis, →East Coast Fever, heart water due to *Cowdria ruminantium* infection, and →anaplasmosis (*Anaplasma centrale* and *A. marginale*) occur. This method involves acaricide administration at regular intervals, either throughout the year or during tick seasons, with the aim of eliminating the tick vector. The application of acaricide can be done in any of three ways. These may be (1) a plunge bath, communal dip, or dip on large farms; (2) a spray-race (system of pipes fitted with spraying nozzles) on large farms, or (3) a hand-spraying system consisting of a large water container and a hand-pump or small motor-pump. The strategic dipping system, i.e., administration of an acaricide at certain time intervals, may lead to temporarily unstable situations since transmission of *Babesia* spp. and *Anaplasma* spp. is not completely interrupted; in this case an additional vaccination against both organisms is advisable.

Tick Control in Livestock to Prevent Babesiosis

Today, the only conventional control measure against argasid and ixodid ticks is the use of acaricides for animals at risk. Pesticides belong to different chemical groups such as chlorinated hydrocarbons, organophosphates, carbamates, diamidines, synthetic pyrethroids, and avermectins. Drugs of these groups have different mode and site of actions. For instance the growth regulator **fluazuron** inhibits the →chitin formation in ticks. Its effect results in reduced production of viable eggs in engorged females and may reduce pasture contamination.

Acaricidal control of vectors to protect animals from disease has been applied in many countries although with only limited success, as ticks rapidly developed resistance to pesticides and acaricides (→Ectoparasitocidal Drugs, →Arthropodicidal Drugs). However, acaricide treatment continues to be necessary although drug tolerance of ticks to most agents, except the macrolytic lactones, is common. In the field, there may occur tremendous economic losses due to breakdown of dipping systems in various regions, the increasing cost of acaricides often beyond the means of many farmers, and the lack of veterinary infrastructure in many countries have made the eradication of tick vectors impossible.

Closantel used for the control of helminthic infections (→Nematocidal Drugs, Animals, →Trematodocidal Drugs) of sheep and cattle, and larval stages of nasal bot fly (→*Oestrus ovis*) of sheep has been shown to have a marked effect also on →fecundity and egg viability of ticks. The strongly plasma-bound drug is ingested by ticks while feeding and probably affects their mitochondrial energy production by inhibiting oxidative phosphorylization and thereby adenosin triphosphate synthesis. Thus closantel may play a role in tick control

Babesiacidal Drugs. Table 1 Babesiacidal drugs used in domestic animals

Chemical group (approx. dose, mg/kg b.w., route, animal)	**Nonproprietary name**, *brand name (company, manufacturer)	**Characteristics** and miscellaneous comments
AZO-NAPHTHALENE DYES		
(cattle, 2–3, i.v.; dog, 10, 1% solution, i.v.) [a]1909	**Trypan blue** (syn. Congo blue, Niagara blue) *Trypan Blue SS (Centauer Lab., S.-Africa): discontinued	first specific drug with activity against *B. bigemina* and other large species; i.v. application leads to blue staining of meat, body secretions and milk (today, largely replaced by diamidines); discoloration of mucous membranes and plasma interferes with clinical and laboratory parameters; there are severe local reactions after extravascular injection; drug can be used in treating *B. canis* infection in dog but relapse may occur; diminazene may sterilize infection.
ACRIDINE DERIVATIVES		
(cattle, 4.4 ml/100 kg, 5% solution, i.v.) [a]1919	*Acriflavine HCl *Euflavine HCl *Gonacrine HCl (Merial, others) (no longer in use as antibabesial drugs)	is active against *B. bigemina* and other large *Babesia* spp.; like trypan blue, it proves less effective against *B. bovis*; i.v. administration limits its use under field conditions; drug is relatively well tolerated at recommended dose; discoloration of tissues is less pronounced than that caused by trypan blue.
Urea derivatives (quinolone derivative) (cattle, 1–2 ml/100 kg, 5% Acaprin solution, 1–2 injections, 24 h interval, s.c; dogs, 0.25 ml/5 kg, 0.5% Acaprin solution, s.c.) [a]1935	**Quinuronium** sulfate *Acaprin (Bayer) *Ludobal (Bayer) *Babesan *Akiron, Pirevan, Piroplasmin, and others (various manufacturers in India and China)	for many years the drug of choice in treating bovine babesiosis (*B. bigemina, B. bovis, B. divergens*); it is active against large *Babesia* spp. of swine, horse, and dog; drug has a low therapeutic index and may stimulate parasympathetic nervous system (excessive salivation, frequent urination, or dyspnea caused by anticholinesterase activity; antidotes are atropine or epinephrine; in fatal cases volvulus of jejunum has been observed, which may result from hyperperistalsis); its mode of action is uncertain; action of drug on *B. felis* see text.
DIAMIDINES		
Carbanilides (cattle, 5–10, i.m.; horses 8, i.m.) [a]1964	**Amicarbalide** diisethionate *Diampron (Merial)	is effective against *B. bigemina, B. caballi, B. motasi* but there are differences in efficacy against large *Babesia* spp.; its effect on small *Babesia* spp. is less pronounced (clinical remission only).
(cattle, 1.2–2.4, s.c; horse, 2–2.4, i.m.; 2 injections, 24 h interval; dog 5–6, i.m. 1–2 injections, 24 h interval) [a]1969	**Imidocarb** diproprionate *Imizol, *Carbesia (Schering-Plough AH) *Forray-65 (Bayer, SA)	is effective in preventing and treating bovine babesiosis without interfering with development of immunity; protection period may last for several weeks depending on dose used; drug shows efficacy against *B. canis* infections, and equine babesiosis. Fine-structural alterations of *B. herpailuri* in cats treated with the drug were less pronounced and resulted in widening of subpellicular endoplasmic reticulum and perinuclear; drug is very slowly eliminated; bile is an important route of excretion; there is a long preslaughter withdrawal period (cattle; sheep) for edible tissues and milk of approx. 90 days and 21 days, respectively; data on toxicity are somewhat erratic; there is a wide range of individual animal tolerance to the drug; side effects are due to anticholinesterase activity, and fatal toxicosis is usually associated with renal disorder (necrosis), edema, hydrothorax, hydroperitoneum, and pulmonary congestion; mortality in equines (which can occur at 4 mg/kg or higher doses) is attributed to acute tubular renal necrosis; mechanism of drug action is known (possibly interferes with nucleic acid synthesis, see diminazene ↓); excess of polyamines (e.g., spermidine) can nullify trypanocidal activity of imidocarb and amicarbalide; the diamidine imidocarb also proved active against *Trypanosoma brucei* mouse infection, and *Anaplasma marginale* infection in cattle at 3 mg/kg b.w. (elimination of parasites is not achieved).

Babesiacidal Drugs. Table 1 Babesiacidal drugs used in domestic animals (Continued)

Chemical group (approx. dose, mg/kg b.w., route, animal)	**Nonproprietary name**, *brand name (company, manufacturer)	**Characteristics** and miscellaneous comments
AROMATIC DIAMIDINES		
(dog, 5–10, i.m., 15, s.c. 1–2 injections, 24 h (48 h: s.c.) interval; horse, 8, i.m., 1–2 injections, 24 h interval) [a]1939	**Phenamidine** diisethionate *Lomidine (Merial) *Oxopirvedine (Merieux) *Phenamidine (Virbac, SA)	is used mainly in treating canine and equine babesiosis; it has also been used successfully in *B. bigemina* infections; frequent relapses may occur in *B. gibsoni* infections in dogs; drug can be used for eradicating carrier infections in horses; side effects of drug are similar to those noticed with pentamidine; it is well tolerated at recommended dose although s.c. injections may lead to moderate swelling (necrosis, mainly in horses); drug may cause transient immunosuppression in dogs; mechanism of drug action is uncertain but may be similar to that of pentamidine and diminazene (→Trypanocidal Drugs, Animals).
(experimental drug, approved for use in humans only; cattle, 1–5, s.c. [a]1939	**Pentamidine** diisethionate *Lomidine (Merial)	is reported to be effective against *B. bigemina* allowing carrier state to persist in chemoimmunization (see text); drug is active against *B. canis* and *B. gibsoni* infections in dogs; relapses occurred with *B. gibsoni* at 16.5 mg/kg i.m.; common side effects are vomiting (dogs), nausea, hypotension, tachycardia, and pain at injection site; it may affect *B. microti* infections in man (see text); pentamidine is highly active in treating early stage of *T. b. gambiense* infection in man (→Trypanocidal Drugs, Man).
[3] (3.5, i.m., cattle, horse) [a]1955	**Diminazene** aceturate [3c]*Berenil (Intervet), not recommended for use in dog *Ganaseg (Novartis, Brasil and elsewhere)	is highly active against bovine, ovine, porcine, equine, and canine babesiosis; small *Babesia* spp. are generally more refractory to treatment than large ones; it can be used in chemoimmunization programs, moderating clinical signs and allowing development of premunition (see text); there are various treatment regimens for eliminating babesiosis in cattle, horses, and dogs: in most cases recommended dose has been varied, e.g., 5 mg/kg, twice in 24 h interval to eradicate *Babesia* spp. infections in horses, or 1.75 mg/kg twice in 24 h interval to reduce or avoid neurotoxic side effects in dogs (e.g., ataxia, opisthotonus, nystagmus, extensor rigidity, coma, and even death); however, there seems to be a wide range of individual animal tolerance to the drug; it is well tolerated in equines at recommended dose, but higher doses may cause severe side effects; in camels there may be mortality at recommended dose but ruminants tolerate the drug at higher doses (7–10 mg/kg); preslaughter withdrawal period (cattle; sheep) for edible tissues and milk is at least 21 days and 3 days, respectively; diminazene was shown to be active against *B. microti* infections in humans (see text); for its activity against African trypanosomes in animals and humans see →Trypanocidal Drugs, Animals and →Trypanocidal Drugs, Man, respectively.
8-AMINO-QUINOLINES		
(experimental drug approved for use in humans only)	**Primaquine** diphosphate *Primaquine (Bayer) *Neo-Quipenyl *Neo-Plasmochin, others	is active against *B. felis* (base 0.5 mg/kg, i.m., or p.o. repeated doses well tolerated); maximum tolerated dose of base was 1 mg/kg, higher doses caused mortality; standard antibabesial drugs proved ineffective against *B. felis*; for its action on exoerythrocytic stages of *P. vivax* see →Malariacidal Drugs (Malaria antirelapse drug).

Babesiacidal Drugs. Table 1 Babesiacidal drugs used in domestic animals (Continued)

Chemical group (approx. dose, mg/kg b.w., route, animal)	**Nonproprietary name**, *brand name (company, manufacturer)	**Characteristics** and miscellaneous comments
TETRACYCLINES		
(long-acting preparation)	**Oxytetracycline** *Terramycin, LA (Pfizer AH)	*B. divergens* field infections in cattle could be controlled by continuous administration of 20 mg/kg every 4 days during natural exposure on grazing heavily infested with *Ixodes ricinus*; no parasites were seen in treated cattle in comparison with untreated animals which developed a patent parasitemia; the antibiotic seems to be useful in chemoimmunization (see text) against bovine babesiosis allowing development of premunition.
TETRACYCLINES		
	Chlortetracycline *Aureomycin, others (many manufacturers)	was shown to control parasitemia in the early course of *B. equi* infection; antibabesial activity was demonstrated by six daily injections of 0.5, 2.5, and 2.6 mg/kg; the antibiotic proved active against *T. parva* (→Theileriacidal Drugs)
MACROLIDE ANTIBIOTICS		
	Clindamycin (Pfizer, others) in combination with **vancomycin** HCl (glycopolypeptide) (Eli Lilly, others) (approved drugs, but considered investigational for this condition)	single drug, and clindamycin + quinine were shown to be effective in treating experimental *B. microti* infection in hamsters; clindamycin/vancomycin combination has successfully been used in eradicating parasitemia and bringing about remission of *B. microti* infections in humans; for more details on standard therapy of human babesiosis see text; side effects caused by clindamycin may be allergic reactions, diarrhea (enterocolitis), hepatotoxicity, occasionally hypotension, ECG changes; vancomycin may reduce antibiotic-associated colitis
HYDROXYNAPHTHOQUINONES		
	Parvaquone *Clexon (experimental drug)	antitheilerial drugs (→Theileriacidal Drugs) had shown some efficacy against *B. equi* (belongs to small *Babesia* spp.) in horses; for more details on *Theileria*-like characteristics of small babesias see text; in splenectomised horses given at 5 mg/kg b.w. 4 times at 48 h intervals the parasitemia was eliminated.

Doses listed refer to recommended dose of the manufacturer and/or to literature and websites on the subject

[a] First practical (commercial) application (approx. year)

Data given in the table have no claim to full information

strategies, due to its effect on tick reproductive cycle being greatest at time of dosing. Current alternative control measures and their effective use in the field are still of minor importance. →Biological control of ticks with living antagonists distributed by man to lower pest (parasite) populations may lead to their reduction and so to acceptable subclinical densities. In the field, however, the use of biological agents as formulations (products) of viruses, bacteria, fungus, protozoans (e.g., →microsporidia), →nematodes, and insects, or →pheromones, are very much limited and less promising in their effects today. A more successful control measure against widely distributed *Boophilus* spp. and other tick species seems to be the immunization of cattle with recently developed antitick vaccines. The antigens of interest against ticks are native or recombinant proteins located in the gut cells' plasmatic membrane. They are called "novel, concealed, or occult antigens" causing lesions in the tick's intestine, thereby, reducing the fecundity of ticks. Other putative antigens seem to be located in cells of the salivary glands preventing feeding of the ticks and thus depressing their fertility.

Control of Babesiosis by Various Application Techniques of Acaricides

Acaricides can be applied to animals by different application techniques. When treating animals for external parasites it is important that agents not absorbed through the skin, or from the digestive tract, or parenteral injection be so applied that contact with the parasite will occur. Dips and sprays generally are suited for treating

most animals (especially herds) except when temperatures are below freezing or extremely thirsty animals are to be treated. Systemic drugs, usually the organophosphates and macrocyclic lactones (ivermectin, moxidectin, doramectin, and eprinomectin) are applied as pour-ons, spot-ons, injectables, sprays, and feed additives, or via dipping vats (tanks). These agents gain access to the host circulatory system and are then distributed throughout the body. **Dipping** probably offers the best means and most cost-effective method of tick control for cattle in tropical areas, and for dogs (is less frequently used for cats). Dipping with acaricides has the advantage of thorough coverage of the skin, coat, and head of cattle (if deep tanks are used). When using such agents caution must be exercised to prevent contaminating humans and their food supply and environment.

Premunization and Use of Antibabesial Drugs (Chemoimmunization)

Bovines of an enzootic area commonly acquire a so-called infection-immunity or **premunition** against babesiosis in the first six months of life. As a result, most of the cattle of enzootic areas are carriers of a few parasites and will therefore develop a certain degree of protective immunity against local *Babesia* strains without showing signs of disease. In contrast, elimination of the infection by curative agents is soon followed by loss of resistance to the parasite in most hosts. Cattle introduced from areas free of babesia or with parasites of different antigenic strains, may acquire babesiosis and die. **Premunization** (artificial induction of premunition) has allowed the introduction of quality cattle into enzootic areas of Australia, USA, Latin America, and elsewhere. Animals introduced are injected with blood from babesia carriers and monitored for the presence of fever and parasitemia. Soon after clinical signs are apparent, animals are treated with subcurative doses of diminazene aceturate or imidocarb dipropionate (Table 1), thereby killing enough parasites to prevent an outbreak of disease but allowing some surviving parasites to induce protective immunity to natural challenges in hosts. Animals can be injected simultaneously with a standardized dose (several million organisms of each species per animal) of *B. bigemina, B. bovis*, and *Anaplasma marginale* (*Rickettsia* species) derived from blood of donor bovines often splenectomized. They are then treated well timed with Imidocarb or with long-acting tetracyclines, which are active against both *Babesia* and *Anaplasma*. Premunization has several drawbacks. The main obstacles, like the occurrence of hemolytic disease in newborn calves (antibodies against erythrocyteisoantigens), transmission of other blood-borne pathogens (e.g., leukosis virus), or storage and transportation problems of the '**vaccines**', have largely been overcome but some problems remain. Thus premunization prevents eradication of the parasites, may cause economic losses (outbreak of disease or occurrence of mortality in herds), may induce a variable resistance status in cattle, and is expensive. On the other hand there may be some advantages concerning premunization. Thus its application is still needed in large enzootic areas because refinements to the system of immunization with attenuated parasites are not yet satisfactory with regard to tolerability of vaccines. Occasionally there are adverse effects such as →abortion, hemolytic neonatal disease, or induction of severe babesiosis. The safety of blood derived vaccines is not always guaranteed and transmission of other hematogenous infections cannot be absolutely excluded. This may also be true for the stability of vaccines. They may fail to induce strong herd immunity because of instability of vaccinal parasites or changes in selection of field strains, or prolongation of vaccine shelf life beyond expiration date. Intolerability of vaccines may be shock and disturbances of the blood-clotting mechanisms, and calcium balance.

Chemotherapy of Babesiosis in Animals

The elimination of babesias (Table 1) in cattle or horses may play an important role for those animals which have a low-grade infection premunition. In these cases it must be guaranteed that carrier animals are free from infection before being imported into *Babesia*-free areas. However, when drugs are used therapeutically in endemic regions the aim is to promote clinical recovery only, and to allow some parasites to survive, reestablishing premunition. Thus, instead of the chemoimmunization programs (see Premunization and Use of Antibabesial Drugs) that are used in districts with enzootic stability or instability, in countries where babesias are rare the so-called diagnosis-treatment method is employed. There are several drugs in use, all of which are "oldtimers" and are more or less afflicted with adverse effects involving long withdrawal periods for meat and other edible tissues. Drugs commonly used in treating acute ovine or porcine babesiosis are quinuronium sulfate, imidocarb, and diminazene, which have sufficient efficacy against clinical attacks. Infections with *Babesia* spp. in sheep, goat, and swine must be treated with somewhat higher doses than those normally recommended in cattle. Repeated administration of drugs may be necessary to cure *B. ovis* infections (for details regarding activity and toxicity of antibabesial drugs see Table 1, →Trypanocidal Drugs, Animals; for pharmacokinetics of diminazene diaceturate and ethidium bromide see →Trypanocidal Drugs, Animals/Pharmacokinetics of Trypanocides and Chemical Residues in Edible Tissues and Milk). The effect of an antibabesial drug may vary and can be modified by the

severity of the disease, the dosage used, the timing of treatment in the course of infection, and the length of time that the drug is present to affect the parasite. As a rule, large *Babesia* spp. are distinctly more susceptible to chemotherapeutic agents than are the small ones. In general, small babesia respond variably to antibabesial drugs. **Sterilization of infection**, i.e., complete elimination of parasites, is usually not achieved with small *Babesia* spp. possibly due to adherence of parasites to capillary walls and consequent obstruction of blood flow. There may be differences in relation and metabolism between small and large *Babesia* spp., and as a result the target and biochemical mode of action of drugs differ. Recovery of ill animals can be achieved if specific and effective treatment is given prior to the onset of severe anemia or disorders of the nervous system, i.e., in the early course of infection. Prognosis is poor for those animals already showing cerebral signs; these are caused by clumps of parasitized erythrocytes blocking capillary blood vessels of cerebral cortex. In severe cases the aim of supportive treatment (e.g., blood transfusion, fluid therapy) is to reduce the occurrence of shock and disturbances of the blood-clotting mechanisms and calcium balance.

Elimination of Babesia in Horses

Equine babesiasis is widespread; severe clinical disease and mortality may occur occasionally. Therefore, the elimination of carrier infection in horses being shipped from endemic zones to *Babesia*-free areas gains increasing importance. Various drugs may be used for clearing *Babesia caballi* infections. Amicarbalide (8.8 mg/kg b.w., × 2, 24 h interval), imidocarb (1–2 mg/kg b.w., × 2, 24 h interval), diminazene (5 mg/kg b.w., × 2, 24 h interval), and phenamidine (8.8 mg/kg b.w., × 2, 24 h interval) may show sufficient action. *B. equi* (small species) has recently been transferred to the genus →*Theileria* (see also Table 1: parvaquone).

Elimination of Babesia in Dogs and Cats

Canine babesiosis is becoming increasingly widespread in the USA, Europe, Africa (*B. canis*), and Asia (*B. gibsoni*). The disease can be treated with a few antibabesial drugs causing more or less toxic side effects, such as diminazene (which is not recommended for use in dogs by the manufacturer, Table 1), imidocarb, amicarbalide, phenamidine, and trypan blue. *B. canis* may cause uncomplicated infections (fever, depression, acute hemolysis with a mild to severe anemia, pale mucous membranes, and splenomegaly), or complicated ones (coagulopathy, hepatopathy, immune-mediated hemolytic anemia, renal failure, cerebral signs, pulmonary →edema, and shock). The specific therapy (if started too late, or in case of complicated infection per se) must be combined with supportive treatment (fluid infusion followed by blood transfusion, liver protectants, diuretics, vitamin B complexes, prednisolone). In general, drugs are distinctly less active against *B. gibsoni* than against *B. canis*. Relapses in *B. gibsoni* infections are common, and may also occur after administering markedly higher doses than those recommended. Thus, diminazene in doses of 7–10 mg/kg b.w. only suppresses parasitemia, but these doses and even lower ones may cause severe side effects and occasionally mortality in dogs (Raether unpublished). *B. felis* infection, which may cause anemia and icterus in the domestic cat, has been reported to respond to trypan blue and quinuronium. These results are inconsistent with those of Potgieter who found that all known antibabesial drugs failed to affect *B. felis*; successful treatment was achieved in using primaquine diphosphate. Concerning differential diagnosis of feline babesiosis →*Cytauxzoon felis* infection (*Theileria* species) should be considered; it may occur in North America and parasitize lymphocytes and erythrocytes of cats.

Chemoprophylaxis of Babesiasis in Animals

The aim of →chemoprophylaxis is to protect susceptible animals from clinical signs of babesiosis caused by natural tick infection, or to moderate the clinical course of infection in immunization programs (see Premunization and Use of Babesiacidal Drugs). The administration of drugs like **diminazene, imidocarb**, or **oxytetracycline** (Table 1) should allow the development of premunition. Imidocarb, which exhibits a fairly long effect on *Babesia* spp. in cattle (4–12 weeks at 2 mg/kg b.w., depending on *Babesia* species, and infection pressure), can also be used for short-term protection of susceptible animals after their introduction into *Babesia*-infected areas.

A single subcutaneous dose of 2.4 mg/kg b.w. **imidocarb** may protect dogs from *B. canis* infections for about 4 weeks. However, controversy exists concerning the duration of its prophylactic efficacy. So in Beagle dogs experimentally infected with *B. canis* (merozoites), a single dose of 6 mg/kg b.w. resulted in a 2-week protection period only. In enzootic *Babesia* areas, dogs can also be protected by long acting acaricides applied in 4-day-intervals, or by application of inactivated vaccines (e.g., Pirodog®). Although these vaccines allow *Babesia* infections under high infection pressure they may prevent infected dogs from mortality.

Resistance

Although →malaria and babesiosis have many similarities, and their causative agents are related, resistance of Babesia and malaria parasites to drugs differs markedly. While resistance of *P. falciparum* to drugs has probably become the most important threat to effective →control of malaria, drug resistance in large

Babesia spp. seems to be a minor problem in the chemotherapy of babesiosis. Resistance to babesiacidal drugs can be induced experimentally. Thus *in vitro* micro-titres tests (96-well flat-bottom plates) may be used to assess drug responsiveness of *B. bovis* or *B. bigemina* to various antibabesial compounds, thereby selecting drug-adapted lines by the presence of sub-inhibitory drug concentrations. Under field conditions drug resistance in *Babesia* spp. may emerge if drugs are used prophylactically or in chemoimmunization programs. Using such dose regimes it is likely that subtherapeutic, low concentrations of the drug are in temporary or permanent contact with the parasites, thereby causing selection of drug-resistant organisms. However, it must be emphasized that the innate poor response of small *Babesia* spp. (e.g., *B. bovis, B. ovis, B. gibsoni, B. felis, B. microti*) to antibabesial drugs should be distinguished from an acquired drug resistance occasionally occurring in large babesias. Compared to the greater drug sensitivity of large *Babesia* spp., the varied action of drugs against small forms (→"Natural Resistance") may well be connected with differences in their relation. Small species undergoing →schizogony in lymphocytes (e.g., *B. microti*) appear in their fine structure very similar to *Theileria* spp. Molecular analyses of the small subunit ribosomal RNA genes (rDNA) suggest that small *Babesia* spp. may have a close relation to *Theileria* spp. There were a number of reasons why *B. equi* was transferred to the genus *Theileria*.

Chemotherapy of Human Babesiosis

Since the first description of human babesiosis in 1957 in a splenectomized patient in Yugoslavia there have been several case reports from the USA, Europe, and other countries on babesiosis in man. The acquisition of human babesiosis may depend on contact with subadult stages of certain *Ixodes* ticks, e.g., *I. dammini* (its main host is white-footed mouse, *Peromyscus leucopus*), and *I. ricinus* possibly transmitting *Babesia microti* (a rodent piroplasm) and *B. divergens* (a parasite of cattle), respectively. *B. gibsoni* is a parasite of dogs, and WA-1, a *B. gibsoni*-like piroplasm, has been documented in residents along the Pacific Coast of the USA, and may infect humans in Taiwan and South Africa too. The host (vector/tick) of WA-1 and its reservoir are still unknown. Although closely related to *B. gibsoni*, WA-1 should not infect dogs. However, it is highly pathogenic for most rodents. In humans WA-1 and *B. microti* may cause a similar course of infection and symptoms. Apparent **clinical signs** are parasitemia (intraerythrocytic parasites show characteristic tetrad forms), fever, rigors, cough, headache, vomiting, anorexia, and dark-colored urine. Spleen-intact humans infected with *B. microti* or WA-1 may well respond to a combination of **clindamycin** (macrolide antibiotic) and **quinine** (*chinchona* alkaloid, Table 1, →Malariacidal Drugs/Malaria of Human) although quinine proved to be totally ineffective against *B. microti*. In many areas of Europe, the enzootic cycle of *B. microti* may obviously depend on uniquely mouse-specific tick, *I. trianguliceps*. Possibly for that reason this species is not transmitted to humans, or its European strains are not pathogenic to humans. Reported cases of human babesiosis in Europe are due to *B. divergens* and chiefly occur in farmers and other persons frequently in contact with cattle. As a rule, *B. divergens* infections in man show rapid increasing parasitemia, and damage of large numbers of infected red cells causing massive hemoglobinuria, intravascular hemolysis, and renal failure. Therefore an early start of specific treatment is important for any patients infected with *B. divergens*. The treatment of choice seems to be the immediate administration of clindamycin (adult dosage: 1.2 g, 2×/d IV or 600 mg, 3×/d PO × 7d) plus quinine (650 mg, 3×/d PO × 7d; all doses cited are from Medical Letter, 2004; pediatric dosage for both drugs see there). Chemotherapy is followed by a massive exchange transfusion to reduce parasitemia, i.e., to remove physically large numbers of infected red cells and prevent extensive hemolysis and renal failure. Exchange transfusion may be used as an alternative or in addition to chemotherapy relying on relatively toxic drugs. However, this therapy with its attendant risks should be reserved for heavily parasitized and seriously ill patients only. Symptomatic and other supportive care should be associated with specific treatment. Clindamycin plus quinine treatment proved to be insufficient in immunosuppressed patients or in HIV infected ones. Therefore, in foudroyant infection courses massive blood exchange may be lifesaving or application of **atovaquone** plus **azithromycin** (Medical Letter 2004) as was recently shown.

Pentamidine isethionate (a trypanocide, see →Trypanocidal Drugs, Man) has shown good activity against *B. microti* but failed to eliminate parasites from blood completely. **Diminazene aceturate** (Table 1 and →Trypanocidal Drugs, Animals), an aromatic diamidine like pentamidine and approved for use in animals only, has also been tested in humans. The drug was successful in treating a *B. microti* infection, which did not respond to therapy with oral chloroquine phosphate. The infection was eliminated, but the patient developed acute iodiopathic polyneuritis, probably related to the diminazene therapy.

Babesians

Members of →*Babesia* species, →Tick Bites: Effects in Animals.

Babesiosis, Animals

Synonym

→Piroplasmosis, →Texas Fever, Meadow Red, →Redwater Disease, →Cardiovascular System Diseases.

General Information

Babesiosis is caused by infection with species of tickborne, intraerythrocytic and generally host-specific protozoan parasites of the genus →*Babesia*. It occurs in a wide variety of vertebrate hosts and has a very wide distribution around the world. The two major factors involved in the pathogenesis of babesiosis are the release of pharmacologically active agents and intravascular haemolysis. The relative importance of each varies with the species of →*Babesia*, e.g., the pathogenesis of *B. bigemina* is almost entirely related to haemolysis while with *B. bovis* the release of proteolytic enzymes which directly or indirectly affect the microcirculation and the viscosity of blood is the most important. Effects on the microcirculation include vasodilatation and increased vascular permeability, leading to hypotension and →oedema. Higher viscosity and coagulability of blood and increased stickiness of the membrane of blood cells cause aggregation of cells in capillaries and obstruction of the blood flow. This may lead to congestion and degenerative changes in the spleen, lymph nodes, kidneys and brain. Whatever the species involved, the disease may follow acute, subacute orchronic courses, and there may be great variation in the clinical manifestations of infection.

Pathology

Cattle

Various species of *Babesia* (*B. bovis, B. bigemina, B. divergens* and *B. yakimovi*) are transmitted by →ticks into wild and domesticated cattle. Large numbers of ruminants are killed by this parasite in tropical and subtropical areas of Australia, South America, Southern USA, and Africa where the parasites are endemic. The fight against babesiosis is a major economic factor in these areas. *B. bovis* infection is probably the most important cause of "tick fevers" of cattle. The fact that some breeds of *Bos indicus* are relatively resistant to the effects of this parasite has led to the suggestion that the organism evolved in these breeds. Young cattle have pronounced resistance to severe infection. The first clinical signs are fever (>40°C), loss of appetite and listlessness. →Anaemia and →haemoglobinuria (→Redwater) follow, and signs of jaundice develop. Diarrhoea is common and pregnant cows may abort. A form of "cerebral babesiosis" develops in some-animals with such clinical signs as hyperaesthesia, nystagmus, grinding of teeth, circling, head pressing, mania, ataxia and convulsion. In terminal cases muscle tremors and wasting may appear, followed by coma and death. At post-mortem examination the blood appears to be thin and watery, and there is haemoglobinuria. All connective and fat tissues are oedematous and show evidence of icterus.The spleen is characteristically enlarged. The liver is swollen and the gallbladder distended. In cases of cerebral babesiosis the grey matter of the brain is congested and shows a typical red discoluoration. Infection with *B. bigemina* causes similar but usually less severe clinical signs than infections with *B. bovis*, though acute anaemia and death also occur. The pathogenesis is here almost entirely related to a rapid haemolysis, with signs of haemoglobinuria and jaundice. There is no cerebral involvement. *B. divergens* and *B. major* are considered less pathogenic than other species in the tropics. In temperate regions, *B. divergens* causes the most severe signs and may be responsible for heavy economical losses. Clinical signs include fever, anaemia, →bilirubinuria and haemoglobinuria. Diarrhoea, icterus, nervous signs and →abortion may also occur in severe cases.

Horses

The horse parasite *Babesia equi* has recently been redescribed as *Theileria equi*. The only *Babesia* spp. which occurs in horses is *B. caballi*. The pathogenesis and clinical signs of infection are similar to those described above for other *Babesia* spp., i.e., that of an haemolytic anaemia which is compounded by phagocytosis of erythrocytes by macrophages. However, most infected animals are not clinically affected. Equine babesiosis is an important reason for the restriction of movements of horses between some countries.

Dogs

Babesia canis infection is a common cause of death in dogs. The pathogenesis resembles that of *B. bovis* in that mechanisms other than a haemolytic anaemia appear to be involved. However, in contrast with other animals, infection is more frequent in young dogs than in older animals. The clinical picture of dogs suffering from babesiosis is diverse and may follow a hyperacute, acute, or chronic course. Experimental infection of dogs with *B. canis* isolates from geographically different areas reveals different pathology which suggest that the aetiology of the disease caused by these isolates is different. Mildly affected animals develop anaemia and fever, are lethargic and have poor appetite. They show no visible signs of jaundice or haemoglobinuria and recover after a few days. More severe cases show a wide variety of signs, including severe depression, salivation, →vomiting, diarrhoea, jaundice and haemoglobinuria or haematuria. Pulmonary involvement

occurs frequently with quickened respirations and frothy blood-stained spittle. →Anorexia and →weight loss may be persistent. Nervous signs may occur. Infections with *B. gibsoni* are less severe and often resemble an uncomplicated haemolytic anaemia.

Other Species

In most cases, babesial infections of other vertebrate host species are mild or clinically inapparent. However, severe reactions have been described, e.g., during *B. perroncitoi* infections in pigs and *B. felis* infections in cats.

Vaccination

The ticks responsible for transmission of cattle babesiosis are, particularly in Australia, resistant against most of the commercial acaricides, so that vaccination against the parasite is the only means of fighting the disease. It has been known for a long time that cattle can develop a prominent and long-lasting premunition against the parasite after recovery from babesia infection. From 1897 until the mid-1960s blood from recovered cattle was used as a simple blood vaccine. More recently this live vaccine was refined by making the *B. bovis* parasite less virulent, passing it through splenectomized calves, and diluting the erythrocytes in a cell-free, plasma-like medium. This live vaccine was mainly produced and used in Australia but was also and still is used in Africa. About 10^7 parasites are administered per vaccination. The vaccine has a short half-life of about 6 days and, like most live vaccines, its quality can vary batch to batch. Lives vaccines prepared in splenectomized calves are used with success in Israel against *Babesia bovis*, *B. bigemina* and *Anaplasma centrale*. They have been proven to be better than vaccines prepared from tissue cultures. The vaccines arestored and dispatched to the field in a concentrated frozen state. The extensive use of the same type of vaccine in Australia from 1959 to 1996, with 27 million doses has been recently reviewed by Callow et al. in 1997 with favourable results. However, this dependence of cold chain facilities is an insurmountable difficulty for poor and tropical areas of Africa and South America in the use of attenuated live vaccines. The search for alternative vaccines has been developed, such as attempts to use irradiated parasites with ^{60}Cobalt with satisfactory results. Efforts to produce parasite extracts or fractions to be used as vaccines have also failed. A breakthrough in the search for a defined vaccine came when it became possible to produce *B. bovis* in a candle-jaw culture system used for growing →*Plasmodium falciparum*. Parasites and culture supernatant, which contains soluble parasite exo-antigens, became available in large quantities and both produced protective immunity in cattle. Lately purified *B. bovis* antigens have been successfully used in animal vaccination trials with reference to the ability to induce protection against heterologous strains challenge. These types of vaccines have been used also in tropical areas of India and Brazil with success. However, antigen →polymorphism of exo-antigens is a limiting factor for generalization of commercially available vaccines of this type.

There is only a vaccine against *B. canis* commercially available (Pirodog®) based on culture-derived antigens. Vaccination, however, has to be repeated regularly and induces poor protection against heterologous *B. canis* parasites.

A second generation of controlled babesiosis vaccines by gene technology methods is being intensively pursued invarious laboratories. A large number of antigens to be used in subunit vaccines have been identified and cloned. However, again, antigenic polymorphism and lack of knowledge on the immune effector mechanisms responsible for protection are limiting factors for preparing practically useful recombinant or synthetic vaccines which can be used in mass vaccinations.

A 37 kDa glycoprotein of *B. bigemina* has been recently identified as the major component of a protective fraction obtained from cultures of these parasites.

Therapy

→Babesiacidal Drugs.

Babesiosis, Man

Synonym

→Piroplasmosis.

General Information

Babesiosis is usually contracted accidentally from the bite of an ixodid tick which transmits →*Babesia* spp., an unpigmented protozoan multiplying in the red blood cell, usually in an asplenic individual. Several species of →*Babesia* give rise to natural infections in cattle, other domestic animals, and field mice, on which one stage of the →ticks normally feeds (→Babesiosis, Animals). Transmission to man occurs in the next stage. *Ixodes dammini* and *I. ricinus* are the principal vectors of *Babesia microti* which is zoonotic in New York State and Massachusetts. *Ixodes ricinus* transmits *B. divergens*. Most European cases of human babesiosis are caused by →*Babesia divergens*. In humans the *Babesia* spp. undergo →binary fission and often are

located at the periphery of mature red blood cells, which are destroyed without production of insoluble →pigment.

Pathology

Bilirubinemia, jaundice, hemoglobinuria, fever, and hematuria often accompany heavy infections of humans with *B. divergens* of cattle or *B. microti* of rodents. However, many infections appear to pass asymptomatically. The infection is lethal in splenectomized individuals but it is very rare and is restricted to small isolated endemic areas.

Main clinical symptoms: Abdominal symptoms, →diarrhoea, continuous fevers of 40–41°C, →anaemia, death.
Incubation period: 1–4 weeks.
Prepatent period: 1 week.
Patent period: 1 year.
Diagnosis: Microscopical determination of blood stages in →Giemsa-stained smear preparations (pigment does never occur), →Serology.
Prophylaxis: Avoid the bite of ticks.
Therapy: Treatment see →Babesiacidal Drugs, combined with blood transfusions.

Babesiosoma

→*Babesia*-like parasites in red blood cells of amphibia.

Baccalaureus japonicus

Cirriped parasite (like →*Sacculina*) in/on coelenterates and echinoderms.

Bacillary Cells

→Nematodes, →*Trichinella spiralis*.

Bacillus sphaericus

→Mosquitoes.

Bacillus thuringensis

→Spores and proteinous crystalline structures (of the serotype H 14) kill the larvae of →mosquitoes. After swallowing these components toxins are produced, the intestinal wall is ruptured and the development of the bacteria proceeds in the body cavity (→Blackflies/Control, →Disease Control, Methods).

Bacot, Arthur William (†1922)

English biologist (Fig. 1), discoverer (1910) of the life cycle of the plague bacillus in the pest flea *Xenopsylla cheopis*. During World War I, he described the agents of the Trench Fever (*Rickettsia wolhynica*). He died in 1922 from louseborne spotted fever (*Rickettsia prowazeki*).

Bacot, Arthur William (†1922). Figure 1 Arthur W. Bacot in his mid-years as director of the Lister Institute in London.

Bacteria

→Nematodes, →*Glossina*, →Diptera, →Mosquitoes, →*Bacillus sphaericus*, →*B. thuringensis*, →*Wolbachia* Species, →*Pseudomonas hirudinis*.

Baer's Disk

Synonym
→Opisthaptor.

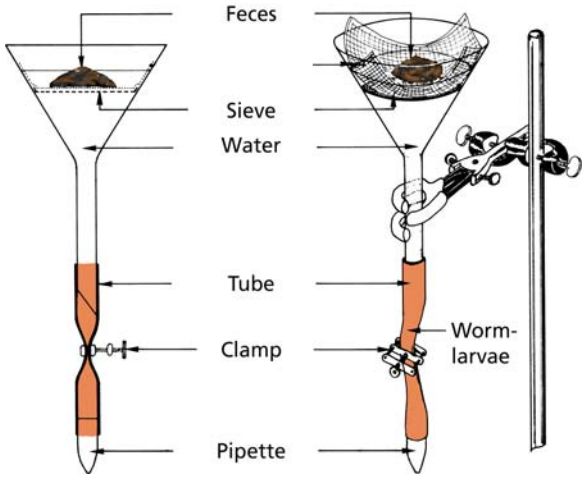
Named by Baer (Swiss biologist). Hookless holdfast organ of →Aspidobothrea; in adultworms it covers nearly the whole ventral side.

Baermann, Gustav Karl Theodor Friedrich (1877–1950)

German physician, discoverer of the Baermann-funnel to separate worm larvae from faeces.

Baermann's Larval Technique

Method to eliminate, e.g., lungworm larvae from faeces (Fig. 1). Larvae in lamp-heated faeces wander to the aquaeous side at the bottom and fall into the water, from where they are taken and studied by light microscope.



Baermann's Larval Technique. Figure 1 DR of 2 aspects of the Baermann-funnel which is used to obtain living larvae from feces.

Baggage Malaria

Other term for →airport malaria.

Baker's Itch

Allergy due to →mites.

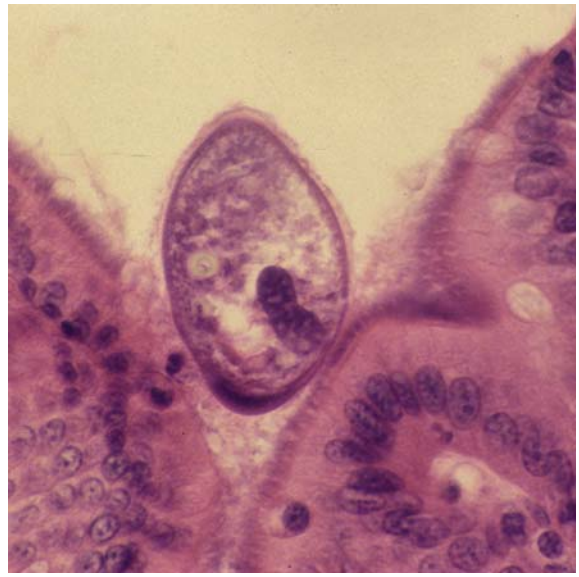
Balamuthia mandrillaris

→Amoebae, →GAE.

Balantidiasis, Man

Disease due to infections with the porcine ciliate →*Balantidium coli* via oral uptake of cysts from feces.

Main clinical symptoms: →Diarrhoea, nausea, obstipation.
Incubation period: Days to weeks.
Prepatent period: 4 days to weeks.
Patent period: Years.
Diagnosis: Microscopic determination of cysts and →trophozoites in fecal smears (Fig. 1).
Prophylaxis: Avoid contact with human or pork feces.
Therapy: Treatment see →Antidiarrheal and Antitrichomoniasis Drugs.



Balantidiasis, Man. Figure 1 Trophozoite of *Balantidium coli* at the intestinal wall.

Balantidium

Name

Greek: *balantion* = sack, *kolon* = terminal intestine.

Genus of trichostomatid ciliates (Ciliophores), the species of which live in the gut of many host species (e.g., →*Balantidium coli* in pigs and humans, *B. depressum* in a mollusc (*Pila*), *B. caviae* in guinea pigs, and many species in freshwater and saltwater fish or in amphibia). Their size is often rather large (50 × 70 mm), they are characterized by an anterior vestibulum, a cystostome-cytopharyngeal complex, several contractile vacuoles, a spherical small micronucleus besides a half-moon-shaped macronucleus and the lack of typical mitochondria. However, they possess hydrogenosomes.

Balantidium coli

Classification

Species of →Ciliophora.

General Information

The ciliate *Balantidium coli*, 50–200 µm in length (Fig. 2, page 158) lives in the lumen of the colon of humans, pigs, rodents, and many mammals but is often invasive, forming deep ulcers with undermining margins. The balantidia are found in these ulcers and extend the →ulcer base to the muscularis and occasionally beyond, leading to perforation. The →inflammatory reaction is neutrophilic, but whether it is due to the ciliates or the accompanying bacteria is not known.

Life Cycle

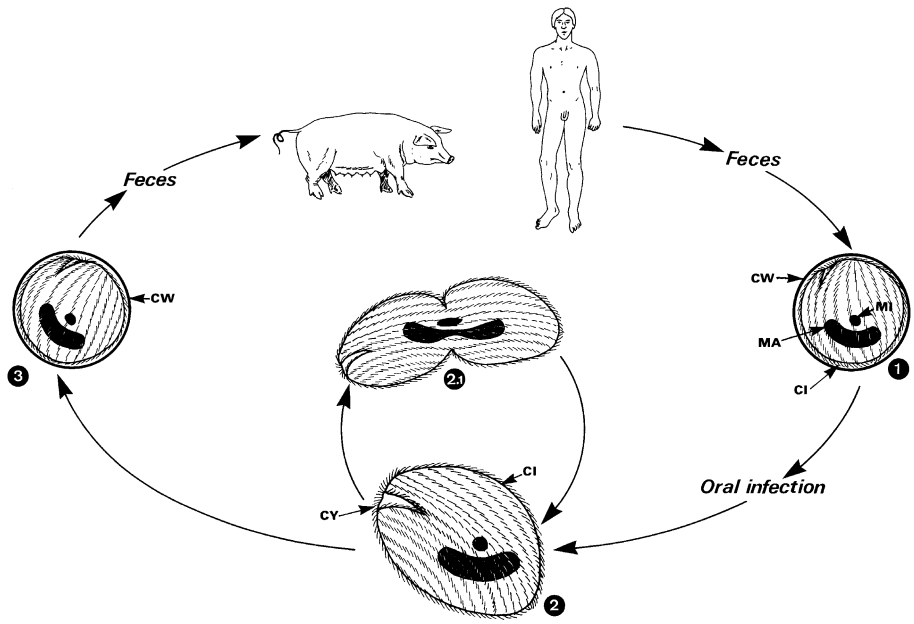
Disease

→Balantidiasis, Man, →Balantidosis, Animals.

Balantidosis, Animals

→*Balantidium coli*, →Alimentary System Diseases, Swine.



Balantidium coli. Figure 1 Life cycle of *Balantidium coli* in the cecum and colon of humans, pigs, rodents, and many mammals. *1* Cysts of 40–60 µm diameter are excreted with the feces. The →macronucleus of this species is sausage-shaped. *2* Cysts are orally ingested with food by the new host. In the intestine the →trophozoites hatch from the cysts and grow to a size of 150 ×100 µm. *2.1* The trophozoite is reproduced by repeated transverse binary fissions. →Conjugation has been observed, but may occur only rarely in man. In mammals the trophozoites may initiate *lesions* and *ulcers* of the intestine. *3* Encystment is initiated by →dehydration of feces as they pass posteriad in the rectum. Trophozoites may also encyst after being passed in feces. *CI*, →cilia; *CW*, cyst wall; *CY*, cytopharynx, *MA*, macronucleus; *MI*, →micronucleus (for other species of →Ciliophora see →Ciliophora/Table 1).

Balantidium coli. Figure 2 Fresh preparation of a trophozoite of *Balantidium coli* of pigs. The cilia are invisible due to movement.

BALF

Abbreviation for bronchoalveolar fluid obtained by lavage in order to detect *Pneumocystis* stages.

Bancroft, Joseph

Irish scientist and physician (Fig. 1; 1836–1894), who discovered the adults of →*Wuchereria bancrofti* in a muscle abscess of humans (1876).

Bancroftian filariasis

→Filariidae.

Barbulanympha

Genus of the protozoan order →Hypermastigina living in the intestine of cockroaches. →Gametes/Fig. 24.

Bancroft, Joseph. Figure 1 Dr. Joseph Bancroft, discoverer of the adult stages of the *Wuchereria* filariae.

Bartonellosis

Disease due to an infection, e.g., with the bacterium →*Bartonella bacilliformis* being transmitted by →sand flies (phlebotomes); other names are →Verruga peruana or Carrion disease.

Baruscapillaria

Synonym of *Capillaria obsignata*, a nematode of chicken and turkeys.

Basal Bodies

→Flagella.

Basis capituli

Apical region of →ticks, which is formed by the basal portions of the 2 pedipalps.

Bats

→Vampire Bats.

Bayliascaris procyonis

Ascarid nematode of racoons; life cycle compare →*Ascaris*; leads to →larva migrans in humans.

Bay-Sore

Other name for chiclero's ulcer, a form of cutaneous →leishmaniasis.

B-Cells

→Immune Responses.

BCG

Bacille Calmette-Guérin.

BDCL

Borderline disseminated cutaneous leishmaniasis.

Bdellonyssus

Name

Greek: *bdallein* = sucking.

Genus of mites, synonymous with →*Ornithonyssus* and →*Liponyssus*.

Beauveria

Genus of entomopathogenic fungi, the species of which are used as biological insecticides to control growth of anophelid mosquitoes. If adult mosquitoes get contact with conidia of *Beauveria*, they die within 24 hours.

Bee Dysentery

Infectious disease of bees caused by the microsporidian species →*Nosema apis*, see also →Nosematosis.

Bee Mites

→Varroa jacobsoni (syn. *V. destructor*), →Acarapis woodi.

Behavioral Alternations

→Behavior.

Behavioral Fever

→Behavior.

Behavior

General Information

Parasites have evolved a wide range of subtle and sensitive mechanisms for locating and invading their hosts, for avoiding and resisting host defense systems and for acquiring resources that are not given to them voluntarily.

In response, the host has evolved remarkable defense strategies to avoid becoming infected and if they fail, to reduce the detrimental impact of the parasites on their individual bodies but also to improve the gene pool of their offspring by choosing mates with high resistance

against parasites. In the context of parasite-driven sexual selection it is interesting to note that, according to the →Red Queen Hypothesis, the advantage of sex and recombination – compared to parthenogenetic reproduction – is, for the host, the means for producing rare offspring that may escape infection and, for the parasite, the means for tracking these genotypes as they become common. Consequently, the evolutionary arms race between parasite and host is getting increasingly sophisticated.

In most of these host–parasite interactions, behavioral aspects play an important role. It is noteworthy, however, that the word behavior is used in different senses. If parasites shed their →glycocalyx, which has become loaded with antibodies, or when they switch the genes involved in their antigenetic variance, these actions are named behavior by certain authors. The scope of this chapter does not include such physiological actions and responses but is rather confined to activities that are carried out by the whole parasite or host body, or at least by certain external extremities or organs of it.

For many years the well-known behavioral changes displayed by ants infected with →*Dicrocoelium dendriticum* have fascinated parasitologists and behavioral ecologists. A vast number of papers reporting behavioral alterations in various infected hosts, mainly intermediate hosts, have appeared since then. Parasitologists were eager to detect the physiological mechanisms behind the abnormal behavior but unfortunately they were not all that successful, except for a few cases where agents such as the neurotransmitter →serotonin could be named as being involved in the behavioral change. Behaviorists on the other hand were keen on debating the theoretical aspects of the phenomenon. In a recent review on parasite transmission authors succeeded in combining both approaches and also suggest criteria for the differentiation between adaptive behavioral changes and such alterations which are just pathological side effects of infection, reflecting, for instance, an altered →energy metabolism.

As pointed out in a review by Poulin, researchers often use the "adaptation" label for host behavioral changes, based on their intuition. He suggests that altered host behaviors following infection can only be considered adaptive in an evolutionary sense if they satisfy certain conditions: (1) they must be complex; (2) they must show signs of purposive design; (3) they are more likely to be adaptations if they have arisen independently in several lineages of hosts or parasites; and (4) they must be shown to increase the fitness of either the host or the parasite.

A landmark paper which opened an entirely new line of research appeared in 1982: →Hamilton and Zuk's hypothesis that there should be a relationship between a species' parasite load and its sexual showiness such as a colorful plumage. In female →mate choice, an individual male's resistance to parasites should be expressed in exterior secondary sexual characters which would allow a female to select parasite-resistant genes for her kin (parasite-mediated sexual selection). Subsequently, this novel concept has been manifoldly confirmed and partly disputed.

The present chapter – written from the host-parasite-interactions viewpoint of its author – aims to describe parasitological items involving the behavior of hosts and parasites, and to focus on new trends in the subject which have come up within the past few years. Such aspects that do fit into the scope of this review but are treated in other chapters have not been considered here.

Alterations of Host's Behavior Faciliating Parasite Transmission

Concerning **trophically transmitted parasites** in their intermediate hosts a few, rather early, descriptions provided conspicuous and astonishing examples of behavioral changes in a host. For instance, there was the discovery of the life cycle of →*Dicrocoelium dendriticum* in which a specialized metacercarial stage, the →brain worm, induces an ant to seek an exposed position on a blade of grass where it stays, thus making itself vulnerable to predation by grazing ungulates. Sporocysts of *Leucochloridium* spp. were shown to mimic animals serving as food-items of warblers, the final bird hosts of the parasite, by forcing the snail intermediate host's tentacles to change size and shape, attain a showy color and perform pulsating movements. Later on, the literature on the behavior of parasitized intermediate hosts of parasites transmitted to final hosts via the food chain became very voluminous. Mostly authors were tempted to assume that alterations in ranging, foraging, cryptic, or antipredator behavior followed a purposive design, either benefiting the parasite in its transmission or the host (which is less frequently postulated).

Theoretically, the parasite can manipulate its host's behavior directly or it can influence its decision-making by imposing a constraint or stress, for instance by causing a drain of energy. Hunger-induced decrease of antipredator behavior induced by a parasite seems to be very common. In 3-spined sticklebacks (*Gasterosteus aculeatus*) infected by *Schistocephalus solidus* the energy flow into the large plerocercoids parasitizing in the peritoneal cavity of the fish result in higher energetic requirements and a higher oxygen demand. Consequently, time spent feeding away from a shelter is prolonged, combined with a reduced aversion to the risk of predation and a shift in habitat preference

emerging to the surface of the water where the availability of oxygen is best.

Toxoplasma gondii, for instance, is known to induce various behavioral alterations in its rodent intermediate hosts, but they do not seem to be driven by hunger. In addition to memory impairment, the propensity to explore novel stimuli in their environment is higher than in uninfected individuals. Infected rats are more active and more easily trapped. Interestingly, this altered perception of predation risk can be prevented not just by anti-*T. gondii* drugs but also by antipsychotic drugs.

In human patients (accidental hosts of *T. gondii*) latent toxoplasmosis, i.e., the lifelong presence of *Toxoplasma* cysts in neural and muscular tissues, leads to a prolongation of reaction times and reduced concentration, and accordingly such infected subjects have a higher risk of committing an accident than toxoplasmosis-negative subjects.

Among the trophically transmitted parasites acanthocephalans offer several good examples of complex and purposive alterations in the behavior of the host, leading to an increased probability that the larvae of the parasites will be transmitted to their final hosts. According to the often-quoted papers by Bethel and Holmes, the altered behavior of *Gammarus lacustris* only becomes apparent when the larvae of →*Polymorphus paradoxus* reach their infectivity to the definitive host. Gammarids infected with infectious cystacanths of this species respond to disturbance by approaching the water surface and clinging to solid objects. Uninfected conspecifics are less sensitive to disturbance; when they are disturbed, they dive toward the bottom and burrow themselves into the mud. Later on Helluy and Holmes, after experimenting with different →neurotransmitters known to play a role in crustacean behavior, offered an explanation of the altered behavior. They succeeded in demonstrating that the clinging behavior is influenced by serotonin, the injection of which also induced the same behavior in uninfected gammarids as in infected individuals.

Among acanthocephalans the induced abnormal behavior is often combined with a conspicuous orange or yellow color of the cystacanths, which is visible through the →cuticle of the crustacean →intermediate host, making the alteration more complex and purposive in terms of an increased predation probability by a final host; this has been demonstrated for several acanthocephalan species. In *Caecidotea intermedius* (formerly *Asellus intermedius*), infected with *Acanthocephalus dirus*, it could be shown that the decreased antipredator behavior of the infected isopods was obviously not simply due to increased energy demands since the time spent away from a refuge, when a predator was present, was not related to the location of the food offered.

The literature on behavioral changes of intermediate hosts of trophically transmitted parasites promoting their transmission to suitable final hosts – often referred to as favorization – has become rather voluminous.

Regarding behavioral alterations of final hosts of parasites and of parasites with monoxenic life cycles little information is available.

Mice subclinically infected with the monoxenic coccidian *Eimeria vermiformis* spent a significantly greater amount of time near to a source of cat odors and generally showed less predator-induced fear compared to uninfected controls. The altered behavior could not be modulated by treatment of the mice with morphine. Interestingly, in this case the resulting increased vulnerability of the infected mice to predation is not beneficial to the parasite which uses mice as the only host. Thus, behavioral changes do not always have to show a purposive direction that increases the probability of transmission of a parasite.

Often infected hosts are subjected to neuromodulatory responses leading to reduced spatial learning (mice infected with the monoxenic nematode →*Heligmosomoides polygyrus*). Also, →*Schistosoma mansoni* infection in humans and animals induces abnormal neurobehavioral responses, following →granuloma formation. In infected mice the exploratory activity and the pain response on the host plate are markedly altered. Also increased sniffing and grooming of the infected mice can be noted. In malnourished schoolchildren the degree of infection with →*Ascaris lumbricoides* was correlated with varying cognitive behaviors.

Human adults infected with *Dracunculus medinensis* revealed lowered sexual activity and poor maternal attention (in females).

All these behavioral changes seem to be side effects of pathology reflecting incomplete reciprocal host–parasite adaptations and thus cannot be considered adaptive in an evolutionary sense.

Nontrophically transmitted parasites may manipulate host behavior in a way aiming at an altered habitat preference benefiting their life cycle requirements. Mermithid nematodes as well as Nematomorpha are capable of driving their terrestrial hosts into water where the parasites can complete their life cycles as free-living adults. Nematomorphs achieve this by altering host transmitters, but the mechanisms used by mermithids have remained less understood. The supralittoral marine amphipod *Talorchestia quoyana* when infected with the mermithid *Thaumamermis zealandica*, seeks water-saturated sand where it burrows more deeply than uninfected individuals. An increase of host haemolymph osmolarity seems to induce "thirst" explaining why parasitized amphipods seek wet substrates.

Concerning **parasites transmitted by bloodsucking vectors**, behavioral changes affecting the vertebrate hosts as well as the arthropod vectors have been described.

Oxen infected with →*Trypanosoma congolense* were about 70% more attractive to the →*Glossina pallidipes* vector than uninfected controls or controls infected with *T. vivax*; and the feeding success of the →tsetse flies on the oxen infected with *T. congolense* was approximately 60% greater than on oxen of the other 2 groups. Both differences were discussed in relation to reduced antifly movements and vasodilatation induced by *T. congolense* in the mammalian host. The transmission of the parasite, however, also seems to be promoted by behavioral changes affecting the insect vector. →Epimastigotes of *T. congolense* attach themselves by mean of →hemidesmosomes to the labral mechanoreceptors of the vector, thus impairing the sensory function and feeding behavior of the infected flies. The impairment of normal receptor function, plus the accumulation of trypanosomes in the labrum, also decreases the flow within the food canal. Infected flies probe more frequently and take longer to engorge than uninfected flies. These features have been calculated to increase the transmission rates for the parasites.

Furthermore, infection of →"kissing bugs" (Reduviidae) with *T. cruzi* reduced the time to detect potential hosts in comparison to control insects. Infected bugs bit about twice as often as uninfected nymphs and defecated 8 minutes after the last blood meal whereas uninfected individuals needed 11 minutes. And from mosquitos infected with *Plasmodium* spp. we know that appetite for blood is stimulated by the infection in themselves and their vertebrate hosts.

Castration, Sexual Reversal, Sex Ratio Distortion

As already mentioned, parasitized hosts are often restricted in their mating behavior and in many cases do not show any sexual behavior at all, which may result from partial or complete castration, more frequently affecting intermediate hosts than final hosts. Castrated, nonreproducing males, like green crabs (*Carcinus maenas*) infected by the monoxenic rhizocephalan barnacle *Sacculina carcini*, tend to become feminized in their phenotype.

But in other host–parasite associations, best described from gammarid crustaceans, feminized males behave as genetic females and can even produce offspring. Once thought to be a rare phenomenon, sex-ratio distortion by parasites is now known to be common in many (mostly arthropod) evertebrates.

Among microsporidians many species undergo partly or even solely vertical transmission. This means that the parasite is transovarially transmitted in the cytoplasma of the eggs from mother to offspring. Infected male emryos become feminized which increases the transmission base to future host generations by converting males, which cannot transmit the parasite in their sperm, into females. Due to such female-biased broods combined with a high prevalence of the microsporidians, eventually host populations should collapse due to a lack of males. However, feminized males are larger than true females and accordingly are less accepted as sexual mates than the latter. Furthermore, as described from *Gammarus duebeni* infected with *Nosema granulosis*, male (uninfected) amphipods provide uninfected, high fecundity females with more sperm than infected females.

These findings again demonstrate that parasites manipulate host behavior in order to promote their transmission, while the hosts' counter measures aim at the selection of good genes useful in resisting future parasite attacks against their progeny (good genes benefits mating, antiparasitic sexual mate choice, see below).

Behavior of the Host in Avoiding, Expelling or Eliminating Parasites

Change of Habitat

Many examples reveal how mammals temporarily change their location in response to attacks by flying insects, e.g., when reindeer enter water or scrub. A special kind of change in habitat preference in response to parasite attack appears to be roost-switching of hosts that live in groups. →Bats change their day roost in response to a severe →ectoparasite attack. High ectoparasite levels were correlated with lower body weights in lactating females. Thus roost-switching might be an important strategy for decreasing ectoparasite loads by interrupting the reproductive cycles of those parasites that spend at least part of their life cycle on the walls of the cave.

Escape and Defence Behavior

Evasive actions of hosts following attacks of ectoparasites have been described from many hosts. The effectiveness of such actions has been demonstrated. A very interesting study was carried out by Laitinen et al. Brown trout (*Salmo trutta*) and roach (*Rutilus rutilus*) were exposed to furcocercariae of a →*Diplostomum* sp. that infects the eyes of fishes and to →xiphidiocercariae of a →*Plagiorchis* sp. that employs insects as second intermediate hosts. Swimming activity increased significantly in the roach exposed to *Diplostomum* →cercariae, even at very low densities, and remained high for 24–36 hours after exposure. Brown trout showed no response to low cercarial numbers but responded significantly at high exposure densities. The increase in activity peaked at 2 hours and returned to pre-exposure levels within 5–6 hours. In contrast, exposure to the cercariae of *P. elegans* did not elicit a response in either fish. This difference in the evasive behavior of the host could be due to the adherence and penetration activity of the

Diplostomum cercariae on the fish. On the other hand, related host species may differ in their success in preventing attacks of ectoparasites, perhaps reflecting different ecological strategies.Tadpoles of *Bufo* and *Rana* species can also make explosive movements when they sense cercariae contacting their skin. Because *Bufo* (toad) tadpoles are unpalatable to many predators they obviously have a different trade-off between predation and infection risk than *Rana* (frog) tadpoles and can afford to make more conspicuous evasive maneuvres than the latter which can be demonstrated in the laboratory. Species-specific differences in antiparasitic behavior are also known from higher vertebrates. In cage experiments with 6 species of herons and one ibis, →mosquitoes preferably fed on 2 of the heron species. When the birds were prevented from moving (most of their defensive behavior was directed toward protecting the legs and the feet) similar numbers of mosquitoes engorged on all the bird species.

Hygienic Behavior

Localized defecation sites as a tactic to avoid (re-) infection by gastrointestinal tract parasites are practiced by many herbivorous as well as by carnivorous hosts such as racoons. But it remains under discussion to which extent the habit to deposit feces at latrine sites is a parasite avoidance measure or whether it also has a social function.

Avoidance of Parasite Transmission by Choosing Uninfected Sexual Mates

The parasite avoidance hypothesis, which applies to horizontally transmitted parasites (ectoparasites, venereal diseases, and directly transmitted microparasites), suggests that females reduce the probability of catching parasites by direct transmission if they choose parasite-free males. The mate's sexual ornament, its odors or acoustic signals may serve as cues in decision-making according to the hypothesis of Hamilton and Zuk (good genes benefits mating; see below).

Distinction and Avoidance of Infected Food

Since many parasites that are transmitted to their subsequent hosts through predation strongly reduce the fitness or even the survival of these hosts, the hosts should theoretically try to recognize and avoid infected prey individuals or to exclude particular prey species entirely from their diet when alternative prey is available. In different trials, sticklebacks constantly, and under all conditions tested, consume copepods infected with the tapeworm *Schistocephalus solidus* in preference to uninfected specimens. The infected copepods were more active and easier to catch. In this case, the procercoid of the parasite inside the copepod was visually inconspicuous, but still one should expect that the pronounced pathogenicity displayed by this tapeworm in sticklebacks would have led to discriminative feeding behavior. If female sticklebacks avoid mating with parasitized males why do they accept parasitized prey? was the question that Bakker asked. He was amazed that sticklebacks did not even avoid gammarids that were marked by the shiny, orange-colored, infected larvae of the acanthocephalan *Pomphorhynchus laevis*. On the contrary, the infected gammarids were preferentially preyed upon because they possessed the conspicuous color mark that was visible through their transparent cuticle and because of their diminished photophobic behavior. This again contrasts with the high discriminating value of small dark spots (metacercariae) on the surface of fish when these fish species choose sexual mates or mates to school with. As far as can be ascertained, no positive report on the avoidance of infected prey or food by animal hosts exists. There has been some debate about an assumed trade-off between the energy gain of ingesting the easily accessible infected prey and the subsequent costs of reduced fitness. But regarding the transmission of *Leucochloridium* digeneans, the sporocyst of the parasite inside the snail's tentacle is the prey, not the snail or the tentacle. Thus, in this case no energetic trade-off could justify the uptake of this (apparent) prey.

Antiparasitic Social Mate Choice

Sexual mate choice under the auspices of parasitism has received plenty of attention but many other forms of →partner choice exist where parasitation plays a role. Banded killifish, *Fundulus diaphanus*, were presented individually with a choice of "shoaling" with either of 2 conspecific stimulus shoals, the one consisting of fish with externally visible black spots (melanized metacercariae of *Crassiphiala bulboglossa*), the other consisting of fish without such spots. Both parasitized and unparasitized test fish significantly preferred to shoal with unparasitized stimulus shoals rather than parasitized ones. It was also shown in another experiment that killifish used black spots as an indicator for the presence of parasites when making their shoal choice. Thus, although in the case described metacercariae cannot spread from one fish to another, the decision of the fish should be interpreted as a parasite-avoidance behavior. Probably many ectoparasites that do have the ability to spread from host to host within a shoal are visually detectable by the respective fish. Furthermore, the parasitized shoal must have been exposed to the parasites and the exposure might be continuous.

Measures to Eliminate Parasites that have Become Established

If an infection could not be prevented, the parasites can be attacked or removed by the host's behavior.

The physical removal of ectoparasites by the hosts has been well studied. Tools available for this task are,

for instance, comblike cleaning claws existing in several families of birds such as herons, and in certain marsupial and lemuriform mammals. House mice (*Mus domesticus*), for instance, have specialized lower incisors (teeth) which are capable of lateral closure and can thus effectively comb ectoparasites (such as the anopluran louse, →*Polyplax serrata*) away from the fur. Most stages of this common louse aggregate on the anterior body (mainly the head) where self-grooming is difficult. If, however, grooming is prevented by placing a collar around the neck of the mouse, →lice and their eggs spread across the whole body, and the number of lice may increase from 100 to more than 1,000 within 4 weeks. Within 24 hours of being permitted to self-groom the number of lice and their distribution begin to return to normal. Furthermore, recent studies have revealed the adaptive significance of avian beak morphology for ectoparasite control. The shape of a bird's beak used to be interpreted in relation to its role in feeding but now it is acknowledged to play an important role in preening. Amputation experiments were carried out with domestic pigeons. When the tips, obviously an improtant tool in preening, of the bills were removed (which did not prevent the birds from feeding) the populations of lice in their plumage increased rapidly.

Until recently we knew rather little about the time terrestrial animals devote to grooming. Cotgreave and Clayton published data on 62 bird species. On average, the birds spent 9.2% of the day in maintenance activities, mainly grooming (92.6%). Interestingly, bird species known to harbor a large number of lice spend more time grooming than do host species with few lice; the time spent on preening can also be experimentally manipulated by loading ectoparasites onto them. Of course, as one may expect, parasites have also adapted to grooming and can even utilize it for their transmission, as is shown in the case of the nematode *Heligmosomoides polygyrus* in the mouse host. After infective larvae have been placed on individually housed mice, significantly higher numbers of adult worms were recovered from the small intestines of the mice that were allowed to self-groom than were recovered from those mice that had been fitted with collars to prevent self-grooming. When larvae were placed on a single mouse housed with 3 other untreated mice, the latter became infected, suggesting that allogrooming may also be important in parasite transmission.

Following transcontinental introductions of parasites, hosts that have not undergone coevolution with the invasive parasite may become colonized and seriously harmed due to a lack of parasite removal behavior. In hives of the Asian honey bee *Apis cerana* serving as the natural host of the mite *Varroa destructor* (syn. *jacobsoni*), most of the infected worker brood is removed from the colony, and bees also pick up mites from their bodies. In contrast, in hives of the naive novel host *Apis mellifera* (European honey bee) infected brood is not efficiently recognized and eliminated and the grooming behavior of the workers is comparatively low.

Self-Medication

Many host species have been found to use substances (mainly plants) from their environment that are deliberately swallowed or otherwise contacted under certain circumstances. Several substances investigated seem to have detrimental effects to the parasites, and in certain cases it even seems that the use of the drugs leads to improved host fitness. Huffman correlated quantitative measures of the health of chimpanzees with observations of leaf-swallowing in an African national park. There was a significant relationship between the presence of whole leaves of certain plants and worms of adult →*Oesophagostomum stephanostomum* in the dung of the apes. But later on other controversial results and discussions about the medical properties of such plants ingested by chimpanzees came up and it appeared that swallowing unchewed rough leaves rather than the drugs in them was the causative agent of the self-cure.

Behavioral Fever

Poikilothermic hosts affected by endoparasites may raise their body temperature by choosing warm and sunny microhabitats in order to improve the function of their immune system. In addition to generating behavioral fever, infected host individuals may prefer microhabitats with a lower temperature than their uninfected mates, slowing down the development of the parasites (digeneans in snails). But thus far only little and controversial literature on this subject exists. In addition, parasites are also known to manipulate their host's behavior making them select certain sites. So the distinction between both phenomena may not be easy to elucidate and further study of this topic is needed.

Host Sexual Mate Choice as an Antiparasitic Selective Mechanism

General Aspects

At breeding time, conspecifics of one sex normally compete intensively for being chosen by the other sex. Mostly, the females choose and many studies have shown that they use male signals as a basis of their choice. Hamilton and Zuk postulated that secondary sexual characteristics may allow females to select

healthy, vigorous males resistant to common and harmful parasites and thus pass resistance genes on to their offspring. Thus, one of the most substantial benefits of sexual reproduction itself could be that it allows animals to rapidly react to changing environmental selection pressures such as coevolving parasites. Indeed it appears as if sexual reproduction itself is favored by selection resulting from host–parasite interactions. In different populations of a →dioecious freshwater snail, showing both sexual and parthenogenic reproduction, the frequency of males was used to estimate the degree of sexual reproduction in each population. The male frequency was significantly positively correlated with the frequency of 2 digenetic →trematodes in the snails. Since the proportion of males infected was not significantly different from that of the females, this interesting result did not appear to be an artifact. The result suggests that parasitism potentially functions as a means of frequency-dependent selection which favors the maintenance of sex. Therefore sex and recombination seems to be a definite strategy of hosts in the evolution of their resistance toward parasites. One may conclude that heritable variation in parasite resistance is maintained by coevolutionary cycles between host and parasite genotypes.

Female's Choice

Among birds, ornamental characteristics, for instance of the plumage, are often related to sexual mating. So when females pick partners to mate with, they may make their decision according to the impression they get of an ornamentation that has been directly altered by parasites, i.e., by the optical presence of the parasites themselves on the host or by marks created by their activity. For example, female saga grouse (*Centrocerus urophasianus*) appear to reject lousy males because their airsacs, inflated during courtship, have many small black hematomas caused by the lice infestation. Males with artificial hematomas applied with a pen are also rejected by females.

More common, however, seem to be indirect adverse effects of parasites on male secondary sexual characteristics, leading to the female's preference for unparasitized males. Among captive flocks of red jungle fowl (*Gallus gallus*), roosters experimentally infected with intestinal nematodes (→*Ascaridia galli*), revealed duller →combs and eyes, shorter combs and tail feathers, and paler hackle feathers upon reaching sexual maturity than did the roosters of a control group. In experimental mate choice tests, two-thirds of the females preferred unparasitized rather than parasitized roosters. Moreover, the hens made their choices according to features indirectly caused by the parasites and not according to nonsexually selected characteristics such as bill size, as evidenced by other tests.

Among many passerine birds, female mate preferences for a shiny, colorful ornamentation such as red breast are well-documented. Among yellow-hammers (*Emberiza citrinella*), for instance, male intensity of infection by the hemoprotozoan *Haemoproteus coatneyi* is reliably revealed by the bright or pale male's yellow plumage. But inconspicuous features like the size of a certain spot can also mediate mate choice. In addition, all signals seem to play a role in territorial behavior appealing to the own sex.

Acoustic cues may reflect the health and vigor of mates and competitors. Among birds, the receivers of songs can gain information relevant to mate choice and to male–male competition from the complexity, duration, and frequency of the song. Furthermore, male parasite loads were found to be correlated with the speed of an acoustic response to an intruder and the structure of the call.

Among fish too, the intensity of the red coloration as a sexually dimorphic characteristic shows relationships with parasite intensities; and in sticklebacks (*Gasterosteus aculeatus*), the role played by male coloration in mate choice and the avoidance of parasitized males has been evidenced.

Breeding tubercles, the sexual ornamentation of many fish species, are induced by several androgens and at least one estrogen. Interestingly, among male roach and other cyprinids it was observed that the more heavily they were infected the fewer breeding tubercles they had. It was concluded that a female could potentially decode these differences in ornamentation in order to gain a sort of clinical picture of the male as her choice of mate. The few data available from male reptiles involving infection by →*Plasmodium* spp. also show alterations in sexually dimorphic coloration combined with less courtship and territorial behavior, which negatively influences the female's choice of mate.

Interestingly, among mammals, odors seem to have the potential for decoding complex information, and this also seems to be true for major histocompatibility complex (MHC)-linked odor components: glycoproteins encoded by MHC loci under the influence of bacteria may simply degenerate to waste products small enough to become evaporating molecules in urine and feces. Urine odors of male mice (experimentally subclinically) infected with coccidians or helminths were offered to female mice in choice experiments. The females showed an overwhelming preference for the odors of the nonparasitized males.

Concerning insects, the few studies that have been conducted also suggest that certain courtship songs are indicators of male quality, and females (of crickets) responded most positively to the songs of males that proved to have high encapsulation abilities (a measure of immunity).

Interestingly, sexual signaling may be dishonest as shown from mealworm beetles. Males, when perceiving a threat to survival, may divert resources into attractiveness traits in order to maximize mating prior to death or parasitic castration which is dishonest with respect to the male's current condition.

As discussed by Wedekind, there are a lot of theories and hypotheses about benefits relating to resistance genes and choosy females. But there is a general consent about the assumption that the maintenance of conspicuous secondary sexual characters is costly to the immune system demonstrating that a vigorous male can bear the cost of the immunosuppressant effects of androgens. Exaggerated ornamentation decreases immunocompetence. On the other hand, the bright yellows, oranges, and reds exhibited by many bichromatic birds are the products of carotenoid pigments, which are known to have health benefits. Therefore, bright colors may also be indicative of a bird's access to a superior diet or of its superior foraging ability. Testosterone is associated with a suppressed immune system in many vertebrates and the sexes differ accordingly in the blood parameters involved in immunity. The comb length of red jungle fowl, for instance, is positively correlated with the plasma testosterone level but negatively correlated with the number of lymphocytes in the blood. Male house sparrows with pronounced secondary sexual characters have a smaller bursa of Fabricius and thus lower current levels of immune response than do males with less conspicuous ornamentation. However, males in good physical condition had a relatively small bursa of Fabricius. Furthermore, in *Plasmodium*-infected lizards infected males have lower levels of plasma testosterone and higher levels of the stress hormone corticosterone. However, when the plasma corticosterone level in uninfected lizards was experimentally raised, the animals showed decreases in testosterone level and other accompanying pathological features as are found in infected males in the wild. All these morphological and physiological findings support the idea that only individuals in good health, such as uninfected ones, can afford the handicap of raised androgen levels.

Male's Choice

Since the selection of females by males is less common than vice versa, the existing mechanisms signaling the health of females are little investigated. In pipefish (*Syngnathus typhle*) males are the choosy sex. They were shown to differentiate between uninfected females and those infected by metacercariae of →*Cryptocotyle* sp., which induces visible black spots in the skin of the fish. Since there was also a negative correlation between parasite load and female →fecundity, males mating with unparasitized females may benefit directly by fertilizing more eggs. But the importance of the intraspecific assessment of genetic resistance against the parasites should also work in this example. In species with predominantly female mate choice, males were found to be choosy to a certain extent. This was first demonstrated from male laboratory mice showing a preference for uninfected females rather than for those infected with →*Trichinella spiralis*. But the apparent preference was interpreted in relation to parasite-induced changes in female ability for conception. It was also reported that male mice can discriminate between the odors of nonparasitized females and those infected by *Heligmosomoides polygyrus*, and that they find the odors of parasitized estrous females aversive. Meanwhile, we also know about male birds performing similar discriminations.

Sexual Mate Choice by Infected Hosts

The evolution of mating systems useful in the search for good genes should not only consider the parasite load of the mate being selected but also the parasite burden of the choosy mate, whether this is a male or a female. So far models of parasite-mediated sexual selection have neglected the potential effects of parasites on the ability of their hosts to choose mates. The reports on this subject that are available show that infected mates are less choosy compared to their conspecifics which is often combined with an impairment of other mating behaviors. Thus, behavioral changes of infected hosts may be pathological side effects of infection. Due to an alteration in energy metabolism or hormone levels, for instance, one should always expect an impact on mating behavior. The reduced courtship and territorial behavior (combined with smaller testes and lowered plasma testosterone levels) as shown for instance by male fence lizards infected with *P. mexicanum* should lead to less success in the choice of mate on the part of the infected hosts and thus work as a driving force in the evolutionary arms race between parasites and their hosts.

Parasite Mating Behaviors

Since the mating systems of the hosts and apparently even sex itself are parasite-driven, one might expect that parasites also show heritable variation in their adaptation to their hosts and that they compete for sexual mates with good genes useful for a parasitic life style.

This seems to be true but so far it is difficult or too early to recognize patterns other than general preference for mates with a high reproductive potential. In the copepod →*Lernaeocera branchialis* on flounders male mate choice has been studied. It depended on the sex ratios of the parasite on its hosts and on the age and

mating status of females. At most sex ratios, males preferred the stages →chalimus 4 and virgin adult females. Mated females were less attractive but were chosen more frequently at strong male-biased sex ratios.

From schistosomes three findings were described: the existence of a specific male mate preference system, the existence of mating competition and the possibility of change of mate. The principal factor in male mate preference is female fecundity. Thus, paired males prefer remaining with developed and fecund females rather than changing to young immature females. Change of mate does occur when a heterospecific female (in mixed infections) can be exchanged for a conspecific female. When there is a surplus of females, the male is faithful and stays with its reproducing mate and arriving virgins do not become fertilized. However, in infections with a greater number of males compared to females, competitive male mate choice does seem to occur, i.e., unpaired males seem to compete for females.

Meanwhile, parasite mating behaviors are known from several additional host–parasite associations. The general pattern is male–male mating competition for females having a high fecundity potential. Females do not seem to play an active role in mate choice. In acanthocephalans female worms do not even possess a genital ganglion. Following copulation they become locked by a copulatory cap imposed on their vagina by male excretion preventing further fertilizations until the eggs are discharged. Interestingly, inferior (smaller) males were also found to carry copulatory caps deriving from superior males (→Selfish Gene Hypothesis). Furthermore, the size of the male testes is modulated by the quantitative presence of mates and competitors. In female-biased infrapopulations the testes are small. In contrast, under competition by a surplus of males worms make the largest testes, probably reflecting upregulation of sperm production.

Data are also available from hermaphrodites with mixed mating systems. Among tapeworms, for instance, partners can modify their rate of cross-fertilization over selfing according to the fecundity potential of the partner. It was shown for *Schistocephalus solidus* that outcrossed offspring achieved both a higher infection success and a higher weight in the copepod, and a higher number of parasites per host in both intermediate hosts (copepod, stickleback), but only under competition. Accordingly, a general preference for cross-fertilization over selfing is practiced but the genetic benefits from outcrossing do not necessarily outweigh the costs of mating with a relatively small individual which has a low fecundity prospect. Furthermore, there seems to be a conflict over who is allowed to give how much sperm, since the opportunity to fertilize a partner's eggs is more attractive in terms of saving energy than getting their own eggs fertilized.

Beltranmyia

Subgenus of →*Culicoides* with the common British species *C. circumscriptus*.

Bendiocarb

Chemical Class

Carbamate.

Mode of Action

Acetylcholine esterase inhibitor. →Ectoparasiticides – Agonists and Antagonists of Cholinergic Transmission.

Beneden, Peter Joseph van (1804–1884)

Belgian physician, famous describer of tapeworms, honoured by application of species names (e.g., *Moniezia benedeni*).

Benedenia melleni

Monogenean trematode parasitic on the pacific puffer fish, angle fish, etc. It is also found on the conjunctiva of their hosts.

Benign Malaria

Malaria due to infection with *Plasmodium vivax*, *P. ovale* (benign malaria tertiana), or *P. malariae*, which can be survived in contrast to malign (= bad) malaria tertiana due to →*Plasmodium falciparum*.

Benign Theileriosis

Disease in cattle due to infection with *Theileria mutans* (→Theileriosis).

Benzimidazoles

Group of compounds acting against nematodes, →Nematocides.

Berlese, Antonio (1846–1927)

Italian entomologist, famous for his books on insects and mites. Inventor of a funnel to collect insects from fallen leaves or detritus material.

Berlese's Organ

Invagination of the fourth abdominal segment of the bed bug →*Cimex lectularius*, which represents the fertilisation pocket. This entrance is also called →Ribaga's organ.

Bernoulli Trial

→Mathematical Models of Vector-Borne Diseases.

Besnoitia

Genus of →Coccidia/Table 5; named in honor of Prof. C. Besnoit, Toulouse, France.

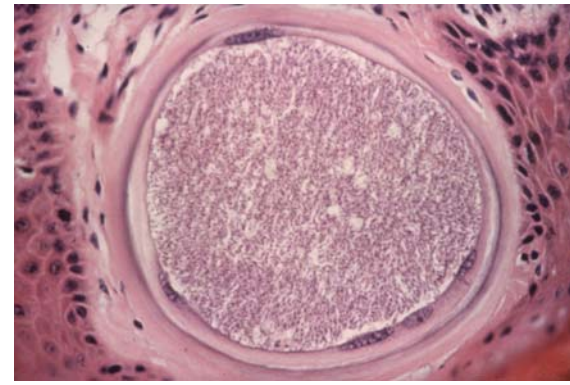
Besnoitia besnoiti

Classification

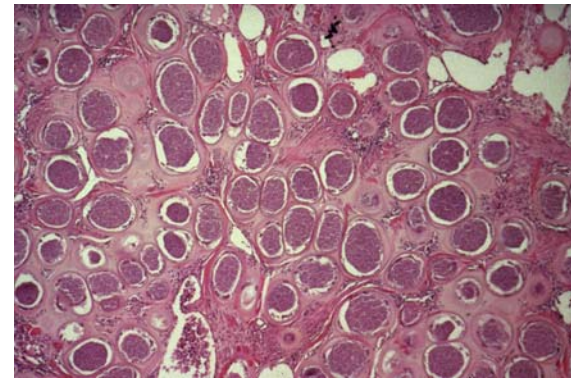
Genus of →Coccidia; Figs. 1–3.

Disease

→Skin Diseases, Animals.



Besnoitia besnoiti. Figure 1 Section through a cyst of *Besnoitia besnoiti* in the skin of a cow. Note that the host cell has become several nuclei (blue) and is widely surrounded by a thick layer of filaments.



Besnoitia besnoiti. Figure 2 LM of a section through the skin of a heavily infected cow showing numerous *Besnoitia besnoiti* cysts.

Besnoitia besnoiti. Figure 3 Horny skin due to infection with *Besnoitia* cysts.

Besnoitiosis

Disease in cattle and goats due to →*Besnoitia besnoiti*/Figs. 1–3 with formation of tissue cysts inside skin (and eye) leading to the so-called elephant-skin. Transmission by body contact; life cycle unclear (→Skin Diseases, Animals/Protozoa, →Coccidia).

Betacyfluthrin

Chemical Class

Pyrethroid (type II, α-CN-pyrethroids).

Mode of Action

Open state voltage-gated sodium channel blocker. →Ectoparasiticides – Blockers/Modulators of Voltage-Gated Sodium Channels.

Biacetabulum meridianum

Caryophyllidean cestode from catostomid fish.

Bilharz, Theodor (1825–1862)

German physician and zoologist; he discovered in Egypt the pairs of the male and female blood flukes, formerly called *Bilharzia* – now *Schistosoma*. He died from typhus in Cairo.

Bilharziella polonica

→Digenea, →Schistosoma.

Bilharziomas

Granulomatous and fibrotic lesions that develop around egg masses of schistosomes in organs (e.g., liver) away from the mucosa.

Bilharziosis

Synonym

→Schistosomiasis, Man.

The name was given in honour of Theodor →Bilharz (1825–1862), a German physician who discovered the →*Schistosoma* worms in Egypt in 1851–1852 and described them originally as →*Diplostomum*.

Bilirubinuria

Clinical symptom in hosts infected, e.g., with →*Babesia* species or *Theileria equi* (→Piroplasmea).

Binary Fission

The most basic type of →Cell Multiplication is binary fission, which always produces 2 daughter cells and needs a preceding duplication of the organelles of the mother cell (→Cell Multiplication/Figs. 1, 2).

Bioallethrin

Chemical Class

Pyrethroid (type I).

Mode of Action

Open state voltage-gated sodium channel blocker. →Ectoparasiticides – Blockers/Modulators of Voltage-Gated Sodium Channels.

Biocid

Compound which acts apart from a body (e.g., on the floor) against pests.

Biocoenosis

From Greek: *bios* = life and *koinos* = together. Biocoenosis was created by K. Möbius (1877) to characterize species living close together in a biotope and/or host.

Bioenergetics

Synonym

→Energy Metabolism.

Biological Control

Arising from →*Bacillus thuringensis* or breeding of gambusian fish to control development of →mosquitoes. →Apanteles, →Tiphia popilliavora.

Biological Methods

→Disease Control, Methods.

Biological Systems

→Disease Control, Strategies.

Biomphalaria

Genus of snails, that are vectors of →*Schistosoma* spp.

Bithynia

Genus of snails, intermediate hosts of →*Prosthogonimus*-trematodes.

Black Disease

Disease due to combined infection with the trematode →*Fasciola hepatica* and the bacterium *Clostridium novyi* type B.

Black Sickness

→Visceral Leishmaniasis.

Blackflies

Synonyms

→Simuliidae.

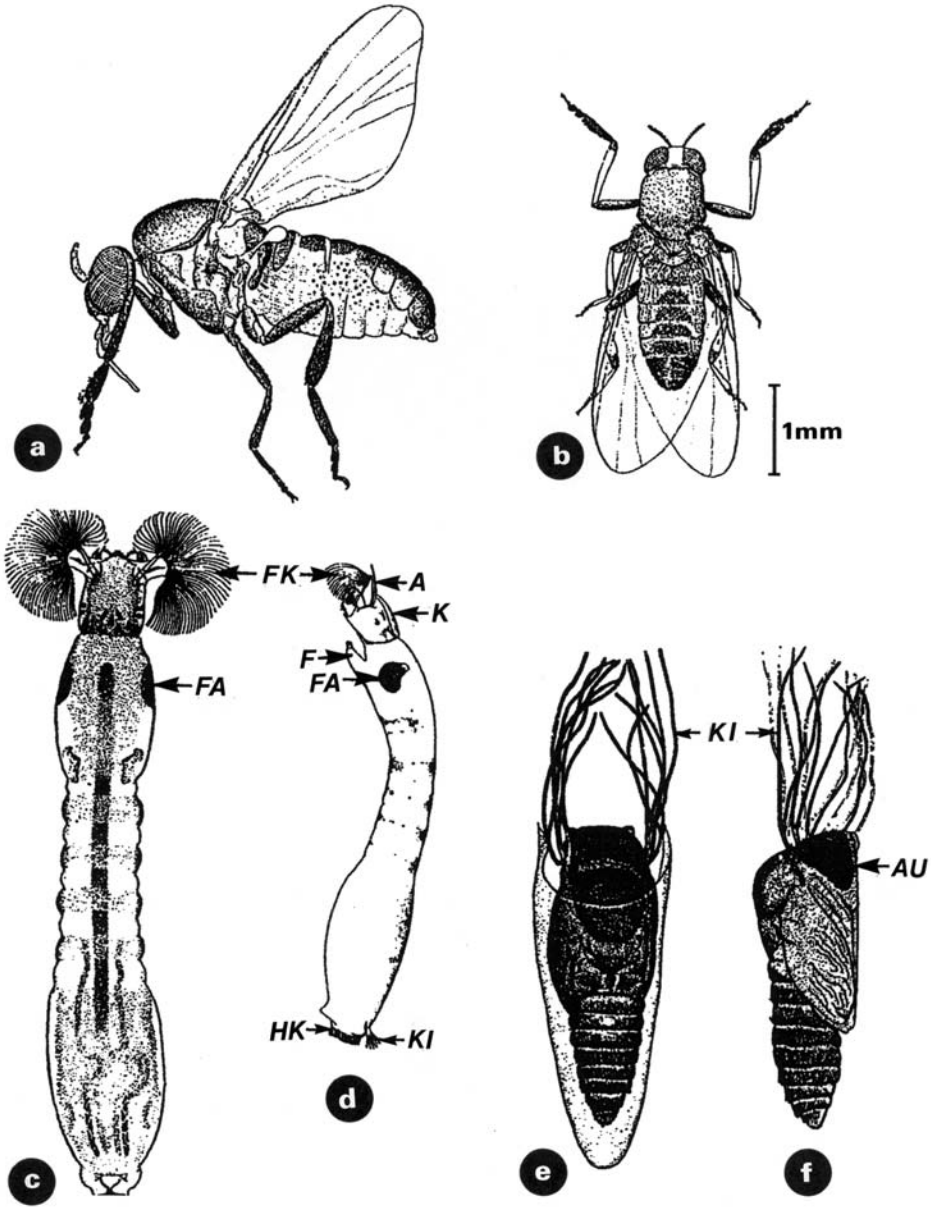
Classification

Family of →Insects, order →Diptera.

General Information

Fossil blackflies are about 170 million years old. Of the approximately 1,600 blackfly species, only about 900 are man-biting species. Only female blackflies suck blood, demoralizing the host by their painful bites. Since the larvae develop only in flowing water, attacks by adults regularly occur there, and after mass attacks by adults these can even induce panic reactions in herds of cattle. Black flies transmit protozoan blood parasites to birds but are mainly known as vectors of filarial helminths, especially →Onchocerciasis (→River Blindness).

Blackflies are holometabolous insects; larvae and pupae live aquatically. Adults are small, stout-bodied, humpbacked →Diptera (Figs. 1, 2). The best identification criteria are little drops of blood on the legs near flowing waters, accompanied by strong itching reactions. Despite the name, many neotropical species are not black but yellow or orange. Especially larvae and pupae can easily be identified, both anchored to immersed substrate in flowing water, larvae with the end of the abdomen, which has a “Coke”-bottle-like



Blackflies. Figure 1 Life cycle stages of *Simulium* sp. (a)/(b) adult female; (c)/(d) larvae seen dorsally and ventrally; (e)/(f) pupae; *A*, antenna; *AU*, eye anlage; *F*, foot protrusion; *FA*, anlage of wing; *FK*, filter fan; *H*, hooks; *K*, head; *KI*, gills.

appearance; pupae with the shoe- or slipper-shaped →cocoon, out of which the spiracular gills emerge.

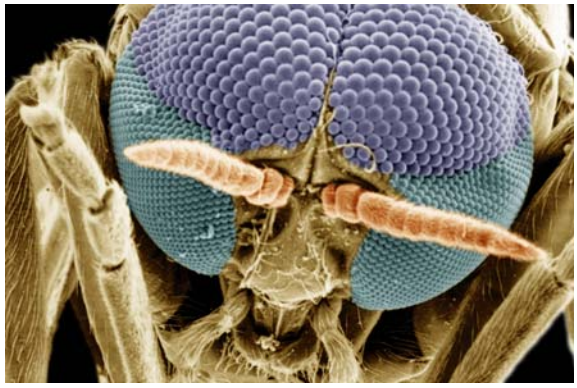
Distribution

Blackflies are cosmopolitans. They occur in all geographical regions, but only if flowing water is present.

Morphology

The adult blackflies are 1.5–4 mm long, having no large scales on wings and a body like many →mosquitoes. The head is short, possessing well-developed eyes. The 9-12 (mainly 11) segments of the short antennae are cylindrical. The →proboscis of the mouthparts is shorter than the height of the head and consists of the posterior labium enclosing 6 stylets (labrum, paired mandibles, paired maxillary laciniae, hypopharynx). The food channel is located between the labrum and the mandibles, the salivary channel between the latter and the hypopharynx. The 5-segmented maxillary palps are longer than the proboscis, containing a large carbon dioxide-sensory pit organ. Males and females can be separated according to the weaker developed and untoothed mouthparts of males, but much better by the compound eyes which are larger in males, leaving no

Blackflies. Figure 2 SEM of a female black fly (*Simulium damnosum*).



Blackflies. Figure 3 SEM of a male of *Simulium damnosum* showing two types of eye-ommatids.

space between them on the frons. In addition, males possess greatly enlarged upper ommatidia (Fig. 3).

The wings are short and broadened by a large anal lobe. The first abdominal tergite forms a prominent scale, bordered by fine hairs.

In the elongated larvae, which measure 4–12 mm in the final →instar, the head capsule is rarely fully sclerotized. The thorax is broader than the anterior abdomen and not sharply separated from it. The abdomen increases in diameter towards the posterior end, giving the larvae a slightly bottle-like appearance. This expansion is more strongly developed in larvae of fast than of slowly flowing waters. The abdomen ends in a →proleg (pseudopodium), possessing many minute hooks, by which the larvae anchor to a pad of silk, secreted by salivary glands which run through the whole body. The thoracic proleg also possesses such hooks. A pair of cephalic fans, covered with a sticky secretion produced by the cibarial glands, is used for filtering food from the water.

The →pupa is protected by a →cocoon and possesses paired thoracal spiracular gills, which act as a gill →plastron, i.e., air remains at the →cuticle and the gas exchange occurs at the air–water interface. The pupa anchors within the cocoon byhooks.

Genetics

In natural populations it is very difficult to recognize the different species. For very similar species the term "group" is used, e.g., the *Simulium neavei* group, for sibling species, which cannot be distinguished according to morphological but only by other criteria the term "complex", e.g., the →*Simulium damnosum* complex. Nonmorphological criteria are offered by the banding pattern of large polytene →chromosomes in the nuclei of the larval →salivary gland cells and sometimes of the Malpighian tubules of adults.

Reproduction

Breeding of blackflies in the laboratory is difficult, but possible for some species. Whereas the larval habitat can be established relatively easily, in most species adults do not mate or suck blood.

Meeting of males and females occurs by chance or when females enter a swarm of males, both near breeding places or hosts. Since in males the copulatory organs do not rotate after emergence as in mosquitoes, copulation, i.e., the transfer of a →spermatophore, occurs on the ground. Presumably one copulation is sufficient to inseminate all eggs. Females lay batches of about 200–800 eggs (0.1–0.4 mm long) mainly late in the day and often on just submerging substrates. In most species females are gonotrophically concordant, i.e., a blood meal is required for the development of each batch of mature eggs, but there are also autogenic species or populations laying at least the first batch of eggs without a blood meal. The number of blood meals and egg depositions determines the possibility of transmission of disease. The parous state can be determined according to changes in the ovarioles. Usually the gonotrophic cycle is completed within 3–7 days and can be repeated several times since females in nature can live up to 3–4 weeks.

Life Cycle

An adaptation to unfavorable conditions is the diapause or aestivation phase of the egg. Hatching occurs after several months in spring or after droughts for up to 2 years. Normally in tropical regions embryonic development lasts up to 2 days. Also larvae can survive the winter by a production of cryoprotectants to reduce the supercooling point. Larvae develop in every kind of running water, filtering microorganisms from the water, especially bacteria and diatomes. If larvae wish to settle on another place, they spin a silk thread, detach

from the pad of silk and drift downstream. Usually they settle on submerged substrates near the surface of the water, i.e., in a region with high oxygen tension. Short distances are covered in a looping manner detaching and anchoring alternatively with the hooks on the abdominal and thoracal proleg. The total duration of larval development varies greatly since the number of larval instars varies from 6 to 11 instars (commonly 7), even within a species, and since the development is temperature-dependent and can be retarded by the winter. In the tropics, larval development lasts from 4 to 10 days. Then the mature larva, which is actually a pharate pupa with the skin of the final larval instar, spins a slipper-shaped cocoon, orientating the open end downstream. The development of the inactive pupa usually lasts between 3 and 10 days. During the day adults emerge from the cocoon in an air bubble which brings them to the surface of the water. The whole developmental cycle (egg to egg) can be completed within less than 2 weeks, but up to several months in diapausing species (→Diptera/Fig. 1).

Transmission/Dispersal

Especially females searching for hosts and breeding sites fly long distances (15–35 km in mark-and-recapture investigations), but when assisted by wind, up to 600 km can be covered.

Feeding Behavior and Transmission of Disease

Host odours induce long-range attraction, followed by →orientation to the carbon dioxide source and then a visual orientation to the preferred region of the host. Simuliids usually bite during the day near running waters, showing species-specific peak diurnal biting activities and preferences to specific parts of the body of the host. In the Amazon basin 400–500 and in New Zealand up to 1000 blackflies settled to bite a man in one hour. Usually the blackflies need 3 to 6 minutes to engorge their own weight in blood. Simuliids are →pool feeders, opening capillaries in a depth down to half a millimeter. The blood is pumped directly into the midgut. Sugar liquids are at first directed into the crop for →sterilization and then into the midgut.

Simuliids transmit filarial helminths and – mechanically – →myxomatosis virus of rabbits. Onchocerciasis is caused by the filarial →helminth →*Onchocerca volvulus* and is common in tropical Western and Equatorial Africa, South America, and Yemen.

Interaction of Vector and Parasite

When the simuliids suck blood from an infected human, microfilariae of *Onchocerca volvulus* are ingested, which penetrate the →peritrophic membranes and the intestinal wall. In the hemocoel they migrate to the thoracic flight muscles, in which they grow and molt twice within 6–9 days. The infective L3 larvae migrate to the labium. Movements of maxillae and mandibles during piercing of the skin and the increase of temperature by the blood induce the penetration of the L3 via the soft parts of the labium.

Only rarely have effects of the parasite on the vector been investigated. The penetration of the gut wall and of the cuticle before transmission does not seem to induce a strong decrease of longevity. However, →immune reactions and reproduction rate are reduced.

Prophylaxis

Since the adults are active outdoors and during the day, only →repellents can be applied to clothing. In addition, people should not be near the water during the various local peaks of biting activity.

Control

→Insecticides could be used against adults, but such an outdoor use is nearly impracticable. The better way is a control of the larvae. In a major project, the Onchocerciasis Control Program (OCP) in West Africa, →*Bacillus thuringiensis* H-14 is also used, meanwhile in rotation with 6 chemical insecticides (phoxim, temephos pyraclophos, etofenprox, permethrin, carbosulfan). After 14 years of larviciding some residual foci remain to be treated, and neighboring countries have established a similar program, the African Program for Onchocerciasis Control (APOC) using not only →larvicides, but also the microfilaricide ivermectin for treatment of humans.

In the OCP countries, the human populations are well informed about the transmission of →*Onchocerca*, but much less so in the APOC region and South America.

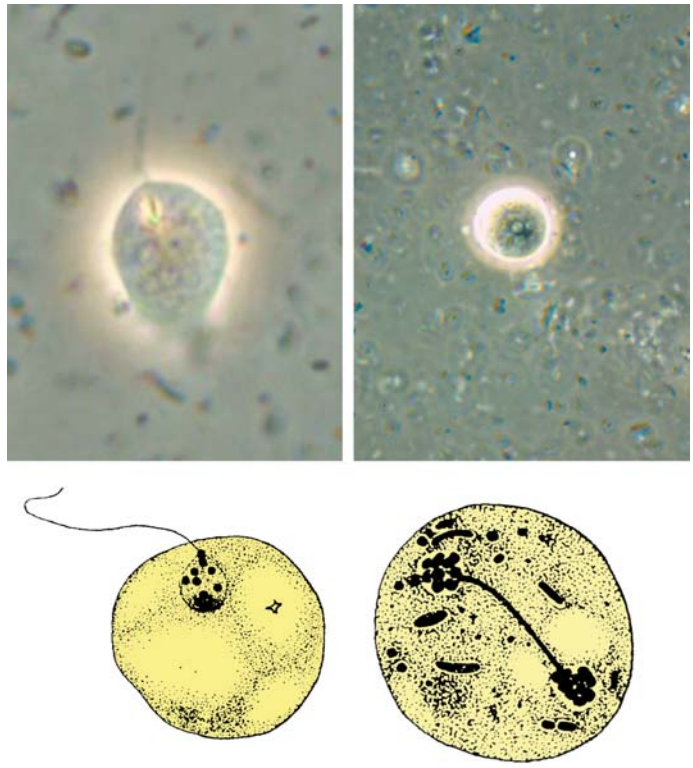
Blackhead Disease

Symptom

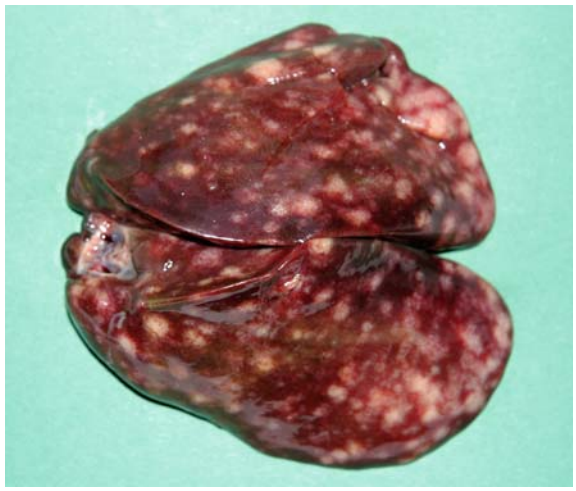
The crest appears black – due to the infection with the amoeboflagellate.

General Information

→*Histomonas meleagridis* in many species of turkeys, chicken or other birds. The parasitic stages (Fig. 1) reach a size of 10–30 µm, some appear with one flagellum others without flagellum, as spherical stage or as slightly amoeboid stage. Stages with two nuclei are apparently in the phase of division (Fig. 1, right below). Recently cyst-like stages also had been



Blackhead Disease. Figure 1 Light micrographs and drawings of uniflagellated and amoeboid stages, of which one is apparently in division (right below) showing two nuclei.



Blackhead Disease. Figure 2 Liver of an infected turkey showing complete necrosis.

described. The (rarely) reported stages with 2–4 flagella are probably not *Histomonas* but due to co-infections with other flagellates.

The mode of infection with *Histomonas* stages is not yet completely clarified. The most reasonable way is the oral uptake of cyst stages, which may develop from the uniflagellated or amoeboid stages in the rectum of the hosts. The quick common start of histomoniasis in a group of birds does underlie this possibility. The contamination of the anal region of the birds with trophozoites is, of course, also possible, when birds place themselves on faeces of infected birds. The most unlikely way of infection is due to eggs of the nematode *Heterakis gallinae.* In this case the unicellular parasite has to penetrate actively into the vagina of the female worm, and swim against the stream of excreted eggs up to the place where the worm oocytes are not yet fertilised, since later a thick egg wall will hinder any penetration. The reported "4 years – infectivity" of *H. gallinae* – eggs is probably related to the fact that the fluid of stored eggs were contaminated with cysts of *Histomonas.*

Pathology

Apparently the amoebic stages enter the intestinal wall, reach the liver, and introduce there huge necrosis (Fig. 2) due to repeated binary fissions of the amoebic stages (Fig. 1, right below).

Main clinical symptoms: →Diarrhoea, →anaemia, black crest, general weakening, death.
Incubation period: 2 days.

Patent period: Several months up to lifelong.
Diagnosis: Microscopic determination of trophozoites in fresh faeces, occurrence of cysts.
Prophylaxis: Separation of young from older animals.
Therapy: Oral application of different nitro-imidazoles (→Antidiarrhoeal and Antitrichomoniasis Drugs).

Bladder Worm

→Cysticercus of →tapeworms.

Blastocrithidia triatomae

Classification

Species of →Trypanosomatidae.

Life Cycle

Fig. 1.

Morphology

Figs. 1, 2A–E, 3 (page 176), →Cell Multiplication/Fig. 2A.

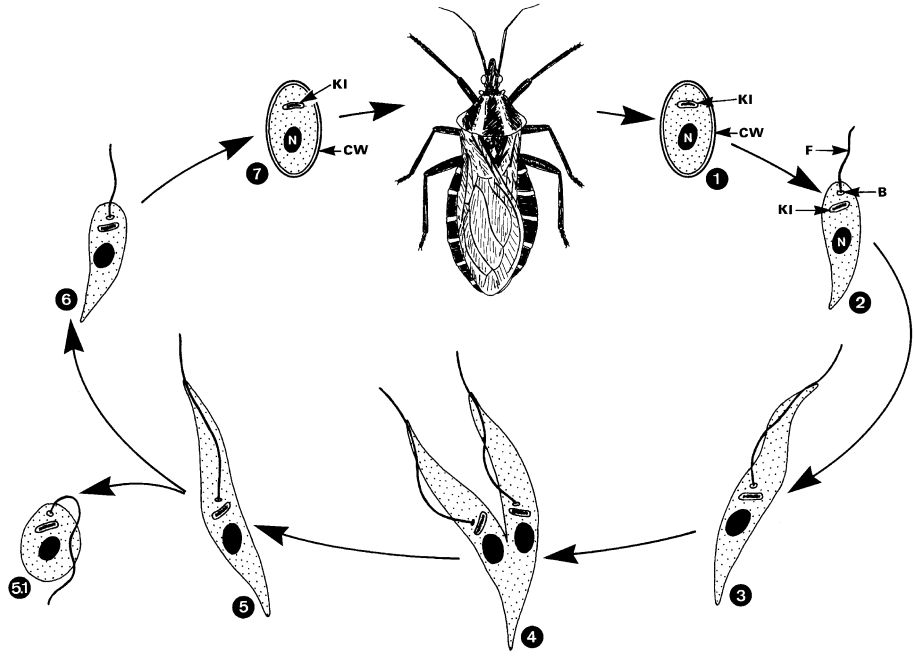
Blastocystis hominis

General Information

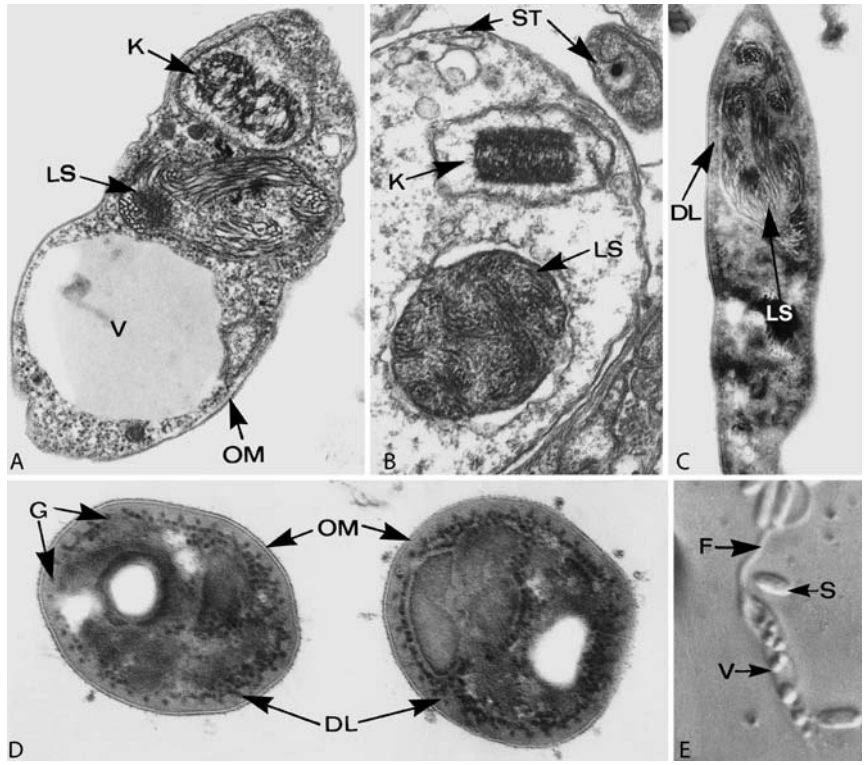
Blastocystis hominis is an organism of uncertain affinities living in the intestine of humans and probably other hosts (Figs. 1, 2). Other species of *Blastocystis* exist in many animals, some of them may also occur in humans (Fig. 1, page 176). Studies indicate that whatever symptoms are present can be attributed to unrecognized concomitant pathogens such as →*Entamoeba histolytica*, →*Giardia* sp. or →*Dientamoeba* sp. These symptoms disappear after appropriate treatment, whereas *B. hominis* persists. No lesions have been recognized.

Life Cycle

Fig. 2 (page 177).



Blastocrithidia triatomae. Figure 1 Life cycle of *Blastocrithidia triatomae* inside its host (the reduviid bug→*Triatoma infestans*, which may be a vector of *Trypanosoma cruzi*). *1* The bug ingests feces containing cysts. *2* Excystation inside the midgut within 12–48 h after uptake. *3–5.1* Development (by→binary fission) of pro-, epi- and sphaeromastigotes inside the whole gut. *6, 7* →Encystation inside the rectum (6 days p.i.). After unegual divisions, the smaller daughter cell remains attached to the flagellum of the other cells and encysts. The cysts are often attached "straphanger-like" along the →flagellum of nonencysted flagellates. After 14–21 days cysts are excreted within the feces of the bug. *B*, basal body; *CW*, →cyst wall; *F*, flagellum; *KI*, →kinetoplast; *N*, nucleus.



Blastocrithidia triatomae. Figure 2 A–E Cyst formation with increasing (A, E) desiccation in *Blastocrithidia triatomae* (see life cycle). Note that the nucleus has a labyrinthine pattern (LS). The cyst wall consists of a dense layer (DL) below the →cell membrane (OM). Cysts (D) are attached (straphanger-like) to the →flagella of mastigote stages (E). (A, B, C ×22,000, D ×33,000; E ×2,000). *DL*, dense layer; *F*, flagellum; *G*, large granules; *K*, →kinetoplast; *LS*, labyrinthine structure of the nucleus; *OM*, cell membrane; *S*, straphanger-like cysts; *ST*, →subpellicular microtubules; *V*, vacuole.

Blastocystis hominis. Figure 2 →Blastocystis hominis. Diagrammatic representation of the follow-up of the different life cycle stages. The infection occurs during oral uptake of cyst stages which had been excreted with the feces. *N*, nucleus; *V*, vacuole.

Disease

→Blastocystosis, Man.

Blastocystosis, Man

Disease due to infection with →*Blastocystis hominis* cysts from human or animal feces.

Main clinical symptoms: Nausea, →diarrhoea, →abdo-minal pain.
Incubation period: Days to weeks.
Prepatent period: 2–3 days to weeks.
Patent period: 2–3 weeks.
Diagnosis: Microscopic determination of cysts in fecal samples.
Prophylaxis: Avoid contact with human feces.
Therapy: Curative treatment unknown; see →Treatment of Opportunistic Agents.

Blepharoplast

Archaic term for →kinetoplast. See also →Mitochondria.

Blepharoprosthium

→Concrement Vacuole.

Blindness

→Filariidae, →*Onchocerca volvulus*.

Blue Tongue Disease (BTD)

Synonym

Ovine catarrhal fever.

Name

French: *fièvre catarrhale du mouton*; Spanish: *lengua atul*; Africans: *bloutang*.

Disease that occurs in wild and stock ruminants due to infections with BTD virus that is transmitted in Africa mainly by →*Culicoides imicola*, in Central Europe (new) by *C. obsoletus*, in the USA by *C. variipennis*, and in Australia by the *C. schultzei* group.

Symptoms of disease are: the name-giving blue tongue due to cyanosis (rather rare), severe nasal discharge, subcutaneous hyperaemia, petechae, lacrymation, facial, mouth, udder and lung oedema, swollen lymph nodes, typical foot lesions leading to general stiffness, abortion, torticollis, death.

Bluebottles

→Calliphora.

Blue Tongue Virus (BTV)

This is a so-called orbivirus within the family Reoviridae, which possesses double-stranded RNA with about 10–12 genome segments. BTV is transmitted during the bite of the very tiny females of insect family →Ceratopogonidae. The most important symptom of the disease in ruminants are haemorrhages in the mouth (i.e., leading to a blue tongue), on the surface of the udder and between the claws introducing painful and stiff movements of cattle. The disease which is common and symptomless in South African game animals leads to 24 different blood serotypes. Although the disease is not contagious it led since its first arrival (1998) in South Europe, to the death of more than one million sheep and also many specimens of cattle. Just recently (2006) it arrived also in Northern Europe (North France, Belgium, Netherlands, Germany).

Bodonids

Member of the flagellated protozoan family Bodonidae. *Ichthyobodo* (syn. *Costia*) *necatrix* and *Trypanoplasma borreli* are important fish parasites.

Body Cover

Synonym

→Integument, →Cuticle, Skin.

General Information

The parasite–host interface is the place where nutrients are taken up and is the site of the attacks of the host's defense system. In the parasitic →Metazoa considered in this book, two main types of body cover exist:

- An acellular filamentous →cuticle (excreted by an underlying cellularly organized hypodermis) is found, e.g., in →nematodes, →pentastomids, and in arthropods (→Ticks, →Mites, →Insects).
- A syncytial cytoplasmic →tegument, where giant nuclei or nuclear fragments may occur, covers the surface of larval monogeneans, →digeneans, →cestodes and →acanthocephalans, whereas the tegument (i.e., →neodermis = new skin) of adult parasitic →platyhelminths lacks nuclei (→Platyhelminthes/Figs. 11, 12).

The surface of both types of outer body cover (cuticle or tegument) may be lined by more or less thick layer(s) of carbohydrates, mucopolysaccharides, or even membranous material depending on the species and the site of parasitism.

The →surface coat, which fulfills its tasks in defense against environmental influences while covering "normal" and parasitic cells, is thought to be the ancestor of all cuticular systems (→Cuticle) of the whole animal and plant world. Apparently during evolution the →glycocalyx while situated between body- and/or cell protrusions (e.g., →microvilli, protuberances) became fortified by enclosure of fibers of →collagen, →chitin, cellulose, and/or calcium carbonate components, etc. Thus, the original protection system received a second function, i.e., the preservation of the body shape as system belonging to the exoskeleton. However, the uptake of nutrients through this increasing outer surface remained possible using a variety of mechanisms and carrier systems (→Membrane Transport; →Endocytosis). Thus, for example, schistosomes are able to take in huge amounts of glucose through their surface

membranes, and →nematodes may also become hidden by several drugs as a result of cuticular uptake.

Bolbosoma

Genus of polymorphid acanthocephalans; most species of this genus (as well as those of the genus *Corynosoma*) live in the intestine of aquatic birds and marine mammals, but a few are also found in humans. The specimens of this genus possess spines not only at the prosboscis but also along the trunk.

Bolus

Small container to be placed into a host (beneath skin, inside stomach) that releases drugs at given intervals (e.g., by corrosion of metal enclosures). Boluses are often used in grazing animals.

Bonamia Species

Intracellular parasites of oysters belonging to the protozoan phylum →Ascetospora.

Boophilus

Name

Greek: *bos* = cattle, *philein* = loving.

General Information

Genus of hard →ticks (Fig. 1) of ruminants (wild and farm). The species apparently originated from Africa, however, are now spread all over the world. Most important species are *B. microplus*, *B. decoloratus*, and *B. annulatus*. They are one-host ticks, which need only about 3 weeks until the females drop down to floor. 5 days later the females depone about 2000–4500 eggs, which need about 3–6 weeks (temperature-dependent) until the larvae hatch. The period of egg deposition can be stretched up to 120 days. The larvae may starve without host for 90 days (summer) or up to 180 days (winter). Due to their life cycle *Boophilus* sp. mainly transmit agents of disease, which enter the eggs of the ticks (e.g., viruses, →Babesia, *Anaplasma*).

Boophilus. Figure 1 *Boophilus microplus*. Engorged females of this one-host cattle tick species laying eggs. This species is found in Australia, Asia, Latin America, East Africa. The development on cattle needs 3 weeks, egg excretion (on the soil) takes 1–2 weeks. Thus 5–6 generations develop per year and may transmit →*Babesia* parasites of cattle. The name comes from Latin *bos* = ox, cow, and Greek *philein* = friend, loving.

Booponus

Genus of calliphorid flies in the Philippines that induce myiasis in the feet of cattle (e.g., *B. intosa*).

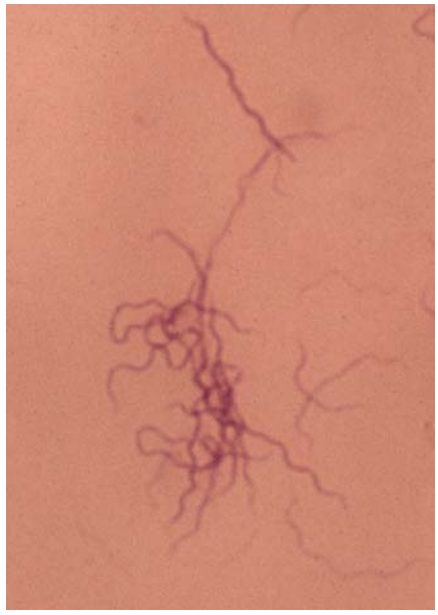
Bore Organ

→*Linguatula serrata*.

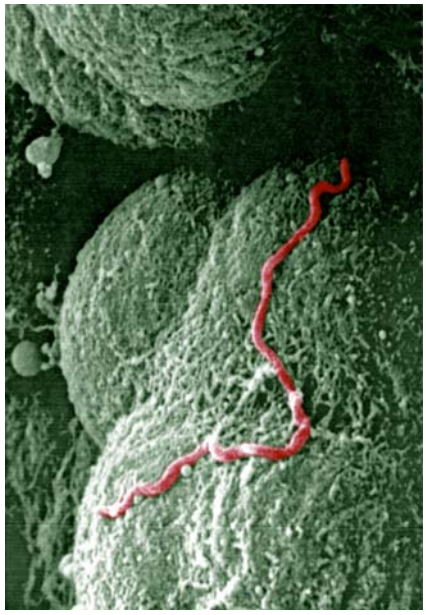
Borrelia

The species of this genus are gram-negative bacteria with a species-specific length of 5-15 µm and 0.2–0.5 µm in width (thus they are thicker as *Treponema* spp.). They show only a few windings (Figs. 1–3) and possess – unique in bacteria – a linear chromosome. The genes for membrane proteins are situated on their circular and linear plasmids.

They may become cultured in artificial media and need a time of about 18 hours for duplication. Some



Borrelia. Figure 1 LM of *Borrelia burgdorferi*.



Borrelia. Figure 2 SEM of the bacteria stage of *Borrelia burgdorferi* on the surface of a tick intestinal cell.

species are apathogens, others are agents of important human diseases and are transmitted by bloodsucking arthropods.

Examples are agents of:

- Endemic and epidemic relapsing fevers transmitted by →lice: *Borrelia berbera* (North Africa), *Borrelia carteri* (India), *Borrelia hispanica* (Spain), *Borrelia recurrentis* (syn. *Borrelia obermeieri*) (Africa, South America, East Asia), *Borrelia turricatae* (Central America), *Borrelia venezuelensis* (South America).
- Relapsing fever transmitted by →*Ornithodorus* ticks: *Borrelia caucasica* (Near East), *Borrelia duttoni* (Central and South Africa, Madagascar), *Borrelia parkeri* (Western USA).
- Tick- or →Lyme-borreliosis transmitted by →*Ixodes* and →*Dermacentor* ticks. *Borrelia burgdorferi* sensu latu (Europe, USA, Japan, including, e.g., *Borrelia burgdorferi* sensu strictu, *Borrelia afzelii*, *Borrelia garinii*, *Borrelia spielmani*). In Europe all types are found, in USA occur mainly *S. burgdorferi* s.s. and in Japan *Borrelia garinii* and *Borrelia afzelii*.
- *Borrelia vincentii* is apathogenic in the respiratory tractus (syn. *Treponema*).
- *Borrelia refringens* (syn. *Treponema*) is apathogenic in the sexual tractus.

→Lyme Disease, →Relapsing Fever, →Tick Bites, →Ticks as Vectors of Agents of Diseases, Man.

Borrelia. Figure 3 SEM of *Borrelia burgdorferi* from culture.

Borrelia burgdorferi

Bacterium transmitted by →Ticks (→Lyme Disease).

Borrelia recurrentis

Bacterium transmitted by →lice.

Borreliosis

→*Ixodes* Species, →Lyme Disease, →Ticks as Vectors of Agents of Diseases, Man.

Bosch-Yaws

Local name for multiple skin lesions in cutaneous →leishmaniasis due to *Leishmania guyanensis* in South America.

Similar forms are called →pian bois and →forest yaws. The sandfly vectors are *Lutzomyia umbratilis, L. anduzei* and *L. whithmani.*

Bosses

Modification (elevations) of the →body cover, e.g., in many →nematodes and male schistosomes (eventually provided with hooks). →Nematodes/Integument, →Platyhelminthes/Integument.

Botfly

Fly, the larvae of which cause myiasis in humans or animals, e.g., →*Dermatobia hominis* (→Myiasis, Animals, →Myiasis, Man).

Bothriocephalus

Genus of the cestode family Bothriocephalidae, often found in freshwater fish in the USA (e.g., the gravid →proglottids of *Bothriocephalus scorpii* possess two ovaries and two uteri which are situated at their anterior and posterior poles).

Bothriocephalus acheilognathi

Name

Greek: *bothrion* = invagination, groove; *kephalon* = head; *a* = lacking; *cheilos* = lip; *gnathos* = jaw.

General Information

This tapeworm (→Bothriocephalus/Fig. 1) originates from East Asia, from where it was imported with the grassfish *Ctenopharyngodon idella* to Europe, New Zealand, and USA. According to some authors it is a synonym of *B. gowkongensis*, which is now found in Cyprinid fish cultures with high pathogenicity. The adult worm reaches a length of 8–31 cm and a terminal width of about 2–4 mm. The scolex is heartlike and has 2 bothria as suckers. The operculated eggs are thin-shelled (50 × 30 µm) and contain already the coracidium larva, when leaving the proglottids. After infection it takes 12–20 days until the tapeworm is mature inside the fish intestine. A related species is: *B. claviceps* in the eel (reaching a length of 55 cm and a width of 3 mm).

Bothrium

→Archigetes Species.

Bouba

Local name for mucocutaneous and cutaneous forms of →leishmaniasis in South America due to *Leishmania braziliense* and *L. peruviana*. Vectors are *Psychodopygus wellcomei* (syn. *Lutzomyia*). Other names are →espundia, buba.

Boutonneuse Fever

Boutonneuse fever is caused by *Rickettsia conori*, which is widespread in Africa, the Mediterranean region, and parts of Southeast Asia. The tick bite lesion takes on a black, button-like appearance (hence the name), with a central dark necrotic area. A large number of tick species appear able to transmit the disease, which can also be acquired by contact with tick tissues when the tick is crushed, for instance when *Rhipicephalus sanguineus* is removed from dogs.

Therapy
Application of antibiotics.

Related Entries
→Rocky Mountain Spotted Fever, →Tick Typhus.

Bovicola bovis

→Lice.

Brachiola

Genus of microsporidians with a diplocaryotic arrangement of the sporoplasm inside the spore. In humans three species have been recorded: *Brachiola vesicularum* (spores measure 2.7 × 2.0 µm), *B. connori* and *B. algerae*, which formerly were called *Nosema algerae* respectively *N. connori*.

Brachiola vesicularum

→Microsporidia.

Brachycera

→Diptera.

Brachylaemus erinacei

3.5 mm long trematode in the intestine of hedgehogs.

Bradyzoites

Name
Greek: *bradys* = slow, *zoon* = animal.

Slowly by →endodyogeny reproducing unicellular stages in tissue-cysts of, e.g., →Toxoplasma gondii.

Brain Worm

Metacercaria of the liver fluke *Dicrocoelium* that has entered the subesophagial ganglion (brain) of the second →intermediate host (ant). Such →metacercariae initiate a change in the behavior of the ants such that they stay overnight outside of their state, anchored at grass, and thus become an easy prey for feeding ruminants.

Branchiura

A class of lower →crustaceans which include ectoparasites (order Argulidae, e.g., →*Argulus* species, carp →lice) which suck blood and body fluid at the skin of fish. →*Argulus*/Figs. 1, 2.

Braula

Genus of the family Braulidae (lice of bees). *B. coeca* (Fig. 1) of the honey bee is rather small (1.5 mm long) and has no wings. They live mainly as commensals on

Braula. Figure 1 Scanning electron micrograph of the bee louse *Braula coeca*.

the thorax and mouthparts of their host. They deposit their eggs inside the brood chambers of the bees. Their larvae eat the food of the bee larvae and thus may have effects on the quality of honey. They possess only 2 ommatids as eyes.

Brill-Zinsser-Disease

Disease due to *Rickettsia prowazeki* (being louse-transmitted and later endogeneously reactivated).

Bromocyclene

Chemical Class
Organohalogenide (organochlorine compound, cyclodiene).

Mode of Action
GABA-gated chloride channel antagonist. →Ectoparasiticides – Antagonists and Modulators of Chloride Channels.

Bromopropylate

Chemical Class
Organohalogenide (organobromine compound).

Mode of Action
Acetylcholine esterase inhibitor. →Ectoparasiticides – Agonists and Antagonists of Cholinergic Transmission.

Bronchoalveolar Lavage

Method to obtain fluid from lung in order to diagnose →*Pneumocystis carinii* stages. →BALF, →Pneumocystosis.

Brood Capsules

→Echinococcus/Life Cycle.

Brood Parasitism

→Behavior.

Brown-Brenn Stain

→Microsporidiosis.

Bruce, David, Sir (1855–1931)

English military physician (Fig. 1), discoverer of the life cycle of trypanosomiasis (→*Trypanosoma brucei*), discoverer (1883) of the agent of the Malta-fever within milk (now-called "Brucellosis") and of the trypanosomes that lead to the animal Nagana (1894–1897).

Bruce, David, Sir (1855–1931). Figure 1 Sir David Bruce, discoverer of the Malta fever of goats (brucellosis) and the transmission of Nagana fever.

Brugia

See Table 1. →Filariidae.

Brugia. Table 1 Comparison: characteristics of *Brugia malayi* and *Brugia timori*

	Brugia malayi	*Brugia timori*
Microfilariae		
Mean length	220 µm	310 µm
Cephalic space	Length to width ratio = 2:1	Length to width ratio = 3:1
Sheath	Stained pink with Giemsa	Stained pale pink with Giemsa
Terminal nuclei	4–5 in a single row	5–8 in a single row
Mean length of anlagen of organs	31 µm	60 µm
Adult worms		
Females	Body length to ovijector length ratio = 360:1	Body length to ovijector length ratio = 170:1
Male adanal papillae	3–4 on a side, regularly spaced	3–5 on a side, irregularly spaced
Ecology	Various ecotypes (anthropophilic or zoophilic); transmitted by *Anopheles* or *Mansonia* spp.	One ecotype (anthropophilic); transmitted by *Anopheles*
Geographic distribution	India, Southeast Asia	Lesser Sunda archipelago, East Timor

Brugia malayi

→Nematodes, →Filariidae, →Brugia.

Brugiasis, Man

Disease due to infection with the filarial worm →*Brugia malayi*.

Main clinical symptoms: see →Elephantiasis Tropical, →Filariasis Lymphatic Tropical.
Incubation period: 30–60 days.
Prepatent period: 50–90 days.
Patent period: 8–10 years.
Diagnosis: see →Filariasis, Lymphatic, Tropical.
Prophylaxis: Avoidance of mosquito bites.
Therapy: Treatment see →Nematocidal Drugs, Man.

BSE

Bovine spongious encephalopathy in cattle due to →prions, which apparently are transmitted to many hosts via oral uptake of infected brain (nerves) or contaminated fly larvae and other destruents (?). Transmission to man is introducing the new Creutzfeldt-Jakob-Disease (CJD).

Therapy

Unknown.

BTD

→Blue Tongue Disease (BTD).

Buba

→Bouba.

Buccal Capsules

At the anterior end of nematodes (e.g., →Hookworms, *Camallanus species*) toothed depressions are formed which are used as suckers to get blood and/or body fluids from their hosts.

Bucephalus

Genus of marine fish trematodes (e.g., *B. cuculus*), the species of which form branched sporocysts (e.g., in the American oyster *Crassostrea virginica*).

Budd-Chiari-Syndrome

Symptom due to alveolar echinococcosis.

Buffon, Georges-Louis Leclerc, Compte de (1707–1788)

Director of the Royal Garden at Paris (1739), describer of the large liver fluke *Strobilocercus (Fasciola) fasciolaris (hepatica).*

Bugs

Classification

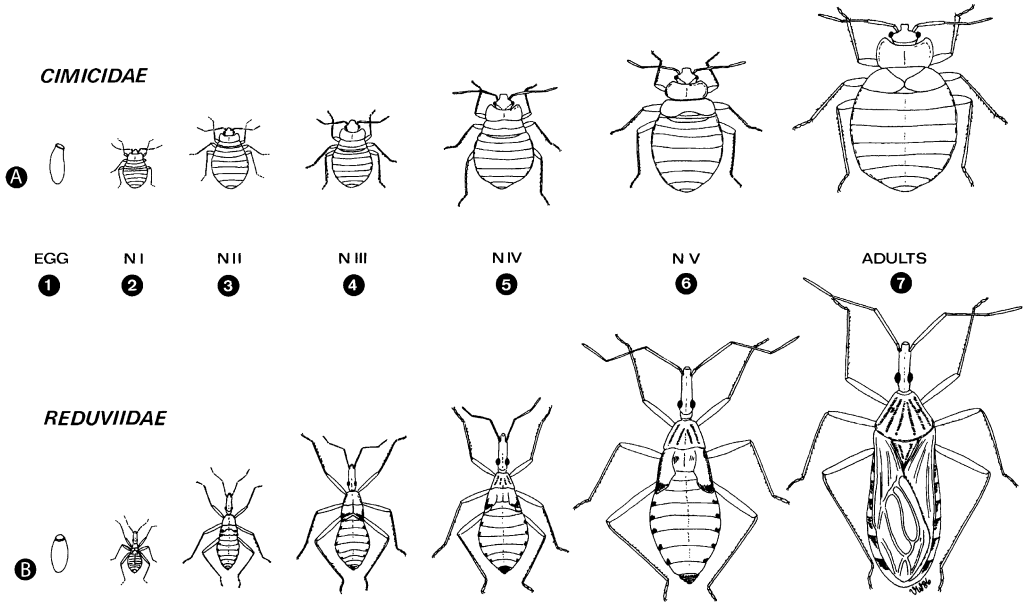
Order of →insects.

Synonyms

→Rhynchota, →Hemiptera.

Bugs. Table 1 Some common parasitic bugs

Family/Species	Length (mm)	Hosts	Transmitted pathogens
Reduviidae			
Rhodnius prolixius	30	**Humans,** many animals	*Trypanosoma cruzi*
Triatoma infestans	30	**Humans,** many animals	*Trypanosoma cruzi*
Panstrongylus megistus	30	**Humans,** many animals	*Trypanosoma cruzi*
Reduvius personatus	18	Insects, **humans**	–
Cimicidae			
Cimex lectularius	5–6	**Humans,** mammals, birds	Eventual mechanical transmission
C. hemipterus	6–7	**Humans,** mammals, birds	Eventual mechanical transmission
Oeciacus hirundinis	2–3	Swallows, **humans**	Eventual mechanical transmission
Leptocimex boueti	3–4	Bats, **humans**	Eventual mechanical transmission



Bugs. Figure 1 Life-cycle stages of the wingless Cimicidae (**A**, →*Cimex lectularius*, bedbug) and the Reduviidae (**B**, →*Rhodnius prolixius*) in dorsal view. *1* The eggs are laid in batches by *Cimex* and mostly singly by *Rhodnius* in the crevices of bed frames, walls, or similar household sites. *2* The larvae (nymphs I) which hatch from the eggs are wingless and feed (as do all other stages) by sucking the blood of humans, and also many other mammals. *3–7* 5 molts of the nymphal instars are needed to reach the sexually mature female or male stage (*7*); in Reduviidae typical fore- and hindwings are eventually formed, but Cimicidae remain wingless in all stages.

Bugs. Figure 2 SEM micorgraph of the ventral side of a reduviid bug showing the attached, but protrudible sucking tube. ×30.

Bugs. Figure 3 Light micrograph of a female bedbug (*Cimex lectularius*) with 2 eggs.

Bugs. Figure 4 Light micrograph of the predator bug *Reduvius personatus*, which may bite painfully humans, too.

General Information

Among the 30,000 species of bugs of the suborder →Heteroptera, 2 families have obtained medical importance due to their periodic bloodsucking activity which allows transmission of pathogens (Table 1, page 185): the →Reduviidae (predacious bugs) including the →Triatominae (→Kissing Bugs) with wings, and the →Cimicidae (bedbugs, Fig. 1A, page 185) without wings. Both groups are dorso-ventrally flattened bugs and feed on the blood of their hosts by means of their stylet-like mouthparts, which are included inside an eversible →proboscis (Fig. 2) located at the tip of their head; furthermore, "stinking glands" which open behind the third to the sixth abdominal tergit (in juvenile bugs) or alongside the metathorax (in adults) are characteristic. The →hemimetabolous development of the Rhynchota includes 5 nymphal instars (Fig. 1B, page 185).

Life Cycle

Fig. 1.

Important Species

Table 1, Figs. 3, 4.

Bulinus

Genus of snails, intermediate hosts of schistosomes of cattle.

Bulla

Anchoring device of lernaepodoid crustaceans (like →*Salmincola*) representing solidified secretions from the head and maxillary glands. The maxillae of these parasites are often fused to the bulla.

Bullis Fever

Disease due to transmission of agents by the tick *Amblyomma americanum*.

Bunodera

Genus of fish trematodes. →Digenea.

Bunodera inconstans

Intestinal fish trematode. →Behavior.

Bunostomum

→Hookworms, →Nematodes.

Bunyaviridae

Classification

Family of →RNA Viruses, mainly transmitted by arthropods (→Arboviruses).

General Information

Negative-sense single-stranded tripartite →RNA viruses (spherical, with envelope); about 200 species.

Important Species

Table 1 (Bunyavirus), page 188–190.
Table 2 (Nairovirus), page 191.
Table 3 (Phlebovirus), page 191, 192.

Buparvaquone

Compound that belongs to the hydroxynaphthochinone group.

→Babesiacidal Drugs; →Theileriacidal Drugs; it blocks the electron transport in theilerian "mitochondria."

Buphagus

→Ticks.

Burkea eisenia

Microsporidian parasite of muscles of earthworms.

Burkitt's Lymphoma

Childhood disease due to infections with the Epstein-Barr-virus causing tumors only in regions where malaria is endemic, while the virus occurs worldwide. Thus the outbreak of such lymphoma tumors are probably related with a malaria-induced immunosuppression.

Bursa copulatrix

The bursa is a lobular modification of the male posterior end in some groups of →nematodes which is highly elaborated in strongylid nematodes (Fig. 1, page 192). During copulation the bursa surrounds the vulvar region of the female worm (→Nematodes/Reproductive Organs).

Bütschli, Johann Adam Otto (1848–1920)

Swiss zoologist, discoverer of many pathogenic protozoans.

Bütschliidae

Family of ciliates that live inside the intestine of mammals.

Buxtonella

→Ciliophora.

Bursa copulatrix. Figure 1 DR of the terminal ends of male worms of different nematode species of horses, which are characterized by their means for copulation. *AP*, anal papillae; *BC*, bursa copulatrix; *CR*, cuticular rings; *SP*, sense papillae; *ST*, stabilizations of the BC (rays).

Caenorhabditis elegans

Free-living small-sized (1.3 mm in length) nematode, which is now one of the most often cultured specimens for laboratory experiments. The Nobel prize winners of the year 2006 worked with the RNA of this fully sequenced worm with a constant number of 959 cells (→Eutely) and about 19,000 genes. Most of the animals are hermaphrodites, which fertilize themselves. They are females, which as adults may produce sperms for a limited period. Males are rare, but they may copulate with the hermaphroditic females.

Calabar Swelling

→Oedema due to infection with wandering →*Loa loa* stages in human skin, →Filariidae, →Loiasis.

Calcareous Corpuscles

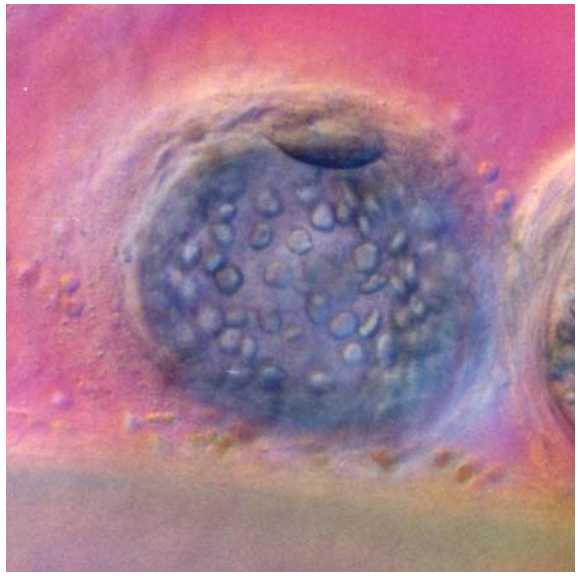
The →tegument and parenchymal cells of adult and in particular larval →tapeworms contain these significant corpuscles (Fig. 1), which may be used for diagnosis (→Cestodes/Tegument). They are composed of an organic base coupled with inorganic substances, such as potassium, sodium, magnesium, calcium, phosphate, and sulfate in different →Cysticercus larvae. In adult tapeworms CaO, MgO, P_2O_5, and CO_2 were determined. The organic base of the corpuscles includes DNA, RNA, proteins, and →glycogen. The function of these organelles, which (after KOH isolation) in electron microscopy appear as concentrically lamellated platelets, is not quite clear. Since they are mainly produced in the absence of oxygen, they were thought to buffer anaerobically produced acids. It has also been suggested that they are a reservoir for inorganic ions. It was recently reported that calcareous corpuscles are also formed in the excretory canals of cysticerci of →*Taenia solium* indicating their possible contribution in osmoregulation and protection against calcification.

Calicophoron

Genus of flukes related to →*Paramphistomum*, e.g., *Calicophoron* (syn. *Paramphistomum*) *daubneyi* in deers.

Caligus

→Crustacea.



Calcareous Corpuscles. Figure 1 Calcareous corpuscles inside a protoscolex within an *Echinococcus* brood capsule.

Calliphora

Name

Greek: *kalos* = beautiful, *phorein* = porting, showing.

Genus of →Diptera, belonging to the fly family Calliphoridae appearing with black thorax and steely dark-blue, bluish-violet, or blue-black, slightly metallic abdomen. This group of flies is also called "bluebottles" reaching a length of 10–14 mm as adults. In Europe occur *C. vicina* (syn. *erythrocephala*) (Fig. 1), and *C. vomitoria*, also named "blue flesh flies." The eggs are ovoid and appear white (Fig. 2).

Callitroga

Genus of flies, the larvae of which penetrate human skin leading to →myiasis. The species *C. americana* is synonym to *Cochliomyia hominivorax*. The common name for this group of flies is "screwworms" or "-flies". →Diptera.

Calpain

This product is released by the skin – penetrating cercariae of →schistosomes. It is postulated to lead to a Th1 cytokine production, which may introduce protection of the host.

Calliphora. Figure 1 LM of an adult *Calliphora erythrocephala* fly.

Calliphora. Figure 2 LM of *Calliphora* eggs close to the border of a 10-cent coin.

Calreticulin

This is a calcium-binding protein (e.g., of →trypanosomes), which is suggested to modulate the vertebrate complement system and provides an effective immune-escape mechanism for, e.g., *T. cruzi*. Since it also inhibits angiogenesis it might protect the host from ongoing neoplasic aggressions.

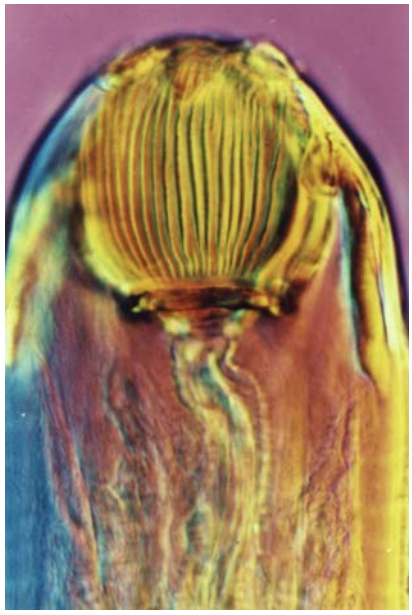
Calyptospora

→Coccidia; Genus of parasites of fish, e.g., *C. funduli* is found in Cyprinodontidae and Atherinidae and needs intermediate hosts (shrimps) to complete the life cycle.

Camallanus

Genus of →nematodes. Several of these red appearing species (e.g., *C. cotti*) live in the hind gut of fish and parasitize by blood sucking (Fig. 1). Since they possess a fortified buccal capsule (Fig. 2), they are also called "fraise-head-worm." Males reach 3–4 mm in length, females grow up to 7–12 mm, hang out of the anus, and

Camallanus. Figure 1 The posterior end of a female *Camallanus* hangs out of the anus of its host (*Papiliochromis* sp.).



Camallanus. Figure 2 LM of the buccal capsules of a *Cammallanus* – nematode.

excrete larva – containing eggs into the water (Fig. 1). These eggs are taken up by intermediate hosts (small crustaceans), within which the infectious larva 3 develops. The infection of the fish (final host) occurs by feeding such intermediate hosts.

Symptoms of Disease

Apathy, anaemia, slow growing, disturbance of bone formation, death due to bacterial superinfections.

Therapy

Medical bath containing compounds such as emamectine (Nematol®) or mosquito-larvae that had been traced with levamisole or fenbendazole (~50 mg/kg food).

Campylobacter coli

Bacterium, the presence of which facilitates in pigs the mucosae invasion of the ciliate →*Balantidium coli*.

Canalis gynaecophorous

In →schistosomes the dorso-ventrally flattened male forms a groove, within which the tiny female – appearing circular in diameter – is hidden. This partnership keeps for the whole lifespan.

Candiru Fish

Synonym

→Vampire Fish.

Canine Parasitic Zoonoses

Often neglected diseases, since dog owner do not know the existence of such parasites. Risks are especially during contacts with stray dogs.

Capacitation

The last stage of spermiogenesis in →ticks, leading to mature sperms (→Ticks/Spermatogenesis and Fertilization).

Caparinia

→Mites.

Capillaria aerophila

→Nematodes, →Respiratory System Diseases, Horses, Swine, Carnivores.

Capillaria Species

Name
Latin: *capillus* = hair.

Classification
Genus of →Nematodes.

Important Species
Table 1, others in ruminants.

Life Cycle
Fig. 1.

Disease
→Capillariosis, →Capillariasis.

Capillariasis

Capillariasis is diagnosed by finding the distinctive →*Trichuris*-like eggs either in the liver (→*Capillaria* species) or in the feces (*C. philippinensis*). In *C. hepatica* infection the embryonated eggs are ingested with soil, and the larvae mature in the liver where adults lay their eggs. They have been found in a number of humans, surrounded by fibrosis. Because *C. hepatica* is normally found in rats, the adults die in humans. Infection with *C. philippinensis* has been described in Thailand and the Philippines. Large numbers of →viviparous adults, larvae, and eggs have been found in the lumen and mucosa of the small intestine of people who are believed to have been infected by eating raw freshwater fish. →Autoinfection with larvae appears to explain the intensity of the infection. Severe protein-wasting enteropathy with edematous jejunal walls but with little inflammation and an inconstant presence of eosinophils are considered characteristic. →Malabsorption with voluminous diarrhea, followed by emaciation, and hypoproteinemic edema, often precedes a fatal outcome after an illness of 2 weeks to 2 months.

Therapy
→Nematocidal Drugs, Man.

Capillariosis

→*Capillaria* species, syn. →Capillariasis.

Capitulum

Anterior part of →ticks and →mites – also called gnathosoma – which presents 2 pairs of mouthparts (cheliceres, pedipalps).

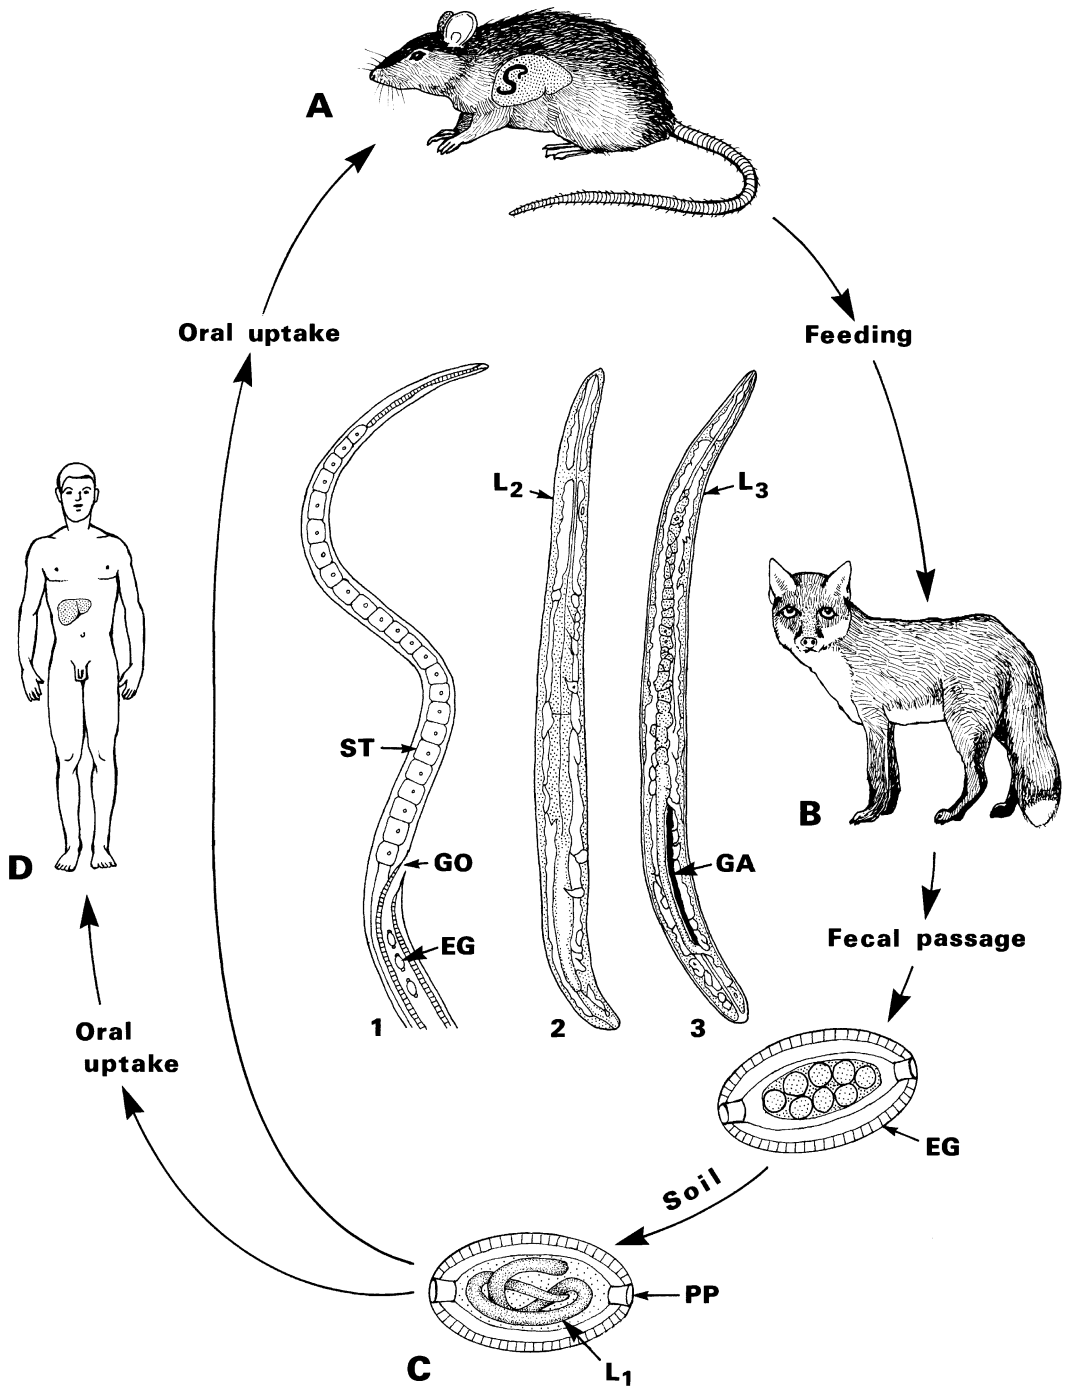
Capping

→Coccidia, motility, →Locomotory Systems.

Capillaria Species. Table 1 Important species of the genus *Capillaria*

Species	Length of adult worms (mm)		Size of eggs (or larvae) (μm)	Final host/Habitat	Intermediate host	Prepatent period in final host (weeks)
	f	m				
C. aerophila	30	25	70 × 35	Cats, dogs, hedgehogs/Lung	–	4–6
Capillaria annulata	10–50	10–25	60–62 × 24–27	Chickens/Pharynx	Earthworms	3
C. hepatica	100	15–30	50 × 35	Lagomorpha, rodents, **humans**/Liver	–	21–28 (remain in liver)
C. philippinensis	45	3	50 × 35	Birds, **humans**/Small intestine	Fish, crustaceans	?

f = female, m = male



Capillaria Species. Figure 1 A–D Life cycle of *Capillaria hepatica*. **A** Adults (male 15–30 × 0.06 mm, female 100 × 0.2 mm) live in liver →parenchyma of their final hosts (rodents and a variety of other mammals). Here the females (**1**) deposit their typical eggs (EG), which measure 45–60 × 30 µm and are characterized by two →polar plugs *(PP)*. **B** The unembryonated eggs have no means of egress until eaten by a predator (mainly foxes, dogs) or until the liver decomposes after death of the final host. In the first case the eggs merely pass through the intestine of the predator and are excreted with the feces. **C** Embryonation occurs on the soil and depends on a favorable combination of temperature, moisture, and oxygen. At room temperature about 4–5 weeks are needed until the first-stage larva (L_1) is formed (which may survive for more than 1 year). **D** Infection of final hosts (**A**; mice and erroneously man) occurs by swallowing of fully developed eggs. After hatching in the cecum the L_1 reaches (via the intestinal wall and portal vein) the liver within 2 days. There, the next 2 larval stages (**2, 3**) are formed by molts; maturity is acquired 21–28 days after infection (prepatent period). The lifespan of males is about 40 days and that of females about 60 days (patent period). The eggs, however, persist until the death of the final host. *EG*, egg; *GA*, genital anlagen; *GO*, genital opening; *L*, larva; *PP*, →polar plug; *ST*, stichosomal cell of esophagus.

Carallobothrium fimbriatum

Species of proteocephalan cestodes (parasitic in fish intestine).

Carbamates

→Ectoparasiticides, →Arthropodicidal Drugs (e.g., Propoxur).

Carbaryl

Chemical Class

Carbamate.

Mode of Action

Acetylcholine esterase inhibitor. →Ectoparasiticides – Agonists and Antagonists of Cholinergic Transmission.

Carbohydrate

→Energy Metabolism.

Carchesium

→Ciliophora.

Carcinogenesis

Some worms may introduce development of tumors in organs of their hosts, e.g., in liver →*Clonorchis*, →*Opisthorchis*, in liver and bladder →*Schistosoma*, in lung →*Paragonimus*, in brain →*Acanthamoeba*.

Card Agglutination Test (CATT)

Antibody detection test for →trypanosomiasis.

Cardiovascular System Diseases, Animals

Blood Disease, Animals (Parasitaemias)

Haemoprotozoal diseases (→Babesiosis, Animals, →Trypanosomiasis, Animals, →Theileriosis and →Leishmaniasis, Animals) are caused by infections which localize either in the blood alone or in the blood and solid tissues. Blood infections affect primarily the microcirculation. However, more important are the lesions caused in solid tissues and organs. They are attributable either to systematic malfunction of the circulation or to disturbances in the microcirculation of a specific organ. An important common feature in all the pathogenesis is the release of large amounts of antigens into the plasma. The interactions of these antigens with the host's immunological responses result also in mechanisms of tissue destruction.

The clinical signs are non-specific and consist of fever, lethargy, weakness, and emaciation. Parasitaemias are often associated with →anaemia, leucopenia, →oedema, and hemorrhages (Table 1).

Heart

Most parasites which form cysts in striated muscles may also invade the myocardium. Such cysts include the tiny tubular sarcocysts formed by the protozoan →*Sarcocystis*, the metacestodes of the →*Taeniidae* (cysticerci and hydatid cysts), or the encysted larvae of the nematode →*Trichinella spiralis*. These infections generally produce few or no symptoms and in most cases the cysts are found incidentally on post-mortem examination of the cardiac muscle. However, in the unusual event of a massive infection death may occur after a febrile course.

The pathognomonic lesion in *Gedoelstia*-fly larva infection (→Uitpeuloog) is a thrombo-endophlebitis which varies in intensity, location, and distribution and is frequently accompanied by thromboendoarteritis. In sheep coronary →thrombosis causes myocarditis or myomalacia cordis with sudden death as the sequel.

Trypanosoma cruzi is the cause of human trypanosomiasis in South America (→Chagas' Disease, Man). It also develops and causes disease in cats, dogs, and pigs which, together with numerous wild animals act as →reservoir hosts for the parasite. *T. cruzi* multiply within the →cytoplasm of the cells of their mammalian host, particularly those in the skeletal and cardiac muscles (amastigote form). The heart is particularly affected, with development of multifocal to diffuse severe granulomatous myocarditis. In dogs non-specific clinical signs such as →weight loss,

Cardiovascular System Diseases, Animals. Table 1 Parasites of the haematopoietic system (according to Vercruysse and De Bont)

Parasite	Host	Location	Clinical presentation	Principal lesions
Babesia				
B. bigemina	Cattle	Red blood cells	Fever, malaise, loss of appetite, listlessness, anaemia haemoglobinuria, icterus	Findings of acute intravascular haemolytic crisis: capillary congestion of most organs, splenomegaly
B. bovis	Cattle		*B. bovis, B. canis:* nervous symptoms	*B. bovis, B. canis*: congestion grey matter throughout the brain
B. divergens	Cattle			
B. major	Cattle			
B. caballi	Horse			
B. canis	Dog			
B. gibsoni	Dog			
B. felis	Cat			
Leishmania				
L. infantum	Dog	Monocyte-macrophage system (visceral and cutaneous)	Lymphadenomegaly, anaemia, splenomegaly, dry exfoliative dermatitis, ulcerations, weight loss, onycogryphosis, ocular signs, anorexia	Haemo-lymphatic hypertrophy with macrophage proliferation and focal granulomas
Theileria				
T. parva	Cattle	Lymphocytes (lymphoblasts), erythrocytes	E C F: fever, dullness, listlessness, anorexia, hyperplasia lymph nodes, salivation, lacrimation diarrhoea, watery cough and dyspnea	Lymphoid hyperplasia, splenomegalia, petechial haemorrhages over most of the serous and mucous surfaces, interlobular oedema, emphysema and hyperaemia of the lungs
T. annulata	Cattle			
T. lawrencei	Cattle			
T. mutans	Cattle			
T. hirci	Sheep, goats			
T. equi	Horse			
Trypanosoma				
T. congolense	Ruminants	Bloodplasma, perivascular tissues	Acute: severe symptoms and death after 3 weeks Chronic: remittent fever, anaemia and progressive emaciation. Less common: watery diarrhoea, abortion, stillbirths, corneal opacity, bottle jaw	Generalized lymphoadenopathia, heart is flabby, liver and spleen are enlarged
T. vivax	Ruminants, Horses			
T. evansi	Horses, Dogs			
T. brucei	Equines, Ruminants, Dogs, cats			
T. simiae	Pigs			

ECF = East Coast Fever

lymphadenomegaly, →diarrhoea, and →anorexia are generally accompanied by signs referable to cardiac dysfunction, such as tachycardia, ascites, weak pulse, lethargy, and hepatomegaly.

Vasculitis

The tachyzoite stage of *Toxoplasma gondii* invades many host cell types including vascular endothelium. Perivascular infiltration, e.g., in the brain is a common feature in

toxoplasmosis-related inflammation. High infective doses of pathogenic *Sarcocystis* spp. (e.g., *S. cruzi*, *S. miescheriana*) may cause multiple haemorrhages in the intermediate host. The pathogenesis is not completely resolved but it appears that both mechanical destruction of the endothelial lining by the intracellularly developing parasite and alteration of blood coagulation are involved.

Haemoprotozoa (→Cardiovascular System Diseases, Animals/Parasitaemia, →*Babesia*, →*Theileria*, →*Leishmania*, →*Trypanosoma*) do not only destroy host cells but also induce occlusion of capillaries and immune complex formation. This leads to necrosis and inflammation in various tissues. Severe, often lethal, disease results from organ malfunction, however, the clinical picture may be quite variable, depending on the main localization of impairment of microcirculation. Moreover, generalized disorder of circulation and acute shock are possible consequences of haemoprotozoan infection.

Arteries

Parasitic →arteriitis is a very common form of arterial disease in animals (Table 2). The lesions are characterized by →inflammatory reaction and thickening of the arterial wall, often accompanied by endothelial damage and thrombosis. Thrombi may partially or completely occlude the artery and emboli arising from pieces of thrombi that have broken loose may occlude vessels distal to the site where parasites have lodged. Rupture of arteries as a result of parasitic lesions is rare. The 2 helminth species which cause by far the most severe damage to arteries are →*Strongylus vulgaris* in horses and →*Dirofilaria immitis* in dogs. Other species eliciting varying degrees of arteriitis are *Onchocerca armillata* in cattle, *Elaeophora schneideri* in sheep, *Angiostrongylus vasorum* and →*Spirocerca lupi* in dogs, and *Aelurostrongylus abstrusus* in cats.

Strongylus vulgaris is often referred to as the most important parasite of horses. It is widely distributed

Cardiovascular System Diseases, Animals. Table 2 Parasites inducing myocarditis and vasculitis (according to Vercruysse and De Bont)

Parasite	Host	Location	Clinical presentation	Principal lesions
Nematoda				
Angiostrongylus vasorum	Dog, fox	Pulmonary artery	Dyspnea	Granulomatous interstitial pneumonia, endarteriitis
Dirofilaria immitis	Dogs, rarely other hosts	Pulmonary arteries and chambers of the right heart	Deep soft chest cough, loss of exercise tolerance, emaciation	Intense endovascular reaction of the pulmonary arteries sometimes in hepatic veins
Elaeophora schneideri	Sheep, deer, elk	Cephalic arteries	Hyperplasia and occlusion of cephalic and other arteries, microfilariae cause dermal lesions	Mild intimal sclerosis to prominent fibrous thickening of the vessel wall
Onchocerca armillata	Cattle	Thoracic aorta	Microfilariae cause epileptiform signs and ophthalmia	Nodules, roughening, and calcifications in the aortic walls
Spirocerca lupi	Dog	Aorta	Usually no clinical signs during the prepatent phase	Local thickening of the intima and media of the aorta
Strongylus vulgaris	Equines	Anterior mesenteric artery and the adjacent aorta and other trunks	Pyrexia, anorexia, weight loss, dullness, colic, and death in severe infections, otherwise varying pyrexia, colic, diarrhoea	Verminous arteritis, thrombus formation, infarction of colon and caecum
Protozoa				
Trypanosoma cruzi	Man, wild mammals, dog, cat, pig	Amastigote forms preference for skeletal and cardiac muscle	Systemic disease, cardial dysfunction as tachycardia ascitis, weak pulse, lethargy	Heart: mild multifocal to diffuse severe granulomatous myocarditis
Trematoda				
Schistosoma curassoni, *S. bovis*, *S. mattheei*	Ruminants Ruminants, horses	Mainly mesenteric and portal veins	Mucoid and haemorrhagic diarrhoea, anorexia, loss of condition, general weakness, anaemia, hypoalbuminaemia	Granulomatous lesions in intestine and liver

and infects horses of all ages, fatal natural infection having been observed in foals as early as 21 days after birth. The pathogenesis of *S. vulgaris* infection is associated with the larval migration of the parasite through the tissues of the host. Third-stage infective larvae ingested by the grazing animal penetrate the wall of the intestine, moult in the submucosa to become fourth-stage larvae, and invade terminal branches of intestinal arteries to begin their migration. This penetration and early migration of larvae results in inflammatory reactions and small haemorrhages throughout the intestinal wall. This coincides with the rise in body temperature detected 5–7 days after heavy infections. The temperature reaction generally subsides as the fourth-stage larvae migrate in the intima of the mesenteric arteries causing inflammatory reactions and mural thrombi. By 2–3 weeks post-infection the larvae reach the cranial mesenteric artery where they remain for several months. They moult to become fifth-stage larvae and eventually return to the lumen of the large intestine where they complete their maturation and start producing eggs 6–7 months after infection. During their long stay in the cranial mesenteric artery, the larvae induce a severe fibrinous inflammatory reaction which can involve all layers of the arterial wall (verminous arteritis). In →chronic infections, the wall of the artery becomes thickened and the lumen partly occluded by thrombi, cellular debris, and larvae which remain firmly attached to the intima. Clinical signs in animals include dullness, progressive weight loss, and varying degrees of pyrexia, often with intermittent abdominal discomfort. At post mortem, aneurysmal dilatation of the artery may sometimes be observed. Larval migration of *S. vulgaris* was generally recognized as a major etiological factor of equine colic, although its incidence is decreasing due to the availability of efficient anthelmintics. Acute colic due to thromboembolic infarction of the caecum or large intestine is a well-documented complication of verminous enteritis. Colic signs have also been observed in early massive infections, before verminous lesions develop in the cranial mesenteric artery. Possible mechanisms for colic include damage to and impairment of nervous innervation to the intestine by migrating larvae, release of toxins by degenerating larvae, and →hypersensitivity or allergic reactions to *S. vulgaris*. A diarrhoeic syndrome in field cases of verminous arteriitis has also been described. The pathophysiology is poorly understood but it may be a response to altered intestinal circulation, local irritation, and/or severe ulceration of the mucosa of the caecum and colon caused by thromboembolism. Clinical signs and lesions have been associated with aberrant larval migration in the aorta, coronary, iliacic, spermatic and renal arteries, and in the heart, kidney, brain, and spinal cord.

The filarial worm Dirofilaria immitis, or "→heartworm," is an important parasite of the dog. The adult worms are 12–30 cm long and live in the right ventricle of the heart and in the pulmonary arteries. Most cases with light infection remain asymptomatic. In heavier infestations, the presence of large numbers of heartworms does both mechanically interfere with the circulation through the right heart and lungs, and induces endarteriitis with severe intravascular changes. Such heavy infection invariably leads to circulatory and respiratory distress. The mechanical interference with the circulation through the right heart generally causes a compensatory hypertrophy of the right ventricle. At the same time, adult worms and juveniles spread within the pulmonary arterial system and cause inflammatory reactions. They also induce the development of typical myointimal proliferative lesions which gradually reduce the lumen of small pulmonary arteries, leading to pulmonary hypertension. Endothelial damage, with thrombosis and thromboembolism has sometimes been reported. Chronic infections eventually lead to insufficiency of the right heart, which results in passive congestion of the liver, spleen, and lungs, ascites and peripheral oedema. The onset of clinical signs of dirofilariasis is insidious and may go unrecognized until substantial vascular damage has occurred. A deep, usually soft chest cough is a common early sign. Coughing may be aggravated by exercise, severe coughing being sometimes accompanied by hemoptysis, a sign highly suggestive of heartworm infection. In the late stages some dogs display characteristic respiratory movements: the rib cage remains expanded, and there is an extra inspiratory effort. The very poor exercise tolerance is a consistent clinical finding in advanced cases. Dogs which are suddenly forced to exercise may rapidly become ataxic or experience syncope. Emaciation develops gradually. The final stage of congestive failure of the right heart is only seen in a small proportion of affected dogs. A relative infrequent complication of *Dirofilaria immitis* heavy infestations is the occurrence of pulmonary embolism by adult worms – or worms killed by chemotherapy – which occlude small pulmonary arteries and cause infarction. Also described in very heavy infections is the "liver failure syndrome" caused by worms which have invaded the vena cava and hepatic veins. The cause of the distribution is not known but it may be related to overcrowding in the normal pulmonary arterial habitat. The syndrome is characterized by sudden onset of weakness, anorexia, →bilirubinuria, →haemoglobinuria, Haemoglobinaemia, and →anaemia. The anaemia develops due to disseminated intravascular coagulation and fragmentation of red cells. Azotaemia develops, and death usually occurs in 1–3 days. Another possible complication of *Dirofilaria* infection is →immune complex →glomerulonephritis.→Microfilaria are usually

of little consequence for the dog. If microfilariae block the arterioles of the skin there is →erythema, →pruritus, and loss of hair. This effect may however be due to concurrent dipetalonemiasis. Infections with *D. immitis* have also been reported in the cat, wild Canidae and Felidae, and rarely in humans.

Onchocerca armillata and *Elaeophora schneideri* are another 2 filarial parasite species which live in large blood vessels, produce microfilariae, and have biting insects as obligate intermediate hosts. *O. armillata* is focally highly prevalent in ruminants in Africa and Asia. In cattle it produces striking lesions in the intima and media of the thoracic aorta: tunnels, →nodules, Roughening, and calcifications. However, the only cardiovascular disturbances that have been reported appear to be slight aneurysmal changes, despite the presence in the aortic wall of worms which may be up to 70 cm long. Other symptoms, such as repetitive episodes of collapse and tetanic convulsions, periodic ophthalmic, and even →blindness sometimes observed in heavily infected animals have been attributed to the microfilariae. *E. schneideri* is common in wild ruminants and sheep in northern America. The adult worms live in the cephalic arteries of the host, while microfilariae are found in the skin, mainly in the head region. In elk and moose, the infection often causes inflammatory reactions and thrombosis of the cephalic arteries, which may lead to obstruction and ischaemic →necrosis. The disease, if not fatal, may induce various neurologic signs such as blindness, and necrotizing lesions in the skin of the head. In sheep, arterial lesions are minimal or absent, but hypersensitivity to microfilariae often results in severeexudative dermatitis, primarily over the head.

Angiostrongylus vasorum and *Aelurostrongylus abstrusus* are small metastrongyle worms. The adult *A. vasorum* lives in the pulmonary artery and right ventricle of the dog where it causes a proliferative endarteriitis and trombosis in pulmonary arteries comparable to that induced by *D. immitis*. *A. abstrusus* is a lungworm of cats. In addition to causing pulmonary nodules, it is believed to incite the smooth muscle hypertrophy and medial →hyperplasia of the pulmonary arteries which may focally be observed in up to 70% of cats. The respiratory clinical signs of these 2 infections are described in →Respiratory System Diseases, Horses, Swine, Carnivores.

The spiruroid worm *Spirocerca lupi* is primarily a parasite of dogs. The major clinical signs of spirocercosis are associated with the presence of adult worms in the oesophagus. They are described in →Alimentary System Diseases, Carnivores. However, significant lesions are also caused by the migrating larvae which spend about 3 months in the adventitia and media of the aorta. Aortic lesions include the formation of small nodules containing larvae, thickening of the intima and media, and deposition of atheromatous plaques. Weakness of the aortic wall and partial rupture of the layers sometimes leads to the development of shallow aneurysmal pouches, with possible rupture, and fatal hemorrhage. In most cases, aortic lesions do not produce any clinical signs.

Veins

Schistosomes are important parasites of the venous vascular system of vertebrates (Table 2). In Africa, *Schistosoma bovis*, *S. mattheei*, and *S. curassoni* occur commonly in ruminants, and *S. rhodhaini* has been reported to infect dogs. In Asia, *S. indicum*, →*S. spindale*, and *S. nasale* occur in a variety of domesticated animals including cattle, water buffalo, sheep, goat, and horse. *S. incognitum* has been reported in pigs, dogs, sheep, goats, and occasionally cattle. Finally, →*S. japonicum* is an important →zoonosis in Southeast Asia. In China, dogs, goats, rabbits, cattle, sheep, pigs, horses, and water buffaloes have all been found to harbour the infection (→Schistosomiasis, Animals). All these parasites live in the mesenteric and hepatic veins of the host, except for *S. nasale* which is found in the veins of the nasal tissue. The presence of adult worms in the veins does not induce reactions from the host, except when dead worms are occasionally blocked into small veins of the intestine or swept into the liver where they give rise to focal inflammatory reactions (phlebitis) and lymphoid nodules. Such lesions are only of clinical consequence after chemotherapy. Schistosomes are relatively large worms (>10 mm) and the sudden accumulation of considerable numbers of them (up to several tens of thousands) in the portal veins may cause diffuse phlebitis and extensive thrombosis. The pathogenesis of schistosome infection is mainly caused by the migration of millions of eggs through the intestinal wall, and their accumulation in the liver. These clinical syndromes are discussed under →Alimentary System Diseases, Ruminants.

Lymphatic Vessels

Filariid worms of the genus →*Brugia* parasitize the lymphatic system of dogs and cats in tropical areas. They do not usually cause lymphoedema and elephantiasis as in humans. *Dracunculus insignis* may occasionally infect dogs in North America, causing obstruction and inflammation of the lymphatic vessels, leading to lymphoedema.

Therapy

→Chemotherapy, →Drugs.

Carnidazole

Compound belonging to the group of →nitroimidazoles acting against specimens of the genera *Giardia, Trichomonas*, *Entamoeba*, see →Antidiarrhoeal and Antitrichomoniasis Drugs.

Caryocyst

Characteristic →tissue-cyst of →Caryospora species.

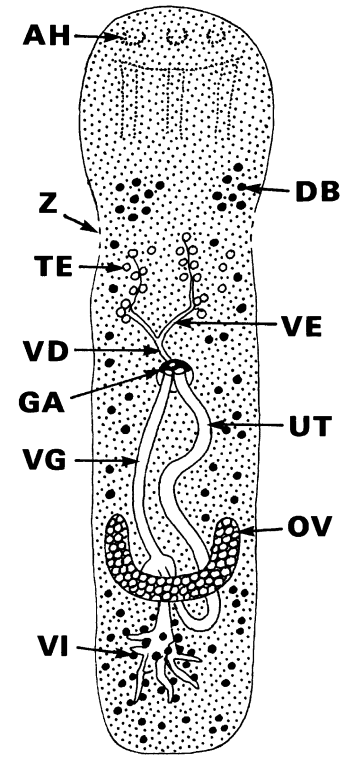
Caryophyllaeus laticeps

Classification

Monozoic tapeworm belonging to the group →Eucestoda in →Cestodes (→*Amphilina foliacea*).

Morphology

Fig. 1.



Caryophyllaeus laticeps. Figure 1 Diagrammatic representation of the adult monozoic →tapeworm *Caryophyllaeus laticeps* (3 cm long) from the intestine of cyprinid and catostomid fish; intermediate hosts are aquatic annelids (*Tubifex* sp.); paratenic hosts are possible. *AH*, adhesion zone; *DB*, →dense bodies in the vitelline system; *GA*, genital atrium (joint pore of UT and VE); *OV*, ovary; *TE*, testes; *UT*, uterus; *VD*, vas deferens; *VE*, vas efferens; *VG*, vagina; *VI*, vitelline glands; *Z*, interruption (animals are longer).

Caryospora Species

Classification

Genus of →Coccidia.

Life Cycle

Figs. 1, 2 (page 204, 205).

Casinaria texana

Ichneumonid insect used for biological control of pests.

Castration

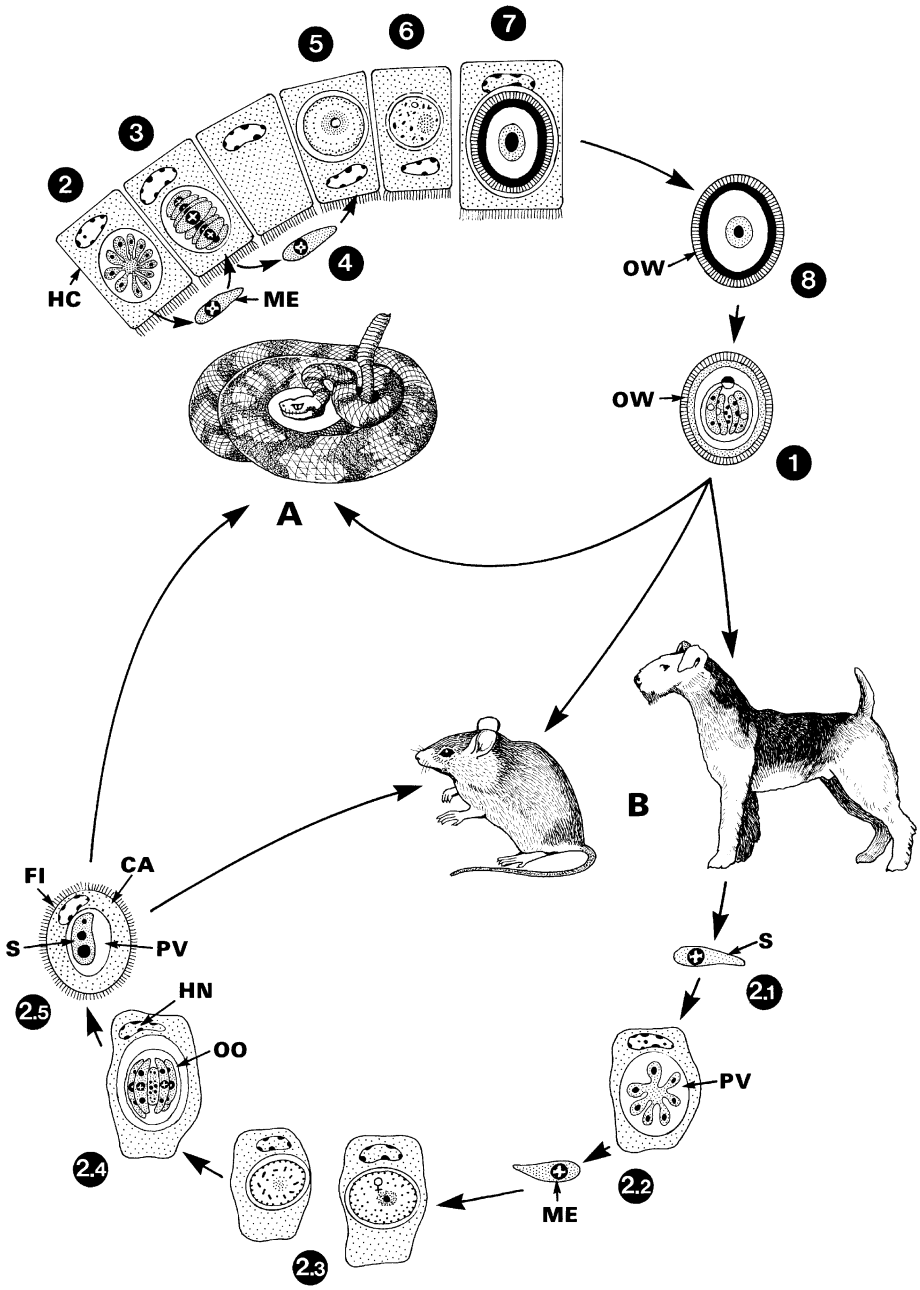
Some parasites castrate their hosts due to chemical or mechanical measurements, e.g., the digeneans *Parorchis* and *Zoogonus* do it in their intermediate hosts (= snails), see →Behavior/Castration.

Catatropis verrucosa

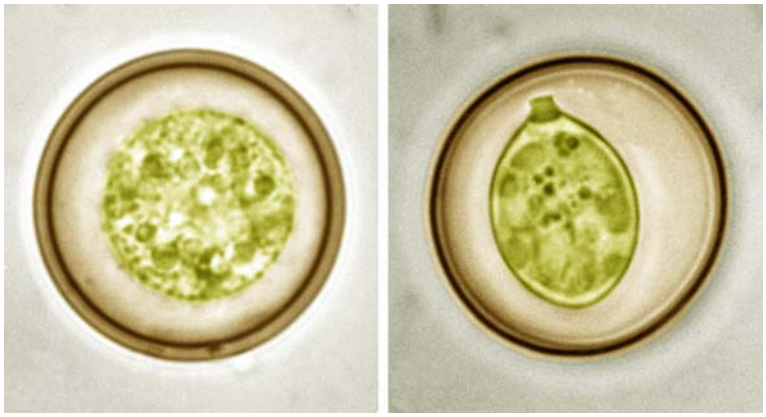
This species (1–6 × 0.7–2 mm), which has no ventral sucker, lives in the caeca of ducks and other waterbirds. The eggs show polar filaments. High infection rates may introduce ulcerative typhlitis. Common in Europe, Africa, Asia, and North America.

Catecholamines

→Nervous System of Platyhelminthes.



Caryospora Species. Figure 1 Life cycle of *Caryospora bigenetica* (according to C. Sunderman). **A** First type of final host (rattlesnake). *1* The sporulated →oocyst contains a single →sporocyst with 8 sporozoites. *2–4* After oral infection with oocysts 2 generations of schizonts are formed inside the intestinal epithelium. *5/6* Male and female gamonts are formed and later →gametes occur. The male →gamont (G) forms numerous gametes. *7/8* After fertilization a thick-walled oocyst is formed inside the host cell and becomes free within the feces. While sporulating on the ground a single sporocyst with 8 sporozoites is formed inside each oocyst. **B** Second type of final host (mice, cotton rats, dogs). *2.1–2.4* Repetition of the schizogonic and gamogonic development (described in 1–8). The →sporulation of oocysts may occur in skin regions (2.4). *2.5* Sporozoites that were set free from their sporocysts while still inside the skin of their hosts enter other host cells and induce formation of so-called caryocysts, i.e., cells being surrounded by fibrillar material. Those caryocysts are infectious for both host types (if taken up orally). Furthermore these caryocysts are infectious for hosts of the second type during close skin contacts. *CA*, →caryocyst; *FI*, filamentous material; *HC*, host cell; *ME*, →merozoite; *OO*, →oocyst; *OW*, oocyst wall; *PV*, →parasitophorous vacuole; *S*, →sporozoite.



Caryospora Species. Figure 2 Unsporulated and sporulated (right) oocyst.

CD-36 Gene

Polymorphism of this gene is often linked to a high susceptibility to severe malaria. Similar effects are described due to polymorphism of the genes of the TNF - λ promotor or the genes for the interferon receptor I.

$CD4^+$-Cells

Memory cells, CT-helper-cells, which inform upon an infection the B-lymphatic system to produce antibodies.

CDC

Centers for Disease Control and Prevention.

Cediopsylla simplex

New World flea.

Celation

From Latin: *celatio* = secrecy. Phase of virus inside insect vector, during which a transmission is not possible.

Cell

Cells are the basic units of life. It was recognized by Virchow in 1855 that they are the smallest units capable of maintaining the continuity of life or, as he expressed it, *Omnis cellula e cellula* (every cell derives from a cell). Organic matter on earth exists in the following forms: various types of cells; short sequences of stable proteins (→Prions); extracellular genomes (viroids, or naked RNA molecules); and protein capsules, or capsids, containing relatively short molecules of DNA or RNA often surrounded by an additional membrane (bacteriophages and viruses). Prions, viroids, phages, and viruses lack their own metabolism and the ability to reproduce independently, whereas all types of cells are true living systems with metabolic ability (→Metabolism) and the capacity for independent reproduction (→Cell Multiplication). All cells share the following attributes:

- They are enclosed by a →cell membrane.
- Their systems of reproduction use DNA for information storage and RNA for directing cellular organization.
- Their genomes may undergo accidental change (i.e., they mutate).
- They can use chemical-bond energy or light energy (autotrophic organisms) to run their metabolic systems.
- They can detect and respond to environmental signals;and they can receive, recognize, and transmit signals and impulses.

They may also be motile and, in the case of eukaryotes, may have a flowing →cytoplasm. Two basic types of true cells are distinguishable: →prokaryotes and →eukaryotes. There are no transitional forms in existence today and thus these 2 forms are quite distinct.

Cell Anus

Synonym
→Cytopyge.

Definiton
Special place for →exocytosis developed by many →Protozoa.

Cell Division

→Cell Multiplication.

Cell Junctions

Membrane-bound structures exist that mediate the joining of cells. These are needed for fusion of →gametes and similar structures and are also found at places where →flagella are attached to the surfaces of →protozoa The undulating membranes and recurrent flagella of trypanosomes and →trichomonads are joined to the cell by means of such cell junctions. Cell junctions also play a role in the attachment of many parasites to the surfaces of host cells. For example, trypanosomes use junctions for attachment to the vector's intestine. Another example is the →moving junction that is formed during cell penetration of Apicomplexa (→Apicomplexa/Fig. 8).

Cell Membrane

Synonym
Unit membrane; →plasmalemma.

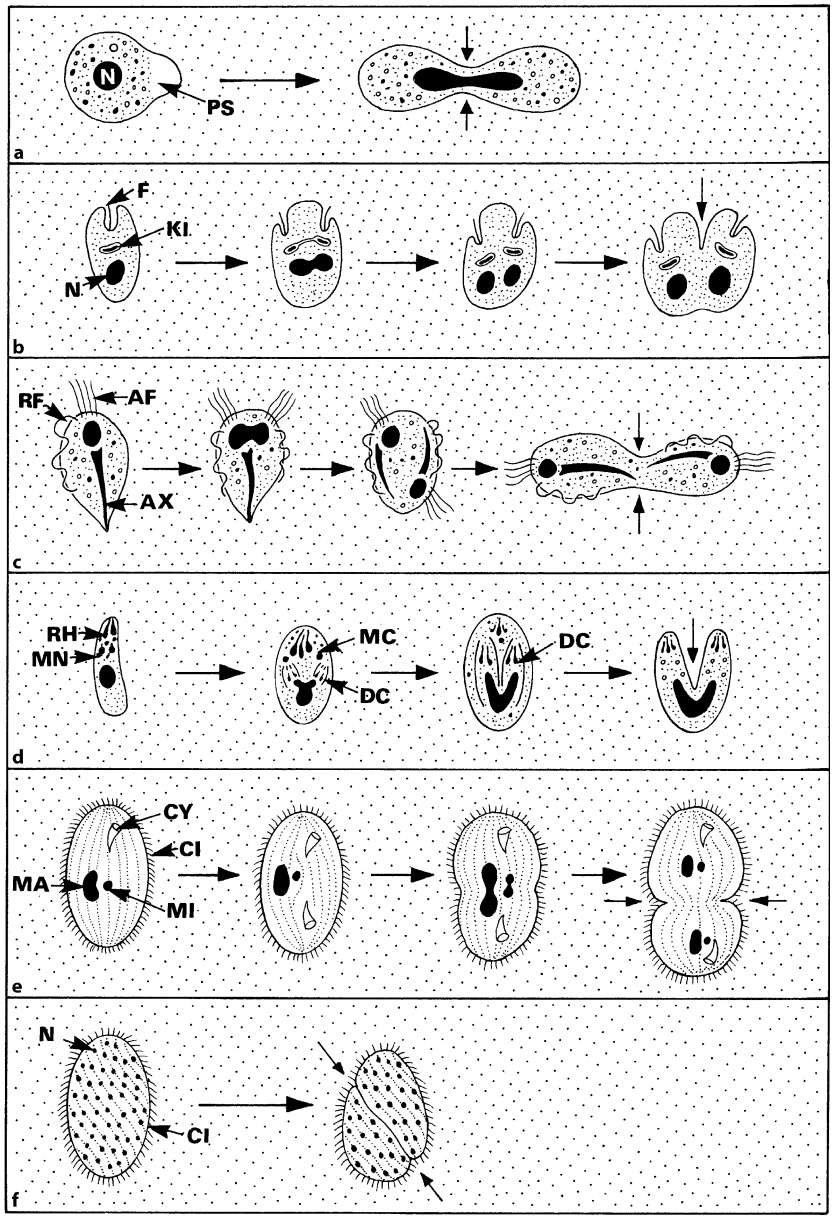
General Information
All cells are surrounded by a 5–10 nm thick cell membrane (→Pellicle/Fig. 1G, →Surface Coat/Fig. 2). In living cells this membrane always forms a closed sac or vesicle. The membrane is composed of species-specific amounts of various proteins and a double layer of lipids. It is physiologically and morphologically asymmetric, presenting a p face (directed towards the →cytoplasm) and an external e face. High magnification electron microscopy reveals that it is composed of 3 layers (trilaminar) (→Pellicle/Fig. 1G). It is semipermeable, i.e., only certain types of molecules may cross it. Several models have been created to explain how this biomembrane functions. The most widely accepted is the fluid mosaic model of Singer and Nicolson in which it is proposed that the membrane consists of a double layer of lipid molecules within which proteins and other components float like icebergs. At least some of the proteins may be structured to form pores. The membranes expand by additive inclusion of vesicles formed inside the cytoplasm and shrink by formation of endocytotic vesicles. The functions of the cell membrane are various and include transport processes such as uptake (→Membrane Transport, →Endocytosis), →secretion of substances, cell recognition, and joining of cells (→Cell Junctions).

Cell Multiplication

In the →Protozoa different ways of cell multiplication have been developed during phylogeny.

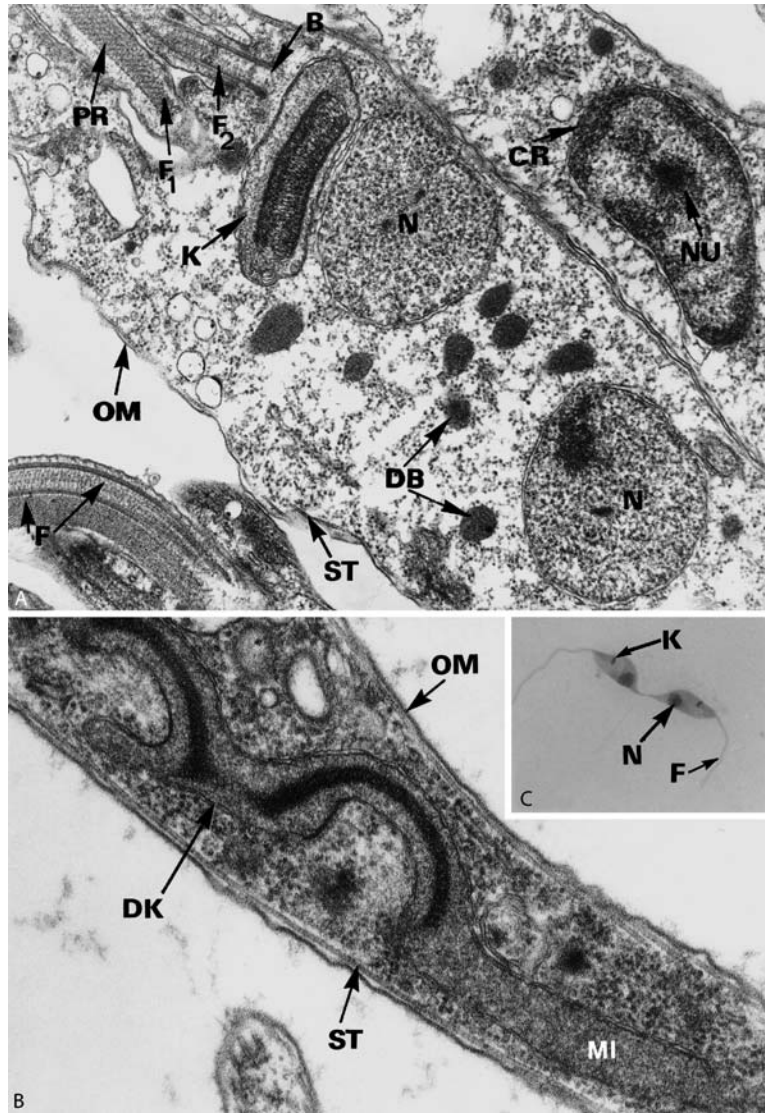
Binary Fission
The most basic type of multiplication is →binary fission, which always produces 2 daughter cells and needs a preceding duplication of the organelles of the mother cell (Figs. 1, 2). Since the axis of →cell division is fixed in the different groups within the Protozoa different types can be distinguished:

- Irregular division. In microsporidians (e.g., →*Nosema*, cf. life cycles) binary fissions occur after nuclear divisions. In these cases the →cytoplasm is divided irregularly and different-sized daughter cells are formed, which, however, obtain a similar shape after feeding.
- Amoeba-like division (Fig. 1A). In rhizopods (e.g., →*Entamoeba histolytica*, →*Acanthamoeba*) the cell division is more or less irregular with respect to the cytoplasm; however, the constriction always occurs perpendicular to the spindle axis.
- Longitudinal division (Fig. 1B–D). In flagellates (e.g., diplomonadids, →trichomonads, trypanosomatids) and sporozoans (e.g., →Coccidia) the axis of binary cell division runs longitudinally. Flagellates determine the polarity of the division axis by the initial duplication of the →basal bodies of the →flagella (Fig. 2). Binary fission is found in only a



Cell Multiplication. Figure 1 A–F Diagrammatic representation of different types of binary fission (invaginations are shown by small arrows). **A** Ameba type: division without fixed axis. **B** Trypanosomatid type (here →*Leishmania*): longitudinal division. **C** Trichomonad type (here *T. vaginalis*, note that it is only a longitudinal division at the beginning). **D** Endodyogeny of tissue-cyst-forming coccidia (e.g., *Toxoplasma*, →*Sarcocystis*): inner development of daughter cells. **E** Ciliata type (e.g., *Balantidium*): cross-division. **F** →Opalina type: oblique division. *AF*, anterior free →flagellum; *AX*, →axostyle; *B*, →basal body of flagellum; *CI*, cilium; *CY*, cytopharynx; *DC*, daughter cell; *F*, short flagellum in a pocket; *KI*, →kinetoplast; *MA*, →macronucleus; *MC*, mother cell; *MI*, →micronucleus; *MN*, →micronemes; *N*, nucleus; *PS*, pale pseudopodium; *RF*, →recurrent flagellum; *RH*, →rhoptries.

few species of the →Sporozoa, e.g., blood merozoites of →piroplasms divide in this way. A peculiar longitudinal division is the →endodyogeny of those →coccidia that form tissue cysts (Figs. 1D, 4). Inside a mother cell 2 daughter cells are formed arching over the 2 angles of the dividing nucleus. The daughter cells produce their inner 2 pellicular membranes *de novo* (using membranes of the →endoplasmatic reticulum) and take over the outer membrane of the mother cell's →pellicle; the 2 inner ones disintegrate



Cell Multiplication. Figure 2A–C Binary longitudinal divisions in trypanosomes (A, B transmission electron micrographs; C light micrograph). **A** →*Blastocrithidia triatomae*; note that the basal bodies of the flagella (F1, F2) and the nuclei are already divided. ×24,000. **B** →*Trypanosoma vivax*; trypomastigote from blood during reduplication of the kinetoplast. ×22,000. **C** →*Crithidia* sp. from cultures; late binary fission. ×1,200. *B*, basal body of flagellum; *CR*, chromatin; *DB*, →dense bodies; *DK*, dividing kinetoplast; *F*, flagellum; *K*, →kinetoplast; *MI*, mitochondrion; *N*, nucleus; *NU*, →nucleolus; *OM*, outer surface (→Cell Membrane); *PR*, →paraxial rod of flagellum; *ST*, →subpellicular microtubules.

(Fig. 5A). In →trichomonads the axis of all cell divisions is longitudinal, but only at the beginning (Fig. 1C) when the flagellar basal bodies and the nucleus are reduplicated; later on the divided nuclei wander below the surface membrane into opposite positions, and finally an oblique or even transverse cytoplasmic division appears (Fig. 1C).

- Oblique division (Fig. 1F). In →opalinids (see life cycles), which are characterized by oblique rows of →cilia, binary fission occurs during the sexual and asexual developmental phases. The axis of the cytoplasmic division initially runs longitudinally, but soon becomes parallel to the oblique rows of cilia. lt is thus intermediate between the longitudinal fission of flagellates and the transverse division of ciliates.
- Transverse (cross) divisions (Fig. 1E). In ciliates (e. g., →*Balantidium*, →*Ichthyophthirius*) binary fission starts with the duplication of the cytostomal kinetosomes (basal bodies) and is followed by the division

of the →macronucleus and →micronucleus. The axis of cytoplasmic division runs perpendicular to the axis of the nuclear spindles (Fig. 1E); cell constriction may occur simultaneously or with some time lag. Since this division proceeds across the rows of cilia, it is also described as homothetogenic fission.

Rosette-like Multiplication

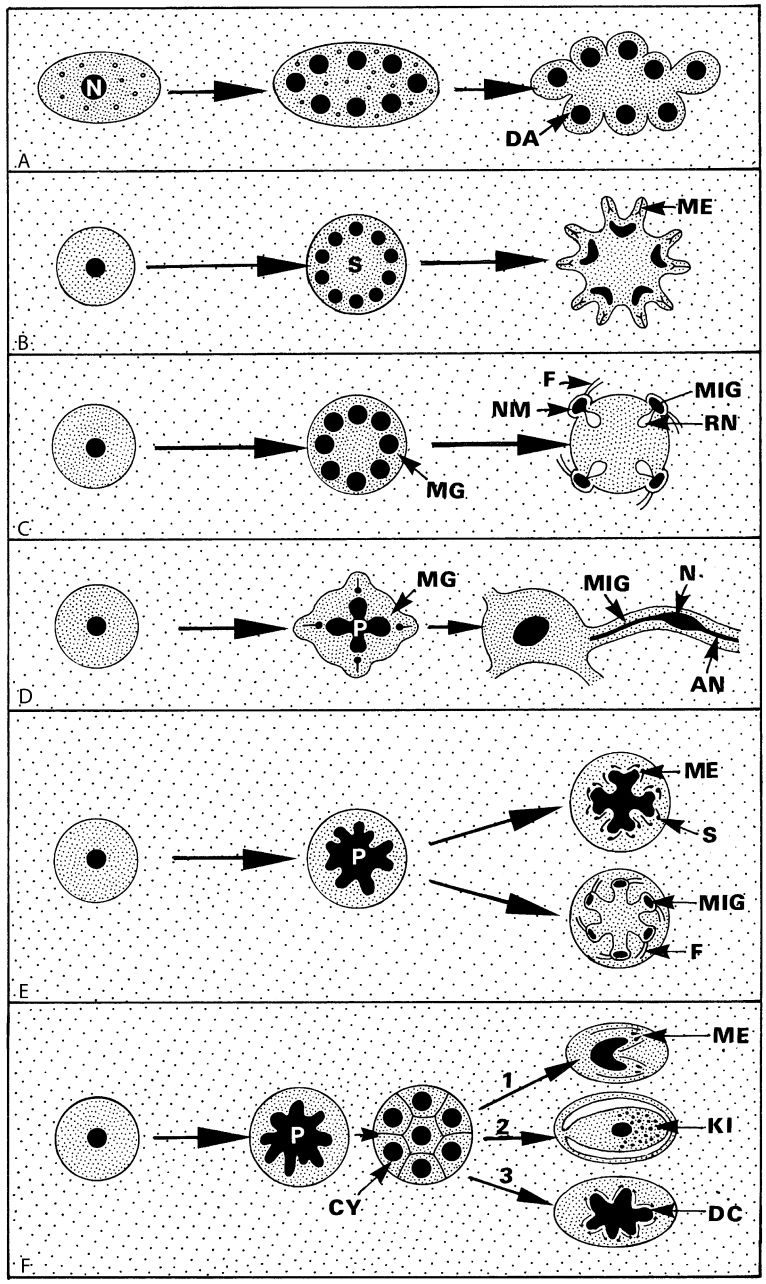
If there is incomplete or delayed division of the cytoplasm the newly formed nuclei may initiate a new division, thus giving rise to a more or less simultaneous development of more than 2 parasitic protozoans that remain attached at their posterior poles. This may be repeated and the whole bulk appears as a →rosette; under light microscopy this was misinterpreted as a stage of multiple division. Such rosettes are frequently found in trichomonads and trypanosomes (especially in cultured forms), and are also relatively common in →*Toxoplasma gondii* during the acute phase of infection when endodyogenies are often repeated inside →parasitophorous vacuoles of macrophages and reticuloendothelial cells. However, in cultures of trypanosomatids most of the rosette-like stages are artefacts, while during movements they became irreversibly tied with their flagella (Fig. 3).

Multiple Divisions

→Multiple divisions are characteristic of amebae, sporozoans, and →microsporidia, but are rarely observed in the other parasitic protozoan groups. The formation of daughter cells may be initiated by three main types of mother cells.

Cell Multiplication. Figure 3 SEM-micrograph of a cluster of cultured →promastigotes of →*Leishmania major* being closely tied with their flagellum. This stage – in light microscope – may be kept for a rosette-like developing stage. ×3,000.

- Multinuclear type. Daughter-cell formation starts at the end of a phase of repeated nuclear divisions (Figs. 3, 4B, 5B). In this way multinucleate plasmodia occur (Fig. 4A–C), which for example led to the naming of the genus →*Plasmodium*. Such multinucleate stages are found in the life cycles of →*Entamoeba histolytica*, in schizonts and sporonts of →gregarines and of some coccidia (Figs. 4B, 5B, 6), in all gamonts of gregarines, but only in →microgamonts of some coccidia (e.g., Fig. 3C), and in some developmental stages of myxosporidia. In these cases the cytoplasm may be divided evenly or not (but always in a species-specific pattern). In eimerian and theilerian schizonts (Fig. 4B), and in sporonts of →hemosporidia and of some piroplasms, daughter-cell formation is connected with the last →nuclear division, thus giving rise to endodyogeny-like features (Fig. 5A) when producing merozoites or sporozoites. In eimerian microgamonts in general a single microgamete is formed from each nucleus (leaving, however, an electron lucent remnant of the karyoplasm). Only occasionally do 2 →microgametes originate from such a microgamont's nucleus.
- Uninuclear type. Daughter-cell formation starts without a preceding phase of nuclear divisions. However, in most cases the nucleus of the parasitic stage has grown considerably and is provided with a lobulated surface (Figs. 4D, E, 5C). During the final division of this eventual giant nucleus, daughter-cell formation takes place simultaneously, incorporating portions of the nucleus, the chromosomal components of which had apparently been increased by preceding endomitosis. Such a splitting process occurs during the →schizogony of →sarcosporidia (Fig. 5C) and has been described as →endopolygeny. The microgamonts of some *Sarcocystis* spp. and of *Plasmodium* spp. produce their microgametes in this way (Fig. 4D,E). A similar simultaneous process is found in sporonts of some piroplasms during the mass production of sporozoites.
- Intermediate type (Fig. 4F). In these cases a large mother cell with a lobated giant nucleus is divided into numerous uninuclear cytomeres; the single limiting membrane of these stages originates from the surface membrane of the original cell or from the endoplasmic reticulum. Such cytomeres are regularly formed in schizonts of some →*Eimeria* and →*Globidium* spp. (e.g., *E. tenella*, Fig. 4F), and in sporonts of →*Babesia* spp., →*Theileria* spp., *Plasmodium* spp., and →*Hepatozoon* spp. The uninuclear cytomeres ultimately produce the daughter cells at once (Fig. 4F), giving rise alternatively to



Cell Multiplication. Figure 4 **A**–**F** Diagrammatic representation of multiple divisions. **A** *Amoeba* spp.; formation of vegetative stages after excystation. **B** Formation of merozoites by schizonts of species of *Eimeria*, *Plasmodium*, *Theileria*, etc. **C** Formation of microgametes, e.g., *Eimeria* spp. **D** Formation of microgametes of *Plasmodium* spp. and other hemosporidia (e.g., "exflagellation"). **E** *Sarcocystis* spp.; formation of merozoites by schizonts (1) and of microgametes by microgamonts (2). **F** Formation of cytomeres. These may each develop: (**1**) 2 merozoites (some *Eimeria* spp.) (**2**) a single kinete (*Babesia* spp.) (**3**) many parasitic stages of the life cycle of various coccidians, i.e., merozoites of *Globidium* spp. or sporozoites of species of *Plasmodium*, *Babesia*, and *Theileria*. *AN*, →axoneme (flagellum of MIG); *CY*, →cytomere; *DA*, daughter ameba; *DC*, daughter cell; *F*, flagellum; *KI*, kinete; *ME*, →merozoite anlage; *MG*, microgamont; *MIG*, microgamete; *N*, nucleus; *NM*, nucleus of microgamete (dense part); *PN*, polymorphous, multilobulated nucleus; *RN*, residual nucleus (light part); *S*, →schizont.

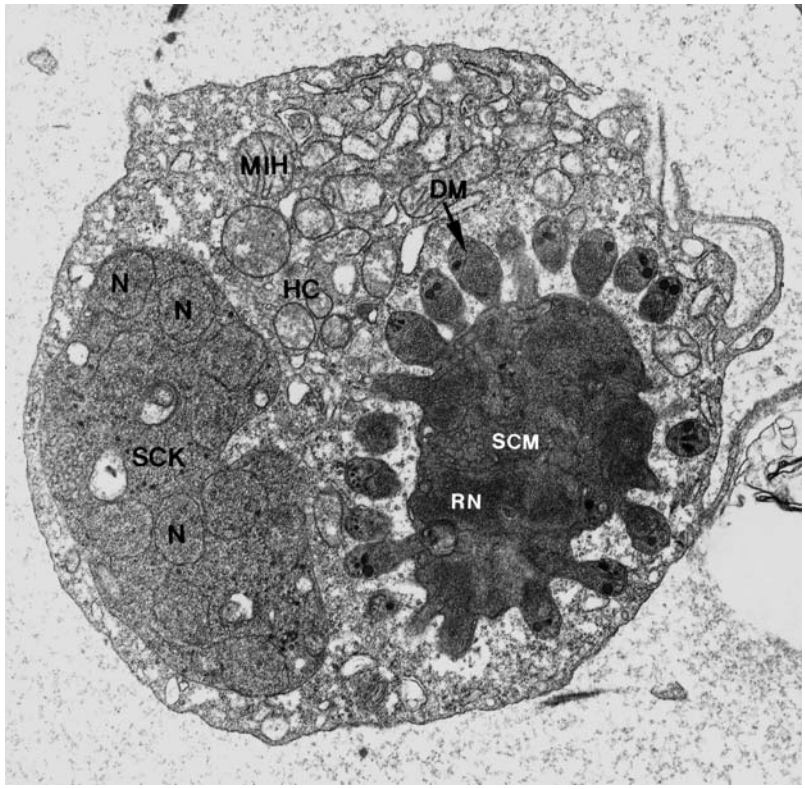
Cell Multiplication. 2 merozoites (*Eimeria* spp.), to a single →kinete (*Babesia* spp., *Theileria* spp.), or to many merozoites (*Globidium* spp.) or sporozoites (*Plasmodium* spp., *Babesia* spp., *Theileria* spp.). Cytomeres join each other in →Myxozoa.

Cellular Immune Reponse

→Immunity.

Cement Glands

Cement glands are significant accessory organs (1–8 in number) in →Acanthocephala. In addition, Eoacanthocephalans have a separate cement reservoir. The vasa efferentia fuse to form a vas deferens, which fuses with one or several ducts of the cement gland(s) to form a genital canal. The cement locks the female vagina after copulation until the first embryonated eggs are released, and forms typical copulatory caps on the posterior tips of inseminated females (→Acanthocephala/Reproductive Organs).



Cell Multiplication. Figure 6 Asexual reproduction in coccidian blood parasites – TEM-micrograph of a section through a lymphoblastic cattle cell containing directly in the cytoplasm a macro- and a microschizont (i.e., Koch's bodies) of the piroplasmean parasite →*Theileria annulata*. The macroschizont is cut during the phase of nuclear reproduction – the microschizont during formation of merozoites at the periphery. ×8,000. *DM*, developing merozoite; *HC*, host cell cytoplasm; *MIH*, mitochondrion of the host cell; *N*, nucleus; *RN*, residual nucleus; *SCK*, macroschizont; *SCM*, microschizont.

Centriole

This cell organelle consists of a hollow tube of a length of 0.3–0.6 μm and a diameter of about 0.2 μm. It is formed by 9 concentrically arranged triplets of short →microtubules (also seen in the basal body of →cilia). A pair of these centrioles (being arranged perpendicularly to each other) form the so-called centrosome, which is thought to function as a microtubuli organizing center (→MTOC) of the spindle apparatus during →nuclear divisions. Centrioles thus reduplicate before cell/nuclear divisions. In →Coccidia so-called centriole-like structures consisting of 9 single outer microtubules and a central one with apparently similar functions occur.

Centrocestus cuspidatus

Digenetic trematode in the intestine of *Milyus parasiticus*; similar species occur in fish as well in cats, dogs, and humans.

Centrocones

Evaginations of the nuclear membrane during →nuclear divisions of →Coccidia.

Centromer

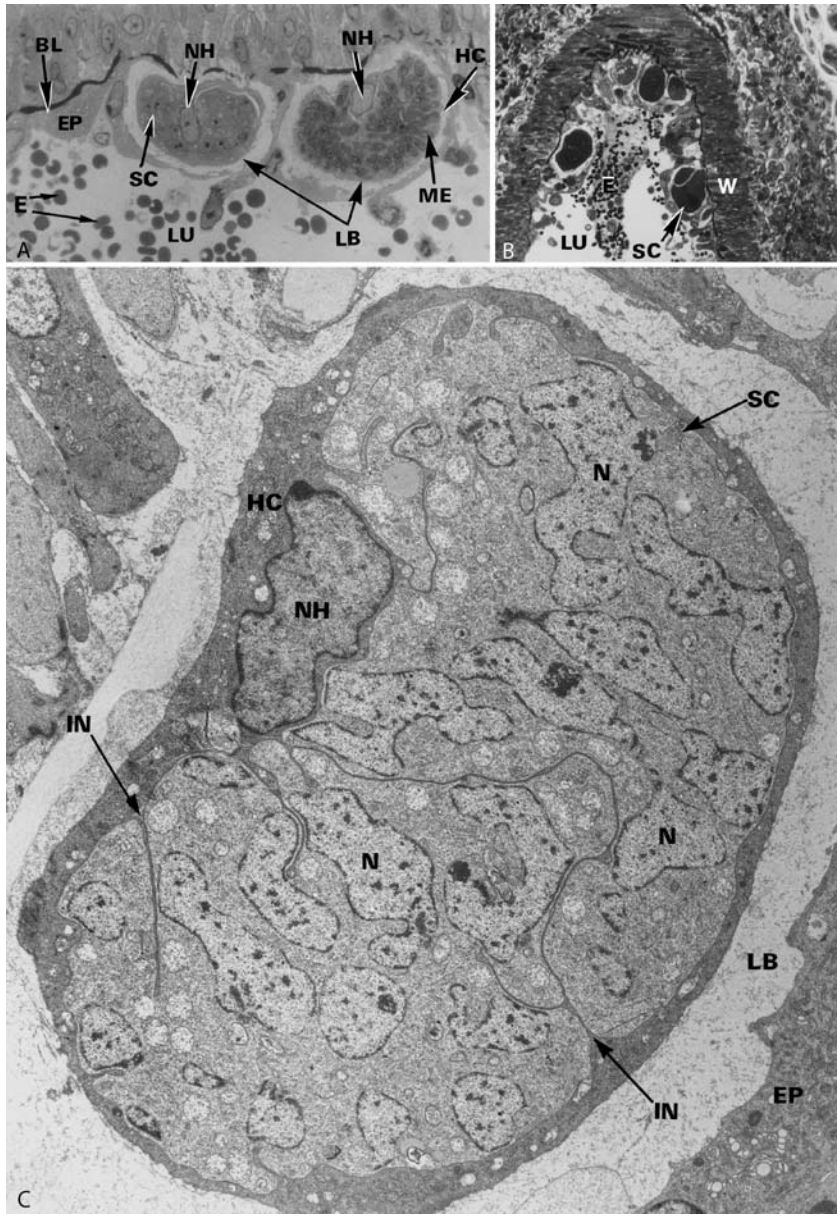
→Cytoskeleton, →Nuclear Division.

Cepaea

Genus of snails, intermediate hosts of →*Dicrocoelium*-trematodes.

Cephalobaenidae

→Pentastomida.



Cell Multiplication. Figure 7 A–C Asexual reproduction by →endopolygeny in →*Sarcocystis arieticanis* schizonts (from sheep). **A, B** Light micrographs of schizonts, which are situated within epithelial cells of branches of blood vessels. (A ×600, B ×80). **C** Transmission electron micrograph of a schizont, the surface of which has deep invaginations (IN); note the large lobulated nuclear system. ×4,800. *BL*, basal lamina; *E*, erythrocytes; *EP*, epithelium; *HC*, host cell; *IN*, invagination; *LB*, lumen of a branch of LU; *LU*, lumen of a blood vessel; *ME*, merozoite; *N*, nucleus, *NH*, nucleus of a host cell; *SC*, schizont; *W*, wall of an arteriole.

Cephalobidae

Name

Greek: *kephalon* = head, *lobos* = lobe.

Genus of free-living nematodes, some species of which may become parasitic in vertebrates when taken up as adult or larva via food, e.g., →*Halicephalobus*.

Cephalothorax

Caput and thorax are combined in →Pentastomida, several crustaceans, and in some →Chelicerata to a functional complex, so that there is no visible border between the former tagmata.

Cephenemyiidae

Family of →Diptera. These flies (belonging to the group of Oestridae) excrete while flying their (15–100) eggs (Fig. 1) in the nostrials of deer, where they grow up and may block breathing. *Cephenemyia stimulator* reaches a length of 14–16 mm and shows a yellowish, bee-like appearance (with long hairs and black bandings) in moderate zones of Europe until East Asia.

Ceramide

→Glycosylphosphatidylinositols.

Ceratophyllus gallinae

→Fleas.

Ceratopogonidae

Name

Greek: *keras* = horn, *pogon* = beard.

Synonyms

Heleidae, biting midges, sand flies of the Caribbean Islands, punkies in the USA, trivial: no-see-ums.

Cephenemyiidae. Figure 1 Larvae of *Cephenemyia* sp. from the pharynpeal/nostril region of a deer.

General Information

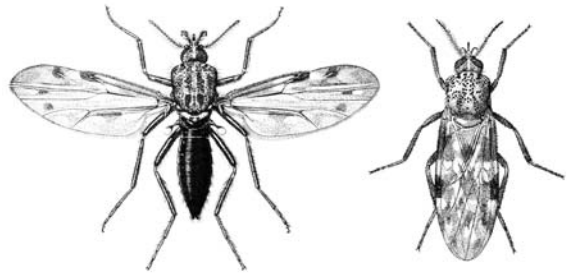
This family of →Diptera comprises 4 genera: *Culicoides, Leptoconops, Lasiohelea*, and *Austroconops* (Figs. 1–3). *Culicoides* is the most widespread and abundant with 800 species (Table 1). There are fewer species (120) of *Leptoconops*, but they are widely distributed and their bite is even more painful than that of *Culicoides*. The genus *Lashiohelea* is as widely distributed as *Leptoconops* with relatively few species (150). Only one species is known of *Austrocopops* (*A. macmillanii*) in Australia.

The size of the bloodsucking females of all species/genera is very small; several do not reach a length of even one mm. Their behaviour, their sucking activities, and their habitats = brood places vary considerably – even among the species of a genus.

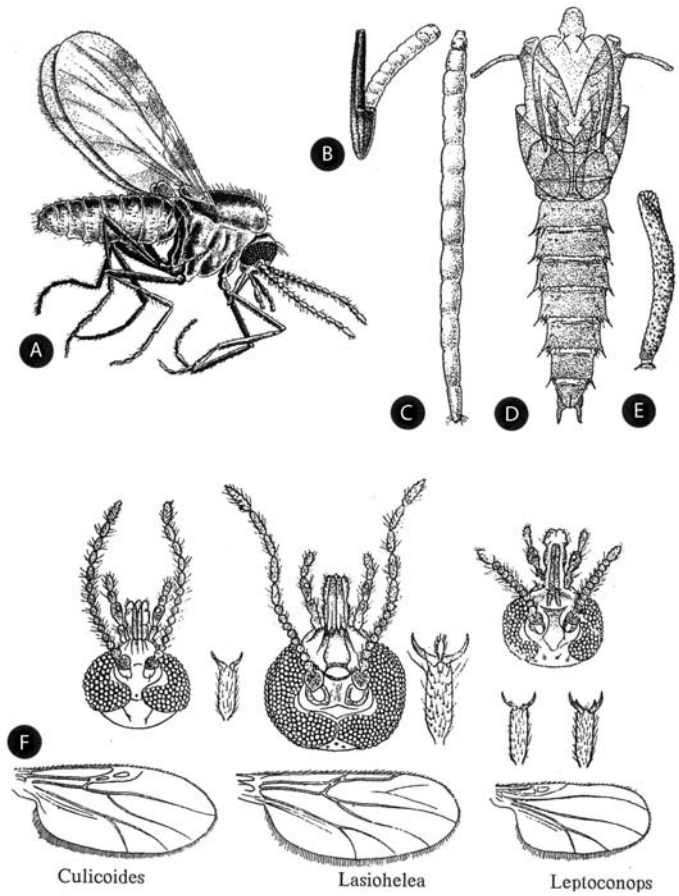
Mating

In general mating occurs prior to bloodmeal, which is in general necessary to lay eggs. However, there are

Ceratopogonidae. Figure 1 LM of a female *Culicoides obsoletus*.



Ceratopogonidae. Figure 2 Diagrammatic representation (DR) of female midges with and without spread wings; the dark spots of wings are used for diagnosis.



Ceratopogonidae. Figure 3 DR of development stages of midges. **A** Female of *Culicoides obsoletus*; **B** Larva leaving the egg; **C** Larva; **D** Puparium; **E** Breathing siphon of puparium (enlarged); **F** Characteristics for genus diagnosis.

species which are apparently parthenogenetic (e.g., *C. circumscriptus*). Males of most species form swarms.

Blood Meals

Most species have preferences for hosts; e.g., humans are heavily attacked by *C. impunctatus*, while others prefer birds, cattle, deer, etc. However, in case of hunger they may switch to other hosts. There are also preferences with respect to the biting spot (leg, arm shaded underside of cattle, etc.).

Eggs

The numbers of eggs produced and laid in batches of less than 100 depend on the amount of blood taken up.

Breeding Sites

Their eggs are – depending on the species – deponed at definite places. For example, *C. imicola* and *C. dewulfi* breed in dung of cattle and horses, *C. pulicaris* is found in swamps/soil, *C. maritimus* uses salt marsh, while the European *C. obsoletus* group breeds hidden in straw of tree leafs or *C. fagineus* are restricted to tree holes. *Leptoconops bequaerti* also breeds in pure sand hidden in holes during tides. The larvae of all 3 genera differ in shape (Fig. 3).

Length of Life Cycle

This depends on the temperatures. Many temperate species have either 1 or 2 generations per year. Others – as *C. obsoletus* in Europe may occur from March until end of October. In general, the temperate species overwinter as larva 4 and pupate in the following year. However, in warm countries *C. pulicaris, C. obsoletus* in South Italy or in the tropics may occur throughout the year.

In general, adult females of culicoids do not live longer than 3–4 weeks. However, *C. obsoletus* specimens were found to survive often up to 3.5 months.

Daily Activity

Most species of *Leptoconops* and a few of *Culicoides* are diurnal, while most *Culicoides* are crepuscular species showing great activity at dawn and dusk (e.g., *C. imicola,*

C. obsoletus). However, some (e.g., *C. grahamii*) are also active throughout the night, others only in the night . Since these insects are all very small they can be driven away easily even by winds with a maximum speed of 5–8 km/hour. Thus potentially infected midges can spread over long distances within a single night.

Vectors

Ceratopogonids are known vectors of viruses and bacteria such as →*Franciscella tularensis*. Recently outbreaks of →Blue tongue virus disease occurred in Europe involving serotypes 1, 2, 4, 9, 16, and most recently in Gemany (2006) serotpye 8. The viruses may survive for more than 150 days inside the defense cells of ruminants. Especially the so-called T-cells may contain these viruses for long and initiate new transmission to the new generation.

Ceratopogonidosis

Disease due to bite of →midges (Table 1).

Cercariae

The characteristic developmental stages of digenean →trematodes initiating infection of the next host in the life cycle (→Digenea/Life Cycle).

Cercarial Dermatitis

Allergic skin reaction due to penetration of cercariae of bird schistosomes like *Trichobilharzia, Dentritobilharzia, Orzithobilharzia, Gigantobilharzia, Macrobilharzia, Bilharzia* into the skin of humans during bathing in lakes or rivers with intermediate hosts (snails) of those bird schistosomes. The most significant symptoms are: formation of reddish pustules and intensive itching.

Cercarien-Hüllenreaktion

→Skin Diseases, Animals/Integument, →Serology.

Cercomer

→Archigetes Species.

Cercomeromorpha

A group of parasitic →Platyhelminthes comprising 4 classes: →Monogenea, →Amphilinidea, →Gyrocotylidea and →Cestoda.

Cercopithifilaria

Genus belonging to the nematode family Onchocercinae. *C. grassi* is found in the connective tissues of subcutis and muscles of dogs in South Europe, Africa, and South America. The vector is the brown dog tick *Rhipicephalus sanguineus*.

Ceratopogonidosis. Table 1 Midges and Control Measurements

Parasite	Host	Vector for	Symptoms	Country	Therapy/Protection		
					Products	Application	Compounds
Culicoides spp. (biting midges, no-see-ums or punkies)	Ruminants, Horse	Bluetongue virus (Cattle, Sheep), African Horse sickness virus, *Onchocerca cervicalis* (Horse)	Edema, allergic reactions. Skin nodules	Worldwide	Butox™ Bayofly™	Spray	Pyrethroids
Forcipomyia taiwana	Humans	Japanese-B-encephalitis virus	Encephalitis	Asia	Repellants	Spray	Deet, Picaridin

Cerebral Ganglion

→Insects.

Cerebral Malaria

→Plasmodium, →Malaria.

Cerebrospinal Fluid – CSF

Puncture of CSF and its microscopical investigation is an effective way to diagnose stained or living *Naegleria* amoebae in cases of PAM (Primary amoebic meningitis).

Cestodaria

Classification

Subclass of →Cestodes.

General Information

Cestodaria are monozoic hermaphroditic worms which are not subdivided and include only a single set of male and female reproductive organs (→Eucestoda/Fig. 2). Their →holdfast organs (if present at all) are not very well developed (→*Amphilina foliacea*/Fig. 1), but allow them to inhabit the intestine or the coelom of their hosts. In ontogenesis a 10-hooked →lycophora larva is involved. With respect to body organization and life cycles 2 orders can be distinguished: →Amphilinidea and →Gyrocotylidea (→*Amphilina foliacea*/Fig. 1, →*Gyrocotyle*/Fig. 1). Members of the Amphilinidea are parasitic in the coelom of sturgeons, other primitive fish, and tortoises, usually reaching a size of 2–8 cm (but up to 38 cm in species of *Gigantolina*). These ribbon-like monozoic and monoecius worms have their genital pores (vagina, male →cirrus) at the posterior end (→*Amphilina foliacea*/Fig. 1), but in the female the uterus opens at the anterior end. The parent worms bore through the body wall of the fish host to lay their eggs. Inside excreted eggs a larva (lycophora) is formed, the surface of which may be ciliated (→*Amphilina foliacea* of the European sturgeon) or not (*Gephyrolina paragonopora* of siluroid fish); the larva can reach a length of about 100 µm and has 10 hooks at the posterior end. In *A. foliacea* the egg must be swallowed by an →intermediate host (an amphipod crustacean), inside which the lycophora hatches, sheds its ciliated epidermis, and finally enters the hemocoel. Inside the body cavity of the intermediate host the lycophora elongates and attains the appearance of a →procercoid and a →plerocercoid. When the amphipod host is ingested by a sturgeon, the plerocercoid burrows through the intestinal wall of the final host, and enters the body cavity, where it attains sexual maturity.

Members of the order Gyrocotylidea primarily inhabit the intestines of marine chimaerid fish, being attached to the wall by their posterior →rosette. They reach a length of up to 25 cm and have all 3 genital pores at their apical pole (→*Gyrocotyle*/Fig. 1). Inside the fecally passed, operculated eggs, the 10-hooked lycophora larva develops within 30 days. In →*Gyrocotyle urna* the lycophora is ciliated (but not in other species) and leaves the egg shell. An intermediate host is not yet known, and apparently not necessary, since 3-5-mm-long procercoid-like larvae with a well-formed typical terminal rosette have been found in several host fish.

Cestode Infections

General Information

→Cestodes live as intestinal parasites firmly attached to the mucosa of the gut in their definitive hosts where they can live for years (e.g., →Taeniasis, Animals, →Taeniasis, Man). Gravid →proglottids or eggs are released in the feces and ingestion of eggs by susceptible intermediate hosts results in the release of larvae, also called oncospheres within the gastrointestinal tract. The oncospheres penetrate the intestinal mucosa and migrate into tissues of the host where they can develop into mature metacestodes (e.g., →Cysticercosis, →Echinococcosis). Important cestode infections are listed in →Platyhelminthic Infections, Man, Pathology.

Immune Responses

While relatively little is known on immunity against the adult →tapeworms in the gut, mechanisms of host–parasite interactions and the immune response have been extensively studied for the tissue stages. In larval cestode infections the intermediate mammalian host harboring egg-derived metacestodes in the tissues becomes completely immune to reinfection with eggs. In contrast, autoinfections with eggs occur in the case of →*Taenia solium* when the host is initially infected with metacestode-derived adult tapeworms in the gut lumen.

Therapy

→Cestodocidal Drugs.

Cestodes

Name

Greek: *kestos* = band, belt.

Synonym

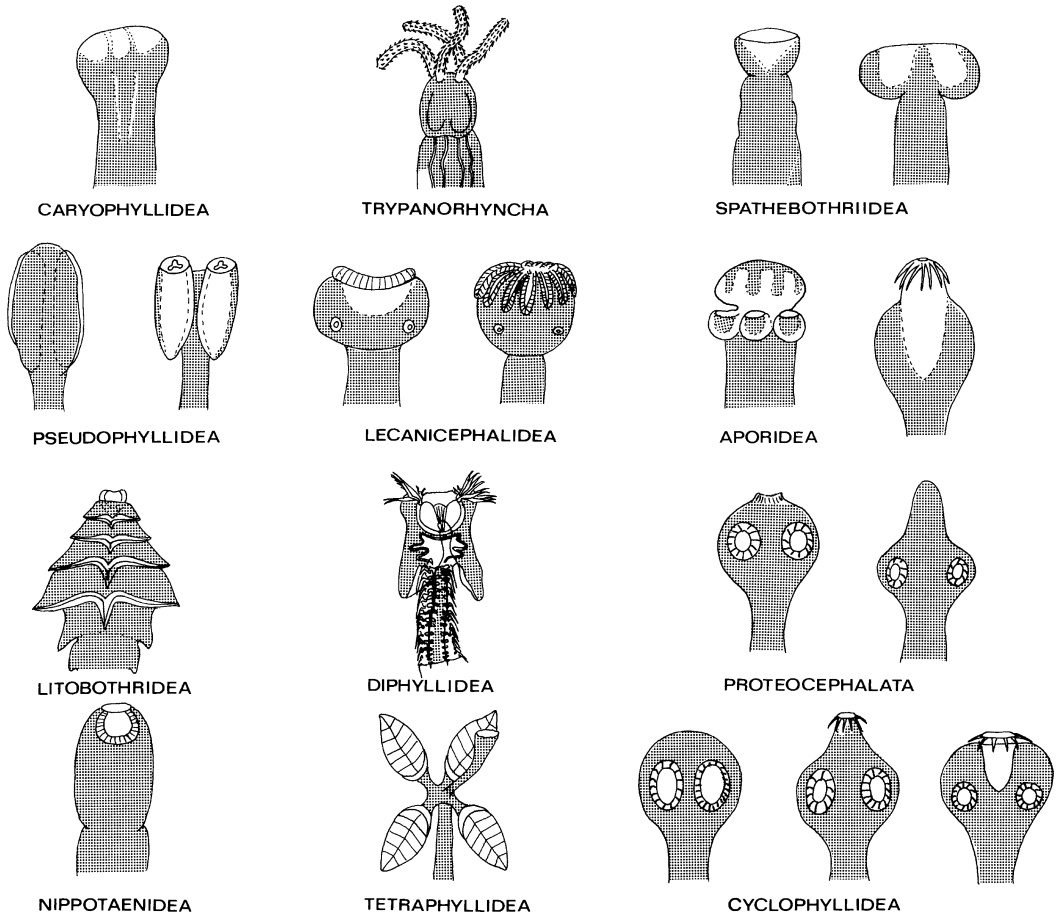
→Tapeworms.

Classification

Class of →Platyhelminthes.

General Information

All members of the class Cestoidea live as parasites, are extremely dorsoventrally flattened, may reach a length of several meters in some species and thus are called tapeworms. In general, the adults inhabit the intestines of their hosts, being anchored to the intestinal wall by means of type-specific →holdfast organs (Fig. 1). Their principal body organization corresponds to that of →trematodes with the exception of the lack of an intestine; thus all nutrients have to be taken up through the syncytial →tegument (Figs. 1, 3–5). The ontogenesis of the cestoda proceeds in most species as →metamorphosis employing different larval stages (Fig. 2). In relatively rare cases (e.g., →*Echinococcus* spp.; Fig. 2), an alternation of different generations is involved in the life cycle; however, all tapeworm need an alternation of hosts (see →Eucestoda/Table 1). The classification of the class Cestoda is far from being solved (cf. →Classification); however, most systems accept 2 subclasses which are differentiated with respect to the number of larval hooks. The medically unimportant →Cestodaria form 10 larval hooks and are thus described as →decacanth, whereas the larvae of the →Eucestoda have only six hooks (→Hexacanth).



Cestodes. Figure 1 Diagrammatic representation of scolices in different orders of tapeworms.

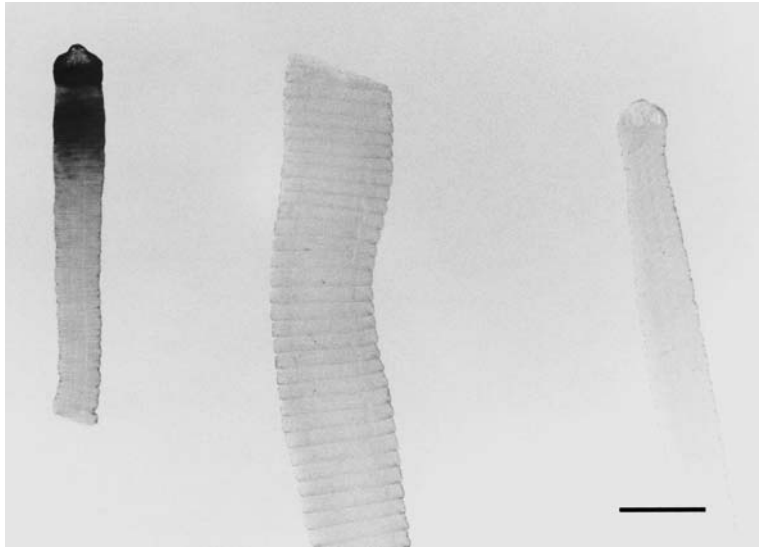
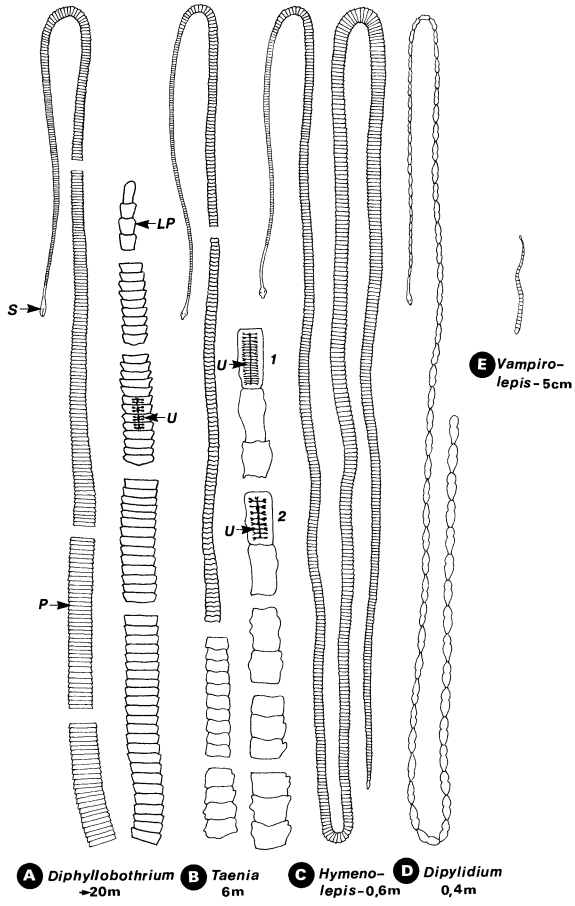
Cestodes. Cestodes. Figure 3 A, B Microtriches at the surface of the tapeworm →*Hymenolepis microstoma* after incubation of intact worms with lectin-gold conjugates. Bars 0.5 µm. **A** The surface coat of the electron-dense spines of the microtriches is densely covered with SBA gold. Only a few granules are present at the proximal part of the microtriches. This pattern of lectin binding was also found with other lectins and in other species, notably *H. nana*. **B** In the anterior parts of the →strobila where the →proglottids grow, a filamentous layer can be observed on top of the microtriches which binds SBA gold strongly.



Cestodes. Figure 4 *Hymenolepis diminuta* after incubation of the intact worm with SBA gold. Only the anterior parts are covered with SBA gold. Bar 0.5 mm.

System

Phylum: Platyhelminthes
  Class: Cestoidea
    Subclass: →Cestodaria
      Order: →Amphilinidea
      Order: →Gyrocotylidea
    Subclass: →Eucestoda
      Order: Caryophyllidea



Cestodes. Figure 5 Diagrammatic representation of 5 tapeworms. *LP*, Empty proglottids; *P*, Proglottids; *S*, Scolex; *U*, Uterus with eggs.

Order: →Trypanorhyncha
Order: Spathebothriidea
Order: →Pseudophyllidea
  Family: Diphyllobothriidae
  Family: Schistocephalidae
Order: Lecanicephalidea
Order: Aporidea
Order: Tetraphyllidea
Order: Diphyllidea
Order: Litobothriidea
Order: Proteocephalata
Order: Nippotaeniidea
Order: Cyclophyllidea
  Family: Dioecocestidae
  Family: →Hymenolepidae
  Family: →Taeniidae
  Family: Mesocestoididae
  Family: Dilepidiidae
  Family: Davaineidae
  Family: Anoplocephalidae
  Family: Dipylidae

Important Species

→Eucestoda/Table 1.

Integument

In cestodes a gut is lacking. Therefore, nutritional uptake has to be mediated completely by the tegument surface. Moreover, the tegument has to resist the attack of digestive enzymes and protect against the immune responses of the host. Tapeworms may be affected by the immune response of their host. Initially, destrobilized worms are not permanently damaged, but will recover if they are transplanted into nonimmune hosts. It has been assumed that inactivation of proteases and lipase occurs on the surface of the tegument.

The external tegumentary membrane covering the →microtriches has a →surface coat which is a highly dynamic structure. Using [^{3}H]-galactose as a label it was shown that the surface coat had a turnover rate of about 6–8 hours in →*Hymenolepis diminuta*. Autoradiographic investigations revealed that the constituents of the surface coat are synthesized by the endoplasmic reticulum and Golgi complexes of the perikarya and that they are transported to the apical part of the tegument. Histochemical methods demonstrated the presence of carbohydrates and negatively charged compounds in the surface coat. Biochemical investigations revealed a variety of glycoconjugates in tegumental extracts of *Hymenolepis diminuta* and →*Spirometra mansonoides* which are assumed to take part in the replenishment of the surface coat.

Extracted surface material and *in vivo* products of larvae of →*Taenia taeniaeformis* have been shown to contain a sulfated glycoconjugate. Its oligosaccharide chains contain glucosamine, galactose, and glucose at proportions of 4:4:1. This glycoconjugate is secreted and able to activate the complement cascade *in vitro*. It is assumed that it lowers the complement level in the surroundings of the parasite and thus prevents activation of complement at the external tegumentary membrane.

Gold-labeled lectins have been used to localize, by light and electron microscope, terminal sugar residues of the →surface coat of *Hymenolepis nana*, →*H. microstoma*, and *H. diminuta* (Figs. 3, 4). Light microscopic sections of Hymenolepis microstoma were labeled with lectin-gold conjugates. It was shown that the tegument binds wheatgerm agglutinin (WGA) and soybean agglutinin (SBA) strongly, but peanut agglutinin (PNA) and Concanavalin A less intensely. Electron microscopic investigations of *H. microstoma* and *H. nana* demonstrated that WGA, succinylated WGA, SBA, *Abrus precatorius* agglutinin (APA), PNA and, to a lesser extent, Concanavalin A were preferentially bound to the spines of the microtriches, which indicated that the surface of these species had exposed →N-acetylglucosamine, galactose, and perhaps glucose

and/or mannose residues. *Ulex europaeus* (UEA) 1 and *Dolichos biflorus* agglutinin (DBA) were not adsorbed, which means that terminal L-fucose and *N*-acetylgalactosamine residues seem to be absent. Specificity was controlled by competition with the respective sugars or sugar derivatives. Lectin-gold particles adsorbed mainly to the surface of the electron-dense spines. Only a few particles were found at the proximal part of the microtriches. This binding pattern does not appear to be the result of →capping, since similar results were obtained with worms which had been fixed with glutaraldehyde prior to incubation. The →carbohydrate constituents of the surface coat seem to be of parasite origin and do not represent adherent intestinal mucus from the host. The latter readily adsorbed UEA 1- and DBA-gold particles which were not bound by the tapeworm surface.

H. nana inhabits the posterior part of the ileum of the mouse, whereas *H. microstoma* is attached in the bile duct and extends into the intestine. Nevertheless, no differences were observed in the lectin-binding pattern of both species. However, the rat tapeworm, *H. diminuta*, differs markedly from these 2 species. It is expelled by normal mice 8–13 days after infection by unknown mechanisms, but it is able to develop in immunodepressed mice. In this species lectins specific for N-acetylglucosamine and galactose are adsorbed only at the scolex and adjacent parts but not on the strobila. The same lectins are adsorbed by the whole tegumental surface of *H. nana* and *H. microstoma*. The immune system of the mouse above all destroys the strobila of *H. diminuta* and leaves the scolex region intact. Destrobilated worms may survive for at least a few days. Therefore, it is tempting to assume that the glycoconjugates which are present in this region might be responsible for the resistance to →immune reactions of the host. A striking difference in the polysaccharide content of 2 species appears to be in accordance with this assumption. A polysaccharide which is present in larger amounts in a resistant species, *H. microstoma*, appears only in traces in *H. diminuta* which is eliminated by the mouse. No protein or uronic acids were demonstrated. Negative charges are due to acetyl groups.

Befus was able to demonstrate the C3 component of complement on the surface of *H. diminuta* in the mouse, but found it inconsistently and only in small amounts in *H. microstoma*. Contrary to these results, other groups found that only small amounts of C3 were deposited on the surface of *H. diminuta in vivo*, whereas *in vitro* C3 was bound in large amounts. Mouse complement proved unable to lyse the tegumental membrane of the rat tapeworm. However, that and human sera are able to destroy the surface of the tegument of *H. diminuta* in a few minutes. Therefore, the complement system of the mouse cannot be responsible for the elimination of *H. diminuta* from its gut, and it appears more likely that this is effected by cellular mechanisms.

Diseases

→Taeniasis, Animals, →Taeniasis, Man, →Cysticercosis, →Echinococcosis, →Cestode Infections.

Cestodocidal Drugs

Tables 1, 2.

Economic Importance and Epizootiology

→Tapeworms, which belong to the phylum Plathyhelminthes, are hermaphroditic, endoparasitic, elongate, flatworms without a body cavity or alimentary tract, a few millimeters to several meters in length. As a rule economic loss, resulting from cestode infections is less severe than that due to trematode or nematode infections. Adult stages of tapeworms living in the alimentary tract of the final host are remarkably benign although adults may be up to 8 or 15 m in length (e.g., *Taenia saginata, Diphyllobothrium latum*). The scolex of the strobilate stage in eucestodes is provided with →holdfast organs (suckers = acetabula), which may be armed with hooks and a rostellum with 2 rows of hooks. Transmission of many important cestodes in livestock, such as *Taenia* spp. and *Echinococcus* spp., usually involves "predator – prey" relationships between carnivores or omnivores (e.g., man) acting as final hosts and herbivores (food animals, occasionally man) serving as intermediate hosts. Food animals like ruminants and horses may also acquire adult tapeworms (*Moniezia* spp. or *Anoplocephala* spp.) by ingestion of arthropod intermediate hosts (mites of the family Oribatidae) with herbage. Large numbers of *A. perfoliata* and *A. magna* may cause clinical signs in horses and donkeys, e.g., catarrhal or hemorrhagic enteritis, ulcerative lesions, and occasionally perforation of the intestine. Although lambs, kids, and calves under 6 months of age may be substantially infected with *Moniezia* spp.; pathogenic effects of these tapeworm infections appear to vary considerably. Major economic impact may result from **zoonotic infections** caused by members of the family of Taeniidae (*Taenia* spp., *Echinococcus* spp.). Close contact of humans, dogs, and foxes (final hosts) with feedlot cattle and other ruminants, rodents, and by chance, humans, acting as intermediate hosts can lead to larval tapeworm infections. Thus, humans infected with *T. saginata* may pass thousands of eggs daily, which may be transmitted to cattle directly in feed or water or via pasture. Pigs running loose scavenging for food and with easy access to human feces may become infected by ingestion of gravid proglottids. Invertebrates such as blowflies, beetles, or earthworms may disperse *Taenia* spp. eggs, and they will remain viable for about 6 months.

Cestodocidal Drugs. Table 1 Drugs used against cestode infections of domestic animals

CHEMICAL GROUP nonproprietary name of active substance (single oral dose, mg/kg body weight = b.w.), other information	*DRUG PRODUCT dose form (formulation), withdrawal time (WT) days (d) before slaughter, manufacturer, supplier, other information	CHARACTERISTICS: miscellaneous comments on pharmacokinetics, metabolism, mode of action, toxicity, and contraindications
ALKALOIDS **arecoline** hydrobromide (1–1.5; repeated administration may be necessary) in veterinary use since 1921 (discontinued in the 1990s)	drug products are now disapproved in the USA, Australia, European countries, elsewhere; bitter-tasting powder; addition of sucrose (15%) is recommended; may be given as 1.5% solution	it may still serve as a diagnostic drug for cestode infections in dogs (*Echinococcus* spp., *Taenia* spp.); it has strong parasympathomimetic actions causing increased peristalsis so that the paralyzed worm looses its attachment to intestinal mucosa and
is expelled live and intact; its action on *E. granulosus* is variable but it shows good efficacy against *Taenia ovis*, *T. pisiformis* (other *Taenia* spp.), and *Dipylidium caninum* if the purging effect occurs sufficiently (onset of catharsis usually occurs 15 minutes after administration but some dogs may not defecate); the drug should not be used in cats, pregnant bitches, or in pups less than 6 months of age; its safety margin is narrow; atropine sulfate (0.04 mg/kg) may be used as antidote (does not interfere with the cestocidal action of arecoline)		
arecoline acetarsol (5) (tasteless, odorless, white powder; was formulated into scored tablets)	drug products (e.g., *Nemural, others) are now disapproved in the USA, Australia, European countries, elsewhere	its action is similar to that of the arecoline hydrobromide; following ingestion of tablet the complex hydrolyzes in stomach releasing
active arecoline which causes increased peristalsis, detachment of paralyzed worm and its expulsion (onset of catharsis usually occurred 30 minutes after administration); pups less than 3 months of age and cats less than 6 months of age should not be treated; arecoline acetarsol was not well tolerated (frequently vomiting, rarely salivation, restlessness, labored breathing, ataxia)		
INORGANIC COMPOUNDS ***tin compounds*** (mixture of metallic tin, tin oxide, or di-butyl-tin dilaureate chloride) were used several decades ago as anticestodals for humans; it has been assumed that anticestodal action of tin compounds may be due to coating tapeworm's integument (cuticle) with a thin layer of tin particles, which renders tapeworm strobila susceptible to digestion; tin preparations exhibited a moderate cestocidal activity (70–90%) against *Taenia* spp. in humans (dose regimen: once a day over a period of several days); di-*n*-butyl *tin* dilaureate (100–125 mg/kg b.w., given in-feed) has been used (may still used occasionally elsewhere) in poultry flocks and in cage birds; today the cheap compound has been replaced by niclosamide and other anticestodals; di-*n*-butyl tin laureate was highly effective against *Raillietina* spp. but not so against *Choanotaenia* spp. and *Davainea proglottina* (variable effects); it was well tolerated at recommended dose but could cause a temporary drop in egg production		
lead arsenate was first used as an insecticidal drug, and has been found by chance to be effective also against tapeworms of sheep; for a long time it had been used worldwide as an inexpensive anticestodal drug with almost 100% effectiveness against *Moniezia* infections in lambs, kids, and calves (single dose in capsules: 0.5 mg/kg b.w.: calves, kids < 3 months of age; 1g/head: lambs > 2 months age, calves > 3 months age); its safety margin was low, and 2 g/head daily for 2 days (or 1g daily for 6 days) caused mortality in sheep (profuse diarrhea, oliguria, extreme weakness, enhanced permeability of capillary, and resulting shock); the drug was contraindicated in poultry		
PHENOL DERIVATIVES **dichlorophene/ toluene** (single dose per os: 220/264 mg/kg b. w. dog, cat,) (divided dose per os: 100/ 120 mg/5 pound b.w. = 20/24 mg/pound daily for 6 days)	*Vermiplex, *Tri-plex, (Schering-Plough), *Anaplex Caps (Boehringer Ingelheim) *Difolin Capsules (Fort Dodge AH), all capsules, many other sponsors (all USA)	several drug products containing *dichlorophene*/*toluene* may still have rather wide use in small animal practice, ***approved indications*** (dogs/cats): for removal of ascarids (*Toxocara canis*, *Toxascaris*
leonina) and hookworms (*Ancylostoma caninum*, *Uncinaria stenocephala*) and as an aid in removing tapeworms (*Taenia pisiformis*, *Dipylidium caninum*, and *Echinococcus granulosus*); ***limitations*** (dogs/cats): withhold solid foods and milk for at least 12 hours prior to medication and for 4 hours afterward, repeat treatment in 2–4 weeks in animals subject to reinfection; ***dichlorophene*** products (as sole active ingredient) are no longer available; they gave an alternative to arecoline that was unpleasant in use; dichlorophene (introduced in 1946) is chemically similar to niclosamide (both are phenol derivatives) it has bactericidal, fungicidal, and anticestodal activity; its anticestocidal spectrum includes variable efficacy (only destrobilating action) against *Taenia* spp. (±72% efficacy) and *Dipylidium caninum* (±85% efficacy) in dogs and cats; its efficacy against *E. granulosus* is variable; it has limited efficacy against *Moniezia* spp. and *Thysanosoma* in sheep (therapeutic dose sheep: 200 mg/kg b.w.); dichlorophene shows low toxicity (LD50 in rats 2.6 g/kg); this is due to poor absorption of the drug from the alimentary tract; however, drug may be toxic in cats; adverse effects are vomiting and colic diarrhea;		

Cestodocidal Drugs. Table 1 Drugs used against cestode infections of domestic animals (Continued)

CHEMICAL GROUP nonproprietary name of active substance (single oral dose, mg/kg body weight = b.w.), other information	*DRUG PRODUCT dose form (formulation), withdrawal time (WT) days (d) before slaughter, manufacturer, supplier, other information	CHARACTERISTICS: miscellaneous comments on pharmacokinetics, metabolism, mode of action, toxicity, and contraindications
toluene (a hydrocarbon obtained from coal tars or methylbenzene) is only available in combination with *dichlorophene*; it has efficacy against GI nematodes as ascarids (∼98% efficacy), hookworms (∼95% efficacy) and whipworms (∼40% efficacy: not approved indication) of dogs and cats; usually it is fairly well tolerated in therapeutic doses; at 5 times the therapeutic dose; adverse effects may occur in older animals as vomiting, muscular tremor, and ataxia		
bithionol (∼200 per os cats, dogs, sheep, goats, quail) (∼200, 2 times in 4-day intervals, chicken) (∼600 geese) **bithionol sulfoxide** (sulfene, syn. sulphene)	preparations of the drug and its derivatives may still be used outside North America, Europe, Australia, elsewhere; earlier known as *Bithin, others; poultry: in-feed, other animals capsules, tablets, or boluses	*bithionol* is a phenolic compound which may be used for treatment of common cestodes in dogs, cats (little efficacy against *D. caninum*), poultry (*Raillietina* spp., *Choanotaenia* in chickens, geese, quail), and *Moniezia*, *Thysanosoma*, and *Paramphistomum* (∼85% efficacy) in ruminants; it is well tolerated in these animals but may stimulate purgation in dogs and cats; in contrast to bithionol, *bithionol sulfoxide* has the advantage of a lower therapeutic dose (60 mg/kg) against adult cestodes (adults are expelled intact); its antitrematodal efficacy against liver flukes in sheep and cattle is superior to that of the parent compound
HEXYLOXY-NAPHTHAMIDINES **bunamidine** hydrochloride (BUH) (25–50 dog, cat) dog and cat, no use class stated or implied	*Scolaban 400 (Schering-Plough AH, USA), coated tablet containing 400 mg BUH do not crush tablet (cf. limitations ↘)	has been used worldwide after its introduction in 1965 against tapeworm infections of dogs and cats; it quickly replaced arecoline and dichlorophene for routine treatment of cestode infections in cats and dogs; *Scolaban is approved in the USA (elsewhere ?); BUH is active against *Taenia* spp., *Dipylidium caninum* (effect varies), *Spirometra* spp., and *Echinococcus granulosus* in cats and dogs; for some years it was the drug of choice against *E. granulosus* (50 mg/kg, repeated after 48 hours empty stomach); however, its effect on *Echinococcus* is not 100% and allows some worms to survive; about 10 years after its introduction, it was replaced in hydatid control schemes by *praziquantel*; BUH exhibits activity against *Moniezia expansa* in sheep, and shows variable efficacy against ascarids in dogs and cats (not approved indications); ***approved indications***: is intended for oral administration to dogs for the treatment of *D. caninum*, *T. pisiformis*, and *E. granulosus*, and to cats for the treatment of *D. caninum* and *T. taeniaeformis*; ***limitations***: oral tablet should not be crushed, mixed with food, or dissolved in liquid (dogs, cats), repeat treatments should not be given to dogs and cat within 14 days, BUH should not be given to male dogs within 28 days prior to their use for breeding, do not administer to dogs and cats having known heart conditions; for use only by or on the order of a licensed veterinarian; *mode of action*: BUH acts as taeniacide; it affects tegument of *Hymenolepis nana* causing disruption of the outer layer, which leads to decrease in the rate of glucose uptake and an increase in the rate of glucose efflux; damaged outer layer allows digestion of the worm in the host; ***tolerability and adverse effects***: it is relatively well tolerated at recommended dose; side effects are transient diarrhea and occasional vomiting: crushed tablet may cause irritation of oral and stomach mucosa, and thus enhanced drug levels in blood plasma producing unexpected toxic effects; detoxification of drug likely occurs in the liver; cases of sudden death have occasionally been seen in dogs without evidence of hepatic dysfunction; liver disorders may lead to higher levels of BUH in the circulation; in excited dogs, high levels of epinephrine may then cause ventricular fibrillation in heart sensitized by BUH to endogenous catecholamines; excitement and exertion should be avoided after treatment; reduced spermatogenesis was found in dogs but not in cats; the drug is well tolerated in bitches (all stages of pregnancy); ***bunamidine hydroxynaphthoate*** (25–50 mg/kg b.w. per os: *Buban) has been used in the UK as a drench for control of tapeworm infections in sheep and goats; the salt (insoluble in water and less irritant to mucous membranes than the hydrochloride) exhibits marked efficacy against *Moniezia expansa* and *M. benedeni* in naturally infected sheep and goats; metaphylactic treatment (single dose) was during spring/summer and in autumn when reinfection occurred; the drug was tolerated in sheep and goats at twice the recommended dose; given in feed, it showed variable activity against *Taenia* spp. in dogs; it was tested in *poultry* with natural infection of *Raillietina* spp. and *Amoebotaenia sphenoides* and was found to be highly active at 400 mg base/kg per os
SALICYLANILIDES *1 **niclosamide** (mono-hydrate) (NIC) ***Australian market***, elsewhere: drug combinations only, doses for oral *tablets*:	1*Mansonil drench (Bayer Australia) for control of tapeworms and immature stomach fluke of sheep and lambs, powder/liquid	announced in 1958 and introduced into the market in 1960; since then it has been used worldwide against tapeworm infections of animals and humans, good

Cestodocidal Drugs. Table 1 Drugs used against cestode infections of domestic animals (Continued)

CHEMICAL GROUP nonproprietary name of active substance (single oral dose, mg/kg body weight = b.w.), other information	*DRUG PRODUCT dose form (formulation), withdrawal time (WT) days (d) before slaughter, manufacturer, supplier, other information	CHARACTERISTICS: miscellaneous comments on pharmacokinetics, metabolism, mode of action, toxicity, and contraindications
NIC/**levamisole** HCl (LEV): e.g., *Ambex (Bomac): (100/4.25 LEV base dog cats) NIC/**pyrantel** pamoate (PYR): e.g., *Troy All Wormer (Troy Labs.): (100/14.4 dog) (60/23 cat, kittens) ***approved indications***: for the control of roundworms, hookworms and tapeworms (except *E. granulosus*) in dogs and cats (do not overdose)	(790 g/kg NIC: 5mL/10kg b.w.) NIC is combined with nematocidal drugs (drug form: tablets, paste) to have an advantage in that both nematodes and cestodes can be treated in dogs and cats (for further information on dosages, drug products, sponsors, suppliers, companies, and characteristics of these drug combinations cf. →Nematocidal Drugs, Animals/Table 5)	tolerability, a wide safety margin, and excellent efficacy against *Taenia* spp. infections of mammals have accounted for its widespread use as a taeniacide in human and veterinary medicine; now, it has largely been replaced in all fields by praziquantel that shows superior cestocidal action compared to niclosamide; NIC may be also used as a molluscicide for the control of freshwater snails, which serve as an intermediate host for
trematodes e.g., *Schistosoma* spp. (cf. →Trematodocidal Drugs); NIC is highly active against tapeworm infections in dogs, cats, ruminants, and poultry; it shows marked activity against *Taenia* spp. but erratic activity against *Dipylidium caninum, Mesocestoides corti,* and poor efficacy against *M. lineatus* and *Echinococcus granulosus* in dogs; immature stages of *E. granulosus* may be susceptible to 50 mg/kg b.w. given on 2 consecutive days; the drug exhibits excellent activity against adult stages of *Moniezia* spp., *Thysanosoma actinoides* (fringed tapeworm), *Thysaniezia giardi* and *Avitellina* spp. in ruminants; it was widely used against infections of anoplocephalids in horses (80–100 mg/kg b.w.) and may still be used for control of *Hymenolepis* spp. and *Raillietina* spp. infections of birds (100 mg/kg); it also affects cestode and skin fluke (*Gyrodactylus*, 0.1mg/L, water-bath for 60 minutes) infections of fish (*Bothriocephalus*: 40 mg/kg daily for 3 days, or 0.5% medicated feed); ***mode of action***: niclosamide inhibits the formation of mitochondrial energy, i.e., oxidative phosphorylation; in susceptible adult stages uptake of oxygen and glucose is blocked; its major action takes place in the scolex and proximal segments; drug produces spastic and/or paralytic action *in vitro* on various preparations of helminths (e.g., *D. caninum*, *F. hepatica*); ***tolerability***: it is a very safe drug (poor gastrointestinal absorption) also during pregnancy and lactation in cattle and sheep; dogs and cats appear to be more sensitive to the drug although twice the normal dose is well tolerated; ***derivatives*** have been prepared mainly by Russians as various salts and esters; among them the piperazine salt *phenolsulfonphthalein* (PSP) is approx. 2 times more effective against *Moniezia expansa* in lambs than the parent drug; in countries of the earlier USSR it may still be used in animals and humans; ***limitations***: it should not be used in combination with *organophosphate* compounds (enhanced toxic effects)		
resorantel (65 mg/kg b.w., per os: drench), chemically a 4'-bromo-γ-resorcylanilide (*Terenol discontinued in member states of European Union, may still commercially available in parts of Europe and Russia) was highly effective (95–100%) against various cestodes such as *Moniezia* spp. infections in sheep and cattle, *Thysaniezia giardi* and *Avitellina* spp. infections in sheep; the drug showed also good efficacy (90%) against mature and immature stages of *Paramphistomum cervi* (rumen fluke) in cattle, sheep, and goats; there was slight, transient diarrhea following treatment at recommended dose; the drug was excreted quite rapidly (total residues 3 days after treatment was about 0.1% of total)		
nitroscanate, chemically a substituted diphenylether, introduced for use in dogs in 1973 (50 mg/kg b.w., per os tablets: micronized particles, earlier *Lopatol (Novartis), others, no longer available in Germany but available in Switzerland, not approved in the USA, Australia, elsewhere, for other information cf. →Nematocidal Drugs, Animals/Table 5); it is a broad-spectrum compound with activity against roundworms (*Toxocara canis*, *Toxascaris leonina*), hookworms (*Ancylostoma caninum*, *Uncinaria stenocephala*), and tapeworms (*Taenia* spp., and *Dipylidium caninum*) of dogs; its action on whipworms is poor and that on *E. granulosus* is somewhat erratic at recommended dose; even at repeated doses of 200 mg/kg, total elimination of adult *E. granulosus* is not always achieved; therefore it is not recommended against these worms; the drug is poorly absorbed from gastrointestinal tract but irritates gut's mucosa resulting in relatively high incidence of vomiting (10–20% of treated dogs) within 3–5 hours after treatment; fasting, 12–24 hours prior to treatment followed by a small quantity of food thereafter will markedly reduce vomiting; nitroscanate should not be used in cats, as it frequently provokes adverse side effects at therapeutic dose; mode of action in cestodes appears to be an uncoupler of oxidative phosphorylation (the drug inhibits ATP synthesis in *Fasciola hepatica*)		
PYRAZINOISOQUINOLINES **praziquantel** (PZQ) *1 (5–10 per os, s.c., i.m. dog, cat, dose may vary depending on b.w. and age of animal) (20–25 wild carnivores per os, s. c., i.m.: *Joyeuxiella pascualei* or *Diplopylidium* sp.)	1*Droncit (Bayer, USA, Australia, Germany, elsewhere) tablets, solution for injection for cat and dogs; spot-on for cats, other drug products in Germany, Australia;	PZQ was introduced in 1975 for treatment of cestode infections in cats, and dogs; it is also the drug of choice for treatment of intestinal tapeworm infections of man (cf. Table 2) and

Cestodocidal Drugs. Table 1 Drugs used against cestode infections of domestic animals (Continued)

CHEMICAL GROUP nonproprietary name of active substance (single oral dose, mg/kg body weight = b.w.), other information	*DRUG PRODUCT dose form (formulation), withdrawal time (WT) days (d) before slaughter, manufacturer, supplier, other information	CHARACTERISTICS: miscellaneous comments on pharmacokinetics, metabolism, mode of action, toxicity, and contraindications
*2 (3.75 as drench, sheep)	2*Cestocur (Bayer), oral liquid (drench) for sheep, WT: sheep 0d, milk 0d Germany; WT: sheep 3d Australia	human schistosomiasis (cf. →Trematodocidal Drugs/Table 2); *Taenia* spp. and *Diphyllobothrium* spp. infections in *humans* may be
eliminated by oral doses of 10 and 25 mg/kg, respectively; PZQ has no action on nematodes; the drug is extremely active after a single oral, subcutaneous (being less effective), or intramuscular dose (route may depend on cestode species) against juvenile and adult tapeworms of carnivores such as *Taenia* spp., *Dipylidium caninum*, *Diphyllobothrium latum*, *Spirometra* spp. (*S. mansonoides, S. erinacei*), *Mesocestoides corti*, *Echinococcus granulosus*, and *E. multilocularis* (i.m. injection is recommended in case of *Echinococcus* infection); for removal of adult *Spirometra* spp., *D. latum* it is necessary to enhance the PZQ dose (25 mg/kg b.w. once a day for 2 days); the drug exhibits also high efficacy against tapeworms of ruminants, e.g., *Moniezia*, or "bile duct" cestodes as *Thysanosoma actinoides* and *Stilesia hepatica* or *Avitellina* in sheep, goats (10–15 mg/kg b.w., single dose not approved), or cestodes of birds, snakes, and fish; it is also active against certain flukes of sheep (e.g., *Eurytrema pancreaticum*) or intestinal fluke *Fasciolopsis buski* of swine (50–70 mg/kg and 30 mg/kg b.w., respectively, single dose not approved) or skin fluke of fish (*Gyrodactylus aculeatus*: 10 mg/L water-bath for 2–3 hours); PZQ has some *ovicidal* action on *E. granulosus* eggs released from the proglottid; however, eggs located in the proglottids are not affected by the drug (this limits epidemiological value of its ovicidal effect); ***action on tissue stages*** (metacestodes in liver, lungs, brain, elsewhere) residing in various intermediate hosts: activity of PZQ against larval forms (hydatid cysts) of the dog tapeworm *E. granulosus* is variable and benzimidazole carbamates (*mebendazole*, *albendazole*) prove to be more active against hydatids in sheep or man following long-term administration of these drugs; in cattle and sheep its action on larval stages (Cysticercus) of most *Taenia* spp. is about 100%; this is also true for the larval stage of the human tapeworm *T. saginata* in cattle; ***pharmacokinetics***: there is almost complete absorption from the alimentary tract following oral administration; PZQ is conveyed throughout the body and reaches high plasma levels in tissues of almost all organs; this puts it in a position to be in close contact with larval and adult stages of cestodes that have highly varied locations in the host; its major pathway of biotransformation is the liver; inactive drug metabolites are excreted mainly by the liver into bile and then feces; ***mode of action***: the drug is rapidly taken up by cestodes and trematodes; however, uptake of PZQ is no guarantee of therapeutic activity (e.g., *F. hepatica* is unaffected by the drug); action of PZQ results in a rapid vacuolization of tegumental layer in the growth zone of the neck region of cestodes; vacuolization leads to disruption of the apical tegument layer (molecular mechanism leading to these alterations is not yet well understood); contraction (spastic and/or paralytic) of parasite musculature depends on drug concentrations used in isolated host tissue preparations; contraction of *Hymenolepis diminuta* muscle depends on endogenous Ca2+ (as in vertebrate skeletal muscle); contraction of *Schistosoma mansoni* muscle depends on uptake of external Ca2+ (as in vertebrate smooth muscle); ***tolerability***: it is a safe drug after the oral or parenteral route; there is a wide margin of safety for PZQ as shown in acute and chronic toxicity studies in mice, rats, rabbits, and dogs; up to 5 times the recommended dose PZQ is tolerated without adverse effects in cats and dogs, 10-fold overdose may cause transitory vomiting and sign of depression; there was no evidence for embryotoxicity or teratogenicity in reproduction studies performed in rats, rabbits, cats, and dogs; the use of PZQ in breeding and pregnant animal is safe		
praziquantel (PZQ) / antinematodal drugs so called "allwormer" = drug combination with 2; 3; or 4 active nematocidal ingredients and PZQ for use in dogs and cats; for drug products cf. **pyrantel, fenbendazole, oxfendazole, oxibendazole, febantel, abamectin, milbemycin oxime, emodepside:** →Nematocidal Drugs, →Animals/Table 5	drug products containing active nematocidal ingredients and PZQ for use in *sheep* and *lambs* cf. **fenbendazole, abamectin, moxidectin** (→Nematocidal Drugs, Animals/Table 1); drug products containing active nematocidal ingredients and PZQ for use in *horse* cf. **pyrantel, ivermectin, abamectin, moxidectin** (→Nematocidal Drugs, Animals/Table 3); *First Drench (Virbac Australia), liquid, WT 3d: **levamisole** HCl/ PZQ (7.5/3.8 mg/kg b.w.)	BZs (e.g., fenbendazole) and pyrantel affect certain flukes (cf. →Trematodocidal Drugs/Table 1) and cestodes; BZs may have good activity against *Taenia* spp. but not so against *Dipylidium caninum* in cats and dogs (cf. BZs ↓); pyrantel pamoate exhibits activity against the ileocecal tapeworm *Anoplocephala perfoliata* of horse at 2 times the recommended dose (13.2 mg/kg b.w.); the drug is inactive against common
tapeworms in cats and dogs; a so called "allwormer" may contain a *macrocyclic lactone* (e.g., ivermectin, milbemycin oxime, or abamectin), BZ (e.g., fenbendazole, oxfendazole, or oxibendazole), pyrantel pamoate, praziquantel, and an *ectoparasiticide* (e.g., fipronil, imidacloprid, and/or s-methoprene or lufenuron); this group of drug products may involve a broad range of indications as relevant external and internal parasites (including prevention of heartworm disease) in cats and dogs, thus a single application of such kit-products may control not only all <11> gastrointestinal worms but also		

Cestodocidal Drugs. Table 1 Drugs used against cestode infections of domestic animals (Continued)

CHEMICAL GROUP nonproprietary name of active substance (single oral dose, mg/kg body weight = b.w.), other information	*DRUG PRODUCT dose form (formulation), withdrawal time (WT) days (d) before slaughter, manufacturer, supplier, other information	CHARACTERISTICS: miscellaneous comments on pharmacokinetics, metabolism, mode of action, toxicity, and contraindications
common ectoparasites (fleas, ticks, and/or biting lice) of dogs; an example for an allwormer is <*The Complete Parasite Control Kit for Dogs 10–25 kg, Bayer, Australia> (active constituents: 0.8 g/L *ivermectin*, 100 g/L *imidacloprid*, 250 mg/Tb *febantel*, 50 mg/Tb *praziquantel*, 49.8 mg/Tb *pyrantel* as pamoate /embonate salt, *formulations*: *topical* solution and *oral* tablet) for the treatment and prevention of heartworms, fleas, and all "11" gastrointestinal worms; an allwormer may have various limitations/ contraindications concerning the indication <prevention of heartworm disease> in regions where *Dirofilaria immitis* is endemic (for details cf. →Nematocidal Drugs, Animals/Table 5/pyrantel)		
HYDROPYRAZINOBENZAZEPINE **epsiprantel** (ESP) (5–5.5 dog, excluding under 7 weeks of age) (2.75 cat, excluding under 7 weeks of age) (*Echinococcus granulosus*: 7.5, not approved dose)	*Cestex (Pfizer AH, USA, Australia), oral tablets (various specifications: 12.5, 25, 50 or 100 mg/kg b.w. of epsiprantel) **ESP/pyrantel** pamoate: cf. →Nematocidal Drugs, →Animals/Table 5/pyrantel	chemically related to praziquantel (PZQ); since 1989 on the market (first USA, early 1990s Canada and Taiwan); unlike PZQ, it is poorly absorbed from the gastrointestinal tract and there seem to be no detectable metabolites in the urine of dogs; this puts the compound in a position to be in contact with
tapeworms of the alimentary tract for a longer time; ESP is used for removal of common cestodes of dogs (*Dipylidium caninum*, *Taenia pisiformis*), and cestodes of cats (*D. caninum*, *T. taeniaeformis*: tapeworm segments may appear in feces for 2–3 days following treatment); if exposure to infected intermediate hosts is not controlled reinfection will be likely and so retreatment necessary; therefore, in cases of *D. caninum* infections an additional flea control program should be applied; immature/adult stages of *Echinococcus granulosus* are not completely eliminated by ESP (immature: 94, mature: 99% at regular dosage of 5 mg/kg b.w.); total elimination of mature worms may be achieved with 7.5 mg/kg b.w.; there are no information on efficacy against other GI tapeworms in livestock; due to its low absorption from GI tract it is not likely that ESP may affect larval cestodes or flukes residing in liver or lungs; ***mode of action*** may be similar to that of PZQ; ESP may disturb regulation of Ca2+ and other cations leading to disintegration and lysis of tapeworm's tegument (cuticle) and digestion of the worm by the host; ***limitations***: for oral use only as a single dose, do not use in animals less than 7 weeks of age; safety of use in pregnant or breeding animals has not been established; federal law restricts this drug to use by or on the order of a licensed veterinarian (USA., elsewhere); pregnant animals may be treated at mating, before birth of puppies or kittens and then every 3 months; ***tolerability***: the drug is claimed to have a wide safety margin in dogs and cats; at 5 times the regular dose (once daily for 3 days) no adverse effects were observed; at 40 times the regular dose (once daily for 4 days) only slight clinical signs were seen		
BENZIMIDAZOLE CARBAMATES ***listed doses*** of benzimidazole carbamates (BZs) refer to *experimental studies* published in literature; BZs are primarily used for their efficacy against nematodes (→Nematocidal Drugs, Animals/Tables 1, 3–5); some of them are also effective against certain cestodes in animals like mebendazole (MBZ), fenbendazole (FBZ), oxfendazole (OFZ), albendazole (ABZ), or cambendazole (CBZ); BZs exhibit no activity against the common tapeworm *Dipylidium caninum* of cats and dogs; BZs have a wide margin of safety in livestock but their use is contraindicated (heavy incompatibility) within 7 days of a bromsalans flukicide administration in cattle (→Nematocidal Drugs, Animals/Table 1)		
DOG AND CATS (adult stage or intestinal tapeworm, larval stage) *M. corti* intermediate stage (tetrathyridium) of *M. corti* can infect dogs (final host)	*Taenia* spp. of cats and dogs, good efficacy: MBZ (22, daily for 5 days), or: FBZ (50 daily for 3 days) *Echinococcus granulosus* in dogs, efficacy against adult stages: MBZ (20, 2 doses every 2 days) *Mesocestoides corti* in dogs, efficacy against adult stages: ABZ (50 every 12 hours, 4 treatments, or 100 × 1) *Mesocestoides corti* larval stage (tetrathyridium) in dogs FBZ (100 twice daily for 14–60 days: 5 of 6 infected dogs were cleared); MBZ is also effective against tetrathyridia of *M. corti* in dogs	
RUMINANTS and CHICKENS (adult stage or intestinal tapeworm)	*Moniezia* spp. infection in cattle/sheep, good efficacy at * regular dose: ABZ (*10/*7.5), OFZ (*5), at enhanced dose FBZ (15), MBZ (20) *Thysanosoma actinoides* in sheep, efficacy against adult stages: FBZ (10) *Raillietina tetragona* in chicken, good efficacy: OFZ (7.5 adults, 10 immature stages)	

Cestodocidal Drugs. Table 1 Drugs used against cestode infections of domestic animals (Continued)

CHEMICAL GROUP nonproprietary name of active substance (single oral dose, mg/kg body weight = b.w.), other information	*DRUG PRODUCT dose form (formulation), withdrawal time (WT) days (d) before slaughter, manufacturer, supplier, other information	CHARACTERISTICS: miscellaneous comments on pharmacokinetics, metabolism, mode of action, toxicity, and contraindications
(larval stage of tapeworm in intermediate host)	*Cysticercus bovis* (larval stage of human tapeworm *Taenia saginata*), marginal effect MBZ (5 daily for 10 days); marked (approx. total) reduction of cysts in beef tissue: FBZ (50), CBZ (35) *Cysticercus cellulosae* (larval stage of human tapeworm *Taenia solium*) reduction of cysts in pork: OFZ (single dose, cf. Gonzalez et al., 1996: *Am J Trop Med Hyg* 54: 391–394)	
HORSE (adult stage or intestinal tapeworm)	drug combinations containing macrocyclic lactones (ivermectin, abamectin or moxidectin) *and* praziquantel are approved for treatment of equine cestode infections caused by *Anoplocephala perfoliata*, *A. magna*, or *Paranoplocephala mammillana*, however, none of BZs products have been labeled for this indication, likely because of their insufficient efficacy against equine tapeworms at regular dose; enhanced dose MBZ (20) and FBZ was shown to be effective against *Anoplocephala* spp.	
LABORATORY ANIMALS (larval stage of tapeworm in intermediate host)	*Taenia* cysticerci in rabbits and pigs, marked (approx. total) reduction of visceral cysts: MBZ (25 daily for 5 days) *Echinococcus granulosus*, hydatid cysts in mice, marked (approx. total) reduction of visceral cysts: MBZ (150 intraperitoneally for 3 days) or FBZ (500 ppm in-feed for 18 weeks)	
ANTIBIOTICS **paromomycin** (isolated in 1955, *Humatin) is a fermentation product of *Streptomyces rimosus* var. *paromomycinus* and commercially supplied as its neutral sulfate salt; first use as a cestocide was in Italy in 1963; in experimental studies, the antibiotic was shown to exhibit a promising effect against *T. taeniaeformis* in cats but not so against *Hymenolepis* spp. in rats and mice; in humans it proved to be effective against *Taenia saginata* and *T. solium* at doses of (40) for 5 days, or at (75); *Hymenolepis nana* infection in man was completely cured at doses of (40) for 7 days; its further use became limited because of the availability of modern drugs with simple regimens for patients; (cf. Table 2, praziquantel); paromomycin is poorly absorbed from GI tract (<1% of oral dose and is subsequently excreted unchanged in urine); it is little known about the structure-activity relationship concerning antibacterial action of paromomycin and not its anticestodal efficacy; destruction of the basic functions of active molecule by N-acylation of primary amino groups results in complete loss of activity; its anticestodal action (*T. saginata*) may be based on fine-structural changes of the tegumental membrane making the tapeworm susceptible to digestive system of host; *Humatin (Parke-Davis, others) may be currently used for the treatment of asymptomatic *Entamoeba histolytica* infection of humans (cf. →Antidiarrhoeal and Antitrichomoniasis Drugs/Table 1); it shows activity against gram-positive and gram-negative bacteria and may cause slight diarrhea after recommended dosage regimen		

Data of drug products (approved labels) listed in this table refer to information from literature, manufacturer, supplier, and websites such as the European Medicines Agency (EMEA), Committee for Veterinary Medicinal Products (CVMP), the U.S. Food and Drug Administration (FDA), Center for Veterinary Medicine (CVM), the Australian Pesticides and Veterinary Medicines Authority (APVMA) and associated Infopest (search for products), VETIDATA, Leipzig, Germany, and Clini Pharm, Clini Tox (CPT), Zurich, Switzerland
Data given in this table have no claim to full information

Cysticerci such as *Cysticercus bovis* (infectious stage of *T. saginata*) or *C. cellulosae* (infectious stage of *T. solium*) develop primarily in skeletal and cardiac muscle. **Neurocysticercosis** of humans may occur by ingestion of *T. solium* eggs with contaminated food or by **autoinfection**. Autoinfection is possible if eggs are released in the upper intestine, and regurgitated into the stomach. Oncospheres released from digested eggs then reenter the intestine where they initiate the life cycle.

Economic loss in livestock may result also from condemnation of carcasses or offal as unsuitable for human consumption at the abattoirs. For instance, *C. bovis* in the musculature of cattle becomes infective about 10 weeks after infections and remains viable for up to 9 months. Humans become infected by the ingestion of raw or undercooked infected beef (Table 2). Despite the availability of more sensitive and specific immunodiagnostic tests (recombinant antigens, PCR techniques) their role for routine diagnosis of cyticercosis in cattle will be very limited. Such tests could be used, however, on a herd basis to find out whether a herd is free of cyticerci or infected. This would be a valuable approach in →epizootiology of →cysticercosis. Today there are no effective drugs, which may be used economically in the treatment of →metacestode infections in livestock. **Prophylactic measures** should therefore always involve treatment of infected persons and management adjustments such as proper meat inspection. However,

Cestodocidal Drugs. Table 2 Drugs used against cestode infections in humans

PARASITE DISEASE distribution, pathology	**Stage** affected (location), morphology of **egg**	**Chemical class** other information (1*, 2* etc. refer to linked chemicals and comments)	**Nonproprietary name** adult dosage (⧫ = pediatric dosage) (oral route), d = days, comments	**Miscellaneous comments**
INTESTINAL TAPEWORMS: adult worms consist of a head (scolex), a neck (growth region), and a strobila (series of proglottids)				
DIPHYLLOBOTHRIASIS: first intermediate host is a copepod, second intermediate host are various freshwater fishes due to lack of specificity of the plerocercoid (sparganum lacking a bladder, see sparganosis); man becomes infected by ingestion of raw or undercooked fish-intermediate host containing plerocercoids; adult tapeworm may live for 25 years or longer in humans and may cause rarely vitamin B12 deficiency (due to absorption of B12 by the worm) and megaloblastic anemia; *D. latum* eggs (small knob at end, opposite the operculum) may be confused with those of *Paragonimus westermani* (cf. →Trematodocidal Drugs/Table 2)				
Diphyllobothrium latum (fish tapeworm), common where cold, clear lakes are abundant; occurs in N Europe, N America, Japan in fish-eating mammals, and man	**adult** (5–15 m long) (upper half of intestine) **eggs** (unembryonated, ovoid, operculate, pass in feces into water)	1***pyrazino-isoquinolines** contraindicated in ocular cysticercosis 2***halogenated salicylanilides** (availability problems)	1***praziquantel** (*drug of choice*) (5–10 mg/kg once, and ⧫) *alternative*: 2***niclosamide** (2 g once) (⧫50 mg/kg once)	1*safe and well tolerated, occasionally skin rashes 2*safe drug, also in pregnant or debilitated patient; occasionally abdominal pain, and pruritus
Dipylidium caninum (dog tapeworm)	humans become infected by swallowing fleas containing infective larval stages (cysticercoids)			
distribution worldwide; infrequent in humans, pathogenic effects are unknown; infection is due to close contact with infected dogs and their fleas	**adult** (approx. 50 cm long) (small intestine) **eggs** (thin-shelled, small, spherical; contain 6-hooked onchosphere) pass in feces (typical egg packets each contains up to 15 eggs)	1***pyrazino-isoquinolines** 2***salicylanilides** (availability problems)	1***praziquantel** (*drug of choice*) (5–10 mg/kg once, and ⧫) *alternative*: 2***niclosamide** (2 g once) (⧫50 mg/kg once)	definite hosts (dogs, cats) should be regularly treated to avoid infection in humans (especially in children); eradication of fleas (pets carpets, rugs, and other sites) is needed
HYMENOLEPIASIS: humans become usually infected by ingestion of embryonated eggs (contaminated food and water); human infection also is possible by ingestion of arthropods (e.g., beetles) containing the infective larval stage (cysticercoid)				
Hymenolepis nana (dwarf tapeworm) occurs worldwide; infects simian primates, rodents, man; oncosphere can hatch also from embryonated *egg* within GI tract causing *autoinfection*; this render eradication difficult; amounts of cysticercoids may damage intestinal mucosa and produce diarrhea	**adult** (approx. 2–4 cm long) (lumen of small intestine; oncosphere develops in lamina propria of a villus to preadult cysticercoid) **eggs** (small, thin- shelled, spherical to subspherical, 6-hooked larva surrounded by a membrane with 2 polar "knobs" from which 4–8 filaments arise, pass in feces)	1***pyrazino-isoquinolines** 2***salicylanilides** 3***aminoglycoside** (<1% of dose is absorbed from gut, excreted unchanged in urine) 4*//**5-nitrothiazole benzamide** (first described in 1984 as a human cestodocidal drug)	1***praziquantel** (*drug of choice*) (25 mg/kg once, and ⧫) *alternative*: 2***niclosamide** (2 g × 1d; 1 g × 6d) 3***paromomycin** minimal side effects 4* **nitazoxanide** (500 mg × 3d) (tablet = 500 mg) (investigational drug)	1* e.g., Biltricide is active against both juvenile and adult stages e.g., 2*Yomesan acts only against adults and mature cysticercoids, therefore treatment for 5–7days 3*(40 mg/kg/d for 7d) may cause total elimination of worm burden

Cestodocidal Drugs. Table 2 Drugs used against cestode infections in humans (Continued)

PARASITE DISEASE distribution, pathology	**Stage** affected (location), morphology of **egg**	**Chemical class** other information (1*, 2* etc. refer to linked chemicals and comments)	**Nonproprietary name** adult dosage (⧫ = pediatric dosage) (oral route), d = days, comments	**Miscellaneous comments**
4* **nitazoxanide:** there have been several reports on preclinical and clinical studies evaluating the activity of the drug against a broad spectrum of intestinal and extraintestinal parasitic infections including cryptosporidiosis, giardiasis, amebiasis, microsporidiosis, equine myeloencephalitis caused by *Sarcocystis neurona* (approved drug for horses = brand-name Navigator, IDEXX Pharmaceuticals, USA), ascariasis, fascioliasis, and other intestinal infections caused by protozoa such as *Balantidium coli*, *Blastocystis hominis*, *Isospora belli,* or helminths as whipworms, hookworms, and threadworm *Strongyloides stercoralis* (cf. Raether W, Haenel H (2003) Parasitol Res 90: S19-S39)				
H. diminuta (rat tapeworm) occurs worldwide; common parasite of rats, may occasionally infect man	**adult** (20–60 cm long) (small intestine) **eggs** (large, thick-shelled, spherical, 6-hooked onchosphere, pass in feces)	**pyrazino-isoquinolines salicylanilides** (availability problems)	**praziquantel** (*drug of choice*) (25 mg/kg once) *alternative*: **niclosamide** (2g × 1d; 1g × 5–7d)	clinical manifestations are inconspicuous (unknown)
sometimes there may be diagnostic problems concerning confusion with *H. nana* eggs: oncosphere of *H. diminuta* is surrounded by a membrane without polar filaments and separated considerably from outer shell; rodent control and protection of food from insect intermediate hosts may prevent infection (infection may be acquired by accidental ingestion of infected beetles present in various grain products)				
TAENIASIS: humans become infected by ingestion of raw or undercooked muscles (beef or pork) containing infective cysticercus; *diagnostic problems*: eggs of human and animal taeniid species (*Taenia* and *Echinococcus* spp.) are all indistinguishable from each other; *T. saginata* and *T. solium* diagnostic is usually done by examination of gravid proglottids injected with India ink or stained by permanent stains to visualize characteristic number of lateral uterine branches (*T. saginata*: 15–30, and *T. solium*: 7–13); some pollen grains found in feces may closely resemble eggs of *Taenia* spp.; taeniid *egg* contains a characteristic 6-hooked embryo (oncosphere); caution should be used in handling unidentified gravid (mature) taeniid proglottids since *T. solium* and *Echinococcus* spp. eggs are infective to humans; they can cause larval tapeworm infections of brain, liver, lungs, and other organs (cf. larval tapeworm infections ↓)				
Taenia saginata (beef tapeworm), worldwide distribution (parallels stock keeping); adult worm causes no distinct lesions; cattle act as intermediate host	**adult** (up to 8 m long) (upper half of small intestine) **eggs** (embryonated spherical, yellow-brown, thick shell striated radially, 30–44μ Ø, pass in feces)	1***pyrazino-isoquinolines** 2***salicylanilides** (availability problems) 3***benzimidazole** carbamates	1***praziquantel** (*drug of choice*) (5–10 mg/kg once and ⧫) *alternative*: 2***niclosamide** (2g once) 3***mebendazole**, Vermox (200 mg BID × 3d)	in most cases there are no clinical signs; on an individual level, infection can be prevent by thorough cooking of meat or by freezing meat at –18°C for 7d
T. solium (pork tapeworm), worldwide distribution (parallels pig keeping); pigs and humans act as intermediate host; they become infected with embryonated eggs by ingestion of contaminated food or by *autoinfection*	**adult** (up to 6 m long) (small intestine) **eggs** (morphology cf. "Taeniasis", and *T. saginata* ↑, pass in feces; egg of *T. solium* may be infective to humans and can cause cysticercosis)	1***pyrazino-isoquinolines** (1* has a moderate effect on larval stages) 2***salicylanilides** 3***benzimidazole carbamates**	1***praziquantel** (*drug of choice*) (5–10 mg/kg once and ⧫) *alternative*: 2***niclosamide** (2 g once) 3***mebendazole** (200 mg BID × 3d)	2* has no ovicidal action on larvated egg; larva liberated from a shed gravid segment in upper intestine can cause cysticercosis; do not use a purgative; an enhanced peristalsis increases risk of cysticercosis
LARVAL TAPEWORMS: there are 2 types of larvae invading human tissues, (1) larva with a bladder, and (2) larva lacking a bladder (sparganum) LARVAL CESTODE DISEASES: man may be infected by ingestion of an oncosphere-containing (embryonated) egg or by ingestion of a larval stage belonging to the genus *Spirometra* (cf. sparganosis ↓) CYSTICERCOSIS, NEUROCYSTICERCOSIS contaminated food containing *T. solium eggs* may infect humans during meal; *autoinfection* is possible; cysticerci with a fibrous tissue capsule may undergo calcification and release antigens that can cause inflammatory reactions				

Cestodocidal Drugs. Table 2 Drugs used against cestode infections in humans (Continued)

PARASITE DISEASE distribution, pathology	**Stage** affected (location), morphology of **egg**	**Chemical class** other information (1*, 2* etc. refer to linked chemicals and comments)	**Nonproprietary name** adult dosage (♦ = pediatric dosage) (oral route), d = days, comments	**Miscellaneous comments**
Taenia solium (larva type: a single scolex invaginated into a bladder) cerebral cysticercosis may occur where pig keeping is done; (prevention of infection cf. "Taeniasis" ↑)	**cysticercus cellulosae** larva may reside in almost any tissue, often brain: larva tends to grow slowly to a large cyst that causes space-occupying lesions and/or hydrocephalus (larva in ventricle blocks CSF circulation)	1***benzimidazole carbamates** 1*Eskazole, Albenza, others 2***pyrazino-isoquinolines** 2* Biltricide experimental drugs: *mebendazole* *flubendazole*	***treatment of choice*** (see below) *alternative*: 1***albendazole** (ABZ) (400 mg BID × 8–30d, can be repeated as necessary) 2***praziquantel** (PZQ) (50–100 mg/kg/d in 3 doses for × 30d)	***treatment of choice*** (see below) *alternative*: 1***albendazole** (ABZ) (♦15 mg/kg/d, <max.800 mg> in 2 doses × 8–30d; can be repeated as necessary) 2***praziquantel** (PZQ) (♦50–100mg/kg/d in 3 doses for × 30d)
treatment of choice of parenchymal cysticercosis*:** Initial therapy for patients with inflammed parenchymal cysticercosis should focus on symptomatic treatment with anti-seizures medication; treatment of parenchymal cysticerci with ABZ or PZQ is controversial and characterized by various limitations: (1) patients with live parenchymal cysts and seizures should be treated with ABZ together with steroids (dexamethasone: 6 mg or prednisone: 40–60 mg daily) and an antiseizure medication; (2) patients with subarachnoid cysts or giant cysts in the fissures should be treated with ABZ for at least 30d; (3) patient with arachnoiditis, vasculitis, or cerebral edema: prednisone 60 mg/d or dexamethasone 4–6 mg/d together with ABZ or PZQ; ***contraindication: any cysticercocidal drug may produce irreversible pathologic alterations when used to treat *ocular or spinal cysts* even with concurrent use of steroids; (4) in case of obstructive hydrocephalus surgical intervention or cerebrospinal fluid (CSF) diversion is indicated (prednisone 40 mg/d may be given with surgery); surgical excision of accessible lesions is the only reliable means of cure and should include the use of anticonvulsant drugs; chemotherapy of neurocysticercosis is further discussed to define guidelines for use of drugs in inoperable patients				
COENURIASIS (infrequent): adult worm occurs in Canidae like dog, fox, coyote, and others (definitive hosts); herbivores serve as intermediate hosts as cattle, horse, sheep, wild herbivores, rarely man; latter becomes infected by ingestion of contaminated food containing embryonated eggs; human *Coenurus cerebralis*-disease mainly occurs in Africa; space-occupying larva usually invades brain				
Taenia multiceps (= Multiceps multiceps) (**larva type**: multiple invaginated scoleces into a bladder), infrequent	***Coenurus cerebralis***, larval cyst contains several hundred proto-scoleces (central nervous system, usually brain)	Prevention is not possible (reservoir hosts include numerous species of wild carnivores)	drug medication is unknown against space-occupying lesions due to larva	only reliable means is excision of accessible cyst
CYSTIC HYDATID DISEASE (hydatidosis, or cystic echinococcosis = CE): *Echinococcus granulosus* larva-type is a *unilocular hydatid cyst* infection of intermediate host (usually sheep, other herbivores as cattle, horse, and occasionally man) is due to close contact with dogs and other canids (definitive hosts), which may be infected with large numbers of adult worms (3–6 mm long, with a single gravid proglottid that is longer than wide; it contains typical *Taenia*-like eggs); feces of dogs contain embryonated eggs infective to potential intermediate hosts (occasionally humans); cestode larval stage in human tissues is characterized by multiple daughter bladders or "brood capsules" with multiple invaginated protoscoleces budding from their walls (inner layer of germinal epithelium of cystic cavity); cyst content (materials) consisting of degenerated scoleces and debris in milky fluid of parent cyst is referred to as *hydatid sand* (calcareous corpuscles)				
Echinococcus granulosus (humans are an accidental intermediate host and are usually infected by handling an infected dog)	**hydatid cyst, unilocular** (solitary or multiple or oval masses on imaging, frequently seen in liver and lungs, but also other tissues)	1***benzimidazole carbamates** mebendazole (40–50 mg/kg/d in 3 divided doses is less efficacious than albendazole in long-term regimen)	1***albendazole** (*drug of choice*), (400 mg bid × 1–6 months) **praziquantel** preoperatively use cf. ↓	1*(♦15 mg/kg/d, <max. 800 mg> × 1–6 months); adverse effects include nausea, hepatoxicity, neutropenia, rarely alopecia (long-term treatment)
sheep and cattle are common intermediate hosts of the larval stage; prevention of hydatidosis may be largely achieved if abattoir and disposal of infected offal are strictly controlled [for details cf. Raether W, Haenel H (2003) *Parasitol Res* 91: 412–438]; most ultrasound surveys of CE reveal that the zoonotic sheep strain of *E. granulosus* is likely the main cause of				

Cestodocidal Drugs. Table 2 Drugs used against cestode infections in humans (Continued)

PARASITE DISEASE distribution, pathology	**Stage** affected (location), morphology of **egg**	**Chemical class** other information (1*, 2* etc. refer to linked chemicals and comments)	**Nonproprietary name** adult dosage (♦ = pediatric dosage) (oral route), d = days, comments	**Miscellaneous comments**
human CE in remote rural areas; clinical symptoms and manifestations in CE patients are highly variable and often nonspecific; infected individuals may be asymptomatic for a long time, symptoms may result from release of antigenic material following cyst rupture and dissemination of viable scoleces (secondary infection); there is a great diversity of clinical manifestations and pathological alterations in liver and lungs and other organs; about 20–40% of CE patients have multiple cysts with involvement of several organs; total surgical resection of an hydatid cyst may be still considered the <gold standard treatment> for CE; medical treatment with benzimidazole drugs is currently used in nonsurgical cases or as supplementary treatment prior to and post-surgery to reduce the risk of secondary CE (intraoperative spillage of viable material) and recurrence; WHO recommends postoperative chemotherapy (in case of spillage of protoscoleces) for at least 1 month with albendazole (ABZ) or 3 months with mebendazole (MBZ); **praziquantel** (PZQ) may be useful preoperatively in case of cyst spillage during surgery; it has also been used (25 mg/kg/d) with ABZ for combined treatment of CE resulting in improved efficacy over ABZ alone (PZQ may increase serum concentrations of ABZ sulfoxide up to 4-fold); percutaneous aspiration-injection-reaspiration (PAIR) with ultrasound guidance plus ABZ treatment has been effective for management of hepatic CE; however, for PAIR there is no ideal agent that is both effective and safe; for optimum efficacy, scolecidal compounds require a 15 minutes "dwell time" within the cavity; relatively safe and effective are ethanol (70–95%), saline (15–20%) and cetrimide solution (formalin should never be used); severe, sometimes fatal chemical (sclerosing) cholangitis can result if there is communication between biliary tree and cyst; in summary, there is yet no formal consensus, as efficacy and safety of the methods require further evaluation to establish comprehensive guidelines for medical treatment of CE; ABZ and MBZ (teratogenic in laboratory animals) are listed as category C drugs in pregnancy in the USA (in Australia category D; B3): neither drug is absolutely contraindicated in pregnancy				
ALVEOLAR DISEASE (or alveolar echinococcosis = AE): *Echinococcus multilocularis* larva-type: *multilocular* or *alveolar multilocular cyst* large numbers of adult worms (3–5 mm long, morphology cf. *E. granulosus*, and eggs of taeniid type) primarily occurring in fox (definitive host, occasionally dogs, cats, and wolves); several microtine rodents serve as intermediate host (sylvatic cycle); major source of infrequent human infection is through fruits and vegetables contaminated with larvated eggs from fox feces; in infected humans, "metastasis" (branches) of the laminated membrane by the alveolar cyst resembles lesion of a neoplasm; lesions in the liver are usually membranous; in contrast to hydatid of *E. granulosus*, neither protoscoleces nor hydatid sand (calcareous corpuscles) are identifiably in human cysts				
Echinococcus multilocularis (infrequent); *E. vogeli* (infrequent) causing **polycystic** echinococcosis	growth of **alveolar (multilocular) cyst** is peripheral and invasive; metastases are frequent (liver, adjacent tissue)	*experimental drugs*: (flubendazole, fenbendazole, oxfendazole, amphotericin B *nitazoxanide*)	***treatment*** if early diagnosed, surgical excision of lesions is a reliable means of treatment	no therapy is fully effective against tumorlike growth of alveolar type of cyst
clinical manifestation produced by the alveolar larva of *E. multilocularis* are related to the extent of tumorlike lesions of the cyst; AE is characterized by a chronic course lasting for months or years; clinical symptoms are variably and usually only follow a long asymptomatic period (5–15 years); in liver, alveolar hydatid presents a mass- producing inflammatory process; metastasis in lungs may be seen as multiple small solid foci and pathological findings may be characterized by marked foreign-body reaction in bones; ***treatment***: AE is difficult to treat; current treatment approach is preferable surgery, or secondarily benzimidazole chemotherapy; radical surgical resection of complete alveolar lesion(s), e.g., in right or left liver lobes, is the only potential curative treatment [cf. details Craig P (2003), *Curr Opin Dis* 16: 473-444]; **albendazole** (ABZ: 10–15 mg/kg/d: long-term treatment: 6.5 years) is the drug of choice for human AE in patients with nonresectable AE; ABZ may be a useful adjunct therapy to surgery; overall its use orally resulted in improved 10-year survival rates up to 80–83% compared to 6–25% for untreated historical controls [a WHO group recommended long-term treatment: 3–24 months: ABZ (10 mg/kg), mebendazole (40–50 mg/kg); high doses are necessary to affect larva →WHO Group Bull WHO, 74:231, 1996]; **nitazoxanide** (NTZ)-treated *in vitro* cultured metacestodes of *E. multilocularis* were nonviable when implanted into susceptible mice; as NTZ is much better absorbed than ABZ following oral administration it provides an attractive alternative for medical treatment of human AE				
SPARGANOSIS: **larva type**: solid-bodied larva lacking a bladder adult worm (pseudophyllidean tapeworm) occurs in cats, dogs, wild canids, or felids and is of little significance to definitive hosts; first intermediate host is a copepod, second one any vertebrate due to lack of specificity of the plerocercoid; humans become infected (1) by ingestion of a copepod (crustaceans) containing procercoids (first larval stage), (2) by ingestion of raw or undercooked flesh or organs of any vertebrate (amphibians, reptiles, mammals, particularly feral pigs raised for human consumption) containing plerocercoids (=**sparganum**, second larval stage, easily mistaken for nerves), or (3) by local application of flesh (poultice to wounds or to the eye) containing plerocercoids sparganum				

Cestodocidal Drugs. Table 2 Drugs used against cestode infections in humans (Continued)

PARASITE DISEASE distribution, pathology	**Stage** affected (location), morphology of **egg**	**Chemical class** other information (1*, 2* etc. refer to linked chemicals and comments)	**Nonproprietary name** adult dosage (♦ = pediatric dosage) (oral route), d = days, comments	**Miscellaneous comments**
Spirometra spp. (infrequent), life cycle is similar to that of *D. latum* (fish tapeworm of humans)	**procercoid** (migrate in subcutaneous and muscular tissue) **plerocercoid** (migrate in connective tissue of muscles, abdomen, hind legs; peritoneum, pleura)	there is no reliable chemotherapy (*praziquantel* may show some larvicidal effects)	*treatment* is surgical prevention is difficult because of entrenched eating habits and other customs	larval worms cause during subcutaneous migration painful edema, urticaria, inflammation, fibrosis; spargana grow into irregular nodules of subcutaneous tissues

Abbreviation(s): BID = bis in die = twice a day

Dosages listed in the table refer to information from manufacturer, literature, and/or Medical Letter (2004) "Drugs for parasitic infections": The Medical Letter (publisher) 46 (issue 1189): e1–e12, New Rochelle, New York

Data given in this Table have no claim to full information

the latter measure is estimated to detect only about 50% of the infected carcasses. To kill cysticerci, beef carcasses must be frozen, e.g., for 6 days at −20°C, or carcasses should be cooked. There are several reports that cattle and sheep (goats) can be successfully vaccinated against *T. ovis* and *T. saginata* (beef tapeworm) with recombinant antigens inducing high levels of protective immunity. This may give some hope for the commercial use of such vaccines against infection in the near future (cf. →Vaccination).

Through chemotherapy, complete elimination of *Echinococcus* spp. infections in dogs must be achieved because of the major agricultural and public health problems due to →hydatidosis in intermediate hosts. Primarily sheep but also other herbivores such as goats, cattle, horses, camels (pigs), and by chance humans serve as intermediate hosts. There are phylogenetic variations in *Echinococcus*, i.e., several strains of *E. granulosus* differing in their morphology and their isoenzyme patterns. Some of these strains appear to be specific for a particular →intermediate host and an endemic area. The horse strain does not appear to infect humans although the sheep strain does. Human hydatidosis (infectious stage of *E. granulosus*, cf. Table 2) is often associated with severe clinical signs, particularly if the brain (hydatid cyst with calcifications) or heart is involved. This is also true in human alveolar cyst formation caused by *E. multilocularis* and *E. vogeli* (Table 2). Hydatidosis in domestic animals rarely produces clinical signs despite heavy infections. Adult *E. granulosus*, only 3.5–5.6 mm in length, is principally harmless to the dog although large numbers of adults may cause enteritis. There has been substantial progress toward successful vaccination against *E. granulosus*; recombinant antigens from *E. granulosus* generated more than 95% protection against challenge in vaccinated sheep or dogs.

Old Remedies and Modern Compounds with Cestocidal Activity

There are many old remedies showing some activity against adult tapeworms. Thus pumpkinseeds, powdered areca (fruits of betel palm, *Areca catechu*), kousso (flowers of an Abyssinian tree, *Hagenia abyssinica*), turpentine (oily mixture of exsudates from coniferous trees, especially longleaf pine), pomegranate root bark (tropical Asian and African tree, *Punica granatum*), and male fern (*Dryopteris filix-mas*) were used as anticestodal remedies. These and other plant products had been gradually replaced by arecoline (alkaloid obtained from seeds of betel palm), organic tin compounds, lead arsenate, or dichlorophene during the first half of this century. Since 1921, **arecoline** has been used in veterinary medicine for many years against *E. granulosus* and *Taenia* spp. in dogs. Because of its relative low efficacy and its severe side effects, it is no longer recommended as a therapeutic drug in dogs and cats. However, its strong parasympathomimetic action causes purging and thus partial removal of paralyzed worms from the intestine. This action makes arecoline a useful diagnostic agent, which may give valuable information on whether a group of dogs on a farm is infected with *Taenia* spp. or *Echinococcus* spp. or not.

Several "modern" **synthetic compounds** are in current use for the control of tapeworm infections preferably in pets (Table 1). Such drugs are for instance dichlorophene, bunamidine, niclosamide, resorantel, benzimidazole carbamates, nitroscanate, pyrantel (e.g., horses), praziquantel, and epsiprantel. They may exhibit good activity against adult stages of intestinal tapeworms while praziquantel (Table 2) and benzimidazole carbamates (mebendazole, albendazole) show action against larval stages of certain cestodes. Thus, mebendazole and albendazole may improve clinical

illness of →hydatid disease (*Echinococcus* spp.) in humans following long-term treatment.

Drugs Acting on Adult Tapeworm Infections in Dogs and Cats

Echinococcus spp., *Dipylidium caninum* (highly active proglottids may cause anal irritation and thus scooting), *Diphyllobothrium latum*, and *Spirometra* spp. have public health implications (Table 2). Other cestode-species occurring in dogs and cats are *Taenia* and *Mesocestoides*. Routine treatment with effective cestocidal drugs at intervals less than the prepatent periods of the parasites should be used in working dogs to reduce the incidence of *Echinococcus* spp. infections, particularly in rural areas. Other control measures should also be considered to prevent hydatidosis in livestock and man, such as control of home slaughtering of small ruminants and consequent condemnation of infected viscera of infected animals, and quarantine regulations for dogs.

The majority of compounds recommended for treatment in dogs and cats (Table 1), such as bunamidine HCl, some benzimidazole carbamates (e.g., mebendazole, fenbendazole), niclosamide, praziquantel, and epsiprantel, prove highly effective against adult stages of *Taenia* spp. and *D. caninum*. The action of **niclosamide** is, however, somewhat erratic against *D. caninum*. **Bunamidine** appears to be the only drug that shows efficacy against *Spirometra* spp., particularly against *S. erinacei* in dogs and cats. Like praziquantel, it also exhibits activity against *Mesocestoides* spp. but requires a 10 times higher dosage than that drug. **Nitroscanate**, introduced in 1973 (not commercially available in Germany, USA, Australia) as a broad-spectrum agent for use in dogs, has marked activity against roundworms (*Toxocara canis*, *Toxascaris leonina*), hookworms (*Ancylostoma caninum*, *Uncinaria stenocephala*), and tapeworms (*Taenia* spp. and *D. caninum*). However, the drug is not recommended for use against *E. granulosus* infection since 100% elimination of adults and juvenile worms is not achievable. **Praziquantel** (Tables 1, 2) is a safe and highly active drug against a broad range of mature and immature tapeworms (including *Echinococcus* spp.), and most trematodes (particularly *Schistosoma* spp. cf. →Trematodocidal Drugs). **Epsiprantel** one of the latest cestocidal products on the market is chemically related to praziquantel. It exhibits good activity against common tapeworm infections in cats (*D. caninum* and *Taenia taeniaeformis*), and dogs (*T. pisiformis* and *D. caninum*), and shows an excellent action on adult *E. granulosus*. The drug is poorly absorbed from the gastrointestinal tract allowing the compound to be in contact with the parasites for a prolonged period.

There are numerous combinations of praziquantel with antinematodal compounds (cf. →Nematocidal Drugs, Animals), e.g., **febantel/pyrantel/praziquantel** (Drontal Plus for dogs), an all wormer against intestinal nematodes and cestodes or **praziquantel/pyrantel** (Drontal for cats) has a high activity against *Ancylostoma caninum* and cestodes but only moderate activity against *Toxocara canis* and *Trichuris vulpis*. **Albendazole/praziquantel** may control various tapeworm infections (*Taenia* spp., *D. caninum*, *Echinococcus* spp.) and nematode infections (roundworms such as *Toxocara* spp., hookworms as *Ancylostoma* spp., the whipworm *Trichuris vulpis*, and *Strongyloides* spp.). **Ivermectin/praziquantel** may be used for heartworm prophylaxis (*Dirofilaria immitis*) and prevention of tapeworm infections in dogs (cf. pyrantel Table 1 for details).

Drugs Acting on Adult and Larval Tapeworm Infection of Sheep and Cattle

There are several species (e.g., *Moniezia expansa*, *M. benedeni*, *Avitellina* spp., and *Thysaniezia giardi*) which occur in the intestine of sheep, goats, cattle, and other ruminants in most parts of the world. *Stilesia hepatica* and *Thysanosoma actinioides* (the fringed tapeworm) are found in the bile ducts of cattle, sheep, and wild ruminants (e.g., deer) in Africa and Asia, or in North and South America (*T. actinioides*). None of these relatively large species appears to be very pathogenic, and therefore there may only be economic return from treatment of lamb and calves if the administered compound is effective against both cestodes and nematodes. Such drugs include the **benzimidazole carbamates** (e.g., albendazole, oxfendazole); they exhibit good efficacy against various intestinal nematodes (→Nematocidal Drugs, Animals) and cestodes (Table 1) in food animals. **Niclosamide** exerts good activity against *Moniezia* spp. and *Avitellina* spp. in ruminants. **Albendazole, fenbendazole**, and **praziquantel** are effective against cestodes occurring in the bile ducts. However, enhanced doses (double and 4 times the recommended dose) of these drugs are necessary to eliminate the tapeworms.

High doses of praziquantel (20–40 times the recommended dose) are required to affect *T. saginata* or *T. hydatigena* **larval stages** in cattle and sheep; cost for treatment precludes, however, the use of praziquantel in the field. The same is true for albendazole showing action on larval *T. saginata* in cattle at 10 times the recommended dose. The mode of action of the **benzimidazole carbamates** is generally thought to be primarily due to alterations in microtubule polymerization via a direct binding of these compounds to parasite tubulin. Thus, the coadministration of **fenbendazole** and the phenylguanidine **netobimin** (a prodrug of albendazole, cf. →Nematocidal Drugs, Animals) has been shown to inhibit solidly the regenerative capacity of hydadit material in gerbils.

Recurrence of hydatid-cyst never took place when using coadministration of both drugs. Different effects have been observed after the administration of **praziquantel** in laboratory animals against larval stages of *Echinococcus*. Thus it affects protoscoleces of *E. multilocularis* but does not inhibit growth of cysts of both *E. multilocularis* and *E. granulosus*.

Drugs Acting on Adult Tapeworm Infections in Horses and Donkeys

Clinical signs associated with tapeworms in equines are uncommon. Occasionally *Anoplocephala magna* and *Paranoplocephala mamillana* occurring in the small intestine and rarely stomach may cause catarrhal (rarely hemorrhagic) enteritis. *A. perfoliata* found in the large and small intestine is often localized near the ileocecal orifice and ulcerative lesions and edema may be produced where the scoleces are attached to the cecal wall. Clinical signs (e.g., diarrhea) are usually seen in autumn and spring when infected oribatid mites may be present in great numbers. Because of the low pathogenicity of these tapeworms, treatment should be considered carefully since use of a compound that acts only specifically is unlikely to be economic. It may be of value to use a compound that combines activity against both cestodes and nematodes. Thus, **pyrantel embonate** (an antinematodal agent, cf. →Nematocidal Drugs, Animals) has been found to have a distinct activity against *A. perfoliata* at twice the nematocidal dose. It is only variably active against *P. mamillana*. However, in confirmed cases of equine cestodiasis **praziquantel** (1 mg/kg: *P. mamillana*; 0.5 mg/kg: *A. perfoliata*) exhibited a marked effect against these tapeworms. **Fenbendazole** (3 × 10–20 mg/kg) and *mebendazole* (dosage see Table 1) also show action on equine tapeworms (cf. also →Nematocidal Drugs, Animals). However, widespread benzimidazole resistance of equine nematodes may limit the economic value of such a therapy. **Niclosamide** (80–100 mg/kg b.w., not approved indication, availability problems) had good activity against anoplocephalids of all ages. Combinations containing praziquantel and a macrocyclic lactone (ivermectin, abamectin, or moxidectin, cf. →Nematocidal Drugs, Animals) may be used for the prevention and control of infections caused by cestodes, nematodes, and *Gasterophilus* spp. (botflies).

Drugs Acting on Adult Tapeworm Infections in Birds

In the poultry industry the meat production has increased continuously worldwide (cf. →Coccidiocidal Drugs/Economic Importance). In 2004, broiler meat production amounted to about 10 million metric tons in the USA and China, respectively (USDA, Vol. 08 NO. 45, 2005). In birds, losses due to moderate and seldom heavier tapeworm infections may be diarrhea (enteritis), weight depression, emaciation, and rarely mortality. Free-range birds, e.g., those in backyard flocks, and cage birds in aviaries with earthen floors are often hosts to many species of tapeworms (e.g., →*Davainea proglottina*, *Raillietina* spp., *Cotugnia* spp., *Amoebotaenia cuneata*, *Choanotaenia infundibulum*, *Hymenolepis* spp., →*Fimbriaria* spp., and other cestodes). Their life cycles require the development of cysticercoids (larval stages) in a large number of intermediate hosts such as various copepods, snails, and insects. Modern husbandry methods may largely prevent access to the various intermediate hosts, thus preventing tapeworm infections in commercial poultry. Consequently, only little information is available about adequately tested compounds in birds. **Niclosamide** (250 mg/kg, per os) seems to be effective and safe in most cases (can be toxic to geese). **Praziquantel** (5–10 mg/kg) is effective against a wide range of immature and mature cestodes in poultry, waterbirds (ducks, geese), and game birds (pheasant, partridge). However, an economic return to its use seems to be questionable. **Benzimidazole carbamates** (fenbendazole, mebendazole, other compounds, →Nematocidal Drugs, Animals), exhibit variable actions on avian cestodes. Fenbendazole is somewhat erratically effective against *Davainea proglottina*, and the activity of mebendazole is limited to *Raillietina* and *Hymenolepis*.

Drugs Acting on Adult and Larval Tapeworm Infections of Humans

Among the adult (intestinal) tapeworms in man, *T. solium* (pork tapeworm, common in Latin America) and *D. latum* (broad tapeworm or fish tapeworm, common in regions where freshwater fishes occur) are particularly important to human health. *T. solium* may cause →cysticercosis (Table 2) and *D. latum* pernicious anemia due to vitamin B_{12} deficiency. Other adult tapeworm species affecting humans are *T. saginata* (beef tapeworm, worldwide distribution, approx. 60 million people currently infected), and *Hymenolepis nana* (dwarf tapeworm, infects not only man but also mice and rats). *T. saginata* may cause economic loss due to taeniasis or cysticercosis in cattle and *H. nana* play a role as →zoonosis since cross-infections between humans and rodents are possible. Mainly two drugs, the older **niclosamide** (a nitrosalicylanilide) and the newer **praziquantel** (pyrazinoisoquinoline) are used for elimination of these tapeworms from the intestinal tract (dosage, cf. Table 2). Old remedies (certain seeds from locally grown plants) or other drugs may still be in use (Tables 1, 2).

Larval cestodes of certain tapeworms lodge preferably in the central nervous system, or in the liver (lung or other organs). Thus the cysticercus of *T. solium* causes neurocysticercosis. The hydatid cyst of

E. granulosus produces cystic →echinococcosis, and that of *E. multilocularis* alveolar echinococcosis. *E. vogeli* causes polycystic echinococcosis in humans, and characteristics of *E. vogeli* metacestode are considered intermediate to those of *E. granulosus* and *E. multilocularis*. Because of the tumor-like growth and proliferation of larval stages, clinical manifestations and pathology are characterized by their great diversity of moderate to severe symptoms. **Treatment** of diseases caused by larval stages is based mainly on 3 measures focusing on symptomatic and causal therapy: (1) Palliative drugs (e.g., antiepileptics and corticosteroids) are used to control seizures and inflammation associated with tissue reactions caused by cestode larva. (2) Measures of palliative surgery are performed to drain CSF by placement of ventricular shunts, and those of causative surgery to remove solitary brain cysticerci or hydatid cyst from liver or lung. (3) Long-term chemotherapy (indicated if surgical resection of cyst is not possible) may result in complete and permanent disappearance of cyst if it is surrounded by minimal adventitial reactions. Patients with complicated cysts (multiple compartments and numerous daughter cysts) and surrounded by solid fibrous reactions appear to be considerably refractory to treatment (drugs used see Table 2). Children suffering from larval cestode infection usually respond more sensitively to chemotherapy than adults. **Albendazole** and **praziquantel** may be useful for affecting and eliminating living cysticerci in brain parenchyma and in the subarachnoidal space. **Antiepileptic drugs** are the treatment of choice for patients suffering from epileptic attacks caused by neurocyticercosis with calcifications. The administration of such drugs is indicated when seizures are the only manifestation of the disease and there is no imaging and immunological evidence of living parasites. **Corticosteroids** should be used simultaneously with chemotherapy (for 2 or 3 days prior to and during drug treatment) to reduce exacerbation of neurological symptoms. Any cysticercocidal drug may cause irreparable damage when used to treat ocular or spinal cysts, even when steroids are used. An ophthalmic examination must be carried out before treatment. **Surgical removal** of cystic echinococcosis (*E. granulosus*) appears to be the treatment of choice if cysts are large (>10cm Ø). When surgical excision cannot be performed because of general condition of the patient and the extent and location of the cyst, **long-term chemotherapy** should be performed either with **albendazole** (10 mg/kg, b.w.) or **mebendazole** (40–50 mg/kg, b.w.) for at least 3 months. These benzimidazole carbamates also inhibit the growth of larval *E. multilocularis*, reduce metastases, and may enhance both the quality and length of patient's survival. Sometimes they may be larvicidal after prolonged therapy but often recurrence may occur.

Alveolar hydatid disease (*E. multilocularis*) is often diagnosed too late so that lesion becomes inoperable. This may also be true for surgical resection of extensive lesions caused by polycystic echinococcosis (*E. vogeli*). Liver transplantation has been successfully performed on otherwise terminal cases. Often combination of surgery with chemotherapy (albendazole) is more likely to be successful in cases in which resection is difficult and usually incomplete. Postoperative chemotherapy should be done routinely for at least 2 years after radical surgery. Also prolonged follow-up of patients for at least 10 years with ultrasound or other imaging procedures is necessary to track down possible recurrence of cysts. Combined methods of percutaneous cyst puncture and drainage under ultrasound guidance can be carried out with or without injection of a protoscolicidal compound (e.g., 95% ethanol, or 20% sodium chloride solution). Thus liquid cyst content is aspirated (or drained), the chemical installed, and then re-aspirated (or drained). Secondary echinococcosis, which may be caused by accidental spill of cyst fluid during this procedure, can be minimized with simultaneous administration of albendazole or preoperative use of praziquantel. Ivermectin directly injected into hydatid cyst of *E. granulosus* has been found to damage viable protoscoleces in gerbils 6–8 weeks after injection. "Percutaneous drainage, i.e., aspiration-injection and re-aspiration" (= PAIR) should be performed only if cysts have no biliary communication. Otherwise, sclerosing cholangitis may occur when the chemical is installed. Therefore prior to PAIR, cyst fluid has to be investigated for the presence of bilirubin.

Chagas' Disease, Animals

→Cardiovascular System Diseases, Animals.

Chagas' Disease, Man

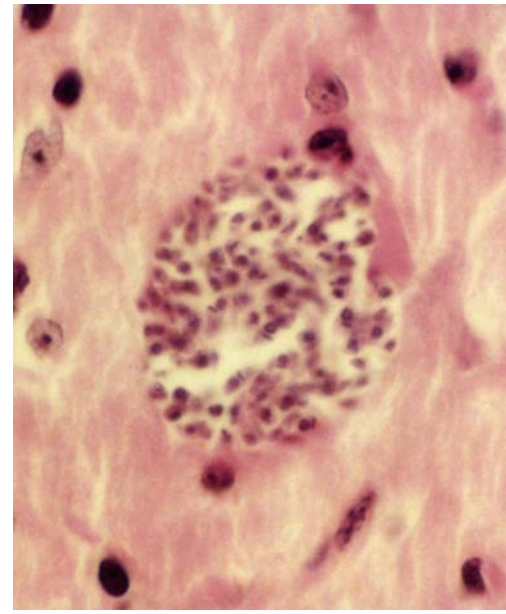
Pathology

→*Trypanosoma cruzi* infection occurs in Central and South America and is transmitted by triatomid →bugs (→Kissing Bugs). These hematophagous →hemiptera evacuate their intestinal contents containing the infection's metacyclic forms, while feeding, in order to ingest more blood. Metacyclic forms enter either the skin through the site of the bite, are inoculated by scratching the itching bite wound, or penetrate the mucosa of the conjunctiva or mouth. →Amastigotes multiply in adjacent muscle and fat cells in the dermis, producing an inflammatory →nodule, the chagoma, which is composed of parasitized cells, histiocytes, and a periphery of neutrophilic granulocytes. This chagoma may persist for several weeks. Trypanosomes are disseminated via the lymphatics, often enlarging the regional lymph nodes. Hematogenous dissemination follows and amastigotes parasitize many tissues, especially histiocytes, adipocytes, myocardial fibers, and autonomic ganglia in the gastrointestinal tract; this is accompanied by fever. The parasitized cells are usually destroyed (→Pathology/Fig. 13D). When the infection is transmitted by blood transfusion it is particularly severe because it starts with the hematogenous phase of dissemination without any preceding immunization during the chagoma stage. However, the majority of patients with naturally acquired *T. cruzi* infection experience a benign or asymptomatic infection.

The most important lesions are in the heart, the esophagus, and the colon. The myocardium contains large →pseudocysts of amastigotes without surrounding inflammation (Fig. 1). Destroyed myocardial cells are also found, with lymphocyte, plasma cell, and macrophage infiltration often forming "microabscesses" that later heal by fibrosis (→Pathology/Fig. 13D). During chronic Chagas' disease, which may last for years, the heart usually undergoes marked hypertrophy (400–800 g) and dilatation. Mural thrombi are commonly found. Next to the apex of the left ventricle myocardial inflammation and fibrosis are often most advanced, and the ventricular wall may become so thin as to be transilluminable. After the Purkinje fibers are destroyed, conduction defects, such as arrhythmias, hypotension, tachycardia, right bundle branch block, and later bradycardia make their appearance. Myocardial failure responds poorly to digitalis and results in death, as does ventricular fibrillation. There are usually few amastigotes in the lesions of chronic Chagas' myocarditis, but the myocarditis with diffuse fibrosis still progresses. This has led to various hypotheses suggesting that delayed →hypersensitivity or →autoimmunity may participate in the pathogenesis. However, reviewing these, here is enough pathologic evidence to support a direct effect of *T. cruzi* on infected cells.

The autonomic ganglia of the esophagus and colon may be destroyed either by parasitization or by an undetermined process. The destruction leads to an interruption of the peristaltic wave and dilatation of the viscus proximal to the destroyed ganglia, often resulting in megaesophagus and megacolon.

Chagas' →encephalitis is seen especially in young children, with parasitization of neurons by amastigotes and destruction of even unparasitized cells. There is marked focal neuronal damage accompanied by lymphocytic infiltration and extending into the meninges. Death may occur after a disease course of only 1–2 months.



Chagas' Disease, Man. Figure 1 Giemsa stained section through a muscle fiber with a pseudocyst of *Trypanosoma cruzi.*

There are many cases known of spontaneous cure and of chronic asymptomatic parasitemia lasting for 20–40 years without apparent progressive organ lesions. Minor lesions include the lipochagoma resulting from the destruction of adipocytes by trypanosomes, and a painful lipogranuloma which, if it occurs in the cheeks, interferes with eating.

Placental infection may occur and lead to →abortion. Sometimes the fetus becomes infected, resulting in encephalitis and death a few days or weeks after delivery.

Immune Responses

T. cruzi is able to infect virtually any nucleated cells of mammals. In infected mammals *T. cruzi* can be found either as flagellated trypomastigote or as amastigote replicating inside of cells. Amastigotes can be found both within phagocytic →vacuoles as well as free in the →cytoplasm. After rupture of the host cell, amastigotes transform into →trypomastigotes, which are the most infective forms. The intracellular habit may be the reason why *T. cruzi* did not evolve mechanisms of adaptive genetic variation to alter expression of surface proteins such as occurring in African trypanosomes. In humans, the majority of infections with *T. cruzi* are thought to be asymptomatic. Chagas' disease typically represents a chronic disease, with a long-term interaction of the host's immune system and the parasite. Sterile immunity is seldom or never achieved and human *T. cruzi* infections are often dormant for decades. As in the case of *T. gondi*, reactivation has been described to occur during intentional immunosuppression for organ transplants or in →AIDS patients. Mouse models of *T. cruzi* infection have been used by many investigators to study both acute and →chronic infections to elucidate immune-response mechanisms leading to the control of the parasite or to autoimmune pathology. Differences in *T. cruzi* strains can greatly influence the immunological characteristics and disease outcome. In addition, inbred mouse strains have been classified as being susceptible or resistant to T. cruzi infection, but this responsiveness clearly depends on the parasite strain as well.

A typical feature of *T. cruzi* infections in mice is a profound suppression in multiple components of the immune system, which for example, can result in exacerbated viral infections (e.g., Murine leukemia virus). Likewise, virtually all immune-defense mechanisms appear to be involved in the control of *T. cruzi* infection and disease development.

Innate Immunity

T. cruzi activates cells of the innate immune system by glycosylphaditylinositol and the Tc52-released protein as TLR2 agonists, glycoinositolphospholipid-containing ceramide as TLR4 agonist, and unmethylated CpG motifs as potential TLR9 agonists. TLR2-deficient mice develop enhanced parasitemia and mice deficient for the TLR adaptor protein Myeloid Differentiation factor 88 (MyD88) display impaired production of pro-inflammatory cytokines and enhanced susceptibility. During the very early phase of infection NK cells are activated via IL-12 produced by macrophages in response to live, infective trypomastigotes. IFN-γ, produced very early by activated NK cells has a protective effect on experimental *T. cruzi* infection *in vivo*. Both, neutralization of IFN-γ or depletion of NK cells by mAb treatment rendered relative resistant mice more susceptible to the infection and increased parasitemia. However, IFN-γ produced in the later phases of acute infection may not be relevant for protection.

As the acute infection progresses, polyclonal activation of essentially all peripheral lymphoid cell types is induced. One minor subset intensely expanded is the γδ T cells. Although the relevance of this subset for host protection is still uncertain, one study showed that γδT cells are able to modulate the intensity of parasitemia, mortality, and tissue inflammation.

B Cells and Antibodies

Polyclonal activation of B cells during the acute phase of infection leads to marked Ig production of all isotypes, but only a minor component of the Ig's appears to be parasite-specific. However, transfer of serum containing *T. cruzi*-specific antibodies mediated significant protection against the infection. In this regard, *T. cruzi* differs from other intracellular pathogens, in that humoral responses do play a protective role against circulating trypomastigotes. $CD5^+$ B1 cells may play an important regulatory role by their capacity to produce IL-10. It has been reported, that mice carrying the xid defect and therefore lacking B1 cells, showed an increased IFN-γ production and were more resistant than the appropriate control mice.

T Cells

A number of studies demonstrated that both $CD4^+$ and $CD8^+$ T cells were needed for parasitemia control and survival in acute infection. Elimination of $CD4^+$ T cells by antibody treatment or in MHC class II deficient mice resulted in markedly increased susceptibility to *T. cruzi* infection while athymic mice receiving syngeneic $CD4^+$ T cells were better able to contain parasitemia. The need for $CD4^+$ T cells has been attributed to the production of cytokines stimulating macrophages to kill intracellular parasites and/or to help in the production of protective parasite-lytic antibodies. Elimination of $CD8^+$ T cells by preventing MHC class I expression in gene-deficient mice or by treatment with mAb also resulted in markedly increased susceptibility to *T. cruzi* infection. Mice made deficient in both $CD4^+$ and $CD8^+$

T cells are even more susceptible to increased parasitemia and death, which is consistent with a crucial role for IFN-γ produced by both $CD4^+$ and $CD8^+$ T cells.

In contrast to other experimental parasitic infections, infection with *T. cruzi* does not result in a clear polarization of Th1 or Th2 cytokine responses, as both IFN-γ and IL-10 were found to be produced simultaneously. Instead, separate Th1 and Th2 waves may occur at different stages of infection within the same resistant host and a higher amplitude and more rapid onset of a Th1-type response correlated with resistance.

At least in the Brazilian strain model of infection, most of the IFN-γ appears to be produced from a very unusual subset of ab TCR^+, $NK1.1^-$, $CD4^-$ and $CD8^-$ (DN) T cells. However, for reasons unclear so far this cell population does not seem to play any major protective or inflammatory role in *T. cruzi* infection.

Immunosuppression

The observation that effector mechanisms were impaired in mice infected with *T. cruzi* led to the search for soluble mediators of this deficiency. TGF-β, which exerts suppressive effects on macrophages and T cells, was found to be released in a biologically active, processed form by cultured spleen cells from *T. cruzi*-infected mice already on day 8 postinfection. Since in most cases TGF-β is produced in an inactive latent form, it was analyzed, how activation occurs in *T. cruzi* infection. Recent findings suggest, that *T. cruzi* trypomastigotes themselves have a potent enzyme capable of activating TGF-β. Since administration of recombinant TGF-β to resistant B6D2 F1 mice significantly increased both →morbidity and mortality in these animals, TGF-β induced and activated by *T. cruzi* may represent a novel mechanism for pathogenesis.

Another candidate for a mediator of macrophage inhibition is IL-10. Like the "host protective" IL-12, IL-10 can also be produced by macrophages in response to live infective trypomastigotes. Since *in vitro* IL-10 is able to inhibit the ability of macrophages to kill intracellular *T. cruzi*, it has been considered as a "parasite protective" cytokine. In line with this, administration of neutralizing anti-IL-10 mAb could block the development of acute disease in susceptible C57BL/6 mice. In addition, it has been established that infections with *T. cruzi* (strains →CL or Tulahuen) trigger a significantly stronger IL-10 production in susceptible than in resistant mice. On the other hand, IL-10 may also possess protective effects, since IL-10 knockout mice infected with the Tulahuen strain showed accelerated mortality, as compared to wild type mice despite a reduced parasite load. In these IL-10-deficient mice, not only rIL-10 but also anti-IL-12 mAb reversed the susceptibility, leading to the conclusion, that IL-10 may prevent toxic immune responses characterized by overproduction of IL-12 and IFN-γ. However, Treg cells as a potential source of IL-10 and TGF-β do not appear to play a major role in regulating $CD8^+$ T cell effector responses during the acute phase of infection, nor in the muscle of mice during chronic *T. cruzi* infection. A second mechanism of immunosuppression beside soluble mediators involves the induction of activation-induced programmed cell death, →apoptosis. Selective triggering of $CD4^+$ T cell apoptosis has been described in experimental *T. cruzi* infection, which is mediated via the TCR-CD3 pathway and not via CD69 or Ly-6.

Autoimmunity

There is strong evidence that much of the pathology of chronic Chagas disease, such as cardiac manifestations or peripheral neuropathy, is caused by autoimmune mechanisms. One antigen of *T. cruzi* (FL-160) has been implicated in molecular mimicry of nervous tissues. About 40% of persons with chronic *T. cruzi* infections had antibodies to the FL-160 antigen, and antibodies to 2 epitopes in this protein have been shown to bind to human sciatic nerve. Ribosomal P proteins of *T. cruzi* are also able to trigger antibody responses against host P proteins, which, interestingly, have previously been implicated as autoimmune targets in SLE patients. Furthermore, human T cells and antibodies reacting with →*myosin* and most likely involved in the pathogenesis of Chagas cardiomyopathy may be triggered by a cross-reactive antigen of *T. cruzi*, which was identified recently.

Vaccination

The approximately 12–20 million individuals in Central and South America infected with *T. cruzi* represent an important medico-social problem. Various chemotherapeutic drugs have become available but no vaccines have been developed. An important effort of Public Health Organization in Brazil, Uruguay, and Argentina has successfully controlled the domestic hemiptera vector →*Triatoma infestans*, and transmission of Chagas' disease in these countries, is practically reduced to blood transfusion accidents. In other South and Central America countries anti-vector campaigns are successfully in progress. This success in transmission control considerably decreases the interest in vaccination against Chagas' disease. However, a large number of animal species from different orders of mammals are *T. cruzi* reservoirs in nature, including domestic animals like cats and dogs, which represent potential sources of infection for man. Thus, if available, vaccination would have a double interest: (1) Control of animal's sources of infection and (2) Protection of humans migrating in new eventual endemic areas will be possible in future in the Amazon Region. No evidence of →antigenic variation has been found in *T. cruzi* as described for the African trypanosomes. However,

2 main lineages of parasites have been recently identified by molecular markers, one more frequent in human infections and the other in →animal reservoirs. In both lineages, the parasite from the vector insect stage (Triatomidae) can be grown easily in liquid culture with semi-synthetic or defined medium while the vertebrate form can also easily grow in tissue culture using a variety of cells from mammals or birds. Thus, the preconditions for developing vaccines directly from parasites' materials are there, either for development of attenuated lines or chemical purification of antigen components.

About 90% of infected persons recover from the acute stage, but continue to have low parasitemias for an indefinite period of time without clinical signs. A small proportion of them later develop the chronic form of Chagas'disease, with chronic myocarditis or mega- esophagus or mega-column syndromes. In the asymptomatic period, carriers have antibodies to *T. cruzi* and this immune response has been considered responsible for resistance to challenge infections in experimental models and man.

Attempts have been made to develop live vaccines using parasites attenuated by chemical modification, by culture passage, and by x-ray irradiation. Most of these live vaccines have induced partial immunity but have also shown pathogenic side effects. Some authors have reported protection of laboratory animals immunized with subcellular fractions of *T. cruzi*. Others have described a 90-kilodalton glycoprotein which exists on the parasite's cell surface throughout the life cycle and which was partially protective in mice and in marmosets. An important objection to the use of natural sources of antigens from *T. cruzi* for vaccination is the description by different authors of molecular mimicry between *T. cruzi* antigens and different cell proteins from the human host with description of parasite-antigen driven human T-cell clones that react with cardiac myosin. Antibodies to ribosomal P proteins of *T. cruzi* have been shown to lead to cross-reaction with heart tissue and eventually be implicated in the induction of myocarditis. Because of these potential cross-reactions and consequent autoimmune pathologies, some authors consider that the development of a classical vaccination against Chagas' disease is not suitable. There are apparently 2 types of antibodies with different functional activities. Protective or complement-dependent "lytic" antibodies (LA) are associated with host resistance, whereas "conventional →serology" antibodies (CSA) are not. Chronically infected patients or animals have both LAs and CSAs, whereas experimentally immunized animals only have CSAs. However, it is not yet possible to decide whether a vaccine induces protection without knowing first if some of its components will not provoke autoimmune pathology with later manifestations as in natural infection.

Different groups have recently shown that $CD8^+$ T cells, IFN-gamma and macrophages play an essential role in the control of parasite multiplication in the acute phase. They have identified cytotoxic epitope in the trypanosome surface antigen 1 (TSA-1) and in trypanosome surface proteins members of the →trans-sialidase superfamily. Effective protection against the acute infection was obtained with immunization by plasmid DNA containing genes corresponding to these antigens.

Main clinical symptoms: Chagom at bite site, →lymphadenitis, →edema, fever, hepatosplenomegaly, cardiomegaly, aneurisms.
Incubation period: 5–20 days.
Prepatent period: 1–2 months.
Patent period: 20 years.
Diagnosis: Serologic tests, microscopic examination of blood smears, →xenodiagnosis using uninfected →bugs, →serology.
Prophylaxis: Avoid bites of triatomid bugs.
Therapy: Treatment see →Trypanocidal Drugs, Man.

Chagom

Initial sign (swelling of skin) of Chagas' disease.

Chalimus

Larval stage of ectoparasitic copepods (→*Lepeophtheirus salmonis*, →Lernaeocera).

Chancre

Papular and later ulcerating lesion caused by African trypanosomes which are present extracellularly in the subcutaneous tissue at the site of the bite of the →Tsetse fly (→Sleeping Sickness).

Charcot-Leyden Crystals

→Pathology, →Angiostrongylus cantonensis, →Schistosomiasis, Animals, →Schistosomiasis, Man, →Paragonimiasis, Man, →Sparganosis, Man; also found in →Amoebiasis and →Angiostrongylosis, Trichuriasis.

Chelae

Sharp claws at the tips of chelicerae of mites (→e.g., *Cheyletiella*) or spiders.

Chelicerae

The first pair of appendages of →ticks and other arachnids; they consist of 3 segments starting from the very end of the →basis capituli. In ticks they become essentially modified and are used for grasping, piercing, cutting, etc. during food gathering or feeding.

Chelicerata

Synonym

→Amandibulata.

Classification

Subphylum of →Arthropods. Arthropods that lack antennae and mandibles are commonly placed in the subphylum Chelicerata, thus named because the first anterior appendages become feeding organs called →chelicerae (→Arthropoda/System). The Chelicerata contain as parasitic group the economically and medically important order of →Acarina (→Ticks and →Mites), while the sister groups of →scorpions and →spiders may have a considerable medical impact as poisonous animals.

Chemokines

→Cytokines that are involved in infectious diseases (e.g., like IL–9) being responsible for the induction and migration of subsets of leukocytes. This is a superfamily of low molecular weight (6–17 kDa) cytokines, which recruit distinct groups of leukocytes and activate them through increased adhesion, degranulation, and respiratory burst. Up to now 44 different chemokines are described plus 21 chemokine receptors. The chemokines represent excreted proteins consisting of 67–127 amino acids. Previously chemokines were grouped into inflammatory or homeostatic chemokines. Today however, it is shown, that at least some have double functions.

Chemoprophylaxis

Administering a chemical agent to avoid the development or spread of a certain disease (→Chemotherapy).

Chemotaxis

Movements of protozoans/cells due to attraction by chemical gradients; from Greek: *taxis* = position.

Chemotherapy

Definition

Drug application after appearance of clinical signs may eliminate or damage pathogens/parasite and lead to recovery of health in the patient.

General Information

Chemotherapy (CT) and →chemoprophylaxis (CP) are experimental sciences dealing with drugs that selectively inhibit or destroy parasites or other pathogens. Thus, attention to selective toxicity of antiparasitic drugs is central to CP and CT, and useful chemotherapeutic agents should affect the parasite more adversely than the host. Until now, there is no completely safe drug. Knowledge of sources of drugs (pharmacognosy), action and fate in the body (pharmacodynamics), use in the treatment of disease (therapeutics), adverse effects (toxicology), and contraindications is a must to evaluate potential risks as well as possible benefits of drugs to the patient's well-being.

Withdrawal Time of Drugs in Target Animals

Claims made by the drug manufacturer for a drug product in treatment of target animals consumed by humans (poultry, bovines, equines) must have been investigated and evaluated in the target animal, besides toxicological studies in rodents (rat, mouse) and other species. The latter are required to determine the ADI. The acceptable daily intake is the dose of a drug residue in edible tissues, like meat, various organs, fat, etc., that during the entire lifetime of a person seems to be without obvious risk to health on the basis of all toxicological data known at the time. The ADI for humans may be determined by applying a safety factor

of 1:100, or a safety factor of at least 1:1,000 in case of a teratogenic drug. Therapeutic claims made by the manufacturer must coincide with safety and tissue residue data for the drug approved by government regulatory agencies. The **preslaughter withdrawal time** refers to the interval from the time an animal is removed from medication until the permitted time of slaughter (→Nematocidal Drugs, Animals/Table 2). During this interval the residue of toxicological concern will reach a safe concentration as defined by the maximum residue limit (MRL). Recent workshops give guidance to the analytical approaches. There may be 3 **types of tolerances** in defining allowable concentrations of drug residues at the time of slaughter up to the time of consumption by humans. (1) The finite tolerance (measurable amount of drug residue permitted in food), (2) the negligible tolerance (insignificant amounts of residue, i.e., a small fraction of maximum ADI), or (3) the zero tolerance (no residue is permitted in feed or food because of extreme toxicity or because the drug is carcinogenic). Questions and answers concerning specific legislation of the establishment of MRLs in the European Union cf. website address http://www.emea.eu.int/htms/vet/).

Drugs

General Information

Drug can be broadly defined as any chemical compound that affects living processes and is used in the diagnosis, prevention, treatment (cure) of disease(s), or for controlling or improving any physiological or pathological disorder or for relief of pain in animals and humans. A drug may have various names: one or more **chemical names** depending on rules of chemical nomenclature used: **(1)** usually one international nonproprietary name **(INN)**, **(2)** one or more nonproprietary names, e.g., in different countries, and **(3)** usually several proprietary names or brand names of a drug product. Drug products are galenic, pharmaceutical, and/or medicinal preparations of drugs, e.g., various drug forms and dosage forms. These may be powders, tablets, pills, capsules, sustained-release boli, or several liquid preparations, e.g., mixtures, or emulsions for oral administration or medicated feed articles. Dosage forms for injections are ampules, multidose vials, large-volume capped bottles, and implants that may be hard, sterile pellets inserted under skin. The parenteral administration of such preparations may be done either by subcutaneous (s.c.), intramuscular (i.m.), intravenous (i.v.), intraperitoneal (i.p.), or intrathecal (i.e., into the subarachnoid space) injection. For application to skin surface several external preparations of drugs may be used such as liniments, lotions, ointments, creams, dusting powders, or aerosols, e.g., topical insecticides.

Critical Use of Drugs in Concert with Other Control Measures

The administration of chemotherapeutic or chemoprophylactic agents can only be regarded as a suitable measure when individual cases or parts of the population or herds are treated under controlled conditions after a diagnosis has been made. Parasitism in the field is often a multifactorial problem. Thus, methods of control must include epizootiological/epidemiological and therefore ecological and economic aspects as well as consideration of the development of resistance to drugs by the parasites. Drug application is important but not the only control measure in a large-scale, complex **control strategy**. The aim of each of the measures that can be taken is to reduce or even completely eliminate the parasite population in its environment. However, the tasks, solutions, and objectives of a certain strategy require profound knowledge of the biology of the parasites and the →epizootiology or →epidemiology of parasitism. Thus, when planning and implementing programs of this type, account must be taken of the many different interactions between host and parasite on the one hand (mode of transmission and susceptibility of the population) and those between parasite and/or host and biotype on the other (e.g., pathogen reservoir). Knowledge of the **environmental factors** such as temperature, humidity, soil structure, and prevailing weather conditions, which are critical within the infection chain, are of practical importance for forecasting parasitic risk in certain areas.

In order for the chemotherapeutic agent administered to have its optimum effect against the parasites, the **time of treatment** must be adapted to the development cycle of the parasite. An example of this is the →metaphylaxis often practiced in veterinary medicine when the aim is to prevent the outbreak of disease in animals already infected, i.e., to kill off certain parasitic developmental stages in the host before serious damage occurs. The correct timing of the treatment in relation to the course of the infection is therefore critical for the success or failure of drug →metaphylaxis.

As is well known, the acquired and often species-specific or even life-cycle-stage-specific **immunity** (→Immune Responses) of the host plays an important role in the elimination of parasites. It would be ideal if CT and immunoprophylaxis (→Vaccination) had a synergistic effect. However, drugs can suppress the development of immunity and the immune response of the host may not materialize. Thus, the lack of an immune response may result from starting treatment at the incorrect time in relation to the course of the infection. This may be true for instance when treatment and infection take place at the same time, or the treatment starts shortly after the infection, as a result of which the parasites are immediately eliminated (without antigenic effect).

In modern livestock farming in which large numbers of animals are reared and fattened in a confined space, continuous drug application must often be performed via the feed. This is because other preventive measures, such as methods for maintaining good →hygiene and disinfection (→Disease Control), have either not yet been developed or are as yet inadequate (such as reliable immunoprophylaxis or vaccination) against the high risk of parasitism that exists with this form of farming. Thus, without prophylactic medication, the rapidly increasing pressure of infection would lead to an outbreak of disease in a herd. Consequently, in the fattening of poultry feed additives such as →coccidiocidal drugs can control outbreaks of coccidiosis and therefore serious financial losses can be reduced to a minimum during the fattening period.

A few examples clearly show that prophylactic or therapeutic agents must not be used in a stereotyped fashion. Often their use must be adapted to varying relationships between the parasite and host populations and their environment; only then will a treatment campaign have the desired success. Flexible handling of the chemotherapeutics also considerably slows down the development and therefore the spread of drug-resistant parasites. Before the start of every course of treatment adverse effects of the chemotherapeutic agent must be taken into account in the treatment plan. They should be reduced to a minimum by varying the dosage regimen and the treatment intervals. Anaphylactic reaction to the drug used or the intrinsic toxicity of the drug including its toxic metabolites may induce a severe and life-threatening risk to a patient. This may be applied also to severe allergic reactions caused through toxic metabolic products of endoparasites released after the drug has killed parasites.

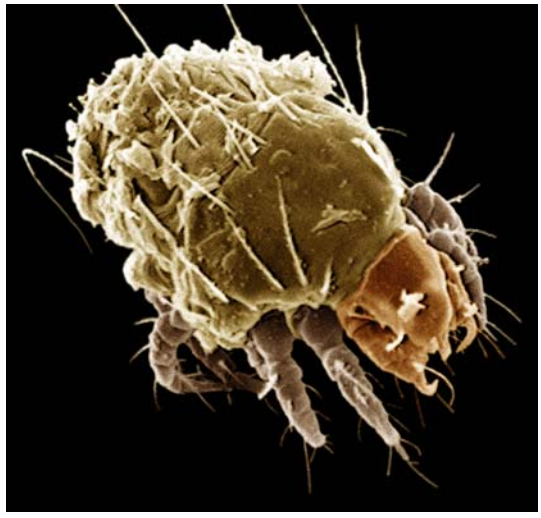
Cheyletiella parasitivorax

→Mites of rabbits.

Cheyletiella Species

Species of the genus *Cheyletiella* reach a size of 0.2–0.5 mm parasitizing the hair of dogs (*C. yasguri*) and of foxes, cats (*C. blakei*), occasionally specimens are found even on humans. They are charcterized by strong claws at the pedipalps (Fig. 1). The eggs (Fig. 2) are attached by filaments to hair. The total development (including egg – 1 larva – 2 nymphs) until adult males and females takes 3 weeks. Due to their feeding activity at the skin, infestations with such mites lead to a strong



Cheyletiella Species. Figure 1 SEM of *Cheyletiella yasguri*-mite.

Cheyletiella Species. Figure 2 SEM of an egg of *Cheyletiella yasguri* being attached to a hair.

itching, to dermatitis, to loss of hair, allergic reactions, and bacterial superinfections. Often such small mites are covered by skin detritus, thus were not clearly seen and therefore called "walking dandruff."

Cheyletiellosis

→Mange, Animals/Cheyletiellosis.

Chicleros Ear / Ulcer

Symptom due to →cutaneous leishmaniasis in South America.

Chikungunya

Disease due to alphaviridae transmitted by bite of →*Aedes*-mosquitoes with considerable muscle and articulation pain.

Chilodonella

Heart-shaped ciliate (e.g., *C. cyprini* of carps) of about 0.07 mm in size, which lives on the skin and gills of fish and leads to the production of slime and eventually to death due to the lack of oxygen. →Ciliophora.

Chilomastix mesnili

→Diplomonadida, →Retortamonadida.

Chirodiscoides caviae

Name

Greek: *cheir* = hand, *diskoides* = disk-like.

Mite of the guinea pig fur, of which the first and second pair of legs are modified for clasping (Fig. 1). This mite

Chirodiscoides caviae. Figure 1 LM of a female.

(3–4 mm) is also called "static louse," since it mainly remains in the fur, leading to itching.

Chironomids

→Mosquitoes, non-biting group.

Chitin

Chitin is a polysaccharide of *N*-acetylglucosamine (GlcNAc) residues joined by β(1 → 4) glycosidic links that forms the cell walls of →fungi and the exoskeletons of →arthropods. In endoparasites, this polymer is a component of the nematode eggshell, the protective sheath of microfilariae and the cyst walls of →protozoa, but is also expressed at the cell surface of trichomonad species. Chitin is synthesized by the stepwise polymerization of GlcNAc from UDP-GlcNAc as catalyzed by chitin synthase. The straight chains of the chitin polymer are important for the maintenance of the structural integrity and protection of the organism from environmental, chemical and mechanical damages. As chitin synthesis and assembly do not occur in higher animals these processes serve as targets for antiparasite chemotherapy.

Chitin Synthesis Inhibitors

Products that hinder molt of insect larvae (they are used e.g., to interrupt larval development of fleas).

Chlordane

Chemical Class
Organohalogenide (organochlorine compound, cyclodiene).

Mode of Action
GABA-gated chloride channel antagonist. →Ectoparasiticides – Antagonists and Modulators of Chloride Channels.

Chlordimeform

Chemical Class
Amidine (formamidine).

Mode of Action
Octopamine receptor agonist. →Ectoparasiticides – Modulators/Agonists of Aminergic Transmission.

Chlorfenvinphos

Chemical Class
Organophosphorous compounds (organophosphate).

Mode of Action
Acetylcholine esterase inhibitor. →Ectoparasiticides – Agonists and Antagonists of Cholinergic Transmission.

Chloride Cells

Cells with the function to withdraw salts (e.g., in insects, →pentastomids) from body fluids.

Chloropyga

Other/new genus name for →*Cordylobia*-type species are *C. anthropophaga* (Tumbu fly) and *C. hominivorax* (New World screwworm).

Chloroquine

→Malariacidal Drugs.

Chlorpyrifos

Chemical Class
Organophosphorous compounds (monothiophosphate).

Mode of Action
Acetylcholine esterase inhibitor. →Ectoparasiticides – Agonists and Antagonists of Cholinergic Transmission.

Choanotaenia infundibulum

Tapeworm of chicken, turkey, which reaches a length of about 25 cm in the intestine. Intermediate hosts are beetles, flies, and grasshoppers.

Cholangitis

Symptom in →microsporidiosis, AIDS.

Cholecystitis

Symptom in →clonorchiasis, opisthorchiasis, microsporidiosis.

Cholesterol

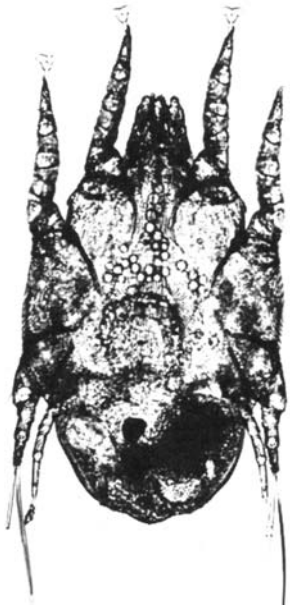
This protein, which is an essential component of host cell membranes was recently shown to be necessary for binding and internalization of *Leishmania* stages and the subsequent presentation of leishmanial antigens in infected macrophages. Cyclodextrin-based compounds modulate cholesterol levels.

Chorioptes bovis

Mange mite of cattle (Fig. 1). All stages feed by eating skin particles thus inducing allergic skin reactions, mainly due to their excretions. Males reach a size of 300–450 μm, females grow up to 600 μm. The complete development needs about 3 weeks on their host. They may survive away from their host for up to 70 days. Since they occur mostly close to the claws, the disease is called "foot-mange," which, however, has mostly not very severe symptoms.

Chorioptic Mange

→Mange, Animals/Chorioptic Mange.



Chorioptes bovis. Figure 1 *Chorioptes bovis* from ventral.

Chromatin Diminution

→Nucleic Acids, →Nematodes.

Chromatoid Bodies

→*Entamoeba histolytica*.

Chromosomal Diminuation

In the nematode of the horse (→*Parascaris equorum*) and in some other →nematodes the large compound chromosome is divided into small portions during divisions of somatic cells, which then have different quantities of DNA, while this does not happen during formation of →gametes.

Chromosomes

Protozoa

In many protozoans the correct number of chromosomes is unknown due to the fact that the nuclei are very small and/or the chromosomes do not condense during the →nuclear division (e.g., in →Coccidia). The ploidy of the different parasitic protozoans is also only poorly understood. DNA-measurements of all life-cycle stages showed that the coccidian genera →*Eimeria*, →*Sarcocystis*, →*Plasmodium*, →*Theileria*, →*Babesia*, and several genera of the hypermastigotes (→Barbulanympha, →Gametes/Fig. 8) are haploid (except for the →zygote), while the trypanosomatid genera →*Trypanosoma* and →*Leishmania* are diploid (except for a few haploid stages in the vector). This diploidy is, however, probably only found in the maxichromosomes (cf. →Gametes/Fig. 7, →*Trypanosoma*). In some groups (e.g., trypanosomatids) the size of the chromosomes varies completely within an individual; thus this →polymorphism also poses problems in counting. The application of different methods (e.g., pulse field electrophoresis, counting of kinetochores in ultrathin sections, etc.), however, allow some conclusions to be drawn (Table 1). Indications for (sex) determination of →gametes are scarce and mostly lacking.

Chromosomes. Table 1 Number of chromosomes in some parasitic protozoans

Number of chromosomes	Species	Stage	Systematic position
2	*Spirotrichonympha polygyra*	Trophozoite	Sarcomastigophora/ Hypermastigida
2	*Mattesia trogodermae*	Trophozoite	Sporozoa/Neo gregarina
3	*Gregarina blattarum*	Trophozoite	Sporozoa/Eugregarinida
3	*Coelotropha durchoni*	Trophozoite	Sporozoa/Coccidia
4	*Trichomonas caviae*	Trophozoite	Sarcomastigophora/ Trichomonadida
4	*Babesia divergens*	Merozoite	Sporozoa/Piroplasmea
4	*Theileria parva*	Merozoite	Sporozoa/Piroplasmea
4	*Klossia helicina*	Macrogamete	Sporozoa/Adeleidea
4	*Stylocephalus longicollis*	Trophozoite	Sporozoa/Eugregarinida
5	*Eimeria tenella*	Macrogamete	Sporozoa/Coccidia
Several mini-, 3 medium and 2 big chromosomes	*Giardia lamblia* (USA[1])	Trophozoite	Sarcomastigophora/ Diplomonadida
5/6	*Entamoeba histolytica*[2]	Minuta-form	Sarcomastigophora/Amoebida
6	*Aggregates eberthi*	Macrogamete/ sporont	Sporozoa/Coccidia
8	*Adelina cryptocerci*	Sporozoite	Sporozoa/Gregarinida
8	*Toxoplasma gondii*	Bradyzoite	Sporozoa/Coccidia
12	*Zelleriella intermedia*	Trophozoite	Sarcomastigophora/Opalinida
12	*Spirotrichosoma normum*	Trophozoite	Sarcomastigophora/ Hypermastigida
12–16	*Pneumocystis carinii*	Trophozoite	unknown
14	*Plasmodium falciparum, P. berghei, P. chabaudi*	Merozoite/ gamont	Sporozoa/Haeosporidia
24	*Spirotrichosoma promagnum*	Trophozoite	Sarcomastigophora/ Hypermastigida
26	*Barbulanympha ufalula*	Trophozoite	Sarcomastigophora/ Hypermastigida
28	*Notila proteus*	Gamont	Sarcomastigophora/ Oxymonadina
48	*Spirotrichosoma paramagnum*	Trophozoite	Sarcomastigophora/ Hypermastigida
60	*Spirotrichosoma magnum*	Trophozoite	Sarcomastigophora/ Hypermastigida
100 mini-, 1–8 medium, 14 megabase chromosomes	*Trypanosoma brucei brucei*	Trypomastigote forms	Sarcomastigophora/ Kinetoplastida
no mini-[3], 17 medium[4], more than 23 big[5] chromosomes	*Leishmania major* and other species	Amastigote forms	Sarcomastigophora/ Kinetoplastida

[1] the Australian isolates possess a further medium sized chromosome

[2] recent result of Willhoeft and Tannich using pulsed field gel electrophoresis indicate the existence of 31–35 chromosomes ranging from 0.3 to 2.2 Mb, and a functional ploidy; the haploid genome size is thought to be around 20 Mb

[3] smaller than 150–200 Kb

[4] 350–900 Kb

[5] bigger than 1 Mb

Metazoa

Fertile adult stages of most metazoan are diploid (=2n) apart from some digeneans and →ticks, which may be either haploid (n) or triploid (3n). →Sex determination- mostly occurs by formation of morphologically different →sex chromosomes. These differences, however, are not very significant in some groups of parasites. Thus heterochromosomes could not be unequivocally identified in the karyotypes of schistosomes, and only after the use of the so-called C-band treatment an univalent sex chromosome has been discovered in the female of several schistosome species. Table 2 summarizes the

Chromosomes. Table 2 Chromosome numbers of some metazoan parasites

Number of chromosomes (2n)	Species	Stage	Systematic position
1 (compound chromosome)	*Parascaris equorum*	Adults	Nematodes
4	*Strongyloides papillosus*	Adults	Nematodes
6	*Strongyloides stercoralis*	Adults	Nematodes
6	*Culex pipiens*	Adults	Diptera, Insecta
6	*Macracanthorhynchus hirudinaceus*	Adults	Acanthocephala
8	*Diplozoon paradoxum*	Adults	Monogenea, Platyhelminthes
8	*Davainea proglottina*	Adults	Cestodes, Platyhelminthes
8–12	*Gyrodactylus elegans*	Adults	Monogenea, Platyhelminthes
8	*Moniliformis moniliformis*	Adults	Acanthocephala
10	*Vampirolepis nana*	Adults	Cestodes, Platyhelminthes
11	*Paragonimus westermani*	Adults	Digenea, Platyhelminthes
12	*Fasciola hepatica*	Adults	Digenea, Platyhelminthes
12	*Hymenolepis species*	Adults	Cestodes, Platyhelminthes
14	*Schistosomatium douthitii*	Adults	Digenea, Platyhelminthes
16	*Fasciola gigantica*	Adults	Digenea, Platyhelminthes
16	*Schistosoma species*	Adults	Digenea, Platyhelminthes
16	*Paragonimus kellicotti*	Adults	Digenea, Platyhelminthes
16	*Taenia taeniaeformis*	Adults	Cestodes, Platyhelminthes
18	*Trichobilharzia* species	Adults	Digenea, Platyhelminthes
18	*Diphyllobothrium* species	Adults	Cestodes, Platyhelminthes
18	*Echinococcus* species	Adults	Cestodes, Platyhelminthes
20	*Heterobilharzia* species	Adults	Digenea, Platyhelminthes
20	*Dicrocoelium dendriticum*	Adults	Digenea, Platyhelminthes Cestodes, Platyhelminthes
20	*Taenia saginata*	Adults	
20	*Otobius megnini*	Adults	Acari, Chelicerata
21	*Rhipicephalus* species *Hyalomma* species	Male adults	Acari, Chelicerata
22	*Rhipicephalus* species *Hyalomma* species	Female adults	Acari, Chelicerata
12–32	*Ornithodoros* species	Adults	Acari, Chelicerata
24	*Argas brumpti*	Adults	Acari, Chelicerata
26	*Argas persicus*	Adults	Acari, Chelicerata
23–28	*Ixodes* species	Adults	Acari, Chelicerata
43	*Ascaris lumbricoides*	Male adults	Nematodes
48	*Ascaris lumbricoides*	Female adults	Nematodes

chromosome numbers of some selected species of metazoan parasites showing a rather large scale.

Chronic Infections

Long persistent infections mostly occurring in natural hosts and characterized by regular fluctuations in the level of parasitemia (e.g., →*Plasmodium* sp., trypanosomiasis) or in the quantity of the parasitic load (e.g., filariae), →Arboviruses.

Chronobiology

→Favorisation.

Chrysomia bezziana

→Diptera. This fly the larvae of which are called Old World Screwworm initiates →Myiasis, Man.

Chrysomya megacephala

Common blowfly, which in Asia is called Oriental latrine fly due to its feeding on filth material, animal carcasses, garbage, etc. The larvae may also cause →myiasis in humans as well as act as mechanical vectors of viruses, bacteria, and parasites.

Chrysops Species

Genus of →Diptera, belonging to the brachyceran family Tabanidae (e.g., *Chrysops caecutiens, C. relictus* in Europe). They are often beautifully coloured blood suckers (as females) of up to 1.5 cm in length and possess large, coloured eyes (Figs. 1, 2). Their sawing mouthparts cut wounds into the skin, which become filled by blood. Thus they are pool-feeders. Their bite is rather painful. They act as vectors of filariid worms (e.g., →*Loa loa*) or mechanical transmitters of viruses and bacteria.

Chrysops Species. Figure 1 Light micrograph of the dorsal side of *Chrysops* sp.

Chrysops Species. Figure 2 Anterior front of *Chrysops* sp.

Chyluria

Symptom in →lymphatic filariasis due to *Wuchereria* or *Brugia* worms.

CIC

Circulating **i**mmune **c**omplexes (→Immune Responses).

Cilia

→Flagella.

Cilia (sing. Cilium) although shorter possess the same internal structures (→Axoneme) as →flagella, but show different (often coordinated) movements due to interconnecting structures at their →basal bodies.

Ciliophora

Synonym

Ciliata.

Classification

Phylum of →Protozoa.

Important Species

Table 1.

Life Cycle

→*Balantidium coli*/Fig.1, →*Ichthyophthirius multifiliis*/Fig. 1, →*Apiosoma*/Fig. 1, 2, →*Cryptocaryon*/Fig. 1, 2.

Cimex lectularius

→Bugs; bed bug of humans.

Cimicidae

See Table 1.

Synonym

Bedbugs (→Bugs).

Ciliophora. Table 1 Some important species of the Ciliophora

Species	Principal hosts	Habitat	Size (εμm)
Balantidium coli	**Humans,** pigs, monkeys	Colon	50–100 × 45
Balantidium sp.	Sheep	Intestine	45 × 35
Buxtonella sulcata	Ruminants	Cecum	50–130 × 60
Nyctotherus sp.	**Humans**	Intestine	26 × 10
N. cordiformis	Frogs	Rectum	60–200
N. ovalis	Cockroaches, millipedes	Colon	90–185
Ichthyophthirius multifiliis	Fish (fresh water)	Integument	50–500
Cyryptocaryon irritans	Fish (salt water)	Integument	30–300
Chilodonella cyprini	Fish	Integument	40 × 15
Trichodina spp.	Fish	Skin	80 × 80
Epistylis spp.	Fish	Skin	30 × 10 (without stalk)
Carchesium spp.	Fish	Skin	30 × 10 (without stalk)
Glossatella spp.	Fish	Skin	35 × 9
Apiosoma piscicola	Fish	Skin	80 × 38
Enchelys parasitica	Salmonid fish	Skin	60 × 20

Cimicidae. Table 1 List of the subfamilies and genera of Cimicidae

Primicimicinae	*Bucimex* (Chile: 1 species) *Primicimex* (USA, Mexico and Guatemala: 1 species)
Cimicinae	*Bertilia* (Argentinia and Chile: 1 species) *Cimex* (Cosmopolitan: 21 species) *Oeciacus* (Nearctic region, western Palearctic region: 2 species) *Paracimex* (Oriental region, Southern Africa: 13 species) *Propicimex* (Argentinia and Brazil: 2 species)
Cacodminae	*Aphrania* (Afrotropical region, South East Asia: 5 species) *Cacodmus* (Africa, Middle East, Oriental region: 10 species) *Crassicimex* (Tropical Africa, Madagascar, Cambodia: 3 species) *Leptocimex* (West Africa, Sudan, Middle East, Sri Lanka: 4 species) *Loxaspis* (Tropical Africa and South East Asia: 6 species) *Passicimex* (Tropical Africa: 1 species) *Stricticimex* (Afrotropical and Oriental regions, Egypt: 10 species)
Afrocimicinae	*Afrocimex* (Equatorial Africa: 3 species)
Latrocimicinae	*Latrocimex* (Brazil and Trinidad: 1 species)
Haematosiphoninae	*Caminicimex* (Argentina and Uruguay: 1 species) *Cimexopsis* (Mid-Western and Eastern USA: 1 species) *Haematosiphon* (Southwestern USA, Mexico: 1 species) *Hesperocimex* (Nearctic region: 3 species) *Ornithocoris* (Southeastern USA, South America: 2 species) *Psitticimex* (Argentina: 1 species) *Synxenoderus* (Western USA: 1 species)

Cinerin

Chemical Class
Natural products (terpenoid).

Mode of Action
Open state voltage-gated sodium channel blocker. →Ectoparasiticides – Blockers/Modulators of Voltage-Gated Sodium Channels.

Ciprofloxacin

Antibiotic that is used to treat →cyclosporiasis in humans that are intolerant to sulfonamides (500 mg twice daily for 7 days).

Circadian Rhythms

Parasites act or are present at special habitats during fixed hours of the day; e.g., →Enterobius females migrate nocturnally from the rectum to the perianal region to lay their eggs; larvae of →*Loa loa* are found in the peripheral blood between 1 pm and 3 pm, while the microfilariae of →*Wuchereria bancrofti* are seen there between 9 pm and 11 pm in the evening. Some mosquito species feed at night, others exclusively during daytime.

Circomyarian Muscle Type

→Nematodes.

Circular DNA

→Kinetoplast DNA.

Circulating Antigen

Elisa – tests have been developed to detect circulating anodic antigen (CAA) and circulating cathodic antigen (CCA) in serum and urine of patients with schistosomiasis. Both antigens are found in more than 90% of the infected people and even diagnosed in people, where stool controls remained negative.

Circumsporozoite Protein

→Malaria, →CSP, →Vaccination.

Cirripedia

Group of lower →Crustacea (= Entomostraca). The larvae are free-living and swim by cilia. Some attach to rocks, ships etc., produce calcareous shells (e.g., genus *Balanus*) and live as filter organisms. Some (e.g., *Sacculina carcini*) become parasites by entering the body cavity of crabs (Fig. 1). Only an amorphous mass (= which contains and excretes the larvae) is seen outside of a parasitized host, which at its inner side is completely filled by tumor – like growing strands of undifferentiated cells. Thus this group with about 230 marine species is called Rhizocephala (from Greek: *rhiza* = root, *kephale* = head), Fig. 1.

Cirripedia. Figure 1 *Sacculina carcini* below the "tail" of a brachyceran crustacean (= crab).

Cirrus

Penis-like structure of Platyhelminthes (→Platyhelminthes/Reproductive Organs).

Cittotaenia

→Eucestoda.

Civil Unrest

Movement of human populations due to different reasons thus spreading agents of diseases, →epidemiology.

CL

Abbreviation for →Cutaneous Leishmaniasis.

Clade

A group of organisms that are related by descent from a common ancestor.

Cladogram

A cladistic representation of a phylogeny, whereby only the branching order is displayed (→Phylogeny).

Classification

General Information

"Nothing remains as it is." This sentence is true in particular with respect to the recent situation of taxonomy, which – since its beginnings – has tried to reflect relationships between taxa. The earlier classifications were based on morphological and developmental similarities; and individuals resembling each other were grouped together as a species, similar species as genera, and so on. So much information accumulated that finally 2 different kingdoms – plants and animals – arose among the eukaryotic organisms, the origin of which, however, remained under constant discussion. Nowadays, the use of molecular →biological methods delivers new and deeper insights into the genetic repertoire of organisms and thus other interpretations are called for. When considering the ideas actually discussed (Fig. 1, page 255), that all recent organisms are a mixture of different hereditary lines, including the genomes of former autotrophic →prokaryotes, heterotrophic prokaryotes, and heterotrophic eukaryotes, the border between animals and plants becomes obsolete. Thus the position of the different parasites in this living world has reached the point of new allocation, and discussion is going on about mono- and polyphyletid modes during the evolution of metazoans. When looking at →spliced leader RNA, →trans-splicing, which was originally described as a mechanism of gene expression in parasitic →Kinetoplastida and which is now also found in free-living and parasitic helminths, new possibilities (Fig. 2, page 256) for explaining the radiation of early →Metazoa were seen by several authors. Since most of the results obtained are preliminary and, moreover, often contradictory, all recently proposed systematics remain hypothetical and will be changed in future. The old classifications that are being adapted in most parasitological textbooks are apparently scientifically wrong, but nevertheless useful for categorizing the knowledge. Thus the only groups that are today fairly stable are the species, the families, and the phyla, although even within them newly discussed strains or systematically unseated groups (such as →*Pneumocystis* or →Blastocystis with protozoan and fungal characteristics) are leading to disturbances. In order to provide a survey and the possibility of retrieving facts at a suggested place both systematic attempts – the new more-correct one and the old better-known one – are presented here one after the other, with special reference to parasitic groups.

Old System

Regnum: Animalia[1]
- Subregnum: →Protozoa
  - Subphylum: →Mastigophora (Flagellata)
    - Diplomonadida
    - Trichomonadida
    - Kinetoplastida

Classis: Dinoflagellidea

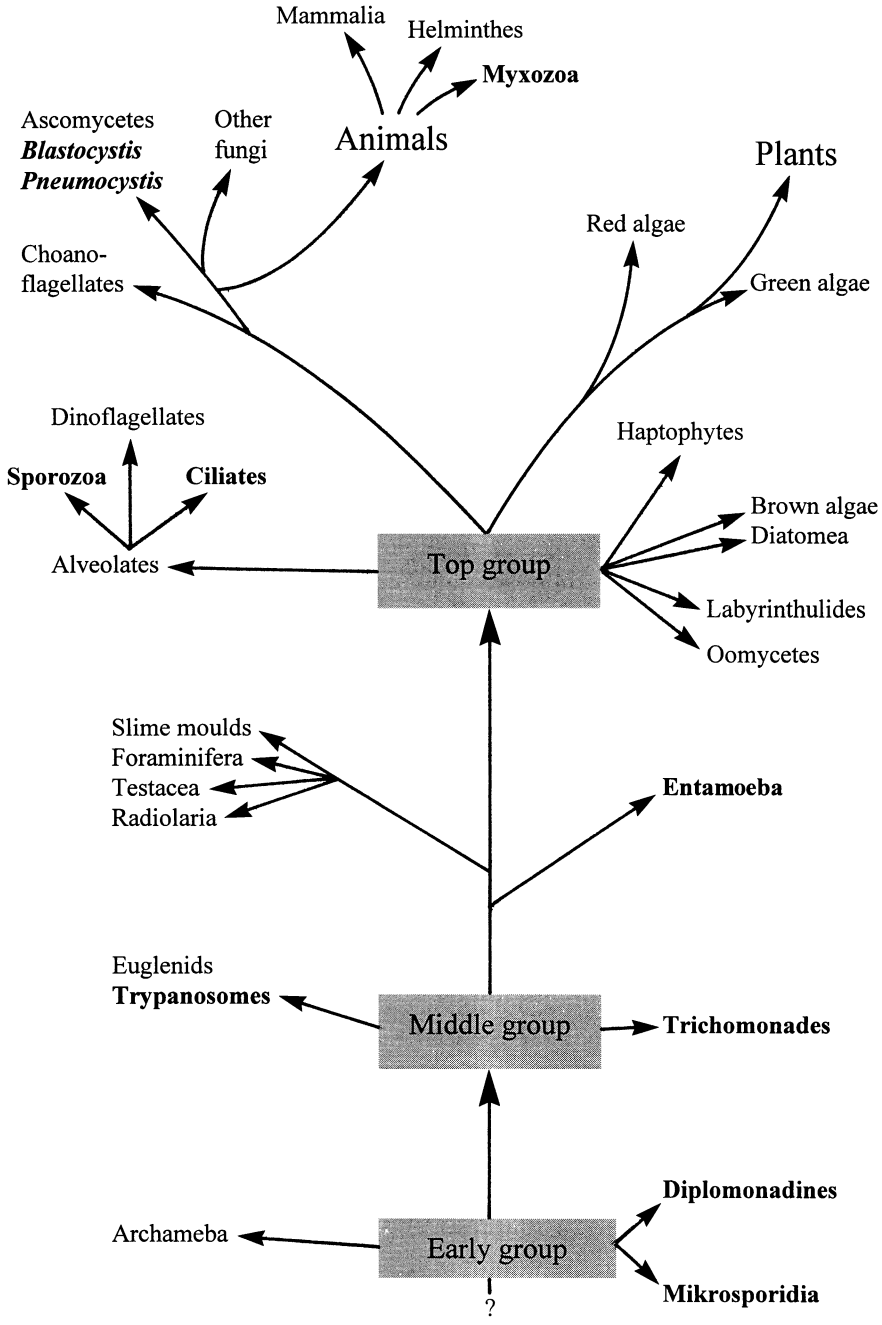
4.3 **Subphylum** Ciliophora

5. **Phylum: Amoebozoa**

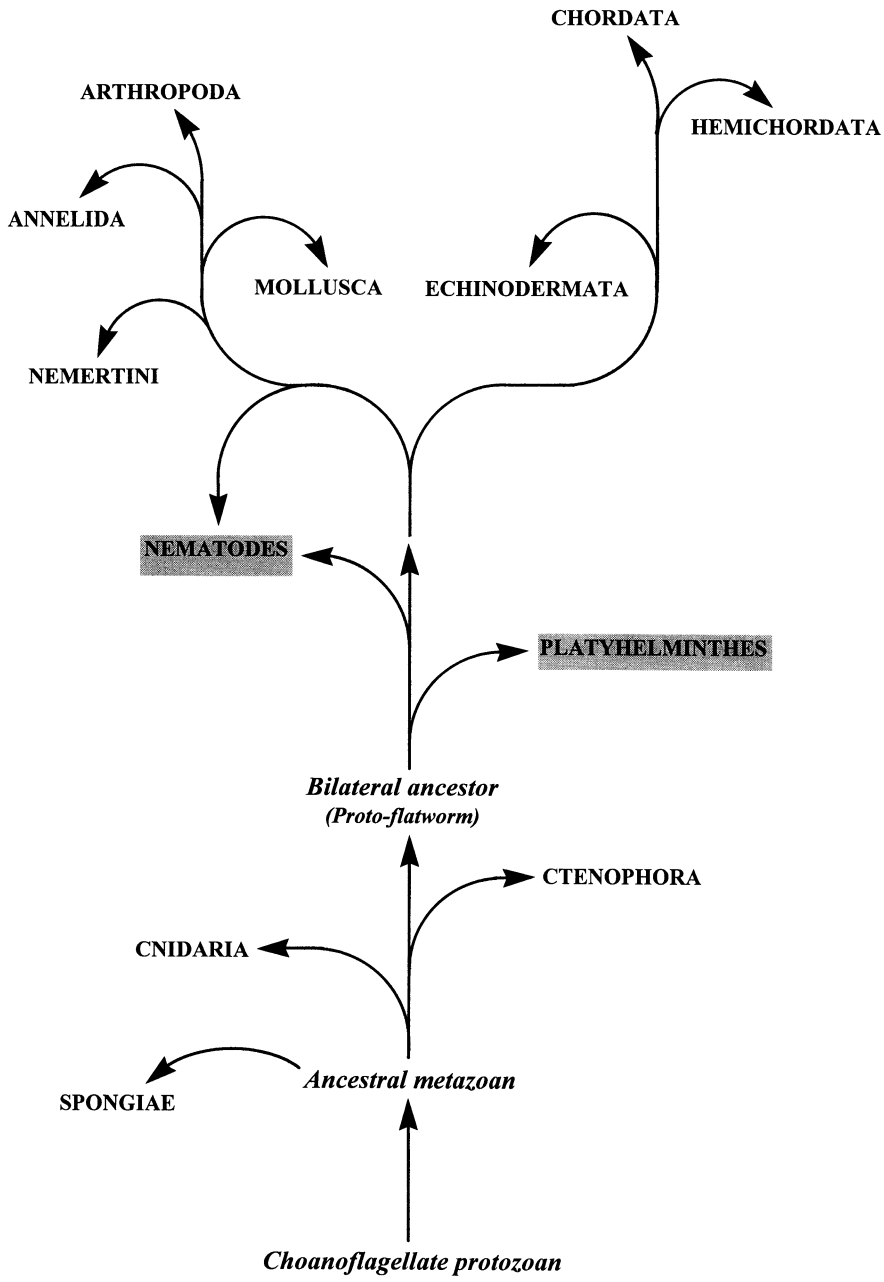
Classis: Amoebida
Classis: Acanthpodida

6. **Phylum: Microspora**

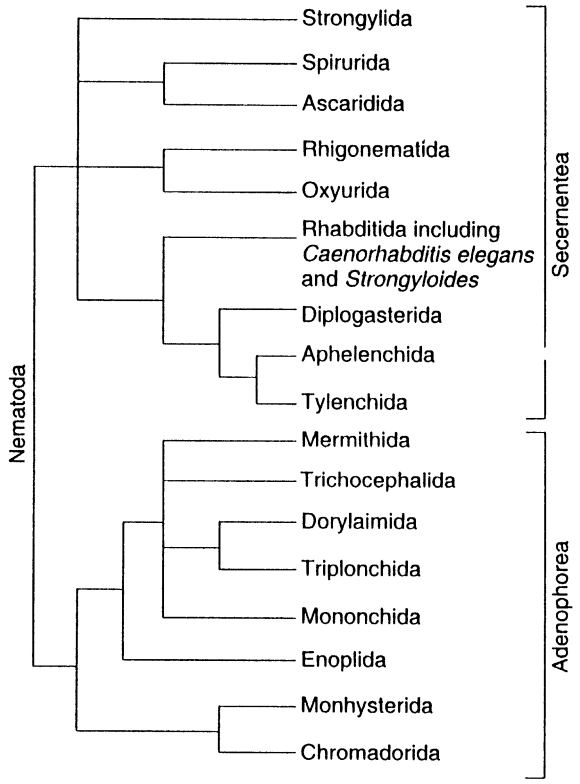
Classis: Microsporea



Classification. Figure 1 Diagrammatic representation on recent ideas of origin and relationships of living organisms (according to Bardele, Tübingen).



Classification. Figure 2 Hypothetical monophyletic evolutionary scheme for the relationship of some early Metazoa and their progeny. This proposal illustrates a potential role for a flagellate ancestor of Metazoa (but not directly the Kinetoplastida) and a proto-flatworm as an ancestor of bilateral Metazoa. Boxed groups represent Metazoa known to have spliced leader →trans-splicing (according to Davis).



Classification. Figure 3 A recent concensus →cladogram of the class/phylum Nematoda (as example).

Clathrin-Coated Pits

→Coated Pits.

Clavus

Distal portion (fortified) of the triatomid bug wing.

Clazuril

A triazine – derivative which blocks DNA-synthesis in coccidians. →Coccidiocidal Drugs.

Clindamycin

Compound used together with sulfadimidin and trimethoprim to treat →neosporosis in dogs. →Coccidiocidal Drugs.

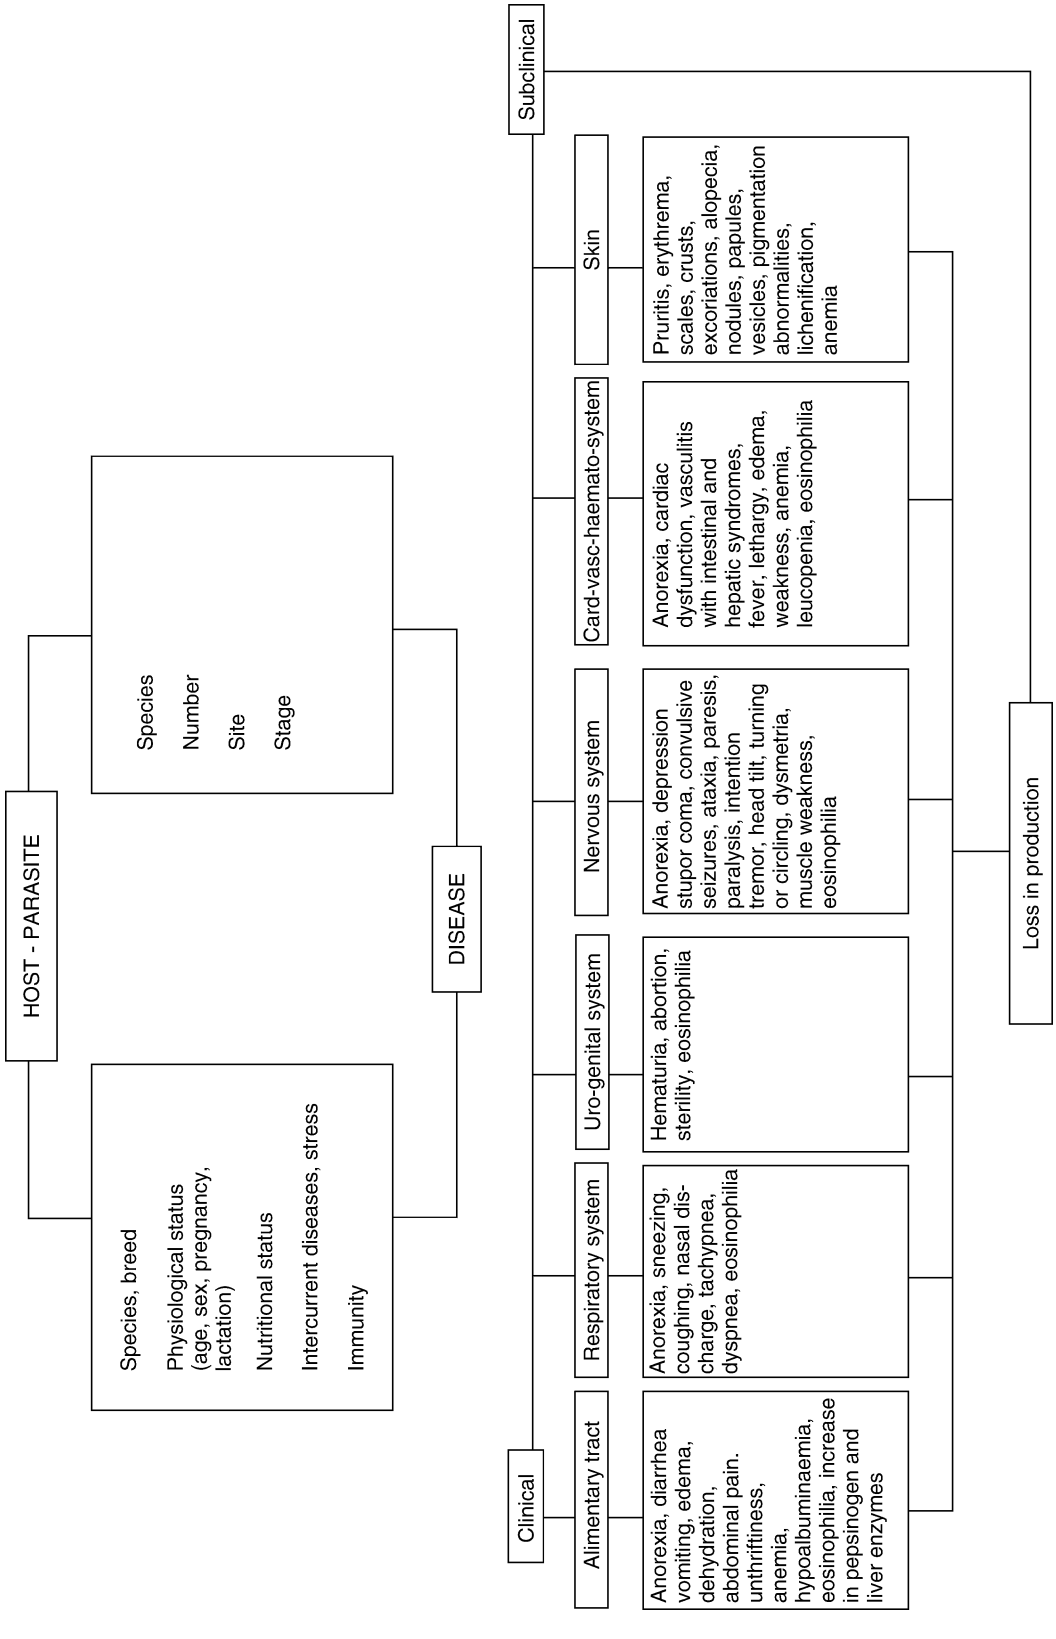
Clinical Pathology, Animals

General Information

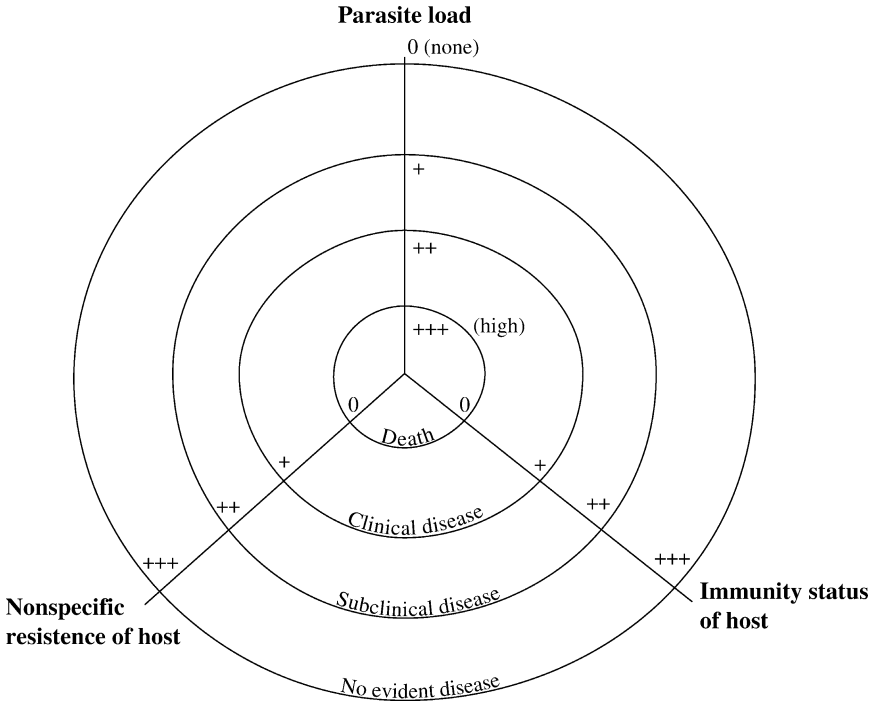
It is difficult to give an estimate of the (economic) importance of parasitic diseases at the world level. Firstly, because the effect of a particular parasitic disease may vary completely from one region to another. Secondly, our knowledge of some parasitic infections is based primarily on experimental infections, which often differ from natural conditions. Finally, appropriate data are missing for a number of diseases. Some parasites are known to induce severe, sometimes highly fatal clinical syndromes, and have a recognized economical importance. Most of the others only produce subclinical, or even asymptomatic infections. However, it has now been established that such subclinical infections cause significant losses due to long-term effects on animal growth and productivity and increased susceptibility to other parasitic or bacterial/viral diseases.

Parasitism causes a wide variety of clinical and pathological changes. This is easy to understand as parasites occur in all organs of the host (Fig. 1). However, most signs are nonspecific and a clinical examination alone is often insufficient to establish an etiological diagnosis. The clinician is therefore dependent on other diagnostic methods such as laboratory examination of feces, blood, and urine.

The pathogenicity of a particular parasite population will depend on the "parasite load," and on the major site of infection. The heavier the infection the more dramatic is the effect, although there is both, a lower and upper threshold. However, in the field many different factors contribute to determine the clinical outcome of a parasitic infection. Age and previous parasite experience increase resistance to infection with most parasites. It is also generally accepted that the plane of nutrition of the animal affects its overall response to the infection, either by affecting the rate of establishment of the parasite or modifying the effects of the infection. Finally, resistance to infection is often reduced by stressful conditions, such as during intercurrent diseases and around parturition (Fig. 2). Caution is needed when applying the results of experimental infections with individual parasites to the field situation in which animals normally acquire several parasite species



Clinical Pathology, Animals. Figure 1 General outline of host–parasite relationships.



Clinical Pathology, Animals. Figure 2 Relationship between parasite load, immunity, and non-specific resistance of host, and severity of disease.

concurrently. The combined pathophysiological effects of several parasite species may be greater than could be anticipated from the effects of monospecific infections.

Anorexia

→Anorexia, or reduction in voluntary food intake, is a feature of many parasitic infections. The degree of appetite loss can vary considerably. In moderate to heavy infections, food intake can be reduced by 20% or more. It may be less obvious in lighter infections. The degree of appetite loss has been shown to vary not only with the level and duration of parasitism but also with the level of protein nutrition. Despite the obvious importance of loss of appetite in parasitized animals, it is still not known why it occurs. The subject has been reviewed by several authors who concluded that anorexia in parasitized animals is certainly complex and that a complete understanding may be difficult to obtain. Possible factors in gastrointestinal parasitism of ruminants are →abdominal pain, anatomical or chemical responses to infection, changes in protein digestion and in the availability of amino acids for absorption, changes in plasma levels of hormones (gastrin, cholecystokinin), alterations in the rate of passage of ingesta, or direct effects on the central nervous system.

Production Losses

Parasites can have a range of effects on animal production. A reduction in growth rate, and even losses of weight, are probably the most widely described effects of parasitism. It has been recorded for infections with →protozoa, →nematodes, →cestodes, →trematodes, and arthropods and it is best studied in cattle, sheep, and pigs. The effect on body weight is independent of the site of infection and the heavier the infection the more dramatic the effect. However, there is both a lower and upper threshold in intensity of infection where weight ceases to be affected. In the latter case, this is because of the early death of the animal. Finally, at equal worm burdens young animals or animals on a poor plane of nutrition are more severely affected than those maintained on a better diet, or adults. In addition to changes in body weight, alterations in body composition also occur. These can be of considerable importance when assessing the economic impact of parasitism. Most authors have found that infected animals had a higher percentage of water and a lower deposition of fat, protein, and skeletal calcium and phosphorus, compared with parasite-free controls. The reasons for impaired growth or loss of weight are complex. They have been studied more particularly in intestinal trichostrongylid infections. Because of the loss of appetite, the enteric losses of proteins and the increased rates of intestinal metabolism, there is a net movement of amino acid nitrogen from the muscles, and possibly the skin, to the liver and intestines. This decreases the availability of nitrogen for growth, milk, and wool production. The drop in appetite was responsible for

nearly 73% of the difference in live weight gain between calves infected with →Ostertagia ostertagi and control animals. Table 1 presents a list of gastrointestinal parasites with their effect upon body weight.

There has been considerable controversy regarding the effect of parasites on milk production and apparently conflicting results have been reported. Some studies have shown that anthelmintic treatment in early lactation is associated with an increased milk production of approximately 5% over the whole lactation, while other studies have not shown such an effect. Evaluation of such experiments is made difficult because of the impossibility of identifying those situations where subclinical infections of helminths are likely to cause depression in milk production. Very few experiments have been conducted to evaluate the direct effect of nematode parasitism on milk production. The administration to cows of 130,000 to 200,000 infective larvae of mixed trichostrolongylid species, given once or over several weeks in early lactation, resulted in a reduced milk production of 1–3 kg/day. Ewes infected weekly (for 12 weeks, starting last 6 weeks of pregnancy) with 2,500 L3 larvae of →*Haemonchus contortus* produced 23% less milk than control animals, despite a similar feed intake. It has also been shown that arthropod parasites such as horn flies, stable flies, cattle grubs, and →mites can reduce milk production by up to 40%–60%.

Many helminths infections adversely affect the quantity and quality of wool. Wool growth can be reduced by up to 66% in some parasitic infections. The reduction in growth rate of wool is accompanied by decreases in staple length and fibre diameter. There are indications that these effects occur at levels of infection below the threshold normally considered to affect body weight.

Reproductive Performance

The impact of parasitism on reproductive performance is of major economic importance. Parasites such as →*Toxoplasma gondii* in sheep and goats and →*Tritrichomonas foetus* and →*Neospora caninum* (syn. *Hammondia heydorni* ?) in cattle often induce →abortion. Preventive treatment of gastrointestinal trichostrongylosis or fasciolosis in ruminants may result in earlier breeding, higher pregnancy rates, and better birth weights.

Clinostomum

Genus of bird, →Digenea.

Clitellum

Belt-like zone in →Annelida (e.g., →Hirudo medicinalis, →leeches) that excretes mucous material, which is used to form the →cocoon around eggs.

Cloaca

Common exit of intestine and male reproductive system (e.g., in →nematodes, Sauropsida), →Nematodes/Reproductive Organs.

Clone

Name

Greek: *klon* = *kladon* = offspring.

Population of protozoans that derived from a single cell by asexual reproduction. Thus all cells have an identical genetic appearance.

Clonorchiasis

Synonym

→Opisthorchiasis, Man.

Clonorchis sinensis

Synonyms

→Opisthorchis sinensis, Chinese liver fluke of humans.

Morphology

Figs. 1–3.

Life Cycle and Geographical Distribution

→Digenea/Fig. 8.

Clonorchis sinensis. Figure 1 LM of an adult *Clonorchis sinensis* (coloured by carmin red), note the two posterior branched testes.

Clonorchis sinensis. Figure 2 LM of a typical egg of *Clonorchis sinensis* with an operculum.

CM

Cerebral malaria, →Malaria.

CoA Transferase

→Energy Metabolism.

Coated Pits

Many cells contain clathrin-coated pits that are involved in the receptor-mediated →endocytosis of macromolecules. The knowledge of coated pits in →Protozoa remains limited.

Clonorchis sinensis. Figure 3 SEM of the ventral side of *Clonorchis sinensis*.

Cobalamin Absorption

The vitamin B 12 (cobalamin) – absorption of the fish tapeworm (→*Diphyllobothrium latum*) leads in humans (especially in children) to a severe pernicious anaemia.

Cobbold, Thomas Spencer (1826–1886)

English physician, famous helminthologist (e.g., author of *Treatise on the entozoa of man and animals*, 1879).

Cobboldia

Genus of the family Gasterophiliidae inducing myiasis in the stomach of elephants (e.g., *C. loxodontis, C. chrysidiformis*).

Coccidia

Classification

Subclass of →Apicomplexa.

General Information

Apart from only a few species, the coccidia are intracellular parasites which have a life cycle consisting of 3 phases: →schizogony (asexual multiplication), →gamogony (sexual phase, which proceeds in general as →oogamy with macrogametes and →microgametes), and →sporogony (the →zygote initiates another asexual reproduction leading to the production of numerous infectious sporozoites). In fecally transmitted species (→Eimeria/Fig. 1) the sporozoites are always included in resistant stages (oocysts and/or sporocysts), whereas in bite-transmitted groups (e.g., →Plasmodium/Fig. 2) oocysts are smooth and always located inside the vector.

Among the life cycles of the coccidia different types can be distinguished:

- →**Monoxenous development:** The whole development is restricted to the tissues of a host individual. The species may be strictly host-specific (using only a single host species, e.g., →Isospora spp., →Eimeria spp.) or not (e.g., →Cryptosporidium spp.) and are found in several host types.
- **Di-or→heteroxenous development:** Parasites belonging to this group have at least 2 different hosts during their life cycle: a final host (where the sexual phase proceeds), and an →intermediate host (with continuing asexual reproduction) or a →paratenic host, inside which no development occurs but only an accumulation of infectious stages (→Cystoisospora spp.). This alternation of hosts may be: facultative, e.g., →Cystoisospora spp., →*Toxoplasma gondii*, →*Neospora caninum*, or obligatory, e.g., →*Aggregata eberthi*, →*Hammondia* spp., →Sarcocystis spp., →*Frenkelia* spp., the →Haemosporidia, →Piroplasms and some species of the →Adeleidea. In some genera (→*Besnoitia*; →*Globidium*) the life cycles of the species are poorly understood, so their final classification remains doubtful.

Important Species

Tables 1–7.

Life Cycle

Figs. 1, 2 (page 267, 268), →*Eimeria*, →*Plasmodium*, →*Toxoplasma gondii*, →*Sarcocystis*.

Diseases

→Coccidiosis, Animals, →Coccidiasis, Man.

Coccidia. Table 1 Some common *Plasmodium* species

Species	Periodicity of fever	Vertebrate host	Vector/mosquitoes	Mortality
Plasmodium falciparum	48 h + irregular	**Humans**	*Anopheles* spp.	+
P. vivax	48 h	**Humans**	*Anopheles* spp.	−

Epieimeria anguillae	Intestine	10–14 (mean)	?	+

Coccidia. Table 4 Important *Cyclospora*-species

Species	Host	Infected tissues	Oocyst size	Prepatent period
Cyclospora cayetanensis	**Humans** (AIDS patients)	Intestinal cells	8–10 μm	?
Cyclospora caryolytica	Mole (*Talpa*)	Intestinal cells	8–12 μm	?
Cyclospora viperae	Snakes	Intestinal cells	9–12 μm	?

Coccidia. Table 5 Toxoplasma gondii and related tissue-cyst-forming coccidia

Species	Intermediate hosts	Final hosts	Size of oocysts (μm)	Pathogenicity
Toxoplasma gondii	**Humans** and many animals	Cats	11–14 × 9–11	+
Neospora caninum[c]	Dogs, cats, lambs, calves, horses, jirds, guinea pigs	Dogs	10–12 × 10–11	+
Hammondia heydorni	Cattle, sheep, goats, roe deer, camels, guinea pigs	Dogs, foxes, coyotes	10–14 × 9–13	−
H. hammondi	Mice and other rodents	Cats	11–13 × 10–12	−
Besnoitia wallacei	Rodents	Cats	16–19 × 10–13	−
B. darlingi	Opossums, lizards	Cats	11–13 × 10–13	−
B. besnoiti	Cattle	Cats[a]	14–16 × 11–14[a]	+
B. jellisoni	Mice, rodents	?	?	+
Frenkelia microti	European voles (*Microtus agrestis*), *Mus, Rattus*	European buzzards (*Buteo buteo*)	Sporocysts 12 × 10	−
F. glareoli	Bank voles (*Clethrionomys glareolus*)	European buzzards (*Buteo buteo*)	12.5 × 8.8	+
Caryospora[b] *bigenetica*	?	Snakes, dogs, rodents	11–20 × 15–17	+
C. colubri	?	Snakes, rodents	17–20 × 18–20	+

[a] Results according to Peteshev et al. (1974); these findings, however, were not confirmed for the Berlin strain of Prof. Heydorn

[b] The species of this genus have 2 types of final hosts

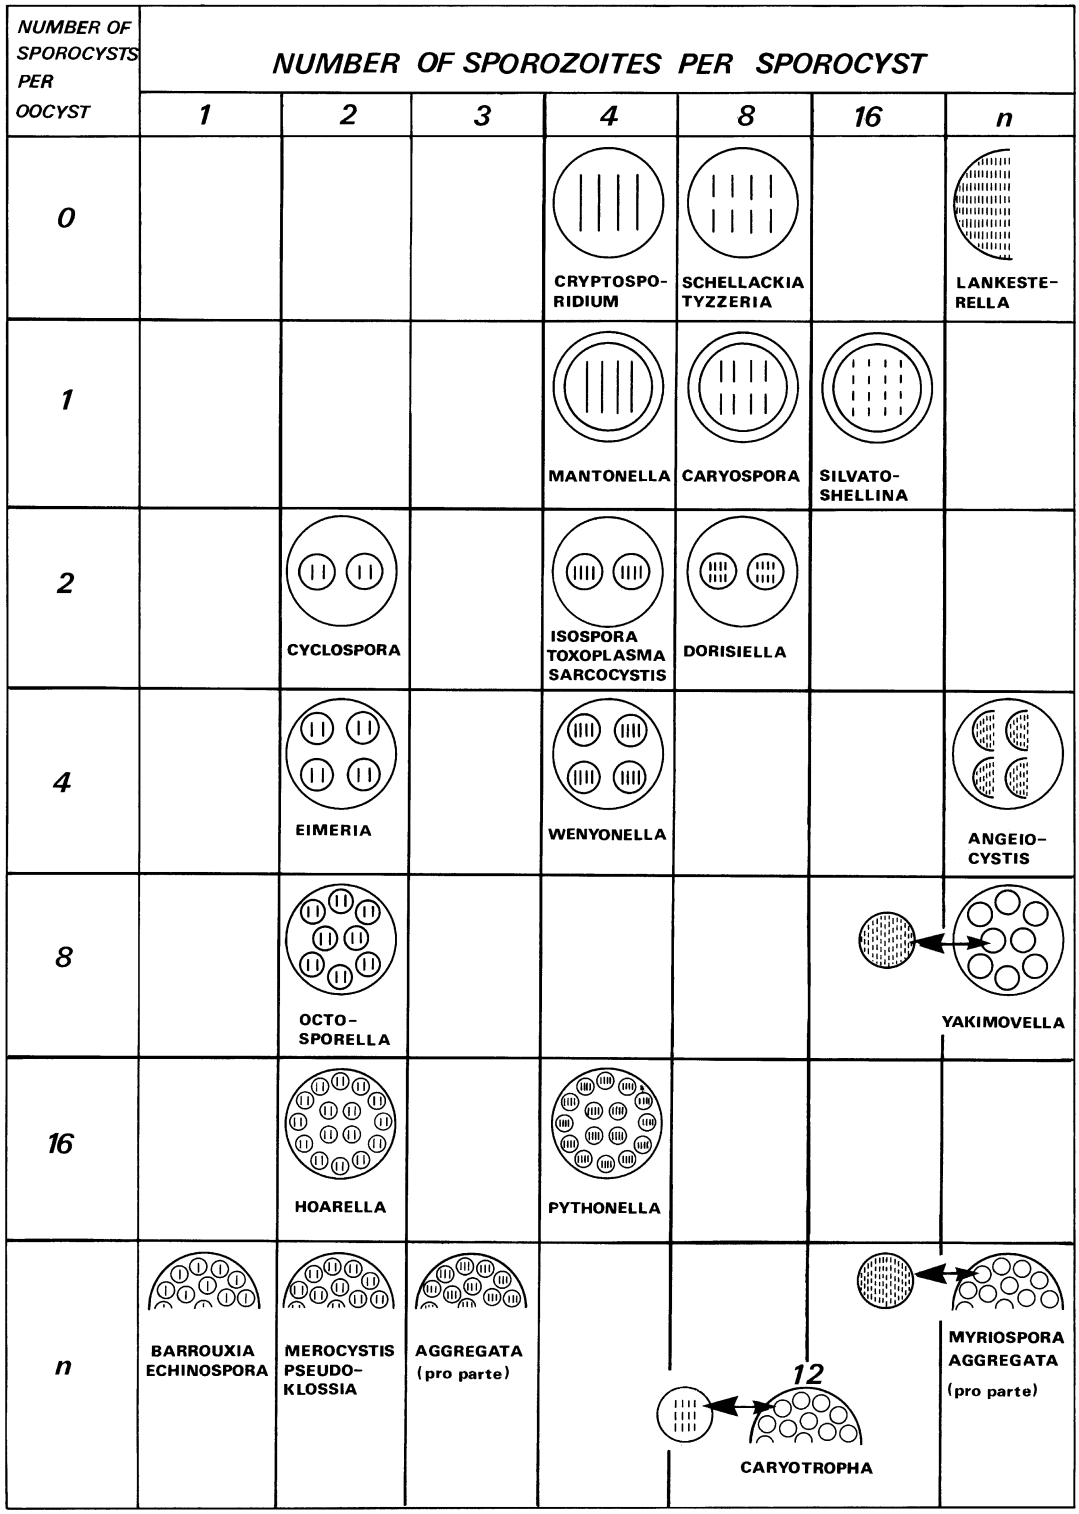
[c] This species is probably synonymous to *Hammondia heydorni* representing a pathogenic strain that introduces under special conditions the described abortions in cattle and dogs

Coccidia. Table 6 Some common species of the Adeleidea

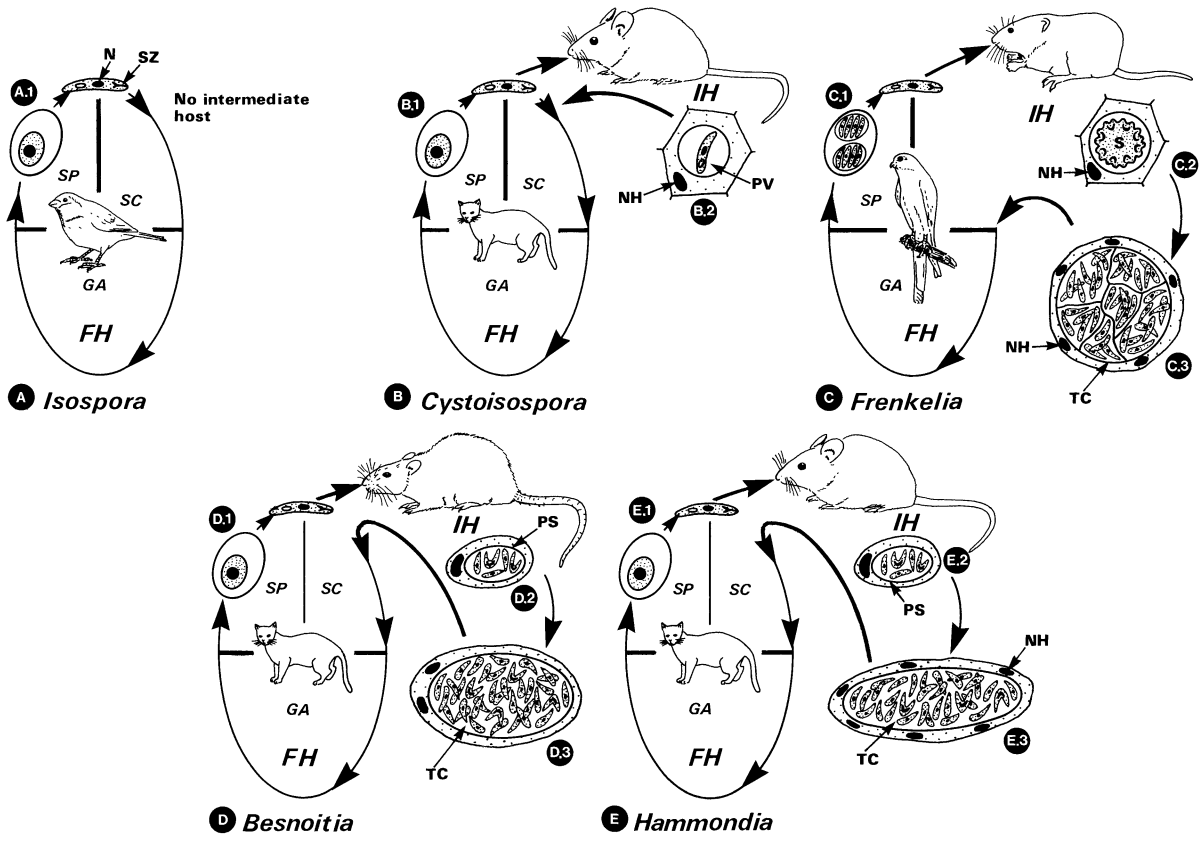
Species	Host	Hosts/Habitat	Vector/Habitat	Mode of infection/transmission
Significant Adeleidea				
Adelina deronis	1	Oligochaetae (*Derolimosa*)/ Body cavitity	–	Oral uptake of oocysts/sporocysts
A. cryptocerci	1	Roaches (*Cryptocercus*)/Fat body	–	Oral uptake of oocysts/sporocysts
A. tribolii	1	Red flour beetles (*Tribolium*)/Hemocoel	–	Oral uptake of oocysts via cannibalism
Klossia helicina	1	Snails (*Helix, Cepaea, Succinea*)/Kidney epithelium	–	Oral uptake of oocysts/sporocysts
Adeleidea of doubtful systematic position				
Haemogregarina stepanowi	2	Water tortoises (*Emys orbicularis*)/Erythrocytes, bone marrow	Leeches (*Placobdella* sp.)/ Intestine	Blood meal of vector
Hepatozoon muris (syn. *Perniciosum*)	2	Rats, mice/Liver cells, leukocytes	Rat mites (*Echinolaelaps* sp.)/Hemocoel	Blood meal of vector
H. erhardovae	2	Bank voles (*Clethrionomys* sp.)/Lung, leukocytes	Rat fleas/Hemocoel	Blood meal of vector
H. aegypti	2	Snakes (*Spalerosophis diadema*)/Lung, erythrocytes	Mosquitoes (*Culex pipiens*)/Body cavity	Blood meal of vector
Karyolysus lacertae	2	Lizard (*Lacerta* sp.)/ Endothelial cell of blood vessels, erythrocytes	Mites (*Liponyssus saurarorum*)/Gut epithelium, hemocoel, yolk	Feeding with shed oocysts or infected whole mites, which were infected during blood meal.

Coccidia. Table 7 Some blood parasitizing genera of doubtful systematic position

Species	Host	Tissue	Vector	Mode of infection
Lankesterella minima	Frog *(Rana esculenta)*	Sporozoites: red blood cells	Leech *(Placobdella marginata)*	Mechanically during blood sucking, by eating the leech
Atoxoplasma spp.	Birds	Merozoites: RES Leukocytes	Mites, mosquitoes	Bite, by eating the vector
Schellackia bolivari (syn. *Lainsonia, Gordonella*)	Lizards	Merozoites: midgut Sporozoites: red blood cells	Mites	By eating the vector



Coccidia. Figure 1 Diagrammatic representation of numbers and relationships between oocysts, sporocysts, and sporozoites in different genera of Eimeriidae. In the genera without sporocysts the numbers of sporozoites per →oocyst are given. In the case of *Cryptosporidium* the smooth oocyst wall disappears and is transformed into the →sporocyst wall. Thus, this genus might also be placed in the second row, but it is probably more related to →gregarines. (After Levine 1973, modified.)



Coccidia. Figure 2 Life cycles of different coccidian tissue-cyst-forming genera, the gamogony (*GA*) of which always occurs in the intestinal epithelial cells of final hosts (*FH*). **A** →Isospora (e.g., *I. serini* of canaries, *I. lacazei* of sparrows): homoxenous (i.e., one-host-type) cycle. Oocysts are excreted unsporulated (B1); after →sporulation (compare C1) they become infectious to other hosts of the same species. Schizogony (*SC*) is not restricted to epithelial intestinal cells, but also occurs in the gut wall and extraintestinally. **B** →Cystoisospora (e.g., *C. felis* and *C. rivolta* of cats, *C. ohioensis* of dogs): heteroxenous cycle. Oocysts are excreted unsporulated (B1). An intermediate host (B2) may facultatively be involved in addition to the typical development (*SC, GA, SP*) inside the intestine of the final host. Rodents and/or cattle are infected by oral ingestion of sporulated oocysts. The sporozoites (*SP*) enter numerous types of host cells, but remain there unchanged in a →parasitophorous vacuole (*PV*) until this cell is eaten by the final host. Since there is no parasitic development inside the intermediate host, it must be considered as a transport or →paratenic host. **C** →Frenkelia (e.g., *F. clethrionomyobuteonis*): heteroxenous cycle with an obligate alternation of final (hawk) and intermediate (bank vole) hosts (like →*Sarcocystis*). The oocysts are excreted fully sporulated (C1) and must be ingested by the intermediate host. Inside the liver cells (C2) typical schizonts (*S*) produce merozoites, which lead to formation of septated tissue cysts (*TC*) in brain and cord (C3). The cysts contain dividing merocytes and finally motile cyst merozoites (→Bradyzoites). The latter are infectious to the final hosts, where they (when oral ingestion occurs) initiate gamogony inside the gut cells. **D** →Besnoitia (e.g., *B. wallacei*): obligatory 2-host cycle. Oocysts are excreted unsporulated by the final host cat (D1); after sporulation they must be ingested by intermediate hosts (rats, mice), where reproduction initially occurs by →endodyogeny in many cells (appearing as →pseudocysts; D2). Later, tissue-cysts (D3) are formed inside fibroblasts, leading to cysts that are often macroscopically visible. The latter exclusively contain cyst merozoites (never →metrocytes), which are infectious to final hosts when ingested. After experimental transmission, cyst merozoites of several →*Besnoitia* species repeat the developmental steps D2 and D3 in other intermediate hosts. **E** →Hammondia (e.g., *E. hammondi*): obligatory alternation of 2 hosts. Oocysts are excreted unsporulated (E1) by the final host cat; after sporulation they must be ingested by intermediate hosts (mice, rodents), where rapid asexual reproduction occurs in lymphoid cells (E2); this is followed by formation of tissue-cysts (*TC*) in striated muscles (E3). The cyst merozoites are finally infectious to final hosts (*FH*), where they initiate schizogony in epithelial cells (*SC*). This species is discussed as strain of →*T. gondii*. **Infection of final hosts** (*FH*) by their own excreted oocysts is only possible in the genera →*Isospora* and →*Cystoisospora*. *FH*, final host; *GA*, gamogony; *IH*, intermediate host; *N*, nucleus; *NH*, nucleus of the host cell; *PS*, pseudocyst; *PV*, parasitophorous vacuole; *S*, →schizont; *SC*, schizogony; *SP*, sporogony; *SZ*, →sporozoite; *TC*, →tissue cyst (for more details see Table 2 and Table 5 of →Coccidia).

Coccidiasis, Man

Infectious diseases of the human small intestine caused by various →coccidians (→Isosporosis, Man, →Cyclosporiasis, →Cryptosporidiosis, Man, →Sarcosporidiosis, Man).

Main clinical symptoms: →Diarrhoea, →vomiting, loss of weight.
Incubation period: 2–13 days.
Prepatent period: 7–9 days.
Patent period: 2 weeks until 1–2 months (in case of →AIDS patients).
Diagnosis: Microscopical determination of oocysts in fecal samples.
Prophylaxis: Avoid contact with human feces.
Therapy: Treatment see →Coccidiocidal Drugs.

Coccidiocidal Drugs

Economic Importance

Most of the anticoccidials used for the control of →coccidia proper in livestock and poultry are approved by government agencies for the prevention of coccidiosis in chickens (Table 1, page 270). Despite the use of anticoccidials in continuous medication programs, global losses chiefly due to subclinical coccidiosis in broiler poultry is estimated at up to US$750 million. The enormous expansion of broiler production over the last 16 years (e.g., in USA: 1991/2006 = 6.1/8.9 billion birds = plus 45.9%) has been reflected in the world market for anticoccidial drugs. In 1991 the total turnover per year was about US$450 million. This figure includes in-feed anticoccidials (~80% ionophores) at about US$370 million, in-water anticoccidials at US$30–40 million, and biologicals at US$25–30 million; the broiler market with about 80% of the total has been large enough to stimulate major screening and development programs in the American and European pharmaceutical industries. However, the rapid emergence of drug resistance can result in a short market life for some drugs (less than 6 months for buquinolate). However, high cost of obtaining government clearance, and the delays involved, have all discouraged pharmaceutical companies. Discovering, characterizing, developing, and registering a new drug may take 8–10 years. The risk of drug resistance may also jeopardize any hope of benefit from the high capital expenditure on registering a new anticoccidial. Several pharmaceutical companies have consequently taken a new approach and abandoned anticoccidial-screening programs although the use of novel high-throughput screening methods would permit large numbers of compounds to be investigated within short periods of time. In future the most promising alternative to controlling coccidia infections with chemotherapy may be coccidiosis vaccines. As a result of public pressure against continuous medication, drug resistance problems, and the high cost of drug clearance vaccines, which are able to induce sufficient immunity (both humoral and cellular response) and thus provide flock protection against →morbidity and →mortality, would be an appropriate alternative.

Epizootiology and Control Measures

The application of any control methods, whether hygienic, chemotherapeutic, or immunological, needs profound knowledge of the →epizootiology of various coccidioses. The term coccidiasis is used to describe relatively nonpathogenic and usually mixed infections, whereas coccidiosis is a severe disease in the host. In papers related to human medicine the ending *iasis*, however, is used to indicate an acute phase of disease with severe clinical symptoms. Thus the parasitological literature may lead to confusion on the severity of the disease. Mixed infections, i.e., those where animals are infected with more than one species of coccidia, are very common and only some species are highly pathogenic. The severity of the disease is the result of the combined actions of the particular mixture of coccidia, the number of sporulated oocysts ingested with feed or water. However, it may be influenced also by the nutritional condition of the host, environmental and climatic factors (such as temperature, moisture, oxygen tension, and sunlight) and the management practices used. Crowding of animals due to intensive rearing, e.g., in the broiler industry where large numbers of chickens are kept in enormous houses, creates conditions favorable to sudden outbreaks of severe coccidiosis. Fecal debris may concentrate large numbers of oocysts, which can rapidly sporulate and become infective under warm and moist conditions. Severe coccidiosis is, therefore, mostly a "man-made" problem with domestic animals and is not a general problem in the wild or on pastures. When coccidiosis is suspected and oocysts are found, the species present should be identified. A periodic examination of feces for oocysts and a postmortem examination in a few animals will give valuable information on the status of infection.

Coccidiosis cannot be recognized clinically until tissue damage associated with second- or third-generation →schizogony occurs. When the disease is present, the **clinical signs** are catarrhalic or hemorrhagic enteritis. The severity of disease is often complicated by the presence of secondary bacterial infections. Moderately affected animals show poor weight gain or weight loss, weakness, and emaciation, severely affected animals

Coccidiocidal Drugs. Table 1 Anticoccidial drugs used in the poultry industry

CHEMICAL GROUP nonproprietary name (oral dose: g/ton feed or ppm: part per million), other information	*BRAND NAMES (manufacturer, companies, distributors), WT, other information	COMMENTS on efficacy, mode of action, toxicity, limitations as withdrawal time before slaughter (WT in days = d), target species, indication(s), contraindications and other information
SULFONAMIDES (introduced around 1940) (approx. 120–250); *sulfadiazine*, *sulfadoxine* *sulfadimethoxine* *sulfadimidine* *sulfaguanidine* *sulfamethazine* *sulfaquinoxaline* *sulfamerazine*, and others	(*various brand names and suppliers) ***limitations***: do not use for ***prevention*** of coccidiosis recommended dose levels may vary and depend on drug and dose form (in feed or in water)	opened up the field for practical use; sulfonamides (***sulfas***) have a broad spectrum of activity against *Eimeria* spp. of the anterior and lower part of the intestine but only a moderate effect on *E. tenella* (residing in ceca) of chickens; in cattle, swine, and rabbits prophylactic feeding of *sulfaguanidine*, *sulfaquinoxaline* and others (not approved indication) may prevent clinical signs and reduce oocyst production thereby allowing development of protective immunity; drug resistance had limited their use as prophylactics in the past; sodium salts of sulfas are usually water soluble and render them useful for *curative treatment* of coccidiosis in ruminants, swine, (game) birds, and dogs (withdrawal time may exceed 14 days in food-producing animals); sulfas are active against first- and second-generation schizonts and probably against sexual stages; their action seems to be coccidiocidal at higher doses and coccidiostatic at lower doses; higher doses used in therapy often cause toxicity (hemorrhagic syndrome, kidney damage, growth depression); sulfas interfere with cofactor synthesis, i.e., block dihydropteroate synthetase and hence synthesis of tetrahydrofolate (cofactor is required for cellular methylation reactions) in the early phases of folate synthesis; their action can be nullified by excess p-aminobenzoic acid (PABA); long-acting sulfas (e.g., sulfadoxine, sulfadimethoxine) combined with *diaminopyrimidines* (e.g., pyrimethamine; other related compounds are ormetoprim, diaveridine, pyrimethamine, and trimethoprim) are highly active antimalarials, anticoccidials, and antibacterials; these combinations may be useful for treating various types of protozoan infections such as toxoplasmosis, sarcocystosis, and neosporosis, various bacterial infections, and human malaria; diaminopyrimidines are dihydrofolate reductase/ thymidylate synthase = DHFR/TS inhibitors showing synergistic effects with sulfas due to effects at different sites in the folate biosynthesis; ***limitations***: sulfas, and combinations of sulfas with DHFR/TS inhibitors are not approved for *prevention* of coccidiosis in poultry or other animals under European Commission Guidelines (additives in feeding stuffs), and feed regulations of Food and Drug Administration (FDA) in the USA and elsewhere, except *ormetoprim* combined with *sulfadimethoxine*, the only DHFR/TS-sulfa combination presently available in the USA as an aid for the prevention of coccidiosis in poultry
DIAMINOPYRIMIDINES **sulfadimethoxine/ ormetoprim** *1 (113.5/68.1 chickens: broilers, replacements, Chukar partridges) (56.75/34.05 turkeys: not laying eggs for human consumption) (454/272.4 for 7d ducks excluding layers) *2 (113.5/68/22.7 chicken broilers)	1*Rofenaid 40 (feed as a sole ration) 2*Rofenaid Plus Roxarsone (Alpharma, USA), Type A medicated Articles (feed as a sole source of organic arsenic) WT: chickens, turkeys, ducks: 5d; Chukar partridges: not released into wild before 18 weeks and can only be used up to 8 weeks of age	1****approved indications***: ***chickens*** (broilers, replacements) as an aid in prevention of coccidiosis caused by all *Eimeria* spp. namely, *E. tenella*, *E. necatrix E. acervulina*, *E. brunetti*, *E. mivati*, and *E. maxima* and bacterial infections due to *Haemophilus gallinarum* (infectious coryza), *Escherichia coli* (colibacillosis), and *Pasteurella multocida* (fowl cholera); ***turkeys***: as an aid in prevention of coccidiosis caused by all *Eimeria* spp. namely, *E. adenoeides*, *E. gallopavonis*, and *E. meleagrimitis* and bacterial infection due to *P. multocida* (fowl cholera); ***Chukar partridges***: for prevention of coccidiosis caused by *E. kofoidi* and *E. legionensis*, *limitations*: feed continuously to young birds up to 8 weeks of age as sole ration; ***ducks***: as an aid in control of bacterial infections due to *E. coli*, *Riemerella anatipestifer*, and severe challenge of *P. multocida* (fowl cholera), ***limitations***: feed as a sole ration for 7d, withdraw 5d before slaughter; medication should be started at the first signs of infection; not for breeding ducks, do not feed to ducks producing eggs for food; 2* ***approved indications***: ***chickens*** (broilers) as an aid in prevention of coccidiosis caused by all *Eimeria* spp., namely *E. tenella*, *E. necatrix*, *E. acervulina*, *E. brunetti*, *E. mivati*, and *E. maxima*, and bacterial infections due to *H. gallinarum* (infectious coryza), *E. coli* (colibacillosis), and *P. multocida* (fowl cholera), growth promotion and feed efficiency, improving pigmentation, WT: 5d
2,4-SUBSTITUTED AMINOBENZOIC METHYL ESTER **ethopabate** (cf. combination with amprolium ↓)	it has a good innate activity against *E. acervulina* but not so against *E. maxima* and *E. brunetti* (it has no activity against *E. tenella*); drug is usually used only in combination with other anticoccidials (cf. amprolium); ethopabate (an aryl-amide containing one phenyl ring belonging to monocyclic aromatics) is a safe drug in mammals and birds; it is an analogue and thus competitor of PABA (p-aminobenzoic acid), which is required for the synthesis of folic acid by the parasite; ethopabate interferes (like sulfonamides) with the dihydropteroate synthetase reaction (conjugation of a pteridine moiety and PABA); however, PABA excess in medicated feed or water can nullify action of ethopabate	

Coccidiocidal Drugs. Table 1 Anticoccidial drugs used in the poultry industry (Continued)

CHEMICAL GROUP nonproprietary name (oral dose: g/ton feed or ppm: part per million), other information	*BRAND NAMES (manufacturer, companies, distributors), WT, other information	COMMENTS on efficacy, mode of action, toxicity, limitations as withdrawal time before slaughter (WT in days = d), target species, indication(s), contraindications and other information
PYRIDINOLES **clopidol** *1 (113.5/227 chicken broilers, replacements), **clopidol/roxarsone** *2 (113.5/45.4) Coyden 25/3-Nitro (Merial USA), Type A medicated Articles, WT: chickens 5d	1*Lerbeck 25, Coyden 25 (Merial USA: Type A medicated Articles, WT: 5d, 1*Lerbeck Australia: oral powder WT: 0d), *limitations*: do not feed to chickens over 16 weeks of age	first commercial use of drug products 1968; it arrests sporozoite and trophozoite development (= coccidiostatic effect: withdrawal of drug leads to relapse of infection); it is active against all *Eimeria* spp. in chickens but considerable problems have been reported with *E. acervulina*; drug resistance problems limit its use to shuttle programs (e.g., last 1–3 weeks of broiler grow-out); it is synergistic when combined with chemically related 4-hydroxy-quinolines; it is very safe for chickens and safe in mammals; ***approved indications***: as an aid in prevention of coccidiosis caused by *E. tenella*, *E. necatrix*, *E. acervulina*, *E. maxima*, *E. brunetti*, and *E. mivati*; *2: also growth promotion and feed efficiency, improved pigmentation); *limitations* (Coyden 25/3-Nitro): feed up to 16 weeks of age if intended for use as caged layers, feed continuously as the sole ration
4-HYDROXYQUINOLINES **decoquinate** *1 (20–40) **decoquinate/roxarsone** (27.2/45.4) *3-Nitro/Deccox (Alpharma USA), Type A medicated Article, WT: chicken, broilers excl. layers, 5d	1*Deccox (Alpharma USA, Germany, and elsewhere), Type A medicated Article for chickens (broilers) *limitations*: chickens not laying eggs, cattle (not lactating), young sheep and goats (not lactating)	first commercial use: buquinolate 1967 (withdrawn), decoquinate 1970, methylbenzoquate/clopidol 1974 (withdrawn); *buquinolate* was "commercially dead" within 6 months (sudden and dramatic appearance of drug resistance); hydroxyquinolines are almost entirely coccidiostatic against sporozoites and trophozoites of all *Eimeria* spp. in chickens (cf. clopidol; as single compounds they had only limited success: methylbenzoquate (10ppm and higher concentrations) proved ineffective against relevant *Eimeria* spp. due to serious and immediate development of drug resistance in the field; ***mode of action***: hydroxy-quinolines target on energy metabolism: compounds block electron transport down the cytochrome chain in the mitochondria of coccidia and hence inhibit NADH oxidation and ATP synthesis as well; *1 *approved indications* (***chickens***): for prevention of coccidiosis caused by *E. tenella*, *E. necatrix*, *E. acervulina*, *E. maxima*, *E. brunetti*, and *E. mivati* (*3-Nitro/Deccox: also growth promotion and feed efficiency, improved pigmentation); *1 (***cattle***): for prevention of coccidiosis in ruminating and nonruminating calves and cattle caused by *E. bovis* and *E. zuernii*; (***goats***): for prevention of coccidiosis caused by *E. christenseni* and *E. ninakohlyakimovae*; (***sheep***): for prevention of coccidiosis caused by *E. ovinoidalis*, *E. crandallis*, *E. parva*, *E. bakuensis*; *general limitations*: bentonite should not be used in decoquinate feeds, and other limitations for use in ruminants concerning dosage regimens (cf. label) in various feed and duration of prophylactic treatment (feed at least 28 days during periods of exposure to coccidiosis or when it is likely to be a hazard)
NITROBENZAMIDES **dinitolmide** (125, chicken broilers, pullets, turkeys), not to be fed on laying hens; drug products available in *Australia*, elsewhere	*CCD D.O.T.: CCD AH and Nutrition (Ridley AG), *DOT 125 Premix: (Provimi Australia), oral powder, premix, WT: 0d chicken (broilers, pullets) and turkeys	first commercial use: dinitolmide 1960, nitromide 1958 (withdrawn in the USA and elsewhere), aklomide 1965; drug arrests development of first- and second-generation schizonts and does not interfere with development of immunity; it is active against *Eimeria tenella* and *E. necatrix* but its effect against *E. acervulina* is limited; drug was combined with sulfanitran or roxarsone to enhance coccidiostatic activity and growth promotion; it may chiefly be used in breeder or replacement chickens (up to 14 weeks of age); mode of action is unknown; ***limitations***: do not use in laying hens (chicken, ***turkeys***)
*1 **nitromide/sulfanitran** (227/227 chickens), *2 **nitromide/ sulfanitran/ roxarsone** (227/22745.4 chicken) *1 **aklomide/sulfanitran** (227/181 chickens) *2 **aklomide/sulfanitran/ roxarsone** (227/181/45.4 chicken)	1*Unistat 2; 2*Unistat 3 (Fort Dodge USA, elsewhere), Type A medicated feed, medicated feed WT: 5d 1*Novostat, 2*Novostat- 3 Type A medicated Article, Premix, others (all Fort Dodge USA)	is not currently marketed as a single agent; it was the first nitrobenzamide on the market and has same similar action on coccidia like dinitolmide; it may be used in breeders, broilers, and roasters; ***approved indications***: as an aid in prevention of coccidiosis caused by *E. tenella*, *E. necatrix*, and *E. acervulina* (*2: also growth promotion and feed efficiency and improved pigmentation); *limitations*: not to be fed to laying chickens, and (*2) feed as a sole source of organic arsenic drug products can be used in breeders, broilers,

Coccidiocidal Drugs. Table 1 Anticoccidial drugs used in the poultry industry (Continued)

CHEMICAL GROUP nonproprietary name (oral dose: g/ton feed or ppm: part per million), other information	*BRAND NAMES (manufacturer, companies, distributors), WT, other information	COMMENTS on efficacy, mode of action, toxicity, limitations as withdrawal time before slaughter (WT in days = d), target species, indication(s), contraindications and other information
and roasters and have similar activity against coccidia like dinitolmide and nitromide; approved indications and limitations (not to be fed to laying chickens, and (*2) feed as a sole source of organic arsenic) cf. nitromide↑		
ORGANIC ARSENICALS **roxarsone** 1*(45.4 chicken, turkeys) **arsanilic acid** (90 chicken, turkey) Pro-Gen Plus Supplement (Fleming Labs, others, USA)	1*A.L. 3-Nitro (OZ-Biopharm, Alpharma, Australia) powder WT: chicken, turkeys 5d; 2*//3 Nitro/ BMD/ Monteban (Alpharma USA)	first commercial use of roxarsone 1946, and arsanilic acid 1949; primary indication of arsenicals like arsanilic acid, or roxarsone (3-nitro-4-hydroxyphenyl-arsonic acid) is growth promotion; ***approved indication*** (1*A.L. 3-Nitro Australia, or *Zoco or *Zuco Tablets for Poultry, Alpharma, USA, oral liquid, WT: chicken, turkey 5d): for growth promotion and improved feed conversion efficiency in chickens and turkeys; ***limitations***: do not use in birds which are producing
or may in the future produce eggs or egg products for human consumption, do not use in ducks, geese, or dogs nor for any other purpose or in any manner contrary to the directions on this label, feed as a sole source of organic arsenic; roxarsone has been reported to have some activity against *E. tenella* and *E. brunetti* (as a single agent or in combination with nitrobenzamides); in the European Union arsenicals have been prohibited and withdrawn from market; roxarsone is also used in combination with other agents as narasin, antibiotics (e.g., bacitracin methylene disalycilate, ↖cf. 2*//3 Nitro/ BMD/ Monteban, Alpharma USA)		
CARBANALIDE DERIVATIVES **nicarbazin** (113.5–125 chicken, breeders, broilers, roasters) ***limitations***: do not feed to laying hens	*Nicarbazin (Phibro AH, USA), Type A Medicated Article, WT: 4d *Keymix Keycarbazin (Internat. AH Products, others Australia), oral powder, premix, WT: 4d	nicarbazin (introduced in 1955) was the first agent with "broad-spectrum" activity against *Eimeria* spp. of chickens; it is an equimolar complex of dinitrocarbanilide and dimethylpyrimidinol and still used as a single agent in the USA, Australia, elsewhere
or in combination with polyether antibiotics (narasin, or maduramicin), roxarsone, or antibiotics (lincomycin, bacitracin, flavomycin in the USA, incl. roxarsone) for prevention and control of coccidiosis caused by *Eimeria* spp. (all relevant species) in broiler chickens; it shows synergistic effect with polyether antibiotics (cf. combination with narasin *Maxiban or maduramicin *Gromax); its action is primarily directed against developing second-generation *Eimeria* schizonts; it has approval for chickens only and may still be used in shuttle programs as starter feed preferably in winter or cooler months; this may be the reason why nicarbazin-resistant coccidia strains do not occur so frequently in poultry industry; however, there may be problems with side effects occurring during summer; it can cause increased sensitivity to heat stress, which may result in growth depression and even mortality in broilers; death may be due to cell degeneration processes in liver and kidneys; at recommended dose, the drug causes occasionally toxic effects in laying hens like reduced hatchability and interruption of egg laying; ***mode of action*** is not yet well understood and potential targets of selective toxicity in coccidia are unknown; ***approved indications*** (USA): aid in preventing outbreaks of cecal (*E. tenella*) and intestinal (*E. acervulina, E. maxima, E. necatrix, and E. brunetti*) coccidiosis; ***limitations***: feed continuously as sole ration from time chicks are placed on litter until past the time when coccidiosis is ordinarily a hazard, do not use as a treatment for coccidiosis, do not use in flushing mashes		
THIAMINE ANALOGUES **amprolium** (APL) *1 (36.3–113.5, chicken broilers, replacements) *1 (113.5–227, chicken laying, 227: treatment) *1 (113.5–227 turkeys) *1 (159 pheasants growing), *1 (5mg/kg b.w. cattle for 21d) *2 **amprolium** HCl (240 mg/ litre for 24 hours every fourth day as long as infection is likely: chickens, turkeys, ducks, pigeons)	*Amprovine: various products for prevention and treatment (Merial USA) 1*Type A medicated Article, poultry WT: 0d, cattle, calves 1d; or 9.6% solutions or 20% soluble powder (WT see above) for the treatment (amount see label) 2*Amprolium 200 Soluble Powder (200 g/kg APL HCl) (Australia), oral powder (drinking water), WT: 0d;	amprolium (introduced 1960) is structurally related to the vitamin thiamine and is soluble in water as HCl salt; its activity is primarily directed against first-generation schizonts of *Eimeria* spp. (prevents development of merozoites and thus reduces production of second-generation schizonts); there is some activity against gamonts (sexual stages); it may affect sporulation process in the oocyst (development of sporozoites); it is coccidiostatic at lower, and coccidiocidal at higher doses and is a very safe agent in poultry and mammals; APL-resistant *Eimeria* strains are prevalent in broiler chickens and floor-reared replacement pullets or turkeys, which limits its use in the field; APL is combined with

Coccidiocidal Drugs. Table 1 Anticoccidial drugs used in the poultry industry (Continued)

CHEMICAL GROUP nonproprietary name (oral dose: g/ton feed or ppm: part per million), other information	*BRAND NAMES (manufacturer, companies, distributors), WT, other information	COMMENTS on efficacy, mode of action, toxicity, limitations as withdrawal time before slaughter (WT in days = d), target species, indication(s), contraindications and other information
*3 **amprolium/ethopabate** (125/8, chicken, turkey) *4 **amprolium/ethopabate/ roxarsone** (113.5/3.6/45.4 chicken broilers)	3*Keymix Keystat Powder Feed Additive (Internat. AH Products) 3* Amprolmix Plus (Merial Australia), oral powder, premix in feed, WT: 0d 4* Broiler PMX No.1620 (Merial USA), Type A medicated Article, WT: broiler 5d	other agents (e.g., *ethopabate* or *roxarsone*) to enhance anticoccidial activity; ***approved indications*** (USA): APL and combinations (APL/ethopabate; APL/ethopabate/ roxarsone: available as feed additives or other dose forms) may be used in poultry (chicken broilers, broiler breeders, or replacement pullets: latter feed from day-old till 6–8 weeks of age), (guinea fowl), turkeys (poults: from day-old till 6–8 weeks of age), ducks and pigeons for
the treatment and an aid in the prevention of coccidiosis caused by *Eimeria tenella*, *E. acervulina* (most strains are affected), *E. maxima* (affected to a lesser degree), *E. necatrix*, and *E. brunetti*, pathogen *Eimeria* spp. of turkeys and other species of ducks and pigeons (*4: in addition, growth promotion and feed efficiency, improved pigmentation); drug products may be used in turkey poults because of its good tolerability and encouraging immunity to develop, needed for satisfactory performance of replacement pullets and poults following withdrawal of agent; in *cattle* and *calves* *Amprovine is used as an aid in the treatment of coccidiosis caused by *E. bovis* and *E. zurnii*; ***mode of action***: in parasites, APL competitively inhibits uptake and active transport of thiamine (coccidia may be 50-fold more sensitive to the system than that of the host); thiamine pyrophosphate is a cofactor of several enzymes involved in decarboxylating processes playing a role in cofactor synthesis; APL cannot be pyrophosphorylated (lacks hydroxyethyl group); ***limitations*** (*3, *4): do not use in birds, which are producing or may in the future produce eggs or egg products for human consumption; (*4): feed as a sole source of organic arsenic		
QUINAZOLINONES halofuginone (introduced 1976) was originally derived from a plant extract (*Dichroa febrifuga* Lour); isolated ***febrifugine*** had an antimalarial and anticoccidial effect but a too narrow safety margin; structural variations of the alkaloid (previously performed by American Cyanamid) led to halofuginone; its mode of action is unknown; the alkaloid is *toxic to fish* and other aquatic species		
halofuginone Hydrobromide (HAL) *1 (2–3 chickens EC) *1 (2.72 chicken broilers, replacement cage layers, and replacement broiler breeders, USA) *1 (1.36–2.72 turkeys growing, USA) **halofuginone/roxarsone** *2 (2.72/ 22.7–45.4 chicken replacement broilers not over 20 weeks age, chicken, replacements for caged layers not over 16 weeks)	1*Stenorol (Huvepharma USA; Intervet Internat. Europe, elsewhere), Type A medicated article: chicken and turkeys (USA, Switzerland, elsewhere), chicken: replacement cage layers and replacement broiler breeders (EC = European Commission), WT may vary (USA cf. text →, Switzerland: 5d, EC: 5d) 2*//3-Nitro/Stenorol (Alpharma, Inc. USA), Type A medicated article: for chicken, WT: 5d	HAL is highly active against asexual stages of coccidia; it has a broad spectrum of activity against all pathogenic *Eimeria* spp. of chickens and turkeys; it affects asexual stages of coccidia, particularly merozoites during the first-generation schizogony maturation; drug action is both coccidiocidal and coccidiostatic but in case of *E. acervulina* not as strong as with other species; drug resistance may occur when drug is used for too long periods in straight medication programs; if used in shuttle (or rotation) programs and alternated with polyether antibiotics it will be more likely that field strains of coccidia remain sensitive to the agent; ***approved indications*** (***chicken*** broilers, replacement cage layers, and replacement broiler breeders, USA): for prevention of coccidiosis caused by *E. tenella*, *E. necatrix*, *E. acervulina*, *E. brunetti*, *E. mivati*/*E. mitis*,
and *E. maxima*; ***limitations*** (broilers: feed continuously as sole ration, withdraw 4 days before slaughter, do not feed to layers); ***limitations*** (replacement cage layers and replacement broiler breeder): feed continuously as sole ration to replacement cage laying chickens until 20 weeks of age, feed continuously as sole ration to replacement broiler breeder chickens until 16 weeks of age, withdraw 4d before slaughter, do not feed to laying chickens or water fowl; ***approved indications*** (***turkey*** growing USA): for prevention of coccidiosis in growing turkeys caused by *E. adenoeides*, *E. meleagrimitis*, and *E. gallopavonis*; ***limitations***: feed continuously as sole ration, withdraw 7d before slaughter, do not feed to layers or water fowl; ***approved indications*** (*chicken*) 2*//3-Nitro/Stenorol, cf. 2*): for prevention of coccidiosis caused by *E. tenella, E. necatrix, E. acervulina, E. brunetti, E. mivati,* and *E. maxima*, for increased rate of weight gain, improved feed efficiency, and improved pigmentation; ***limitations***: feed continuously as sole ration to replacement cage laying chickens until 20 weeks of age, and to replacement broiler breeder chickens until 16 weeks of age, use as the sole source of organic arsenic; drug overdose or lack of water intake may result in leg weakness or paralysis, do not feed to laying chickens or waterfowl; ***general limitations***: avoid contact with skin, eyes, or clothing, do not contaminate dams, rivers, streams, or other waterways with the chemical; ***tolerability and metabolism***: at recommended dose, HAL is well-tolerated in chicken and turkeys; however, it is unpalatable at the recommended feed concentrations for anseriformes (ducks, geese, swans), water fowl, guinea fowls, partridges, or other game birds and rabbits; if fed continuously there is a drastic reduction in feed intake followed by serious toxic reactions and		

Coccidiocidal Drugs. Table 1 Anticoccidial drugs used in the poultry industry (Continued)

CHEMICAL GROUP nonproprietary name (oral dose: g/ton feed or ppm: part per million), other information	*BRAND NAMES (manufacturer, companies, distributors), WT, other information	COMMENTS on efficacy, mode of action, toxicity, limitations as withdrawal time before slaughter (WT in days = d), target species, indication(s), contraindications and other information
occasionally mortality; other adverse effects may be associated with skin tears in chicken (HAL is an inhibitor of collagen type I synthesis in avian and mammalian fibroblasts thereby decreasing skin strength and increasing incidences of skin tears during processing); however, in shuttle programs, in which halofuginone is included in grower feed, it seems to maintain skin integrity in broilers; in toxicity studies on laying hens it was shown that HAL is transmitted to eggs (there were no adverse effects on egg production or egg quality); it irritates skin and eyes after contact (precaution should be taken during handling this agent)		
GUANIDINE DERIVATIVES robenidine (introduced 1972) is a synthetic anticoccidial derivative of guanidine; if not withdrawn 5 days before slaughter or used at higher than the recommended dose edible tissues and eggs of layers of medicated birds will have an unpleasant (medical) taste; mode of action of robenidine is believed to interfere with energy metabolism by inhibition of respiratory chain phosphorylation and ATPase activity in rat liver mitochondria; however, other guanidine derivatives lacking anticoccidial activity also share this inhibitory activity on oxidative phosphorylation process		
robenidine hydrochloride *1 (30–36 chicken broilers, fryers; EC: and turkeys growing) **robenidine/roxarsone** (30/22.5–45.4, chicken broilers, fryers) 2*Robenz Plus Roxarsone (Alpharma USA)	1*Cycostat 66G (Alpharma Australia; EC) for broiler chickens (Australia) and growing turkeys (up to 12 weeks of age) and ***rabbits*** (EC) 1*Robenz (Alpharma USA) for chickens (broiler and fryers): 1*/ 2*: all Type A medicated articles (WT: all 5d)	has broad anticoccidial spectrum of activity including *Eimeria* spp. of birds and mammals (EC approval for ***rabbits*** at 50-66ppm for prevention of coccidiosis caused by intestinal *Eimeria* spp. only); it affects late developing stages of first- and second-generation schizonts; it may have some activity against gamonts (sexual stages); its action is both first coccidiostatic and then coccidiocidal; *Eimeria* spp. may easily and quickly develop resistance to the agent; there were reports of unexpected outbreaks of drug resistance in the USA and Canada within a year of its introduction in poultry farms; ***approved indications*** (USA): an aid in prevention of coccidiosis caused by *E. mivati*, *E. brunetti*, *E. tenella*, *E. acervulina*, *E. maxima,* and *E. necatrix* (EC: in addition *Eimeria* spp. of turkeys such as *E. adenoeides, E. meleagrimitis, and E. gallopavonis*); *limitations*: do not feed to layers, feed continuously as the sole ration, Type C feed containing robenidine HCl must be fed within 50 days from the date of manufacture, do not use in Type B or Type C medicated feeds containing bentonite; 2*Robenz Plus: in addition: feed as a sole source of organic arsenic
POLYETHER IONOPHOROUS ANTIBIOTICS (discovered in the early 1950s and anticoccidial activity recognized in late 1960s) are fermentation products of various *Streptomyces* spp. or *Actinomadura* sp. (maduramicin, semduramicin) containing mycelial biomass (maduramicin can be extracted into granular carrier); ionophores have different affinities to different cations; their mode of action is related to their ability to interact with physiologically important monovalent and divalent cations (e.g., Rb+, Na+, K+, Cs+, or Ca2+) to form lipophilic complexes and transport so cations across biological membranes thereby destroying their cross-membrane gradients; sporozoites of *E. tenella* are killed after 12–24 hour-incubation in "solutions" of monensin, salinomycin and lasalocid, respectively, at very low concentrations (Raether W. et al. (1991) Parasitol Res 77: 386); ionophores also altered irreversible free *Eimeria tenella* merozoites and mature (first- and second- generation) schizonts or erythrocytic stages of various chloroquine-resistant strains of *Plasmodium berghei in vitro*; *Eimeria*-infected chickens fed with polyether antibiotic-medicated feed show usually relatively high oocyst outputs in feces; this may be due to ionophores' lack of activity against sporozoites *in vivo*; broad-spectrum activity of polyether antibiotics against all pathogenic *Eimeria* spp. in poultry gave them continuing commercial success till mid- to late 1980s as first [Raether W. et. al. (1991) Parasitol Res 77: 386]; ionophore-resistant strains of chicken *Eimeria* spp. were documented in Europe, USA, and elsewhere; today, ionophore resistance is common though response of resistant strains to specific ionophores may be different; there may be side resistance between monovalent ionophores (e.g., salinomycin/monensin) or cross-resistance between monovalent and divalent ionophores (e.g., monensin/lasalocid); in general, side-resistance among monovalent ionophores is widespread because this group of compounds is frequent used in the poultry industry; however, *Eimeria* spp. of poultry will retain their susceptibility to monovalent and divalent polyether antibiotics if concerned drug products are used strategically in the field (e.g., rotation programs); ionophores are potential toxic for highly susceptible animals such as horses and other equines, their safety margin is narrow in birds and mammals; concurrent use of tiamulin (a macrolide antibiotic) and certain anticoccidial ionophores produces adverse effects in poultry, such as weight depression and mortality due to retarded elimination of the ionophores via feces; lasalocid, maduramicin, and semduramicin are compatible with tiamulin but most of the ionophores may interact with sulfonamides and erythromycin; dose-related toxicity is evident by weakness, leg paralysis, and sharp reduction of water intake; anticoccidial ionophores may be used as feed additives for preventing coccidiosis in poultry (rabbits: EC?; ruminants: USA, Australia, elsewhere) or as feed additives for improving feed conversion efficiency and/or weight gain in cattle or swine in the USA and elsewhere (an EU-wide ban on antibiotics as growth promoters in animal feed entered into effect on January 1, 2006; Commission Regulation, EC No. 600/2005, April 2005 concerning a new authorization for 10 years of a coccidiostatic as an additive in feedstuffs including certain polyether antibiotics, see also below)		

Coccidiocidal Drugs. Table 1 Anticoccidial drugs used in the poultry industry (Continued)

CHEMICAL GROUP nonproprietary name (oral dose: g/ton feed or ppm: part per million), other information	*BRAND NAMES (manufacturer, companies, distributors), WT, other information	COMMENTS on efficacy, mode of action, toxicity, limitations as withdrawal time before slaughter (WT in days = d), target species, indication(s), contraindications and other information
monensin-Na (sodium) (MON) ●USA: (90–110 chicken broilers, replacements) (54–90 turkeys, no use class stated or implied) (73 Bobwhite quails, growing) ●Australia: (100–120 chicken broilers, replacements) ●EC (100–125 chicken broilers), (100–120 chicken replacements) (60–100 turkeys growing)	*Coban; *Elancoban, others (Elanco AH, Eli Lilly USA, Australia, EC), Type A medicated articles, others, WT: USA and Australia 0d, EC 3d, other drug products (in the USA: roxarsone or antibiotics combined with MON); ***general limitations***: do not feed to laying chickens, do not allow horses, other equines, mature turkeys, or guinea fowl access to feed containing MON	fermentation product of *Streptomyces cinnamonensis* (introduced in 1968); MON was the first ionophore used in poultry industry; ***approved indications*** (USA, elsewhere): as an aid in prevention of coccidiosis in chickens caused by *E. necatrix, E. tenella, E. acervulina, E. brunetti, E. mivati*, and *E. maxima*, in turkeys: *E. adenoeides*, *E. meleagrimitis*, and *E. gallopavonis*, in growing bobwhite quail: *Eimeria dispersa* and *E. lettyae*; ***limitations***: feed continuously as sole ration as MON sodium, do not feed to chickens (and turkeys: EC) over 16 weeks of age; chicken broilers: in the absence of coccidiosis, the use of MON sodium with no withdrawal period may limit feed intake resulting in reduced weight gain; feed continuously as the sole ration to growing turkeys from 1 day of age as MON sodium; ***tolerability***: MON may produce poor feathering when feeding diets with low energy and low sulphur-containing amino acids; tiamulin interferes with metabolism of MON in chickens; at recommended doses MON may be toxic to guinea fowl and other avian species; horses are very sensitive to MON (LD 50%: horse 2–3 mg/kg b.w., cattle 25 mg/kg; chickens 200 mg/kg); ***contraindication*** MON will cause deaths in equines that ingest feed containing it
lasalocid-A-Na (sodium) (LAS) ●USA (68–113 chicken broilers, fryers, turkeys growing), (113 Chukar partridges) ●EC (75–125 chicken broilers, replacements up to 16 weeks of age) (90–125 turkeys up to 12 weeks of age) ●Australia (75–100 chicken broilers, rearing replacement pullets, turkeys)	*Avatec (Alpharma EC, USA, Australia), Type A Medicated Article, others (medicated feed), WT: USA, Australia 0d, EC 5d; other drug products (in the USA: roxarsone or antibiotics combined with LAS) *limitations*: feed continuously as the sole ration, not to be added to feed consumed by hens producing fertile eggs or by game birds other than turkeys and Chukar partridges;	fermentation product of *Streptomyces lasaliensis* (introduced in 1974); it structurally differs from other ionophores and has strong affinity to *divalent* cations; metabolism of LAS appears to differ from that of monovalent ionophores, for its usage is associated with wet litter at the higher dosage levels and it is well tolerated when fed with tiamulin; at 75 ppm its activity against *E. acervulina* is unsatisfactory but good against *E. tenella*; *E. tenella* strains resistant to monovalent ionophores may be controlled with LAS; in the USA (elsewhere), LAS is approved for the prevention and control of coccidiosis caused by various *Eimeria* spp. of ***cattle*** (excluding veal calves), ***sheep*** and young ***domestic rabbit*** (only *E. stiedae*); it shows efficacy against *Eimeria* spp. of sheep, cattle, and domestic rabbits (*E. stiedai*) may be used in the USA (e.g., *Bovatec, or *Avatec, others, various oral drug forms, cattle and sheep: also for improved feed efficiency and increased rate of weight gain: ***approved indications*** *in birds* (*Avatec, USA, elsewhere): for prevention of coccidiosis in chickens (broilers, fryers) caused by *E. necatrix*, *E. tenella*, *E acervulina*, *E. brunetti*, *E. mitis*, (*E. mivati*), and *E. maxima*; in turkeys (growing) *E. adenoeides*, *E. meleagrimitis*, *and E. gallopavonis*; and in Chukar partridges (up to 8 weeks of age) *E. legionensis*; ***contraindications***: not to be fed to horses or other equid species
salinomycin-Na (sodium) (SAL) ●USA (40–60 chicken broilers, roasters, replacements, excluding layers), (50 quail, no use class stated or implied) ●EC (60–70 chicken broilers), (50: up to 12 weeks age replacements) ●Australia (60 chicken broilers, replacements, excluding layers)	*Bio-Cox (Alpharma USA, Australia) Type A Medicated Article, others (medicated feed), WT: USA, Australia 0d; other drug products (in USA: roxarsone or antibiotics combined with SAL) *Sacox 120; (Intervet EC), Type A Medicated Article (medicated feed), WT: EC 5d; other drug products	fermentation product of *Streptomyces albus* (introduced 1978); SAL is active against all pathogen *Eimeria* spp. of poultry and affects particularly developmental stages in the early and late phase of coccidia life cycle as sporozoites and late asexual stages (second/third schizont-generation); SAL has been reported to have a pronounced effect against *E. tenella* and *E. acervulina* (including against drug-resistant *Eimeria* spp. in the field); SAL is active against coccidia of the ***domestic rabbit*** (approval by EC, e.g., *Sacox 120: 20–25ppm); ***tolerability***: at recommended dose, SAL is toxic for turkeys (particularly in adult birds: growth depression, excitement followed by paralysis with head and legs extended, mortality), horses, and other equines; *tiamulin* interferes with metabolism of SAL in chickens and causes weight depression; ***approved indications*** *in birds* (*Bio-Cox, *Sacox, others): for prevention of coccidiosis in chickens (broilers, roasters, replacements) caused by *E. necatrix*, *E. tenella*, *E. acervulina*, *E. brunetti*, *E. mitis*, (*E. mivati*), and *E. maxima*; and in quail: *E. dispersa* and *E. lettyae*; approved indication as *growth promotor* (Australia, elsewhere): for improvement of productivity by stimulating the growth rate and increasing feed

Coccidiocidal Drugs. Table 1 Anticoccidial drugs used in the poultry industry (Continued)

CHEMICAL GROUP nonproprietary name (oral dose: g/ton feed or ppm: part per million), other information	*BRAND NAMES (manufacturer, companies, distributors), WT, other information	COMMENTS on efficacy, mode of action, toxicity, limitations as withdrawal time before slaughter (WT in days = d), target species, indication(s), contraindications and other information
conversion of grower (30–60ppm)/finisher (15–30ppm) ***pigs*** and **feedlot beef cattle** (15ppm), do not use in cows, which are producing, or may in the future produce milk or milk products for human consumption; ***limitations*** (USA, elsewhere): feed continuously as sole ration, do not feed to laying hens producing eggs for human consumption, not approved for use with pellet binders, may be fatal if accidentally fed to horses or adult turkeys		
narasin (approval for broiler chickens only) *1●USA (54–72) *1●EC (60–70) *1●Australia (60–80) **narasin/nicarbazin** (1:1) (total active ingredient) *2●USA (54–90) *2●EC, Australia (80–100) (in the USA: roxarsone or antibiotics combined with narasin or narasin/nicarbazin)	1*Monteban (Elanco AH; Eli Lilly, USA, Australia, EC) Type A Medicated Article, others (medicated feed), WT: USA, Australia 0d; EC 5d 2*Maxiban (Elanco AH; Eli Lilly, USA, Australia, EC) Type A Medicated Article, others WT: USA, EC 5d, Australia 0d	fermentation product of *Streptomyces aureofaciens* (introduced 1983) and closely related in its structure to salinomycin but not as active as this; to enhance activity, narasin has been combined with synergistic acting nicarbazin (2*Maxiban, introduced 1988); the combination may be used in starter phase of shuttle programs followed by a different ionophore in grower-finisher phase; 1*/2* ***approved indications***: for prevention of coccidiosis in chickens (broilers only) caused by *E. necatrix, E. tenella, E. acervulina, E. brunetti, E. mitis,* (*E. mivati*), and *E. maxima*; approved indication as *growth promoter* (Australia, elsewhere): for improved feed conversion efficiency in lot-fed *cattle* (approved: 5–13ppm); 1*/2* ***limitations***: feed continuously as the sole ration, do not feed to laying hens, do not use in laying hens, turkeys, or game birds, nor in horses or other equines (may be fatal), poultry consuming narasin should not be treated with *tiamulin* (severe growth depression or death may occur)
maduramicin ammonium (MAD) • EC (5 chicken broilers, turkeys growing up to 16 weeks) • USA (4.54–5.45 chicken, broilers only) • Australia (5 chicken broilers only)	*Cygro (Alpharma USA, Australia, EC) Type A Medicated Article, others (medicated feed), WT: USA, EC 5d, Australia 0d; ***limitations***: feed continuously as sole ration, do not use in birds which are producing or may in the future produce eggs or egg products for human consumption	fermentation product of *Actinomadura yumaense* (introduced 1984), having a sugar moiety as side chain (monoglycoside polyether); it has affinity to both monovalent and divalent cations and shows at very low dose levels a good activity against all pathogenic *Eimeria* spp. of chickens; cross-resistance with other polyether antibiotics has been reported soon after its introduction in the poultry industry and *Gromax (MAD/nicarbazin, introduced 1992) increased anticoccidial activity; ***limitation***: for the prevention of coccidiosis in broiler chicken; medicated feed containing *Gromax should be fed continuously to broiler chickens as the only ration; MAD is not as toxic as other ionophores for birds and mammals (not approved species like turkeys, guinea fowl, pheasants, geese, ducks, cattle, sheep, horses, pigs, or rabbits tolerate it at recommended dose level); it is well tolerated when fed with tiamulin; ***approved indications*** for *Cygro (*Eimeria* spp. of chickens and turkeys cf. lasalocid)
MAD/nicarbazin (3.75/40 chicken broilers) ***limitation***: do not use in birds, which are producing or may in future produce eggs or egg products for human consumption	*Gromax (Alpharma Inc. Australia) oral powder, Premix, WT 1d	
semduramicin Na (sodium) (SEM) approval for broiler chickens only • EC (20–25) • Australia (25) • USA (25) **SEM/roxarsone** (22.7/45.4) *Nitro/Aviax WT: 5d use as sole source of organic arsenic	*Aviax (Phibro AH; USA, Australia, EC), Type A Medicated Article, others (medicated feed), WT: USA, Australia 0d, EC 5d; other drug products (in USA: roxarsone or antibiotics combined with SEM, all WT 5d); do not feed to laying hens	fermentation product of a mutant of *Actinomadura roseorufa* (introduced 1991, latest ionophore on the market) developed as feed additive for the prevention of coccidiosis in broiler chickens; it is a monovalent monoglycoside polyether ionophore (parent strain produced a diglycoside form of SEM; this can be semi-synthetically modified to obtain the monoglycoside; both forms have identical anticoccidial activity); it is active against all pathogenic *Eimeria* spp. of chickens with pronounced efficacy against *E. maxima*;
cross-resistance with other polyether antibiotics has been reported in Europe, South America, and the USA soon after its introduction in the poultry industry; concurrent use of tiamulin and SEM is well tolerated; approved indications (USA): for prevention of coccidiosis caused by *E. tenella*, *E. acervulina*, *E. maxima*, *E. brunetti*, *E. necatrix*, and *E. mivati*/*E. mitis*;		

Coccidiocidal Drugs. Table 1 Anticoccidial drugs used in the poultry industry (Continued)

CHEMICAL GROUP nonproprietary name (oral dose: g/ton feed or ppm: part per million), other information	*BRAND NAMES (manufacturer, companies, distributors), WT, other information	COMMENTS on efficacy, mode of action, toxicity, limitations as withdrawal time before slaughter (WT in days = d), target species, indication(s), contraindications and other information
*Nitro/Aviax: including some field strains of *E. tenella* that are more susceptible to SEM combined with *roxarsone* than SEM alone; *general limitations*: feed continuously as sole ration, do not use in birds which are producing or may in the future produce eggs or egg products for human consumption		
ASYMMETRIC (1,2,4) TRIAZINES in the early 1980s there have been several 1,2,4-triazine derivatives under development, e.g., *clazuril* and *diclazuril* (US patent application to Janssen 1984) and HOE 092 V (DE patent application to Hoechst AG, 1985, drug development as a feed additive was discontinued during preclinical studies; there were adverse effects on endocrine system in rodents and feathering in chickens); HOE 092 V proved to be highly active against all pathogenic *Eimeria* spp. of chickens, turkeys, and rabbits; it had also an excellent effect against various pathogen protozoa and crustacean parasites of fish including a variety of gill- and skin-parasitizing monogeneans; thus a single medical bath (10 μg HOE 092 V/ml for 4 hours) was sufficient to kill trophozoites of *Ichthyophthirius multifiliis*; at higher dose levels also *toltrazuril* is active against various fish parasites; it belongs to the symmetric (1,3,5) triazines (cf. toltrazuril (below) and may be used as a therapeutic drug against coccidiosis of birds and mammals, e.g., swine)		
diclazuril (DZU) • USA (0.91/1ppm chicken, broilers not laying eggs for human consumption), (0.91 in combination with bacitracin methylene disalycilate 4-50g/ton of feed: turkey, growing, not laying eggs for human consumption) • EC (1 chicken broilers, replacements up to 16 weeks of age, turkeys, growing up to 12 weeks of age)	*Clinacox (Schering-Plough AH, USA, Janssen AH EC) (not commercially available in Australia), Type A medicated article (medicated feed), WT: USA 0d, EC 5d *Vecoxan (Janssen-Cilag, Germany, elsewhere) for calves (5 months of age), lambs, oral suspension (2.5 mg/ml), WT: 0d (single dose: 1mgDZU/kg b.w.) for prevention of coccidiosis	synthetic agent (introduced 1988), chemically a benzeneacetonitrile derivative with high anticoccidial activity when fed at low levels in feed; it has a strong anticoccidial activity against developing first- and second-generation schizonts, and gamonts of *E. tenella* and other pathogenic *Eimeria* spp. of chickens but developmental stages most affected by DZU varies with the *Eimeria* spp.; it is highly effective against *E. tenella* (all stages) but not so against *E. maxima* (gamonts only); because it is effective against this species later in its life cycle, subclinical intestinal lesions may be present for a short time after infection; nevertheless, DZU was shown in studies to reduce lesion scores and improve performance and health of birds challenged with *E. maxima*; when used for longer periods in straight programs, coccidia of chickens may develop resistance to the drug; for that reason it may be frequently used in shuttle programs; complete cross-resistance with *toltrazuril* may be evident in the field; DZU may be useful in the treatment of hepatic and intestinal coccidiosis of the domestic rabbit (currently not approved indication); ***approved indications*** (EC, USA, elsewhere): for prevention of coccidiosis caused by *E. tenella, E. necatrix, E. acervulina, E. brunetti, E. mitis* (*mivati*), and *E. maxima* in chicken, and *E. adenoeides*, *E. gallopavonis*, and *E. meleagrimitis*, for increased rate of weight gain and improved feed efficiency in turkeys; it appears to be compatible with other feed additives and is a very safe drug in various animals (chicken broiler, breeder, turkey, guinea fowl, quail, duck, mouse, rat, rabbit, dog, piglet, horse, cattle, sheep, and goat); ***limitations***: chicken feed continuously, not for use in hens producing eggs for human food; turkeys feed continuously as the sole ration, do not feed to breeding turkeys, not for use in hens producing eggs for human consumption
clazuril (5 mg/kg b.w., minimum, carrier pigeons only) not for use in pigeons producing eggs for human consumption	*Appertex (Janssen-Cilag, Germany, elsewhere), oral tablets (2.5 mg clazuril/tablet)	highly active against coccidiosis in pigeons (*Eimeria labbeana*, *E. columbarum*); law may restrict this drug to be used by or on the order of a licensed veterinarian; standard dose is usually 1tablet per pigeon (young, adult); treat all birds of a pigeon house; drug is well tolerated (overdose of 80, 320, and 640 mg/kg b.w. may produce emesis and diarrhea only); *limitations*: do not treat pigeons intended for human consumption
SYMMETRIC (1,3,5) TRIAZINES **toltrazuril** (TZU, *Baycox Bayer, Australia, Germany, elsewhere, introduced 1987) differs from diclazuril (an asymmetric 1,2,4 triazine above) principally in its pharmacokinetic properties (different biotransformation and excretion processes result in a long elimination half-life of TZU and consequently in long withdrawal periods before slaughter); thus TZU is not suitable to be fed continuously as a sole ration in poultry, other birds, and mammals; it is active against both developing first- and second-generation schizonts and gamonts of pathogenic *Eimeria* spp. of birds (e.g., chicken, geese, ducks and others) and mammals (e.g., cattle, sheep, goats, pigs, rabbits, and others); TZU inhibits nuclear division of schizonts and		

Coccidiocidal Drugs. Table 1 Anticoccidial drugs used in the poultry industry (Continued)

CHEMICAL GROUP nonproprietary name (oral dose: g/ton feed or ppm: part per million), other information	*BRAND NAMES (manufacturer, companies, distributors), WT, other information	COMMENTS on efficacy, mode of action, toxicity, limitations as withdrawal time before slaughter (WT in days = d), target species, indication(s), contraindications and other information
microgamonts and the wall-forming bodies of macrogamonts; because of similar mode of action of symmetric and asymmetric triazines there is cross-resistance between toltrazuril and diclazuril; intermittent administration of TZU via drinking water may help to establish efficient metaphylactic programs against coccidiosis in chickens and turkeys thereby allowing development of protective immunity; TZU may be used for the control of coccidiosis in neonatal ***piglets*** caused by *Isospora suis* (*Baycox Piglet Coccidiocide, Australia, oral liquid: 50 gTZU/L: 1mL/3–6 day-old piglet once, WT: 70d); *Baycox Bovis (50 mg/ml suspension, Bayer Vital Germany) can be used (15 mg/kg b.w. × 1, per os) to prevent coccidiosis in ***calves*** up to 5 months of age (WT 63d); moreover it has a broad-spectrum antiprotozoal activity against *Sarcocystis* spp., *Toxoplasma gondii*, *Cystoisospora* spp., and *Hepatozoon* spp. of mammals; its activity is also directed against **fish parasites** such as microsporidia, myxozoa, and monogeneans, or *Nosema* apis of bees; TZU is very well tolerated in birds, mammals, and fish; ***approved dosage regimens*** in ***chickens*** (Australia, elsewhere) (*Baycox Coccidiocide Solution, 25 gTZU/L oral liquid, dose rate: 3L/1000L, WT: 14d chickens) is intended for use in treatment programs (e.g., in case of a clinical outbreak of coccidiosis in chickens) and is given via drinking water in an 8-hour treatment period each day for 2 days, if required, treatment may be repeated after 5 days; it can be also used in preventive coccidiosis programs on days 9 and 10, 16 and 17, and 23, and 24 of life; an additional administration may be necessary after 35 days but not within the 14 days withdrawal period of slaughter; approved dosage regimens (Germany, elsewhere): treatment of coccidiosis in chickens and turkeys via drinking water on 2 successive days continuously for 24 hours/day (*Baycox 2.5%, oral liquid, WT: chicken 21d, turkeys 18d; dose rate 1mL/L drinking water = 25 ppm TZU), or as alternate: continuously for 8 hours/day (*Baycox 2.5%, oral liquid, dose rate 3mL/L drinking water = 75 ppm TZU), minimum dose should be 7 mg/kg b.w./day; ***general limitations***: eggs do not use TZU within 6 weeks prior to laying of eggs to be used for human consumption or processing, do not use in replacements over 15 weeks of age; law may restricts this drug use by or on the order of a licensed veterinarian; drug products containing TZU are not commercially available in the USA		
AUTHORIZATION OF FEED ADDITIVES AS COCCIDIOSTATS Only feed additives that were granted an authorization following a scientific evaluation for example by the US Food and Drug Administration (*FDA) Center for Veterinary Medicine (*CVM), the Australian Pesticides and Veterinary Medicines Authority (APVMA's), the European Food Safety Authority (EFSA), or other National Authorities will be put on the market. These authorities regulate the manufacture and distribution of approved feed additives (*and drugs) that will be given to animals. Concerning this table, approved feed additive products for target species (animals) listed as of year 2006/2007 (and possibly following years), are available on the market in all Member States of Europe, the USA, Australia, and elsewhere.		
Currently, European Parliament and Council Regulation 1831/2003 (replacing Directive 70/524/EEC) regulate the use of additives in animal nutrition. It sets out rules for the authorization, marketing, and labelling of feed additives, including the category <coccidiostats and histomonostats> previously authorized under Regulation 70/524/EEC. Regulation 1831/2003 also completes the *ban on antibiotic growth promoters* (January 1, 2006) in feed by prohibiting the use of 4 antibiotic substances (monensin sodium, salinomycin sodium, avilamycin, and flavophospholipol). The EU has already banned antibiotics used in human medicine from being added to animal feed. The Commission's overall strategy is to tackle the emergence of bacteria and other microbes resistant to antibiotics, due to their overexploitation or misuse. Antibiotics will now only be allowed to be added to animal feed for veterinary purposes.		
Commission Regulation (EC) No. 600/2005 (Annex I 'coccidiostats and other medicinal substances') laid down conditions for submission and application for a new authorization for 10 years of coccidiostats as additives in feeding stuffs. Most in-feed substances (at least one target species as broiler chicken, doses) listed in Table 1 are already authorized for 10 years (2014/15), such as decoquinate (756), monensin natrium (E 757), robenidine hydrochloride (758), lasalocid-A-natrium (E 763), narasin (E 765), salinomycin natrium (E 766), or less than 10 years such as diclazuril (E 771: 2009-2013), halofuginone hydrobromide (E 764: pullets, 2009), narasin 80 g/kg-nicarbazin 80 g/kg (Maxiban G160) (E 772: 2009), maduramin-ammonium alpha 1g/100 g (E 770: 2009/11: broiler chicken/growing turkeys), and semduramicin natrium (29/: June 2006, withdrawn ?). Withdrawn authorization (Directive 70/524/EEC) of feed additives as coccidiostats entered into effect on 1999 for arprinocide and dinitolmide (EC regulation 45/1999), and on 2001 for amprolium, amprolium/ethopabate, meticlorpindol, meticlorpindol/methylbenzoquate, and nicarbazin (EC regulation 2205/2001).		

Data of drug products (approved labels) listed in this table refer to information from literature, manufacturer, supplier, and websites such as the European Medicines Agency (EMEA), Committee for Veterinary Medicinal Products (CVMP), the US Food and Drug Administration (FDA), Center for Veterinary Medicine (CVM), the Australian Pesticides and Veterinary Medicines Authority (APVMA) and associated Infopest (search for products), VETIDATA, Leipzig, Germany, and Clini Pharm, Clini Tox (CPT), Zurich, Switzerland. Data given in this table have no claim to full information

(chiefly young ones) may die very soon after the first clinical signs are seen. Since coccidia have a self-limiting life cycle, the acute phase of infection may have already passed before therapeutic treatment can be started. Thus, **treatment** is usually too late to prevent economic loss. All classes of domestic animals can be affected by coccidia, and losses due to coccidiosis in mammals (particularly in bovines: cattle, sheep, goats, swine, and rabbits) are difficult to determine. The expenses of management practices and the cost of preventive or therapeutic drugs are the main points of consideration. Using suitable control measures can minimize symptoms of the disease. There should be **strict sanitation** to prevent feed and water being contaminated by feces, and feedlots, pens, cages, or hutches should be kept dry and well drained and be cleaned out regularly (preferably every day in rabbitries). When outbreaks occur in pasture, water holes and ditches should be fenced off. Crowding of young animals should be avoided.

Negative effects of intensive animal production are numerous. Thus manure/mineral (phosphate/nitrate) accumulation (used as fertilizer), →ammonia emission, (one of main causes for acid rain), dead animal disposal, flies nuisance in densely populated areas, and availability of sufficient water of feed quality may increasingly lead to legislative restrictions and costs involved in preserving protection.

Development of Acquired Immunity

Anticoccidials (Table 1) used in poultry may affect stages of the parasite inducing immunity. Pullets intended as commercial layers must develop immunity to coccidiosis when they receive preventive drugs. However, **anticoccidials**, which are effective against second-generation schizonts, can seriously delay the development of immunity if they are given at the dose levels recommended for broilers. Therefore, they should be fed at the lowest possible dose level and for the shortest practical period that give sufficient anticoccidial protection and allow progressive development of immunity in replacement pullets. One of the effects of immunity is to reduce the biotic potential of the coccidia; each →oocyst of the common chicken coccidium *E. tenella* is theoretically able to produce about 2.5 million second-generation merozoites although this maximum number may only occur in the case of initial infection. In partially immune animals, however, only some of the parasites complete their life cycle and produce variable oocyst numbers. In completely immune animals a few or no oocysts are produced for prolonged periods of time; some of the parasites may persist in an asexual stage within the host and thus fail to get further than the initial stage of trophozoite or first-generation meront. As a result, immunity to a challenge inoculum usually leads to a reduction in the clinical signs and in parasite multiplication. The specificity of immunity to →*Eimeria* spp. is well known, although there may be considerable strain variations in immunity in some species of coccidia in commercial poultry houses as has been shown with *E. acervulina* and the very immunogenic *E. maxima*. The duration of protective immunity is uncertain and depends on several factors like mode of immunization, inoculum dose, age of the host, as well as on *Eimeria* spp. and strain variation. It is not yet clear whether immunity is of the sterile or premunition type. It seems likely that immunological control of poultry coccidiosis is achievable. In the not too distant future it will replace →chemoprophylaxis coming increasingly under public pressure because of drug residues in edible tissues and occasionally in eggs (→Chemotherapy/Withdrawal Time of Drugs in Target Animals). →Vaccination with attenuated or precocious strains of *Eimeria* spp. will be therefore an attractive alternative for parasite control since it lacks residual problems. In general, anticoccidials do not adversely affect build up of immunity after vaccination programs against bacterial and viral infections.

Coccidiosis in the Domestic Fowl

The disease is responsible for considerable losses in the poultry industry. Rearing of thousands of birds on litter-covered floors in enormous houses may result in a tremendous and dangerous buildup of the oocyst population (→*Eimeria*). A change from litter-covered floors to wire-floored pens greatly reduces the exposure to coccidia. Thus, outbreaks of coccidiosis in laying hens maintained in cages rarely occur. In general, the prophylactic use of anticoccidial drugs is not required if the cages are kept clean and the feces do not contaminate watering and feeding systems. However, discouraging results have been obtained from experiments to convert broiler and breeder flocks entirely to cage operations (the most obvious problems being high equipment and maintenance costs, breast blisters, leg problems, removal of droppings and dead birds, and housefly control). Today most poultrymen rely on **floor rearing methods** for broiler production or breeder flocks and use continuous medication programs. Poultry producers also attempt to control coccidiosis by employing good sanitary programs. Litters should be kept dry so that oocysts cannot sporulate – many outbreaks occur after leaks in roofs or waterers. Wet litter must be cleaned out and replaced with dry litter. When broiler houses are emptied for a new batch of chickens the litter should be piled up for about 24 hours so that the heat generated can destroy the majority of oocysts. **Disinfection** is usually impractical since oocysts are resistant to disinfectants used against bacteria, viruses, or fungi. In parasitology laboratories where disinfection is needed, heat (30 minutes at 60°C) or "effective" fumigants such as ammonia and methyl bromide may be used.

Despite the use of continuous medication programs (see Drugs Acting on Coccidiosis of Domestic Fowl, Table 1), coccidiosis is still the most important parasitic disease in chickens. As a rule young birds are prone to mixed infections and older birds are carriers. In many outbreaks, however, clinical signs can be ascribed to one species or a combination of 2 or rarely 3; signs of coccidiosis become apparent about 3 days after infection; chickens cease feeding and huddle together for warmth; on the fourth day of infection blood may appear in the feces.

The *Eimeria* spp. of the domestic fowl show marked differences in their **pathogenicity**. *E. tenella* is the most pathogenic and important species occurring in the epithelial cells and submucosa of the ceca; it may produce severe hemorrhagic enteritis, which leads to high mortality in young birds. *E. necatrix* is also a common and highly pathogenic species, which occurs in the small intestine (first- and second-generation schizonts) and in the ceca (third-generation →schizont and gamonts). It tends to cause predominantly chronic enteritis in older birds but in acute cases severe submucosal hemorrhaging and even death may occur. *E. acervulina* (probably the most common species seen) occurs in the small intestine. The pathogenicity of *E. acervulina* strains may vary, and the clinical signs consist of weight loss and watery, whitish diarrhea. *E. maxima* is also common; it occurs in the small intestine and is moderately pathogenic causing numerous petechial hemorrhages and a marked production of mucus. *E. brunetti* is markedly pathogenic but relatively uncommon. In heavy infections, characteristic necrotic (hemorrhagic) enteritis is evident in the lower small intestine, colon, and tubular part of the ceca. *E. mitis* is common worldwide and occurs throughout the small intestine, even in the tubular part of the ceca. This species is slightly or moderately pathogenic; in severe infections numerous petechial hemorrhages may be present. *E. mivati* is fairly common in the USA and Canada (presumably worldwide) and seems to be more pathogenic than *E. acervulina*. It primarily occurs in the upper small intestine and has been included by several authors as a variant of *E. acervulina*. The pathogenicity of *Eimeria* spp. in particular that of *E. acervulina* and *E. tenella* seems to be reduced by intestinal digesta viscosity reducing enzymes as xylanases, glucanases, and pectinases. These enzymes may improve the nutritional value of wheat- or maize-based diets but mechanisms involved in reducing growth depression in coccidial infections are not yet known and need to be elucidated.

Economic losses (see Economic Importance) due to **subclinical infection** of avian coccidia are enormous and much more common than coccidiosis, and coccidiasis should be regarded as ubiquitous in commercially reared poultry. Because some species of coccidia are highly pathogenic while others are only slightly or moderately pathogenic the species present must be identified. Scrapings from the mucosal surface of the intestine of affected birds should be examined microscopically for oocysts and endogenous stages of the parasite, and the location and type of lesions determined to establish a definite diagnosis.

Coccidiosis of Turkeys

The disease may cause heavy economic loss in the turkey industry; it is primarily a disease of young turkey poults (aged 3–10 weeks); older birds are carriers. **Clinical signs** are enteritis, watery or mucoid diarrhea, and →anorexia. The most pathogenic and important coccidia are *E. meleagrimitis* (located in the jejunum) and *E. adenoeides* (located in the lower ileum, ceca, and rectum); several species (in particular *E. innocua*, *E. subrotunda*, and *E. meleagridis*) are nearly nonpathogenic. Therefore, oocysts of the latter species must be differentiated from the pathogenic ones as well as those of *E. gallopavonis* (lower small intestine, ceca, and rectum) and *E. dispersa* (duodenum, jejunum, ileum), which are not so common, and only slightly or moderately pathogenic. The presence of oocysts (even large numbers) in the feces can only be a tentative diagnosis for coccidiosis; satisfactory diagnosis can only be made at postmortem.

Coccidiosis of Geese and Ducks

The disease seems to be of relatively little importance although several homoxenous coccidia are known. Some of these may be associated with severe disease and even death. *E. truncata* is highly pathogenic to goslings, and occasionally causes up to 100% mortality within a few days; older birds are carriers. This species occurs in the kidney tubules; its endogenous stages destroy the epithelial cells, causing enlarged and light-colored kidneys. Other species (goose: *E. anseris, E. nocens, E. truncata, E. kotlani*, duck: *E. kotlani, E. danailovi, Tyzzeria perniciosa*) appear to be important in areas where crowding and poor sanitation are present. Thus, large numbers of sporulated oocysts in a muddy environment often lead to sporadic outbreaks of intestinal coccidiosis.

Action of Drugs on Developmental Stages of Eimeria spp.

The terms coccidiostatics and coccidiocidals (coccidiocides) for drugs, which characterize actions on coccidia, are often used confusingly. Drugs with a **coccidiostatic action**, such as clopidol or decoquinate, dinitolmide (Table 1), arrest the development of certain parasite stages in a reversible way; thus withdrawal of the drugs leads to completion of the life cycle and possibly the appearance of clinical signs several days after medication is discontinued. Drugs with **coccidiocidal action**, such as arprinocid, halofuginone, polyether antibiotics, toltrazuril, diclazuril and clazuril

(Table 1), kill or irreversibly damage most of certain parasite stages, and there is no evidence of clinical relapse after drug withdrawal. Some drugs (e.g., nicarbazin, amprolium) may have both coccidiostatic and coccidiocidal activity depending on how long the drugs and in which concentration they have been given in the feed or water. Continuous medication of these drugs for more than 48 hours usually results in the majority of parasitic stages being damaged. Polyether antibiotics mainly affect asexual *Eimeria* stages as sporozoites, schizonts of the first and second generation. Flow cytometric analysis has been shown to be a reliable and sensitive technique for characterizing coccidiocidal effects on sporozoites exposed to various ionophores *in vitro*. Diclazuril acts against most stages of *Eimeria* spp. but this may vary between species (e.g., in *E. maxima* gamonts only); this is also true for clazuril. Prophylactic drugs may preferably act on early and/or late asexual stages in the life cycle, like polyether antibiotics, decoquinate, clopidol, robenidin, nicarbazin, halofuginone, diclazuril, or amprolium +ethopabate. A few **therapeutic drugs** used for treating outbreaks of coccidiosis may affect stages of second- and third-generation schizogony and to a certain degree →gamonts (sexual stages) as well; drugs reducing clinical signs of coccidiosis are amprolium, sulfonamides, clazuril, toltrazuril, and combinations of sulfonamides+dehydrofolate reductase inhibitors (Table 1). Toltrazuril administered in drinking water has brought substantial progress in treatment of coccidiosis in various animals. It has a broad spectrum of activity against various parasitic protozoa, and unlike other anticoccidials, it acts against schizonts and gamonts of various →*Eimeria* and →*Isospora* spp.

Drugs Acting on Coccidiosis of Domestic Fowl

Today, chemoprophylaxis in continuous medication programs appears to be the only effective tool for controlling coccidiosis in floor-reared poultry although drug resistance in *Eimeria* spp. populations is a widespread problem in the broiler industry today. Strategic use of anticoccidials may thwart the development of resistance processes (see Measures Against Drug Tolerance in the Broiler Industry). However, neither improved sanitation nor vaccination of birds with pathogen species of live precocious oocysts (e.g., Paracox, Livacox, see →Coccidiosis, Animals/Table 1) via drinking water or feed can sufficiently substitute continuous medication programs today. The prophylactic use of anticoccidials is based on the application of additives in-feed, i.e., drugs are added directly to bird feed in small quantities, usually in concentrations of a few ppm (part per million). Such anticoccidials are approved by governmental agencies for use in growing birds (e.g., chickens, turkey, others). Thus, prescribed concentration rations of these drugs can be fed to licensed table birds *ad libitum* from the beginning of their life (fattening/growing period) to a prescribed preslaughter withdrawal time, or age at first egg, or start of cage or battery keeping of pullets. Additives in-feed used worldwide for the prevention of poultry coccidiosis and therapeutic anticoccidials are listed in Table 1. There are (1) synthetic compounds (e.g., amprolium, clopidol, decoquinate, diclazuril, halofuginone, nicarbazin, or robenidine), (2) polyether antibiotics or ionophores (lasalocid, maduramicin, monensin, narasin, salinomycin, semduramicin), and (3) drug combinations (e.g., amprolium+ethopabate, narasin+nicarbazin, maduramicin+nicarbazin). Most **continuous medication** programs may last 35–40 days, i.e., from the beginning of the fattening period to a fixed time prior to slaughter of birds. **Withdrawal times** (→Chemotherapy/Withdrawal Time of Drugs in Target Animals) for most prophylactically used anticoccidials may last 0–5 days and longer (e.g., toltrazuril, 14 days), or may exceed 5 days for other reasons, e.g., to minimize costs, or to promote "compensatory growth." A withdrawal time longer than 5 days may lead to enhanced risk of coccidiosis at the end of fattening period, particularly if environmental →hygiene is poor. The prophylactic use of anticoccidials in-feed in **egg-laying birds** is not permitted, although the occurrence of residues of anticoccidials in eggs has been widely proven; carryover of medicated feed in the feedmill or elsewhere must be the cause. Sensitive and specific analytical assays, as spectophotofluorometry, liquid chromatography, high performance liquid chromatography (HPLC), the qualitative vanillin test and others, are available to detect the parent compound (metabolites) or their residues in feed, edible tissues, and eggs of target animals or nontarget animals. In case of outbreaks of coccidiosis **therapeutic drugs** (e.g., amprolium, sulfonamides, dehyrofolate reductase inhibitors plus sulfonamides, toltrazuril) are preferably administered via drinking water for a 3- or 5-day treatment course, and withdrawal periods may exceed 14 days. In practice, this means that medication towards the end of the growing life of birds is not economically possible, and this is also true for drugs used outside their product license; such drugs may also require withdrawal periods that exceed 14 days. So often the medicines regulations how they relate to the withdrawal periods stipulated for therapeutic drugs and given to food animals withhold birds (meat chickens, ducks, turkeys) from the possibility of treatment for a significant part of their life.

Drugs Acting on Coccidiosis of Turkeys, Geese, Ducks, and Gamebirds

Approved additives in feed, and maxima concentrations (EC directives, for new regulation 1831/2003: use of additives in animal nutrition cf. last page of Table 1) for prevention of coccidiosis in turkeys are

shown in Table 1. Drugs may be e.g., amprolium + ethopabate, diclazuril, halofuginone, lasalocid, monensin, and robenidine. The turkey industry (mainly found in the USA) has till now been rather small compared to that of chicken broilers. The most suitable drug program in turkeys is continuous medication but anticoccidial treatment covers only a part of the growing period of birds (till 12–16 weeks of age or 8–10 weeks of age if birds are moved to outside pastures or larger facilities). At this time →acquired immunity may be established in most of the birds; however, some birds may still be susceptible to damaging infections 12 weeks after the growout start. Intermittent medication is used relatively often since continuous anticoccidial programs are not universally practiced with turkeys up to 8 weeks of age because of the high resulting costs. Concentrations in the feed are generally in the same range as those administered in chicken broiler rations. There is evidence from field experience that drug resistance in coccidia of turkeys may exist. Generally it seems not to be a major problem although monensin resistance has been demonstrated in *E. meleagrimitis* field isolates. Under experimental conditions a drug sensitive laboratory strain became resistant to the drug after 10 generations of selection.

Drugs Acting on Coccidiosis (Eimeriosis) of Ruminants and Horses

Bovine →**eimeriosis** (the most pathogenic species are *E. zuernii* and *E. bovis*) is primarily a disease in calves between the ages of 3 weeks and 6 months; older calves and adult animals are usually symptomless carriers. Crowding and lack of sanitation greatly increase outbreaks of disease. Coccidiosis in sheep and goats is often a disease of feedlot lambs, and often occurs in breeding flocks. Mixed infections build up to a peak that may last 1–4 weeks and then decline. *E. ovina* (sheep), *E. ashata* (sheep), *E. ovinoidalis* (sheep), *E. arloingi* (goat), and *E. christenseni* (goat) are of clinical importance. Batch rearing of lambs or calves in groups of similar ages may limit the buildup and spread of oocycts to younger animals thereby targeting potential treatment measures. Little information is available on the eimeriosis of **equines**, mainly caused by *E. leuckarti* in the small intestine or *Klossiella equi* in the kidneys of foals. Coccidiosis in horses (including asses and mules) seems to be very rare. Beware of polyether antibiotics in-feed in environment of horse facilities; they are highly toxic to equines.

Most drugs used in **cattle** are approved for the prevention of coccidiosis in poultry. The demand for grainfed beef has led to cattle rearing techniques (large feedlot complexes) that may encourage damaging infection pressure. Only a few drugs have been approved for treatment in cattle by some governments. **Decoquinate** (Table 1) is approved in several countries for the treatment and prophylaxis of bovine coccidiosis. The tissues of treated calves that had been on continuous medication with decoquinate were free of schizonts, gamonts and oocysts. The drug apparently kills *E. bovis* sporozoites or arrests their further development if administered at 1.5 mg/kg b. w. in-feed.

Coccidiosis in bovines is often wrongly considered to be a sporadic disease with the result that drugs have rarely been used for prophylaxis. Outbreaks of the disease are still handled by spot treatment using therapeutic drugs as sulfonamides, e.g., sulfaguanidine, sulfamethazine, and sulfadimidine or sulfaquinoxaline. Combinations of sulfonamides with trimethoprim are used in manifest coccidiosis in cattle, sheep, and goats. Decoquinate or amprolium (Table 1) are also effective against bovine coccidia. Amprolium and lasalocid are used in the USA for treatment of clinically ill calves and lambs. **Toltrazuril** (15 mg/kg × 1 orally) is very effective against bovine coccidiosis of cattle, sheep and goats (Table 1). **Preventive drugs** such as ionophorous antibiotics (monensin, or salinomycin) only approved for prevention of coccidiosis in poultry also exhibit distinct activity against coccidiosis in ruminants. The doses of monensin, and salinomycin used for improving feed efficiency in feedlot and pasture cattle correspond to the doses reported to prevent coccidiosis; it is assumed that the anticoccidial "side effect" of these "growth promotors" may considerably reduce coccidiosis problems in feedlot cattle. Calves artificially infected with *E. bovis* (88%) and *E. zuernii* were given lasalocid in-feed at 0.50, 0.75, or 1.0 mg/kg b.w., daily for 45 days. There were no dose-dependent effects but equal reduction rates in oocyst output and preventing clinical coccidiosis. Calves given lasalocid, decoquinate, or monensin in-feed at 33 ppm for 46 days had significantly fewer oocysts in feces and fewer clinical signs of coccidiosis than those given nonmedicated rations. Mixing lasalocid in milk replacer or fresh milk (1mg/kg b.w./day) is an effective method of protecting young calves against early infection with coccidia. **Decoquinate** can be also used as a feed additive approved for the prevention of coccidiosis in sheep and **goats** (Table 1). Ionophores in-feed such as monensin, lasalocid, or salinomycin prove effective also in preventing coccidiosis in sheep, and goats; against caprine coccidia they are, however, only moderately active. Treatment of coccidiosis in lambs and kids is done with drugs used in cattle. Often animals are clinically ill when the disease is diagnosed. At this time the intestinal mucosa is already extensively damaged, and consequently treatment cannot lead to a radical cure. As a rule, all lambs and kids in a flock should be treated, as even those showing no symptoms are likely to be infected. Fluid therapy using either oral rehydration solutions or parenteral solutions, and appropriate anthelminthic treatment are indicated in severely affected animals.

Drugs Acting on Coccidiosis (Eimeriosis) of Rabbits

Coccidiosis in rabbits is essentially restricted to the young (adults are carriers) and occurs particularly in breeding and rearing establishments (rabbitries) although outbreaks of coccidiosis in warrens or similar types of habitat are not uncommon. The most important species seems to be *E. stiedai*, which is common, worldwide and occurs in the walls of the bile ducts in the liver causing hepatic coccidiosis. Other important and pathogenic species, which may occur in the intestine, are *E. irresidua*, *E. magna*, *E. intestinalis*, *E. media*, and *E. perforans*; mixed infections are the rule. The presence of parasites in a case of enteritis does not necessarily indicate the cause. Coccidia may be present in large numbers without any serious clinical signs. Therefore, the most satisfactory diagnosis is made at postmortem; only the presence of characteristic lesions are evident in the liver/or the intestine.

There are only a few additives in-feed approved for the prevention of rabbit coccidiosis in Europe or elsewhere. These are robenidine (50–66 ppm), and salinomycin (20–25 ppm). Preventive administration of salinomycin in pelleted feed at 25 ppm may not only reduce markedly the oocyst production but lead to almost total inhibition of hepatic and intestinal lesions as well. Several **sulfonamides** can be used for the **therapy** of coccidiosis. They may be given in various routes and dosage forms (in-feed, in-water, and as injection). Their preslaughter withdrawal times may range between 8 and 15 days. **Sulfaquinoxaline** (relatively cheap and water soluble) seems to be the most widely used sulfonamide for treating rabbit coccidiosis, and it has been found to be just as helpful in preventing coccidiosis when given in continuous medication programs in feed or water. The drug of choice for treatment of intestinal and hepatic coccidiosis appears to be toltrazuril. However, a proper management and good hygiene in rabbitries can markedly reduce long-term medication and treatment with anticoccidials.

Drug Acting on Coccidiosis of Swine, Dogs, and Cats

Coccidiosis in **swine** is mainly restricted to young pigs; older pigs are carriers. *E. debliecki* and *E. scabra* are probably the most pathogenic species. *Isospora suis* has also been found to cause severe enteritis; however, intestinal disorders are so common in baby and young pigs and are caused by so many different pathogens that a diagnosis based only on fecal examination is not definite. Only a very large number of oocysts can indicate that coccidiosis is present. *Isospora suis* is an important causative agent of porcine neonatal diarrhea worldwide; it may occur on any farm with any type of management system and at any time of the year although feces samples of sows always proved negative. Most canine and feline coccidia are usually nonpathogenic or only moderately pathogenic; however, coccidiosis in **dogs** and **cats** may be an important cause of the diarrheic syndrome often associated with secondary infections in puppies and kittens. Affected animals are frequently seen in breeding kennels and runways where sanitation is poor. Diagnosis is not definite if it is only based on clinical signs (e.g., diarrhea with blood in the feces), or on the presence of large numbers of *Isospora* spp. oocysts in the feces; postmortem examination is the most adequate diagnosis method. Coccidial infections in dogs and cats may also be caused by heterogeneous genera (→*Sarcocystis* spp. in dogs, and *Sarcocystis* spp. and →*Toxoplasma gondii* in cats, see respective entries).

The most commonly used compounds for treatment of coccidiosis in dogs, cats (and piglets: Table 1) are **sulfonamides**, and **toltrazuril** affecting mainly later asexual stages of the schizogony cycle and to a certain degree sexual stages (gamonts). There are only a few controlled studies with experimental infections and no reliable evidence of practical problems associated with *Eimeria* spp. in swine. In contrast, *I. suis* infections appear to have become an economically important diarrheal disease in young piglets during the last 2 decades, and modern production systems seem to encourage the disease. Mortality due to *I. suis* infections may reach 10–20% in nursing pigs, and a similar percentage may be severely stunted. *I. suis* infections causing severe enteritis or even death in piglets have been treated successfully with amprolium (not approved indication); medication of sows with amprolium for 1–2 weeks before and after farrowing and of neonatal piglets may be helpful in reducing morbidity and mortality. Administration of toltrazuril in piglets (a single dose: 20 mg/kg, orally between 3 and 6 days of age) has been shown to reduce the morbidity in piggeries. There was a significant reduction in the number of antibacterial treatments given to piglets, fewer piglets developing diarrhea, and a significant improvement in growth rate of piglets. *I. suis* was detected in 38–50% of fecal samples from several piggeries and in 93% of those from the experimental piggery. Supportive treatment with antibiotics (e.g., chlortetracycline or oxytetracyclines) may reduce secondary bacterial infections in the intestine of piglets with severe enteritis. **Good sanitation** can effectively reduce diarrhea caused by *I. suis* infection in neonatal piglets in large farrowing facilities.

Drug Tolerance Problems in the Broiler Industry

A new successful drug should have competitive advantages over other available drugs, e.g., high potency and broad-spectrum activity. Furthermore, at the recommended doses the coccidia must not be allowed to develop resistance or to survive for a longer

period. The reduction in coccidial sensitivity to any drug (partial drug resistance) encourages the development of subclinical or subacute coccidiosis. Low levels of infection usually cause a moderate drop in feed conversion and thus lead to considerable economic losses in the poultry industry.

The development of drug resistance may be evident if a change in the parasite can be demonstrated by comparing sensitivity before and after exposure to the anticoccidial. Possible causes for **drug failure** in the field may result from selection of resistant organisms, which rapidly become the dominant phenotype in broiler houses. Resistance is commonly believed to arise initially in the presence of "subtherapeutic" or lower than recommended drug concentrations. Contrary to that suggestion, it has been argued that resistance may occur more rapidly in the presence of higher drug concentrations as a result of a more rapid change in gene frequency caused by increasing the intensity of selection. Studies on the incidence of drug resistance in the field and in experimental investigations have shown that resistance among strains of coccidia to **synthetic drugs** such as 4-hydroxyquinolines (e.g., decoquinate, methylbenzoquate), arprinocid, meticlorpindol, and halofuginone is relatively high. The resistance may result from the selection of preexisting mutants in the parent population. Thus drug resistance appears to be a genetic trait and tends to remain in a coccidia population for some years. Recent investigations on intraspecific polymorphisms of *Eimeria* spp. due to drug resistance indicate that differences in drug sensitivity correlate with genetic differences and polymorphisms detected by random amplified polymorphic DNA (RAPD) might facilitate the selection of molecular markers for resistance genotyping.

***In vitro* studies** on uptake of [^{14}C] monensin by *E. tenella* sporozoites in primary chicken kidney cell cultures infected with ionophore-sensitive (IS) or ionophore-resistant (IR) isolates showed significant differences in [^{14}C] monensin accumulation between IS and IR isolates. The latter isolates had decreased uptake of monensin and the amount of the drug required to inhibit development of *E. tenella* by 50% was 20–40 times higher for IR isolates of *E. tenella*, which might reflect differences in membrane chemistry. Studies on an *E. tenella* field isolate that was resistant to monensin, salinomycin, and lasalocid at double-use level and resistant to narasin and maduramicin at normal-use level showed good agreement between *in vitro* and *in vivo* results. Flowcytometric analysis of fluorescence after simultaneous exposure to fluorescein diacetate (FDA) and propidium iodide is a suitable indicator of cellular viability and proved to be a valuable technique in the study of →sporozoite response to anticoccidials. Thus, various improved *in vitro* techniques in research programs have become increasingly important in recent years. They may be a supplement to and, occasionally, a substitute for *in vivo* experiments in certain fields of the basic research, as in the field of biotechnology of poultry and farm animals. A first practical approach to countering **drug resistance** in the field may be an increase in the drug concentration. Increasing the drug concentration to compensate drug tolerance of coccidia is not only uneconomical but can also lead to toxic problems since several anticoccidials (e.g., nicarbazine, halofuginone, and various ionophorous antibiotics) are used at doses which are close to toxicity levels in birds. With the exception of some ionophorous antibiotics, such as monensin, salinomycin, and lasalocid, none of the synthetic drugs introduced have enjoyed prolonged marketability without developing tolerance problems in the broiler industry. The continuing success of the ionophorous antibiotics (monensin was introduced in the USA in 1971) is a result of their broad-spectrum activity, and possibly because resistance in coccidia may not be able to develop by the mechanisms known to occur for synthetic drugs. There have also been early reports that monensin "resistant" *E. maxima* strains may be present in the field. Later selected *Eimeria* spp. from broiler farms in the USA and Europe revealed that control of some isolates to *ionophorous drugs* was poor although none of the isolates judged in sensitivity tests was found to be completely resistant to the ionophores tested. Thus, prolonged use of ionophores in poultry units for nearly 10 years led to a decrease in their anticoccidial activity. Salinomycin provided the best overall control, followed by lasalocid and monensin. The latter findings are in agreement with results obtained from field studies on the comparative efficacy of salinomycin and monensin in 17 controlled field trials. They included more than 2 million broilers and were carried out in several European countries, and salinomycin at 60 ppm showed performance advantages over monensin at 100 ppm. Maduramicin proved to be more effective against ionophore-tolerant field isolates of broilers than monensin and narasin, but showed similar activity to salinomycin in reducing lesions and mortality and in protecting performance. Although **side-resistance** (colateral resistance) among related ionophores such as monensin, salinomycin, and narasin may occur "cross-resistance" between maduramicin and unrelated ionophores has also been reported; it is believed by some investigators that maduramicin is effective against strains resistant to the other ionophores. Results from drug-sensitivity tests with isolates of coccidia from broiler chickens in the USA, Brazil, Argentina, and Europe suggested in many cases incomplete side resistance of coccidia to polyether ionophorous drugs. Some field isolates revealed even complete multiple **cross-resistance** to synthetic and polyether antibiotics including maduramicin, and semduramicin (latest ionophore introduced into the market). An *E. acervulina*

laboratory strain, which was resistant to monensin by passaging the strain 14 times in the presence of the drug (100 ppm), was shown to be sensitive to lasalocid but not to maduramicin, narasin, and salinomycin. Cross-resistance between the latter ionophores may suggest a similar mode of action in coccidia. Thus, monensin, maduramicin, narasin, and salinomycin, preferentially form complexes with monovalent (e.g., Rb^+, Na^+, K^+, Cs^+) rather than divalent alkali metals (e.g., Ca^{++} in case of lasalocid), which may mediate electrically neutral exchange diffusion cation transport across membranes. Contrarily, a monensin-resistant *E. meleagrimitis* strain exhibited cross-resistance to narasin and lasalocid and a field isolate of *E. tenella* showed cross-resistance between lasalocid and several ionophores preferentially forming complexes with monovalent cations. To slow down development of drug resistance in coccidia alternate use of anticoccidials is widely practiced in the poultry industry.

Measures Against Drug Tolerance in the Broiler Industry

As shown by epizootiological investigations, coccidial drug resistance poses a serious economic problem to intensive poultry farming both in the USA, in Europe, and elsewhere. Today, there is therefore an increasing use of **shuttle** or **dual programs** (rapid rotations), i.e., the switching of anticoccidials during broiler growout. The drug(s) to be switched should belong to different chemical classes (e.g., ionophore/synthetic drug or vice versa during starter/final phase of production) and should be effective at different stages of the parasites' life cycles. Any resistant coccidia, which appear during the use of the first drug, should be affected by the second. In **straight** or **slow rotation** programs a single and often the same drug may be used for several broiler growouts (e.g., about 6 months; each fattening period may last 35–40 days or longer); it is then replaced by an alternative drug. Shuttle programs are still being discussed with regard to their value in delaying drug resistance. Although alternation of the drugs between crops may delay the appearance of resistance, it is likely that the outcome will be the acquisition of multiple resistance. There may also be the risk of underdosing or insufficient activity of drug mixtures resulting from switching the drugs. This might allow resistance to be developed faster. However, by switching the drug, underdosing can be excluded if new and exactly medicated feed is poured onto remaining feed; then the 2 drug fractions at the base of the silo funnel must add up to 100% of any resulting mixture. Mixtures of ionophorous antibiotics were as effective in controlling drug-sensitive *E. tenella* and *E. acervulina* infections as a single antibiotic mixed in the feed at recommended prophylactic concentrations. However, such mixtures (e.g., monensin + narasin or salinomycin) may have limited additive action if there is already a partial resistance to one of the partners. In these experiments it was also shown that combinations of ionophorous antibiotics and synthetic drugs are complementary, even against field isolates with unknown drug response.

Drug combinations (Table 1) have commonly been used for synergism in order to minimize the occurrence of drug resistance (e.g., Lerbek roxarsone + clopidol), or to extend the species spectrum to all 6 pathogenic *Eimeria* spp. in chickens. Amprolium, which shows activity against *E. tenella* and *E. necatrix* have been combined with ethopabate and organic arsenicals respectively, in order to expand their spectrum to include the upper intestinal species *E. maxima*, *E. acervulina*, and *E. mitis*. The only experimental evidence of retardation of drug resistance by synergistic effects of drugs was seen with methylbenzoquate + clopidol (discontinued); complete resistance occurred to methylbenzoquate 10 ppm and meticlorpindol 125 ppm, respectively, after 3 passages of *E. maxima*, but not with a 8.35 and 100 ppm combination of the 2 drugs.

To keep up their competitive position with other anticoccidials, narasin (and maduramicin) have been combined with nicarbazin, an old-timer among anticoccidials; these products, however, reveal no performance advantages over related monodrugs.

Drugs Acting on Cryptosporidiosis in Birds

Species of the genus →*Cryptosporidium* are coccidian parasites that infect epithelial cells (extracytoplasmic) of the intestinal and respiratory tract of vertebrates (see Opportunistic Infections). Although immunocompetent hosts show no, or only mild, clinical signs after *Cryptosporidium* infections, particularly young birds under stress may suffer from life-threatening watery diarrhea, or severe respiratory symptoms. Cryptosporidiosis in chickens, turkeys, quail, and pheasants is usually manifest as respiratory disease caused predominantly by *C. baileyi* or as enteritic disease (small intestine) caused by *C. baileyi* and *C. meleagridis*. The severity of infection depends on the immunocompetence of the host. Infections are due to aerosol transmission of infective oocysts coughed up by carrier (seeder) birds, or may be transmitted by feed or water supplies containing sporulated oocysts derived from feces of infected birds. Clinical signs in birds are coughing, mucoid discharge, dyspnoe, diarrhea, →dehydration, weakness, and weight loss.

Causal therapy and chemoprophylaxis of chicken cryptosporidiosis with ionophorous antibiotics is problematic. Many approaches to anticryptosporidial efficacy of commercial drugs have failed to improve symptoms in birds suffering from *Cryptosporidium* infections. Several other anticoccidials as sulfonamides, lasalocid sodium, halofuginone, and decoquinate, or other antibiotics (e.g., paromomycin) have

proved to be insufficiently effective in controlling or even eradicating *Cryptosporidium* infection in birds. The drugs may exhibit positive short-term effects such as improvement of watery diarrhea and reduction of oocyst output in feces due to their "static" rather than "cidal" action on cryptosporidia.

Coccidia of Humans

Coccidia that may cause clinical signs in humans are rare. →*Isospora belli*, a single host species in the small intestine, may be responsible for mild intestinal symptoms in some cases. Infections due to heterogeneous species like →*Sarcocystis* spp. (→Sarcocystosis) or →*Toxoplasma gondii*, and related protozoans with a 2-host life cycle are seen more often, especially in areas where raw meat is eaten and human beings have contact with cats or other felines. Moreover, *Isospora belli*, *Cryptosporidium parvum*, *Toxoplasma gondii*, and *Cyclospora* spp. belong to the opportunistic protozoa associated with immunosuppression caused by HIV →(AIDS), or other pathogens and pathogenic processes. →Coccidiasis, Man.

Coccidiosis, Animals

General Information

The →coccidia are members of the suborder Eimeriina. They are typically highly host-, organ-, and tissue-specific. Under natural conditions, most mammals pass small numbers of coccidial oocysts in their faeces, without apparent clinical effect. Coccidiosis becomes important as a disease when animals are reared under conditions that permit the build-up of high numbers of infective oocysts in the environment. This is because the degree of damage caused by coccidia depends upon the numbers of parasites able to replicate in any given site, which depends firstly upon the numbers of infective stages (oocysts) ingested. This is different from other →protozoa which may reproduce indefinitely by →binary fission, until halted by host immunity or death. →*Eimeria* infections are self-limiting because the parasites only pass through a limited number of asexual multiplications. Coccidiosis involves (extensive) destruction of the intestinal epithelia. The effects of intestinal coccidiosis in mammals vary with the host–parasite system. They are mainly related to →malabsorption induced by villous atrophy and reduction of brush border enzymes, or to →anaemia, hypoproteinaemia, and →dehydration due to exudative enteritis and colitis caused by epithelial erosion and ulceration. High mortality may occur in ruminants infected by the most pathogenic species (see also →Alimentary System Diseases, Ruminants).

Pathology

Cattle

About 15 species of *Eimeria* parasitize cattle; of these *E. zuernii* and *E. bovis* are potentially highly pathogenic. Other species, such as *E. auburnensis* may at times contribute to the general clinical picture. In general, the infection occurs in calves or weaned feeder cattle under one year of age, but clinical disease occasionally occurs in adults, especially if massive infections are acquired during stressful situations. The diseases caused by *E. zuernii* and *E. bovis* are very similar; they are characterized by a haemorrhagic →diarrhoea which may become so severe that pure blood is passed instead of faeces. Tenesmus is marked, and there is anaemia, weakness, →anorexia, and emaciation. In severe infections death may occur. The first clinical signs appear just before the peak in oocysts output (day 18–19), when there is maximal loss of epithelium in the large intestine due to destruction of cells by second-generation →schizogony and →gamogony. This causes the exposure of the lamina propria and the formation of diphtheritic membranes. The destruction of the epithelium leads to reduction in the reabsorption of water, Na+ and Cl- from the intestinal contents. The abrupt loss of weight and the reduction of the plasma concentration of these 2 ions support this contention. Exposed capillaries of the large intestinal lamina propria may rupture, leading to loss of erythrocytes and plasma.

Sheep and Goats

Coccidial infection is virtually universal in sheep and goats, and large numbers of oocysts may be found in the faeces of clinically normal animals. Coccidiosis in small ruminants is chiefly restricted to young animals up to 4–10 weeks of age. Close morphological similarity between the oocysts of *Eimeria* spp. from sheep and goats has caused some confusion in the literature. Relatively little is known about the pathogenicity of the different species, but it has been established that *E. ovinoidalis* in sheep and its analogue in goats, *E. ninakohlyakimovae* can be very pathogeni. Other species such as *E. bakuensis* (*E. ovina*) and *E. crandallis* in sheep, and *E. arloingi* and *E. christenseni* in goats may exacerbate the symptoms of the former 2 species. Outbreaks of coccidiosis are usually acute and characterized by moderate →morbidity and low mortality. There is a green or yellow watery diarrhoea with a fetid odour, occasionally with blood. →Abdominal pain, some anaemia (macrocytic, hypochromic), loss of appetite, dehydration, tenesmus, weakness, and loss of weight occur. Depression, inactivity, and recumbency are prominent. Pathological changes include thickening of the caecum and colon mucosa, →oedema, haemorrhage, and hyperaemia. Myiasis, bacterial diarrhoea, and bacterial septicaemia often accompany coccidiosis outbreaks.

Horses

The only species occurring in horses, *E. leuckarti*, is not known to cause disease.

Swine

At least 12 species of *Eimeria* are thought to occur in swine, and a single species of →*Isospora*. *Eimeria* spp. are not considered a major cause of disease in pigs and many animals are asymptomatic carriers. *I. suis* is the only important species. It causes porcine neonatal coccidiosis, a disease of piglets from about 5–6 days to about 2–3 weeks of age. It is characterized by a yellow, foul-smelling diarrhoea, dehydration, occasional →vomiting, loss of condition, and death, or at the least a temporary check in growth. Morbidity is usually high, mortality low or moderate. Necropsy reveals villous atrophy and a marked, sometimes necrotizing, enteritis of the small intestine. Simultaneous infection of *I. suis* with viruses and *E. coli* results in more severe lesions and clinical disease than with coccidia alone.

Carnivores

There are at least 14 species of coccidia in canine faeces: *Isospora canis*, *Isospora (Cystoisospora) ohioensis*, *I. burrowsi*, *I. neorivolta*, →*Hammondia heydorni*, →*Neospora caninum*, and 8 species of →*Sarcocystis*. A total of at least 15 species exist in cats: *Isospora felis*, *I. rivolta*, 5 species of →*Besnoitia*, *Hammondia hammondi*, →*Toxoplasma gondii*, and 6 species of *Sarcocystis*. In relation to pathogenicity, it is usually the intermediate hosts rather than the dog or cat that are adversely affected. Clinical coccidiosis in dogs or cats is apparently caused by certain species of *Isospora* and by *T. gondii*. For example *I. ohioensis* can cause clinical disease in newborn pups. Diarrhoea is caused by inflammation of the intestinal crypts, with →necrosis and massive desquamation of the tips of villi, especially in the lower part of the small intestine.

Immunity and Vaccination

Reports from the literature suggest that immunity to coccidia is short-lived in young animals. In contrast, repeated coccidian infections induce a more long-lasting immunity than a single (primary) infection. An increasing infection pressure may cause a deterioration of immunity that is evident by an enhanced number of intracellular developmental stages and so, output of oocysts, and possibly the development of clinical signs. The effect of immunity can range from complete (or close on zero) inhibition of oocysts production (premunition) to the passage of smaller numbers of oocysts in the faeces (partial immunity). It is assumed that **premunition** (immunity of the non-sterile type) to coccidia depends upon the persistence of some (occult, extraintestinal) development stages in the immune host from initial infection and/or reinfection. Thus, the acquired (often) species- or even life cycle stage-**specific immunity** of the host to coccidia plays an important role in the control of parasites and may depend on various host factors such as individual immune status, age of the host and its genetic background (breed type: →innate immunity). It seems that development of natural immunity to coccidiosis through digestion of sporulated oocysts is rather slow and may take several weeks or even longer. Therefore, using **vaccines** to prevent coccidiosis in the short lifespan of fattening young animals appears problematic because protective immunity resulting from vaccination may be insufficient. This is true particularly in case of broilers' life span which lasted about 35–40 days only. On the other hand, breeder replacement chicks and commercial layers are able to profit from the immunity protection against coccidiosis. They may be exposed to a controlled number of sporulated coccidia oocysts, i.e., to **live virulent vaccines**. Today, various types of live vaccine for the control of poultry coccidiosis are available (see Table 1). Coccivac or Immucox (sporulated oocysts of wild-type) has been used mainly for replacement birds, which represent a relatively small market in comparison with that of the broiler industry. In using such vaccines it appears economically acceptable to have some loss of performance as a result of immunization. However, live virulent *Eimeria* vaccines for control of coccidiosis in broiler chicken have rarely been used because of loss of body weight, and its effect on feed conversion is not acceptable. **Attenuated parasites** for water delivery (spray) or gel delivery are "sub-lines" of sporulated oocysts from chicken derived from the progeny of single oocysts. They may be attenuated after long-term passages through the chorioallantoic membranes of embryonating eggs (Livacox), or they may be recovered after only a few passages with selection for early

Coccidiosis, Animals. Table 1 Live vaccines on the market

Trade name	Pathogenicity	Administration	Producer
Immucox for chicken I; II and for turkeys	virulent	water or gel delivery	Vetech Labs. Inc., Canada
Coccivac-B; D; T	virulent	water delivery (spray)	Schering–Plough
Paracox-S	attenuated	water delivery (spray)	Schering–Plough
Livacox-Q, T	attenuated	water delivery	Merial Brasil, Biopharm Czech Republic

development by passages through chickens (Paracox, Livacox) or rabbits. **Precocious lines** of coccidia species are drug sensitive and thus any use of anticoccidial drugs should be avoided during the month following vaccination. Precocious lines are characterized by a shorter life cycle, i.e., decrease in prepatent period, number, and size of endogenous stages (e.g., deletion of the terminal generation of schizonts of the wild-type parents). They can induce protective immunity against coccidiosis in spite of distinct attenuation of their virulence. Such parasites (oocysts) are no longer able to cause infections with severe clinical signs in chickens or rabbits (the production of precocious lines in cattle obviously failed). Problems arising from vaccination in the poultry industry or elsewhere may be the delivery and application practice of such live vaccines. Thus the application management of vaccines seems to be more sophisticated than that of feed-in products in widely used →chemoprophylaxis. Another problem may arise through genetic instability in precocious sublines. In addition, cost of production of live **"cocktail" vaccines** containing all (Paracox) or only certain *Eimeria* spp. (Livacox) may be considerable and above that of in-feed delivered anticoccidial drugs.

The chances for developing protective **→recombinant vaccines** against coccidiosis in **chickens** appear promising though *E. maxima* shows antigenic diversity, and live-*Eimeria* vaccines may show differences in their virulence and immunogenicity in the individual recipient and different breeds of poultry. The development of effective recombinant vaccines (genetically engineered *Eimeria* antigens) against poultry and farm livestock coccidiosis has become a major goal in modern parasitology. Since coccidiosis involves the intestinal immune system, understanding of the **complex gut-associated immune system** is most important in the development of immunological control strategies to coccidian parasites. **Different types of antigens** (surface-, internal-, secretory antigens of sporozoites, merozoites, gamonts) that induce parasite-specific immunity have been identified by means of monoclonal antibodies against various Coccidia species. Recombinant proteins derived from these antigens have been shown to induce either humoral or cellular response or both, whereas protection against live challenge (sporulated oocysts) proved to be insufficient to weak or partial only. For instance, responses of different poultry breeds vary considerably to such recombinant antigens (epitopes). Sub-unit vaccines developed so far lack epitopes that induce strong protection and this seems to be also true for optimal delivery systems that release these epitopes at the site of infection. Suitable live recombinant vectors derived from bacteria or viruses will be necessary to induce a persistent stimulation of the local immune system by presentation of "perfect" recombinant target antigens to adequate immune effectors. Such approaches are only possible by using biotechnology that requires great skills of molecular biology as well as a profound knowledge of host immune responses to coccidian infection. Until now, there are large gaps in our existing knowledge concerning precise definition of target antigens and immune effectors. Consequently, the development of protective recombinant coccidiosis vaccines will be in any case a long-term and high-risk research project. Furthermore, such a vaccine must not only confer resistance but also be cheap and fit in with current management practice in the poultry industry and farm livestock. An exiting new approach to vaccine development may be highly attenuated bacterial vectors that have the ability to enter epithelial cells and direct plasmid DNA to the →cytoplasm of the host cell for protein synthesis and processing for →antigen presentation. **Delivery of DNA-encoded antigens** should permit mucosal immunization against the parasite simultaneously with multiple antigens that can stimulate T helper cells and antibody production, especially the proper folding and conformational epitopes for the immunoglobulins A (IgA) and G (IgG). Aside from the practical oral application of bacterial DNA delivery, this type of vaccines does not need DNA purification and can be produced for the →fermentation, lyophilization, and packaging.

Therapy

→Coccidiocidal Drugs, →Vaccination.

Cochliomyia

→Callitroga.

Cochliomyia hominis

In this genus there exist 4 species, 2 of them are active in humans →myiasis/*C. hominivorax* (Figs. 1, 2) – (the New World screwworm fly), and *C. macellaria* (secondary screwworm fly).

C. hominis attacks besides man cattle, horses, sheep, goats, pigs, dogs, and many species of wild life. The adults (Fig. 1) are common in slaughter houses (Southern USA, South America). The females lay up to 1,000 eggs in batches of 40–250. The larvae hatch in about 4 hours and develop to adults in 6–20 days.

Cochlosoma anatis

Flagellated trophozoite with a ventral attachment disc and 6 flagella, measures 6–12 mm × 4–7 mm, and is found in the cloaca, caecum, and colon of ducks and turkeys (experimentally transmittable to chicken). This organism is apparently able to introduce enteritis.

Cocoon

There are several meanings:

- Cover of →puparium, inside which the adults of holometabolous insects (e.g., →fleas) are developed.
- Chitinous ootheca of cockroaches containing 16–40 eggs (depending on the species).
- Egg-sack in annelids formed by →clitellum to surround the fertilized eggs (e.g., *Hirudo*).
- Eggs of →trematodes and other →Platyhelminthes, if they are composed of a →zygote plus a number of vitelline gland cells.

Codworm Disease

Disease due to infection with anisakid worms (→Anisakiasis), e.g., from cods.

Coelom

Secondary body cavity (e.g., in annelids, vertebrates).

Coelomyarian Muscle Type

→Nematodes.

Coelotropha

Classification

Genus of →Protococcidia (Apixomplexa).

Life Cycle

C. durchoni lives in the body cavity of the polychaete *Nereis diversicolor*, it has not schizogonic reproduction, see →*Grellia* (syn. *Eucoccidium*) *dinophili*. See also →Chromosomes.

Coenurosis, Animals

Coenurosis is a nervous system disease caused by the presence in the cranial cavity of *Coenurus cerebralis*, the larva of →*Taenia multiceps* (→Nervous System Diseases, Carnivores). The infection occurs in sheep and less commonly in other ruminants. It is rare in horses and man. In lambs, an acute →meningoencephalitis may develop if a large number of immature stages migrate in the brain. More commonly, the infection follows a chronic course and is associated with the presence of 1 or 2 coenuri in the brain, 4–6 months after infection. The →coenurus acts as a space-occupying lesion anywhere in the central nervous system. It occurs most often in the cranial cavity, sometimes between the hemispheres and cerebellum, and sometimes underneath, in the region of the mid-brain. Pressure signs develop slowly and are usually preceded by dullness, cessation of feeding, loss of weight, and the habitual resting of the head against any support. The ultimate signs depend upon the site of the cyst, and include →blindness and incoordination, as well as the turning movement which is said to be characteristic of the infection. Other locomotor signs include reacting, stumbling, abnormally high or low carriage of the head, and lunging forwards. These signs occur in attacks of some minutes duration followed by a remission of one or more hours, but the background of dullness and abnormal head carriage is continuous. Eventually the animal becomes recumbent, and death soon follows. A case of coenurosis has been described in a bullock, which resulted in the development of hydroencephalus.

Therapy

→Cestodocidal Drugs.

Coenurosis, Man

Coenurosis, is an infection with larval forms of the genus →*Multiceps* of canids, which gives rise to small cysts in the brain typically with prominent multiple scolices, but without daughter cysts. These are surrounded by a layer of fibrous tissue. Degenerating cysts

give rise to intense →inflammatory reaction with symptoms depending on location. Fibrosis and calcification follow.

Therapy

→Cestodocidal Drugs.

Coenurus

Larval stage of the →tapeworms *Taenia seralis* and *Multiceps multiceps*. →Eucestoda.

Coevolution

Coevolution is an evolutionary change in 2 or more species resulting from reciprocal selective pressures.

In parasite-host systems, the demonstrations of

- genetic variability in parasites for transmission to hosts and survival in hosts on the one hand,
- genetic variability in hosts for avoidance of parasites and resistance mechanisms on the other hand

constitute what Hochberg and Crompton call "a cornerstone prediction of active coevolution."

When reciprocal selective pressures occur, parasites and hosts are engaged in arms races. Coevolution between parasites and hosts might thus be a universal phenomenon, although it has been rarely demonstrated.

Optimal pathogenicity is at the cross-roads of 2 arms races: In a first arms race (the encounter arms race), the parasite selects genes to improve the probability of contact with the host whilst the host selects genes to avoid meeting infective stages of the parasites. In a second arms race (the compatibility arms race), the host selects genes to kill the parasite whereas the parasite selects genes to survive. The first arms race implies reciprocal behaviours whereas the second implies defence and →evasion mechanisms. A selective process in 1 of the 2 arms races can be compensated by a counter-selective process in the other; for instance, selection of adaptive behaviour in the parasite's genome can be counter-balanced by selection of immune defence in the host's genome. "Attack and defense invariably favor diversification …. The biochemical mechanisms that mediate attack and defense determine the limits of diversification" (Frank).

Coevolution must not be confounded with parallel evolution. When a phylogeny of hosts and their parasites is established (for instance by comparison of DNA sequences or any other method), it can happen that host and parasite phylogenies are "parallel" (topologically identical) because parasites have regularly cospeciated with their hosts; in other cases, there is no congruence between the phylogenetic trees of parasites and hosts because a number of lateral transfers of parasites occurred between different host lineages. It is sometimes tempting to assume that parallel evolution and coevolution are linked to each other, or even synonymous. This is not true because coevolution implies that each partner has actually exerted selective pressures on the other and reciprocally. →Cospeciation can result from external factors (for instance geographical isolation) which caused parasite and host to speciate synchronously, and not as a result of reciprocal pressures.

Examples

Parallel evolution of host and parasite, e.g., humans and their highly specialized lice species (*Pediculus, Phthirus*), live together since long, and the lice use exclusively humans as hosts.

Collagen

→Energy Metabolism.

Collyriclum

→Digenea.

Colonisation

From Latin: *colonia* = settling; other term for infections due to the entering of a parasite.

Colorado Tick Fever

Synonym

CTF.

Colorado tick fever is caused by the CTF virus (ungrouped →arbovirus) and is chiefly transmitted by the tick *D. andersoni*. After an →incubation period of 3–6 days there may be →encephalitis and bleeding in children. Fatalities are rare.

Combs

→Fleas.

Commensalism

Name

Latin: *commensalis* = guest at table = co-eater.

This term describes the activity of an organism to feed at the costs of a host without introducing a disease.

Communities

In ecology, the word community designates a set of populations of different species which occupy, at least partially, the same environment and are susceptible to interact. In parasitology, the meaning is the same, with the particularity that it is always difficult to decide what are the limits of a community.

In general, a parasite community is considered as consisting of parasites of different species susceptible to interact in the same organ of the same individual host. It is more correct to call this community an →infracommunity, since it is composed of several infrapopulations (→Populations). For instance, the parasites which inhabit the digestive tract of a host constitute a infracommunity. It is clear that the definition of the infracommunity can be restricted (for instance to the duodenum) or enlarged (e.g., to the entire host, because, even in the absence of physical contacts, parasites in a same individual host can interact in a number of ways).

The difficulties increase if one considers the community at a scale greater than that of the individual host.

Holmes and Price, among others, accepted the following definitions:

In general ecology, a component community is an assemblage of species associated with a particular "microenvironment" (e.g., species living in tree holes); in parasitology, all the infracommunities in a population of hosts make up a component community.

In general ecology, a compound community is a mixture of component communities that interact to various degrees (e.g., species living in a forest); in parasitology, all parasites in an ecosystem, whatever their stage of development, constitute a compound community.

Combes suggested to simplify and homogenise the terms: a community of parasites comprises all the parasites of an ecosystem, a →xenocommunity comprises all the parasites of a particular host species of that community, an infracommunity comprises all the parasites of a particular individual host (Fig. 1).

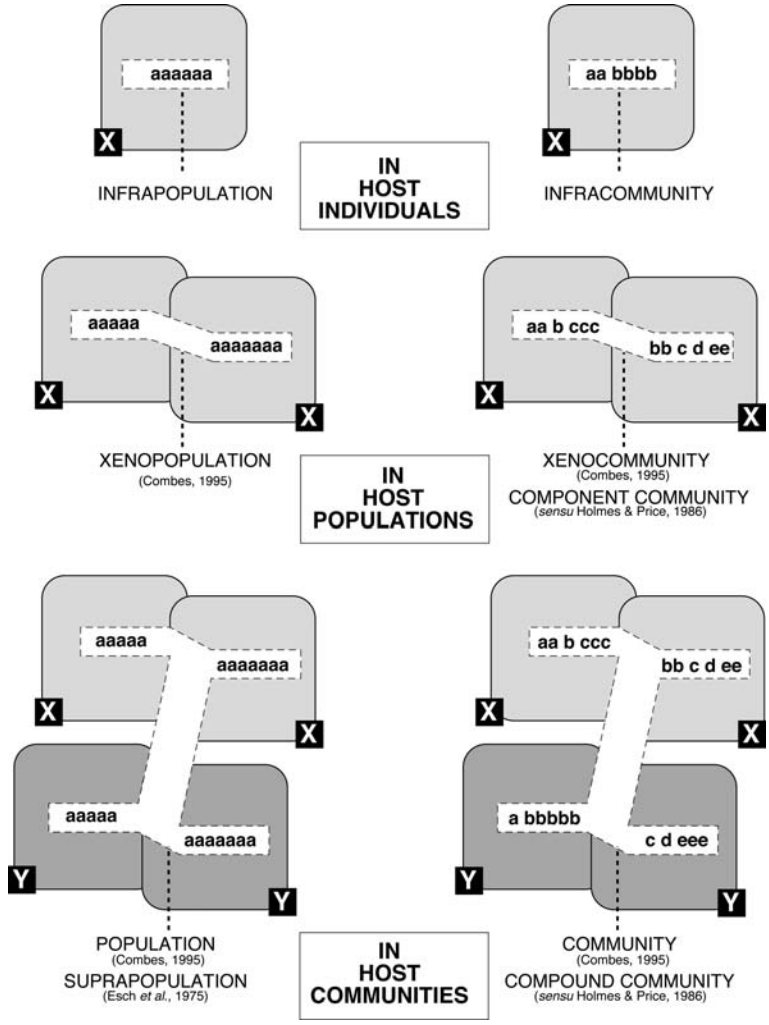
Competition, Interspecific

The level at which different species of parasites can interact (and thus in which interspecific competition can occur) is that of the →infracommunity (→Communities).

Infracommunities are thought to range from isolationist to interactive, but there have been 2 main tendencies concerning the degree of interaction.

Price and Rhode think that infracommunities are principally isolationist because the host is rarely saturated. When different parasite species occupy different "niches" in a host (e.g., distributed along the digestive tract of a bird or at particular places of the gills of a fish), this is not the result of a competitive displacement, but rather of habitat preferences. In the case of monogeneans, which are ectoparasites on the gills, Rohde suggested that the gathering of different parasite species in particular areas has been selected to facilitate genetic exchanges between individuals when densities are low and do not reflect interspecific competition.

Holmes is more in favour of interactive communities, especially in the intestines of birds. Bush and Holmes, for instance, have demonstrated that the intestinal →helminth species of lesser scaup ducks are arranged in a strictly predictable pattern and that high densities of certain species provoke displacements of less competitive species. The occupation of different organs or parts of organs by the different species of an infracommunity is seen as the result of selective pressures. When a niche appears to be empty, this can be a "ghost of competition past." Bush and Holmes have applied the notion of core and satellite species to



Communities. Figure 1 Populations and communities as defined by various authors [original]. Grey boxes represent individual hosts of species X, Y, ... Letters represent individual parasites of species a, b, c, d, e, ...

parasite communities with success: core species constitute the predictable component of the community, are often specific to the host and compete for space and resources; satellite species are unpredictable, generalist, and do not intervene in the structure of the community. Satellite parasites in a given host species can be core species in another host.

Competition, Intraspecific

Intraspecific competition is the rule on earth, and is one of the important mechanisms underlying regulation of populations. Individuals of a same species compete for space, for resources, for mates. Competition can be by exploitation (what is taken by certain individuals is no longer available for others) or by interference (individuals show direct or indirect aggressiveness to each other). The consequence of intraspecific competition is a reduction of →fecundity and/or survival (which affects part or all of the populations), which contributes to regulate the populations. The effect is density-dependent: when density increases, competition increases, so that fecundity and/or survival decrease in proportion.

Intraspecific competition is one the major components of regulatory processes in parasite populations. Surveys as well as experiments have often demonstrated that the density of parasites in a host cannot exceed a certain level. It is, however, always difficult to separate the effects of competition from the effects of immune defence, which are also density-dependent. One of the most convincing demonstrations of intraspecific competition is the "enlargement of the niche": in

the gut of a vertebrate, for instance, it is possible to determine what location is preferred when the individuals of a parasite species are in low densities; this is the "preferendum" of the species. When the size of the →infrapopulation increases, a part of the individuals are constrained to occupy less favorable places, sometimes far from the preferendum. It is then easy to show that these individuals have a →reduced fecundity and/or size. However, not all infrapopulations show signs of intraspecificic competition: hosts are sometimes far from being saturated (→Competition, Interspecific).

Complement Fixation Test (CFT)

Classic indirect diagnostic test, →serology.

Compound Eye

The eyes of insects are composed of several single ommatidia, which are everse eyes containing 8 nerve cells, and a cuticular lense plus lateral covering cells.

Concinnum procyonis

Synonym

Eurytrema procyonis.

1.7–2.5 mm long, common fluke (family Dicrocoeliidae), in racoons (*Procyon lotor*) and occasionally in cats in the USA.

Concomitant Immunity

→Premunition.

Concrement Vacuole

Inclusion with sensory activity inside ciliates of the family Bütschliidae inside the alimentary channel of mammals (e.g., *Blepharoprosthium*).

Congo Floor Maggot Myiasis

Disease of humans in Africa due to the activity of nightly sucking larvae of the fly species *Auchmeromyia luteola* (syn. *Senegalensis*). The larvae are thought to be mechanical vectors of trypanosomes.

Conjugants

→Gametes.

Conjugation

Sexual process during which 2 stages of →Ciliophora (= →conjugants) fuse for a short while with each other and exchange a so-called wandering →micronucleus, thus executing DNA exchange. After this process the cytoplasmic bridge is broken off, each individuum lives on its own, and finally starts reproduction by →binary fission. (See also →*Balantidium coli*, →*Ichthyophthirius multifiliis*).

Conjunctivitis

→Eye Parasites.

Connatal Infection

Name

Latin: *connatus* = during birth.

Infection of the newborn during birth (e.g., →malaria and →AIDS may then become transmitted).

Connatal Toxoplasmosis

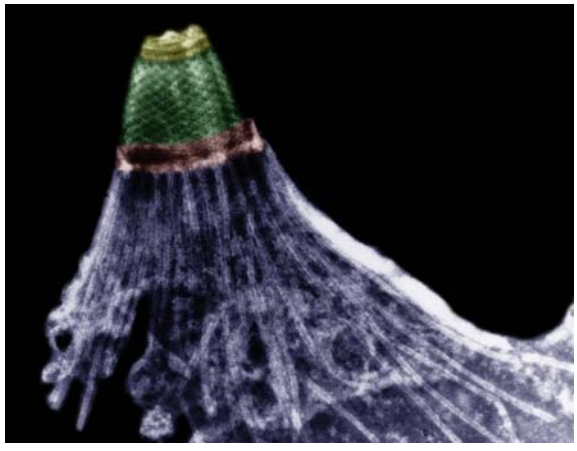
Disease due to infection with →*Toxoplasma gondii* being already present during birth (prenatal infection; Latin: *natus* = birth) via the intrauterine way (= congenitally). This infection may only occur in pregnant women who were infected for the first time during pregnancy. →Prenatal Toxoplasmosis.

Connexivum

Lateral fortified portion of the abdomen of some bugs (e.g., Triatomae), not covered by the wings.

Conoid

The conoid (→Kinete/Fig. 2, →Pellicle/Fig. 5B) is a hollow truncated cone composed of spiralling →microtubules 25 nm in diameter (Fig. 1). Two accessory structures, the conoidal or preconoidal rings, form an integral part of the conoid and they are connected with each other by a canopy-like membrane. During cell penetration the conoid protrudes through the anterior →polar ring system. The conoid is apparently involved in penetration of host cells. Conoids are found in the motile stages of some →Coccidia, such as →*Eimeria*, →*Sarcocystis*, and *Toxoplasma* (→Kinete/Fig. 2,→Pellicle/Fig. 5), but are always absent from the corresponding stages of haemosporidians (e.g., →*Plasmodium*) and →piroplasms (→*Babesia*, →*Theileria*).



Conoid. Figure 1 TEM of the anterior pole of a coccidian cyst-merozoite (= bradyzoite) showing the conoid being protruded anteriorly to the polar ring system, at which the subpellicular microtubules are attached.

Conscutum

Dorsal plate of male ixodid ticks covering the whole backside.

Constipation

Clinical symptom in animals due to parasitic infections (→Alimentary System Diseases, →Clinical Pathology, Animals).

Continua

Constantly high fever being a leading symptom in →malaria due to *P. falciparum*, →amoebic liver abscess, flea transmitted plague, louse-transmitted typhus exanthematicus, and typhoid fever.

Contracaecum

Genus of ascarid →nematodes of marine mammals, larvae are found in marine fish (→Anisakis).

Contractile Vacuole

→Amoebae, →*Ichthyophthirius multifiliis*, →excretion.

Control

→Disease Control, Epidemiological Analysis, →Disease Control, Methods, →Disease Control, Planning, →Disease Control, Strategies, →Disease Control, Targets, →Drugs, →Chemotherapy.

Control of Malaria

Factors see →Disease Control, Epidemiological Analysis/Table 2.

Cooperia

Genus of the nematode family →Trichostrongylidae. Species of *Cooperia,* live (as those of the genera *Trichostrongylus* and *Nematodirus*) in the small intestine of ruminants. The adult worms (male 5–8 mm, female 8–11 mm) are rather small, appear reddish, and are often spiral-shaped. Species are, e.g., *C. oncophora* (cattle), *C. curticei* (sheep/goat).
Disease: →Cooperiosis, →Alimentary System Diseases, Ruminants.

Therapy

Nematocidal Drugs.

Cooperiosis

Trichstrongylid →trematodes of the genus *Cooperia* (→Trichostrongylidae) live in the upper part of the small intestine of ruminants. The important species include *C. curticei*, which mainly infect sheep and goats, and *C. pectinata*, *C. punctata*, and *C. oncophora*, which mainly infect cattle. *C. oncophora* is less pathogenic for cattle than either *C. pectinata* or *C. punctata*. *C. curticei* is of little pathological significance in sheep. *C. oncophora* only produces pathological lesions in animals experimentally infected with very large numbers of infective larvae (250,000 or more). The lack of pathogenicity is probably explained by the rapid acquisition of resistance by the host, and the superficial character of the intestinal lesions induced. They rather brace or coil themselves among villi to maintain their place. *C. punctata* worms have been reported as penetrating into the mucosa or submucosa. Villous atrophy with reduction in the brush-border enzymes only occurs after heavy infections. Signs of the infection include soft faeces, intermittent or continued →diarrhoea, progressive emaciation, reduced feed consumption, →weight loss, and listlessness. There is no →anaemia. The lack of any significant effect on serum calcium or phosphorus concentrations, or on the skeleton suggest little interference with intestinal absorption. The slight →hypoalbuminaemia may, however, indicate macro-molecular leakage into the gastrointestinal tract. Mixed infections with →*Ostertagia ostertagi* produce severe adverse alterations of the metabolism in calves, which exceed those produced by infection with either of the species alone. The presence of *C. oncophora* in the small intestine seems to limit the extent of the compensatory digestive responses to *O. ostertagi* infection of the abomasum (→Alimentary System Diseases, Ruminants).

Therapy

→Nematocidal Drugs, Animals.

Copepoda

Morphology

Fig. 1. →Crustacea, →*Lepeophtheirus salmonis*.

Copepodit

Invasive larvae of →Copepoda (→Lepeophtheirus salmonis).

Copra's Itch

→Mites.

Copepoda. Figure 1 Antarctic ice fish (*Macrourus* sp.) with a female copepod, the anterior end of which has penetrated the body wall. Note the long paired egg bags.

Coproantigen

From Greek: *kopros* = faeces; DNA – material of parasites that is excreted within the host's faeces.

Coproscopy

Microscopical analysis (Greek: *skopein* = look at) of the faeces of hosts to diagnose parasitic stages.

Coracidium

Swimming larva of pseudophyllidean →tapeworms provided with →cilia and centrally bearing a hooked →oncosphaera larva.

Cordylobia

Genus of the fly family Calliphoridae. *C. anthropophaga* – the so-called →tumbu fly (Figs. 1, 2) causes the boil-like (furuncular) type of →myiasis like that produced by →*Dermatobia hominis*. These flies occur in Continental Africa, South of the Sahara. *C. rodhaini* is a related species (called Lund's fly), which infects humans much less frequently than *C. anthropophaga.*

1. *C. anthropophaga*, the Tumbu fly of continental Africa south of the Sahara. The eggs are laid in batches of 200–300 on dry, shaded ground.
2. *C. rodhaini* is found in the moister parts of tropical Africa in Central Africa.
3. *C. ruandae*, these flies attack humans as well as animals and lead to myiasis. Inside the skin of the host the development takes 8–15 days, before the larvae 3 emerge, fall to the ground, and pupate. Often up to 50 larvae may be found within one host.

Corium

Thickened portion of the bug wing.

Corpora Allata

→Insects, contain →Juvenile Hormones.

Corpora Cardiaca

→Insects, contain →neurohormones, that induce the release of ecdyson (→Moulting Hormones) of the prothoracic glands of insects.

Corridor Disease

→Piroplasms, →Theileriosis.

Corynosoma semerme

→Acanthocephala.

Co-speciation

→Phylogeny/Host-Parasite Co-speciation.

Cost Effectiveness

→Disease Control, Planning.

Costa

Elements of cell stabilization in →trichomonads (→Trichomonas).

Costia necatrix

Syn. *Ichthyobodo necator*, a 10–20 µm by 6–10 µm – sized protozoan with 2 flagella – one measures 9 µm, the other is 18 µm long. It attaches to the skin and gills of sweet water fish and introduces severe slimy covers often leading to death due to the lack of oxygen.

Cotugnia

Genus of tapeworms of the family Davaineidae.

Cotylocidium

→Aspidogastrea.

Cotylophoron

Genus of flukes related to →*Paramphistomum*.

Cotylurus

→Digenea.

Coumaphos

Organophosphate compound acting as →Arthropodicidal Drugs; it blocks the activity of cholinesterases.

Courtship Behavior

→Behavior.

Cowdria ruminantium

→Heartwater; *Rickettsia* transmitted to ruminants in Africa by the tick *Amblyomma hebraeum*.

Coxa

Basal segment of the legs in insect and ticks, by means of which legs are attrached to the ventral body side.

Coxiella burneti

Rickettsial bacteria which are transmitted by *Dermacentor* and *Amblyomma* ticks introducing the so-called Q-fever of cattle, sheep, humans, and other hosts in Queensland (Australia).

Crab Louse

→Lice *(Phthirus pubis)*.

Craterostomum

Genus of small strongylid nematodes in horses.

Creeping Eruption

Route of wandering larvae of →Hookworms (Fig. 1) in human skin (→Cutaneous Larva Migrans).

Crenosoma striatum

→Lungworms, →*Dictyocaulus*.

Creeping Eruption. Figure 1 Larvae of hookworms dig the inflammed channels after skin penetration.

Crepidostomum

Genus of flukes, →Digenea.

Crepidostomum cooperi

→*Megalodiscus temperatus*/Fig. 1.

Creutzfeldt-Jacob Disease

→Prions; see also →BSE.

Crimean-Congo Hemorrhagic Fever

Synonym

CCHF.

General Information

Crimean-Congo hemorrhagic fever is caused by the CCHF virus (→Bunyaviridae). It is a disease which shows hemorrhagic symptoms, together with serious acute febrile conditions. The virus has been isolated mainly from *Hyalomma* →*ticks* (*H. marginatum marginatum*, *H. m. rufipes*, and other species) in South Europe and the Southwest of the former USSR, and several areas in Africa. These 2 foci are linked by migrating birds which can carry ticks. Ticks in other genera, including 1-, 2-, and 3-host ticks, have also been found to harbor the virus. Recently, this disease has been associated with mortality in scientific and medical staff in South Africa after laboratory handling of ticks.

Crista

There are several meanings:

- Crista sterni: Place of attachment of flight muscles at the breast of birds.
- Type of infolding of the inner membrane of →mitochondria.
- Comb-like structures.

Cristae

This is the number for infoldings (single: crista), the inner membrane of some mitochondria at the surface of which the →TCA cycle is anchored. For example, erythrocytic stages of avian malarial parasites (such as *Plasmodium lophurae*) are cristate, while those of rodent and most other mammalian *Plasmodium* spp. are acristate. Asexual stages of *P. falciparum* have a single acristate mitochondrion, which apparently gives rise during the formation of gamonts (gametocytes, →Kinete/Fig. 3) to several cristate ones. This fact suggests, that there is apparently a metabolic change. The mitochondria of the gamonts of the piroplasms remain, however, acristate (→Gametes) as are the trypanosomal mitochondrion in the region of the →kinetoplast (TAC). Energy metabolism, →Kinete/Fig. 3.

Other types of mitochondrial infoldings are tubuli (e.g., →Gametes/Figs. 1, 2A) or – if those are enlarged – they are named sacculi.

For further information see →Energy Metabolism.

Crithidia

→Trypanosomatidae.

Crithidia fasciculata

→Amino Acids.

Crowding Effect

Blocking of development of individual parasites due to overcrowding of a habitat.

Crura

Apart from aspidobothreans (and a few other exceptions) the intestine of →Platyhelminthes divides after the esophagus into 2 lateral terminally closed branches = crura (→Digenea/Fig. 6, →Platyhelminthes/Intestine and Food Uptake).

Crust

Clinical and pathological symptoms of infections with skin parasites (→Skin Diseases, Animals, →Ectoparasites: New Approaches).

Crustacea

Classification

Class of →Arthropoda.

General Information

The crustaceans were termed with respect to their often very strong chitinous →cuticle, which is strengthened in comparison to that of insects by the inclusion of calcium salts; thus growth can only proceed after repeated molts. The heteronomously segmented →dioecious Crustacea appear in a great variety, although lower (former: Entomostraca) and higher (Malacostraca) groups can be clearly differentiated according to their larvae (→nauplius or zoea). Common to all crustaceans are the following features:

- They have 2 pairs of antennae (possibly of different size).
- The uptake of O_2 occurs by means of inner or outer gills.
- A pair of mandibles and 2 pairs of maxillae act as mouthparts. They are located ventrally at the head,

Crustacea. Table 1 Some common parasitic crustaceans

Subclass, Order/Species	Length (mm)	Host/Habitat	Transmitted pathogens
Branchiura			
A. coregoni	10–15	Salmonids/Skin	Fungi, bacteria (*Pseudomonas punctata*)
Argulus foliaceus	m 8–10 f 15	Many fish, amphibian species/Skin, gills	Fungi, bacteria (*Pseudomonas punctata*)
Cirripedia			
Sacculina carcini	20–40	Crabs/Inner organs	–
Copepoda			
Caligus elongatus	7	Salmonids/Skin, gills	–
Clavella adunca	f 4	Marine fish/Skin	–
Cyclops spp.	up to 3	Free-living	Larvae of cestodes and nematodes
E. gibbus	1.0	Eals/Skin, gills	–
Ergasilus sieboldi	1.7	Freshwater fish/Gills	Fungi, bacteria
Lepeophtheirus salmonis	10	Salmonids/Skin	–
Lernaeocera branchialis	m 1.5 f up to 60	Marine fish/Gills	–
Penella balaenoptera	300	Whales/Skin	–
Salmincola spp.	1–1.5	Salmonids/Skin	–
Sarcotaces arcticus	m 2 f 25	Marine fish/Skin	–
Isopoda			
Aega psora	50	Marine fish/Skin	–
Anilocra physodes	20	Marine fish/Skin	–
Cirolana borealis	30	Marine fish/Skin	–

m = male; f = female

which is often closely connected to the thorax (→Cephalothorax) and covered dorsally by a carapax in some groups.
- Each of the heteronomous body segments is ventrally provided with a pair of extremities, which appear as maxillipodia, pereiopodia, or pleopodia (depending on their location along the body).
- These extremities show a typical biramous organization and are composed of an inner endopodite and an outer exopodite.
- Eyes of the compound type are situated, if present, dorsally on stalks; eyes of the median type (e.g., nauplius eye) are composed of 3 or 4 small pigment-cup ocelli of the inverse form.
- The circulatory system is open, involving a dorsally located heart (in thorax or abdomen).
- Antennal or maxillary nephridial glands work as an excretory system supported by different cells (nephrocytes) opening at the body's surface.
- The development occurs in general as a →metamorphosis involving different larval stages (nauplius or zoea) and growth by repeated molts.

System

The following taxa include some parasitic forms, although most members of the Crustacea are free-living:
- Class: Crustacea
  - Subclass: Ostracoda (some species are parasitic on gills of fish)
  - Subclass: →Copepoda (some are ectoparasites of fish, some are intermediate hosts for →Cestodes and →Nematodes)
  - Subclass: →Branchiura (some species are blood suckers on fish, thus named fish lice, →Argulus)
  - Subclass: →Cirripedia (some species are endoparasites in marine crabs)
  - Subclass: Malacostraca (higher Crustacea)
    - Order: Amphipoda (free-living, some are intermediate hosts for endoparasites)
    - Order: →Isopoda (some species are ectoparasites of fish)
    - Order: Decapoda (many species are intermediate hosts for endoparasites)

Important Species

Table 1.

Life Cycle

→*Lepeophtheirus salmonis*.

Integument

The cuticle of the crustaceans is constructed according to the same plan as in →Ticks, →Mites and →Insects. However, in crustaceans minerals such as $CaCO_3$ and $Ca_3(PO_4)_2$ may occur additionally, thus leading to a further hardening of the cuticular exoskeleton (needed, e.g., to overwhelm high water pressures). The →molt (→Ecdysis) in crustaceans occurs due to activity of hormones such as in other arthropods. Here the so-called Y-organs are steered by →neurohormones. →Ecdysis starts in Crustacea when the excretion of the molt-inhibiting hormone (MIH) is stopped and the Y-organs produce →crustecdyson (→Ecdysteroids).

Nervous System

The nervous system shows trends towards concentrations at the anterior pole to form a large brain and in the thoracal region, where a large thoracic ganglion is formed by fusion of segmental ganglia during evolution. In the highly aberrant body shapes of the parasitic crustaceans many variations of the nervous system occur.

Crustecdyson

Hormone that induces →molt in higher →Crustacea (Malacostraca) within the so-called Y-organ (= carapax gland).

Cruzipain

→Thiolproteinases.

Cryptobia

Genus of Kinetoplastea (phylum Euglenozoa). The 2-flagellated members of the different species are either ectoparasites on the body surface or endoparasites in the digestive tract or in the blood of fish. *C. branchialis* is found on the gills of craps and other cyprinids reaching a length of 10–20 µm. *C. salmositica* occurs in salmonid fish in Western and Northern America in the blood and on the gills. An attenuated strain has been produced and is routinely used as an experimental live vaccine, which protects fish for up to 2 years. *Cryptobia* (syn. →*Trypanoplasma*) *iubilans* was described as an intracellular parasite in cichlid ornamental fish to destroy portions of the intestine liver and/or spleen.

Cryptocaryon irritans

Name

Greek: *cryptos* = hidden, *karyon* = nucleus, Latin: *irritare* = disturb.

The life cycle of this ciliate which parasitizes on/in the skin of marine fish is similar to that of →Ichthyophthirius, although it belongs to another group of ciliates. The trophozoites inside skin are only 0.5 mm in diameter. The macronucleus is only badly seen and appears as white dots in higher magnification (Fig. 1). The fish appears with white dots and may die due to heavy infections.

Cryptocotyle

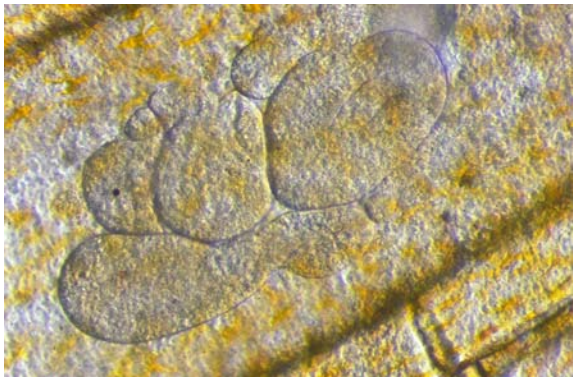
→Behavior, →Digenea.

Cryptomitosis

→Nuclear Division occurring in most parasitic protozoans during which the nuclear membranes are retained.

Crypto-Orthomitosis

→Nuclear Division.



Cryptocaryon irritans. Figure 1 Trophozoite of *Cryptocaryon irritans* in the skin of a tropical fish.

Crypto-Pleuromitosis

→Nuclear Division.

Cryptosporidial Relations

The genus is more closely related to the →gregarines than to true →Coccidia. This was shown by phylogenetic analysis of apicomplexan parasites inferred using small-subunit ribosomal RNA gene sequence. These findings may explain why *Cryptosporidium* stages are not sensible to drugs which affect a broad spectrum of coccidians.

Cryptosporidiosis, Animals

Pathology

Cryptosporidiosis is an important infectious disease affecting mucosal surfaces commonly found in snakes, lizards, birds, and mammals. →*Cryptosporidium* spp. have been reported in all domestic animals including cats, dogs, and pigs. In horses, symptoms have been particularly observed in animals with inherited or acquired immunodeficiency. Cryptosporidiosis is economically most significant in calves and lambs. Symptoms are: enterocolitis in newborn animals manifested by →diarrhoea of variable severity; signs of depression, →anorexia, and →weight loss are also seen. The most prominent lesions occur in the ileum. They include blunting and some fusion of villi, and hypertrophy of the crypts of Lieberkühn. There are great individual variations in clinical reactions to *Cryptosporidium* infection and controversy exists as to whether the parasite occurs as a primary pathogen or whether it causes disease by interacting with other enteropathogens.

Immune Responses

As the replication and development of the parasite is confined to mucosal surfaces, local immune functions of the mucosa-associated lymphoid tissue (→MALT) are of special importance. Interest in the nature of these host responses is heightened by a unique feature of the parasite's development. Merozoites reside intracellularily in epithelial cells and remain anchored at the lumenal surface segregated from the host cell →cytoplasm. Since *C. parvum* infections of animals are generally found in neonates and refractoriness to infection develops 2–3 weeks after birth, most investigations

on the immune responses have been performed in suckling or immunocompromised mice. Some studies have been alternatively performed with *C. muris* which is able to infect adult immunocompetent mice.

Innate Immunity

As with other coccidian, e.g., *T. gondii*, macrophage activation by IFN-γ leads to partial control of microbial reproduction. In T cell deficient individuals such as →AIDS patients or nude or SCID mice a →chronic infection characterized by gradual expansion of inflammatory foci develops, which in the case of immunodeficient mice eventually results in →morbidity and death. Several studies, however, have demonstrated the existence of partially protective innate immune mechanisms mediated by IFN-γ. Treatment of SCID mice with anti-IFN-γ or anti-IL-12 antibodies increased susceptibility to infection and reduced the time till death from >12 to 5–6 weeks. Although cryptosporidium sporocoites or →oocyst antigen preparations enhanced IFN-γ production by splenic NK cells *in vitro*, treatment of mice with anti-ASGM1 antibodies to deplete NK cells had no effect on susceptibility to infection. In other experiments *C. parvum* infection of SCID mice was not influenced by IL-2 treatment which activates NK cells. Thus, the *in vivo* data on the role of NK cell activation conflict with the *in vitro* findings. Obviously, the cell type in the mucosa which produces IFN-γ in the absence of T cells still has tobe identified. Likewise, the accessory cells involved in the local inflammatory response have also to be identified, since the gut epithelium contains only few macrophages.

B Cells and Antibodies

Different subclasses of parasite-specific Igs increase in serum and mucosal secretions during *C. parvum* infections of humans and animals and IgG titers especially may persist for up to several years post-infection. Coproantibody titers of IgA and IgM increase during infection and decrease after resolution of the disease. The antibodies produced recognize a number of immunodominant →sporozoiteantigens of approximately 11, 15, 20/23, 44, 100, 180, and >200 kDa. Different antibodies induced by immunizations possess protective capacity as shown by (1) inhibiting the *C. parvum* development *in vitro* or in suckling mice by administering antibodies orally or by (2) effectively attenuating the clinical symptoms of human cryptosporidiosis by treating immunocompromised patients with hyperimmune bovine colostrum containing high concentrations of anti-cryptosporidia antibodies. Some of the antigens recognized by protective antibodies have been molecularly cloned, but the exact localization and characterization of the function of these proteins awaits further studies.

Although antibodies induced by immunization with antigens could inhibit parasite development, there is considerable doubt about the protective role of antibodies during natural infection. AIDS patients with severe cryptosporidiosis have high titers of *C. parvum*-specific secretory IgA. Furthermore, depletion of B cells in neonatal mice by anti-μ chain treatment, did not alter the ability to control crytosporidiosis. On the other hand, breast-fed babies are less likely to experience cryptosporidiosis while patients with congenital hypogammaglobulinemia sometimes develop chronic cryptosporidiosis.

T Cells

C. parvum induces inflammatory infiltrates in the lamina propria of the gut containing lymphocytes, macrophages, and plasma cells. In the Peyer's patches of mice increased numbers of $CD4^+$ and $CD8^+$ cells were found and purified T cells from spleens of infected animals showed a proliferative response towards parasite antigens. A parasite-specific delayed type →hypersensitivity (DTH) can be elicited in *C. parvum*-infected rats by oocyst antigen injection. The functional importance of a specific T cell immune response was demonstrated by the increased pathology villus atrophy, crypt →hyperplasia, erosions of gut epithelium found in T cell-deficient hosts such as nude rats and mice, SCID mice, as well as, in normal mice depleted of T cells by administration of anti-T cell antibodies. In studies with *C. muris*, →chronic infections in T cell-deficient mice developed similar pathology to those found in immunocompromised patients with cryptosporidiosis. In neonatal mice γδ as well as αβ TCR-expressing T cells are both involved in immunity against *C. parvum* while in adult animals the infection appears mainly to be controlled by αβ T cells. Clinical studies of human cryptosporidiosis in HIV patients and experiments with mice, both, indicated that $CD4^+$ T cells are the major players in host protection. Susceptibility to and severity of *C. parvum* infection increases with the decrease of $CD4^+$ cell counts in AIDS patients. In mice the continuous administration of anti-CD4 antibodies allowed chronic *C. parvum* infection to develop. The protective effect of lymphocyte transfer to SCID mice is abrogated by the depletion of $CD4^+$ cells. In contrast to the dominant role of $CD4^+$ T cells, $CD8^+$ cells play a negligible role as shown by cell depletion experiments *in vivo* or by using mice deficient for MHC class I expression. Only some investigators reported a small increase in oocyst production and/or a prolongation of patent infection as a result of treatment of mice with anti-CD8 antibodies. Using intraepithelial lymphocytes (IELs) from immune donor mice to adoptively transfer protection it was found that also in this cell population the $CD4^+$ subpopulation is the most effective.

One of the most important effector molecules produced by protective T cells is IFN-γ as shown by

enhanced susceptibility of mice as a consequence of treatment with IFN-γ-neutralizing antibodies. Production of this cytokine by IELs was found to be upregulated during the course of infection. However, IFN-γ-independent mechanisms of immunity may also exist, since mice continuously treated with anti-IFN-γ antibodies nevertheless eventually overcome the infection with Crytosporidia. In line with this, mouse-strain-dependent differences in susceptibility to infection (BALB/b versus BALB/c mice) were not linked to differences in IFN-γ production.

The mechanisms by which IFN-γ mediates control of the parasite remain to be determined. Treatment of mice with inhibitors of →nitric oxide production did not influence reproduction of *C. parvum*, unlike the effects found in other experimental infections with parasites such as →Leishmania. Alternatively, documented IFN-γ effects such as enhancement of the production of the secretory component of IgA or the enhancement of the respiratory burst may be operative in the IFN-γ-mediated control of Cryprosporidium infection. IL-12 appears to be critically involved in the upregulation of IFN-γ production as shown by treatment of newborn mice with anti-IL-12 antibodies resulting in enhanced disease susceptibility. Another cytokine involved in the protective immune mechanisms may be IL-2 since treatment of mice with anti-IL-2 increased oocyst production and in a human study IL-2 therapy resulted in less severe diarrhea and oocyst shedding in AIDS patients.

Recently, a protective role of Th2 cytokines in cryptoporidial infection has been reported. Although the amounts of IL-4 or IL-5 produced during the infection appear to be low, treatment of mice with anti-IL-4 or anti-IL-5 antibodies, especially when both were combined, increased oocyst shedding. In addition, adult IL-4-deficient mice excreted oocysts in feces approximately 23 days longer than control mice. Mast cells or eosinophils as effector cells stimulated by these cytokines are unlikely since these cells were not found in significant numbers by histopathological observation in the epithelial infiltrates and mast-cell-deficient mice were not significantly more susceptible to infection than control mice. Other studies, however, suggest that overproduction of IL-4 might correlate with increased susceptibility to infection. BALB/b mice produced significantly more IL-4 than the less susceptible BALB/c mice and onset of recovery in BALB/b mice coincided with a reduction of IL-4 production.

→Alimentary System Diseases.

Therapy

→Treatment of Opportunistic Agents.

Cryptosporidiosis, Man

The coccidium →*Cryptosporidium parvum*, the oocysts of which are 4–5 μm in diameter, containing 4 sporozoites, parasitizes the microvillar border of the intestinal epithelial cells projecting into the lumen. With heavy infections the bile ducts, trachea, and possibly conjunctive may also be involved. In addition to the regular coccidian cycle, thin-walled oocysts are formed that sporulate in the intestine and are a source of →superinfection; the thick-walled oocysts pass to the outside and develop 4 sporozoites. In healthy volunteers, acute infection can be produced by ingestion of 30–300 or more oocysts accompanied by →abdominal pain, cramps, diarrhea, and fever lasting for 3–10 days.

C. parvum causes debilitating gastrointestinal illness in humans and other mammals and is a frequent opportunistic pathogen in →AIDS patients. →Chronic infection in immunosuppressed patients is associated with flattened villi resulting from loss of epithelial cells and lack of regeneration (→Pathology/Fig. 6A). This is accompanied by often copious and frequent diarrhea, →malabsorption, and →weight loss. Both the light and evanescent infections in the immunocompetent and the heavy infections in the immunosuppressed show little →inflammatory reaction. As studied in experimental animals, developing immunity is accompanied by the infiltration of lymphocytes into the lamina propria.

Main clinical symptoms: Abdominal pain, heavy →diarrhoea (*in immunocompromised persons*).
Incubation period: 1–2 days.
Prepatent period: 2–4 days.
Patent period: 12–14 days.
Diagnosis: Microscopic determination of oocysts in fecal samples (Ziehl-Neelsenstain), →*Cryptosporidium* Species/Fig. 1–3.
Prophylaxis: Avoid contact with human or animal feces.
Therapy: Treatment see →Coccidiocidal Drugs and →Treatment of Opportunistic Agents.

Cryptosporidium Species

Name

Greek: *kryptos* = hidden, *spora* = seed.

Classification

Genus of →Coccidea (of the Subphylum Apicomplexa).

Cryptosporidium Species. Table 1 Valid species of the genus *Cryptosporidium*

Species	Size of oocysts (µm)	Main hosts	Prepatent period (days)	Pathogenicity

Trachea, cloaca Whole intestine, bile ducts, respiratory system	*C. baileyi* *C. hominis*, *C. parvum* in HIV-patients

General Information

The species of this genus are very small (Table 1) and were known since more than 100 years within diarrheic feces of young animals. They obtained importance as important →opportunistic agents in AIDS-patients. In *C. parvum* there occur several genotypes: one is pathogenous for humans, one for calves, another for pigs and man. Cryptosporidia are peculiar, since the are attached by a so-called feeder-organelle to the surface of their host cells (like some →gregarines), have only a few tubular →mitochondria and are not susceptible to any known antiparasitic drug. The wall of the →oocyst apparently develops into that of the →sporocyst. This may explain the observation of thin and thick-shelled oocysts. Recent molecular biological studies showed that *Cryptosporidium* spp. are closely related to gregarines. Although *Cryptosporidium* spp. possess the organelles of other coccidians, a typical mitochondrion is lacking. However a similar organelle, but without genome is present.

Important Species

Tables 1, 2.

Life Cycle

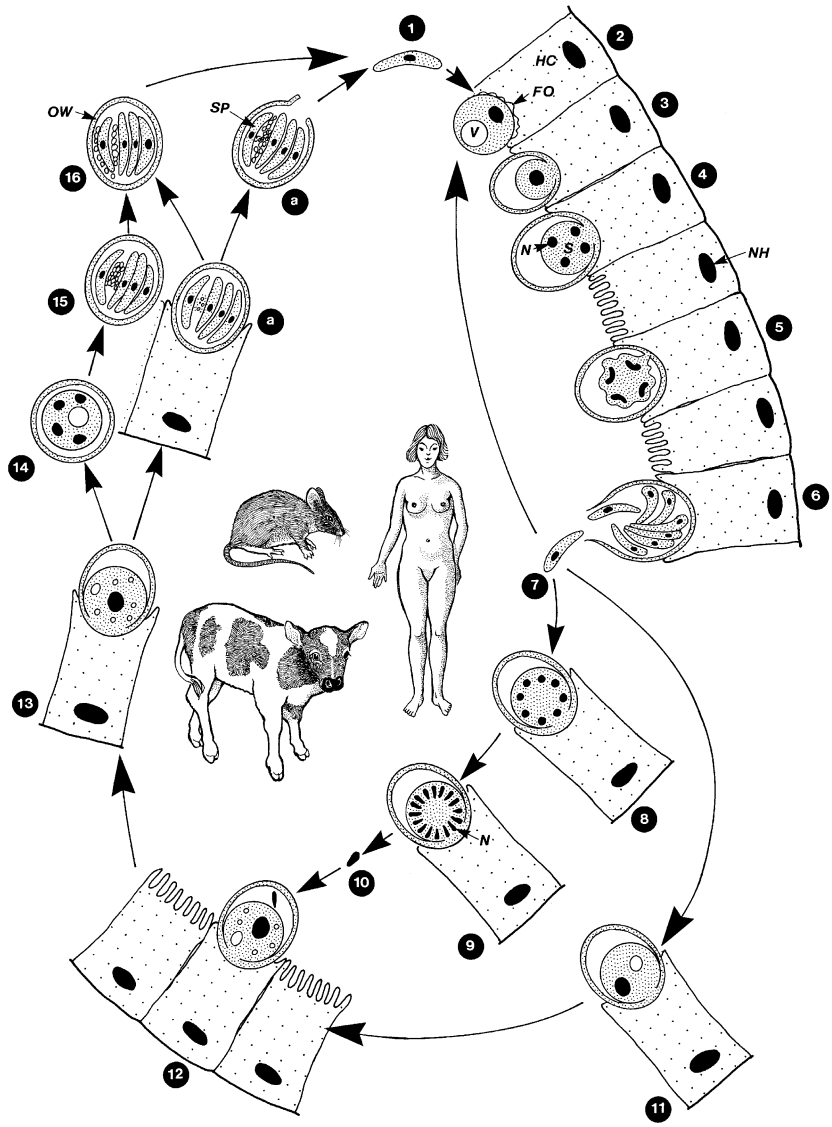
Figs. 1–4.

Infection

Mostly due to contaminated water or fecal contact.

Disease

→Cryptosporidiosis, Animals, →Cryptosporidiosis, Man.



Cryptosporidium Species. Figure 1 Life cycle of *Cryptosporidium parvum*. Species determination is still confusing as some authors believe in 2 species (*C. parvum, C. muris*), each parasitizing a wide range of mammals. Cross-transmission experiments by Göbel, however, indicate that there is only a single nonhost-specific species in mammals. Differences in pathogenicity depend on passages in different hosts. *Cryptosporidium parvum* is important, since infections in immunocompromised humans (e.g., →AIDS patients) are often fatal due to permanent endo-autoinfections (14), opportunistic agent 1 First infection of mammalian hosts occurs by ingestion of sporocysts (16) containing 4 sporozoites (1). The latter are set free in the small intestine when the sporocyst wall is ruptured along its suture. *2–7* From the interpretation of electron micrographs it appears that the →sporozoite becomes attached to the →microvilli of a gut cell and grows to form a →schizont with an inner vacuole (2; V). This vacuole is enlarged (3) and the nucleus divides twice (4). During the next →nuclear division (5) 8 merozoites (6) are produced and are set free (7). These merozoites may become attached to noninfected epithelial cells (2) and repeat the schizogonic process (2–7). *9–11* Formation of →gametes: some merozoites start formation of multinucleate →microgamonts and up to 16 nonflagellated →microgametes (10), which fertilize macrogametes (11) that had developed via macrogamonts from other merozoites (7). The →zygote (12, 13) may follow 2 different ways of development. 15a, 16a Endo-autoinfection: the oocyst sporulates on its host cell and releases the 4 sporozoites, leading to an increasing →autoinfection (important for immunosuppressed hosts including man). Such oocysts may also sporulate inside the intestine, but do not release their sporozoites (13–16). In this case they are excreted with the feces. During the →sporulation process a sporocyst wall is formed around the 4 sporozoites, replacing the apparently smooth and rupturing oocyst wall, so that the stages found in feces are sporocysts. This interpretation is supported by the occurrence of a peculiar suture of the wall, which is known from sporocyst walls of other →coccidia. Oocysts (13) may also be excreted unsporulated and then form their inner sporocyst wall and 4 sporozoites outside their host. The resulting sporocysts are as infectious to the range of host animals as the sporocysts excreted in sporulated form or the oocysts obtained by scraping the host's mucosa. *FO*, attachment zone, →feeder organelle; *HC*, host cell; *N*, nucleus; *NH*, nucleus of host cell; *OW*, oocyst wall; *RB*, residual body; *S*, schizont; *SP*, sporozoite; *V*, inner vacuole (for further species see Table 1).

Mansonella	Filariasis	**Humans**, monkeys,	Africa, South America
Onchocerca	Filariasis	cattle, equids	Worldwide

Cutaneous Larva Migrans

Cutaneous larva migrans is caused by →hookworms mainly of dogs and cats. The itching dermatitis often takes the form of tracks or "→creeping eruption" indicating the route of migration of the larvae in the epidermis of the skin. These papular and serpiginous lesions sometimes become vesicular and hemorrhagic, and are often secondarily infected with bacteria after scratching. These larvae never mature into adults, to live in the intestine, but will die within 3 months at the latest.

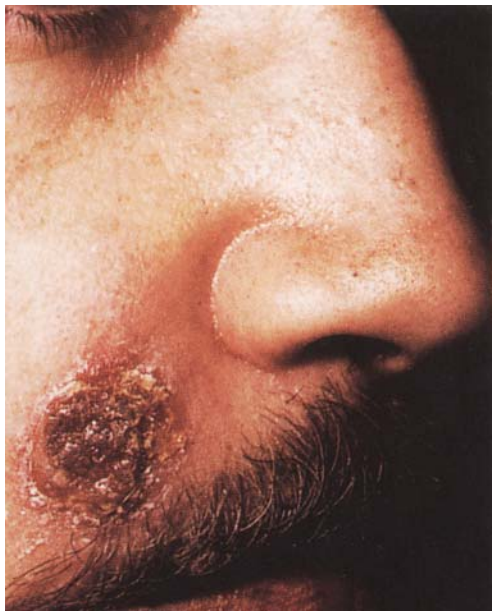
Therapy

Local application of a 15% tiabendazole-ointment.

Cutaneous Leishmaniasis

→Leishmania, examples of symptoms: Figs. 1, 2.

Cutaneous Leishmaniasis. Figure 1 Leishmanial lesion in a muco-cutaneous skin portion of a person from South America.



Cutaneous Leishmaniasis. Figure 2 Leishmanial lesion in a dry region of the skin.

Cuterebra

Genus of the fly family Cuterebridae, the species of which induce ophthalmomyiasis in humans in the Americas.

Cuticle

The acellular filamentous type of →body cover excreted by an underlying cellularly organized hypodermis. Found, for example, in →Nematodes, →pentastomids, and in arthropods (→Ticks, →Mites, →Insects, →Crustaceans) with or without →chitin (depending on the group).

Cuticulin

In the cortical layer of large ascarids there is a tanned structural protein which does not exhibit the striations characteristic for →collagen, and which is not attacked by collagenase. →Nematodes/Integument.

Cyanobacteria-Like Bodies

The oocysts of →Cyclospora species were at first kept for bacteria when seen in the feces of →AIDS patients.

Cyathocephalus

Genus of tapeworms in the intestine of freshwater fish.

Cyathostoma

Synonymous to →*Syngamus*.

Cyathostomum

→Nematodes.

Cyclophyllida

From Greek: *kyklos* = cercle, *phyllon* = leaf. Order of tapeworms, e.g., →*Taenia* spp.

Cyclops

→Crustacea.

Cyclorrhapha

→Diptera.

Cyclospora Species

Classification
Genus of →Coccidia.

Important Species
Table 1.

Life Cycle
In diarrhoeic stools of some immunocompetent, but mostly of immunodeficient people spherical, 8–10 µm-sized cysts were described as CLB = →cyanobacteria-like bodies, which turned to be typical coccidian oocysts belonging to the genus *Cyclospora*, which is known from millipeds, insectivores, rodents, and reptiles. The human species is now called *C. cayetanensis*. Outside the body within 5–13 days (at 25–32°C) 2 sporocysts are formed within each →oocyst. These sporocysts contained each 2 sporozoites with a size of 9 × 1.5 µm. Infection of humans apparently occurs via inoculation of such oocysts (Fig. 1). However, the further development is still unknown.

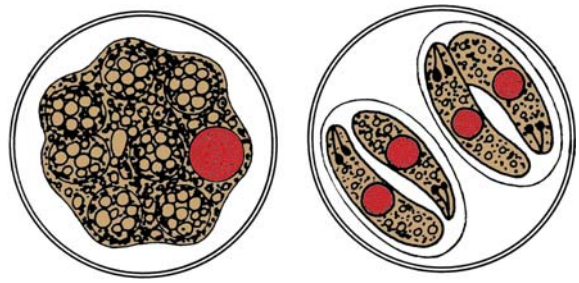
Disease
→Cyclosporiasis, →Ciprofloxacin.

Cyclosporiasis

In diarrhoeic stools of man especially in AIDS-patients the 8–10 µm-sized, unsporulated oocysts of →*Cyclospora cayetanensis* have been described. At first they were misdiagnosed as CLB (→Cyanobacteria-Like Bodies). They apparently induce watery intermittent →diarrhoea (3–4 times per day), which last for 2–9 weeks and may disappear without treatment. Infection apparently occurs by inoculation (with contaminated food) of sporulated oocysts containing 2 sporocysts with 2 sporozoites. The source of the oocysts is not yet clear, since *Cyclospora* exists in many animals without clinical symptoms. **Treatment** may be carried out with Cotrimoxazol (2 × 800 mg Sulfamethoxazol/160 mg →Trimethoprim).

Cyclospora Species. Table 1 Important species of the genus *Cyclospora*

Species	Host	Infected tissues	Oocyst size	Prepatent period
Cyclospora cayetanensis	**Humans** (AIDS patients)	Intestinal cells	8–10 µm	?
Cyclospora caryolytica	Mole (*Talpa*)	Intestinal cells	8–12 µm	?
Cyclospora viperae	Snakes	Intestinal cells	9–12 µm	?



Cyclospora Species. Figure 1 Diagrammatic representation of an unsporulated and a sporulated oocyst.

Cyfluthrin

Ectoparasiticide (→Arthropodicidal Drugs) of the group of pyrethroid acting against flies on grazing cattle.

Cyhalothrin

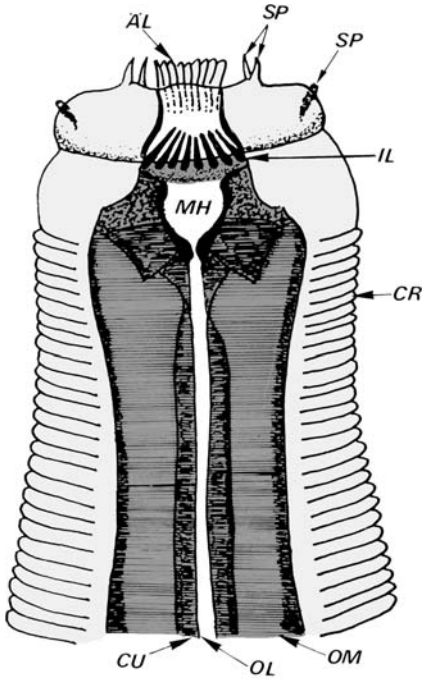
Pyrethroid, →Ectoparasiticides, →Arthropodicidal Drugs.

Cylicocyclus nassatus

→Nematodes.

Cylicodontophorus

Genus of the subfamily Cyathostominae = small strongylids.



Cylicostephanus. Figure 1 DR of the anterior of a small strongylid nematode of horses: *Cylicostephanus* sp. *AL*, outer lamellae; *CR*, cuticular rings; *CU*, cuticle; *IL*, inner lamellae; *MH*, buccal cavity; *OL*, lumen of oesophagus; *OM*, muscles of oesophagus; *SP*, sense papillae.

Cylicostephanus

Genus of small strongylid nematodes of horses (Fig. 1), subfamily Cyathostominae = small strongylids.

Cymiazole

Chemical Class
Amidine (formamidine).

Mode of Action
Octopamine receptor agonist. →Ectoparasiticides – Modulators/Agonists of Aminergic Transmission.

Cynomya mortuorum

C. mortuorum (fly family Calliphoridae 7–18 mm, metallic, blue-green) excretes its eggs on dead bodies (especially on fish). This species is found in the holarctic region.

Cypermethrin

Chemical Class
Pyrethroid (type II, α-CN-pyrethroids).

Mode of Action
Open state voltage-gated sodium channel blocker. →Ectoparasiticides – Blockers/Modulators of Voltage-Gated Sodium Channels.

Cyromazine

Chemical Class
Aminotriazine.

Mode of Action
Insect growth regulator (IGR, cuticle sclerotization effectors) →Ectoparasiticides – Inhibitors of Arthropod Development.

Cyrtocyte

Synonym
→Terminal Cell.

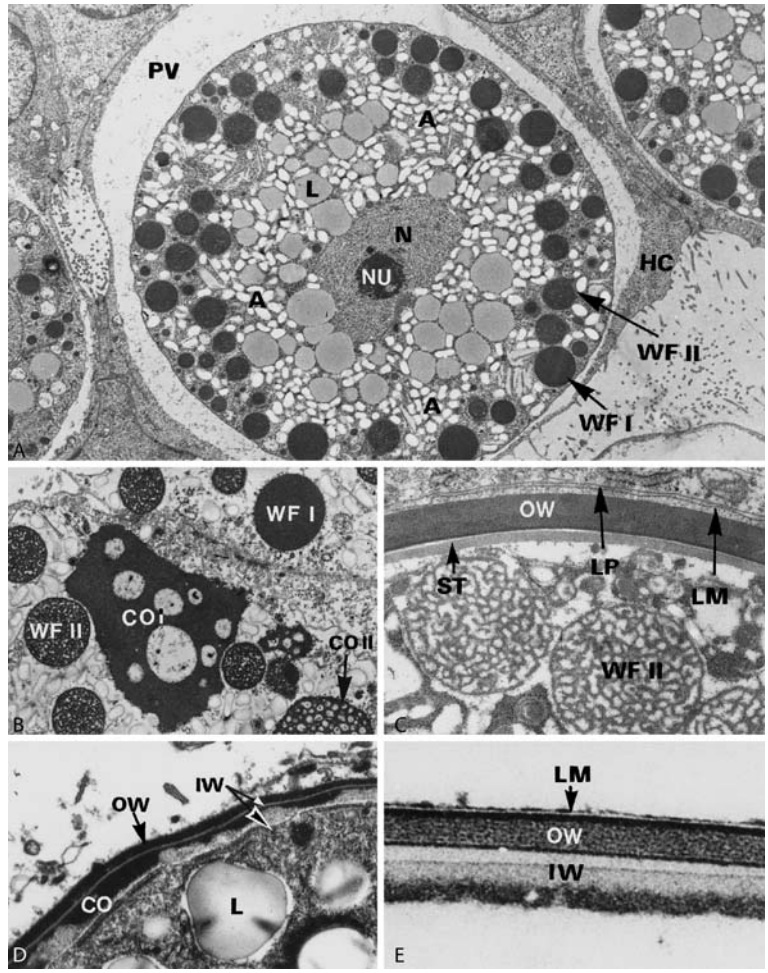
Portion of the excretion system of Platyhelminthes (→Platyhelminthes/Figs. 24, 25).

Cyst Forming Coccidia

→Toxoplasma, →Sarcocystis, →Besnoitia.

Cyst Wall

Many parasitic →Protozoa (e.g., →*Giardia*, →*Entamoeba histolytica*, →Coccidia) are capable of undergoing



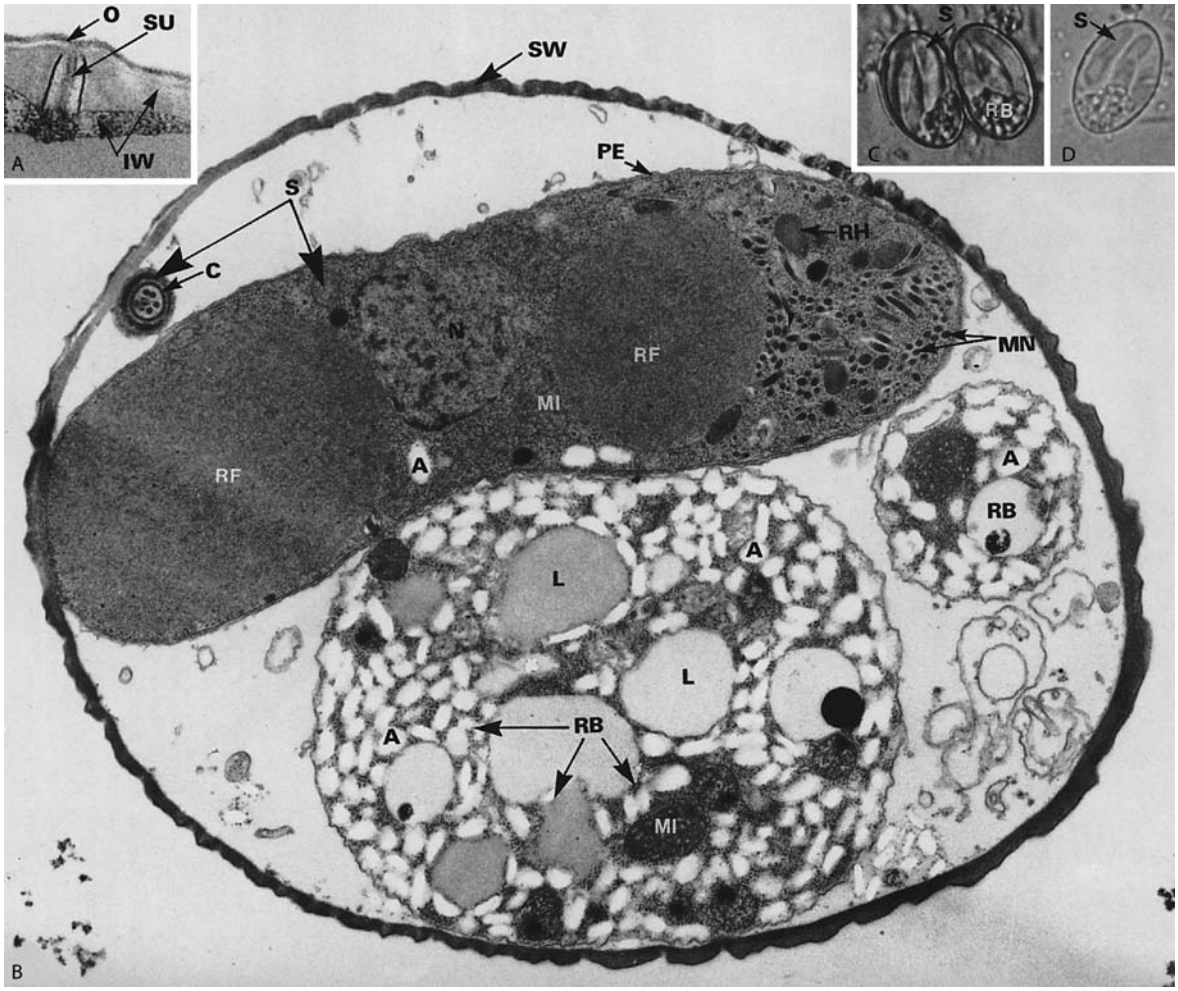
Cyst Wall. Figure 1 **A–E** Transmission electron micrographs of the formation of the oocyst wall in members of the Eimeriidea. **A–C** *Eimeria stiedai* in the bile ducts of rabbits; typical eimerian macrogamete with 2 types of wall-forming bodies, which combine to form the inner and outer layers of the oocyst wall (A × 2,000, B × 3,500, C × 15,000). **D** *Sarcocystis clethrionomyelaphis* from the intestine of the snake *Elaphe longissima* (× 15,000). **E** *Isospora* sp. from sparrows (× 18,000). *A*, amylopectin; *CO I, II,* confluent wall-forming bodies of types I and II; *HC*, host cell; *IW*, inner layer of oocyst wall; *L*, lipid; *LM*, limiting membrane of the parasite; *LP*, limiting membrane of the parasitophorous vacuole; *N*, nucleus; *NU*, nucleolus; *PV*, parasitophorous vacuole; *ST*, starting formation of IW; *WF I, II*, wall-forming bodies of type I, II.

→encystation, which involves formation of a cyst wall either outside or inside the →cell membrane. This cyst wall may be single- or multilayered. Walls formed outside the →plasmalemma are produced by →exocytosis of materials (→Wall-Forming Bodies). Cyst walls have 2 main tasks: (1) to protect the organism against unfavorable →environmental conditions when passing from one host to another, and (2) to create spaces for reorganization and →nuclear division. Cyst walls may also aid the parasite in its transmission from one host to another by facilitating attachment to host cell surfaces.

The cyst wall has one layer in cysts of →*Entamoeba histolytica*, *Giardia*, and some ciliates, such as the fish parasite →*Ichthyophthirius multifiliis* and the human parasite →*Balantidium coli*. There are usually 2 types of cysts in the stages of →coccidia in feces: the oocysts and the sporocysts. The →oocyst wall is usually 2-layered but in a few species it may have 4 layers. It is formed by 2 types of cyst-→wall-forming bodies (→*Eimeria*) (Fig. 1).

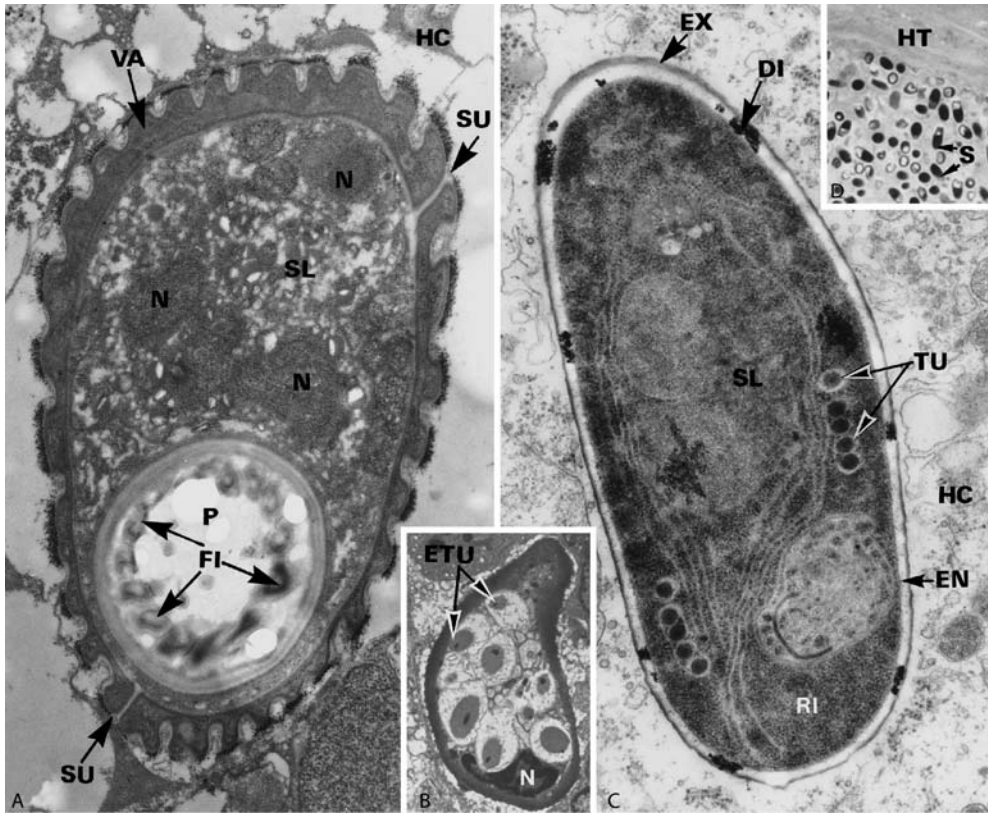
The chemical composition of cyst walls varies according to the species, although proteins are usually the basic component. The cyst walls of *E. histolytica* and →*G. lamblia* contain proteins which are keratin-like or elastin-like albuminoids, composed of lysine, histidine, arginine, tyrosine, glutamic acid, and →glycine.

The 2-layered oocyst wall of the sporozoans is periodic acid-Schiff-positive (PAS-positive). The outer layer of these oocysts consists mainly of fatty alcohols



Cyst Wall. Figure 2 **A–D** Sporocysts under light (C, D) and transmission electron microscopy (A, B). **A** Suture of the sporocyst wall (characteristic of the genera *Sarcocystis, Toxoplasma, Isospora*); the wall ruptures here during the excystation of the sporozoites inside the intestinal tract of the host (× 40,000). **B** *Isospora* sp. from sparrows. Section through a sporocyst with 2 (of 4) sporozoites (S) in the section plane. Note the large, membrane-bound residual body (× 12,000). **C, D** *Sarcocystis* sp. oocysts (OC) contain 2 sporocysts with 4 sporozoites when excreted with feces; due to the smooth oocyst wall mostly sporocysts (D) are found in feces (× 2,000). *A*, amylopectin; *IN*, inner part of the sporocyst wall; *L*, lipid; *MI*, mitochondrion; *MN*, micronemes; *N*, nucleus; *O*, outer part of the sporocyst wall; *PE*, pellicle; *RB*, residual body; *RE*, retractile body; *RH*, rhoptries; *S*, sporozoite; *SU*, suture; *SW*, sporocyst wall.

(e.g., hexacosanol), some phospholipids, and fatty acids. It contains no carbohydrates or proteins. The inner layer is composed of glycoproteins and contains most of the carbohydrates found in the oocyst wall. These carbohydrates are composed of mannose, galactose, glucose, and hexosamine. The oocyst wall is highly resistant to the passage of potassium dichromate, sodium hypochloride, sulphuric acid, and sodium hydroxide and therefore these chemicals are used in the storage and cleaning of oocysts. It is permeable to O_2, CO_2, NH_3, methylbromide, carbon disulphide, and various organic solvents. The oocyst wall is highly susceptible to mechanical pressure and therefore may be easily ruptured by shearing forces. Thus, the mechanical rupture of oocysts in the gizzard of the avian host is likely to be the normal method of excystation of avian coccidia. The →micropyle (a preformed opening) is probably rarely used as a passage for the escape of sporocysts. The sporocysts in the oocyst are bound by a 2-layered wall, the inner layer of which is relatively smooth (Fig. 2). The sporocysts of eimerians have an opening which serves as an exit for the sporozoites. This is closed by the →Stieda body, which can be dissolved by trypsin. The sporocysts of →*Isospora* and the tissue-cyst-forming coccidia (e.g., →*Sarcocystis*, *Toxoplasma*) have sutures on which the excystation fluids act, causing collapse of the →sporocyst wall (Fig. 2).



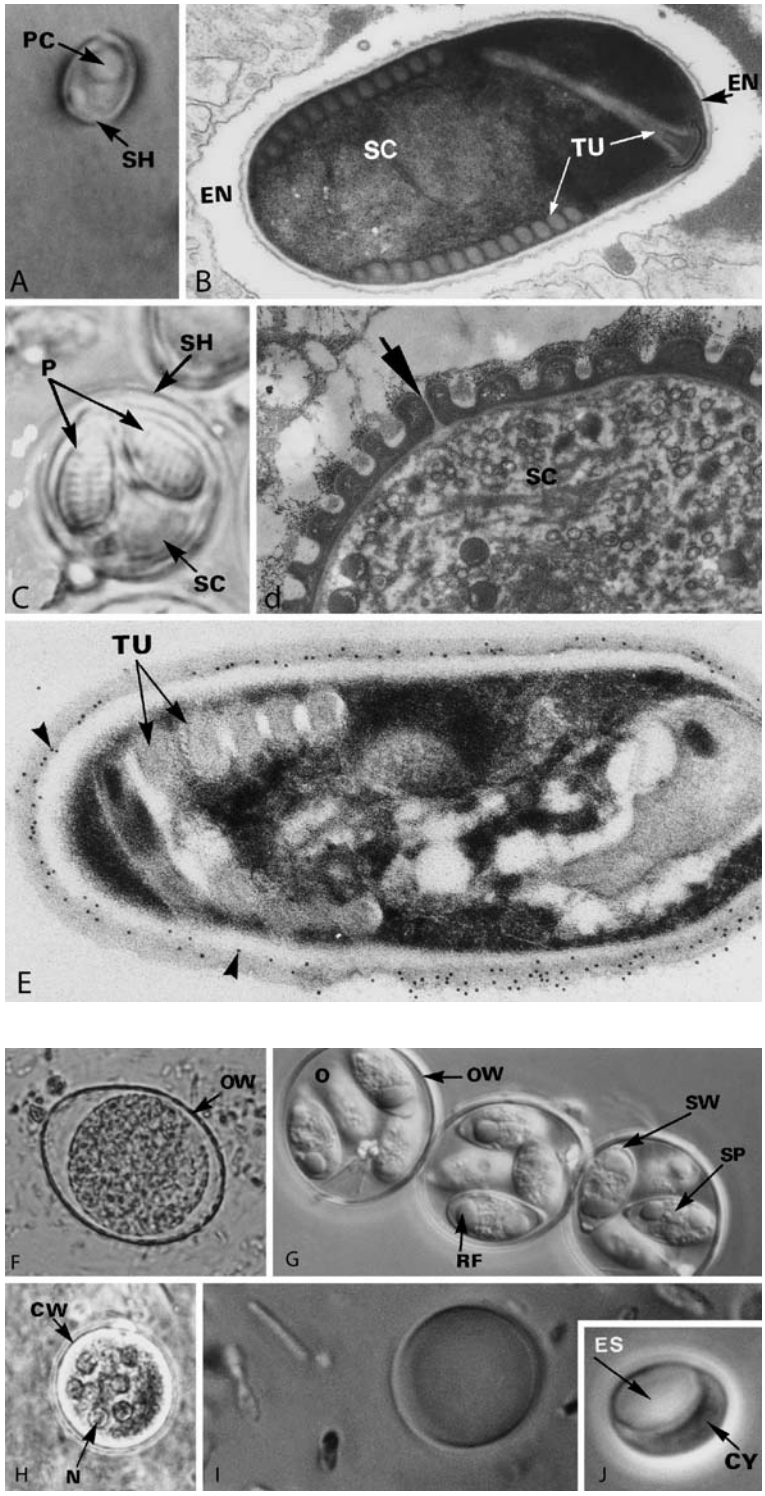
Cyst Wall. Figure 3 A–D Myxo- (A) and microsporidian cysts (B, D) in electron (A, C) and light micrographs (D). **A** *Myxosoma* sp. from fish skin, due to the oblique section only one polar capsule is seen (× 10,000). **B, D** *Glugea* sp. from intestinal wall of fish (B × 3,500, D × 2,000). **C** *Nosema* sp. from tissues of *Pimpla* sp. (× 12,000). *DL*, densification in EN; *EN*, light endospore; *ETU*, enlarged TU; *EX*, dense exospore, *HC*, host cell; *HT*, host tissue; *N*, nucleus; *RL*, ribosomes; *S*, spores; *SC*, sporoplasm; *SU*, suture of valves; *TU*, polar tube (filament); *VA*, valve of shell.

The cyst walls of the members of the →Myxozoa and →Microspora are at least double-walled in most species (Fig. 3), but the layers can only be resolved by electron microscopy. In Myxozoa, the wall consists of 2 valves that open at pre-formed sites to release the infectious →sporoplasm (Fig. 3A). The Microspora have developed a hollow tube that protrudes from the surface of the wall (Figs. 3B, 4). It penetrates into a host cell and the infectious sporoplasm is passed through it. The →exospore layer in Microspora is proteinaceous and is 15–100 nm thick, depending on the species. The →endospore layer is chitinous and ~150–200 nm thick (Fig. 4). The →Spores are Gram-positive (i.e., stain reddish purple with the Gram stain), a fact that is of diagnostic value. They are also stained light blue by →Giemsa. Besides these typical cysts, some genera such as *Toxoplasma* and *Sarcocystis*, form so-called →tissue-cysts. They develop from a "normal →parasitophorous vacuole," the membrane of which becomes fortified to a so-called →primary cyst wall, which starts to form species-specific protrusions. Such tissue-cysts, while inside divisions go on, may become covered by host defense cells so that a →secondary cyst wall is produced (e.g., →*Sarcocystis ovifelis*, →Tissue Cyst).

Encystation is also done by →cercariae of some digenean →trematodes (→*Digenea*) which excrete (via cystogenous glands) material to produce the wall of →metacercariae, →*Fasciola*. Further similar processes are seen in →Acanthocephala/→Cystacanth.

Cystacanth

An infective →acanthella is commonly called a cystacanth, referring to the cyst-shaped larvae of *Macracanthorhynchus hirudinaceus* (→Acanthocephala/Fig. 2) or →*Moniliformis moniliformis* (→Acanthella/Fig. 2C). Most



Cyst Wall. Figure 4 Cyst stages (A, C, F–I light micrographs, B, D, E electron micrographs). **A, B** Microsporidian spore (*Nosema*). A × 2,500, B × 15,000. **C, D** Myxosporidian cyst (*Myxobolus*). C × 1,000, D × 30,000. **E** Immunogold reaction with a gold-labelled antibody against chitin (arrows). × 20,000. **F, G** *Eimeria* oocysts (G = sporulated). × 1,000. **H** *Entamoeba coli* cyst. × 2,000. **I** *Blastocystis hominis* vacuolar and cystic stage (inset). × 2,000. *CY*, cytoplasm; *CW*, cyst wall; *ES*, empty space in cyst interior; *N*, nucleus; *OW*, oocyst wall; *P*, polar capsule; *PC*, polaroplast; *RF*, refractile body; *SC*, cytoplasm; *SH*, shell valve; *SP*, sporocyst; *SW*, sporocyst wall; *TU*, tubular polar filament.

acanthocephalans, however, have elongated sausage-shaped infective larvae (→Acanthella/Fig. 2C), which resemble immature adults with an invaginated →praesoma. Such larvae have well-developed sexual organs whereas the "cystacanth-like larvae," with a large gap between them and the surrounding envelope, are usually retarded in the development of their sexual organs and may have a very solid body wall (→Acanthella/Fig. 2C). Therefore the general term infective larva appears more appropriate than the misleading term cystacanth. But usually names that have become established cannot be changed anymore. Cystacanths have almost-closed tegumental pores and compressed crypts in their outer membranes, corresponding to the dormant metabolism of this larva. The size of the →surface coat usually significantly exceeds that of the adult worms inside the gut of the final host.

Cysticercoid

Tailed second larva, e.g., of →tapeworms of the families Anoplocephala, Davaneidae, Dipylidae, and Hymenolepidiae (→Cestodes, →Eucestodes).

Cysticercosis

Pathology

Cysticercosis results from the development of larval →tapeworms in humans harboring adult →*Taenia solium* (→Autoinfection) or from ingesting soil containing eggs shed in the feces of humans, in areas where there are no latrines, or where they are so filthy that they are not used. Humans are accidental intermediate hosts and pigs are the normal intermediate hosts; their meat being "measly pork". Oncospheres released from eggs penetrate the intestinal mucosa and develop into bladder-like, →cysticercus larvae of 1–2 cm which develop in many tissues, mostly in skeletal muscle and subcutaneous tissue. Clinically they are most serious when located in the central nervous system or in the eye where they persist for months to years. The intact cysticerci are surrounded by a fibrous capsule and rarely give rise to symptoms, unless they involve special areas of the brain such as the aqueduct or are present in large numbers. However, degenerating cysticerci give rise to fever with an intense eosinophilic →inflammatory reaction (→Eosinophilic Reaction) accompanied by tissue swelling, being especially serious in the brain. The dead parasites often calcify and become demonstrable by radiography; the living cysticerci can be diagnosed by computerized axial tomography and magnetic resonance imaging and should correlate with positive serological findings.

Main clinical symptoms: Dysfunction of the organs, within which the cysticerci are located.
Incubation period: 8–10 weeks.
Prepatent period: 8 weeks.
Patent period: 2 years.
Diagnosis: Serodiagnostic methods, computer tomography, →Serology.
Prophylaxis: Avoid contact with human feces.
Therapy: Treatment with praziquantel, see →Cestocidal Drugs.

Immune Responses

The cysts have developed mechanisms to avoid the host inflammatory and immune response. The analysis of experimental infections of rodents with →*Taenia crassiceps* or →*T. taeniaeformis* has significantly contributed to our understanding of the host–parasite relationship.

Complement and Macrophages Granulocytes

Destruction of oncospheres in sera of patients or immune animals is mediated by the classical complement pathway. However, also the primary resistance to *T. taeniaeformis* infection in naive mice is complement-dependent. C3b is deposited on the surface of oncospheres and proto-oncosphere larvae but only in resistant and not in susceptible murine hosts is C5a produced. In contrast, complement has little effect on viable metacestodes.

In experimental infections, the developing →metacestode is surrounded by neutrophils and eosinophils, which appear to have no detrimental effect on the parasite. The formation of infiltrates may be directly initiated by the parasite via the production of several chemotactic factors. *Taenia*-induced macrophages upregulate molecules like death ligand 1 (PD-L1) and PD-L2. These molecules are responsible for the inhibition of parasite-specific response of lymphocytes, thus representing an immune-escape mechanism operative during *Taenia* infection.

B Cells and Antibodies

Antibodies are thought to play a decisive role in the immune response to →*Taenia* oncospheres. Passive immunization studies have shown that protection can be transferred with antibody alone, while T cells are involved in the generation of protective immunity. In contrast, antibodies have little effect on

metacestodes. However, most viable parasites contain immunoglobulin on their surface, of which the majority is not specific for the parasite. It has been suggested that the parasites may have Fc receptors for host immunoglobulins, which could be taken up, digested, and thus serve as a primary protein source for the parasite.

T Cells

Acute infections with taeniid oncospheres as well as viable cysts are associated with suppression of the host immune response. For example, spleen cells from acutely infected rats displayed decreased mitogenic responses, and in infected pigs a decreased number of $CD4^+$ T cells in the peripheral blood has been reported. The immune-suppressive effects seem to be mediated, at least in part, by modulation of the role of macrophages as antigen-presenting cells and appear to be dependent on the presence of viable parasites.

In mice infected with Taenia crassiceps, elevated levels of IgG1 and IgE suggested a dominant Th2 response. Increased production of IL-4, IL-6, and IL-10 has been detected, and active infection was also associated with a suppression of pro-inflammatory and Th1 cytokines.

The death of the parasite is associated not only with a granulomatous response but also with a switch to IgG2a production, a pattern associated with IFN-γ production. In humans, parasite death is accompanied by elevations of neopterin within the spinal fluid, a marker for macrophage activation. In addition IL-12 and IFN-γ expression has been detected in granulomas surrounding dying cyst, consistent with the idea, that death of the metacestodes results in a shift to a Th1 response.

Evasion Mechanisms

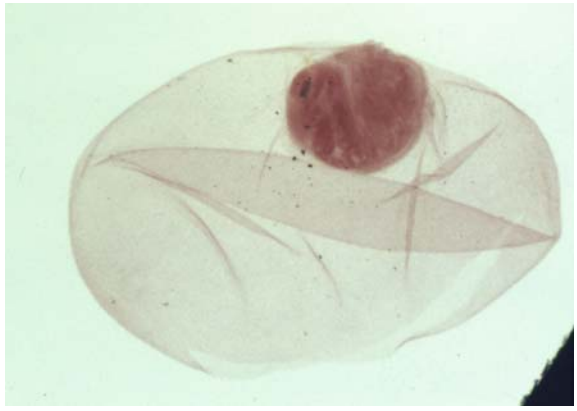
Molecules able to detoxify reactive oxygen intermediates, such as superoxide dismutase and glutathion-S-transferase, were purified from *T. taeniaeformis*. →Paramyosin, excreted by →*T. solium*, is able to bind to C1 thereby inhibiting the classical complement activation. The protease inhibitor taeniastatin, a glycoprotein secreted by *T. taeniaeformis* metacestodes, not only inhibited the classical and alternative pathway of complement activation but also suppressed mitogen- or IL-1-induced proliferation of rat spleen or mouse thymus cells, respectively. Furthermore, taeniaestatin interfered with neutrophil chemotaxis and aggregation *in vitro*. Prostaglandin E2 isolated from the excretory fluid of *Taenia* metacestodes may contribute to the inhibition of Th1 responses.

Cysticercus

Name

Greek: *kystis* = bladder, *kerkos* = tail.

Type of the second tapeworm larva (→Eucestoda, →*Taenia solium*), →bladder worm, →Cysticercosis, Figs. 1, 2.



Cysticercus. Figure 1 LM of a cysticercus of *Taenia solium* isolated from pig. The scolex region (dense part) is folded into a thin walled bladder, which thus is called *Cysticercus cellulosae*.

Cysticercus. Figure 2 Evaginated *Cysticercus* in human eye.

Cysticercus cellulosae

Larval stage of →Taenia solium in pigs, →Nervous System Diseases, Swine, →Cysticercus/Figs. 1, 2.

Cystidicola farionis

Synonym

Fissula.

Nematode (male 10–20 mm, female 11–36 mm) in salmonids (trouts) in the wall/inside the swim bladder.

Cystocaulus

Genus of the nematode family Protostrongylidae. *C. ocreatus* is found in the lungs of sheep and goats. Genus of 3–5 cm sized nematodes (lungworms) in cattle; larva 1 hatches already in the final host and thus are found in faeces.

Cystoisospora

Classification

Genus of →Coccidia.

Important Species

Table 1.

Life Cycle

→Coccidia/Fig. 2.

Disease

→Coccidiosis, Animals.

Cystozoites

Developing stage inside of apicomplexan tissue-cysts (e.g., →Toxoplasma gondii, →*Sarcocystis* species); another name is →bradyzoite describing that it is developing at low speed in contrast to →tachyzoites = quickly reproducing stages of the same species found, e. g., in macrophages.

Cysts

→Amoebae, →*Giardia*, →Coccidia.

Cytauxzoon

Synonym

→Theileria.

Cytauxzoon felis

Piroplasmean parasite of cats (mainly in North America) that enters white and red blood cells leading to a →theileriasis-like disease with rapidly progressing clinical signs (fever, lethargy) and shortly followed by death. →Reservoir hosts are bobcats and vector is the ixodid tick *Dermacentor variabilis*. It was recently suggested that *C. felis* is a *Theileria* species as *C. taurotragi* (→Theileria).

Cystoisospora. Table 1 Important species of the genus *Cystoisospora*[1]

Species	Host/Habitat	Size of oocysts (µm)	Prepatent period	Pathogenicity
Cystoisospora burrowsi	Canids/Small intestine, cecum, colon	21 × 18	6–9	+
C. canis	Dogs/Small intestine, cecum	36–44 × 29–36	8–11	–
C. felis	Cats/Small intestine, Ileum	30–53 × 23–32	6–17	–
C. ohioensis	Dogs/Small intestine, cecum, colon	19–27 × 18–23	6	–
C. rivolta	Cats/Small intestine, cecum, colon	22–36 × 21–27	5–7	–

[1] Some authors keep *Cystoisospora* synonym to *Levineia*, other retain the old name *Isospora*

Disease
→Cytauxzoonosis.

Cytauxzoonosis

Disease of domestic cats and bobcats (→Reservoir) in the USA due to infection with →*Cytauxzoon felis*, a 2 µm-sized piroplasmean parasite of lymphocytes and erythrocytes being transmitted by →ticks (e.g., *Dermacentor variabilis*). Some authors believe that →*Cytauxzoon* is synonymous to →*Theileria*. The disease shows rapidly progressing clinical signs such as high fever, icterus, lethargy, shortly followed by death.

Therapy
Unknown, try →Theileriacidal Drugs.

Cythioate

Chemical Class
Organophosphorous compounds (monothiophosphate).

Mode of Action
Acetylcholine esterase inhibitor. →Ectoparasiticides – Agonists and Antagonists of Cholinergic Transmission.

Cytoadherence

Binding of parasite-infected red blood cells to human endothelial cells, e.g., in →*Plasmodium falciparum*, leading to thrombus.

Cytochromes

→Energy Metabolism.

Cytodites

→Mites.

Cytokines

Name
Greek: *kytos* = cell and *kinein* = move.

This term describes proteins produced and excreted by cells, which stimulate the activity of other cells (e.g., immune modulation).

Cytomere

→Cell Multiplication/Multiple Divisions, →*Myxosoma cerebralis.*

Cytoplasm

Eukaryotic cells consist of a membrane-bound cytoplasm containing one or more nuclei and various organelles that are also often membrane-bound, their compartments and membranes acting as sites, where reaction processes can occur. The cytoplasm in →Protozoa is generally divided into 2 zones: (1) the peripheral, electron-lucent →ectoplasm (→Hyaloplasm); and (2) the denser central →endoplasm. The endoplasm contains the cell organelles and the nucleus. This differentiation is particularly prominent in the amebae and in the →gregarines (→Pellicle/Fig. 1A, →Pseudopodia/Fig. 1), but is not apparent in all species. In some species, endoplasm and ectoplasm cannot even be distinguished by electron microscopy. Male →microgametes of most sporozoans, apart from those of the →piroplasms, have a very reduced cytoplasm. They are comprised mainly of →flagella, a mitochondrion, and a nucleus (→Gametes). The cytoplasm of most cells shows high viscosity and stability and has a prominent →cytoskeleton.

Cytoplasmic Inclusions

The →endoplasm contains a variety of organelles and other structures within which metabolic processes occur, e.g., →nucleus, →mitochondria, →Golgi apparatus, →microbodies, →rhoptries, →micronemes, →wall-forming bodies, →vacuoles, endoplasmic reticulum, →ribosomes, →kinetoplast, →apicoplast.

Cytopyge

Synonym

→Cell anus.

Definition

Special place for →exocytosis developed by many →protozoa.

Cytoskeleton

The network of protein filaments and →microtubules in the →cytoplasmis called cytoskeleton.

Contractile elements are responsible for the cytoplasmic flow and these include →actin filaments with a diameter of ~6 nm. These filaments are composed of a double chain of globular bodies. Cytoskeletons may also contain 10 nm filaments or intermediate filaments which, to date, have been found only in the cells of higher vertebrates. The various types of filaments are organized into the microtubules of the cytoskeleton. The tubules have an outer diameter of 25 nm and an inner diameter of 15 nm. They are composed of protofilaments that are visible in cross-sections. The protofilaments consist of a- and b-tubulin elements in a helical arrangement. The microtubules are polymerized at particular points called microtubule organizing centers (→MTOCs). These centers exist at →centromeres, →centrioles and at certain places in membranes. They also occur as constituents of →flagella and →cilia (→Locomotory Systems, →Flagella/Fig. 1C).

The processes that bring about motility of the cytoplasm are well documented for metazoan cells, but for →Protozoa these processes are still poorly understood (→Apicomplexa/Motility). In all cases, it is probably the aggregation of →actin with →myosin and tropomyosin to form an actomyosin complex that leads to movement, as proposed in the sliding filament model of Huxley and Hanson. This ATP-dependent system may produce relatively rapid movements, as occur in ameba (20 μm per second), and in the sporozoites and merozoites of sporozoans. In addition to the cytoskeletal system, most parasitic protozoa have developed unique skeletal elements composed of combinations of the usual cytoskeleton elements. These structures include the following:

- The →subpellicular microtubules of trypanosomes and the motile stages of the →Coccidia (→Pellicle/Figs. 2, 3, →Apicomplexa/Fig. 4).
- The kinetodesmal fibrils of ciliates.
- The bundles of cytoplasmic microtubules in gamonts of →piroplasms (→Gametes/Fig. 6B).
- The combined microtubules and filaments observed in the ventral disc of the diplomonadids (→*Giardia lamblia*/Fig. 2).
- The crystalloid protein densifications that occur below the membrane of giardial →trophozoites, at the apex of eimerian →microgametes (→Gametes/Fig. 6A) and in the gamonts of piroplasms (→Gametes/Fig. 6B).
- The →axostyles and →pelta, occurring prominently in the →trichomonads and consisting of one or more parallel rows of microtubules (→Trichomonadida/Fig. 1).
- The →costa and parabasal filaments, the filamentous, sometimes striated elements (→Mitochondria/Fig. 1F, →Trichomonadida/Fig. 1) that line the →recurrent flagellum or the →Golgi apparatus in trichomonads.
- The →paraxial rods, which consist of a network of microfilaments that run along the axonemal microtubules of the →flagella of →Kinetoplastida (→Pellicle/Fig. 2A, →Trypanosoma/Fig. 5, →Flagella/Fig. 1D,E).
- The →conoids, which are found in the motile stages of some Coccidia, such as →*Eimeria*, →*Sarcocystis*, and *Toxoplasma* (→Pellicle/Fig. 5, →Kinete/Fig. 2), but which are always absent from the corresponding stages of haemosporidians (e.g., →*Plasmodium*, piroplasms).

Cytostome

Cell mouth (→Micropore of →Apicomplexa). Special place for the uptake of food developed by many →Protozoa (→Endocytosis/Figs. 1, 2).

Dactylogyrus vastator

→Monogenea, →Platyhelminthes/Fig. 17A.

Dactylosoma

Genus of babesoid parasites in red blood cells of amphibian animals.

Daily Biting Rate (DBR)

Number of bites of vectors of agents of diseases (e.g. →Malaria, →Onchocerciasis) at a given place. This number is used to evaluate the infection risk.

Daily Visiting Frequency

Presence (man × hour) at places, where vectors may transmit agents of disease. This factor measures the population at risk for an infection.

DALY

Disability **a**djusted **l**ife **y**ears (due to parasites) represents a measure of disease burden. In the case of →malaria the number is around 40 million.

Dapaong Tumour

Swelling as a result of adhesions around developing juvenile young stages of *Oesophagostoma* species in the colon of humans. These swellings may be seen on the skin surface and can be painful or painless depending on the obstructions of the colon.

Dasymetra conferta

Plagorchiid trematode in mouth and gastrointestinal tract of snakes.

Davaine, C. I. (1812–1882)

French physician and parasitologist, describer of tapeworms of the family Davaineidae.

Davainea proglottina

Fig. 1 (page 322); →Eucestoda.

DCL

Diffuse Cutaneous →Leishmaniasis.

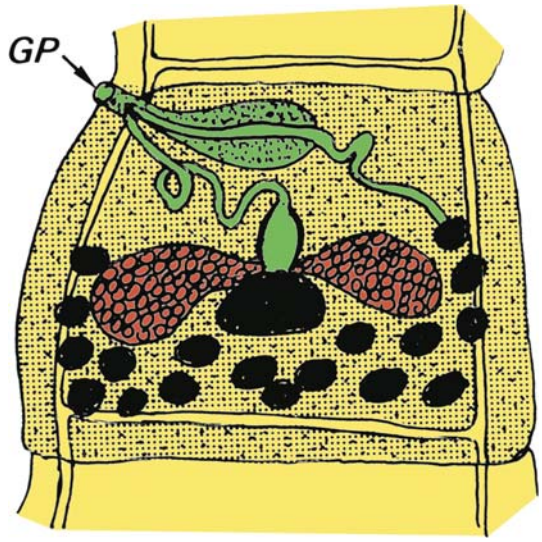
DDT (Dichloridiphenyltrichlorethane)

Chemical Class

Organohalogenide (organochlorine compound).

Mode of Action

Open state voltage-gated sodium channel blocker. →Ectoparasiticides – Blockers/Modulators of Voltage-Gated Sodium Channels.



Davainea proglottina. Figure 1 Diagrammatic representation of a rather young proglottis of a *Davainea* tapeworm showing the ovoid testes (black) and the female systems, the discharging channels of which open both at the genital pore (GP).

Deamination

→Amino Acids.

Death

Some parasites have severe lethal effects on some of their hosts especially in combination with an existing immune deficiency (→Opportunistic Agents, Man). Parasites with a high mortality rate in a given population (e.g., children) are among others →*Plasmodium falciparum*, →hookworms, schistosomes, etc.

Debilitation

Name

Latin: *debilitas* = weakening.

Decrease of immune reaction due to parasitic infections, e.g., during toxoplasmosis or helminthosis.

Decacanth

In contrast to the larvae of the →Eucestoda which have only 6 hooks (→Hexacanth) the →Cestodaria form 10 larval hooks (5 pairs) and are thus described as decacanth.

Decontamination

Deletion of soiling.

DEET

Diethyltoluamide, a repellent against mosquitoes.

Defensines

Arthropods produce AMPs (antimicrobial peptides), which protect them against penetrating parasites. Some defensines got varying names since their compositon is different, e.g., attacin, cecropin, diptericin, stomoxin, drosomycin, etc.

Dehydration

Excessive loss of water from the body tissues caused by various factors (e.g., diarrhoea, repeated vomiting, excessive perspiration or urination).

Clinical symptom in animals due to parasitic infections, an excessive loss of water from the body tissues (→Alimentary System Diseases, →Clinical Pathology, Animals).

Delamination

→Peritrophic Membranes.

Deltamethrin

Chemical Class

Pyrethroid (type II, α-CN-pyrethroids).

Mode of Action

Open state voltage-gated sodium channel blocker. →Ectoparasiticides – Blockers/Modulators of Voltage-Gated Sodium Channels, →Arthropodicidal Drugs.

Demethylmenaquinone

→Quinones.

Demodex folliculorum

Name
Greek: *demas* = body, *dex* = stretched.

Synonym
Follicle mites, sebaceum gland mites.

Classification
Subclass – Acari, Order – Acariformes, Suborder – Prostigmata.

Life Cycle
D. folliculorum mites are 0.4 mm long (Fig. 1) and live in the follicles of the hair. *D. brevis* lives in the sebaceous glands with a similar size. Adults have a lifespan of about 5 days, while the development of the whole generation needs about 15 days (→Mites).

Demodex folliculorum. Figure 1 *Demodex folliculorum*; SEM of an adult mite, from ventral; note the 8 short legs.

Demodicidae

Family of →Acarina.

Demodicosis, Animals

→Mange, Animals/Demodicosis, →Skin Diseases, Animals.

Demodicosis, Man

Demodicosis occurs in the hair follicles and sebaceous glands usually of the face (→*Demodex folliculorum*/Fig. 1). The elongate, about 0.4 mm long →mites feed on the contents of the sebaceous glands and also penetrate the follicular epithelium with their mouthparts. A mild dermatitis may be produced with inflammation and fibrosis. Immunosuppression may accentuate the severity of infection as observed in certain breeds of dogs infected with another species of →*Demodex* (→Demodicosis, Animals).

Main clinical symptoms: Dermatitis, →alopecia, pyodermia.
Incubation period: 2 weeks.
Prepatent period: 2 weeks.
Patent period: Years.
Diagnosis: Microscopic inspection of hair bulbi and sebum from skin.
Prophylaxis: General →hygiene; avoid body contact with heavily infected people.
Therapy: Treatment see →Acarizides, →Arthropodicidal Drugs, →Ectoparasiticidal Drugs; use of ivermectin, neem.

Dengue

Four types of virus exist to induce diseases (type of hemorrhagic fever) being transmitted by bite of →mosquitoes (→Arboviruses).

Dense Bodies

The dense bodies occur in the motile stages such as sporozoites, merozoites (inclusive zoites, brady- and →tachyzoites and are found in front of the nucleus among the →micronemes and the bulbous ends of the club-shaped

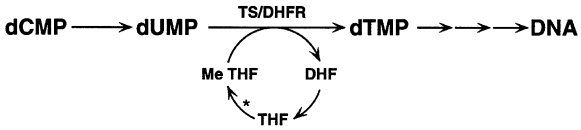
→rhoptries (→Merozoite/Fig. 1). They appear spherical, are membrane-bound and have an electron dense interior. Their diameters are rather similar in most species, reaching about 0.2 µm at the maximum. Just after penetration of the parasitic stages into a host cell, the contents of the dense bodies, which consist of at least 6 different proteins (enzymes?, GRA 1-6), are excreted into the surrounding →parasitophorous vacuole and are found also on the outer surface of the parasite. It is thought that the contents of the dense bodies protect the parasite, which starts development, from the attack of the host cell's digestive enzymes.

Dense Granule Protein (RESA)

→Apicomplexa.

Deoxynucleotides

Deoxyribonucleotides, the building blocks of DNA, are derived in most parasitic protozoa and in helminths, as in mammalian cells, primarily from the corresponding ribonucleotides as catalyzed by ribonucleotide reductase. Some protozoa, including *Entamoeba*, *Giardia* and →*Trichomonas vaginalis*, lack ribonucleotide reductase and have to meet their deoxynucleotide requirements by salvage pathways. The synthesis of deoxythymidine nucleotides, which are required for →DNA synthesis, is initiated by the conversion of dUMP to dTMP (Fig. 1). In this process, the necessary methylation of the pyrimidine ring is catalyzed by the tetrahydrofolate-dependent enzyme thymidylate synthase (TS). In protozoa, TS is unusual in that it differs in its kinetic and structural properties from the corresponding mammalian enzyme and exists as a bifunctional protein associated with dihydrofolate reductase (DHFR) (Fig. 1). In →helminth and mammalian cells, both the synthase and reductase activities are attributed to separate enzymes. The greater susceptibility of the parasite DHFR domain of the bifunctional enzyme toward inhibition by antifolate drugs than the mammalian enzyme and the absolute dependence on the *de novo* synthesis for dTMP forms the basis for the selective toxicity of these compounds against apicomplexan parasites. The conversion of nucleoside mono- and diphosphates to the corresponding triphosphates is carried out in parasites primarily by nucleotide kinases as is common to most living organisms. Because of the lack of TS in *Entamoeba*, *Giardia*, and trichomonads, these organisms are unable to synthesize dTMP from dUMP and rely entirely on the host for this deoxynucleotide.



Deoxynucleotides. Figure 1 The biosynthesis of deoxythymidylate (dTMP) in parasitic protozoa. TS/DHFR, thymidylate synthase/dihydrofolate reductase complex. MeTHF (N^5, N^{10}-methylenetetrahydrofolate) is produced from THF by the action of serine transhydroxymethylase (*). DHF, dihydrofolate; THF, tetrahydrofolate. Protozoan TS and DHFR extists as a single bifunctional enzyme. Amitochondriate protozoa lack TS and are therefore unable to produce dTMP from dUMP.

Dermacentor

Genus of 3-host ixodid ticks, e.g., *D. reticulatus* parasitic in dogs (→Dermacentor reticulatus/Fig. 1).

Dermacentor marginatus

Sheep →tick in Germany, that also sucks on cattle, man, and dogs, where it may transmit →*Babesia canis*.

Dermacentor reticulatus

Name

Greek: *derma* = skin, *centeo* = biting; Latin: *reticulum* = small net (English = ornate cow tick).

Synonym

Formerly it was thought that *D. marginatus* (Sheep tick) is identical with *D. reticulatus*.

Life Cycle

This 3-host tick (Fig. 1) is characteristic for southern Europe, but now enlarges its biotopes considerably northward; e.g., it is found in almost all German regions (perhaps a reaction to global warming). Larvae and nymphs feed on rodents, mice, rabbits, and birds, while adult stages attack larger animals (e.g., cattle, deer, horse, dogs) and humans. This species involves, obligatorily, 3 hosts in its life cycle, while other *Dermacentor* spp. (e.g., *D. albopictus, D. venustus* = *Anocentor* = *D. nitens*) may be 1-host ticks which molt on their hosts. The development of *D. reticulatus* in the egg takes 14–21 days, sucking as larva needs 2–6 days and molting takes 14 days on the ground to develop into the nymph. The nymphs feed for about 5 days on a new host and after dropping down to the ground they develop by molting within 12–14 days to adults, which can starve for up to 545 days before catching a new host. Thus there may be several genera within one season, if the larva, nymph, and adult are successful in catching a host. Since females lay up to 4,500 eggs and often 2 generations may occur per year, their spreading is rather quick. The unfed females are 4.5–5.5 mm long, the fed ones up to 1.5 cm.

Transmission: Besides of considerable blood loss, this species can harm its hosts by transmission of severe agents of disease (e.g., theileriosis of horses, babesiosis of dogs, spotted fever, borreliosis, arbovirosis, tularaemia).

Dermanyssidae

→Acarina.

Dermacentor reticulatus. Figure 1 LM of an adult female of *Dermacentor reticulatus* luring on grass.

Dermanyssus gallinae

Name

Greek: *derma* = skin, *nyssein* = bite.

Blood sucking mite, found on birds, humans etc. (Figs. 1, 2). →Mites.

Dermanyssus gallinae. Figure 1 LM of *Dermanyssus gallinae*. Surface view of an adult stage.

Dermanyssus gallinae. Figure 2 LM of *Dermanyssus gallinae*. Nymph with host blood in its intestinal tract.

Dermatitis

Clinical skin symptom due to infections with skin-penetrating parasites (e.g., →cercariae, hookworm larvae) or blood-sucking arthropods (e.g., →ticks, →fleas, →bugs, →lice, →*Culicoides* sp.); →Skin Diseases, Animals.

Dermatobia hominis

Synonym

→Human botfly.

Classification

Species of →Diptera.

Life Cycle

Figs. 1, 2.

Disease

→Myiasis, Man.

Dermatomyasis

From Latin: *derm* = skin, *myia* = fly →Myiasis.

Dermatophagoides pteronyssinus

House dust mite (Figs. 1, 2), see →Mites.

Dermatotropism

Name

Latin: *derm* = skin, Greek *trope* = turning.

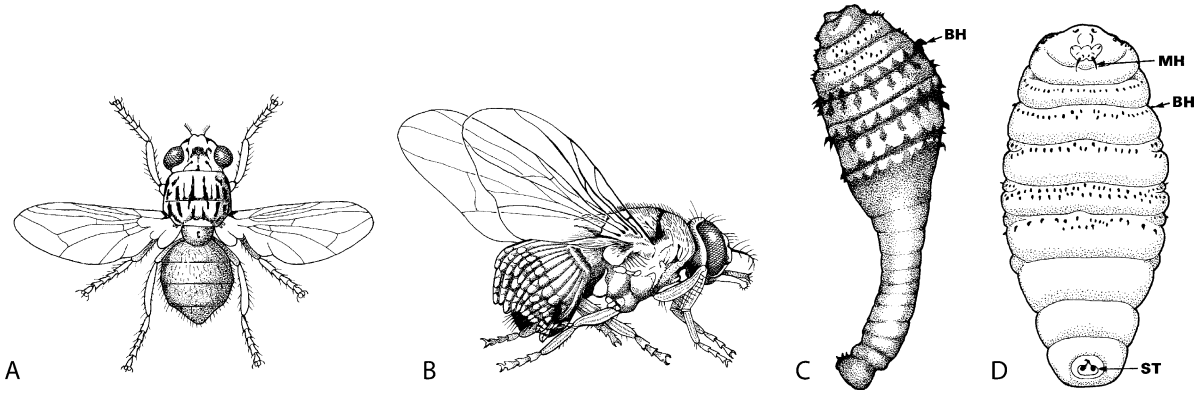
Activity of parasites that wander to the skin (from in-or outside of the body).

Derrengadera

Disease of horses due to *T. brucei evansi*: transmitted by →vampire bats in Venezuela.

Desmodus rotundus

→Vampire Bats.



Dermatobia hominis. Figure 1 Life-cycle stages of *Dermatobia hominis* (human botfly), which parasitizes man, cattle, dogs, and a number of wild and domestic mammals and birds (in Middle and South America). The females (**A**) deposit their eggs on day-flying →Mosquitoes (e.g., *Psorophora*), on other flies (→*Sarcophaga*, →*Musca*, →*Stomoxys*, **B**) or even on →*Amblyomma* →ticks. Eggs are laid directly on these arthropods or in their vicinity, so that they may become attached by help of their superficial cement. This peculiar way of transportation is known as →phoresis. The warmth of the vertebrate host induces the larva to hatch from the egg within 5 minutes and to penetrate the host's skin. At the site of the penetration the host tissue develops a →nodule, keeping open a breathing pore. Larvae (especially larvae 2 and 3 – **C, D**) have a characteristic shape with an attenuation of the posterior end. The larva feeds for 6–12 weeks in man's skin, then it drops to the ground, pupates, and develops inside the new adult stage. *BH*, body hooks; *MH*, mouth →hooks; *ST*, terminal stigmal plate.

Dermatobia hominis. Figure 2 Second stage larva of *Dermatobia hominis* (inset) and the cavity in the skin, where it had been located.

Dermatophagoides pteronyssinus. Figure 1 LM of adults of the house dust mite in food.

Dermatophagoides pteronyssinus. Figure 2 SEM of a house dust mite (dorsal side).

Desmosomes

Structures attaching cells to cells or flagella to Protozoans. →Flagella.

Deutomerite

→Gregarines.

Deutonymph

The second of up to 3 →nymphal stages found in mites. In most cases the deutonymph molts to the adult stage. →Mites/Ontogeny.

Diaemus youngi

→Vampire Bats.

Diamanus montanus

New World flea of the family Ceratophyllidae (→Ceratophyllus, →Nosopsyllus).

Diapause

Name

Greek: *diapausis* = interruption, rest.

This phase of inactivity during a development of arthropods may occur when the living conditions become bad, e.g., in winter. The individuum is then able to reduce considerably the processes of metabolism.

Diaptomus

First intermediate hosts (crustaceans) of →*Diphyllobothrium* tapeworm.

Diarrhoea

An intestinal disorder characterised by abnormal fluidity and frequency of fecal evacuations as a result of increased motility in the colon.

Clinical symptom in animals and humans due to parasitic infections (→Alimentary System Diseases, →Clinical Pathology, Animals).

Diarthrophallus quercus

Prostigmata mite species found on beetles.

Diazinon (Dimpylate)

Chemical Class

Organophosphorous compounds (monothiophosphate).

Mode of Action

Acetylcholine esterase inhibitor. →Ectoparasiticides – Agonists and Antagonists of Cholinergic Transmission, →Arthropodicidal Drugs.

Dichelyne minutus

Nematode species in the intestine of the round goby (*Neogobius melanostomus*) in the Baltic and Black Sea.

Dichlorvos (DDVP)

Chemical Class

Organophosphorous compounds (organophosphate).

Mode of Action

Acetylcholine esterase inhibitor. →Ectoparasiticides – Agonists and Antagonists of Cholinergic Transmission, →Arthropodicidal Drugs.

Diclazuril

→Coccidiocidal Drugs.

Dicranotaenia

Genus of tapeworms of the family →Hymenolepidae. *D. coronula* lives in the small intestine of ducks.

Dicrocoeliasis, Man

Disease due to infections with the digenetic trematode →*Dicrocoelium dendriticum* by oral uptake of infected ants being attached, e.g., to salad.

Main clinical symptoms: →Abdominal pain, liver enlargement.
Incubation period: 2–4 weeks.
Prepatent period: 7–8 weeks.
Patent period: Years.
Diagnosis: Microscopic determination of eggs in fecal samples (Fig. 1).
Prophylaxis: Clean thoroughly salad, plants, etc., from attached ants.
Therapy: Treatment see →Trematodocidal Drugs.

Dicrocoelium dendriticum

Name

Greek: *dikroos* = bi-branched, *koilia* = body hollow.

Classification

Species of digenetic →trematodes.

Dicrocoeliasis, Man. Figure 1 Egg of *Dicrocoelium dendriticum*.

Morphology
Fig. 2 (page 331). Size →Digenea.

Life Cycle
Fig. 1 (page 330).

Disease
→Dicrocoeliasis, Man, →Alimentary System Diseases.

Dicrotophos

Chemical Class
Organophosphorous compounds (organophosphate).

Mode of Action
Acetylcholine esterase inhibitor. →Ectoparasiticides – Agonists and Antagonists of Cholinergic Transmission.

Dictyocaulus

Name
Greek: *diktyon* = net, *kaulos* = stab, stick.

General Information
The adult worms of *D. viviparus*, which reach as females a length of 70 mm and 40 mm as males and live in the trachea and bronchial cavities of cattle. Similar species (*D. eckerti*/deers), *D. filaria*/sheep/goat, *D. arnfieldi*/horses/donkeys) are found in other hosts in identical habitats. The females lay thin-shelled eggs which contain already the L_1. This stage is set free inside the host, so that the larvae are found in the faeces. Within 1 week the sheathed infectious L_3 develops in the faeces (if there is a temperature higher than 16° C). After oral uptake the L_3 enters the mesenterial lymph nodes, where the L_4 is formed. By lymph and blood transport the L_4 reaches the lung beginning at the end of the 7th p.i. Within 21–25 days maturity is reached and after this prepatent period eggs/larvae can be found. The larval excretion extends over a period of only 5–6 weeks.

Diseases
→Respiratory System Diseases, Ruminants.

Therapy
→Nematocidal Drugs.

Dictyocaulus arnfieldi

Species of →nematodes. →Respiratory System Diseases, Horses, Swine, Carnivores.

Dictyocaulus viviparus

→Nematodes, →Respiratory System Diseases, Ruminants.

Dictyosomes

→Golgi Apparatus.

Dicyclanil

Chemical Class
Aminopyrimidine.

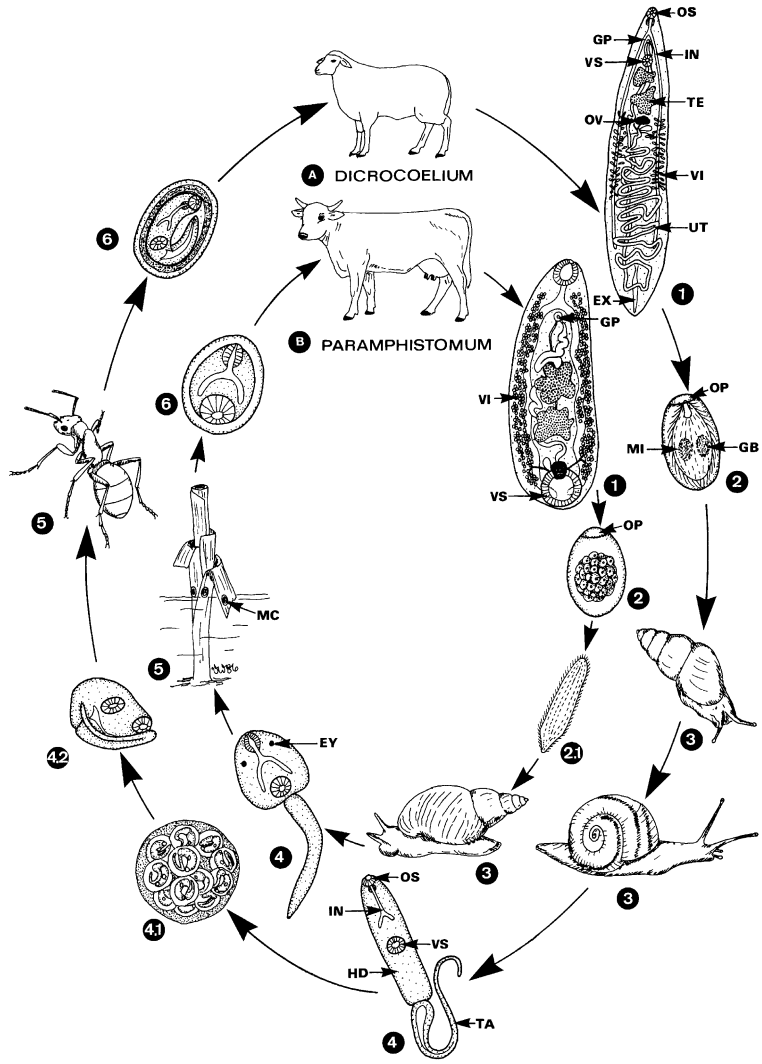
Mode of Action
Insect growth regulator (IGR, cuticle sclerotization effectors). →Ectoparasiticides – Inhibitors of Arthropod Development.

Dicyema

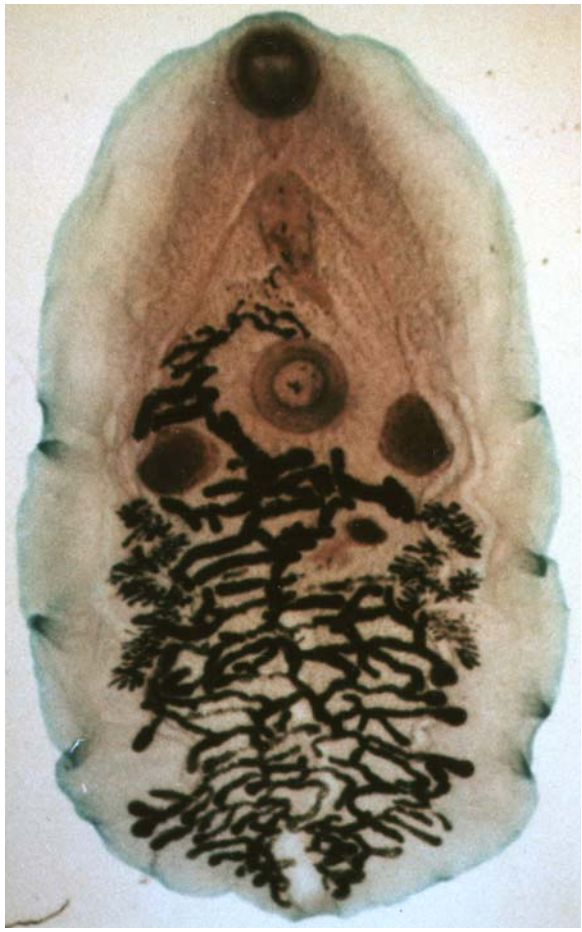
Genus of mesozoan parasites in, e.g., cephalopod hosts.

Dientamoeba fragilis

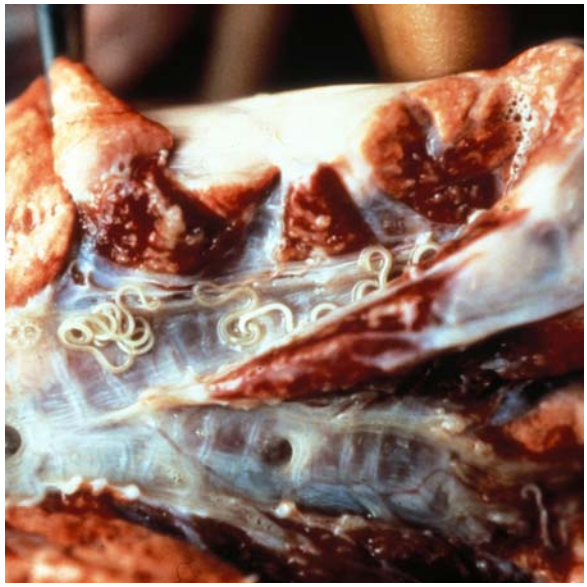
The →trophozoites of this species (→Amoebic Infections) reach a size of 3–12 µm, possess mostly 2 nuclei, include many food →vacuoles, and live in the colon of humans and monkeys (often in Zoological Gardens), Fig. 1 (page 331). They may cause as facultative parasites →abdominal pain and →diarrhoea. The transmission occurs by oral uptake of cysts from faeces



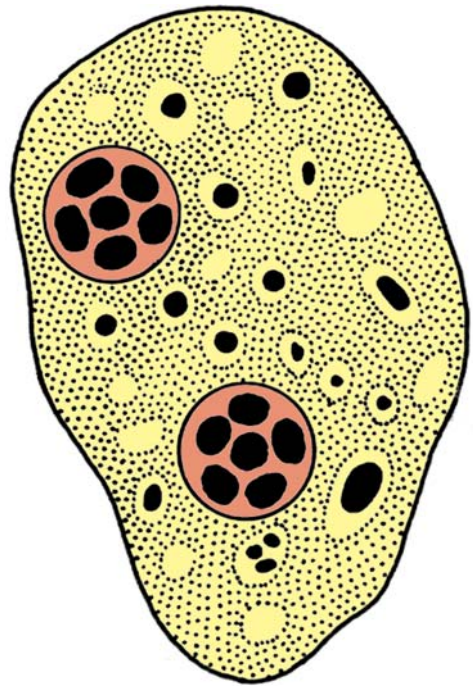
Dicrocoelium dendriticum. Figure 1 Life cycles of the →flukes *Dicrocoelium dendriticum* (**A**) and (→*Paramphistomum cervi*) (**B**) in sheep and cattle (final hosts: →Digenea/Table 1). *1* Adult worms in the bile ducts (a) or rumen (B). *2* Eggs are excreted in feces fully embryonated (A) or not (B). **2.1** In *P. cervi* the finally formed →miracidium hatches from the egg and enters a water snail, whereas in *D. dendriticum* land-living snails swallow the eggs containing the miracidium. *3–4* Intermediate hosts for *P. cervi* are water snails of the genera *Bulinus*, *Planorbis*, *Stagnicola*, and *Anisus*, whereas in *D. dendriticum* land snails of the genera *Zebrina* or *Helicella* are involved. Development in snails proceeds via 2 generations of sporocysts in *D. dendriticum*, whereas in *P. cervi* a →sporocyst and 2 →rediae occur. Finally, tailed →cercariae are produced, which leave the snail (**3**) or are excreted by the snails within slime-balls (**4.1**), but remain immotile (**4.2**). *5–6* In *D. dendriticum* ants become second intermediate hosts when eating slime-balls. Most of the cercariae encyst in the hemocoel (**6**) as →metacercariae and can then infect the final host. Where 1 or 2 cercariae enter the subesophageal ganglion, encyst there, and cause an alteration of the ant's behavior. When the temperature drops in the evening hours, the infected ants climb to the tips of grass (and other plants) and grasp them firmly with their mandibles, while uninfected ants return to their nests. The infected ants remain attached until the next morning, when they warm up, and resume normal behavior. These attached ants may be swallowed by plant-eating mammals. In *P. cervi* the free-swimming cercariae (with 2 eye spots) encyst on herbage andother objects (**6**), thus becoming metacercariae. Upon being swallowed along with forage, excystment of the metacercariae of both species occurs in the duodenum. From there they enter the bile duct (*D. dendriticum*) or return (via the intestinal wall) into the abomasum (*P. cervi*), and from there go to the rumen, where they attach among the villi. *EY*, →eye spot; *EX*, excretory bladder; *GB*, →germ balls; *GP*, genital pore; *HD*, head; *IN*, intestine; *MC*, metacercaria; *MI*, miracidium; *OP*, →operculum; *OS*, oral sucker; *OV*, ovary; *TA*, tail; *TE*, →testis; *UT*, uterus; *VI*, →vitellarium; *VS*, ventral sucker.



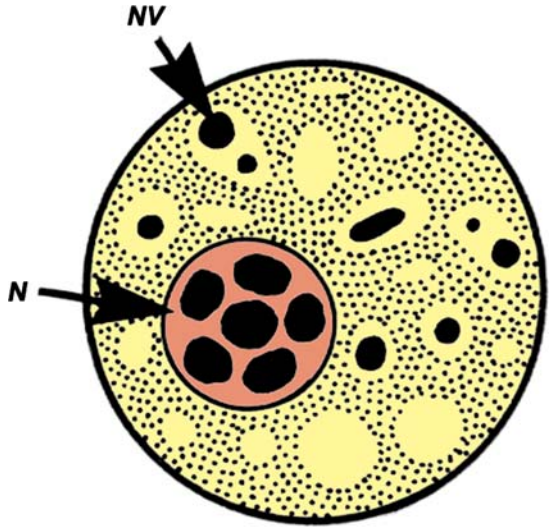
Dicrocoelium dendriticum. Figure 2 Coloured preparation of the small liver fluke (*Dicrocoelium dendriticum*).



Dictyocaulus viviparus. Figure 1 *Dictyocaulus viviparus* – worms in cattle lung system.



Dientamoeba fragilis. Figure 1 Trophozoite in division (two-nucleated).



Dientamoeba fragilis. Figure 2 Cyst. *NV*, food vacuole; *N*, nucleus.

(Fig. 2). It is discussed that trophozoites may become included in the eggs of the nematode (doubtful!). →*Enterobius vermicularis*. →Diplomonadida, →Trichomonadida.

Therapy
→Antidiarrhoeal and Antitrichomoniasis Drugs.

Diethyl Maleate

Chemical Class
Synergist.

Mode of Action
Glutathion-S-transferase inhibitor.

Diethylcarbamazine

Drug to control the larvae, i.e., the microfilariae of →filariae. →Nematocidal Drugs.

Diethyltoluamid (DEET)

Chemical Class
Repellent.

One of the most often used insect repellents since 1945.

Diflubenzuron

Chemical Class
Benzoylphenyl urea.

Mode of Action
Insect growth regulator (IGR, chitin synthesis inhibitor). →Ectoparasiticides – Inhibitors of Arthropod Development.

Digenea

Synonym
→Flukes.

Classification
Class of →Platyhelminthes.

General Information
The 6,000 species of digenetic →trematodes are very common and widespread parasites of all classes of vertebrates and may inhabit (as adult or juvenile worms) nearly every organ of their hosts (Table 1). Externally they are characterized by a sucker around the mouth and an additional ventral sucker or →acetabulum that is involved both in the attachment to host surfaces and in locomotion. The shape and location of these suckers is species-specific. Digenean development occurs in at least 2 different hosts and involves several generations. The basic life cycle pattern employed by digeneans and examples of their larval stages are displayed diagrammatically in Figs. 1–5.

System
The proposed classification of the class Digenea according to the origin of the protonephridial excretory system (→Cyrtocyte, →Platyhelminthes/Fig. 24) is, in outline (excluding several families), as follows:

- Class: Digenea.
  - Superorder: →Anepitheliocystidia (in the adult worms the wall of the larval excretory bladder is retained).
  - Order: Strigeatida (→cercariae fork-tailed; miracidia with two pairs of protonephridia).
    - Families: Diplostomatidae, Schistosomatidae, Spirorchidae, Bucephalidae, Strigeidae, Cyclocoelidae.
  - Order: Echinostomatida (cercariae with simple tail, miracidia with a single pair of protonephridia).
    - Families: Echinostomatidae, Fasciolidae, Gastrodiscidae, Paramphistomatidae.
  - Superorder: →Epitheliocystidia (excretory bladder is newly formed by mesodermal cells; tail of cercariae unforked).
  - Order: Plagiorchiida (eggs operculated: →oral stylet usually present in oral sucker of cercariae; tail of cercariae often lacks excretory vessels).
    - Families: Dicrocoeliidae, Plagiorchiidae, Prosthogonimidae, Troglotrematidae.
  - Order: Opisthorchiida (eggs operculated; cercariae lack anoral stylet; tail of cercariae always contains excretory vessels).
    - Families: Opisthorchiidae, Heterophyidae.

Important Species
Table 1.

Life Cycle
Except for some groups (e.g., the →dioecious Schistosomatidae; Table 1), flukes are hermaphroditic, utilizing sexual reproduction (with cross-insemination) in

Digenea. Table 1 Important families and species of digenean trematodes

Family/Species	Final host/Habitat	Size of adults (mm)	Size of eggs (μm)	First intermediate host[a]	Second intermediate host[b]	Prepatent period (weeks)
Allocreadiidae

[a] Several other species of gastropods may become first intermediate host

[b] There is no reproduction either in the true second intermediate hosts or on water plants

[c] Here so-called mesocercariae are found; third intermediate hosts are snakes or rats which contain metacercariae

the final host. The tanned eggs are produced after fertilization inside a complex system consisting of a central →ootype (→Oogenotop), an ovary, →vitelline glands, Mehlis's glands, and uterus (Figs. 6, 7). These eggs leave the host in feces, urine, or sputum, and the →zygote within the eggs develops (or has already developed by this stage) into a ciliated larva (→Miracidium; Fig. 2) In general this stage infects a gastropod mollusk or a lamellibranch (by penetration or via oral uptake = →*Clonorchis*) as first →intermediate host, inside which a polyembryonic, mitotic reproduction occurs involving different developmental stages (→Sporocysts, →Rediae) and leading finally to the production of numerous motile and infective →cercariae (Fig. 5). The latter leave the first intermediate host, often with a marked rhythm and, in some species, enter a second intermediate host (e.g., *Clonorchis*) or attach to the surface of plants, or in others directly penetrate the final host (Table 1, Fig. 2).

Inside the second intermediate host or on the surface of plants the cercariae encyst and develop into →metacercariae; cyst walls are totally or partly produced by cystogenous glands in the cercarial apex.

The metacercariae grow and become mature adults when orally ingested by the final host. Inside the final host they feed on its fluids depending on their final habitat (Table 1). Nutrients are taken up and digested by means of their anus-less, branched intestine (Figs. 3, 4) and via the characteristic syncytial →tegument (→Platyhelminthes/Figs. 11–13).

Reproduction

While the formation of the digenean eggs and of the first larva (miracidium) is rather well understood (reproductive organs), the ontogeny of other larvae remains a problem which is very complex and far from being solved. Electron microscopic studies have shown that the light microscopically visible →germ balls consist of mitotically dividing cells which give rise to embryos (→Polyembryony?) (Fig. 9; sporocysts, rediae, or cercariae) and to a line of new germ cells that

(*2*) Egg-miracidium-redia I-redia II-cercaria-metacercaria-adult worm (e.g., *Stichorchis* sp.). (*3*) Egg-miracidium-sporocyst-redia-cercaria-metacercaria-adult worm (e.g., →*Metorchis* sp.). (*4*) Egg-miracidium-sporocyst I-redia I-redia II-cercaria-metacercaria-adult worm (e.g., →*Fasciola hepatica*, →*Clonorchis sinensis*). (*5*) Egg-miracidium-sporocyst-cercaria-metacercaria-adult worm (e.g., Bucephaloidean species). (*6*) Egg-miracidium-sporocyst I-sporocyst II-cercaria-metacercaria-adult worm (e.g., →*Dicrocoelium dendriticum*, *Prosthogonimus* sp.). (*7*) Egg-miracidium-sporocyst I-sporocyst II-cercaria-adult worm (e.g., →*Schistosoma* sp.). (*8*) Egg-miracidium-sporocyst I-sporocyst II-cercaria-mesocercaria-metacercaria-adult worm (e.g., *Alaria* sp.).

become included in these embryonic stages. Since the absence of meiotic processes is not proven, the exact definition remains doubtful. The same is true for embryonic development in the monogenean genus →*Gyrodactylus*. In any case, however, both processes are successful means of increasing the biotic potential and producing numerous daughter organisms.

Some digenean species belonging to the superfamilies Brachylaemoidea (e.g., *Postharinostomum* spp., *Leucochloridium* spp.) and Bucephaloidea (e.g., *Bucephalus* spp.) form branching sporocysts. By constrictions such branches may split off and finally grow to their former size. This occurs by mitotic divisions of undifferentiated cells which are found below the body wall (→Platyhelminthes/Fig. 10).

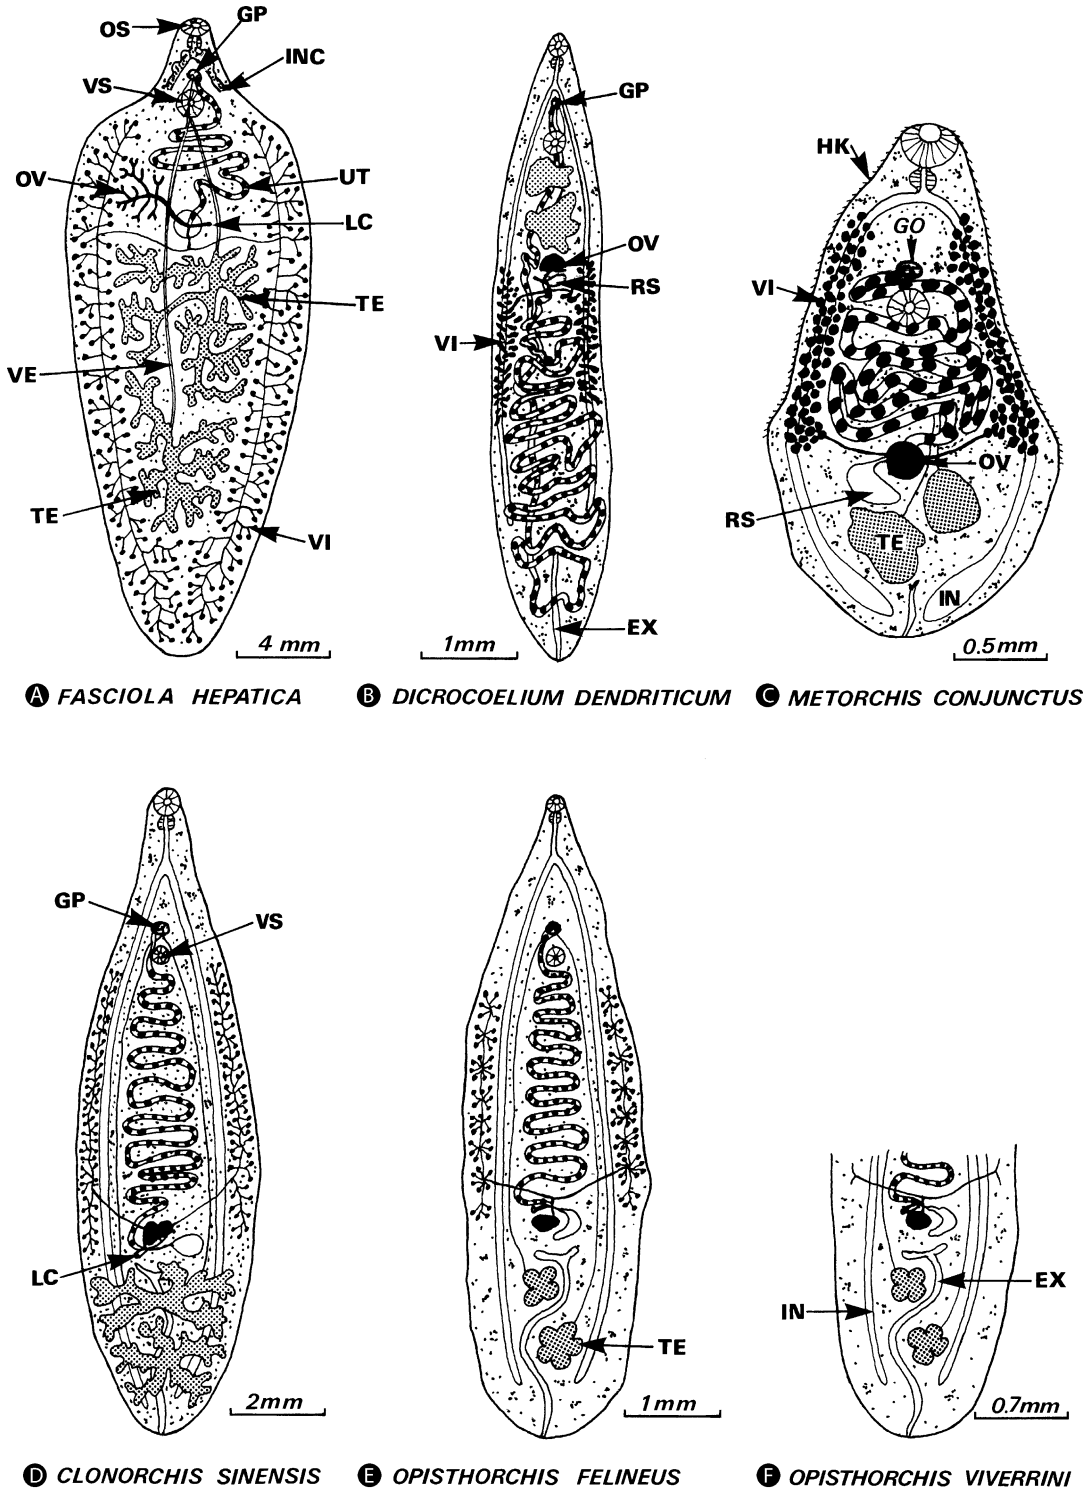
Integument

The shape and the development of the peculiar →body cover is described under →Platyhelminthes/Integument. In addition it is noteworthy that all larval stages seem to have a →surface coat containing proteoglycans (acid mucopolysaccharides). In the miracidium even the →cilia are covered by a →surface coat. Mother sporocysts of *Fasciola hepatica and Schistosoma mansoni* show an amplification of the surface area by a mixture of branching folds and →microvilli. Both are covered by a fuzzy surface coat. Vesicles at the base of the microvilli suggest the occurrence of →endocytosis. Rediae also have a surface coat. Although there is evidence that they are able to take up nutrients through the mouth into the small digestive system, absorption of nutrients by endocytosis through the tegument has been observed for glucose, a polysaccharide, and amino acids.

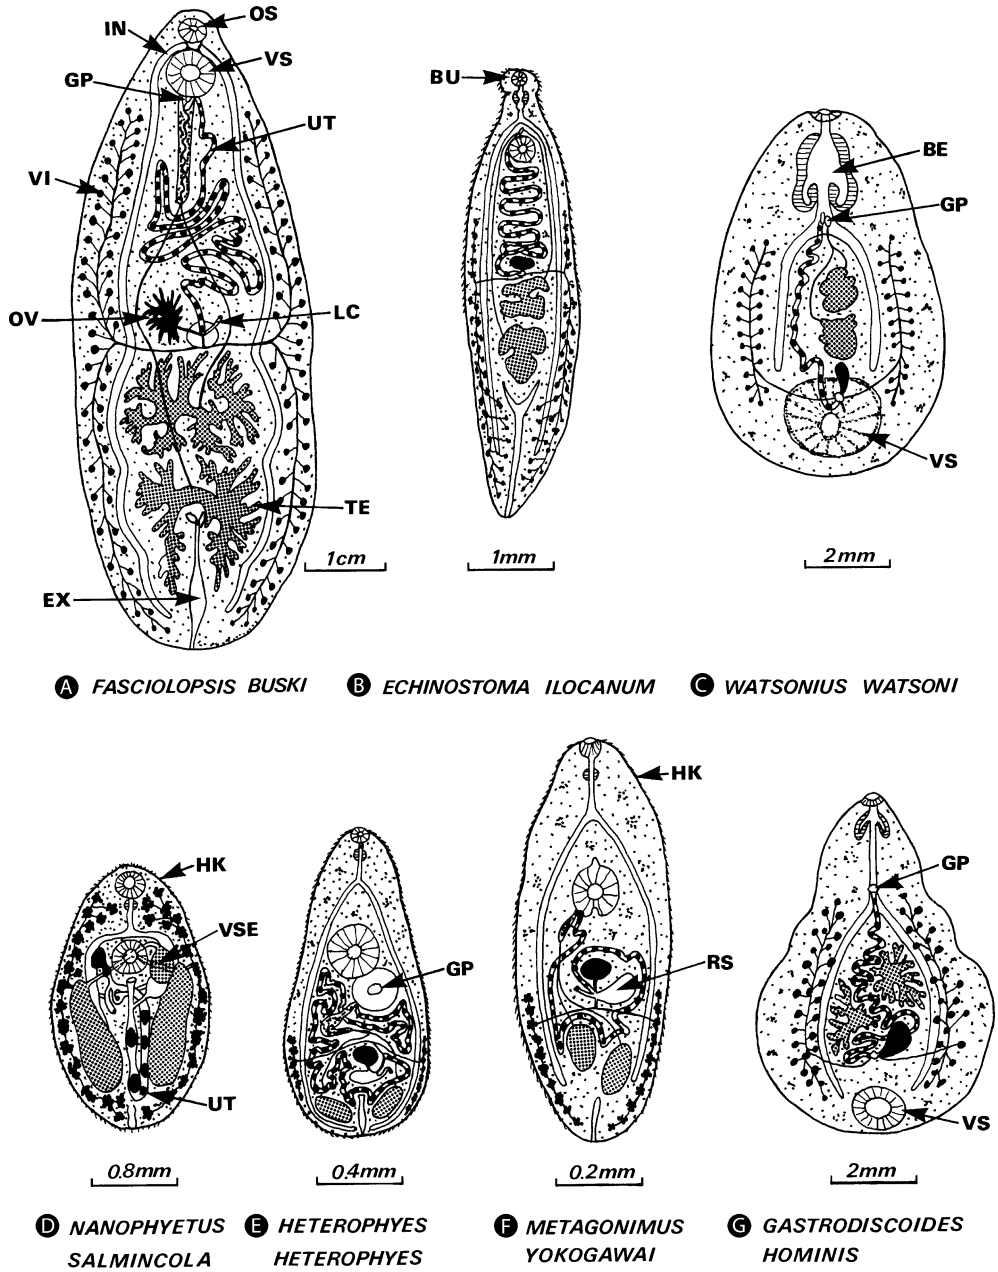
Host Finding

Miracidia

Miracidia which actively reach their aquatic snail hosts are infectious for only a few hours, and their behavior seems to center entirely around finding and invading the host snail. Their behavior patterns have functions in at least four phases of host finding:

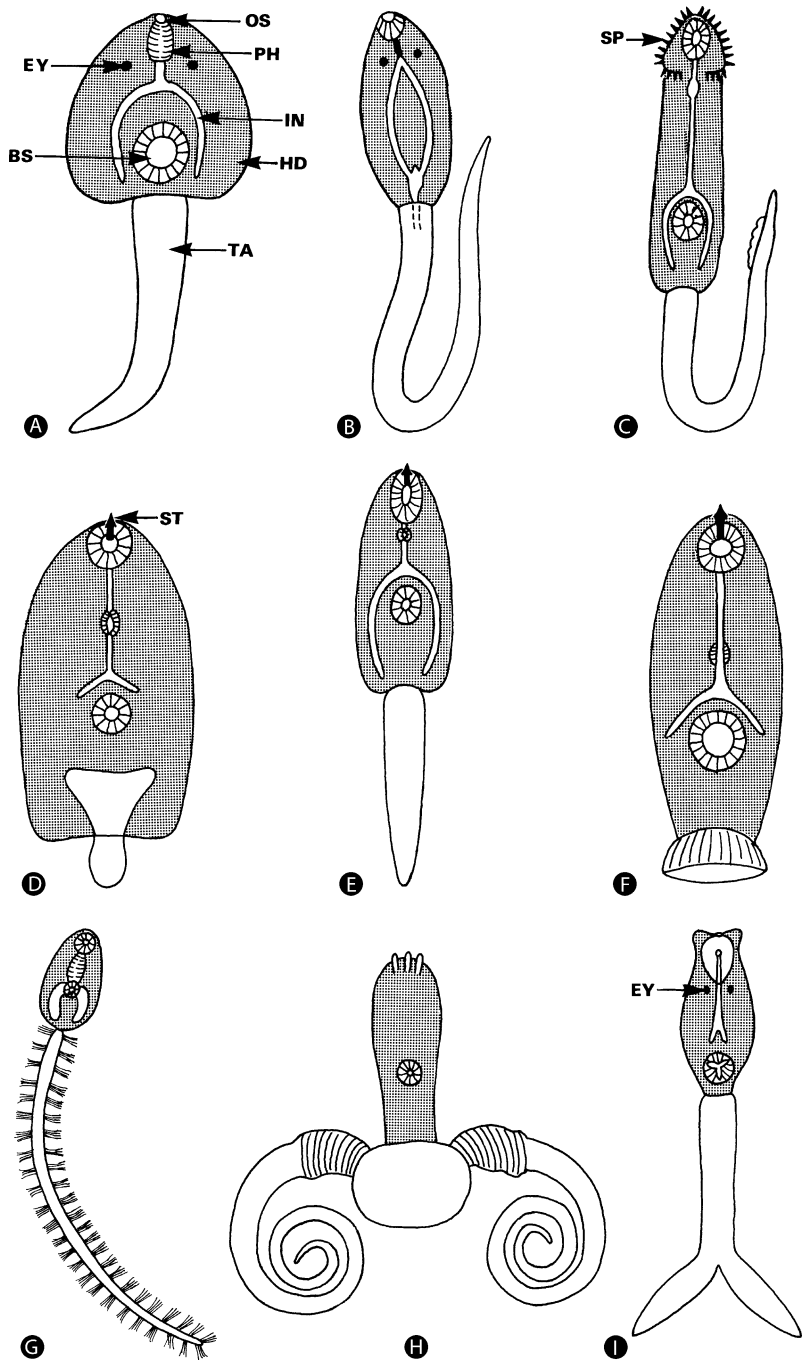


Digenea. Figure 3 A–F Some common adult →liver flukes. *EX*, excretory bladder; *GP*, genital pore; *GO*, genital bulbus; *HK*, hooks, spines of →tegument; *IN*, intestine; *INC*, intestine (cut off on drawing); *LC*, →Laurer's canal; *OS*, oral sucker; *OV*, ovary (→Germarium); *RS*, receptaculum Seminis; *TE*, →testis; *UT*, uterus with eggs; *VE*, vas efferens of *TE*; *VI*, vitellary glands (→Vitellarium); *VS*, ventral sucker (→Acetabulum).



Digenea. Figure 4 A–G Some common adult intestinal flukes. *BE*, bulbus of esophagus; *BU*, bulbus (apical); *EX*, excretory bladder; *GP*, genital pore; *HK*, hooks, spines of tegument; *IN*, intestine; *LC*, →Laurer's canal; *OS*, oral sucker; *OV*, ovary (→Germarium); *RS*, receptaculum seminis; *UT*, uterus with eggs; *VI*, vitellary glands (→Vitellarium); *VS*, ventral sucker (→Acetabulum); *VSE*, vesicula seminalis (sperm →reservoir).

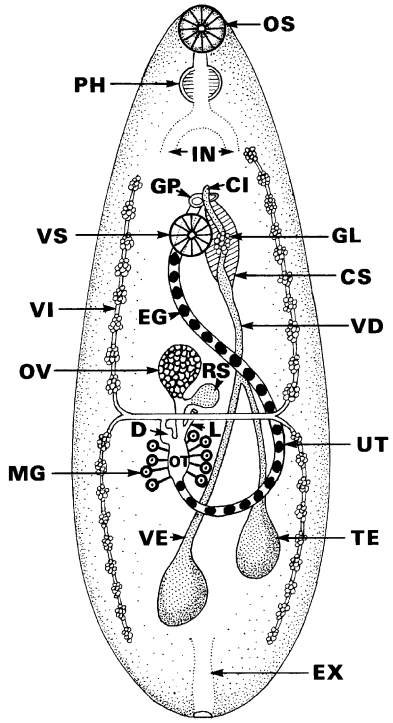
- Dispersal. After escaping from the egg, some miracidial species tend to disperse from the site of origin. They swim relatively fast and linearly, and even their →orientation to light and gravity seems to be conductive to dispersal. Species which later infect ground-dwelling hosts can exhibit photopositive and geonegative orientation for approximately the first hour after emergence. During this phase some miracidia are not as responsive and infective to their host snails as they are in later phases of the host-finding process.
- Microhabitat selection. Most miracidia tend to accumulate in the microhabitats which are preferred by their host snails. This is achieved by responding to environmental stimuli such as light, gravity, temperature, and the magnetic field. The type of orientation



Digenea. Figure 5 A–I Some common **types of cercariae**. *A* Amphistome cercaria (Ophthalmocercaria). *B* Monostome cercaria. *C* Echinostome cercaria. *D-F* →Xiphidiocercariae *D* Microcercous cercaria *E* Xiphidiocercaria *F* Cotylocercous cercaria. *G* Trichocercous cercaria. *H, I* →Furcocercous cercariae *H* Gasterostome cercaria *I* Apharyngate cercaria. *EY*, eyespot; *HD*, head; *IN*, intestine; *OS*, oral sucker; *PH*, pharynx; *SP*, tegumental spines; *ST*, stylet inside the oral sucker; *TA*, tail; *VS*, ventral sucker.

may resemble very closely that of the host snail. For example, *Schistosoma mansoni* miracidia show a geonegative and photopositive orientation as do their host snails. The type of orientation may be modified by certain →environmental conditions. For example, the negative photo-response of →*S. haematobium* miracidia reverses with decreasing temperature and they were found to infect their host snails in summer

preferentially at the bottom of the water and in winter near the water surface. Miracidia of →*S. japonicum* reverse their photopositive orientation to a negative one with increasing temperature and/or light intensity, a behavior which also resembles that of the host snails.

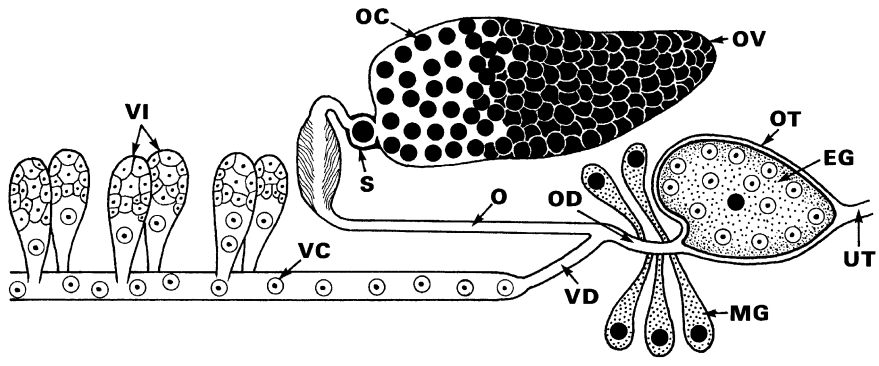


Digenea. Figure 6 Diagrammatic representation of the reproductive organs of a digenean trematode. *CI*, →cirrus; *CS*, cirrus sac; *D*, fused vitelloduct; *EG*, egg; *EX*, excretory bladder; *GL*, glands; *GP*, genital pore; *IN*, intestinal branches (interrupted); *L*, Laurer's canal; *MG*, →Mehlis' glands; *OS*, oral sucker; *OT*, →ootype; *OV*, ovary; *PH*, pharynx; *RS*, receptaculum seminis; *TE*, testis; *UT*, uterus; *VD*, vas deferens; *VE*, vas efferens; *VI*, vitellarium; *VS*, ventral sucker.

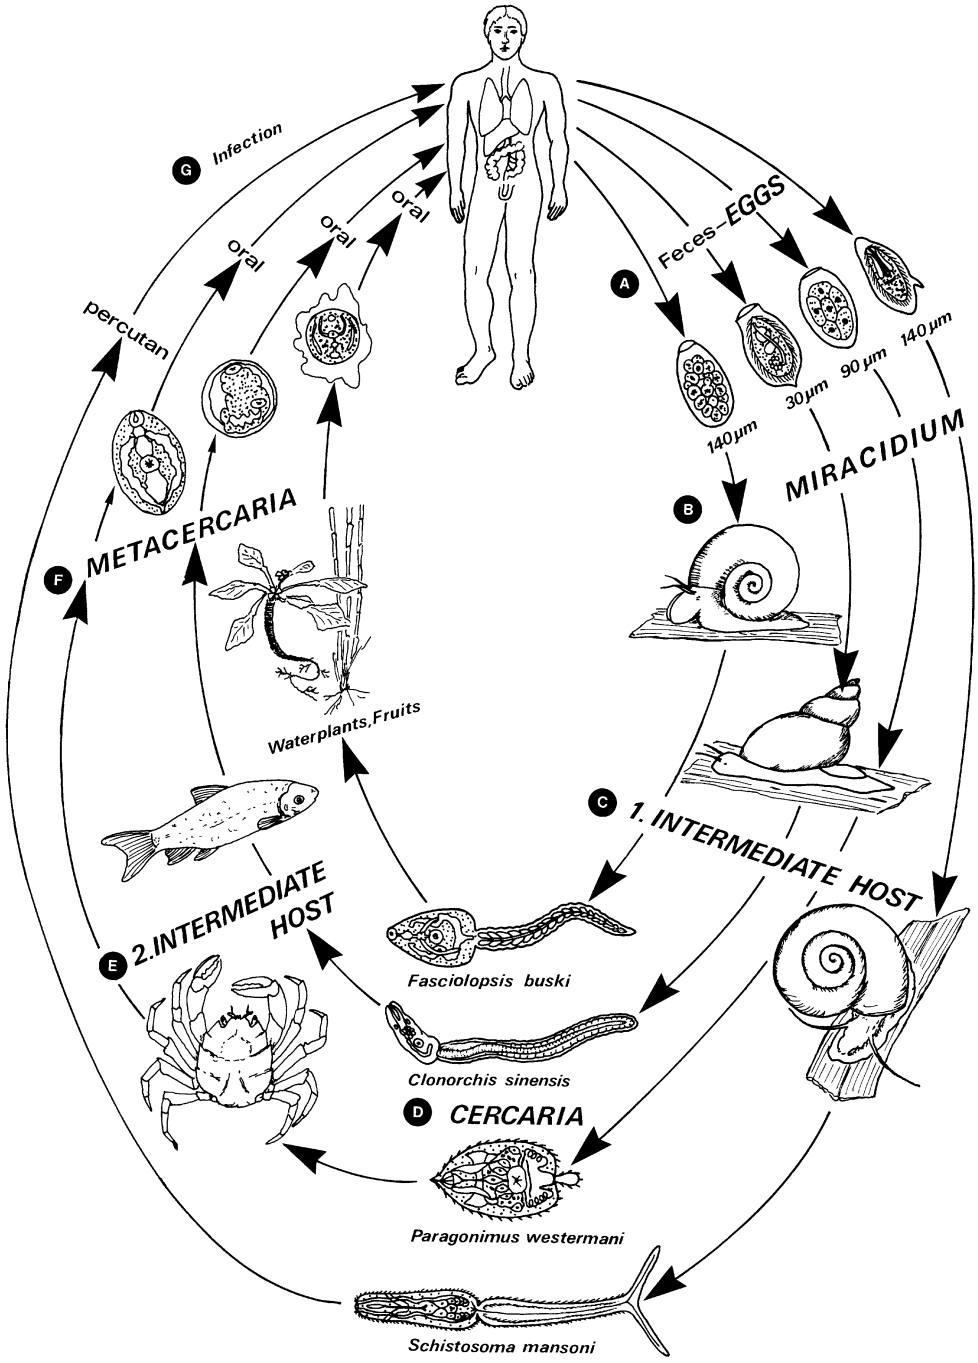
The photopositive orientation of at least *S. mansoni* miracidia is a phototaxis, as the miracidia are able to detect the relative intensites of two separate sources of light. The wavelengths to which the organisms respond have been determined for miracidia of *Fasciola hepatica,* →*Schistosomatium douthitti, S. mansoni*, and *Bunodera mediovitellata*. They all respond maximally to blue-green light between 500 and 550 nm, which penetrates deepest into clear water. *S. mansoni* and *B. mediovitellata* miracidia prefer in addition red-brown light of 650 nm, which is typical for muddy waters.

Several miracidial species are able to perform geoorientation independently of their photoresponses, but the mechanisms involved in this type of orientation are not well understood. A special mechanism occurs in miracidia of *Philophthalmus gralli*. Their strong geopositive orientation seems to be brought about by a sensitive north-seeking magnetotaxis in the northern hemisphere.

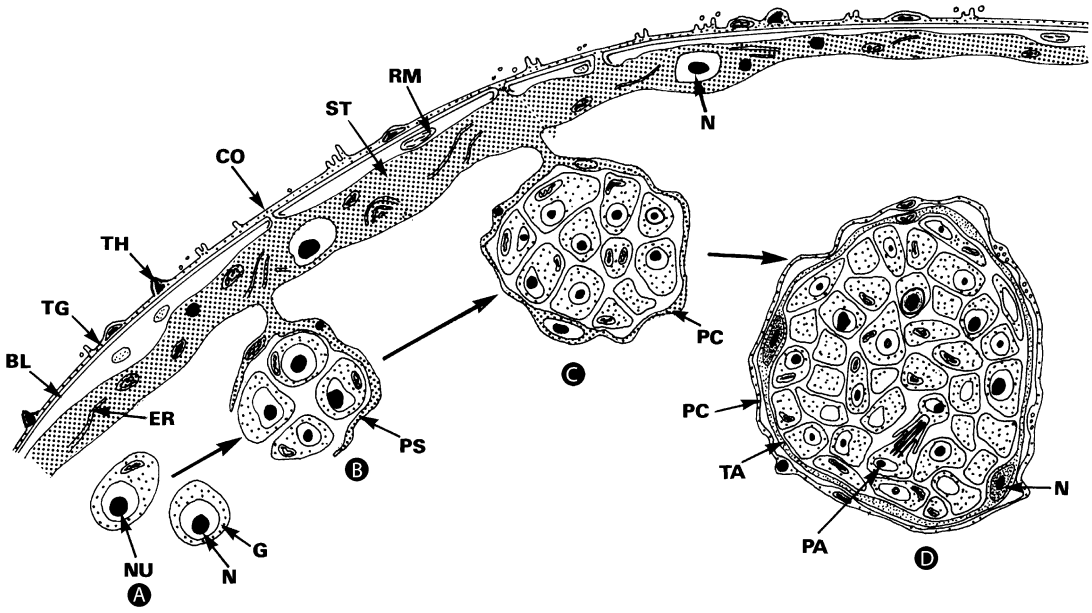
- Host-directed orientation. When miracidia enter the host snail's active space, they approach the host by responding to snail-emitted chemical signals. The type of orientation is a chemokinesis in most species studied so far, e.g., in *Schistosoma mansoni, S. haematobium,* →*Trichobilharzia ocellata, Fasciola hepatica, Echinostoma caproni*. The organisms increase their rate of change of direction (RCD) in increasing stimulus concentration gradients and they perform a sharp 180 degree turn when the concentration of the stimulus decreases (Fig. 10 A, B). For this type of orientation, the miracidia must only detect an increase or a decrease of the stimulus concentration. This is possible although the miracidia rotate along their long axis, which supports a straight path of movement. However, *S. japonicum* miracidia show a directed chemotaxis (Fig. 10C) and the rotating organisms seem to detect the direction of the concentration gradient in an unknown way.



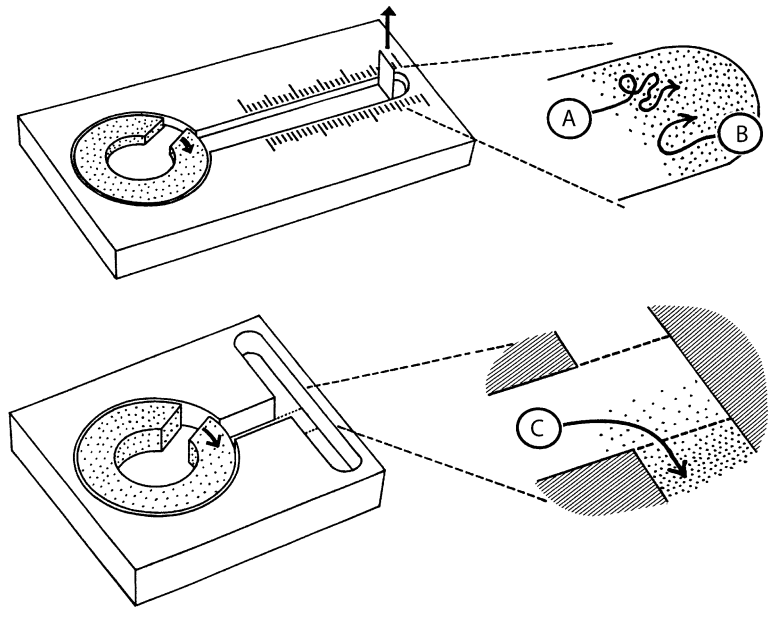
Digenea. Figure 7 Diagrammatic representation of the reproductive organs of a female of →*Schistosoma mansoni*. *EG*, egg (containing the zygote and vitellary cells); *MG*, Mehlis's glands; *O*, oviduct; *OC*, oocyte; *OD*, ovovitellary duct; *O*, ootype; *OV*, ovary; *RS*, receptaculum seminis; *S*, sphincter; *UT*, uterus; *VC*, vitellary cell; *VD*, vitellary duct; *VI*, vitellarium.



Digenea. Figure 8 Life cycles of four species of digenetic trematodes parasitizing different human organs, thus representing different types of development and transmission (for similar species and details see Table 1). **A** Freshly excreted eggs may or may not contain a →miracidium (in the latter cases it develops after excretion). Egg size and shape vary with species (Table 1). **B** Except for *Clonorchis* (where the whole egg is swallowed) this miracidium hatches from the egg in water. **C** The miracidium (mother →sporocyst) penetrates the hepatopancreas of the first intermediate host (Table 1). **D** Inside the intermediate host cercariae are formed by sporocysts (*Schistosoma*) or by →rediae (other genera); these cercariae leave the host. **E** The cercariae follow species-specific pathways; they may encyst on waterplants (*Fasciolopsis*), penetrate and encyst in a second intermediate host forming metacercariae (*Clonorchis*) or immediately penetrate the final host (schistosomes). **F** Encysted metacercariae need some time for development (maturation) before they can infect the final hosts. **G** The final host is infected by oral uptake of metacercariae or by cutaneous penetration of metacercariae. The worms reach maturity in the intestine (*Fasciolopsis*), bile duct (*Clonorchis*), lung (→*Paragonimus*), or in blood vessels of the intestine (*Schistosoma*).

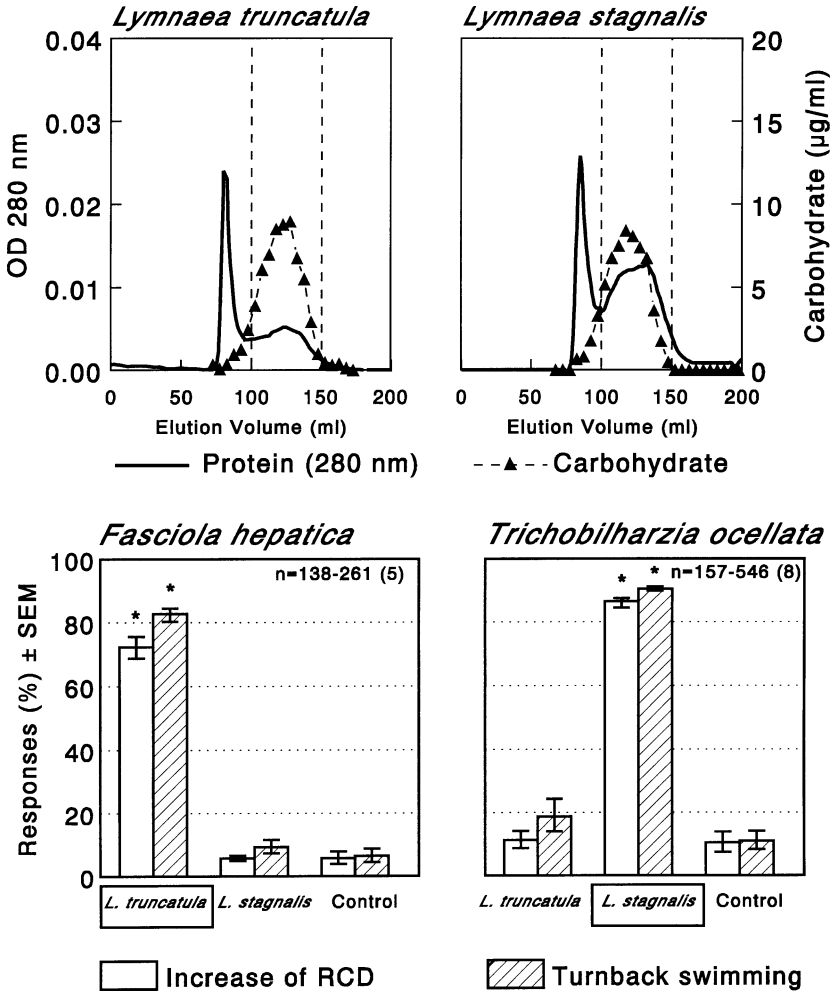


Digenea. Figure 9 A–D Diagrammatic representation of the formation of daughter individuals in digenean trematodes. **A** Germinal (undifferentiated) cells are found singly inside the lumen of the mother individual (mother sporocysts, daughter sporocysts, rediae). **B** Protruding parts of the syncytial subtegumental layer surround the dividing germinal cells. **C** Now the subtegumental layer has completely surrounded the dividing cells. **D** The growing daughter organism increases in size. It is covered by a smooth primary layer, under which a new syncytial tegument is formed by fusion of undifferentiated cells. Stages in C and D are also described as "germ balls". *BL*, basal lamina; *CO*, connection between tegument and subtegumental layer; *ER*, endoplasmic reticulum; *G*, germinal cell; *N*, nucleus; *NU*, →nucleolus; *PA*, protonephridial anlage; *PC*, primary cover (formed by ST); *PS*, protruding part of subtegument; *RM*, remnant of muscle; *ST*, subtegumental layer; *TA*, tegument anlage; *TG*, tegument (differs in the different developmental stages); *TH*, thorn (hook).



Digenea. Figure 10 Mechanisms of chemoorientation of miracidia towards their snail hosts or snail conditioned water and its fractions can be studied in choice chambers. The →miracidia are released from the miracidia chambers by opening the closure ring (spotted) and their swimming paths in increasing and decreasing concentration gradients of attractants recorded. Most miracidia show an increase of their rate of change of direction (RCD) in increasing concentration gradients of the attractants (A) and a turnback swimming in decreasing gradients (B). Only *S. japonicum* miracidia were found to be capable of a directed chemotaxis in increasing concentration gradients (C). (Modified after Haas et al. 1995, Haas and Haberl 1997).

Much research was performed using various methods to identify the attractive components of snail tissues, mucus, and snail conditioned water (SCW). Most work dealt with miracidia of *S. mansoni*, but the results were very controversial. Small molecular compounds with low host-specificity were described, such as amino acids, magnesium ions, decreasing calcium ion concentration, peptides, short-chain fatty acids, N-acetylneuraminic acid, →ammonia, hydrogen ions, →glutathione, glucose. However, recent studies identified macromolecular glycoconjugates as the exclusively attracting molecules of SCW in miracidia of *S. mansoni, S. haematobium, T. ocellata, F. hepatica,* and *E. caproni*, and there is some evidence that other species are also attracted by macromolecules. The molecules which attract *S. mansoni, T. ocellata*, and *F. hepatica* have very similar chemical characteristics, their saccharide chains are linked to a core protein via an *O*-glycosidic linkage probably between threonine or serine and *N*-acetylgalactosamine, and their identification signal is encoded in the →carbohydrate moiety. At least the miracidia of *F. hepatica, T. ocellata* and an Egyptian strain of *S. mansoni* identify their respective host-snail species with a very high specificity and sensitivity (Fig. 11). The signaling macromolecules are effective at concentrations as low as 1 mg in 10,000 liters of water, and the signaling carbohydrate structures not



Digenea. Figure 11 Specificity of miracidial host finding: The miracidia of *Fasciola hepatica* and *Trichobilharzia ocellata* orientate exclusively toward the isolated signal fraction of their respective host-snail species (framed) with the responses increase of RCD (spotted bars) and turnback swimming (hatched bars) (Fig.10). The signal fraction (elution volume 100–150 ml) was isolated from snail conditioned water (SCW) by molecular filtration, followed by ion-exchange chromatography and 2 succeeding size exclusion chromatographies; lines indicate the protein content, triangles the carbohydrate content of the fractions. (Modified after Kalbe et al. 2000).

analyzed so far may be recognized at an even considerably lower concentration.

- Host contact and invasion. After contact with solid surfaces miracidia show at least 12 different behavior patterns (MacInnis), the typical behavior at the suitable host snail's surface is "repeated investigation". This response is stimulated by the same host-specific glycoconjugates which stimulate the preceding chemo-orientation, at least in *S. mansoni, S. haematobium, T. ocellata*, and *F. hepatica*. The releasing cues for the subsequent attachment and penetration behavior patterns are poorly studied. At least in *S. mansoni* attachment and penetration is stimulated by the same glycoconjugates which release the preceding host-finding behaviors. This suggests that miracidia, in contrast to other parasites, use only this single complex signal for all of their host-finding phases.

A typical characteristic of digenean-snail interactions is a stringent degree of specificity. Each species of digenean is capable of developing only in very few of the available snails, often only a single species or geographic strain. The highly specific →host-finding behavior of miracidia is obviously fully adapted to this situation. The degree of miracidial specificity in host finding may vary even within a species: An Egyptian strain of *S. mansoni* responded highly specifically only to its host snail species, but a Brazilian strain could not differentiate between snail species. This could mean that the Brazilian parasites may have lost their original specificity as an adaptation to new intermediate host snails after they were introduced by slave transports from West Africa. The high specificity, which normally underlies miracidial host finding, may be easily overlooked in laboratory experiments, where the miracidia are exposed to the snails in a few milliliters of water. However, in the field the specific host-finding behavior might be a determining factor of the parasite-snail compatibility. First semi-field studies demonstrated that a high host-specificity of the host-finding behavior in miracidia greatly supports their transmission success. The fact that the host snails signal their species-specificity with such precision despite 400 million years of →coevolution with their digenean parasites suggests that the snails might need the signal molecules for other purposes. They might serve as →pheromones for intraspecific communication of the snails, and the digeneans possibly just misuse them for safe host identification. Whether the attractants can be used for specific control methods still has to be investigated.

Cercariae

Cercariae of many digeneans find and recognize their hosts with complex behavior patterns and via very different, highly sensitive and specific receptors. They have evolved an enormous diversity of host-finding strategies and can achieve very high host-specificities. This indicates that cercarial host finding plays a central role in the transmission of digeneans and that it is an important determinant in the evolution of their life cycles.

Cercariae of many digenean species invade their hosts directly within aquatic habitats. They are provided with limited accumulated energy reserves and must invade the hosts within their short life span of only 1–3 days. Most species support the transmission success by producing high numbers of cercariae (up to 500,000 cercariae per host snail daily). In addition to this, most cercariae show complex behavior patterns which seem entirely dedicated to finding hosts. The various cercarial behavior patterns have functions in the following host-finding processes:

- Departure from the snail host and dispersal. Immediately after leaving the snail hosts some species (such as →*Diplostomum spathaceum* and *Schistosoma haematobium*) show a particularly high swimming activity which carries them away from the snails towards their preferred position within the habitats. Some cercarial species that infest snails as second intermediate hosts avoid superinfections of the first intermediate host snails that emit them with characteristic behavior. They show phases of converted orientation towards light and gravity in their immediate postshedding period, and they search their second intermediate hosts later. For example, cercariae of *Hypoderaeum conoideum* start chemotactic orientation towards snail hosts at the earliest 1 h after they have left their first intermediate host snails.
- Habitat selection. Most cercariae tend to disperse in the habitats normally frequented by their potential hosts. For example, cercariae of human schistosomes accumulate in the uppermost water layers, whereas parasites of ground-dwelling invertebrates orientate towards the bottom of waters, and some of them select microhabitats there with a defined light intensity. This habitat selection is achieved with different types of spontaneous swimming behavior and by responses to environmental stimuli, such as gravity, light and shadow, water currents, temperature, and physical boundaries. The different species show an enormous diversity of mechanisms in responding to environmental cues. For example, some species achieve geoorientation exclusively by gravity-determined swimming movements, other species respond only to the direction of light radiation, and still others adjust their position in the water column by responding only to light intensity, independent of the direction of the light source.

- Localization in host time. Even the time of day the cercariae occupy the microhabitats is correlated with the habits of the subsequent hosts. This is in part achieved by the pattern of cercarial emergence from the host snail. For example, the human schistosomes leave their host snails in the middle of the day, *Schistosomatium douthitti* at night when their rodent hosts are active, and *S. margrebowiei* shows two emission peaks, one at dawn and one at dusk, i.e., when their antelope hosts water. Even an intraspecific →polymorphism in the shedding patterns was found: *S. mansoni* cercariae left their snails in foci with humans as hosts mainly at 11–12 h, but in nearby foci with rats as hosts at 16–17 h. The emergence behavior is hereditary and it is synchronized in schistosomes mainly by the photoperiod, but the thermoperiod and other factors also have an effect.
- Host-directed orientation. In many cercariae a first contact with the host seems to occur by chance. However, some species respond to stimuli emanating from their hosts in such a way, that the chances of encountering the host increase. Three types of stimulating host cues have been studied in more detail: chemical cues, water turbulence and touch, and dark stimuli (Table 2).

  Chemical cues: Chemoorientation towards the host has been found in echinostome cercariae, which invade slowly moving aquatic snails (Table 2). Three species show chemokinetic orientation, they simply turn back when the concentrations of snail-emitted amino acids, →urea, and ammonia decrease. However, one species can swim by being directed chemotactically along increasing concentration gradients of snail-emitted peptides. A prerequisite for this chemotaxis is that the cercariae can detect the direction of the concentration gradient. Most other cercariae, which invade faster moving hosts, do not seem to use long-distance chemoorientation. Only *S. mansoni* responds to skin compounds (fatty acids and arginine-residues) by a reversal of the swimming direction, and this may guide them from hairs to the skin surface.

  Water turbulence and touch: The schistosome cercariae respond only poorly or not at all to water currents. This may help to avoid energy-consuming responses to the frequent encounters with water-inhabitating nonhost organisms. The cercariae of the duck parasite *T. ocellata* react to water currents with forward swimming and a readiness to respond to host cues with attachment. This response is inhibited when the parasites save energy by clinging to the water surface (Fig. 12). All fish-invading cercariae of Table 2 respond to water currents by starting to swim, which may increase the chance of a contact with the moving hosts. At least in *D. spathaceum* and →*Opisthorchis viverrini* water turbulence not only triggers long swimming movements but also evokes attachments, when the current-excited cercariae swim against solid substrates.

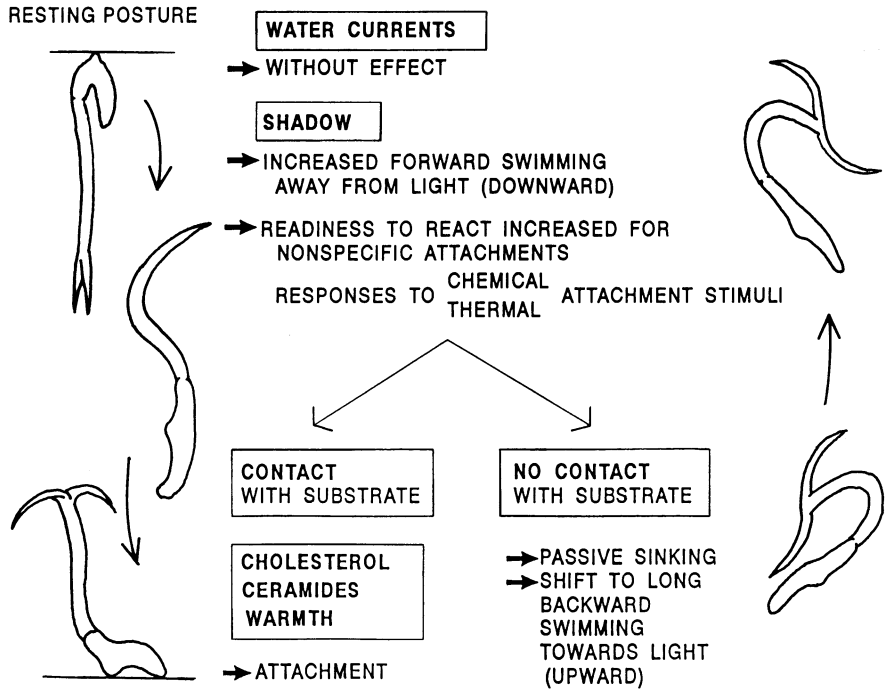
  Dark stimuli: All fish parasites of Table 2 respond to shadow stimuli with the start of swimming movements. Whether this behavior may support an encounter with the fish hosts is not clear, as the shadow stimulus simultaneously inhibits the triggered swimming bursts and as it does not stimulate attachments. Among the *Schistosoma* species of Table 2 only *S. haematobium* responds significantly to shadows. The cercariae shift to a high swimming activity, which leads them upward in the water column, and this may increase the chance for an encounter with their human hosts. In the duck parasite *T. ocellata* a shadow response plays a dominant role in host finding (Fig. 12). These cercariae prefer an energy-saving position clinging to the water surface, where they do not respond to the frequent water current stimuli. But when a shadow falls on them they swim away from its source, usually downward.This may increase the chances of encountering the feet of their duck hosts. The shadow simultaneously triggers a readiness to respond to thermal and chemical duck foot cues with attachment behavior. Wavelengths to which cercariae respond maximally are 500 nm in *T. ocellata*, 490 nm in *S. mansoni*, and 550 nm in *Bunodera mediovitellata*.
- Host contact and invasion. After contact with the host's surface, the cercariae recognize and invade the host with a series of behavior patterns which can be carried out spontaneously, or in response to host signals of quite different host-specificity: (1) Attachment to the host; (2) enduring contact with (remaining on) the host; (3) creeping to suitable entry sites; (4) penetration into the skin with elements such as penetration movements, shedding of the tail, secretion of acetabular gland contents, and tegument transformation for →immune evasion. Each of these behavior patterns may be stimulated independently by separate host signals. Some species achieve a very narrow host-specificity employing strategies including: (1) A chronological succession of responses to different stimuli, which themselves may be of low specificity; (2) responses to a combination of different stimuli; (3) sensitive responses to individual stimuli with a high host-specificity. A typical characteristic of cercarial host finding is a high diversity of strategies. Each species studied so far recognizes its host with responses to host signals that differ considerably from those of other species, even when these invade the same host genera. This may reflect adaptations to maximal transmission successes within differing ecological conditions. The stimulating cues for cercarial behavior after host contact have been analyzed for species invading mammals, birds, and fish (Table 3).

Digenea. Table 2 Host cues supposed to facilitate approach of swimming cercariae toward the host; -, no effect; [], weak effect

	Chemicals	Water turbulence or touch	Dark stimuli
Schistosomatids invading mammals and birds			
Schistosoma haematobium	- (?)	-	Start of long swimming movements - During swimming
Schistosoma japonicum	- (?)	- Passive adherence to hydrophilic substrates	-
Schistosoma mansoni	Fatty acids, arginine, peptides with arginine: reversals of swimming direction, leading to accumulation	[Tendency to attach when swimming]	[Start of swimming] - During swimming
Schistosoma spindale	- (?)	- During passive sinking Inhibition of active swimming	- During passive sinking Inhibition of active swimming
Trichobilharzia ocellata	- (?)	- In resting position Activation during sinking and swimming; start of forward swimming, readiness to attach	Activation in resting position, sinking and swimming; start of forward swimming, readiness to attach
Species invading fish			
Acanthostomum brauni	- (?)	Start of swimming, no readiness to attach	Start of swimming, [weak readiness to attach]
Cryptocotyle lingua	Fish extracts and amines; prolonged swimming, shorter sinking periods	Start of swimming, (attachment?)	Start of swimming, (not attachment?)
Diplostomum spathaceum	- Fish skin mucus; no effect on swimming, sinking, and readiness to attach	Start of long swimming with readiness to attach	Start of swimming, but inhibition of swimming and no readiness to attach
Opisthorchis viverrini	- (?)	Start of long swimming with readiness to attach	Start of swimming, but inhibition of swimming and no readiness to attach
Posthodiplostomum cuticola	?	Start of swimming, (attachment?)	Start of swimming, (not attachment?)
Echinostomatids invading snails			
Hypoderaeum conoideum	Small peptides; chemotactic swimming toward increasing concentration	-	-
Pseudechinoparyphium echinatum, Echinostoma revolutum, Echinostoma caproni	Amino acids, urea, and ammonia; turnback swimming in decreasing concentration gradients	-	-

Adapted from Haas (1994) and Haas and Haberl (1997)

Schistosomes invading mammalian hosts (Table 3) find their host in a characteristic manner, either by responses to different host signals or by an individual sensitivity of the responses. For example, *S. mansoni* cercariae respond in each of the host-finding phases with a particular sensitivity to chemical host cues. It was speculated that this might represent an adaptation to clear water habitats or to an infection near the water surface, where the detection of chemical cues is not disturbed by mud components. In contrast to that, *S. haematobium* cercariae respond most sensitively to thermal stimuli. They attach maximally to substrates when their temperature exceeds ambient temperature by only 1° C (*S. mansoni* 11–13° C), and they migrate along temperature gradients as low as 0.03° C/mm (*S. mansoni* 0.15° C/mm). This specialization on thermal host cues was interpreted as adaptation to invading the hosts in cooler habitats, where warm



Digenea. Figure 12 Host finding of the duck parasite *Trichobilharzia ocellata*: Function of the cercarial responses to external stimuli (boxes). (From Haas, 1992).

host surfaces are especially contrasting. A very low specificity occurs in the host finding of *S. japonicum* cercariae. They attach to and remain on the host purely by chance and their penetration behavior and tegument transformation can be stimulated by warmth alone. This bears the risk of cercarial losses by penetration attempts into warm nonhost substrates. However, this behavior enables the *S. japonicum* cercariae to invade a broad spectrum of mammals including species with a low content of free fatty acids in their skin surface. Their poor response to chemical host cues was interpreted as an adaptation to the muddy habitats in which they actually invade their hosts, i.e., habitats where chemical components of mud could interfere with chemoreception.

A common characteristic of all schistosomes studied so far is that they respond very sensitively to certain free fatty acids of mammalian skin surface with penetration behavior and transformation of their tegument for immune evasion. There is evidence that the fatty acids act via chemoreceptors and neural mechanisms. However, they may also have other functions in the invasion processes. *S. mansoni* and *T. ocellata* cercariae synthesize various eicosanoids when they are incubated in essential fatty acids, and it was suggested that these might directly act in the tegument transformation and immune evasion processes.

Host recognition of bird-invading schistosomatids has been studied only in 3 species in detail (Table 3). The host cues to which they respond are also characteristic for mammalian skin and this suggests, that they are not adapted to avoiding unsuccessful penetrations into mammals. In fact, several bird-invading schistosomatids are known to cause →cercarial dermatitis in humans. Each of the species studied so far responds to ceramides or cholesterol as host cues. These lipids also occur in mammalian skin surface, but they are lacking in the birds' uropygial gland secretions which are distributed on the feathers. Therefore, the response to these lipids may help to avoid useless attachments or penetration attempts to bird feathers.

Detailed data are available only for 3 fish-invading species (Table 3). The attachment response of *D. spathaceum* is stimulated by host-derived carbon dioxide, and the cercariae attach to nearly all animals. The disadvantage of the low specificity may be overcome by a high sensitivity to carbon dioxide, which allows a very fast attachment. The fish specificity is then achieved during the enduring contact and penetration phases, where the *D. spathaceum* cercariae respond to glycoconjugates. Each of the 3 fish-invading species achieves its fish-specificity by responses to 1–2 types of macromolecules. How the specificity is

Digenea. Table 3 Host signals as stimuli for cercarial host-recognition and invasion phases

	Attachment	Enduring contact	Directed creeping	Penetration
Species invading mammals				
Schistosoma haematobium	[L-arginine] Warmth	No stimuli?	L-arginine Temperature gradients	Fatty acids (Not warmth)
Schistosoma japonicum	No stimuli	No stimuli (Favored by solid hydrophobic surfaces)	Temperature gradients (Not chemical gradients)	Fatty acids Warmth
Schistosoma mansoni	[Water turbulence] L-arginine Warmth	Ceramides Warmth	L-arginine Temperature gradients	Fatty acids (Not warmth)
Schistosoma spindale	Warmth (Not chemical stimuli)	Warmth (Not chemical stimuli)	Temperature gradients (Not chemical gradients)	Fatty acids (Not warmth)
Species invading birds				
Austrobilharzia terrigalensis	Touch	?	?	Free sterols
Austrobilharzia variglandis	?	?	?	Cholesterol, fatty acids, triacylglycerols
Trichobilharzia ocellata	Dark stimuli Ceramides, cholesterol Warmth	Ceramides, cholesterol	? (Not warmth)	Fatty acids
Species invading fish and amphibians				
Acanthostomum brauni	[Dark stimuli] Glycoproteins with sialic acids	?	?	Combination of fatty acids and proteins
Diplostomum spathaceum	Water turbulence $CO_2 + H_2CO_3$	Carbohydrates	?	Fatty acids, glycoproteins with sialic acids
Opisthorchis viverrini	Water turbulence Glycosaminoglycans	?	?	Proteins

Modified after Haas, 2003

encoded in the signaling proteins and glycoconjugates is poorly understood. There is some evidence that terminally positioned sialic acids in the mucus are used to distinguish a host fish from mucus-covered aquatic invertebrates.

Dilepis

Genus of cestode family Dilepididae, the species of which live in birds. Related genera are →*Dipylidium* in mammals, *Liga* in birds, *Paradilepis* in birds, *Ophiovalipora* in snakes.

Dimethoate

Chemical Class

Organophosphorous compounds (dithiophosphate).

Mode of Action

Acetylcholine esterase inhibitor. →Ectoparasiticides – Agonists and Antagonists of Cholinergic Transmission.

Dimetridazol

Drug to control infections with *Giardia, Trichomonas, Entamoeba*. →Antidiarrhoeal and Antitrichomoniasis Drugs.

Diminazen

Drug that acts against →*Babesia* and →*Trypanosoma* by interference with the DNA – synthesis. →Babesiacidal Drugs.

Dinobdella ferox

Leeches of this species enter the nasal cavities of domestic animals in Southern Asia to suck blood (→Leeches).

→Respiratory System Diseases, Horses, Swine, Carnivores, →Respiratory System Diseases, Ruminants.

Dinotefuran

Chemical Class
Neonicotinoide

Mode of Action
Nicotinic acetylcholine receptor agonist. →Ectoparasiticides – Agonists and Antagonists of Cholinergic Transmission.

Dioctophyme renale

Classification
Species of →Nematodes.

Life Cycle
Fig. 1 (page 350).

Disease
→Urinary System Diseases, Animals.

Dioecious

Males and females being different individuals.

Dioecocestus

Genus of →tapeworms, the specimens of which are not →hermaphrodites but form male and female adults.

Diorchis stefanskii

Tapeworm in the intestine of ducks.

Dipetalogaster

Classification
Genus of triatomid →bugs. →Kissing Bugs.

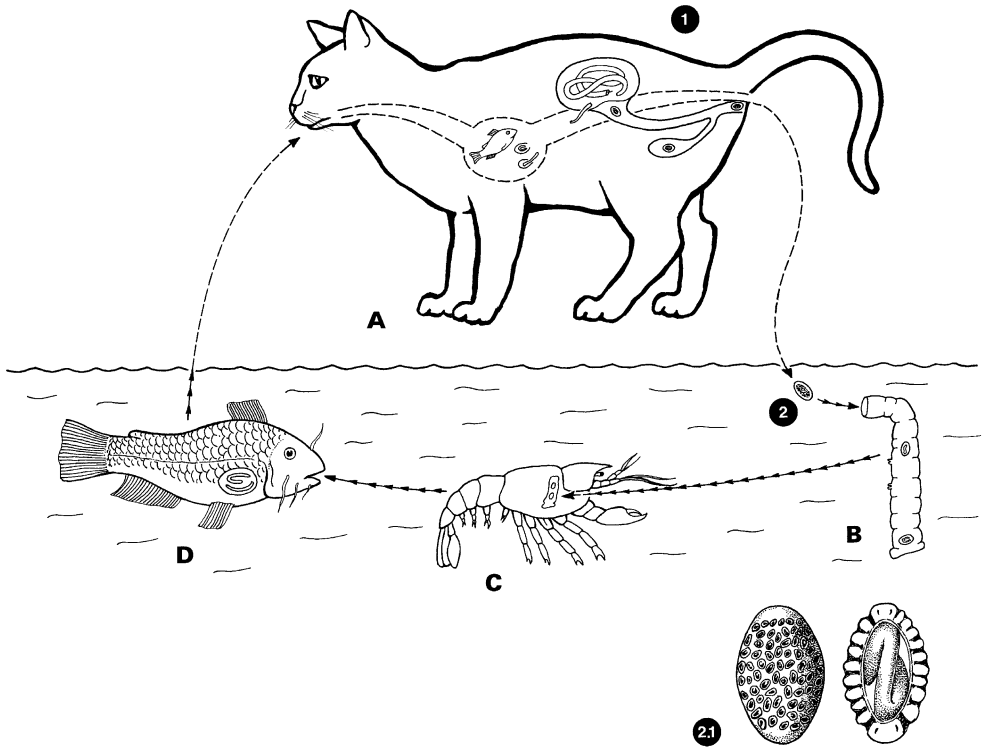
Dipetalonema

→Filariidae, →Nematodes, →*Dirofilaria immitis*.

Dipetalonemiasis, Man

Zoonotic dipetalonemiasis is usually an infection of porcupines, beavers, or other mammals which is transmitted accidentally to man by →mosquitoes. The adults live subcutaneously or in body cavities of the natural host, and are found subcutaneously or in the eyes of humans. Very rarely microfilariae are found, but their specific affinities usually remain undetermined. Living worms give rise to little inflammation, but dead worms cause →hypersensitivity, →necrosis with eosinophils, followed by granulomatous reaction and fibrosis (compare →Onchocerciasis, Man).

Therapy
→Nematocidal Drugs, Man.



Dioctophyme renale. Figure 1 Life cycle of the →kidney worm *Dioctophyme renale*. *1* Adult worm (females up to 1m long, males 30 cm long) live in the kidney of fish-eating mammals (**A**, cat, dogs, rarely man). *2* Eggs with a thick shell are laid uncleaved and need about 6 months to develop the larva 1 (2.1). Intermediate hosts (**B, C, D**, i.e., worms, crustaceans, fish) orally take up larva-containing eggs. In fish (**D**) the larva finally accumulate and develop until larva 4. When such contaminated fish are eaten by the final hosts, the larvae leave the intestine and migrate via the blood to the bowl of the kidneys. There they reach maturity after another 3–6 months and produce fertilized eggs for about 1–3 years if both sexes have reached the kidneys.

Diphylla ecaudata

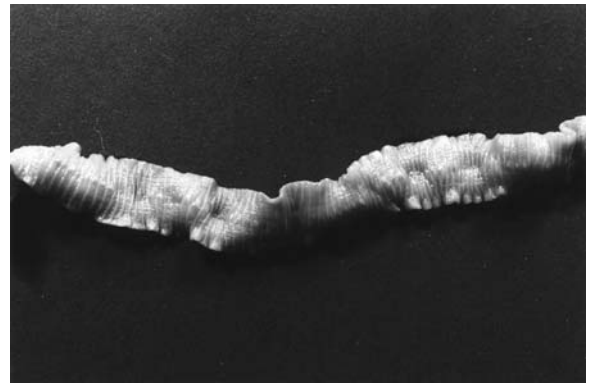
→Vampire Bats.

Diphyllidea

Family of cestodes with 2 genera: *Echinobothrium* and *Ditrachybothrium*, all parasitizing in fish (elasmobranchs).

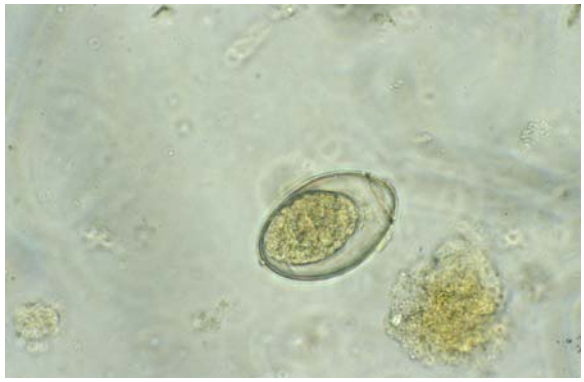
Diphyllobothriasis, Man

Disease due to infection with the tapeworm →*Diphyllobothrium latum* (→Pseudophyllidea) by oral uptake of larvae (plerocercoids) in undercooked fish.



Diphyllobothriasis, Man. Figure 1 Proglottids of *Diphyllobothrium latum*, which are broader than long.

Main clinical symptoms: →Abdominal pain, →anaemia due to deprivation of vitamin B12.
Incubation period: 3 weeks, if symptoms occur.
Prepatent period: 21–24 days.
Patent period: 10 years.
Diagnosis: Microscopic observation of proglottids and eggs in faecal samples (Figs. 1, 2).



Diphyllobothriasis, Man. Figure 2 Operculated egg of *Diphyllobothrium latum* containing the coracidium larva.

Prophylaxis: Avoid eating raw fish.
Therapy: Treatment with praziquantel, see →Cestodocidal Drugs.

Diphyllobothrium

Classification
Genus of →Pseudophyllidea, →Eucestoda.

Life Cycle
→Pseudophyllidea/Life Cycle/Fig. 1.

Morphology
→Nervous System of Platyhelminthes/Fig. 8, →Eucestoda/Fig. 2A.

Disease
→Diphyllobothriasis, Man.

Diplectanum aequans

Monogenean worm on the gills of *Dicentrarchus labrax* (European sea bass), which is the second most important cultured marine fish species in Italy. The adults measure about 8 mm in length.

Diplocaryon

Late stage of spore formation (with two nuclei), e.g., in species of the genus →*Amblyospora*.

Diplodiscus

→Megalodiscus, →Digenea.

Diplomonadida

Classification
Order of →Mastigophora.

General Information
The diplomonadids are characterized by the occurrence of a symmetrically arranged double set of each group of organelles (→*Giardia lamblia*/Fig. 1). This unique appearance may be explained by the omission of cellular division after reduplication of organelles. The species of diplomonadids (Table 1) inhabit the intestines of their hosts, where they are attached to the →microvilli (→*Giardia lamblia*/Figs. 2, 3) by means of their ventral sucker-like surface and feed by →pinocytosis on the intestinal fluid (→Endocytosis/Fig. 1). Reproduction proceeds as longitudinal →binary fission of the intestinal →trophozoites, whereas transmission from one host to the other occurs via oral uptake of cysts, which are formed by →Encystation of trophozoites when feces enter the colon and begin to dehydrate. In some cases heavy infections may lead to severe diseases characterized by intensive diarrhea (→Giardiasis, Animals, →Giardiasis, Man).

Important Species
Table 1.

Life Cycle
→*Giardia lamblia*/Fig. 1, →Endocytosis/Fig. 1, →Flagella/Fig. 3.

Diplopylidium

Genus of the tapeworm family Dipylidiidae. *D. noelleri* and *D. acanthotetra* are found in cats and dogs. The egg package (cocoon) contains only a single egg.

Diplomonadida. Table 1 Important species of the Enteromonadina and Diplomonadina

Genera/species	Size (μm)	Hosts	Pathogenicity
Enteromonadina			
Chilomastix mesnili	10–20	**Humans**	−
Dientamoeba fragilis[a]	7–12	**Humans**	+
Enteromonas hominis	4–10	**Humans**	−
Retortamonas intestinalis	8	**Humans**	−
Diplomonadina			
Hexamita (= Octomitus) spp.	6–12	Fish	+
Octomitus intestinalis	9–12	Mice	−
Spironucleus (= Hexamita) spp.	6–14	Chickens, birds	+
S. muris	10	Mice	−
Trepomonas sp.	12	Fish	+
Giardia lamblia[b] (syn. *Lamblia intestinalis, G. duodenalis*)	10–20	**Humans,** dogs, cats	+
G. agilis	8–14	Anurans	+/−
G. bovis	11–19	Cattle	+
G. caprae	12–17	Sheep, goats	+
G. canis	11–17	Dogs	+
G. duodenalis	13–19	Rabbits	+

[a] Systematic position remains doubtful

[b] Systematics are far from being clear. Recently 3 genotypes were found: **A**: In man and many animals. **B**: in man, dogs, and cats. **C**: only in dogs

Diplostomulae

→*Alaria canis*.

Diplostomum

Genus of the →Digenea.

Diplostomum spathaceum

→Behavior, →Digenea.

Diplozoon paradoxum

Classification
Species of →Monogenea.

Life Cycle
Figs. 1, 2 (page 353).

Diporpa

Larva of the Monogenean species, →Diplozoon paradoxum.

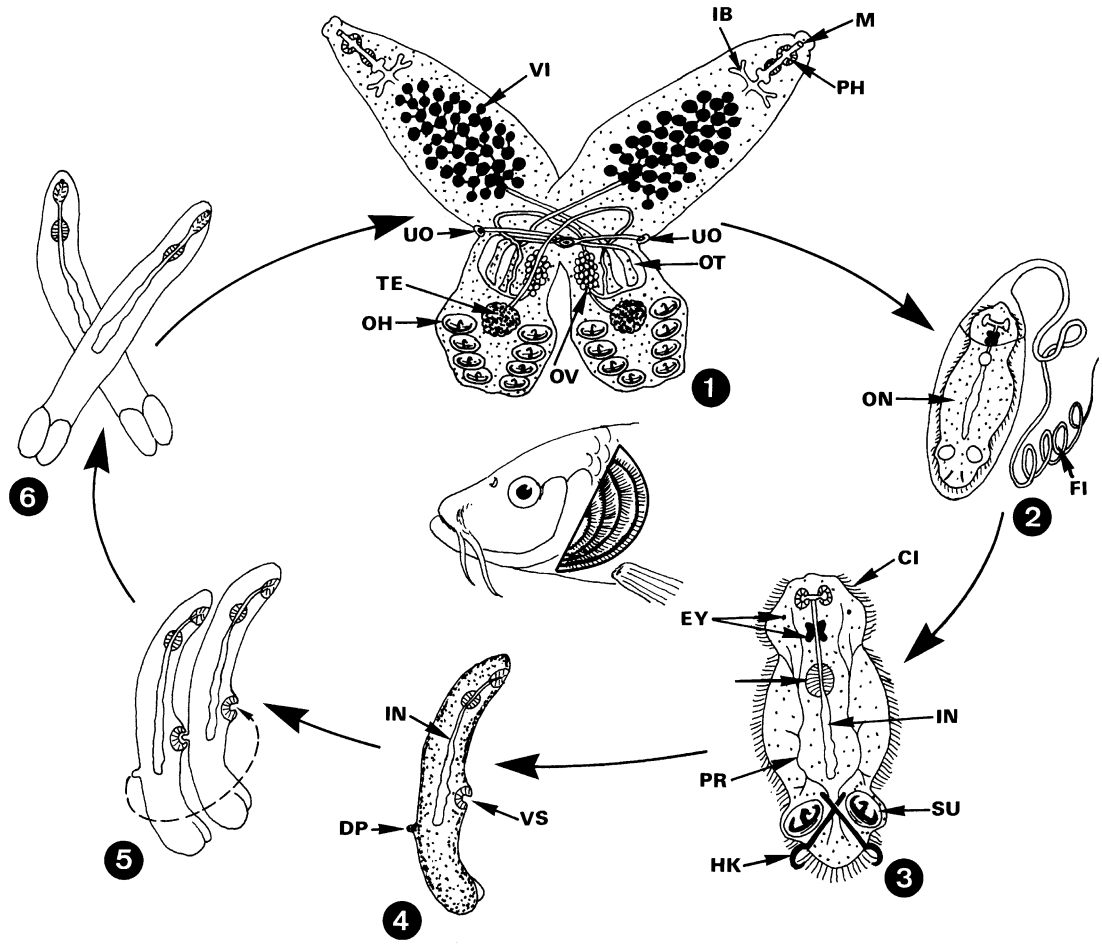
Diptera

Name
Greek: *di* = two, *pteron* = wing.

Classification
Order of →Insects.

General Information
The usually ectoparasitic and only seldom endoparasitic dipteran species show the following common features, although their basic body organization is modified according to their different ways of living:

- The pair of forewings is always present; the hindwings have been reduced to so-called halteres (→Peritrophic Membranes/Fig. 1).
- Eyes are in general large compound ones composed of numerous ommatidia (→Insects/Figs. 8, 9).
- Mouthparts are of the licking-sucking type (in true flies) or of the biting type (in blood-sucking species).



Diplozoon paradoxum. Figure 1 Life cycle of *Diplozoon paradoxum* on the gills of cyprinid fish. ***1*** Adults on the gills of fish. ***2*** Egg with an →oncomiracidium larva. ***3*** Free oncomiracidium. ***4*** After attachment to the gills of a host the oncomiracidium is transformed into the diporpa larva. ***5, 6*** Fusion of 2 diporpas on the host; each →diporpa attaches its sucker (*VS*) to the dorsal papilla (*DP*) of the other. This process stimulates their maturation and cross-fertilization. The blood-sucking adults can live for years in this form of complete copulation. *CI*, →cilia; *DP*, dorsal papilla; *EY*, eyes; *FI*, filament; *HK*, hook; *IB*, intestinal branch; *IN*, intestine; *M*, mouth; *OH*, →opisthaptor with suckers; *ON*, oncomiracidium; *OT*, ootyp, *OV*, ovary; *PH*, pharynx; *PR*, →protonephridium; *SU*, sucker (clamps); *TE*, →testis; *UO*, uterus opening; *VI*, →vitellarium (vitelline gland); *VS*, ventral sucker.

Diplozoon paradoxum. Figure 2 Coloured stage showing both partners being united for ever.

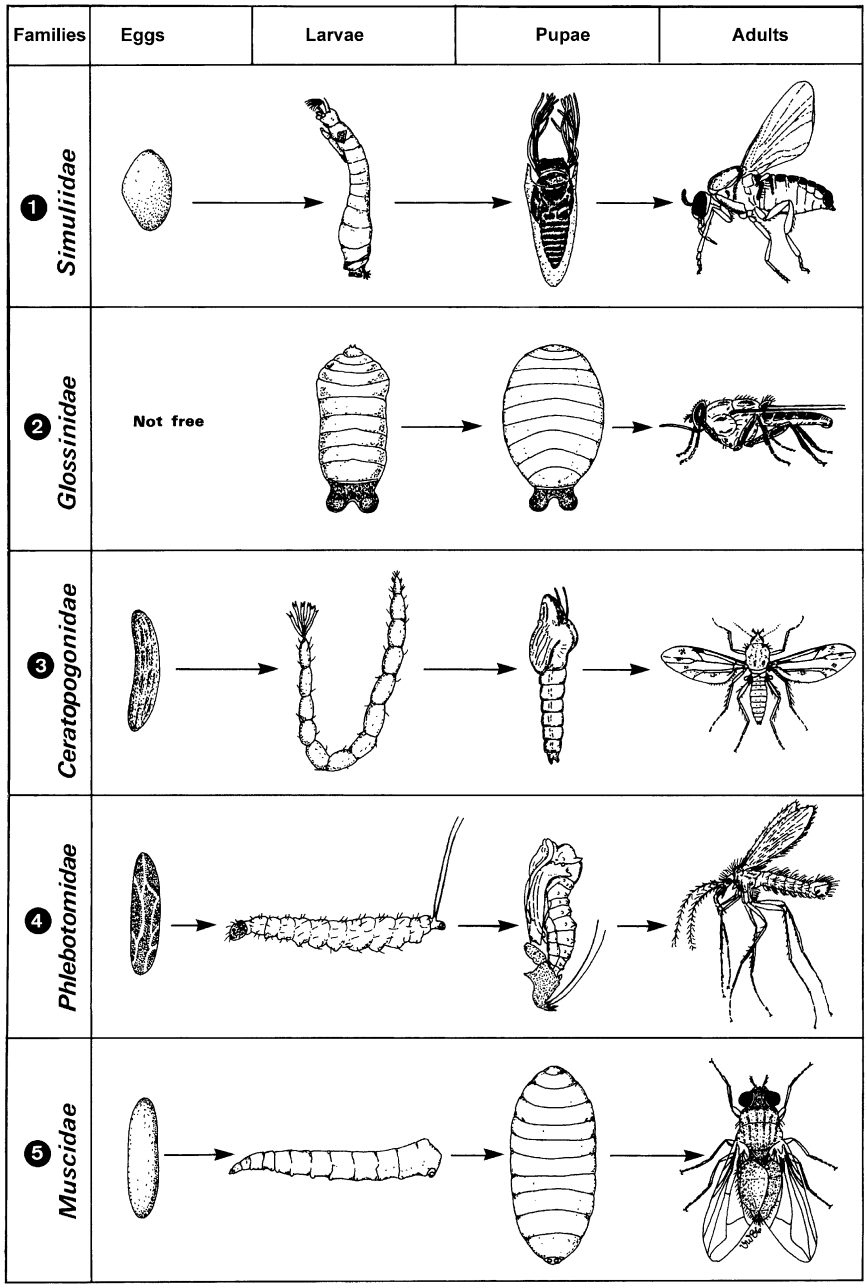
- The life cycle runs as →holometabolous development including apod (feetless) larvae, a non-feeding or even immotile →pupa, and →dioecious adults (Fig. 1).
- Larvae and adults may live as parasites, larvae in general as endoparasites, and adults as ectoparasites. With the exception of a few species (→Hippoboscidae), the adult dipterans feed periodically on their hosts (Table 1).

Important Species

Table 1.

Life Cycle

Fig. 1.



Diptera. Figure 1 Developmental stages in the holometabolic life cycle of important groups of Diptera (cf. Table 1). Note that several larval stages may occur; temperature and other outer conditions regulate the developmental speed. ***1*** Family →Simuliidae (→Blackflies). The 2–5 mm long females of →*Simulium* spp. usually feed diurnally on blood of their hosts (→Pool Feeders), but males do not suck blood. The filtering larvae and the non-feeding pupae are enclosed in cocoons (not drawn) that are attached to the surface of objects submerged in swiftly running waters. ***2*** Fam. →Glossinidae (→Tsetse Flies). Both sexes of the 6–14 mm long →Glossina spp. feed on blood of their hosts (pool feeders). Females pass at once a single fully grown third-instar larva which has developed inside the uterus with the aid of →symbionts and uterine glands. The pupation occurs in protected areas of the soil. ***3*** Fam. →Ceratopogonidae (biting →midges). The members of the (drawn) genus →Culicoides are very small (1–4 mm long). Females suck blood of their hosts. Larval development proceeds in wet, semisolid media or even in holes in trees. ***4*** Fam. →Phlebotomidae (→Sand Flies). The members of the (drawn) mammal-biting genus →Phlebotomus are about 2.5 mm long and are characterized by numerous body hairs. Females suck their hosts's blood during the night. Larval development (four instars) proceeds in wet soil. ***5*** Fam. →Muscidae (houseflies). *Musca domestica* lays its eggs on urine- and dung-contaminated stable refuse, where larval development (three instars) proceeds. →*Musca* is saprophagous, whereas both sexes of →Stomoxys calcitrans feed on blood.

V, Virus; R, Rickettsiae; B, Bacteria; S, Spirochaeta; P, Protozoa; N, Nematodes

Dipteraviridae

Viruses transmitted by dipteran insects (e.g., flies and →mosquitoes).

Dipylidiasis, Man

Disease due to the infection with the tapeworm →*Dipylidium caninum* which is common in cats and dogs. Infection occurs via oral uptake of tapeworm larvae in crushed →fleas.

Main clinical symptoms: →Diarrhoea, →urticaria, loss of weight, and anal →pruritus.
Incubation period: 10–25 days.
Prepatent period: 19–25 days.
Patent period: 1 year.
Diagnosis: Occurrence of typical →proglottids in the faeces (Figs. 1, 2).
Prophylaxis: Deworming of dogs, cats, and treatment against fleas.
Therapy: Treatment with praziquantel, see →Cestocidal Drugs.

Dipylidiasis, Man. Figure 1 Typical proglottids of *Dipylidium caninum*.

Dipylidiasis, Man. Figure 2 A typical egg-cocoon of *Dipylidium caninum*.

Dipylidium caninum

Classification
Species of →Eucestoda.

Life Cycle
Figs. 1–3 (page 358, 359).

Disease
→Dipylidiasis, Man, →Alimentary System Diseases.

Dirofilaria immitis

Synonym
→Heartworm.

Classification
Species of →Nematodes.

Life Cycle
Figs. 1–3 (page 359).

Other Species
D. repens is found in canids and cats in South Europe, Asia, and Africa. The adults live in the subcutis, the 205–300 µm long microfilariae are found in blood vessels of skin. The vectors are Culicidae (mosquitoes).

Acanthocheilonema reconditum is endemic in Europe, Asia, America, and Australia and is transmitted to dogs by fleas. It lives in the subcutis and body cavities.

Dipetalonema dracunculoides is transmitted by ixodid ticks (*Rhipicephalus sanguineus*). The adults live in the body cavity of dogs in Europe, Asia, and Africa.

Diseases

→Dirofilariasis, Man, →Heartworm Disease, →Cardiovascular System Diseases, Animals, →Nervous System Diseases, Carnivores.

Dirofilariasis, Man

Synonym

Zoonotic filariasis.

Pathology

Dirofilariasis is an infection of dogs, raccoons, bears, etc., caused by →*Dirofilaria immitis*. It is occasionally transmitted by →mosquitoes to humans. The young adult worms wander to the right heart and are usually propelled into a pulmonary artery branch, which they thrombus (→Pathology/Fig. 28B) giving rise to a localized pulmonary infarct. The worm is usually dead in the thrombus. The release of worm antigens provokes an intense hypersensitive reaction, with central →necrosis accompanied by eosinophils and a granulomatous or fibrotic reaction peripherally. Some of the older lesions calcify and become visible on radiological examination of the chest.

Main clinical symptoms: Undifferentiated heart pain, hypertrophy of heart, ascites.
Incubation period: 3–9 months.
Prepatent period: 7–9 months.
Patent period: 6–7 years (at least in dogs).
Diagnosis: Difficult, since no microfilariae are formed in humans; serological tests.
Prophylaxis: Avoid bites of mosquito vectors.
Therapy: Treatment see →Nematocidal Drugs, Man.

Disease Control, Epidemiological Analysis

Parasitic diseases originate from an interplay between parasite, vector or carrier, and principal host in an environment that is suitable for the parasite's maintenance or propagation. It is customary to differentiate broadly between food-borne, water-borne, arthropode-borne, and directly invasive parasitoses. However, this rather coarse classification will be of little use in identifying targets of control intervention.

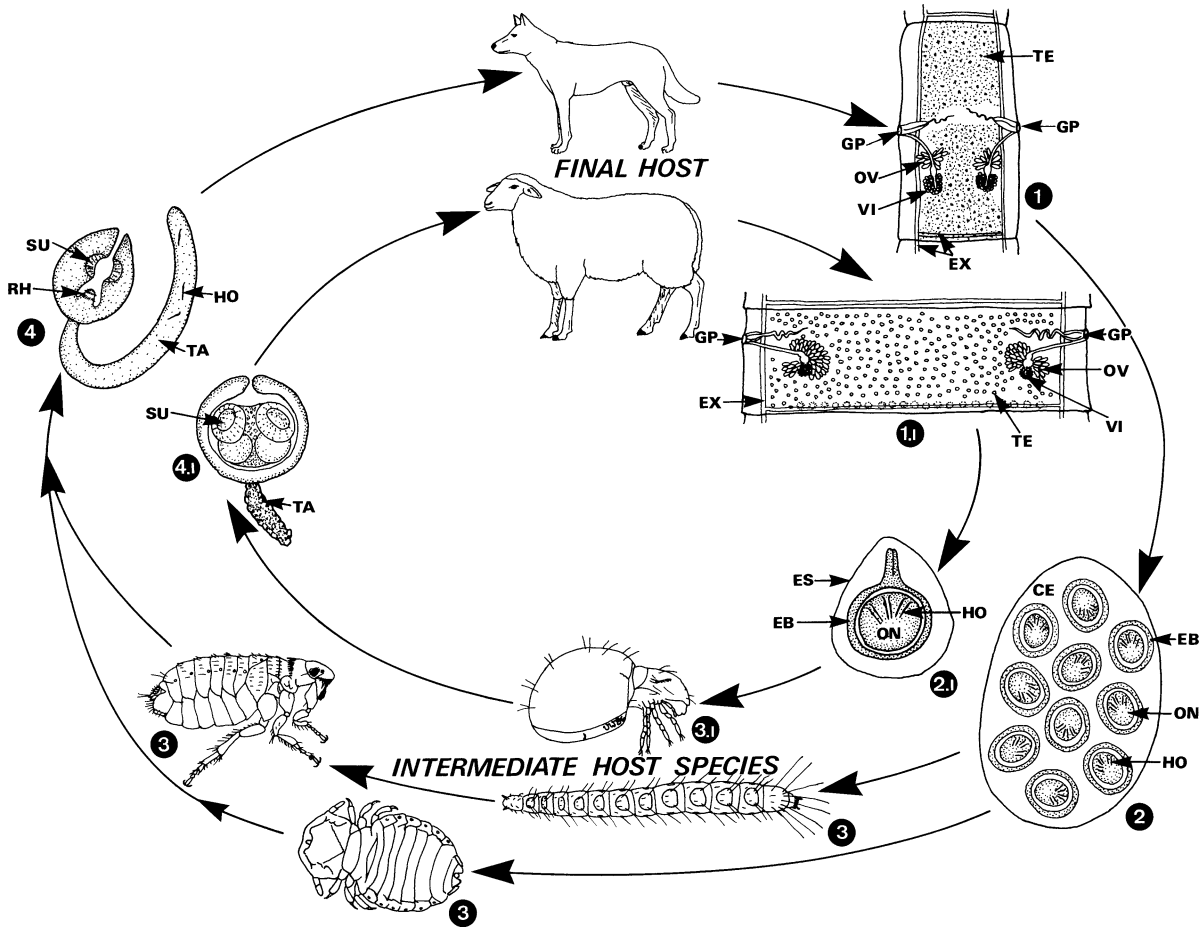
Some of the principal →modes of infection are given in Table 1, but this grouping does not provide more than a summary →orientation. With the individual parasitoses it will be indispensable to analyze, in detail, all stages of the parasite's life cycle and the biological and environmental factors governing its transmission, i.e., to consider the epidemiology of the disease. As an example, the main epidemiological components of the →malaria situation are summarized in Table 2. The resulting picture will be specific for a given area and important inter-area differences are commonly seen. Since the epidemiological situation may change over time, resulting from modifications of environment, host – vector relationships and other factors, the analysis requires regular updating. The approach to analyzing the factors governing the transmission of other parasitic diseases is similar, and should yield the elements required for the identification of targets of intervention.

Mathematical models can be quite useful in epidemiological analysis inasmuch as they facilitate a quantitative appreciation of particular features in the parasite's life cycle and permit projections of the expected efficacy of specific interventions. Such models exist for malaria and some other diseases of major public health importance. The quality of results obtained from such models depends primarily on reliability and exhaustiveness of the data input (→Mathematical Models of Vector-Borne Diseases).

Disease Control, Evaluation

The control of parasitic diseases has the purpose of reducing the burden caused by such diseases in the human population or in livestock, or both. The control programmes are usually supported by public funds. The planning of such programmes should be sound and based on a realistic strategy and target projections, and a reasonable expectation of success. The performance and efficacy of control measures should therefore be subject to monitoring as the basis of regular and continuous evaluation.

Parasitic diseases span a wide spectrum of severity and impact on human or animal health. On the other hand, the target levels of control may vary, dependent on technical and financial feasibility. Realistic planning should take these limitations into account. Whenever a plan of operation is drawn up, monitoring and evaluation should be integral components of it.



Dipylidium caninum. Figure 1 Life cycles of tapeworm with two sets of sexual organs per proglottid: *Dipylidium caninum* (1–4) of carnivores and man reaching a length of ablut 50 cm and *Moniezia expansa* (1.1–4.1) of ruminants with a maximum length of 6 cm. *1, 1.1* Premature proglottids of adult worms parasitizing the intestines of their final hosts. *2, 2.1* The uteri of fecally excreted cucumber-like proglottids are filled with typical eggs, which in the case of *D. caninum* are always enclosed in capsules (2). *3, 3.1 D. caninum* uses larval and adult fleas (*Ctenoceohalides* spp.) or chewing lice (*Trichodectes canis*) as intermediate hosts, whereas *M. expansa* develops in oribatid mites (3.1). When the eggs are eaten by such intermediate hosts, the oncosphaera hatches and migrates to the hemocoel. *4* Inside the hemocoel transformation to the second larval type (cysticercoid) occurs. The growth rate is dependent upon the ambient temperature. Infection of the final host is accomplished when infected intermediate hosts are swallowed. The cysticercoids evaginate in the intestine and develop directly into adult tapeworms; this takes 2–3 weeks for *D. caninum* and 4–8 weeks for *M. expansa*. *CE*, capsule containing eggs; *EB*, →embryophore; *ES*, egg shell; *EX*, excretory vessels; *GP*, genital pore; *HO*, hooks of oncosphaera, *ON*, oncosphaera; *OV*, ovary; *RH*, rostellar hooks; *SU*, sucker; *TA*, tail of cysticercoid; *TE*, testis; *VI*, vitelline gland.

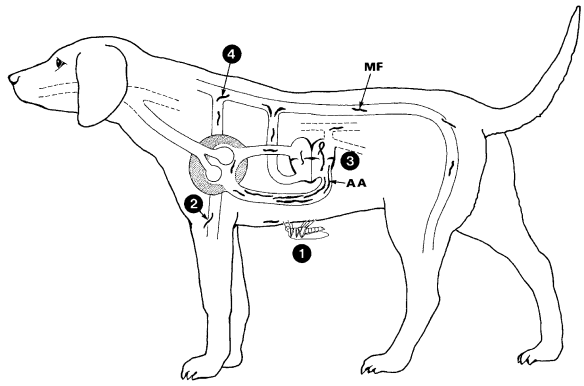
The selection of monitoring tools is determined by the methods of intervention which might be relatively simple or complex, depending on the disease and the envisaged targets of intervention. In the following, examples of the choice of monitoring tools are given for some major tropical parasitic diseases.

In the control of African trypanosomiasis caused by *Trypanosoma brucei rhodensiense*, for instance, the early detection and treatment of human trypanosomiasis will be the objective of control as long as the effective control of the vector population (*Glossina morsitans* group) and the sanitation of wildlife reservoir are not feasible. In this case morbidity and mortality from the human infection will be the primary parameters for monitoring, supported by quality control monitoring related to diagnosis and treatment of the disease.

The control of American trypanosomiasis, Chagas disease, is mainly based on the control of the vectors (reduviid bugs). While the diagnosis of infections with *T. cruzi* has become easy due to the development of

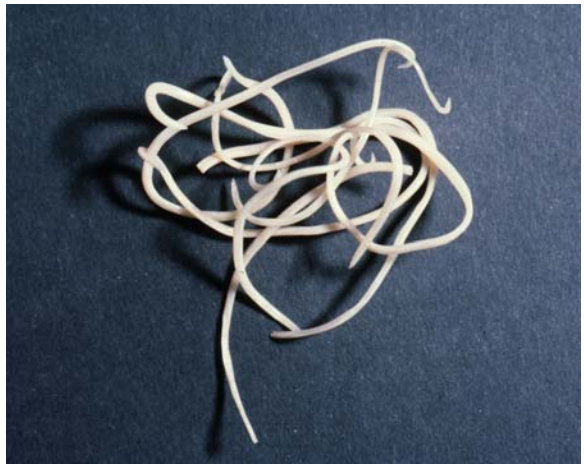
Dipylidium caninum. Figure 2 LM of the scolex with the extruded rostellum.

Dipylidium caninum. Figure 3 SEM of the scolex.



Dirofilaria immitis. Figure 1 Life cycle of the heartworm *Dirofilaria immitis*. *1–3* During blood meal of female →Mosquitoes larvae 3 are transmitted, which wander via lung to the heart and reach maturity within 6 months. While growing to a maximal length of 20 cm they may block the pulmonary arteries. *4* After copulation the females produce unsheathed microfilariae (MF) of about 200–3002 8 μm in size. *AA*, adult worms in artery; *MF*, microfilariae.

Dirofilaria immitis. Figure 2 Open heart of a dog showing the slender worms that may block the blood vessels.



Dirofilaria immitis. Figure 3 *Dirofilaria* worms from dog's heart.

Disease Control, Epidemiological Analysis. Table 1 Principal modes of infection in parasitic diseases of man and other animals (according to Wernsdorfer)

Mode of infection (principal host)	Examples of parasite species
No alternation of host species	
Ingestion of infective stage, followed by self-replication within principal host	*Hymenolepis nana*
Ingestion of infective stage, often followed by self-contamination (immediate infectiousness)	*Enterobius vermicularis*
Ingestion of infective stage the development of which requires a period of non-parasitic existence in a suitable environment	*Ascaris lumbricoides*
Active invasion of infective stage the development of which requires a period of non-parasitic existence in a suitable environment	*Ancylostoma duodenale*
One or several alternations of host species	
Ingestion of free infectious stage (often on carrier material)	*Fasciola hepatica*
Ingestion of infectious stage within alternate host	*Gnathostoma spinigerum*
Active invasion of free infective stage	*Schistosoma* spp.
Active invasion, through bite wound inflicted by alternate host	*Wuchereria bancrofti*
Introduction of infective stage with insect bite at blood meal	*Plasmodium* spp.
Deposition of infective stage with faeces of vector at time of blood meal	*Trypanosoma cruzi*

reliable immunodiagnostic tests, the treatment continues to pose problems due to poor tolerability and relatively low efficacy of available medicaments, particularly in the management of chronic disease. The major operational approach relies currently on the prevention of future infections by environmental sanitation, i.e., reduviid-proofing of human habitations and animal shelters, which are simple and technically feasible measures applicable at low cost. In this case, the criteria for monitoring and evaluation of control measures will be the number of structures targeted for improvement and those actually improved as well as the adequacy of improvement work, in addition to a thorough search for structures missed, but deserving improvement. In addition, regular monitoring of the specific seropositivity rate for *T. cruzi* in the areas subject to housing improvement, and particularly the absence of new infections, will reflect the impact of the control measures.

The control of lymphatic filariasis caused by *Wuchereria bancrofti* relies mainly on the annual mass single-dose administration of ivermectin and albendazole that is also the principal tool adopted for eradicating the disease in scheduled areas. In urban areas endemic for lymphatic filariasis, this measure is usually complemented by vector control (*Culex* spp.). Effective monitoring of mass drug administration requires geographical reconnaissance and detailed population census in the entire operational area; information that needs regular updating. Monitoring criteria are the coverage of mass drug administration in the scheduled population, the prevalence of infections with *W. bancrofti*, measured by microscopic diagnosis or antigen-detection tests, the incidence of new infections, and the prevalence and new occurrence of advanced clinical forms of lymphatic filariasis such as lymphoedema and elephantiasis. In addition, monitoring requires quality control of the diagnostic procedures. The complementary vector control operations need to be evaluated for the degree of coverage achieved in the detection and the sanitation potential confirmed breeding places, if possible supported by regular checking of vector density.

In malaria control the type of intervention will be largely determined by the envisaged and feasible target level. There are, basically, three target levels:

1. The elimination of mortality and the reduction of suffering from malaria
2. The elimination of mortality from malaria and the reduction of malaria prevalence, expressed in a significant decrease of morbidity
3. The elimination of malaria from a particular area or country

While the first objective can be reached by early diagnosis and treatment of all malaria cases, the achievement of the second objective usually requires also vector control measures and disease surveillance. The realization of the third objective necessitates rigorous precision in the performance of focus recognition and elimination as well as perfect coverage by disease surveillance in space and time.

Disease Control, Epidemiological Analysis. Table 2 Major factors related to the transmission and control of malaria (according to Wernsdorfer)

Parasite	Human host	Anopheline vector	Environment

The elimination of mortality from malaria is usually the objective in areas where the currently available tools for malaria control are insufficient for achieving the reduction of prevalence of and morbidity from malaria. The goal can only be achieved by the competent operation of adequate diagnostic and curative facilities. Countries having adopted this primary objective, mainly in Africa, are still far from having established such adequate facilities. More than 80% of all "clinical" malaria cases are treated for falciparum malaria without laboratory-based diagnosis, thus unnecessarily increasing non-target drug pressure and promoting drug resistance. Here the structural and functional improvement of the health service infrastructure is the prerequisite for achieving the full coverage of the population in space and time which can ensure early recognition and treatment of true malaria cases. Such a system of evidence-based treatment requires continuous quality control at all levels and back-up by competent tertiary treatment facilities for the referral and management of patients with severe or complicated malaria. The key parameter for measuring success will be the mortality from malaria, but continuous monitoring of the efficacy of routine treatment will also be required in order to recognize therapeutic failure and to prevent avoidable mortality.

In areas aiming at the reduction of malaria prevalence, the type of appropriate interventions will depend on the baseline degree of prevalence and morbidity. Usually it will require the application of vector control measures for the rapid reduction of malaria transmission and the building up of surveillance and focal sanitation activities to replace blanket vector control when the annual inoculation rate has dropped below 0.1%. Usually, such operations will be carried out in the framework of the general health infrastructure under the guidance of a specialized technical service. Given the complexity of operations, the criteria for monitoring encompass a relatively wide range and need to be adapted according to the progress of the control programme. The monitoring activities related to the vector control aspects depend on the selected operational methods, e.g., larval control by environmental sanitation, larviciding or deployment of larvivorous fish, or control of adult anopheline vectors by intradomiciliary application of residual insecticides. Here the validity and updating of geographical reconnaissance, the degree and regularity of operational coverage as well as the quality of material and logistics will be criteria for evaluation, complemented by the regular assessment of important entomological indices in well-chosen sentinel areas. These indices may, inter alia, include anopheline density, parous rate, human blood index, stability index and calculation of the inoculation rate. With regard to the disease-based parameters it will initially suffice to monitor the prevalence and the monthly and annual incidence of malaria, the area- and age-specific slide

positivity rates and the quality of diagnostic and therapeutic activities. With the implementation of surveillance the time has come for ensuring and monitoring quality and coverage of case detection, diagnostic and therapeutic activities in space and time, and the epidemiological classification of all malaria cases detected in the course of surveillance. These activities include the post-therapeutic follow-up of malaria cases and, if so indicated, revision of the treatment policies as well as the application of remedial focal vector control operations.

The achievement of the third and highest target level, i.e., the elimination of malaria from a larger geographical area or country may be attempted if preceding malaria control operations have shown consistent success and the likelihood of feasibility, based on an adequate and functionally competent service infrastructure. The indices for evaluation are essentially the same as those in the advanced phases of malaria control. Quality control of all aspects of passive case detection, diagnostic and therapeutic procedures, rapid implementation of epidemiological investigation and remedial focal measures need to be brought to near perfection. Once autochthonous malaria transmission has ended, the vigilance activities should be devoted to the rapid detection of imported malaria cases and preventing the establishment of new foci of transmission.

Disease Control, Methods

General Information

The approaches to the control of parasitic diseases are crucial components of the control strategy. The realization of the various approaches is dependent upon the use of individual measures the selection of which will be determined inter alia by expected efficacy, convenience, economy and acceptability. In most cases a variety of measures will be required simultaneously. This applies particularly to →anthropozoonoses and →zooanthroponoses with highly adaptable →biological systems. Such diseases are the most difficult to control, especially if non-domestic animals are involved as →reservoirs of infection. Another general aspect is man's awareness of parasitic diseases affecting humans and livestock, and the motivation for taking remedial action. If such broad motivation is lacking among the afflicted population, it is likely that imposed control programmes will have only limited and ephemeral success. →Health education in the widest sense, encompassing both the health of humans and of domestic animals, should therefore prepare the ground for a systematic effort against the diseases affecting the community.

The simplest measures for achieving a set purpose are usually the best, but in their planning and execution due attention should be paid to acceptability, compatibility with cultural and religious background, and technical feasibility. For instance, it would be expecting too much if the dietary patterns of large populations were to be changed abruptly. Here the practical solution will consist of rendering the incriminated food safe rather than banning it. The adoption of particular individual protective measures will depend on the person's economic status. Wearing shoes will generally protect against →ancylostomiasis, and the use of impregnated bed nets supports protection against →malaria. However, shoes and bed nets have their price and not everybody may be able to afford them or even be willing to use them. Selection of the most appropriate measures for disease control requires therefore a sound appreciation of advantages, limitations and disadvantages of the methods.

Parasitic diseases encompass a wide range of biological systems. Hence, the control of these diseases has many facets, implying a host of different measures the most important of which are detailed in the following sections.

Water Supplies

Water is one of the most important vehicles of parasitic diseases. It harbours a number of pathogens which can reach the human or animal host through transdermal penetration (e.g., →Schistosomiasis, Man) or through ingestion (e.g., →Dracunculiasis). It is also the medium through which the larvae of many parasitic species reach molluscan hosts, ultimately to be transmitted to man or livestock as a food-borne pathogen. Safe water is therefore an important means of controlling numerous parasitic diseases, especially →helminth infections (in addition to controlling the transmission of non-parasitic water-borne pathogens). Safe water should be available for consumption, bathing, washing and leisure activities. Ideally, piped, treated water should be available for household use. However, this will not be feasible as yet in most of the vast rural areas in the tropics and the subtropics. Well-maintained deep wells with elevated rims made out of masonry or concrete for the prevention of contamination will be an acceptable and feasible alternative in many places. The use of traditional step wells or ponds should be discouraged, but, if there is no other source, boiling or sieving water through a fine mesh may render it

largely innocuous. The installation of a supply of piped, treated water may permit the abolition of unhealthy water collections. There may be public objection to this if the water collections are used for producing food (e.g., fish, crabs) or for the irrigation of crops. However, larger pools can be constructed on a community basis and maintained in such a way that they do not permit the transmission of pathogens while fulfilling the purpose of pisciculture and serving as a source of water for agricultural and household needs.

Excreta Disposal

Most helminth eggs or larvae have to reach water or humid ground for further development. They achieve this as a result of urination or defecation into water or onto wet soil. This may be part of a deliberate pattern, e.g., for the fertilization of family fish ponds in some parts of eastern Asia. In other instances it is due to an ingrained behavioral pattern or due to the lack of appropriate facilities for the safe disposal of excreta, or a lack of incentive for using available facilities. →Health education is probably the most important remedial factor in such situations. It is not advisable to embark on a major programme of building latrines before the population is willing to use them. This applies especially to rural areas in which the population has easy access to various types of surface water. The acceptability of latrines or of even better facilities for excreta disposal is usually higher in urban areas where the installation of sewage treatment will also often prove to be feasible and cost-effective. If the right type of sewage treatment plant is chosen, the resulting sludge will be biologically safe and usable as fertilizer.

Agricultural Hygiene

The agricultural, pastoral and piscicultural environment is often intimately associated with the transmission of parasitic diseases. Agricultural labourers may serve as a source of infective material, especially if they do not dispose of their excreta in a safe way whilst in the fields. They are also exposed to a variety of pathogens, particularly in irrigated areas. In addition to these occupational aspects, the use of unsafe biological fertilizers (fecal matter) on vegetables will promote thespread of some parasitoses, e.g., →amoebiasis and ascariasis. Another important feature is the grazing of livestock in wetland areas. Again, health education and community efforts towards the development of safe grazing areas, e.g., through drainage, will be required to remedy the situation. Particular precautions should be taken when using wastewater and excreta in agriculture and aquaculture. Improperly managed water resource development entails the risk of the propagation of parasitic diseases. This should be avoided through appropriate water management.

Personal Hygiene

Apart from the obvious impact of unsafe excreta disposal, the lack of personal →hygiene is a leading cause of infection with a variety of parasitic pathogens such as →*Giardia lamblia*, →*Entamoeba histolytica* and →*Enterobius vermicularis*. Washing hands after defecation and before eating would largely reduce the transmission of these pathogens. The use of water and soap would also impede the transition from reversible lymphoedema to irreversible elephantiasis in →lymphatic filariasis. However, personal hygiene must go further than water and soap. It should include the seeking of treatment if there are symptoms of disease, and the avoidance of dangerous foodstuffs and of situations conducive to the contraction of infections. Health education will be an important vehicle for imparting the necessary knowledge, awareness and habits. This process should start at as early an age as possible and schools will have to play a major role in this endeavour.

Housing

Siting and type of human habitations are closely related to the risk of contracting certain parasitic diseases. Houses with cracked masonry, mud walls and/or earth floors were found to be a particularly suitable environment for reduviid →bugs responsible for the transmission of Chagas disease. Simple housing improvement was found to reduce or even remove the risk of infection. Siting of settlements away from mosquito breeding grounds was an empirical yet highly effective means of protection against malaria. The siting of settlements at a long distance from irrigation canals (accompanied by the provision of safe household water) is an effective preventive measure against schistosomiasis since it will reduce the frequentation of the canals for washing, bathing and swimming.

Type and standard of housing play a major role in allowing the entrance and exit of disease-carrying mosquitos. It also determines the feasibility of mosquito and fly proofing, and the efficacy of ancillary →vector control measures such as mosquito coils and knock-down sprays.

Environmental Management

Some measures of →environmental management as a means of disease control have been known since ancient

times. Environmental management was the mainstay of malaria control before the advent of residual →insecticides and synthetic antimalarials. It is making a comeback due to the limitations of other methods. The applicability of such measures in the control of parasitic diseases is very wide. The most important methods belong to environmental sanitation and water management. Water collections of various types are known to be breeding grounds for arthropod vectors of disease and the homestead of intermediate hosts of many helminthic organisms. Unless local economic (piscicultural and agricultural) and ecological reasons militate against them, filling, levelling and draining operations (drains, canals and use of trees) will be appropriate measures. The same applies to the sanitation of wetlands to be converted into safe land for agriculture and livestock.

Environmental sanitation, including peridomestic areas and the safe disposal of waste, is a field in which individual and community initiative can be used to great advantage, the more so when the necessary equipment is easily available and cheap (e.g., pickaxes and shovels) or obtainable on loan from various government departments (e.g., earth-moving machinery).

Water management applied to water-storage reservoirs (level management) and irrigation systems (watering and drying cycles) will facilitate disease control by rendering the areas unsuitable as a habitat of intermediate hosts or vectors of parasitic diseases. Water management should be an integral part of design and operation of water impoundments and irrigation schemes.

Control of Vectors and Intermediate Hosts

The control of vectors and intermediate hosts of parasitic diseases may, to a large extent, be achieved through environmental sanitation. However, in some situations the applicability of such measures will be severely limited, as in the control of →*Simulium* spp., the vectors of onchocerciasis. Similarly, widespread temporary breeding places occurring during the rainy seasons in the tropics may pose insurmountable obstacles to environmental management. Alternative control approaches are therefore necessary.

At the beginning of the 20th century mosquito control was improved by the use of light oils and chemicals such as Paris Green. In spite of their efficacy the application of these measures has remained quite limited due to the need for repetitive use and high cost. The introduction of chemical insecticides has not fundamentally changed the situation. Moreover, ecological considerations and non-target effects against aquatic fauna and flora restrict the widespread repetitive use of insecticides. Chemical →larvicides, rapidly biodegradable insecticides with low non-target toxicity, are still useful in the rapid control of epidemics of some vector-borne diseases. The same applies to the control of →*Cyclops* spp., the intermediate hosts of →*Dracunculus medinensis* and various other helminths.

→Biological methods for larval control have a long tradition inasmuch as larvivorous fish, e.g., *Gambusia affinis*, have been used since the beginning of the 20th century. Although appealing as a natural solution to a natural problem, larvivorous fish have a limited usefulness since seasonal and shallow breeding places are not suitable for their maintenance. It may also be difficult to find a local species of larvivorous fish. The introduction of non-local species may have a disastrous impact on the local aquatic fauna and interfere seriously with the production of food fish species.

Bacterial toxins from →*Bacillus thuringiensis* and →*B. sphaericus* are selectively directed against mosquito larvae and being used in the control of →*Culex* spp. and →*Aedes* spp. As the microorganisms sink to the ground they are not suitable for controlling →*Anopheles* spp. (surface feeders). *B. thuringiensis* does not reproduce in the breeding places, but *B. sphaericus* does to some extent though not sufficiently to relinquish the need for regular retreatment of the breeding places.

The intradomiciliary application of residual insecticides such as chlorinated hydrocarbons (DDT), organophosphorus compounds (malathion), carbamides (propoxur), fenitrothion and synthetic pyrethroids is suitable and often quite cost-effective for the control of adult endophilic →mosquitoes. However, the occurrence of specific resistance, aided and abetted by the agricultural use of insecticides of the same chemical groups, the presence of exophilic mosquitoes, increasing cost of insecticides and labour, and rising ecopolitical constraints have reduced their usefulness or applicability. Their use is still important, though, in the control of threatening or manifest epidemics where they are generally applied on a focal basis. These are situations where the ultra-low-volume (ULV) dispersal of suitable insecticides, may also show rapid effect. On the whole, the use of integrated vector control opens better prospects for an environmentally acceptable control of arthropod-borne parasitic diseases.

Pyrethroid-impregnated bed nets (deltamethrin or permethrin) or impregnated curtains and screens bar or reduce the contact between man and vector. They gained a firm place in malaria control, especially in areas with moderate or intensive transmission. Their efficacy is due to a repellent effect rather than specific insecticidal action, promoting also epidemiologically desirable vector deviation to animals.

The control of aquatic snails continues to present a serious problem. Environmental management is the only effective and widely acceptable procedure for snail control. The available molluscicides are either not

sufficiently effective (e.g., copper sulfate) or they are too toxic for the non-target fauna, including fish.

Diagnosis

The ability to diagnose the presence of infections is an important factor in guiding the treatment of individuals, and forms the basis of epidemiological assessment which should enable the health authorities to determine the dimensions of the specific human and/or animal health problem. It is also an essential tool for monitoring the impact of disease control activities. Macroscopic and/or microscopic diagnosis of parasitic diseases may be relatively simple and reliable with some parasite species, especially intestinal helminths, but exceedingly difficult with others, mostly tissue-dwelling parasites, e.g., certain types of →nematodes. Serological methods based on the detection of specific antibodies usually reflect past or present host–parasite contact and therefore do not provide proof of current infection. Similarly, relatively fresh infections may not have given rise to detectable antibodies as yet and show seronegativity in spite of the living pathogen's presence. Demonstration of circulating antigens is a more reliable and specific basis for diagnosing current infections. Rather simple and reliable antigen detection tests have been developed for several human parasitoses, e.g., infections with *P. falciparum* or *W. bancrofti.* They are based on the detection of highly specific parasite antigens. However, relatively high costs continue to restrict their use in the framework of control programmes. The same still applies to tests for the detection of lactate dehydrogenase from malaria parasites.

Identification of infections by polymerase chain reaction (PCR) has been developed for numerous parasite species. However, the routine use of PCR is currently limited to research institutions and to diagnostic laboratories in prosperous countries. Its cost and operational requirements are too high to be affordable by most of the tropical countries.

In order to be widely practicable, diagnostic techniques for the most important human and animal parasitoses must be simple, cheap and undemanding in terms of sophisticated equipment, electricity supply and operator skill. Human and veterinary health services in many parts of the world still lack the infrastructure required for establishing reliable data on prevalence and incidence of major parasitic diseases and associated mortality. This accounts for serious deficiencies in national and international disease statistics.

Treatment

Effective agents for the treatment of numerous parasitic diseases are available (see chapters on disease control). Some are reasonably cheap, such as those for the treatment of intestinal nematode infections of humans and domestic animals. Other medicaments are expensive, such as third-line drugs for the treatment of →falciparum malaria. High costs may limit their use or encourage sub-optimal medication, and consequently allow a parasite →reservoir to be maintained that will be an obstacle to the effective control of the disease concerned. There are, however, a large number of parasitoses for which the therapeutic armamentarium is grossly deficient, e.g., Chagas disease, kala-azar and liver fluke infections.

With regard to malaria the situation was relatively satisfactory after the wider introduction of the 4-aminoquinolines in the late 1940s. However, the advent of chloroquine resistance in *P. falciparum* has compromised the efficacy of this group of drugs in wide parts of tropical Asia and South America. In the hyper- and holoendemic areas of tropical Africa juveniles and adults continue to derive therapeutic benefit from chloroquine, but young children whose immunity is not yet sufficiently developed generally require treatment with alternative drugs. →Resistance to the first-line alternative drugs, i.e., combinations of sulfonamides with pyrimethamine, already affects large areas in south-eastern Asia and South America, and is rising in parts of tropical Africa, necessitating the use of second-line alternative drugs which are considerably more expensive. Resistance to mefloquine and structurally related quinine occurs in Cambodia, parts of southern Vietnam and eastern Myanmar and in some parts of Thailand bordering on Myanmar and Cambodia. Here, combined treatment with artesunate or artemether with mefloquine still yields satisfactory results.

On the whole the veterinary health sector has had greater success in the development of anti-parasitic drugs than the human health sector. This is largely due to a better financial endowment of agricultural and livestock development and to the more stringent toxicological requirements governing the registration of medicaments for use in man. The situation is compounded by the fact that the development of medicaments against human parasitoses holds little attraction for the pharmaceutical industry since the main market for such drugs is in poor tropical countries.

Immunization

In many parasitic diseases there is evidence of the natural development of immunity to the specific pathogen. Such immunity rarely induces total refractoriness to reinfection, but it will restrict parasite reproduction or acceptance and induce tolerance to the pathogen. The development of immunity is quite slow. Considerable efforts have been made in the field of immunization against parasitic diseases, especially against those caused

by →protozoa. In bovine babesiosis, attenuated live *Babesia bigemina* is being used for inoculation of livestock. The resulting immunity is satisfactory, but there is still significant mortality associated with vaccination which is, on balance, economically acceptable. Such approaches are not feasible in human parasitic diseases except for agents with low virulence, e.g., *Leishmania major*.

Although immunization holds substantial promise in the control of many parasitic diseases and the progress in gene technology and polypeptide synthesis is likely to pave the way to economically acceptable products, there is still a long and arduous way to go before well-tolerated and reliable vaccination with more than palliative activity will become a reality in the control of parasitic diseases.

Clinical Relevance

Diagnostic and therapeutic measures have direct clinical relevance. Other disease control measures have indirect clinical relevance inasmuch as they are geared to the reduction of the community's disease burden, and thus a lessening of the pressure on the health services.

Disease Control, Planning

An almost universal shortage of resources, particularly marked in tropical developing countries, renders the simultaneous control of all major parasitic diseases difficult in most areas of the world. The available resources must therefore be used to address important issues with a reasonable prospect of success. Parasitic infections may be important and if the disease causes severe symptoms and kills humans or livestock people will be aware of it. Other parasitoses, however, though less spectacular, may cause even more damage on account of their wide distribution, but public awareness may be low due to the disease's unobtrusive manifestations.

The shortage of resources and competition for those available make it necessary to set priorities on the basis of human suffering and death, or on economic loss caused by particular diseases of man or domestic animals. Many such diseases are important obstacles to development but their impact needs to be quantified in terms of disease-associated loss in order to provide a solid basis for priority ranking by governments or other interested groups. Public awareness of the disease in question may influence priority selection via political pressure and may promote community participation, but there is a risk that priorities so selected may not represent the most appropriate choice.

Once the control of a particular disease or group of diseases has been tentatively allocated high priority, the time has come to review the existing approaches that seem to be feasible in the local situation. Knowledge of the local epidemiological features and earlier experience in control within or near the area will be an asset. The feasible approaches and the specific measures required to implement them need to be projected, on a provisional basis, in terms of requirements for resources, skills, infrastructure and expected results. At this stage, or earlier, it may be necessary to strengthen epidemiological information.

After the feasibility of possible approaches has been scrutinized the preliminary objectives should be determined. These may range from elementary forms of control for the prevention of death from parasitic disease(s) to the complete elimination of the parasitosis from a particular area, country or geographical region. The setting of the objectives should be realistic and take into account the available resources. A staged procedure may be envisaged that permits the future upgrading of objectives in keeping with the growth of resources and general development.

Provisional objectives should then be put to the test in realistic →feasibility studies to be undertaken under qualified technical guidance through the service structure that is expected to be ultimately responsible for the implementation of the control activities. There is little room for so-called pilot projects since they usually operate with relatively greater resources, more qualified and more motivated personnel, and much higher staffing levels than those ultimately available to the large-scale control programme. Results from pilot projects should therefore not be used for the extrapolation of the probable impact of more extensive routine operations. Feasibility studies of single or combined approaches will permit the →validation of approaches as well as technical adjustments to improve their efficacy. Such studies will also clarify requirements in terms of financial and manpower resources, training, equipment and supplies, logistics, mechanisms of evaluation and remedial action, and will provide the elements for determining →cost-effectiveness.

In the light of feasibility studies, which need to be done in each major epidemiological and operational stratum, it will be possible to conclude whether the provisionally set objective can be reached with the available resources, whether the objective should be upgraded or downgraded or, in the worst of cases, whether attempts at any form of control would be futile under the present circumstances. Some thought should also be given to the capability of sustaining the control effort in the future when prevalence and/or incidence of the disease have been reduced since potentially infective →reservoirs will in most situations still be present and cause serious repercussions with any slackening of the

control effort. For this reason it may be more appropriate to use an existing general service structure (with technical backup and guidance from a specialized group) rather than a vertical, disease-specific service structure which is subject to political and budgetary vagaries and often lacks popular support. Control of parasitic diseases of man can be incorporated in the development and delivery of general health care, while livestock health can become part of community development activities. This approach would promote community understanding and involvement which are recognized as essential prerequisites for sustained effort and success.

Preliminary and intermediate feasibility assessment and the scrutiny of the inventory of requirements are followed by the preparation of a master plan for the control of a specific disease or group of diseases. Its successful implementation will largely depend on continuous and well-qualified technical guidance and evaluation, timely recognition of technical and administrative problems, and rapid remedial action.

Current strategies for the control of widespread and economically important human diseases such as →malaria, →schistosomiasis and →filariasis are described under the respective headwords.

Remote sensing by meteorological satellite technology is currently being developed as a tool for forecasting epidemics of mosquito-borne diseases. The application holds particularly high promise for areas where epidemics are known to occur as a result of cyclical changes of rainfall (e.g., the Sahel zone of Africa).

Although providing promising leads, efforts directed to the development of vaccines against →malaria and schistosomiasis have so far not been successful enough to make projections for the availability of operationally deployable products in the immediate future.

Disease Control, Strategies

General Information

Parasitoses are widespread in the animal kingdom and in plants, causing a wide spectrum of pathologic effects ranging from little more than commensalism to severe, even fatal disease. Many parasitic diseases cause considerable suffering and have an important impact on human health, and on livestock and crop production. Some parasitic diseases have a relatively low incidence but show high severity and a potential for producing epidemic outbreaks. Others are widespread, rarely causing gross pathology, but sapping the strength and health of those affected. The mode of transmission also shows considerable variety, ranging from direct contact to obligatory passage through several host species. The distribution of such hosts and environmental factors may therefore limit the occurrence of specific parasitoses. Thus some parasitic diseases are cosmopolitan while others may be restricted to very small ecological niches, with many nuances between these extremes. Some parasites have a rather wide choice of vertebrate hosts, others are highly stenoxenic. In addition, naturally →acquired immunity may modify the manifestations of many parasitoses and lead to age-specific patterns of disease.

The detrimental impact of many parasitic diseases makes their control desirable if not indispensable in the interests of health and economy. The great variety of parasitic diseases and of the factors involved in their transmission requires widely different control approaches and strategies tailored to the specific epidemiological conditions and the goals of intervention.

In planning control strategies, it is helpful to classify the various parasitic diseases of man and other animals, irrespective of the causative species' taxonomic standing, into those affecting only humans (→Anthroponoses), those affecting only other animals (→Zoonoses), and those affecting both man and other animals (→Anthropozoonoses or →Zooanthroponoses). (Major representatives of the three groups are listed under the respective headwords in order to facilitate an appreciation of the wide range of causative agents and the modes of transmission involved.) In the majority of parasitic diseases, the causative organism's life cycle provides the essential elements for developing a control strategy. Such strategies invariably aim at the interruption or reduction of transmission at vital points.

Approaches to the control of parasitic diseases are based, essentially, on an analysis of the biological system characteristic of the given parasite species, the determination of targets of intervention, the critical consideration of measures suitable for such intervention, and an inventory of available experience in the control of parasitoses.

Some measures directed against parasitic diseases may exert a non-target environmental impact that needs to be considered in the planning of control activities. This may require environmental compatibility studies before clearing specific methods for wider application.

In all human parasitoses with gross pathology, e.g., →malaria, →visceral leishmaniasis, (→Kala Azar), African and →American trypanosomiasis, onchocerciasis and →lymphatic filariasis, clinical relevance is the motor for developing and enacting disease control strategies. These aim at improving human health and reducing disease incidence or prevalence. Similar considerations apply to diseases affecting livestock, where also economic aspects play a substantial role.

Disease Control, Targets for Intervention

Knowledge of the parasite's life cycle is a prerequisite for determining feasible targets of control intervention. However, before such knowledge became available it was not rare for communities afflicted or threatened by certain parasitic diseases to take, empirically or intuitively, appropriate measures such as the prohibition of pork as a means of avoiding →trichinosis, the siting of habitations to evade →malaria or the use of *Cinchona* bark as a febrifuge.

A rational approach to the control of parasitic diseases requires a full knowledge of potential targets. Measures directed against such targets may be practical, i.e., feasible and effective with currently available means and technology. Other targets may be too elusive for basing a strategy on their successful control. These are, nevertheless, worthy of exploration since a multifaceted approach to disease control usually offers better prospects for success than the deployment of a single measure.

Disease control is, by definition, clinically relevant. Community participation in disease control programmes depends largely on the visibility of results. Effective treatment is usually the best advertisement for a control programme and promotes the understanding for, and acceptance of, other programme activities. Programmes without a therapeutic component are generally unpopular. In order to be viable, programmes for the control of acutely life-threatening diseases, e.g., malaria in areas with *P. falciparum*, require an efficient mechanism for the rapid and competent management of severe and complicated cases.

Nitroimidazoles

Important Compounds

Metronidazole, Nimorazole, Ornidazole, Tinidazole.

Synonyms

Metronidazole: SC-32642, Artesan, Flagyl I.V., Clont, Arilin, Cont, Danizol, Deflamon, Fossyol, Gineflavir, Klion, Orvagil, Sanatrichom, Trichazol, Trichocide, Tricho Cordes, Torgyl Forte, Tricho-Gynaedron, Tricocet, Trivazol, Vagilen, Vagimid.
Nimorazole: N-2-morpholinoethyl-5-nitroimidazole, Nitrimidazine, K 1900, Acterol, Esclama, Naxofen, Naxogin, Nulogyl, Sirledi, Radanil, Rochagan.
Ornidazole: Tiberal.
Tinidazole: CP 12574, Fasigin, Fasigyn, Pletil, Simplotan, Sorquetan, Tricolam.

Clinical Relevance

The 5-nitroimidazoles (Fig. 1) exert a wide variety of activities against different pathogens. Their antibacterial activity is useful in different indications. Thus, they are useful against obligatory anaerobic intestinal bacteria, intra-abdominal gynaecological infections, aspiration pneumonia, superinfected bronchial carcinomas, brain abscesses, *Bacteroides fragilis* infections, gut wall necrosis as well as polymicrobial pelveoperitonitis. The antibacterial activity of metronidazole is also useful in the treatment of →*Dracunculus medinensis* infections. Moreover, 5-nitroimidazoles are applied in chronic non-bacterial diseases of the intestine like Morbus Crohn. In addition, metronidazole or tinidazole are effective in the treatment of peptic ulcera in combination with omeprazole (lansoprazole or pantoprazole) and clarithromycin (with or without amoxicillin).

5-nitroimidazoles are in addition useful in protozoal infections caused by →*Giardia lamblia*, →*Trichomonas vaginalis*, →*Entamoeba histolytica* (Table 1), in urogenital infections caused by →*T. foetus* in cattle, as well as in intestinal trichomoniasis, giardiasis and →amoebiasis in dogs, cats and monkeys. The drug has additional activities against →*Blastocystis hominis in vitro* and *in vivo* and →*Balantidium coli* infections of pigs.

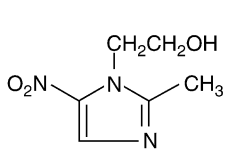
The antiprotozoal action of 5-nitroimidazoles is directed against *G. lamblia* →trophozoites and cysts in the duodenum, against *T. vaginalis* trophozoites in vagina, cervix, urethra, epididymis, prostate and in *E. histolytica* infections against trophozoites (minuta forms) in the phase of →binary fission and cysts in the intestinal mucosa and trophozoites (magna forms) in liver and other extraintestinal organs. The activity against *B. coli* is directed against the intestinal trophozoites which divide by binary fission and cysts in the feaces.

Molecular Interactions

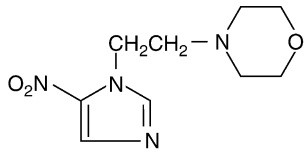
The antibacterial action of metronidazole relies on its activation in anaerobic bacteria (*Bacteroides, Clostridium*) mediated by pyruvate-ferredoxin-oxidoreductase (PFOR). Metronidazole is generally not toxic to mammalian cells, because they lack electron transport proteins like PFOR with sufficiently negative redox potential for drug activation. The biochemical target of 5-nitroimidazoles is also the enzyme PFOR in *Giardia*, →*Trichomonas* and *Entamoeba* (Fig. 2). In *T. vaginalis* PFOR is located in the →hydrogenosomes. Comparison of the genes from *E. histolytica*, *T. vaginalis* and →*G. lamblia* encoding PFOR show 35–45% sequence identity. The PFOR from these parasites are dimeric or tetrameric proteins of 240 kDa subunits. 5-nitroimidazoles exert their activity only after the reduction of the nitro group by PFOR which occurs in single electron steps (in total 4 electrons) and results in the formation of a hydroxylamine derivative. The formation and disappearance of the nitro-free anion radical could be detected in →trichomonads (Fig. 2). Until now there is only indirect evidence for cytotoxicity of the intermediate nitroso-free radicals and hydroxylamines. It is presumed that the interaction of toxic intermediates with various cellular macromolecules (DNA, proteins, membranes) leads to an irreversible cellular damage by DNA-alkylation. Indeed, there is a correlation between the reduction of the nitro group of metronidazole and DNA damage *in-vitro* and *in-vivo*.

Resistance

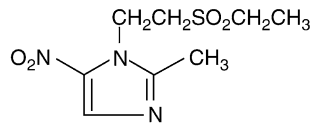
PFOR is in the centre of the resistance mechanism in *G. duodenalis* resulting in reduced production of



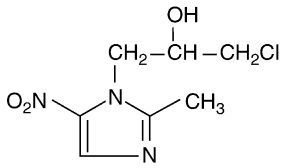
Metronidazole



Nimorazole



Tinidazole



Ornidazole

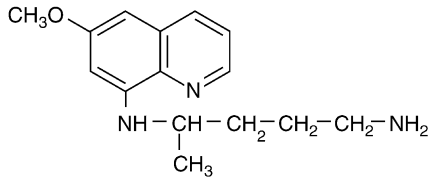
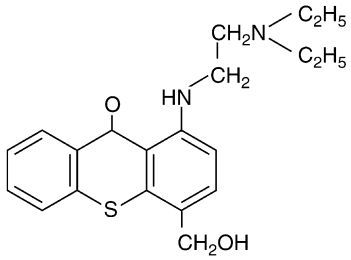
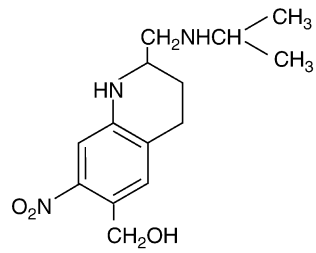
Pamaquine



Primaquine



Hycanthone



Oxamniquine

DNA-Synthesis-Affecting Drugs I: Alkylation Reactions. Figure 1 Structures of drugs affecting DNA-synthesis by alkylation reactions.

toxic radicals by decreased PFOR activities. Indeed, in *T. vaginalis* there is a correlation between increased metronidazole-resistance and decreased activity of the PFOR and hydrogenase. Besides PFOR in *T. vaginalis* ferredoxin (Fd) also seems to play an important role in the resistance mechanism. Thus, in metronidazole-resistant *T. vaginalis* a decrease of intracellular Fd levels by 50%, a decrease of Fd mRNA levels by 50–65% and a reduced transcription of Fd gene can be observed. Moreover, there is a correlation between resistance and the appearance of point mutations in the 5′ flanking sequences of the gene. Two mutations could be identified with a reduced binding affinity of a 30 kDa protein to a 28 bp region within the mutated region upstream of the Fd gene. Thus, metronidazole resistance strongly correlates with an altered regulation of the Fd gene transcription. The limitation of the ability of the cell to activate metronidazole by reduced gene transcription finally results in decreased intracellular levels of Fd, so that metronidazole is less efficiently reduced to its cytotoxic form.

There is an alternative hypothesis of the resistance mechanism in *T. vaginalis* in which a half-type P-glycoprotein should be overexpressed by a mechanism other than gene amplification. However, there is no clear correlation between levels of expression of the gene for this putative transporter protein and levels of resistance. Thus, the role of this gene in resistance remains doubtful.

Furazolidone

Synonyms

3-(5-nitrofurfurylideneamino)-2-oxazolidinone, NF180, Furovag, Furoxane, Furoxone, Giarlam, Giardil, Medaron, Neftin, Nicolen, Nifulidone, Ortazol, Roptazol, Tikofuran, Topazone.

Clinical Relevance

This drug is active against *Giardia lamblia* (Table 1). The action is directed against *G. lamblia* trophozoites in the small intestine which divide by binary fission.

Molecular Interactions

The enzyme PFOR seems to be of great importance in the furazolidone action. The reduction of this nitro compound *in vivo* to cytotoxic products is assumed to be similar to that of 5-nitroimidazoles (Fig. 2). The reduction potential of furazolidone is regarded as being even greater than that of metronidazole. An additional reduction mechanism of furazolidone via an NADPH/NADH oxidase to its nitroanion radical is also in discussion.

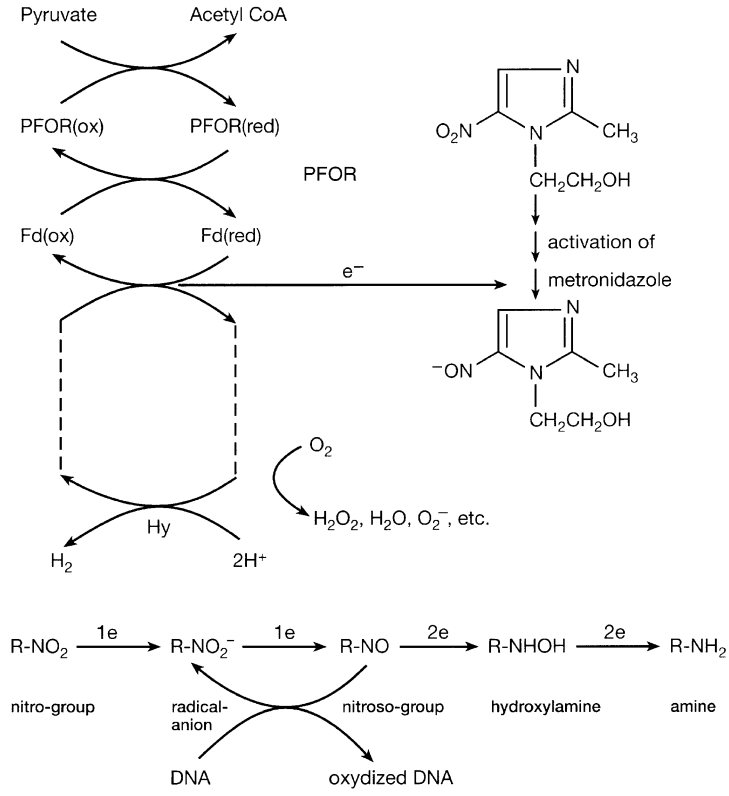
Resistance

The molecular mechanism of furazolidone resistance is unclear to date. An involvement of thiol detoxification pathways is discussed. But any correlation between a decrease in furazolidone sensitivity and an increase in thiol cycling in *G. lamblia* is very doubtful since these parasites lack the enzymes of →glutathione metabolism.

Primaquine/Pamaquine

Synonyms

Primaquine: 8-(4-amino-1-methylbutylamino)-6-methoxyquinoline, SN 13272.
Pamaquine: Aminoquin, Beprochine, Gamefar, Plasmochin, Plasmoquine, Praequine, Quipenyl.



DNA-Synthesis-Affecting Drugs I: Alkylation Reactions. Figure 2 Model of the mechanism of action of Metronidazole and other 5-nitroimidazoles.

Clinical Relevance

Both drugs belong to the chemical class of 8-aminoquinolines. Pamaquine was discovered in 1924, primaquine was introduced in 1950. Primaquine is a very effective prophylactic antimalarial agent and very effective in preventing relapses of →malaria so that it can be used for a radical cure (→Haem(oglobin) Interaction/Table 1). Exoerythrocytic stages of →malarial parasites in the liver (sporozoites, →hypnozoites, schizonts) and the erythrocytic gamonts get severely damaged (→Haem(oglobin) Interaction/Fig. 2). Primaquine has an additional influence on the →sporogony in the mosquito vector, however, it has no effect on erythrocytic schizonts (parasitic stages responsible for fever). Besides the antimalarial activity primaquine shows an additional activity against *Theileria sergenti* infections.

Molecular Interactions

Primaquine is presumably metabolised *in vivo* to products including 5,6-quinoline diquinone which structurally resembles hydroxynaphthoquinones. It is therefore assumed that the respiratory chain of the parasites is disrupted and the pyrimidine nucleotide synthesis is inhibited. In an alternative theory the generation of free radicals during the primaquine interaction with the respiratory chain is believed to be of great importance.

Oxamniquine

Synonyms

Mansil, Vansil, Vancil.

Clinical Relevance

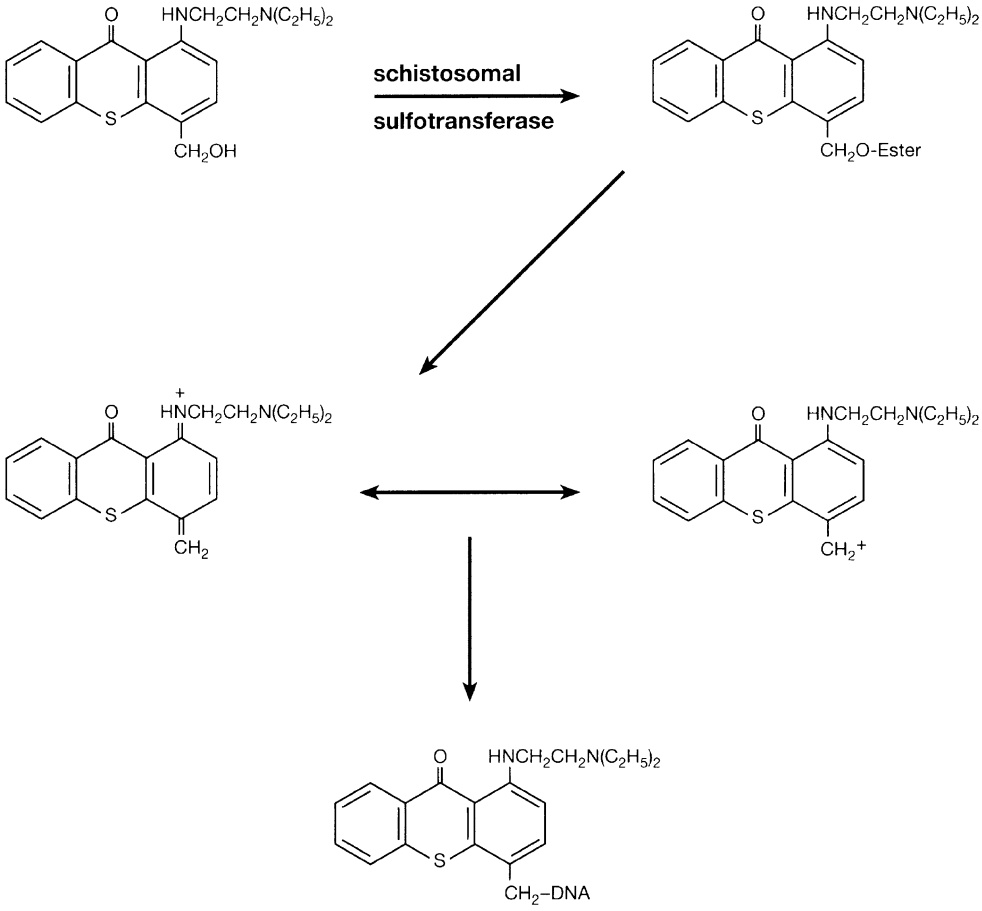
Oxamniquine was introduced in 1973. The antitrematodal activity is directed only against →*Schistosoma mansoni*. Oxamniquine has no activity against →*S. haematobium* or →*S. japonicum* (→Membrane-Function-Disturbing Drugs/Table 2).

Molecular Interactions

The *in vitro* activity of oxamniquine is very similar to that of the structurally related hycanthone. Oxamniquine leads to a delayed death of schistosomes until day 14. Thereby, an *in vitro* exposure of only 1h is sufficient for the delayed death of the worms. Because the worm motility is increased at oxamniquine concentrations comparable to hycanthone, an anticholinergic action of

oxamniquine was formerly proposed. However, this hypothesis is disproved in the meantime. Indeed, it could be shown that nucleic acid synthesis becomes irreversibly inhibited in drug-sensitive worms, in drug-resistant worms, in *S. japonicum* and in immature worms. The inhibition is more pronounced in male than in female schistosomes. The →mode of action of hycanthone and oxamniquine is summarised in Fig. 3 according to the model of Cioli et al. 1995. At first hycanthone (and also oxamniquine) is converted to an ester (sulphate, phosphate or acetate) by a specific schistosomal enzyme. Thereafter, the ester spontaneously dissociates resulting in the formation of an electrophilic reactant which is capable of alkylating schistosomal DNA. Thus, the initial drug esterification is the only enzymatic step in the whole pathway (Fig. 3). The validity of this model is supported by experiments using the N-methylcarbamate esters of hycanthone. These hycanthone esters have been shown to be equally active against sensitive and resistant worms, since the first enzymatic esterification step can be surconvented by these hycanthone esters. As a result covalent binding of hycanthone and oxamniquine to macromolecules including DNA occurs *in vitro*. In female and in immature schistosomes binding of hycanthone and oxamniquine to DNA is diminished compared to males. Adducts of hycanthone with guanosine residues of schistosomal DNA are formed.

ATP, Mg^{++} and another unknown small molecule are cofactors during the esterification step by the schistosomal enzyme. The activity of this enzyme can be restored by sulfate ions. Thus, this enzyme may function as a sulfotransferase with a molecular weight ranging from 30 to 35 kDa. The real function of this sulfotransferase is still unknown. A possible detoxifying function is discussed as well as an involvement in modifying male and female steroid hormones. Such a sulfotransferase is presumably also present



DNA-Synthesis-Affecting Drugs I: Alkylation Reactions. Figure 3 Proposed mechanism of action of hycanthone and oxamniquine.

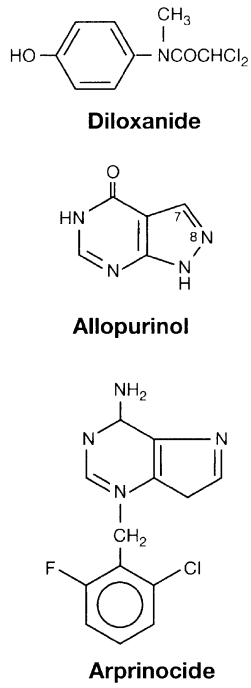
in *S. haematobium* and *S. japonicum*. However, structural differences of the sulfotransferases between the different →*Schistosoma* spp. may be responsible for different binding of hycanthone and oxamniquine to this enzyme. While there is a strong binding of both drugs to *S. mansoni* sulfotransferase, only hycanthone can be bound by *S. haematobium* sulfotransferase. The sulfotransferase of *S. japonicum* is even unable to bind hycanthone or oxamniquine.

Additional Features

There are also differences in the mutagenicity between hycanthone and oxamniquine. Oxamniquine has very low mutagenic activity compared to hycanthone. The mutagenicity of hycanthone is due to production of frameshift mutations as a consequence of its ability to intercalate between DNA base pairs resulting in an unwinding and distortion of the double helix. Therefore, hycanthone has been withdrawn as an antischistosomal drug. Oxamniquine also has some minor intercalative properties which are not enough for strong mutagenic effects.

Resistance

Resistance against hycanthone and oxamniquine is controlled by a single, autosomal, recessive gene. Resistant schistosomes lack the activity essential for antischistosomal effects of oxamniquine in sensitive worms, because the enzymatic esterification step is missing in resistant parasites similar to the susceptible *S. japonicum*.



DNA-Synthesis-Affecting Drugs II: Interference with Purine Salvage. Figure 1 Structure of drugs affecting DNA-synthesis by interfering with →purine salvage.

DNA-Synthesis-Affecting Drugs II: Interference with Purine Salvage

Structures

Fig. 1.

Diloxanide

Synonyms

2,2-dichloro-4'-hydroxy-N-methylacetanilide, Furamide, Entamide, Ame-Boots.

Clinical Relevance

Diloxanide is exclusively used as fuorate ester. The antiprotozoal activity is directed against →trophozoites and lumen cysts of →*Entamoeba histolytica* (→DNA-Synthesis-Affecting Drugs I/Table 1). Diloxanide has only minor activity in acute ulcerative intestinal →amoebiasis. Combinations of diloxanide with 5-nitroimidazoles, emetine or chloroquine for the treatment of amoebic dysentery and liver abscesses can be very useful.

Molecular Interactions

It is suggested that diloxanide interferes with the purine salvage system by impairing adenine incorporation during the RNA-synthesis in *E. histolytica*.

Allopurinol

Synonyms

Allopurinol, Zyloric.

Clinical Relevance

Allopurinol is in medical use against →*Leishmania* spp. In addition, it has experimental activity against →*Trypanosoma* spp. (Table 1). Furthermore, allopurinol is clinically used in the treatment of gout as urikostatic drug.

Molecular Interactions

The antiprotozoal →mode of action against *Trypanosoma cruzi* and *Leishmania* spp. relies on the metabolisation of allopurinol to adenosine nucleotide analogues. These are then incorporated into RNA with

the result that the growth rate of sensitive parasites is significantly reduced.

The mode of action in gout is quite different from the antiprotozoal action presumably by the inhibition of xanthine oxidase.

Arprinocide

Synonyms

9-(2-chloro-6-fluorobenzyl)adenine, MK-302, Aprocox.

Clinical Relevance

Arprinocide exhibits good anticoccidial and anticoccidiostatic activity (→DNA-Synthesis-Affecting Drugs IV/Table 1). Its activity against *Eimeria tenella* is weaker compared to that against other →*Eimeria* spp.

Molecular Interactions

Arprinocide is simultaneously a purine and pyrimidine analogue. The activity is directed against sporozoites, merozoites and first generation schizonts. The main mechanism of action remains unclear. Many pyrimidine nucleotide-requiring enzymes are inhibited. Also, the uptake of hypoxanthine and guanine in infected eukaryotic cells is inhibited. The anticoccidial activity of arprinocide is mediated by the N-1 oxide metabolite. Interestingly, the N-1 oxide metabolite itself is not a potent inhibitor of the biochemical pathways in spite of the very potent *in vitro* and *in vivo* activity. Electronmicroscopically, a vacuolization and degeneration of intracellular membrane systems of →coccidia can be observed.

DNA-Synthesis-Affecting Drugs III: Interference with Polyamine Metabolism and/or Trypanothione Reductase

Mode of Action

Fig. 1.

Structures

Fig. 2.

Melarsoprol

Synonyms

Melarsen oxide, Mel B, Arsobal.

Clinical Relevance

Melarsoprol was explored in 1949 and was the drug of choice for late phase of infections with *T. b. gambiense* and *T. b. rhodesiense* until 1990 (Table 1). An intravenous application is necessary with 3.6 mg/kg b.w. in 3–4 series of 4 injections separated by at least one week. Melarsoprol possesses serious toxic side effects such as reactive encephalopathy in 5–10% of the cases with a mortality rate of 1–5%. In veterinary medicine melarsoprol is exceptionally used against *T. equinum* in horse. It has only low efficacy against *T. simiae* in pigs.

Molecular Interactions

Melarsoprol is a trivalent organic arsenical. The activity is directed against →trypomastigotes in the liquor. An inhibition of trypanosomal pyruvate kinase (PK) as the →mode of action was proposed very early. There is a loss of motility of drug-treated trypanosomes, and cell lysis occurs within minutes. However, there is no correlation between melarsoprol-induced lytic effects and inhibition of pyruvate kinase. In the meantime trypanosomal phosphofructokinase (PFK) ($K_i < 1$ μM) and fructose-2,6-biphosphatase ($K_i = 2$ μM) are found to be better melarsoprol targets than PK ($K_i = 100$ μM), resulting in a complete inhibition of the formation of fructose-2,6-bisphosphate.

As an alternative hypothesis the inhibition of trypanothione reductase (TR) by complexation of trypanothione with melarsoprol or melarsen oxide is discussed (Fig. 1). This complexation would lead to a complete disturbance of the redox balance within the trypanosomal cell. An inhibition of TR would have lethal effects on trypanosomes. The melarsen-trypanothione adduct Mel T has a stability constant of $1.05 \times 10^7\ M^{-1}$. The inhibition of →glutathione reductase and the *T. b. brucei* TR is characterised by K_i values of 9.6 and 17.2 μM, respectively.

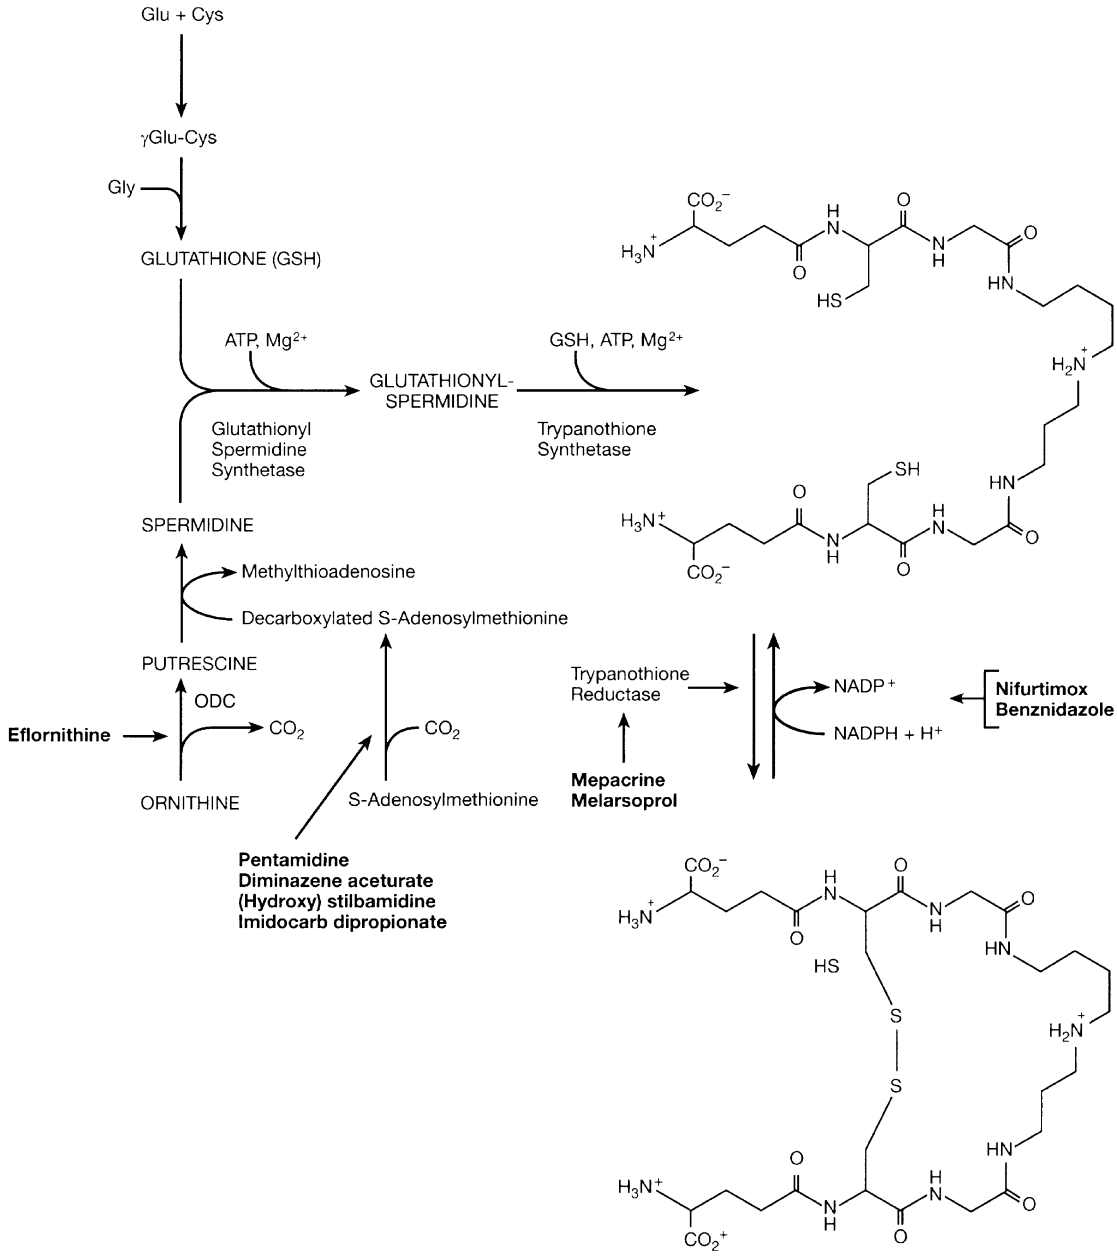
The main argument against TR as target for melarsoprol is the 18-fold-higher K_i value for the inhibition of TR compared to PFK. Furthermore an association of trypanothione with trivalent arsenicals is much weaker than that of 2,3-dimercaptopropanol or lipoic acid. Thus, the selective advantage of the presence of trypanothione in kinetoplastids has remained speculative until now. Melarsoprol is very efficient in forming adducts with a variety of dithiols (coenzyme dihydrolipoate, some proteins with cysteine residues). A nonspecific inhibition of many different enzymes may explain many severe toxic side effects of melarsoprol.

Resistance

Resistance against melarsoprol is a general serious problem in the treatment of →sleeping sickness. Resistant trypanosomes are not lysed by melarsoprol or by the chemically related melarsen oxide at concentrations even higher than 100 μM. A significant decrease in free trypanothione levels could not be detected in resistant strains, whereas a rapid decrease in trypanothione levels was described in sensitive strains just before lysis. Isolated TR from resistant or sensitive strains was shown to be equally inhibited by the melarsoprol-trypanothione adduct Mel T, indicating that TR may not be a validated target for melarsoprol.

A new hypothesis for the resistance mechanism of melarsoprol relies on alterations of melarsoprol transport in resistant trypanosomes with a possible participation of drug efflux mechanisms similar to multidrug-resistant cancer cells. Indeed, there is no lysis of melarsoprol resistant strains in the presence of melarsoprol plus Ca^{++} channel-blockers (verapamil, diltiazem or nifedipine). The mechanism of this so-called melarsen-based drug resistance in trypanosomes is due to their absolute purine requirement. Two non-identical purine transporters P1 and P2 have been identified in trypanosomes. The transporter P2 is responsible for the uptake of melarsen or melarsoprol, adenine and adenosine. The melarsen oxide-induced trypanosomal lysis can be inhibited by adenine, adenosine and dipyridamol, an inhibitor of nucleoside transport in mammalian cells. Adenine, adenosine and melarsoprol thus compete for the transporter P2 in *T. b. brucei*. There is a reduction of the rate of adenosine transport by 80% in melarsen oxide resistant *T. b. brucei* compared to sensitive strains indicating a possible lack of transporter P2 in melarsen oxide-resistant *T. b. brucei*.

There is high cross-resistance between melarsoprol and the diamidine berenil in strains of *T. b. rhodesiense* clinical isolates, *T. b. brucei* veterinary isolates, in laboratory strains of *T. evansi* and others, but low cross-resistance between melarsoprol and pentamidine. Cross-resistance between melarsoprol and pentamidine



DNA-Synthesis-Affecting Drugs III: Interference with Polyamine Metabolism and/or Trypanothione Reductase.
Figure 1 Trypanothione metabolism and inhibition by drugs in kinetoplastid →protozoa.

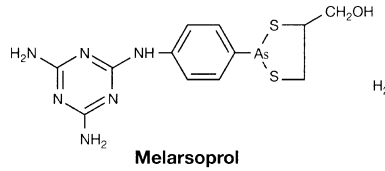
can be correlated with differences in their uptake rates in *T. b. brucei*.

Resistance against the so-called phenyl-based tryparsamide has been known since the 1930s. Interestingly, melarsen-resistant strains are sensitive to phenylarsenoxide and there is no cross-resistance between melarsoprol and phenylarsenoxide. This fact may be explained by the existence of another transporter (P1) for adenosine and inosine, which, however, does not transport melarsen oxide. Thus, phenylarsenoxide-induced lysis of trypanosomes cannot be inhibited by adenine or adenosine in sensitive trypanosomes which supports the idea of different uptake mechanisms of melarsoprol and phenylarsenoxide into trypanosomes.

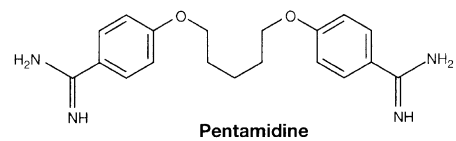
Eflornithine

Synonyms

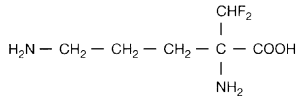
DFMO, DL-a-difluoromethylornithine.



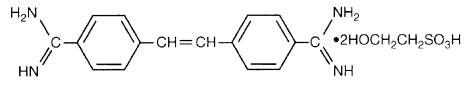
Melarsoprol



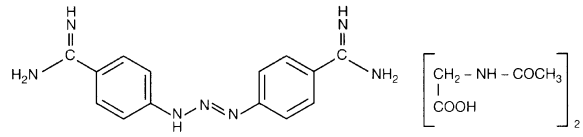
Pentamidine



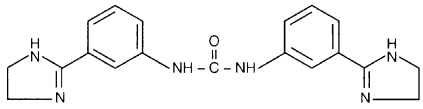
Eflornithine



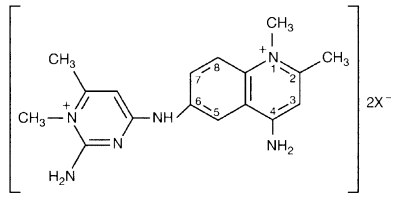
Stilbamidine



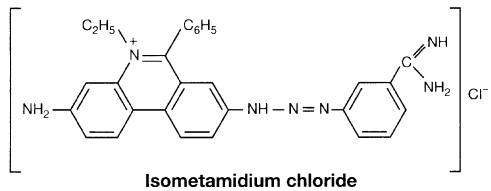
Diminazene aceturate



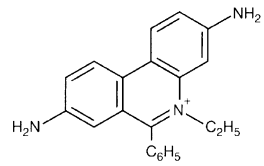
Imidocarb



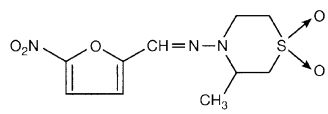
Quinapyramine



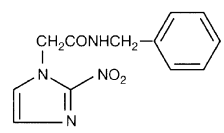
Isometamidium chloride



Homidium



Nifurtimox



Benznidazole

DNA-Synthesis-Affecting Drugs III: Interference with Polyamine Metabolism and/or Trypanothione Reductase. Figure 2 Structures of drugs affecting DNA-Synthesis by interference with Polyamine Metabolism and/or Trypanothione Reductase.

Clinical Relevance

Eflornithine was introduced in 1982 for the treatment of West African sleeping sickness (*T. b. gambiense*). It is active against early and late stages of *T. b. gambiense* (→DNA-Synthesis-Affecting Drugs II/Table 1). Eflornithine is characterised by a remarkably great safety index but possesses a relatively weak overall efficacy and a short duration of activity. An intravenous application is necessary with a dosage of 400 mg/kg b.w. per day in 4 equal doses every 6 hours for 14 days. Eflornithine also has activity against *T. b. brucei* and *T. congolense* and against multiresistant strains of *T. b. gambiense* (bloodstream forms and liquor forms). For the activity of eflornithine an intact immune system is necessary. A disadvantage of eflornithine is its ineffectivity against *T. b. rhodesiense* infections.

In addition eflornithine exerts some activity against leishmania and different opportunistic parasites such as →*Pneumocystis carinii*, *Cryptosporidium* in →AIDS patients as well as *in vitro* or *in vivo* activity against exoerythrocytic schizonts of *Plasmodium berghei*. Moreover, there is a report about some antitumor activity.

Molecular Interactions

Eflornithine is a fluorinated amino acid derivative with zwitterionic properties. Under physiological conditions, it is poorly absorbed and rapidly excreted in the urine. The mechanism of action is well established and the *T. brucei* →ornithine decarboxylase (ODC) is a fully validated therapeutic target. In trypanosomes, which are fully dependent on their own polyamine biosynthetic machinery, DFMO acts as an irreversible "specific suicide" inhibitor of ornithine decarboxylase ODC (Fig. 1) by formation of a covalent adduct between the decarboxylated and defluorinated DFMO and the residue 360 in ODC. As a result the trypanothione biosynthesis is inhibited (Fig. 1) and also the biosynthesis of the →polyamines putrescine, spermidine and spermine. Thus, an *in vitro* and *in vivo* depletion of the putrescine and spermidine from dividing (→Binary Fission) *T. brucei* trypomastigotes in the blood and liquor occurs. As a result of the inhibition of polyamine metabolism many different cell functions are impaired, e.g., the differentiation of trypanosomes into non-dividing short stump-like forms. In addition, DFMO-treated *T. brucei* are kept in the dormant G1 phase by loss of ODC activity. Moreover, the synthesis of →variant surface glycoprotein is inhibited. The selective toxicity of eflornithine must be seen in direct connection with the slow turnover of ODC of *T. brucei* compared to the mammalian enzyme. Mouse ODC possesses an extra 36 amino acid peptide at the C-terminus (PEST sequence) triggering *in vivo* degradation of mammalian ODC. This is responsible for the short half-life of ODC of about 20 min in mammalian cells. By contrast the *in vivo* half-life of *T. brucei* ODC is longer than a day because of the lack of the PEST sequence. A further consequence of the DFMO-induced increased levels of adenosylmethionine may be an inappropriate methylation of proteins, nucleic acids or lipids. The lack of polyamines which are essential for the trypanothione synthesis may itself be sufficient for the explanation of the death of trypanosomes caused by DFMO.

Resistance

Until now there are no reports about DFMO resistance because of the short time of its clinical use. Experimental resistance was examined *in vitro* using either procyclic forms of trypanosomes or naturally resistant strains. However, the mechanism of resistance on the molecular level remains unclear. In some resistant strains a reduced DFMO-uptake could be observed accompanied by an increase of intracellular concentrations of ornithine, whereas in other resistant strains no such reduced DFMO-uptake was detectable. There is no increased ODC activity in *T. brucei rhodesiense* field strains. However it could be shown that the ODC in DFMO-resistant *T. gambiense* possesses a rather short half-life compared to ODC in DFMO-susceptible trypanosomes which have an extraordinarily long half-life. As a result of the rapid *in vivo* turnover rates and synthesis of new active ODC molecules in resistant strains DFMO-inhibited ODC molecules are rapidly replaced. Thus, cells with a rapid ODC turnover are much less affected by the inhibition of ODC. A further difference between DFMO resistant and -susceptible trypanosomes seems to be the different increase in the adenosine methionine content by DFMO. Thus, in resistant strains an only 7-fold increase is observable compared to the up to 100-fold increase in sensitive strains. There also seems to be a correlation between DFMO resistance and decrease in adenosine methionine synthetase.

Pentamidine/(Hydroxy)stilbamidine

Synonyms

Pentamidine isethionate, 4,4'-diamidinodiphenoxypentane, M&B800, RP2512, Lomidine, Pentacarinat.

Clinical Relevance

The diamidines are in clinical use since 1937. Pentamidine is a therapeutic and prophylactic drug against bloodstream forms in sleeping sickness (Table 1). It is, however, active only against early stages of *T. b. gambiense* infections, but not against the liquor forms. 7 to 10 intramuscular injections are necessary with 4 mg/kg b.w. daily or on alternative days. Pentamidine also exhibits activity against *Leishmania donovani* and *L. chagasi* in spleen, liver and skin, but has only minor activity against the American mucocutaneous leishmaniasis (*L. brasiliensis*). Furthermore pentamidine possesses

antibabesial activity and is becoming increasingly important in replacing chloroquine against infections with →*Babesia* spp. Pentamidine has no effect against *Trypanosoma cruzi*. (Hydroxy)-stilbamidine has a similar antiprotozoal spectrum and is useful in antimonial-resistant Kala-Azar (*L. donovani*).

The main indication for pentamidine is its activity against opportunistic parasites. It is the drug of choice for the *Pneumocystis carinii* →pneumonia in AIDS patients. Moreover, pentamidine has some antifungal activity against North American blastomycosis (*Blastomyces dermatididis*).

Molecular Interactions

The mechanism of action of pentamidine is directed against trypomastigotes in the blood which divide by binary fission. Following the uptake into the bloodstream forms of *T. b. brucei* via a carrier-mediated process the binding of pentamidine to nucleic acids is believed to be of great importance. Recently a pentamidine-dodecanucleotide-complex could be identified by cocrystallisation. Drug binding occurs in the 5′-AATT minor groove region of the duplex, preferentially to the minor grooves of the →kinetoplast DNA in *T. brucei*. Thereby, the amidinium groups of pentamidine become H-bonded to adenine N_3 atoms. As a result the kinetoplast DNA is disrupted so that dyskinetoplastic cells are generated with intact mitochondrial membranes but lacking detectable kinetoplast DNA. Pentamidine has no effects on the trypanosomal nuclear DNA.

Furthermore, a 13-fold increase in lysine and 2.5-fold increase in arginine content is induced in the trypanosomes at the therapeutic dose. Electronmicroscopically, an intercalation of diamidines into the kinetoplast DNA (kDNA) could be detected resulting in lampbrush →chromosomes. This observation supports the proposed inhibition of →DNA synthesis by diamidines. Additional nuclear aggregation in diamidine-treated trypanosomes may also explain the inhibition of ribosomal RNA synthesis. The disintegration of kDNA begins at the periphery of the →kinetoplast, where DNA replication starts. Moreover, pentamidine interferes with the trypanothione metabolism by inhibiting the decarboxylation of S-Adenosylmethionine (Fig. 1). Because of their close structural similarity to pentamidine, (hydroxy)stilbamidine presumably has the same mechanism of action (Fig. 1).

Resistance

Resistance to diamidines is well established under field conditions. Resistant strains are characterised by a diminished ability to import pentamidine into the cells. However, it is unclear to date whether an impaired pentamidine uptake, drug efflux or drug metabolism is responsible for the mechanism of pentamidine resistance.

Diminazene

Synonyms

Berenil, Diminazene aceturate, Diminazene diaceturate, Azidin, Ganasag, Trypan, Veriben.

Clinical Relevance

Berenil was originally introduced in 1955 as a trypanocide and babesiacide. It is active against *Trypanosoma b. gambiense* and *T. b. rhodesiense* (Table 1). Of especial interest is the activity against liquor forms of *T. b. rhodesiense*. Berenil is often used in chronic human infections, although it is a veterinary product. The treatment of human trypanosomiasis with berenil is recommended in cases of arsen resistance or before starting treatment with melarsoprol. In veterinary medicine berenil is used against *T. brucei*, *T. congolense, T. vivax* and *Babesia* spp. in cattle, sheep and goats in Africa. Higher dosages are usually necessary for curative effects against *T. equiperdum* in horses. Berenil has only minor activities against *T. simiae* in pigs, *T. evansi* in camels and cattle and *T. equinum* in horses. It should be mentioned that berenil also has experimental effectivity against →*Leishmania* spp. (Table 1).

Furthermore, berenil has activity against →piroplasms of domestic animals (*Babesia* spp. with large erythrocytic parasitic stages). It has good efficacy against *Babesia bigemina*/cattle, *B. ovis* and *B. motasi*/sheep, *B. caballi*/horse, *B. canis*/dog, *B. hepailuri*/cat. However, the drug has far less activity against *Babesia* spp. with small erythrocytic stages (*B. bovis* and *B. divergens*/cattle, →*Theileria* (formerly *Babesia*) *equi*/horse, *B. gibsoni*/dog) and apparently no effect against *B. felis*/cat.

Molecular Interactions

Berenil as an analogue of pentamidine exerts a similar mode of action. The activity of berenil is directed against trypomastigotes in the blood and liquor. In berenil-treated *Leishmania tarentolae* the kDNA content is greatly reduced. It is reported that berenil binds to the minor groove of DNA with a higher affinity to 5′-AATT-3′ than to 5′-TTAA-3′. The attachment to specific sites in DNA occurs via electrostatic and H-bond forces. In addition, it is discussed that berenil may inhibit the kinetoplast topoisomerase II in trypanosomes, resulting in the cleavage of 2% of the →minicircle DNAs in the presence of 1 μM drug. Also a possible interference of berenil with the trypanothione metabolism by inhibiting the decarboxylation of S-Adenosylmethionine is worth mentioning (Fig. 1).

Resistance

Interestingly, there is no widespread development of berenil resistance in the field in spite of long-term use. There are reports on cross-resistance between quinapyramine, melarsomine and berenil in laboratory and

field strains. The mechanism of resistance to berenil is possibly due to a diminished drug uptake by resistant trypanosomes.

Imidocarb Dipropionate

Synonyms

Carbesia, Imixol, Imizol, Imizocarb, 4A65.

Clinical Relevance

The antiprotozoal activity of this drug is directed against *Theileria* (formerly *Babesia*) *equi* and *Babesia caballi* in donkeys and mules. In addition, babesiosis of cattle may be controlled relatively easily by imidocarb.

Molecular Interactions

Imidocarb is a diamidine derivative. Thus, its action may be similar to that of berenil (→DNA-Synthesis-Affecting Drugs III/Fig. 1).

Quinapyramine, Homidium, Isometamidium

Synonyms

Quinapyramine: M7555, Antrycide, Triguin, Trypacide.
Homidium chloride: RD1572, Novidium, Babidium.
Homidium bromide: Ethidium, Dromilac.
Isometamidium: Metamidium, M&B4180, Samorin, Trypamidium.

Clinical Relevance

Quinapyramine (Table 1) has activity against *Trypanosoma equiperdum* in horses and donkeys. Homidium and Isometamidium are used in →chemoprophylaxis against *T. brucei evansi* in cattle, sheep and goats in Africa, and they have also activity against *T. vivax* and *T. congolense*.

Molecular Interactions

Quinapyramine probably acts indirectly by inhibition of protein synthesis by displacement of magnesium ions and polyamines from the ribosomes. Homidium bromide belongs to the phenanthridinium derivatives. Its antitrypanosomal activity has been known for about 50 years. It is routinely used for staining nucleic acids in research laboratories because it intercalates into nucleic acids. It possesses mutagenic properties. The mechanism of antitrypanosomal action of homidium is unclear. There are reports on an interference with glycosomal functions, interference with the function of an unusual AMP binding protein, on impaired trypanothione metabolism and impaired replication of kinetoplast minicircle (2% of total minicircle become linearised by 1 μM homidium) in trypanosomes.

As isometamidium is structurally related to both – homidium and berenil, the properties and activities may be similar. Isometamidium has a great acute toxicity to mammals which is not observed with homidium or berenil. The acute toxic effects of isometamidium in mice can be reversed with atropine indicating probable inhibitory effects on acetylcholinesterase. However, the mechanism of antitrypanosomal action of isometamidium is not yet fully understood. A linearisation of 6% of the total minicircle DNA from *T. equiperdum* at 1 μM may also contribute to the drug's action. *In vitro* an intercalation between the base pairs of the DNA can be observed which may explain the interruption of DNA functioning observed *in vivo*.

Resistance

The extensive use of homidium in the 1960s and 1970s has greatly reduced its usefulness by widespread trypanosomal resistance. The mechanism of resistance is so far unknown. The mechanism of resistance against isometamidium is presumably associated with reduced accumulation of the drug in trypanosomes. There are reports on cross-resistance between isometamidium and homidium, which supports the idea of a similar mode of action of both drugs.

Nifurtimox

Synonyms

Lampit, Bay2502.

Clinical Relevance

Nifurtimox was introduced in 1972 as a causal therapeutic drug for →American trypanosomiasis (=Chagas disease) caused by *T. cruzi* (Table 1). It has curative effects in acute, subchronic and chronic disease. Infection-induced damages of organs, however, are not improved by this drug.

Molecular Interactions

Nifurtimox is a nitrofurfurilidene derivative. It induces a destruction of non-dividing trypomastigote bloodstream forms and intracellular amastigote tissue forms in the muscles of heart, skeleton, oesophagus and intestine, in the lymph nodes and in the nervous system. One possible action may be the inhibition of trypanothione reductase (Fig. 1). As *T. cruzi* has only low detoxification capacity, it is completely dependent on the trypanothione metabolism. As another action the generation of reactive oxygen derivatives (superoxide, H_2O_2 and hydroxyl radicals) is discussed, which cause peroxidation of lipids and damage of the nucleic acids.

Resistance

At present there are no great problems concerning clinical resistance against nifurtimox.

Benznidazole

Synonyms

Ro7-1051, Radanil, Rochagan.

Clinical Relevance

Benznidazole was introduced in 1978. It damages trypomastigote bloodstream forms and amastigote tissue forms of *T. cruzi* (Table 1). There are reports on a low efficacy against the Brazilian →cutaneous leishmaniasis.

Molecular Interactions

The activity is directed against the same stages as by nifurtimox. Probably the trypanothione metabolism becomes disturbed (Fig. 1) and an involvement of generation of free radicals similar to nifurtimox is discussed. There are additional reports on an inhibition of protein- and RNA-synthesis and a damage of DNA.

Cycloguanil

DNA-Synthesis-Affecting Drugs IV: Interference with Cofactor Synthesis. Figure 2 Structures of drugs affecting DNA-Synthesis by interfering with Cofactor Synthesis.

Clinical Relevance

Sulfonamides exert activities against a variety of pathogens. They possess a broad-spectrum activity against gram positive and gram negative bacteria such as *Nocardia* spp., *Chlamydia* spp., *Yersinia* spp. and atypical mycobacteria (*Mycobacterium scrofulaceum*).

The first anticoccidial sulfonamides were introduced in 1946. Sulfonamides currently used in veterinary medicine are sulfaquinoxaline, sulfadimidine, sulfadiazine, sulfadimethoxazole, sulfadoxin and others. They are characterised by a narrow anticoccidial spectrum against →*Eimeria* spp. residing in the small intestine (*E. acervulina*), and they have only minor activity against *E. necatrix* and *E. tenella*. Sulfaquinoxaline is used in combination with amprolium or 2,4-diaminopyrimidines or in a multidrug combination together with ethopabate and pyrimethamine (Table 1). There are also other combinations of veterinary importance (Table 2). Sulfonamides have been very useful against →*Plasmodium falciparum* as single drug or in combination with pyrimethamine (sulfadoxin/pyrimethamine), because of their schizonticidal effects against both exoerythrocytic and erythrocytic stages (→Hem(oglobin) Interaction/Table 1, Fig. 2). In general, they have greater efficacy against *P. falciparum* compared to *P. malariae*, *P. ovale* or *P. vivax*. Other indications in which sulfonamides are used are infections with →*Toxoplasma gondii*, →*Pneumocystis carinii*, →*Sarcocystis* spp., *Cystisospora* spp., →*Isospora* spp. and others. A sulfadiazine/clindamycin-combination is active against →*Neospora caninum* in young dogs, if started very early in the disease (Table 2).

Molecular Interactions

The antisporozoal activity of sulfonamides is primarily directed against second →schizont generations. There is also activity against first schizont generation and sexual stages (→Hem(oglobin) Interaction/Fig. 2). The activity of antimalarial sulfonamides such as sulfadoxin is directed against exoerythrocytic liver schizonts, erythrocytic schizonts and also oocysts in the gut of →mosquitoes (→Hem(oglobin) Interaction/Fig. 2). Sulfadoxin belongs to the long-acting sulfonamides. The first hint about the →mode of action of sulfonamides came from the observation that the anticoccidial activities of sulfonamides can be reversed by paraminobenzoic acid (PABA), an intermediate in folate biosynthesis. Now it has been known for a long time that the action of sulfonamides and of sulfones like dapsone relies on the inhibition of dihydropteroate synthase in intracellular →sporozoa *Eimeria, Toxoplasma* and →*Plasmodium*. Thus, the coccidial →folic acid biosynthesis is inhibited by sulfonamides which is lethal to the →coccidia because they do not utilise exogenous folate but synthesise folate as cofactor of →DNA synthesis de novo (Fig. 1).

Resistance

Dihydropteroate synthetase (DHPS) is a validated target enzyme of sulfadoxin. This could be shown for sulfadoxin-resistant *P. falciparum* isolates. DHPS from resistant and sensitive strains differ in their amino acid sequences. Indeed, there is a correlation between point mutations in the bifunctional DHPS and sulfadoxin resistance. Interestingly, DHPS of *P. falciparum* is a bifunctional enzyme which includes the dihydro-6-hydroxymethylpterin pyrophosphokinase at the amino terminus.

Ethopabate

Synonyms

Methyl 4-acetamido-2-ethoxybenzoate, Ethyl pabate, in combination with amprolium: Amprol Plus.

Clinical Relevance

Ethopabate is only a narrow anticoccidial spectrum drug against *Eimeria acervulina*. It has no or only slight activity against *E. maxima*, *E. necatrix*, *E. tenella* or *E. brunetti*. Today, ethopabate is applied only in combination with amprolium and sulfonamide (Table 1).

Molecular Interactions

Ethopabate is a 2-substituted PABA derivative (= 4-acetamido-2-ethoxybenzoic acid methylester) and functions as a prodrug. Its activity becomes potentiated by pyrimethamine and antagonised by the simultaneous administration of PABA. Thus, the mode of action of ethopabate is similar to that of sulfonamides or sulfones (Fig. 1).

Nicarbazine

Synonyms

4,4'-dinitrocarbanilide, Altek, Elancocin, Nicarb, Nicoxin, Nicrazin.

Clinical Relevance

Nicarbazine is used against coccidiosis in poultry. It has a coccidiostatic action by impairing the →oocyst formation of the late life cycle stages. The numbers of oocysts are only reduced so that a latent infection up to the last life cycle stages is always detectable. Thus, nicarbazine-treated animals can develop immunity against coccidia.

Molecular Interactions

The activity is directed against schizonts of the second generation of *Eimeria* spp. An inhibition of folate biosynthesis is proposed (Fig. 1).

2,4-Diaminopyrimidines

Important Compounds

Pyrimethamine, →Trimethoprim, Diaveridine, Ormetoprim, Epiroprim, Pirithrexim.

Synonyms

Pyrimethamine: Daraprim, RP4753, Chloridin, Darapram, Malocide, Tindurin; in: Fansidar, Suldox, Malocide, Maloprim, Metakelfin.
Trimethoprim: 2,4-diamino-5-(3,4,5-trimethoxybenzyl) pyrimidine, Monotrim, Proloprim, Syraprim, Tiempe, Trimanyl, Trimopan, Trimpex, Wellcoprim; in: Borgal, Cosumix, Leotrox, Protox, Tribissen, Trafigal, Vetoprim, Bactrim, Eusaprim, Septrin, Sultrim.
Diaveridine in: Darvisul, Rofenon.
Ormetoprim in: Rofenaid-40, Ektecin.
Epiroprim: none.
Pirithrexim: none.

Clinical Relevance

2,4-diaminopyrimidines (pyrimethamine, trimethoprim) are active against a wide variety of human and veterinary pathogens. Thus, they possess a broad antibacterial spectrum. Antiprotozoal active 2,4-diaminopyrimidines used in human medicine are pyrimethamine and trimethoprim. They are used for →prophylaxis in →malaria, but the onset of antimalarial activity is very slow. They have no general effect on gamonts and no effect on →hypnozoites of *P. vivax* (→Hem(oglobin) Interaction/Fig. 2). Because of the frequently occurring resistance against pyrimethamine they are applied in combinations with sulfonamides (sulfadoxin) (Fansidar). In general, combinations of pyrimethamine and trimethoprim with sulfa drugs are of great medical importance for treatment of toxoplasmosis (Table 2), →*Isospora belli* infections and *Cyclospora cayetanensis* infections in →AIDS patients. Thus, combinations of pyrimethamine with sulfonamides such as sulfadiazine, sulfadimidine or sulfadoxin belong to the standard treatment for human toxoplasmosis. However, these combinations are restricted for the treatment of →prenatal toxoplasmosis in the time after the 20th week. In addition, a pyrimethamine-sulfonamide combination is the drug of choice for postnatal infections with *Toxoplasma gondii* in children and in AIDS patients. For tolerability reasons and especially for prophylactic treatment, a combination of trimethoprim and sulfamethoxazole sometimes in a combination with clindamycin is recommended. There are only anecdotal reports of treatment of →microsporidiosis in AIDS with trimethoprim/sulfamethoxazole.

2,4-diaminopyrimidines used in veterinary medicine are pyrimethamine, ormetoprim, epiroprim, pirithrexim and diaveridine. They are routinely used against coccidiosis in combinations such as ormetoprim/sulfadimethoxine or sulfaquinoxaline/amprolium/ ethopabate/ pyrimethamine (=Supracox). A combination of clarithromycin and pyrimethamine has been shown to be effective against toxoplasmosis in animals, but is not well tolerated. In addition, a pyrimethamine/sulfamethazine-combination is reported to be effective against *T. gondii* in sheep and goats (Table 2). Trimethoprim or pyrimethamine as single drugs or together in combination show curative effects in *Neospora caninum* infections, when motor nerve disturbances have already occurred (Table 2). Epiroprim is a relatively new 2,4-diaminopyrimidine for the treatment of toxoplasmosis. It possesses an *in vitro* activity against *T. gondii*. There are promising results in animal experiments with a dapsone/epiroprim-combination. Pirithrexim, another 2,4-diaminopyrimidine, and pyrimethamine have been shown to be active against *N. caninum* →tachyzoites in cell cultures.

Besides the antibacterial and the antiprotozoal activities 2,4-diaminopyrimidines are useful as anticancer drugs and in therapy of rheumatic diseases.

Molecular Interactions

Pyrimethamin is a selective inhibitor of the dihydrofolate dehydrogenase (DHFR) of exoerythrocytic schizonts (in the liver) and erythrocytic schizonts of →malarial parasites (→Hem(oglobin) Interaction/Fig. 2) and other sporozoa such as *Toxoplasma* and *Eimeria*. Schizonts become damaged by pyrimethamine only during →nuclear division. There is no effect on the parasitic ring forms of *P. falciparum*. Pyrimethamine has an additional activity against oocysts in mosquito gut. Besides pyrimethamine the parasitic DHFR is also inhibited by the other 2,4-diaminopyrimidines trimethoprim, epiroprim, diaveridine and ormethroprim (Fig. 1). It has been well established for a long time that there are synergistic effects between the 2,4-diaminopyrimidines as DHFR-inhibitors and sulfonamides as inhibitors of dihydropteroate synthetase, when given in combination (Fig. 1).

Resistance

Most knowledge about the resistance mechanism against pyrimethamine at the molecular level comes from experiments with plasmodia. A modification of the target receptor DHFR in the folic acid pathway in resistant strains very likely results in a decrease of DHFR sensitivity to inhibition. There are several reports that the molecular basis of pyrimethamine

resistance in naturally resistant isolates of *P. falciparum* are single point mutations (e.g., Ser-108 ⇒) in the DHFR active site (Fig. 3). There is a good correlation between mutations with natural pyrimethamine resistance in a variety of geographically distant isolates. In addition, the two ancillary mutations Asn-51 ⇒ Ile-51 and Cys-59 ⇒ Arg-59 are associated with increased pyrimethamine resistance in the presence of Asn-108.

Another mechanism of pyrimethamine resistance in *P. falciparum* has been proposed. Thereby, an overproduction of DHFR achieved either by gene duplication or by other mechanisms resulting in increased expression is discussed as being responsible for resistance on the molecular level.

Chlorproguanil

Synonyms

Chlorguanil, 1-(3,4-dichlorophenyl)-5-isopropylbiguanide, M5943, hydrochloride: Lapudrine.

Clinical Relevance

Chlorproguanil serves as a causal prophylactic, but not as a therapeutic drug for malaria. Its effectivity is not different from proguanil.

Molecular Interactions

The target of chlorproguanil is the dihydrofolate reductase of the parasitic stages. It has an influence on sporozoites and the exoerythrocytic stages of all four *Plasmodium* spp. (→Haem(oglobin) Interaction/Fig. 2). The onset of the effect on erythrocytic stages is very slow. The activity is directed against exoerythrocytic schizonts, erythrocytic schizonts and oocysts in mosquito gut (→Hem(oglobin) Interaction/Fig. 2).

Resistance

There is cross-resistance between chlorproguanil and pyrimethamine indicating the same mode of action by inhibition of the DHFR (Figs. 1, 3).

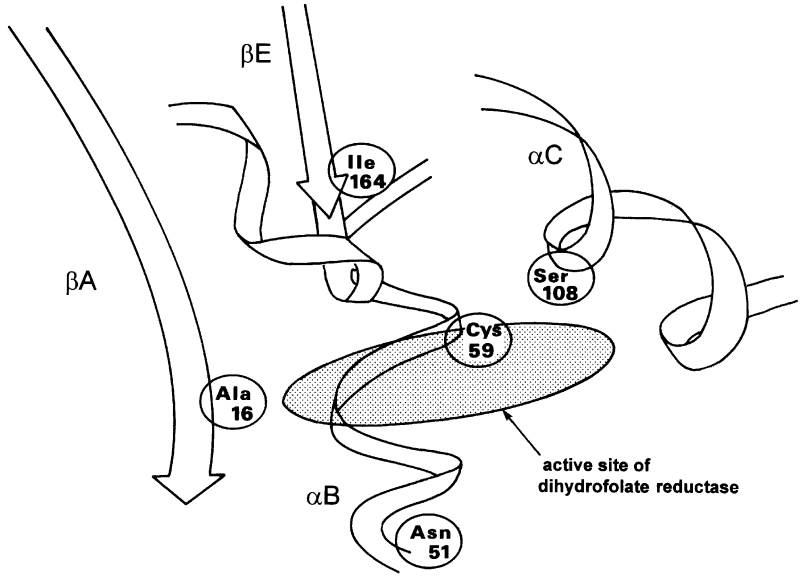
Proguanil

Synonyms

Chlorguanide, 1-(p-chlorophenyl)-5-isopropylbiguanide, Chloroguanide, M4888, RP3359, SN12837, Diguanyl, Drinupal, Guanatol, Paludrine, Palusil, Tirian; Combination: Proguanil, Atovaquone (Malarone®).

Clinical Relevance

Proguanil was explored in 1945. It was developed for prophylaxis against malaria, but the prophylactic activity is not complete. It leads to a damage of exoerythrocytic schizonts. It has no effect on the hypnozoites in the liver. The fixed combination of proguanil and atovaquone (Malarone®) is used for prophylaxis and therapy (including emergency self-medication) of uncomplicated *P. falciparum* infections for adult patients as well as for children. The combination shows good efficacy and tolerability (→Hem(oglobin) Interaction/Table 1). For atovaquone see DNA-Affecting Drugs V.



DNA-Synthesis-Affecting Drugs IV: Interference with Cofactor Synthesis. Figure 3 Schematic model of the point mutations in the active site of dihydrofolate reductase of *Plasmodium falciparum* (Gutteridge (1993) In: Cox FEG (ed) Modern Parasitology, 2nd edition, Blackwell Science, pp. 219–242).

Molecular Interactions

Proguanil belongs chemically to the biguanids. It is a prodrug, which is converted to cycloguanil, a cyclic triazine with antimalarial activity. The activity is directed against exoerythrocytic schizonts in the liver, erythrocytic schizonts and oocysts in mosquito gut (→Hem(oglobin) Interaction/Fig. 2). The mode of action is the selective inhibition of the DHFR of malarial parasites (Figs. 1, 3).

Resistance

There are specific DHFR point mutations responsible for resistance to cycloguanil which could be shown in a variety of independent *P. falciparum* clones and isolates. From examination of the point mutations of DHFR it becomes clear that there is a different molecular basis for resistance to cycloguanil and pyrimethamine, depending on the positions of the mutations and on the residues involved. Point mutations result in an inhibition of pyrimethamine binding at the active site of the reductase (Fig. 3). But there are presumably different effects of the DHFR point mutations on pyrimethamine and cycloguanil, since proguanil is sometimes effective against pyrimethamine-resistant *P. falciparum*, indicating that there may be different binding sites for both drugs. In other cases there is cross-resistance between proguanil and pyrimethamine observable.

DNA-Synthesis-Affecting Drugs V: Interference with Dihydroorotate-Dehydrogenase

Structures

Fig. 1.

Hydroxyquinolines

Important Compounds

Amquinate, Buquinolate, Decoquinate, Methylbenzoquate.

Synonyms

Amquinate: none.
Buquinolate: 4-Hydroxy-6,7-diisobutoxy-3-quinolinecarboxylic acid ethyl ester, Ethyl 6,7-diisobutoxy-4-hydroxyquinoline-3-carboxylate, Bonaid.
Decoquinate: Ethyl 6-(n-decyloxy)-7-ethoxy-4-hydroxyquinoline-3-carboxylate, M&B15497, Deccox.

Clinical Relevance

4-hydroxyquinolines have antiparasitic activities against *Toxoplasma* spp., →*Pneumocystis carinii*, and *Cryptosporidium parvum*, and they furthermore possess anticoccidial, antimalarial, and antitheilerial activity. Decoquinate is active against *T. gondii* in cats (→DNA-Synthesis-Affecting Drugs IV/Table 2) and is still used in shuttle programs against coccidiosis. For such shuttle programs it is of great advantage when the single components exert synergistic activity. This is the case for methylbenzoquate and meticlorpindol (clopidol) (→Energy-Metabolism-Disturbing Drugs), which are used in combination in such shuttle (rotation) programs. However, as single compounds they have only limited success as anticoccidials.

Hydroxynaphthoquinones

Important Compounds

Parvaquone, Buparvaquone, Atovaquone, Menoctone; Combination: Atovaquone/Proguanil (Malarone®).

Synonyms

Buparvaquone: Butalex; Menoctone: Menocton; Parvaquone: Clexon.

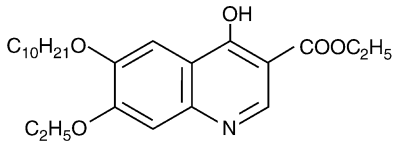
Clinical Relevance

The potential of this class of 2-hydroxynaphthoquinones was realized over 50 years ago. Parvaquone and buparvaquone have antibabesial and antitheilerial activity (*Theileria parva* in cattle). Against →theileriosis parvaquone acts against the schizonts in lymphoid cells, thereby, selectively destroying infected lymphocyte cells thus setting free the schizonts which are not protected against the host defense system in contrast to merozoites with their surface-coated →pellicle. Menoctone (= 2-hydroxy-3-(8-cyclohexyl-octyl)-1,4-naphthoquinone) is active *in vitro* in infected bovine lymphoid cell cultures and against theileriosis in cattle *in vivo*.

Atovaquone exerts antimalarial and anticoccidial activity. It is used for treatment of →malaria in combination with proguanil and shows activity in opportunistic infections in →AIDS (→*T. gondii* cysts in the brain of mice). It has high efficacy in humans suffering from malaria after oral applications. Very recently a new drug combination atovaquone/proguanil (Malarone) was introduced for treatment of acute uncomplicated →Malaria tropica. It is also effective for →prophylaxis. There are no more clinical trials of atovaquone against cryptosporidiosis.

Molecular Interactions

The action of **atovaquone** against multidrug-resistant strains of →*Plasmodium falciparum* may be explained by its new →mode of action being different from that of the other antimalarial drugs. It is assumed that the antimalarial actions of 2-hydroxynaphthoquinones and 4-hydroxyquinolines are identical. Their activity is directed against schizonts in lymphocytes or against



Decoquinate

Ponazuril

DNA-Synthesis-Affecting Drugs V: Interference with Dihydroorotate-Dehydrogenase. Figure 1 Structures of antiparasitic drugs affecting DNA-Synthesis by interference with Dihydroorotate Dehydrogenase.

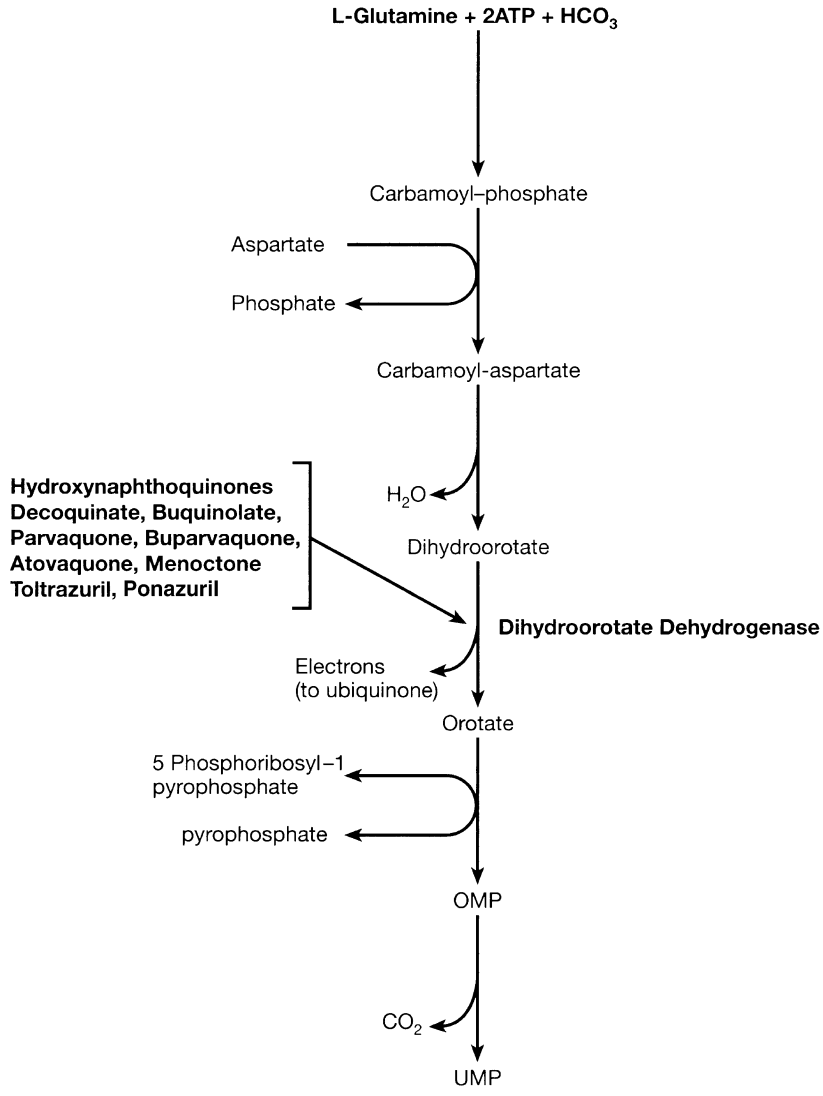
erythrocytic schizonts (→Hem(oglobin) Interaction/Fig. 2). There is additional activity against liver and mosquito stages of *P. berghei*. Besides, the formation of ookinets from mature gametocytes of *P. falciparum* is inhibited. As analogues of ubiquinones these compounds have structural similarity to reduced coenzyme Q, and they act through an inhibition of the electron transfer at complex III of the →mitochondrial respiratory chain of parasites. Moreover, there are several reports of an inhibition of cellular respiration by 4-hydroxyquinolines and an inhibition of mitochondrial succinate dehydrogenase and NADH-dehydrogenase activities from different sources. In isolated →mitochondria from *P. falciparum* atovaquone is bound strongly and selectively to the ubiquinol-cytochrome c reductase site of the respiratory chain (= complex III). The point of block is located between the →ubiquinone and cytochrome b. The inhibition can be reversed by addition of

coenzyme Q. The high therapeutic index and thus the high selectivity of 4-hydroxyquinolines correlates with the lack of inhibition of cell respiration in the chicken host. The reason for this is presumably the great difference of the electron transport chains between →coccidia and their vertebrate hosts. Indeed, atovaquone is 2000-fold more active against the plasmodial respiratory chain compared to the corresponding rat liver mitochondria.

There is another hypothesis for the action of hydroxyquinolines, which relies on the inhibition of pyrimidine nucleotide synthesis at the level of dihydroorotate dehydrogenase (Fig. 2). This then would result in an inhibition of →sporozoite and trophozoite development in the intestinal epithelium. Indeed, a strong inhibition of pyrimidine nucleotide synthesis could be shown for amquinate, buquinolate, decoquinate, and meticlorpindol probably due to an inhibition of dihydroorotate dehydrogenase (DHOD) (Fig. 2). In →*Plasmodium*, where ubiquinone plays an important role as an electron acceptor for dihydroorotate dehydrogenase (DHOD), atovaquone is believed to inhibit the pyrimidine synthesis at this level.

Resistance

There are high frequencies of serious drug resistance in the field against 4-hydroxyquinolines of veterinary medicine. Thus, resistance against buquinolate already appeared within 6 months. There is cross-resistance between different quinines as indication for a similar mode of action. Mitochondria from 4-hydroxyquinoline-resistant *Eimeria tenella* are insensitive to drug



DNA-Synthesis-Affecting Drugs V: Interference with Dihydroorotate-Dehydrogenase. Figure 2 Model of dihydroorotate dehydrogenase as target for anticoccidial drugs.

inhibition. The mitochondrial respiration of amquinate resistant cells is nearly 100-fold less sensitive to 4-hydroxyquinolines, but the real mechanism of resistance on the molecular level is still unknown. Until now resistance of malaria parasites against the 2-hydroxynaphthoquinone atovaquone does not play any role.

Toltrazuril

Synonyms

Baycox.

Clinical Relevance

Toltrazuril exerts high efficacies in the treatment of poultry coccidiosis. Moreover, the drug is very useful in the treatment of *Cystoisospora ohioensis* and *Isospora canis* in dogs under experimental and field conditions, *I. suis* in piglets, *Eimeria bovis* and *E. zuernii* in calves. Unlike other anticoccidials toltrazuril acts on all intracellular developmental stages of all known *Eimeria* and *Isospora* spp. In addition, toltrazuril exerts an activity against the schizogonous and gametogonic stages of *Toxoplasma gondii* in the cat (→DNA-Synthesis-Affecting Drugs IV/Table 1). For extraintestinal infections of *T. gondii* in cats longer treatment periods with toltrazuril are necessary. Toltrazuril has additional activity against sarcocystosis (→DNA-Synthesis-Affecting Drugs IV/Table 2).

Molecular Interactions

Toltrazuril is a symmetrical triazinetrione. Its action is directed against first and second generation schizonts, →microgamonts, and macrogamonts. It has no activity against free sporozoites and merozoites. Toltrazuril probably acts by inhibiting the mitochondrial respiration and nuclear pyrimidine synthesis in the parasite. A destruction of the →wall-forming bodies II can be observed in the macrogamonts. Histochemical and biochemical studies reveal that dihydroorotate dehydrogenase may act as a further target of toltrazuril (Fig. 2). There is ultrastructural evidence that plastid-like organelles are present in *T. gondii*, *Sarcocystis muris*, *Babesia ovis*, and *P. falciparum* containing protochlorophyllidae as well as traces of chlorophyll bound to the photosynthetic reaction centers PS I and PS II. These plastid-like structures have been described as membranous cytoplasmic structures containing a →circular DNA molecule of 35-kb length having a →plastid ancestry. It is assumed that the sensitivity of apicomplexans to toltrazuril depends on the interaction of this drug with the D1 protein, a vital constituent of the photosynthetic reaction center II.

Until now there are only reports of isolated cases of resistance against toltrazuril. Under laboratory conditions resistance is relatively difficult to achieve.

Ponazuril

Synonyms

→Toltrazuril-sulfone; Marquis.

Clinical Relevance

Ponazuril treatment is approved for equine neurological disease, called equine protozoal myeloencephalis, which is caused by *Sarcocystis neurona*. Moreover, the drug is effective experimentally against *Neospora caninum* (syn. *Hammondia heydorni*) in mice and calves, *Toxoplasma gondii* tachyzoites in cell culture and mice, and *Eimeria vermiformis* infected mice.

Molecular Interactions

Ponazuril (toltrazuril-sulfone) is the antiprotozoally active metabolite of toltrazuril. Therefore it presumably exhibits the same molecular interactions as the mother compound toltrazuril (Fig. 2).

Dollo's Law

This reflects the long-held assumption, that in evolution an organism, which had changed from a complex to a simple state will never return to the complex one, e.g., a free-living stage, when having lost structures and living as a parasite, will never return to the free-living state. Recent findings, however, indicate that there may be reversal.

Dracontiasis

Synonym

→Dracunculiasis, →Dracunculus medinensis.

Dracunculiasis

Synonym

→Guinea worm infection, →Dracontiasis, Medina worm disease, Fil d'Avicenne.

General Information

Dracunculiasis is acquired by the swallowing of copepods infected with larvae of →Dracunculus medinensis with drinking water. The larva molts and may leave the copepod to be ingested by another one. Or, the ingested L3 larva matures in the deep tissues of humans, and as mature female migrates to a subcutaneous site (usually arm or leg). Larvae are deposited into the tissue and because of →hypersensitivity a cutaneous vesicle is formed which may ulcerate. Upon immersion of the extremity into water, the adult projects into the →ulcer or vesicle and releases the larvae which wait to be ingested again by copepods. Two types of lesions are produced in man, vesicles which ulcerate and subcutaneous or deep abscesses around dead adult worms. →Inflammatory reaction in the microabscess includes epithelial and giant cells, lymphocytes, and plasma cells; neutrophils and eosinophils are also present close to degenerating worms. These lesions eventually calcify.

Targets for Intervention

The infective larvae of *Dracunculus medinensis* are ingested by the human host with water while they are still contained within their copepod host (→*Cyclops* spp.). Figure 1 illustrates that dracunculiasis is a disease that lends itself to simple and highly effective control. The major targets of intervention are the cycle of infection and the environment of the copepod host. The approaches to control include detection of infected persons, extraction of the adult worm, prevention of contamination of water used for human consumption, and control of *Cyclops* spp. in such water collections, as well as the use of safe drinking water.

Main clinical symptoms: Allergic skin reactions, skin →necrosis.
Incubation period: 3–4 months.
Prepatent period: 10–14 months until emergence of the female (→Dracunculus/Fig. 3).
Patent period: Female die usually within 2–6 weeks after emerging from the skin.
Diagnosis: Macroscopic inspection of appearing females.
Prophylaxis: Avoid drinking uncooked water in endemic regions.
Therapy: Surgical withdrawal of adult females, treatment see →Nematocidal Drugs.

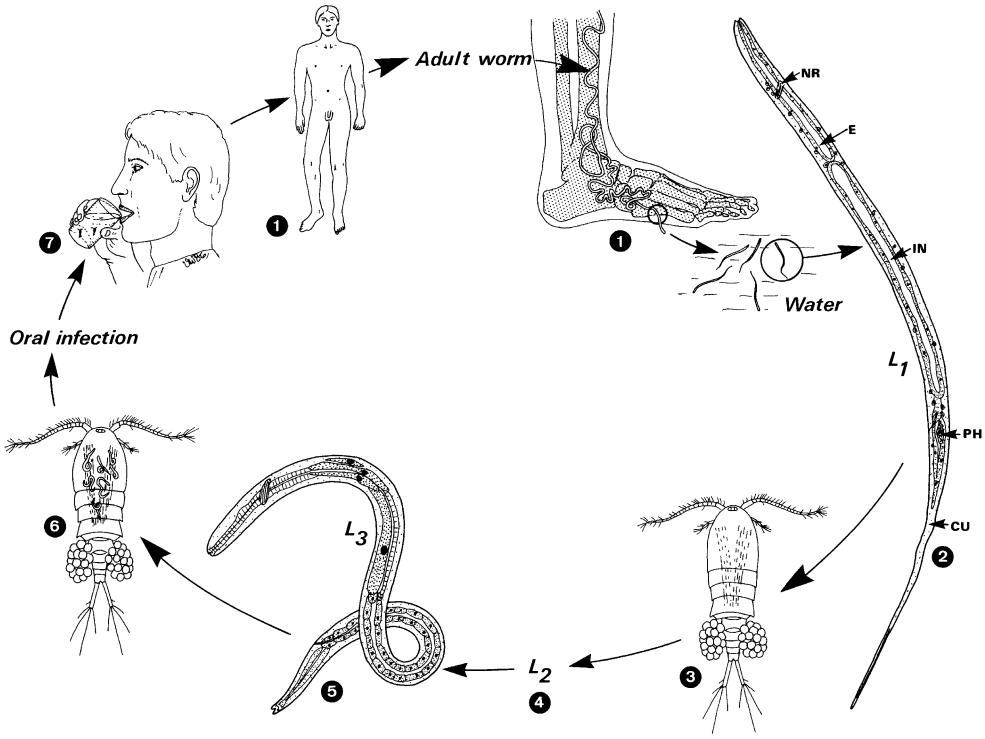
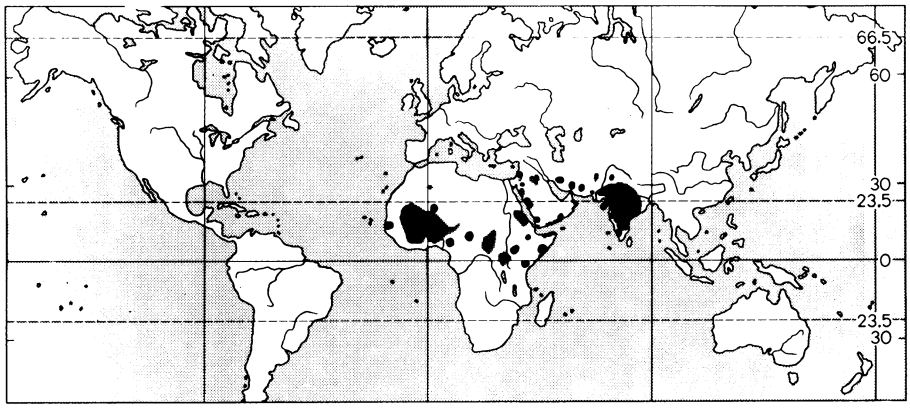
Draschia

Genus of nematodes of the family Habronematidae (found in the intestinal tract of equines – being transmitted by flies).



Dracunculus medinensis. Figure 1 Life cycle of *Dracunculus medinensis* (i.e., Medina worm, fil d'Avicenne). *1* Adults (male 4 cm, female 80 cm × 2 mm) live in the subcutaneous tissues of the final host, man, where a gravid female induces the formation of an ulcer-like sore, through which it can protrude its anterior end (with water contact). Its body wall is ruptured by pressure, allowing the gravid uterus to prolapse and release a mass of first-stage larva (L_1) - up to half a million per day. *2, 3* L_1 remain active in the water up to 1 week until being ingested by a suitable →intermediate host (copepodid crustaceans). *4–6* Inside the hemocoel of the intermediate host the transformation to infectious third-stage larvae (300–600 × 15 µm) occurs (via two molts) within 12–14 days (at 25°C). In general, a single larva is found inside a copepod. *7* Infection of man is effected when swallowing infected copepods in contaminated drinking water. Between 10 and 14 months are needed until a new blister in the skin appears (prepatent period). *CU*, →cuticle of first stage larva; *E*, esophagus; *IN*, intestine; *NR*, nerve ring, *PH*, →phasmid cell anlage.



Dracunculus medinensis. Figure 2 Distribution map of *Dracunculus medinensis*, which now occurs focally in the dark and grey zones.

Dracunculus medinensis. Figure 3 Patients with female worms leaving the skin.

Drepanidotaenia

Syn. *Hymenolepis lanceolata*, a worldwide occurring tapeworm of goose, ducks, and waterbirds, reaches a length of up to 25 cm, uses intermediate hosts (small crustaceans, e.g., *Cyclops*) and various transport hosts (water snails, e.g., Fam. Lymnaeidae).

Drepanidotaenia lanceolata

Tapeworm in the intestine of ducks.

Drug Discovery

The drug discovery and drug development process to screen and evaluate new chemical entities (NCE) with antiparasitic actitivity is similar to the well-known classical way in pharma industry. These are because of a high number of excellent, recent reviews in this field and distinct problems in the area of antiparasitic drug discovery should be discussed.

The use of antiparasitic drugs is a broad field ranging from ectoparasites, like lice, up to endoparasites like malaria or African sleeping disease, indicating that each parasite needs specific and well-targeted drugs for treatment. Because of the high diverse group of parasites in this review, we focus mainly on endoparasites that

belong to the group of protozoa like *Plasmodium*, *Leishmania*, *Trypanosoma*, and *Cryptosporidium*. Most of these protozoa cause diseases which affect, so-called low-income, countries in the Third World, and only a small market exists in industrialised countries affected by people travelling and contracting mostly malaria. Most of the diseases were neglected, because of low economic interest; in recent years non-profit organisations, like DnDi, MMV, Wellcome Trust, and Institute for OneWorld have taken action to bring these diseases to public awareness and to push academia and industry in private–public partnerships. This positive development has been supported by philanthropic institutions like Rockefeller and Gates Foundation allowing projects with million-dollar budgets. In recent years, product development partnerships have become the principal means, internationally, for the successful development of new medicines, and vaccines and diagnostics for diseases that predominantly affect people in the developing world.

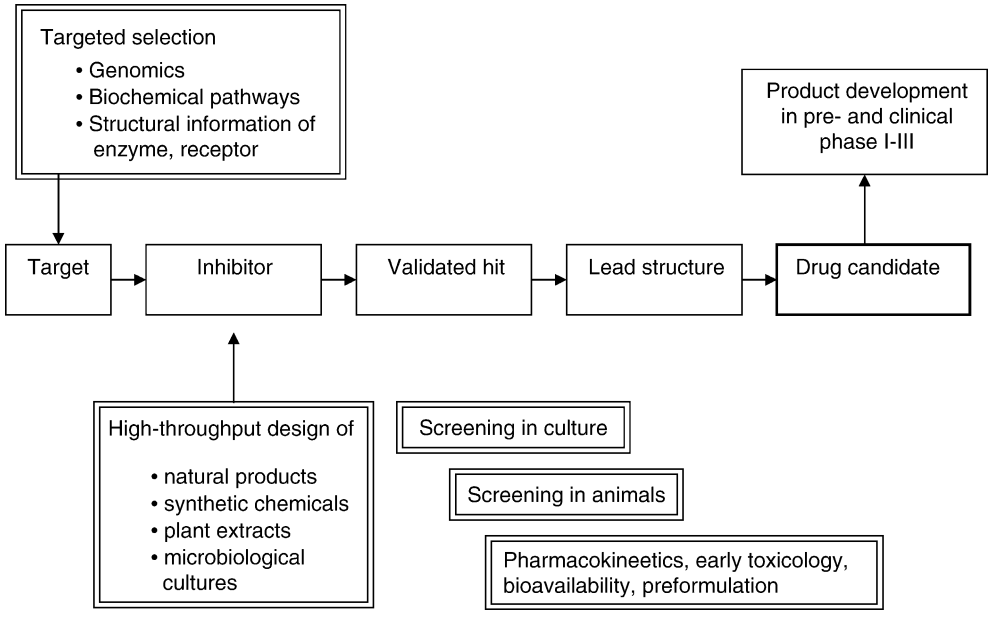
Drug Development Process

Development of new antiparasitic drugs is expensive, time consuming, and a complex and risky process that takes up to 10–12 years, costs in average €300–700 million Euros and requires a strict drug approval procedure. These aspects affect the willingness for the development of new drugs for neglected diseases. Figure 1 displays the major steps in drug development over 10–15 years.

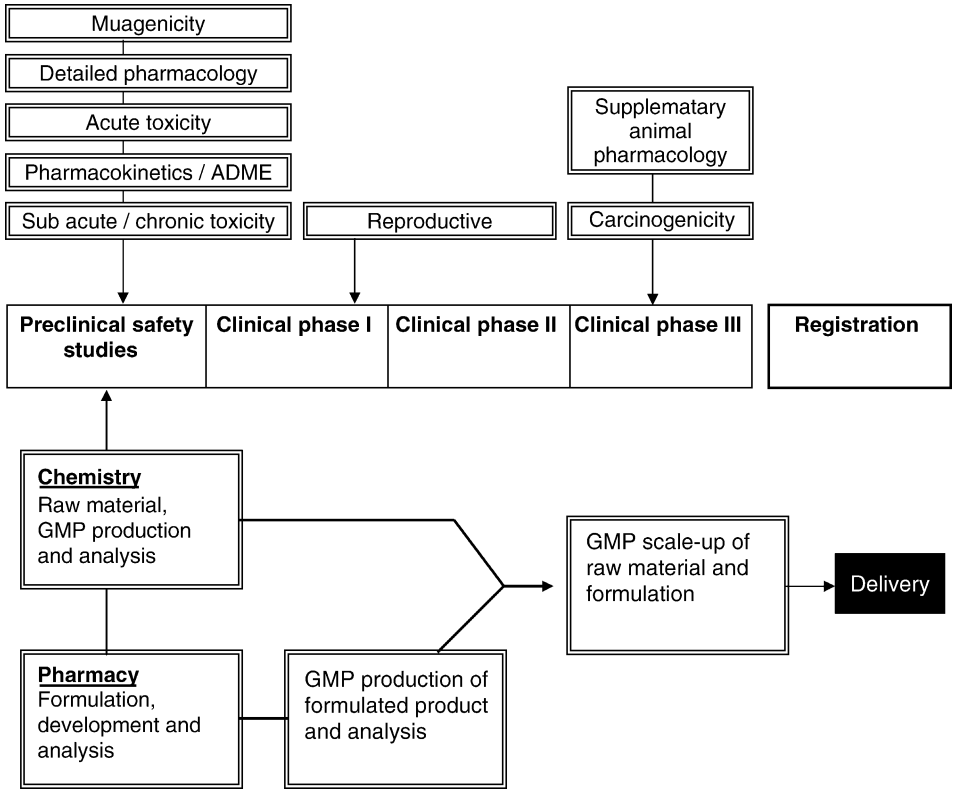
The most important aspect is health impact of the final product for the target developing country patients. A literature survey of the parasitic disease literature related to the drug development process, a series of 21 independent metrics for safety, efficacy, affordability, and suitability of neglected disease drugs are published. An ideal antiparasitic drug would receive a maximum score on all criteria, what can be considered as not realistic, while a drug with low scores on all criteria would represent a very poor product and would be selected out of the drug development process. On the basis of the scores, drug development experts discriminate valuable antiparasitic drug candidates and products are then classified as below average (less than or equal to half the maximum score for an ideal drug) or above average (more than half the maximum score) on each metric. The major 4 criteria in drug development will be discussed here.

Efficacy

Resistance is most crucial point and seriously affects efficacy when treating parasitic diseases. This was and is still obvious for chloroquine in malaria treatment; therefore efficacy must be measured for both the short term (cure rates) and the long term (likelihood of rapid development of resistance). Efficacy metrics are also tailored to each disease. For example, schistosomiasis treatments are assessed for whether they are active against all common strains and species, and lymphatic filariasis treatments are assessed for activity against both larval and adult worms.



Drug Discovery. Figure 1 Drug discovery process (modified according to Nwaka and Ridley, 2003).



Drug Discovery. Figure 2 Drug development process to market authorisation (modified according to Nwaka and Ridley, 2003).

Safety

In principal, the safety concern should be on the same high level in Western or Third World countries. However, for antiparasitic drugs we have to consider a different safety profile, because of the low number of available drugs and cost-benefit analysis, the non-use of a medicine could be more harmful then the potential side effects. It must be under serious consideration to apply Western settings and safety assessment must take into account the incidence and severity of adverse effects (as usually experienced and reported). In that particular case a pharmacovigiliance network should be installed to report about adverse events after administration to patients by trained physicians, but also given as over-the-counter drug. The lack of modern public health infrastructure explains high non-prescription use, but also buying drugs illegally from the black market.

Market Costs and Suitability for Developing Country Use

No medicine can be as good as it is not available on the market. Therefore the price for antiparasitic can meet the realistic price for development and production in industrialised countries, but would be rather inaccessible for the majority of patients in Africa and Asia. The average budget in a so-called low income country allows public health care by US$4 per person and year. As an example artemisinin-based chemotherapy costs US$2–2.5 per dosage, and artemisinin covers US$1–1.5 from these costs. Annually each patients has to follow 10–12 treatment courses summing up the total price to US$25–30 per year.

Logistically suitability has to be installed and is depending on several indices, including:

(1) ease-of-use for patients and health care workers, e.g., dosing intervals, length of treatment required, availability of oral formulations
(2) appropriateness to developing country health systems, e.g., requirement for cold chain, or for hospital-based administration
(3) percentage of the affected patient group covered by the therapy, e.g., adults and
(4) children, or only adults; all patients, or only second-stage or severely ill patients.

This index was also tailored to each disease, but special diseases like tuberculosis, what is not a parasitic disease, needs a long term treatment covering other

additionally indices, while antimalarials were additionally assessed for usefulness in pregnant women and paediatric patients, who make up the majority of malaria mortality figures.

For latest literature information please contact the author Professor Dr. Kayser.

Drug Resistance

→Resistance Against Drugs.

Drugs

Synonyms

Compound, substance, agent, medicament, product.

Definition

Drug can be broadly defined as any chemical compound that affects living processes and is used in the diagnosis, prevention, treatment (cure) of disease(s), or for controlling or improving any physiological or pathological disorder, or for relief of pain in animals and humans.

General Information

→Chemotherapy/Drugs.

Drugs Against Microsporidiosis

General Information

→Microsporidians are eukaryotes of ancient origin (lack of →mitochondria) and obligate intracellular parasites entering host cells via a →polar tube within a spore. The organisms are ubiquitous and may occur in humans and a wide range of animals (wild, fish, and arthropods) but also dogs and other domestic animals commonly associated with humans. Today, there are no efficient control measures for prevention of →microsporidiosis in humans and →animal reservoirs. →Spores seem to be resistant to various physical effects such as sonification, freezing or thawing, ultraviolet or gamma radiation.

Humans

Serious microsporidiosis may develop in immunocompromised individuals (e.g., →AIDS patients, travellers going to tropical areas). Ocular infection is manifest by conjunctival, corneal, and/or stromal invasion, predominantly by *Encephalitozoon hellem*, and *Vittaforma cornea* (syn. *Nosema corneum*). Intestinal infections are due to →*Enterocytozoon bieneusi*, *Encephalitozoon*

intestinalis, and →*E. cuniculi*. Clinical signs may be severe diarrhea, →malabsorption, and wasting. Disseminated infections may be produced by *E. hellem*, *E. cuniculi*, and →*Pleistophora* spp. and are often accompanied by concurrent HIV infection (→Treatment of Opportunistic Agents/Drugs Acting on Cryptosporidiosis of Mammals and →Antidiarrhoeal and Antitrichomoniasis Drugs/Drugs Acting on Giardiasis, respectively).

Pathology

Immunosuppressed humans have been sentinels of microsporidial infection, with enteric, neurologic, ocular, and pulmonary manifestation being recognized. Their symptomatology, pathology, and differential diagnosis, based on ultrastructure and the polymerase chain reaction, has been widely established. Microsporidiosis appears to be a common asymptomatic infection, that is not clinically recognized; about 10% of animal handlers were reported to have antibody to →*Encephalitozoon* sp. The organism grows intracellularly, destroying the infected cells. There is little inflammation. The →Brown-Brenn stain (Gram-stain for tissues), basic fuchsin, toluidin blue, Azur II-eosin, the →Warthin-Starry silver impregnation, and polarization facilitate recognition of →microsporidia in tissue sections. Tissue imprints (smears), dried, fixed, and stained as for blood smears, are useful for diagnosis of corneal and conjunctival lesions. Stool and sputum smears can be stained with a modified →trichrome stain employing chromotrope 2R or with a fluorochrome →chitin stain, such as Calcofluor.

A fatal disseminated infection of a 4-month-old thymic alymphoplastic baby with *Nosema connori* involved the smooth musculature, skeletal muscles, the myocardium, parenchyma! cells of the liver, lung, and adrenals. *Encephalitozoon* sp. was isolated from the cerebrospinal fluid of a 9-year-old Japanese boy with →meningoencephalitis who recovered (Matsubayashi). Intestinal microsporidiosis has been described in several patients with AIDS due to *Enterocytozoon bieneusi* also with cholangitis and due to *Encephalitozoon* (*Septata*) *intestinalis*. The patients had →diarrhoea, with →weight loss from malabsorption. Inflammation was minimal and the diagnosis was made ultrastructurally. Disseminated *Encephalitozoon cuniculi* infection was noted and *E. hellem* had been isolated from AIDS patients with nephritis and prostatitis and from others with keratoconjunctivitis, bronchitis, and sinusitis. Microsporidial myositis due to *Pleistophora* and *Trachypleistophora hominis* was reported in patients with AIDS. Intraocular microsporidiosis was diagnosed from the cornea next to Descemet's membrane with a subacute to granulomatous →inflammatory reaction; other HIV-negative cases with corneal stromal infection were linked to *Nosema ocularum* (possibly *Vittaforma corneum*).

Treatment

Treatment is problematic since the gram-positive staining spores (most familiar stage of microsporidia) are resistant to most drugs (→Treatment of Opportunistic Agents/Table 1). Several topical antimicrobial and anti-inflammatory drugs have been used for treating ocular disease such as keratoconjunctivitis. **Topical drugs** such as propamidine isethionate or the water-soluble fumagillin derivative Fumidil-B (eyedrops) may resolve ocular symptoms caused by *E. hellem*, which reoccur, however, when treatment is stopped indicating a static rather than a cidal action of drugs. For lesions due to →*V. corneae*, topical therapy is generally not effective and keratoplasty may be required. Oral administration of **albendazole** may improve ocular, nasal, and enteric symptoms; the drug has a marked static effect on intestinal microsporidians like *Ent. bieneusi* and *E. intestinalis*. The latter species proves more susceptible to treatment with albendazole. The drug seems to inhibit polymerization of →microtubules within intranuclear spindles in dividing nuclei only, and for that reason growth of parasites will continue in the absence of →nuclear division. In the current situation almost nothing is known about epidemiology of human microsporidiosis; an open question is whether microsporidians in man are solely human infections or are some episodes of zoonotic origin.

Fish

With respect to chemotherapy of microsporidiosis in fish, it was shown that the antibiotic **fumagillin** acts against *Glugea plecoglossi* in the Japanese ayu (*Plecoglossus altivelis*), but in some cases the mortality of treated fish was higher than that of untreated fish. The →mode of action of fumagillin is thought to inhibit DNA or RNA synthesis. More recent investigations have shown that a symmetric triazine **toltrazuril** and an asymmetric triazine (HOE 092V) kill the merogonic and the sporogonic stages of the microsporidian *G. anomala*. The drugs are also highly active against other fish and crayfish parasites. As revealed by ultrastructural investigations, the effects of the triazine derivatives on *G. anomala* comprised a decrease in the number of ribosomes, enlargement of the smooth ER, depletion of the nuclear membrane, and destruction of the nuclear structures. In a further study it was demonstrated that different **benzimidazole** derivatives (albendazole, mebendazole, and fenbendazole) disturbed the intracellular development of the microsporidian *G. anomala* by damaging its merogonic, sporogonic, and prespore stages as well as the mature spores.

Drugs Against Sarcocystosis

→*Sarcocystis* spp. are obligate, heterogeneous coccidian parasites. Definitive host may be carnivores, felidae, humans, and primates. Their asexual reproduction may occur in herbivores (horse, cattle, sheep, goat, camel), omnivores (pigs, humans), and also birds (chicken, ducks). Consumption of feed contaminated with sporocysts (oocysts) from the feces of the definitive host leads to infection of herbivores.

Pathology and Treatment

Experimental →sarcocystosis in cattle (*S. bovicanis*) or that of horses (*S. equicanis*) has been associated with acute and chronic myositis caused by intramuscular sarcocysts. Long-term treatment with orally administered pyrimethamine, and →trimethoprim + →sulfamethoxazole is necessary to achieve remission of clinical signs. This can be applied also to cases of naturally occurring equine protozoal myeloencephalitic (→EPM) caused by *S. neurona*. The treatment lasted between 45 and 211 days; adverse effects in horses were mild to severe, including →abortion. **Halofuginone** (→Coccidiocidal Drugs/ Table 1) appears to be effective against acute sarcosporidiosis in goats and sheep at 0.67 mg/kg on 2 successive days. In humans, who may serve as accidental →intermediate host for several unidentified *Sarcocystis* spp. sarcocysts have been found in striated muscles. Their clinical significance is unknown in naturally occurring life cycles. For **control** of sarcocystosis, carnivores should be excluded from animal houses, and from feed, water, and rearing facilities for livestock or dead livestock. Cooking or heating (60° C for at least 20 minutes) of contaminated material will kill sarcocysts.

Vaccination

There is no protective vaccine against sarcocystosis in animals or humans.

Drugs with Unknown Antiparasitic Mechanism of Action

Structures

Fig. 1.

DL-Propranolol

Clinical Relevance

The antiparasitic activity of propranolol is directed against →*Giardia lamblia*.

Nitrobenzamides

Important Compounds

Dinitolamide, Zoalene, Nitromide.

Clinical Relevance

Dinitolmide, zoalene have activity mainly against first and second generation schizonts of *Eimeria tenella* and *E. necatrix*. They have only limited effects against *E. acervulina*. They do not interfere with the immunity of chicken hosts. Nitrobenzamides are assumed to act as a nicotinamide antagonist.

Diclazuril/Clazuril

Clinical Relevance

Diclazuril and clazuril belong to 1,2,4-triazine-derivatives. They have broad-spectrum activity in →*Eimeria* infections. They exert additional activity against →*Neospora caninum* →tachyzoites in cell cultures. The →mode of action is unknown. The activity of diclazuril is directed only against specific endogen stages of *Eimeria* species. Thus, diclazuril is active against second generation schizonts of *E. acervulina*, *E. mitis*, and *E. necatrix*, against gamonts, late schizonts of *E. brunetti*, zygotes of *E. maxima* and first and second generation schizonts, and sexual stages of *E. tenella*. The →sporulation becomes delayed by diclazuril.

Febrifugine

Clinical Relevance

Febrifugine is an antimalarial drug from traditional Chinese medicine.

Pyronaridine

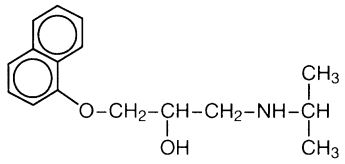
Clinical Relevance

Pyronaridine has high efficacy in clinical studies in China against chloroquine-resistant →*Plasmodium falciparum*. There is cross-resistance to 4-aminoquinolines and quinolinemethanol antimalarials. Morphological effects on →mitochondria, endoplasmic reticulum, and ribosomes can be observed. Food →vacuoles are probably a primary target of pyronaridine.

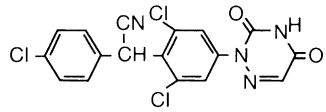
Halofuginone

Clinical Relevance

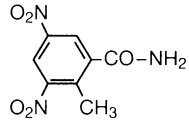
Halofuginone is a quinazolinone derivative. It is an alkaloid originally isolated from the plant *Dichroa febrifuga*. It is effective against the six pathogenic *Eimeria* spp. of chicken. Halofuginone has an influence on sexual first-generation →schizogony. It specifically suppresses the skin →collagen synthesis in mammalian cells *in vivo* resulting in an increase in skin fragility. *In vitro* the incorporation of radiolabelled →proline into collagen by avian skin fibroblasts is impaired. Thereby,



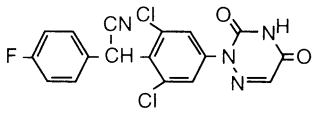
Propranolol



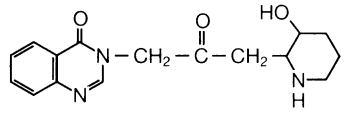
Diclazuril



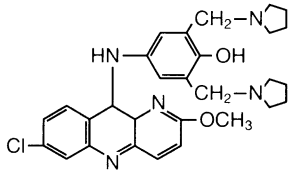
Zoalen



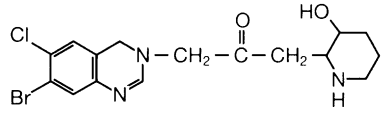
Letrazuril



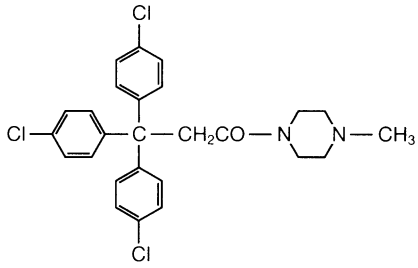
Febrifugine



Pyronaridine



Halofuginone



Hetolin

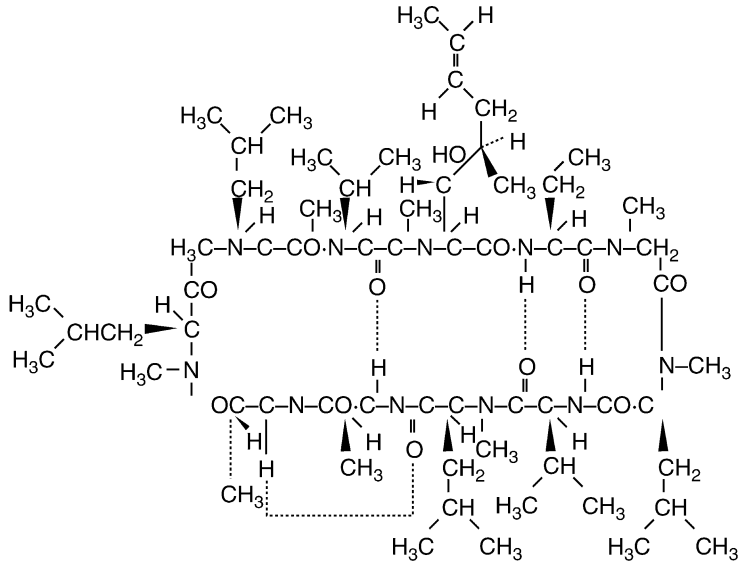
Drugs with Unknown Antiparasitic Mechanism of Action. Figure 1 Structures of antiparasitic drugs with unknown mechanism of action.

the expression of a1 gene of collagen type I is specifically depressed but not that of collagen type II in skin fibroblasts and growth-plate chondrocytes. This results in a decrease in synthesis of collagen. The mechanism of action against *Eimeria* spp. is unknown at present. Furthermore, halofuginone has been used in *Theileria parva* and *T. annulata* infections in cattle. The activity is directed against schizonts in lymphocytes. Thereby, infected lymphocytic cells are destroyed setting free the schizonts, which in contrast to merozoites with their surface-coated →pellicle are not protected against the defense system of the host. Halofuginone has additional activity against *Cryptosporidium parvum* in calves.

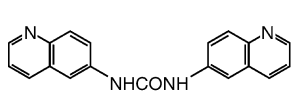
Halogenated Hydrocarbons

Clinical Relevance

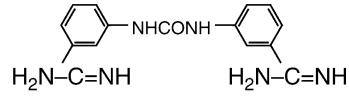
The halogenated hydrocarbons carbon tetrachloride, hexachloroethane, tetrachloroethylene and hexyloesorcinol were used until very recently in veterinary medicine.



Cyclosporin A



Quinuronium Sulfate



Amicarbalide

Drugs with Unknown Antiparasitic Mechanism of Action. Figure 1 Structures of antiparasitic drugs with unknown mechanism of action. (Continued)

Now they are no longer used because of mutagenic properties. Hetol (= hexachloroparaxylene) was used to a limited extent in veterinary medicine against →*Fasciola hepatica* infections and for human →*Clonorchis sinensis* infections (→Energy-Metabolism-Disturbing Drugs/Table 2). However, it is characterized by serious side effects.

Hetolin

Clinical Relevance

Hetolin is a specific compound against →*Dicrocoelium dendriticum* (→Energy-Metabolism-Disturbing Drugs/ Table 1) with erratic efficacies.

Cyclosporin A

Clinical Relevance

The antiparasitic activity of cyclosporin A was discovered in 1981. The antiprotozoal activity is directed against →*Leishmania* spp., *Toxoplasma* and →*Plasmodium*. In addition, cyclosporin A has anticestodal and antischistosomal activity. The latter is directed against schistosomes. Here the compound has a long-lasting prophylactic effect up to 100 days before infection. After treatment the number of worms is reduced. Immature worms and female worms are more affected than male worms. The use of cyclosporin A would mean important qualitative progress in the control of schistosomiasis since there would be protection by a single dose over a good part of the transmission season. A correlation between the antiparasitic and the immunosuppressive effects of cyclosporin A seems unlikely, since cyclosporin analogs with antischistosomal activity show only minor immunosuppressive activity. Cyclosporin A has lethal effects *in vitro* against schistosomes. Cell-mediated immunity does not play a role in the antischistosomal action of cyclosporin A. Furthermore, the compound has antifilarial activity and is used in human medicine as an immunosuppressing drug.

Quinuronium sulfate (= Acaprine), Amicarbalide

Clinical Relevance

Babesiosis of cattle may be controlled easily by these two drugs. A single parenteral treatment results in the disappearance of clinical symptoms and premunity against, e.g., *Babesia divergens*. In general, however, improvement of parasitaemia is obtained only after several treatments with higher dosages.

Duffy Blood Group

→Natural Resistance.

Dum-Dum Fever

→Leishmania, →Visceral Leishmaniasis.

Duncker's Muscle Fluke

Mesocercariae of →*Alaria allata* in pig muscles.

Duplicidentata

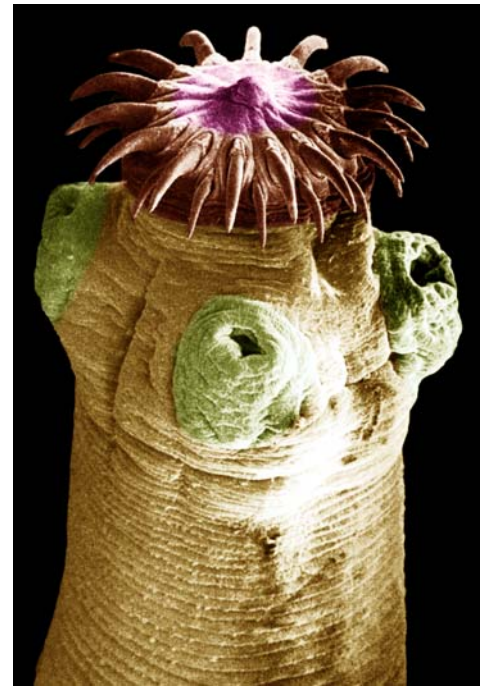
Order Lagomorpha (hares, rabbits) →Simplicidentata (rodents = rats, mice, hamster).

Dutton, John Everett (1874–1905)

English scientist, who discovered the tick-borne relapsing fever (due to transmission by →*Ornithodorus moubata*). His friend, the Canadian scientist J.L. Todd, honoured Dutton by naming the agent of this disease *Spirochaeta* (now *Borrelia*) *duttoni.* Dutton died at only 31 years of age from this disease on the February 5, 1905, while his colleague survived. The louse-borne relapsing fever was detected by →Obermeier.

Duttonella

Subgenus of →*Trypanosoma*.



Dwarf Tapeworm. Figure 1 SEM of the head of *Hymenolepis nana*.

Dwarf Tapeworm

Hymenolepis (syn. →*Rodentolepis*, →*Vampirolepis*, Fig. 1) *nana* (→Hymenolepidae, →Eucestoda), Fig. 1.

Dye Test (DT)

Serologic test, e.g., to diagnose acute toxoplasmosis during pregnancy, →serology.

Dyskinetoplastic Stage

The →kinetoplast of some trypanosomatids loses its DNA content in some developmental stages these stages may survive in mammals, but not in the vector.

EANMAT

East African Network for Monitoring Antimalarial Treatment.

Earcanker

Trivial name of the mite *Psoroptes cuniculi* entering the ear of goats and causing otitis. →Acariosis, Animals.

East Coast Fever (ECF)

→Theileria, →Theileriosis.

Eastern Equine Encephalitis (EEE)

→Arboviruses.

EBA

Synonym

Erythrocyte-binding Antigens. →Apicomplexa.

Ecdysis

Name

Greek: *ecdysis* = hatch.

During growth arthropods have to discharge several times their cuticle. →Ecdysteroids, used during →molt of →nematodes and arthropods.

Ecdysteroid Receptor

Synonym

→EcR.

General Information

Genomic ecdysteroid effects in insects and crustaceans are mediated via an intracellular ecdysteroid receptor (EcR). This receptor belongs to the superfamily of nuclear receptors and is related to all vertebrate steroid hormone receptors. In its functional form the EcR is usually a heterodimer of EcR and another transcription factor, belonging to the same superfamily, which is called ultraspiracle (USP) and which is a homologue to the vertebrate retinoid X receptor (RXR). EcR and USP are phosphoproteins and can occur in different splice variants. They possess a ligand (= →Hormone) binding domain (LBD), a DNA binding domain (DBD), and a transactivation domain as well as interfaces for dimerization, interaction with →heat shock proteins and comudulators, and for nuclear transport.

Highest ligand affinity has been shown for ponasterone A and muristerone A, followed by 20-hydroxyecdysone (→Ecdysteroids). Depending on the insect taxon high affinity for non-steroidal molting hormone agonists was shown. The EcR expression is under control of its own ligand.

→Nematodes are claimed to be closely related to arthropods according to molecular criteria and →ecdysteroids have been demonstrated in this →helminth group unequivocally (→Ecdysteroids). Therefore, one could assume the same →mode of action of ecdysteroids and thus the presence of ecdysteroid receptors also in nematodes, but so far all attempts to demonstrate ecdysteroid-binding proteins by ligand binding were unsuccessful. Using consensus sequences of the nuclear receptor superfamily for screening in →*Caenorhabditis elegans* libraries, cDNA clones were found with high sequence identity to steroid hormone receptors. Since orphan receptors and other transcription factors are also members of this superfamily, this is no proof for the existence of an ecdysteroid receptor in *C. elegans*. Expression of these cDNA clones and subsequent

binding studies must be performed before an unequivocal proof for the presence of an ecdysteroid receptor in *C. elegans* is valid.

Gene Regulation

The concept of gene expression by steroid hormones was originally derived from studies on puff induction in giant →chromosomes by ecdysteroids and subsequently improved. Functional ecdysteroid receptors are essential for gene regulation by ecdysteroids and induce a set of gene products. As early responses transcription factors are induced which are members of the nuclear receptor superfamily themselves.

Implications

Non-steroidal molting hormone agonists which bind to the functional ecdysteroid receptor are used for insect pest control by evoking precocious and incomplete molting. Successful applications of ecdysteroid agonists and antagonists to nematodes were not described so far. The ecdysteroid receptor in combination with RXR is used as an ecdysteroid-inducible expression system in mammalian cells.

Ecdysteroids

Synonym

→Molting hormones.

General Information

The name ecdysteroids refers to a class of steroid hormones whose main function the regulation of →ecdysis in arthropods. Ecdysteroid is a generic name for a total of more than 120 different polyhydroxylated steroids present either in plants (phytoecdysteroids), invertebrates (zooecdysteroids), or both. The ecdysteroids are present in all invertebrate phyla and thus represent the most widespread steroid hormones. The molecular weight is between 464 (e.g., ecdysone, ponasterone A) and 480 (20-hydroxyecdysone).

Structure

In contrast to vertebrates, the invertebrates studied so far are unable to synthesize sterols de novo and are therefore dependent on the presence of cholesterol or related sterols. Another difference is the presence of a full side chain as in cholesterol. Zooecdysteroids are therefore mainly C27 steroids, in contrast to the vertebrate steroid hormones (C18, C19, and C21) (Fig. 1). All ecdysteroids bear a *cis*-fused A/B ring junction which is again different from the situation in vertebrates (*trans*-fused A/B ring junction). A further difference to vertebrate steroid hormones is the good water solubility of ecdysteroids, caused by the high number of hydroxyl groups. Ecdysteroids can occur either in free form or as conjugates. The position of →conjugation as well as the main groups which are conjugated with ecdysteroids are shown in Fig. 1.

Like in vertebrate steroid hormone research, non-steroidal molting hormone agonists (bisacylhydrazines) are useful tools for the study of hormonal action and for interference with molting processes. Recently molting hormone antagonists (cucurbitacins; triterpenoids of plant origin) have also been described.

Physiological Function

In contrast to insects and crustaceans, much less information is available on the physiological roles of ecdysteroids in other phyla. Among parasites there are some data on presence, titer, and putative functions available for →cestodesand →trematodes but most information has accumulated for →nematodes. Analogous to arthropods, there are mainly 2 processes, which are probably regulated by ecdysteroids in nematodes, i.e., development and reproduction. At least in some nematodes there is a clear correlation between titer of ecdysteroids and the molting cycle and there is also an effect of ecdysone on reinitiation of meiosis, on differentiation during early →embryogenesis, cell rearrangement during gastrulation, and on →fecundity.

Implications

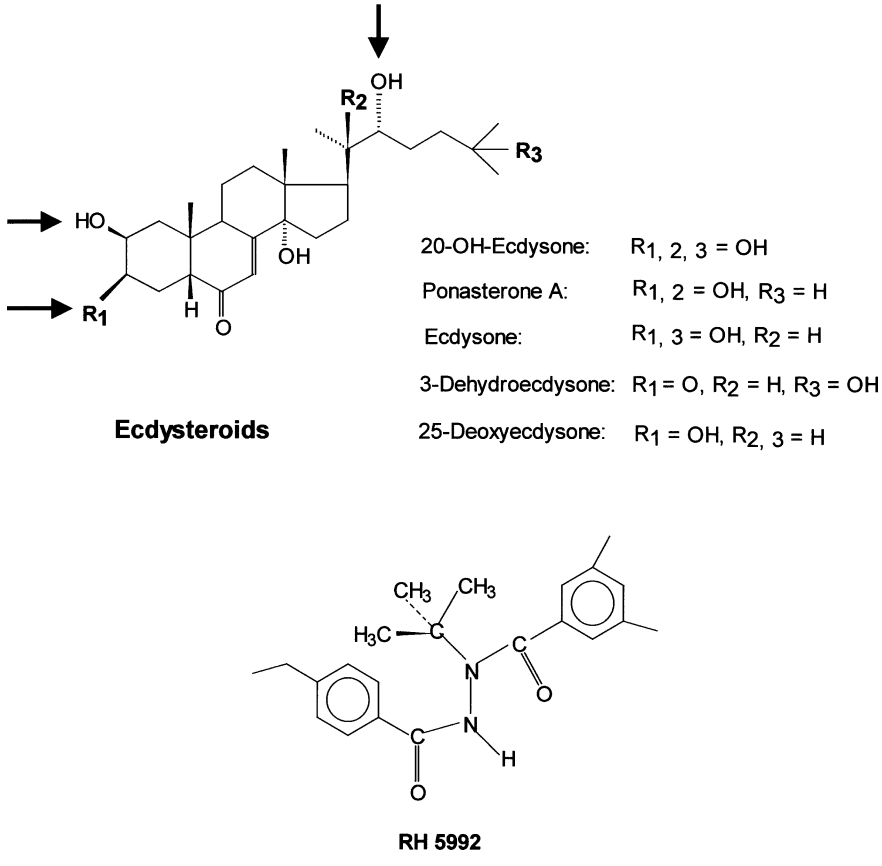
Non-steroidal moulting hormone agonists induce precocious and incomplete molt and are used for insect pest control. High concentrations of ecdysteroids are deleterious to insects (hyperecdysonism) and also kill nematodes both *in vivo* and *in vitro*. Certain amines and amides inhibit phytosterol dealkylation in insects and free-living nematodes and steps in the ecdysteroid biosynthetic pathway in insects and are powerful schistosomicidal agents.

Echenebothrium dubium

Tetraphyllid tapeworm in Chondroichthyes (rays).

Echidnophaga gallinacea

The name of this 2.5 mm-sized so-called crest-flea of birds comes from the old name of the ant-hedgehock (*Echidna hystrix*), at which the first specimen of this flea was detected. *Echidna* is a *Greek* mysterial monster



Ecdysteroids. Figure 1 Ecdysteroids. (**A**) Structure of ecdysteroids (20-OH-ecdysone, ponasterone A) and primary synthesis products. Arrows indicate preferential sites of conjugation with phosphate, fatty acids, acetate, glucosides, glucuronides and sulfates. (**B**) Representative of the group of nonsteroidal molting hormone agonists.

and Greek: *phagein* = feeding. Besides birds, *E. gallinacea* parasitizes worldwide at many host species including man. Since the females attach for a long time for feeding at the skin of their host, they were often erroneously kept for sand fleas (→*Tunga penetrans*). The smaller males mate with the skin-fixed females for 15 minutes. The mouthparts of females are used as anchor and -form a deep hollow, from which the English common name "tight-stick-flea" derives.

Soon after the artistically copulation (the male hangs back down in the air; Fig. 7 in (→Fleas) the female starts to lay eggs (about 11–14 per day), which fall onto the soil for further development. Besides *E. gallinacea* 20 other species are described (e.g., *E. larina*, *E. aethiops* also occurring in Africa). →Fleas.

Echinochasmus

Genus of →Trematodes.

Echinochasmus perfoliatus

Species of the trematode order Echinostomatida.

Echinocirrus melis

1 cm long echinostomatid flukes in the intestinal system of hedgehocks.

Echinococciasis

→Echinococcus; syn. →Echinococcosis.

Echinococcosis

Pathology

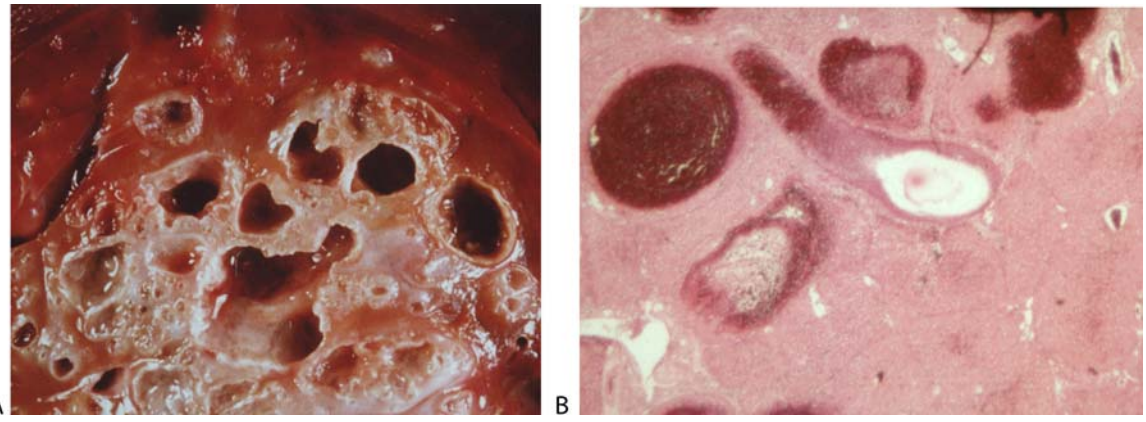
→*Echinococcous granulosus* is the causative agent of cystic →hydatid disease or cystic echinoccocosis whereas infection with *E. multilocularis* in man leads to the more aggressive form of alveolar echinococcosis (Figs. 1, 2). In both cases, the primary site of contact with the parasite is the mucosal surface of the host's gastrointestinal tract. Echinococcosis is contracted by the inadvertent ingestion of eggs from the feces of dogs or other carnivores. Thus humans serve as intermediate hosts instead of normally, sheep, mice, or other herbivores. Larval cysts or →hydatids can be found in many tissues, most often in the liver, lung, mediastinum, and peritoneum, giving rise only to pericystic fibrosis when intact. Hydatid cysts attain a large size because of asexual reproduction and proliferation of the innermost cyst layer, the germinal epithelium. In *E. granulosus* small protoscolices develop in the hydatid cysts with suckers, hooklets, and calcareous bodies. Detached →brood capsules and sometimes daughter cysts develop, again with internal multiplication; the gross appearance may be one of a bunch of grapes of various sizes. In *E. multilocularis*, the external laminated membrane of the cyst is incomplete and the inner germinal epithelium proliferates diffusely in an alveolar pattern, spreading like a neoplasm through the human liver, which is destroyed (→Pathology/Fig. 16, 29E,F). Folded laminated membranes are usually present. Protoscolices are rarely found in humans, although they are common in natural hosts. The cysts of *E. vogeli* usually contain primitive scolices. Production of lesions by all species depends on the location, number, and state of the cysts. Slow seepage of cyst fluid may lead to seeding of new areas, and cystic metastases to brain and lung can occur. Sudden hydatid cyst rupture can produce →anaphylactic shock. →Eosinophiliaaccompanies the infection. Molecular immunopathology is reviewed in detail by Gottstein and Hemphill.

Immune Responses

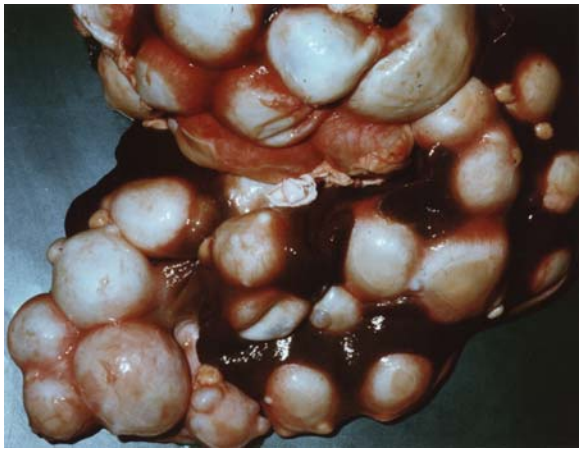
The cellular and humoral →immune response in humans in response to migrating oncospheres and established metacestodes varies enormously as evidenced, for example, by different antigens recognized by individual patients with different courses of disease. Hydatide growth despite the presence of humoral and cellular anti-metacestode immune responses may result from the variation or downregulation of the parasite's antigens or from active immunomodulation by these →cestodes.

B Cells and Antibodies

Most serological studies in humans were performed to monitor patients after long-term chemotherapy or postoperatively. In cystic echinococcosis strain variations of the parasite as well as genetic differences between host populations may significantly affect the antibody response. For example, conventional serological tests were often negative in patients from Kenya or in patients with lung localizations of the cysts. However, rapid seroconversion was observed in most of these patients early after treatment arguing in favor of immunosuppressive mechanisms which are reverted after surgical removal of the cyst. Much emphasis was given to the determination of parasite-specific antibody isotypes. However, only in the case of IgE has a significant (negative) correlation with the response to chemotherapy been reported. IgE bound to basophils may be involved in anaphylactic reactions upon preoperative or intraoperative cyst rupture.



Echinococcosis. Figure 1 Section through a human liver with the alveoles of *E. multilocularis*. **A** Total view, **B** Section through small strands of *E. multilocularis* in the liver.



Echinococcosis. Figure 2 Liver of a sheep with numerous hydatids of *E. granulosus*.

In most patients with alveolar echinococcosis parasite-specific immunoglobulins of all isotypes can be measured at diagnosis and an association with hyperglobulinemia has been reported. Although protoscoleces and oncospheres of E. multilocularis can be lysed by antibody-mediated complement interaction *in vitro*, antibodies appear unable to control parasite proliferation *in vivo*. This inability may be due in part to complement-neutralizing factors released by the →metacestode or to the inactivation of C3 as it enters the metacestode tissue. Antibodies are produced against many different proteins of the parasite, and some of these antigens were postulated to critically participate at the host–parasite interplay. For example, antibodies against the protein Em2, localized in the laminated layer of the metacestode, were found to be associated with disease susceptibility in experimental murine alveolar echinococcosis. While in resistant C57BL/10 mice anti-Em2 antibodies of the IgG3 and IgG1 isotype were synthesized, only low levels of anti-Em2 IgG2a were detected in susceptible AKR and C57BL/6 mice.

T Cells

In cystic echinococcosis patients there was no correlation between the detection of specific antibodies and the lymphoproliferative response to *E. granulosus* antigens. The fact that seronegative patients showed a positive proliferation assay and vice versa was taken as an argument for the existence of different pathways initiating humoral or cell-mediated responses. In murine cystic echinococcosis a marked reduction of the mean T cell percentage combined with an increase in suppressor activity was reported. An impairment of the →host response by the formation of anti-MHC antibodies or by parasite-derived immune-suppressive or -modulatory substances may account for the enhanced susceptibility to mycobacterial infections close to the parasite lesions. In long-term infected BALB/c mice a higher percentage of $CD4^+$ T cells in peripheral blood and a relative increase of $CD8^+$ T cells in the spleen was observed. These cells appeared to be activated, because they showed a high level of interleukin-2 receptor expression. The finding that PBMCs from patients responding well to chemotherapy produced significantly more IFN-γ and less IL-4 and IL-10 than cells from partial and low responders, indicated an implementation of Th1 cells in protective immunity.

In patients with alveolar echinococcosis the lymphoproliferative response to *E. multilocularis* antigens was highest in cured patients who had undergone radical surgery and significantly lower in patients with partial or no resections. A protective role of T cells has been found in murine models of alveolar echinococcosis. Depletion of T cells or the infection of nude or SCID mice resulted in enhanced metastatic formation and development of *E. multilocularis* accompanied by a drastically reduced host-tissue reaction. *E. multilocularis* infection of permissive mouse strains resulted in the depletion of T-dependent zones of lymphoid organs and thymic involution during rapid growth of the metacestode. Although the responsible mechanism has not yet been defined, activated macrophages adhering to the metacestodes *in vivo* and/or immunomodulatory products of the parasite may account for it. Immunosuppression in murine alveolar echinococcosis appears to be a more general phenomena since there was an enhanced frequency of malignant sarcomas in A/J mice infected with *E. multilocularis* when compared to noninfected controls.

Analysis of cytokine mRNA expression revealed the enhanced production of Th2-type factors such as IL-3, IL-4, IL-10, and predominantly IL-5 in stimulated cells of patients with alveolar echinococcosis. In murine alveolar echinoccocisis there was an enhanced production of IFN-γ, IL-2, IL-5, and IL-10 by stimulated spleen cells *in vitro* over the first weeks of infection which was almost completely suppressed at 21 weeks of infection. Analysis of the local intrahepatic periparasitic cytokine expression in tissues of patients showed an enhanced expression of IL-1, IL-6, and TNF by activated macrophages. These findings together with the observation that treatment of SCID mice with TNF promoted the formation of granulomatous changes around larval cysts argue for an involvement of the locally secreted proinflammatory cytokines in the development of periparasitic granulomas and fibrogenesis. In resistant hosts activated macrophages appear to kill protoscoleces by arginine-dependent generation of reactive nitrogen intermediates and other, ill-defined destructive effects on the parasite-protective laminated layer surrounding the oncospheres and vesicular cysts.

The genetic basis for either host resistance (no immunosuppresssion?) or susceptibility (→Immune Suppression?) is still unclear. Preliminary investigations showed that the frequency of certain HLA allelels (HLA-DR13) was increased in patients with a regressive course of disease after therapy compared to controls or patients with progressive alveolar echinococcosis. However, since inbred mice of the same H-2 haplotype differ significantly in their susceptibility to *E. multilocularis* there are obviously other, non-MHC-linked genes contributing to the disease susceptibility.

Main clinical symptoms in humans: Liver dysfunction, lung problems, ascites, →abdominal pain.
Incubation period: Years.
Prepatent period: Years.
Patent period: Years.
Diagnosis: Serologic tests, computer tomographic analysis of liver and other organs, →Serology.
Prophylaxis: Avoid contact with infected final hosts (dog, fox, cat).
Therapy: In *E. granulosus* infections hydatids may be removed by surgery, while it is **not** recommended in alveolar cysts of *E. multilocularis* since the eventual setting free of undifferentiated cells initiates metastasis-like formation of new cysts (thus biopsies are strongly forbidden). Chemotherapy see →Cestodocidal Drugs, →Nematocidal Drugs, Animals and →Nematocidal Drugs, Man (Albendazole, Mebendazole).

Echinococcus

Name
Greek: *echinos* = spine, *kokkos* = grain.

Synonym
→*Alveococcus*, *E. cysticus, E. unilocularis, E. hydatidosus*.

Classification
Genus of →Eucestoda →Platyhelminthes/Fig. 19A.

Important Species
Table 1, Figs. 1, 2, 7, 8 (pages 411, 412, 416).

Life Cycle
Fig. 1.

Distribution
Fig. 2.

Reproduction
Figs. 3–6 (pages 412–415).

Diseases
→Echinococcosis, →Echinococciasis, →Hydatidosis, →Alveococcosis.

Echinococcus oligarthrus

New species from the *E. multilocularis* complex, which may also infect humans. Intermediate hosts are rodents, final hosts are felids in Central and South America.

Echinococcus ortleppi

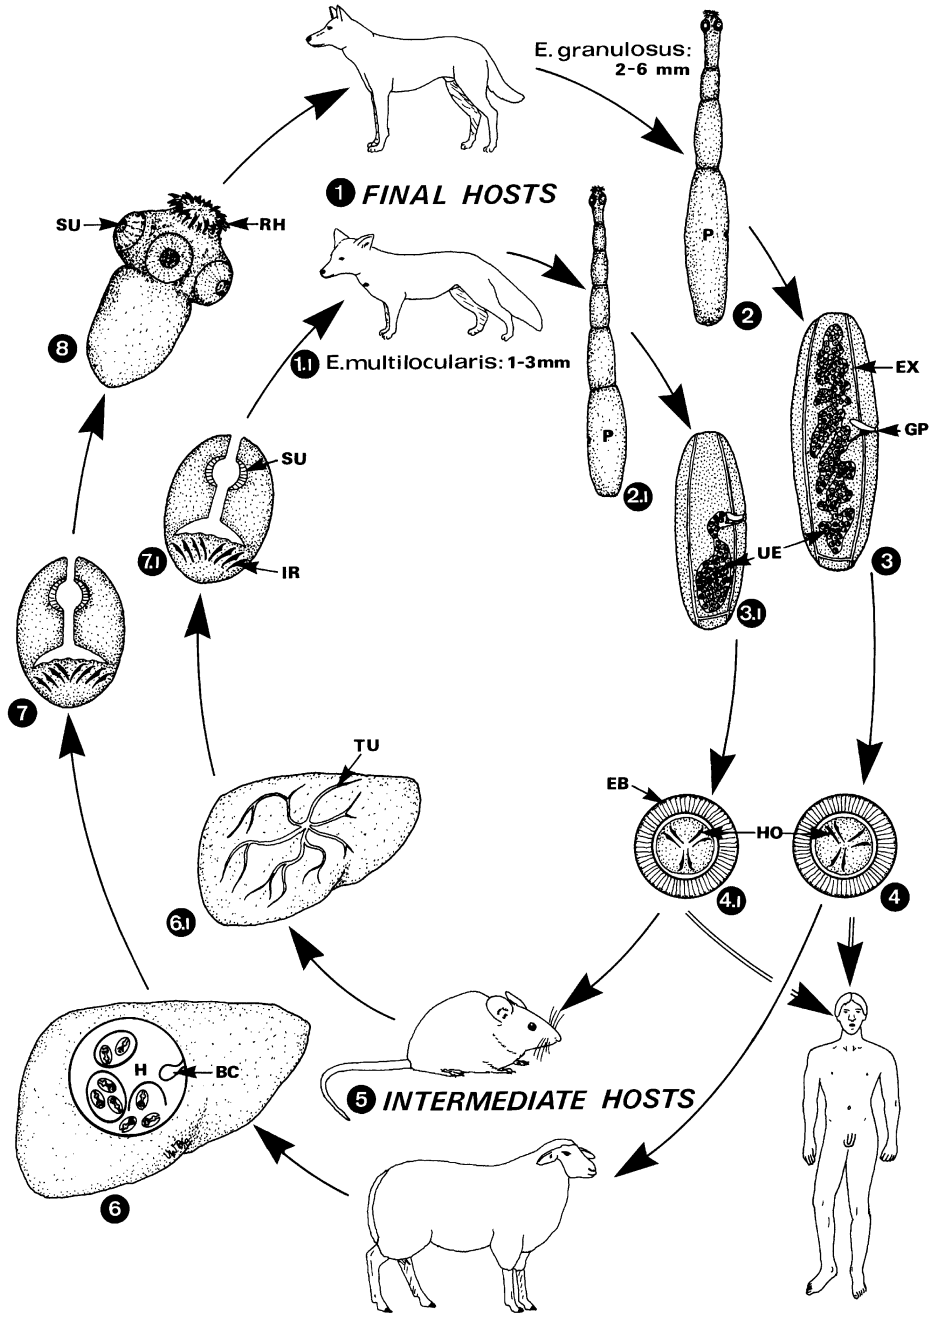
Cattle strain (G 5) of *E. granulosus*, being infective to humans, occurs in Europe, South Africa, India, Sri Lanka, Russia, South America. Final host is dog.

Echinococcus vogeli

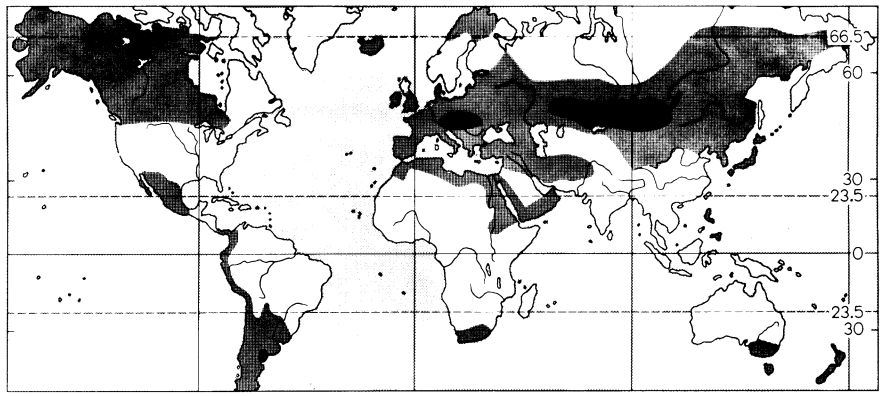
New species from the *E. multilocularis* complex, occurs in Central and South America. Rodents are intermediate hosts; humans may be infected. Final hosts are bush dogs.

Echinococcus. Table 1 Most important species of the genus *Echinococcus*

Order/Species	Length of adult worm (m)	Egg size (µm)	Final host	Prepatent period	Intermediate host (i.h.)/Habitat	Stage inside intermediate host (i.h.)
Echinococcus granulosus	2.5–6 mm	35	Dogs, foxes	6–9	Ruminants, **Humans**/Liver, etc.	Hydatid; *Echinococcus hydatidosus (= cysticus)*
E. multilocularis	1.4–3.4 mm	35	Foxes, cats, dogs	4–6	Mice, **Humans**/ Liver, etc.	Multilocular cyst: *Echinococcus alveolaris*



Echinococcus. Figure 1 Life cycles of *Echinococcus granulosus* (1–8) and *E. multilocularis* (1.1–7.1). *1, 1.1* Final hosts may be dog, cat, or fox with clear, species-specific preference. *2–3.1* Adult worms, which live in the small intestine of the final host, may be differentiated according to the size of the terminal →proglottids (P), shape of uterus (UE) and size of rostellar hooks. *4, 4.1* Eggs containing an infectious →oncosphaera larva are released from the detached drying proglottid in the feces of the host; eggs are indistinguishable from those of →*Taenia* spp. *5, 5.1* Eggs are orally ingested by intermediate hosts or man with contaminated food. *6, 6.1* Inside the intestine of the intermediate hosts (including man) the oncosphaera hatches, enters the wall and may migrate (via blood) to many organs. Cysts are formed mostly in the liver and lung; in *E. granulosus* large unilocular →hydatids occur, which are filled with fluid (containing thousands of protoscolices), whereas in *E. multilocularis* a tubular system infiltrates the whole organ (giving rise to alveolar aspects in sections). *7–8.1* In →brood capsules of both cyst types, →protoscolices are formed, which may become evaginated (8) even inside their cysts. Evaginated or not, protoscolices are fully capable of infecting final hosts when they feed on infected organs of intermediate hosts. *BC*, →brood capsule; *EB*, →embryophore of the egg; *EX*, excretory vessels; *GP*, genital pore; *H*, hydatid; *HO*, hooks of oncosphaera; *IR*, invaginated rostellar hooks; *P*, →proglottid; *RH*, rostellar hooks; *SU*, sucker; *TU*, tubular system; *UE*, uterus containing eggs.



Echinococcus. Figure 2 Distribution map of *Echinococcus granulosus* (grey) and *E. multilocularis* (black), which is now found in Hokkaido (Japan), Alaska, and also in the whole of Germany. *E. oligarthrus* and *E. vogeli* are found in Middle and South America in forest dogs, respectively, wild cats as final hosts, and a series of sylvatic animals.

Echinococcus. At some distance from the tip, hollows (CA) occur inside the strand which becomes lined outside by eosinophilic granulocytes (EO) from the host defense system. Arrows indicate direction of growth. **B, C** The hollows (CA) in the strand become larger at the periphery undifferentiated cells (UT) initiate formation of brood capsules. *AS*, amorphous substance = laminated layer; *CA*, cavity; *CN*, connective tissue; *CO*, →collagen; *DC*, developing cavity; *DG*, degenerating defense cells; *DI*, division of undifferentiated cells; *EG*, eosinophilic granules; *EO*, eosinophilic granulocytes; *GR*, granules; *IF*, infiltration zone of hosts' defense system; *IT*, intact tissue; *M*, membranes of fusing UT; *MI*, mitochondrion; *MT*, microtriches of the tegument; *N*, nucleus; *NH*, nucleus of the host cell; *NU*, nucleolus; *PT*, protrusion of tegumental surface; *TG*, tegument; *U*, undifferentiated cells; *UT*, undifferentiated cells when fused with the tegument; *V*, vacuole.

Echinoparyphium recurvatum

→Digenea.

Echinorhynchus truttae

→Acanthocephala.

Echinostoma ilocanum

Name

Greek: *echinos* = spine, *stoma* = mouth.

Morphology

Fig. 1 (page 416); →Digenea.

Disease

→Echinostomiasis, Man.

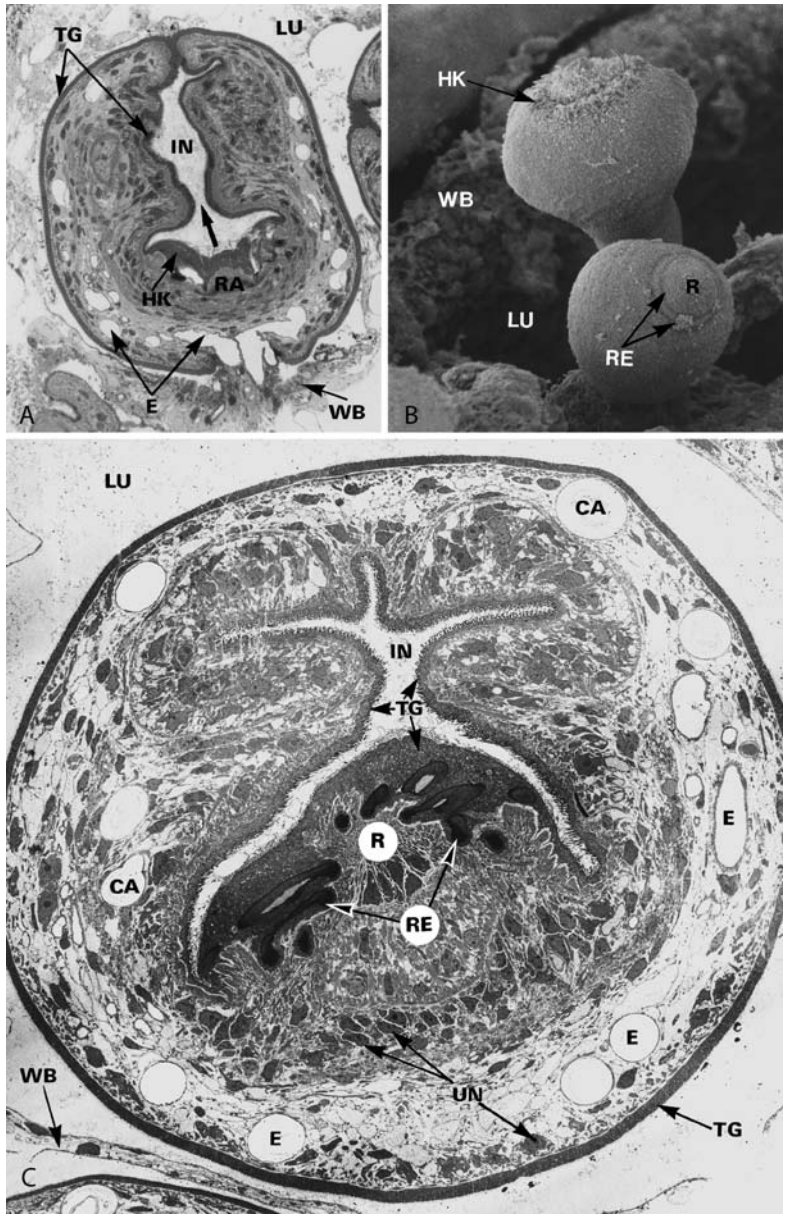
Echinostoma revolutum

→*Parorchis acanthus*/Fig. 1.

Echinostomiasis, Man

Disease due to infections of →*Echinostoma* species via oral uptake of infected, uncooked snails and clams.

Main clinical symptoms: →Diarrhoea, →abdominal pain, →anaemia, →eosinophilia.
Incubation period: 1–3 weeks.
Prepatent period: 2–3 weeks.
Patent period: 6–12 months.
Diagnosis: Microscopic determination of eggs in faecal samples.
Prophylaxis: Avoid eating raw snails and clams.
Therapy: Treatment see Trematodocical Drugs.



Echinococcus. Figure 6 A–C *Echinococcus* protoscolices within brood capsules of →tissue-cyst (hydatid, tubular system). **A** Light micrograph of a semithin longitudinal section through an inverted protoscolex of *E. granulosus*. During growth, which may start to occur inside the brood capsule, the rostellar anlage (RA) protrudes (arrow). × 1,000. **B** Scanning electron micrograph of already protruded protoscolices of *E. multilocularis* found inside a brood capsule. × 500. **C** Transmission electron micrograph of an obliquely sectioned inverted protoscolex of *E. granulosus*. Note the typical tegument lining the surface and the invagination through which the →rostellum finally protrudes. ×3,000. *CA*, →calcareous corpuscles; *E*, excretory channel; *HK*, hooks of →scolex; *IN*, invagination; *LU*, lumen of brood capsules; *R*, rostellum; *RA*, rostellar anlage; *RE*, retracted hooks; *TG*, tegument; *UN*, undifferentiated cells; *WB*, wall of brood capsule.

Echinuria uncinata

Stomach worms of ducks and geese (male = 10 mm, female = 19 mm).

Eclosion

Shedding of pupal exuviae in insects (e.g., in *Nasonia* spp. among Ichneumonoidea).

Echinococcus. Figure 7 SEM of adults of *Echinococcus* species, left: *E. granulosus*, right: *E. multilocularis*.

Echinostoma ilocanum. Figure 1 LM of the anterior end of a carmin-red coloured echinostomal worm showing the characteristic apical spines.

Ecoparasitological Aspects

Such factors have been taken into account when explaining fluctuations of population densities in the field. For example, some trematode developmental stages limit the number of their hosts in a given ecosystem.

Ecosystems and Parasitism

The role of parasites can be extremely important in the equilibrium of ecosystems because a change in the impact of parasites, due, for instance, to an alteration of climatic or other conditions, may have unexpected and profound consequences.

Although the relationship between parasites and ecosystems is still little documented, the following examples illustrate the mechanisms by which apparently little parasitological causes can have dramatic effects.

Lindström et al. have shown that an epizooty of →sarcoptic mange, which decimated the populations of red foxes in Scandinavia, has favoured the demographic growth of several small mammals which were the prey of the foxes; some of these mammals rapidly tended to pullulate, destroying certain plants, and finally modifying the landscape.

Holmes has drawn attention to the importance of ecosystem shrinking, due for instance to agriculture, deforestation, construction of highways, etc. In the new landscapes created by such fragmentation, there is an intrication of different faunas which lead some parasites to attack unusual host species, which have often limited innate defenses against them. Holmes mention the case of a Californian bird parasite, the brown-headed cowbird, *Molothrus ater*, which, in shrinking ecoystems, tend to lay its eggs in the nests of passerine it had never parasitized before. These new bird hosts are incapable of rejecting the eggs of the parasite, whereas the "usual hosts" identify and reject "alien" eggs to a certain extent. Some passerine species seem to have been threatened so much with extinction that scientific meetings have been organized to try to stop the process.

Parasites intervene also in the structure of biodiversity (composition of faunas) by interfering with competition processes (→Host Demography) and significantly alter the structure and functioning of ecosystems, as recently demonstrated by Lafferty, Dobson, and Kuris.

EcR

Synonym

→Ecdysteroid Receptor.

Ectoinsecticides

Drugs acting against ectoparasites such as →ticks, →fleas (→Insecticides, →Ectoparasiticides, →Arthropodicidal Drugs, →Ectoparasites: New Approaches).

Ectoparasite

Organism living parasitically (e.g., sucking blood) on the outside of another organism.

Ectoparasites: New Approaches

Biological Control

The control of parasitic flies by →biological methods has become a viable method in some specific cases.

The release of large numbers of genetically manipulated (either by irradiation of genetic transformation) sterile or "less fit" flies into the environment has led to the elimination of the screwworm fly (*Chrysomya*) in the USA. This control method has also been applied to blowflies (*Lucilia cuprina*) and is part of a long-term strategy to control sheep blowfly. In Australia the use of natural pesticides as another "environmentally friendly" biological pesticide is an area where innovative applications are expected to investigate these opportunities for future products. First biopesticides such as →*Bacillus thuringiensis* and *Metarhizium anisopliae*-based products reached the crop protection market in the late 1980s. But both approaches are still in their infancy in the animal health sector, since due to their high specificity they were suitable for combating only few fly species and never reached broad regional application.

Vaccination

The growing problems of resistance and persistence of residues in meat and milk have created a renewed interest in antiparasitic vaccines.

It has been known for a long time that certain arthropods stimulate an immune response in infested animals. Apart from 2 x-irradiated worm vaccines there were no significant parasite immunologicals available until the late 1980s. The discovery and improvement of recombinant DNA technology has created hope that the capability of expressing specific, protective antigens not only against endoparasites, but also parasitic arthropods will lead to new innovative vaccines.

This field is potentially very interesting, but both the life cycle of the arthropods targeted and the limited range of cross-reactivity between related strains as well as the technology involved is highly complex.

Table 1 shows where certain activities have been focused, but considering market success as final proof, none of these vaccines achieved a significant share either in treatment numbers or in sales, when compared even to "weak" chemicals.

One fundamental problem with vaccine research is the identification of the protective antigens. For complex organisms, such as arthropods, this makes the isolation of useful antigens very difficult, but in the future due to improvements in DNA technology, this technique may start to have a significant impact on treatment against arthropods.

Ectoparasiticides – Agonists and Antagonists of Cholinergic Transmission

Mode of Action

Fig. 1.

Ectoparasites: New Approaches. Table 1 Vaccine approaches against ectoparasites

Target parasite	Approach/Status
Warble fly/Cattle grub (*Hypoderma bovis, Hypoderma lineatum*)	The most advanced immunization trials against myiasis have been performed against *Hypoderma*. Some protection against later infections was observed in the field. More detailed investigation revealed, that particularly first-instar larvae were sensitive. Studies on the protein composition of *H. lineatum* larvae which might induce protection showed that so-called hypodermins were potentially useful antigens. Hypodermins (type A,B,C) are serine proteinases which are of importance for larval tissue migration. Vaccination with hypodermin antigens resulted in up to 90% protection (hypodermin A) and some degree of cross-protection between *H. lineatum* and *H. bovis*. So far, as with almost all insect ectoparasite vaccination approaches no field vaccine is currently available.
One-host ticks (*Boophilus microplus*)	Tickgard is a vaccine based on a recombinant hidden antigen, membrane-bound glycoprotein Bm86. The vaccine has achieved some success in Australia against *B. microplus*, particularly in dairy herds. Vaccination results in some mortality in engorging ticks and to significant tick mortality between full engorgement and egg laying. The discovery of these specific tick antigens has opened the possibility of identifying similar proteins in other *B. microplus* strains and probably in other tick species as well. Other interesting antigens (Bm91, Qu13) have been identified, but so far none appear to be as effective as Bm86. Since the current vaccine is particularly effective in reducing the reproductive capacity in engorging female ticks, the continual introduction of ticks or tick-infested animals into a vaccinated herd significantly interferes with a successful strategic vaccination. Highest performance of the vaccination was observed when vaccinated animals were isolated from continual reinfection.
Blowfly strike (*Lucilia cuprina*)	For the time being it is believed that binding of antibodies to the respective antigens leads to a layer covering the peritrophic membrane (PM) which results in restricted permeability of *L. cuprina* larvae fed on vaccinated sheep. Peritrophins of different molecular weight have been identified, which led to starvation through the binding of antibodies to these PM-associated antigens. Despite substantial progress in comparison to the past a useful vaccine is not available so far.
Fleas (*Ctenocephalides felis*)	Hyperimmunized rabbit antisera against concealed antigens of flea midgut, the major digestive organ, revealed when fed in an artificial feeding system, significant decrease of survival rate and egg production of *C. felis* fleas. These preliminary studies demonstrated the feasibility of vaccination against cat fleas. Similar results were obtained following the vaccination of dogs with subsequent challenge. In these preliminary studies statistically significant reduction of about 25% regarding flea numbers remaining on the animal in comparison to control animals was observed. Despite the fact that at least partially protective antigens have been identified, so far no recombinant vaccine displaying substantial field success is available.
Salmon louse (*Lepeophtheirus salmonis*)	Vaccination might be a valuable method to control copepod infestation which are major parasites of farmed salmonids. Antibodies were raised against various *L. salmonis* antigens. When assessed with immunohistochemical methods gut and ovarial hidden antigens were recognized by respective Mabs*. Then MAbs were used to screen *L. salmonis* DNA libraries in order to identify DNA fragment coding, for proteins which might be useful as a basis for recombinant vaccines.

* Monoclonal antibodies

Structures

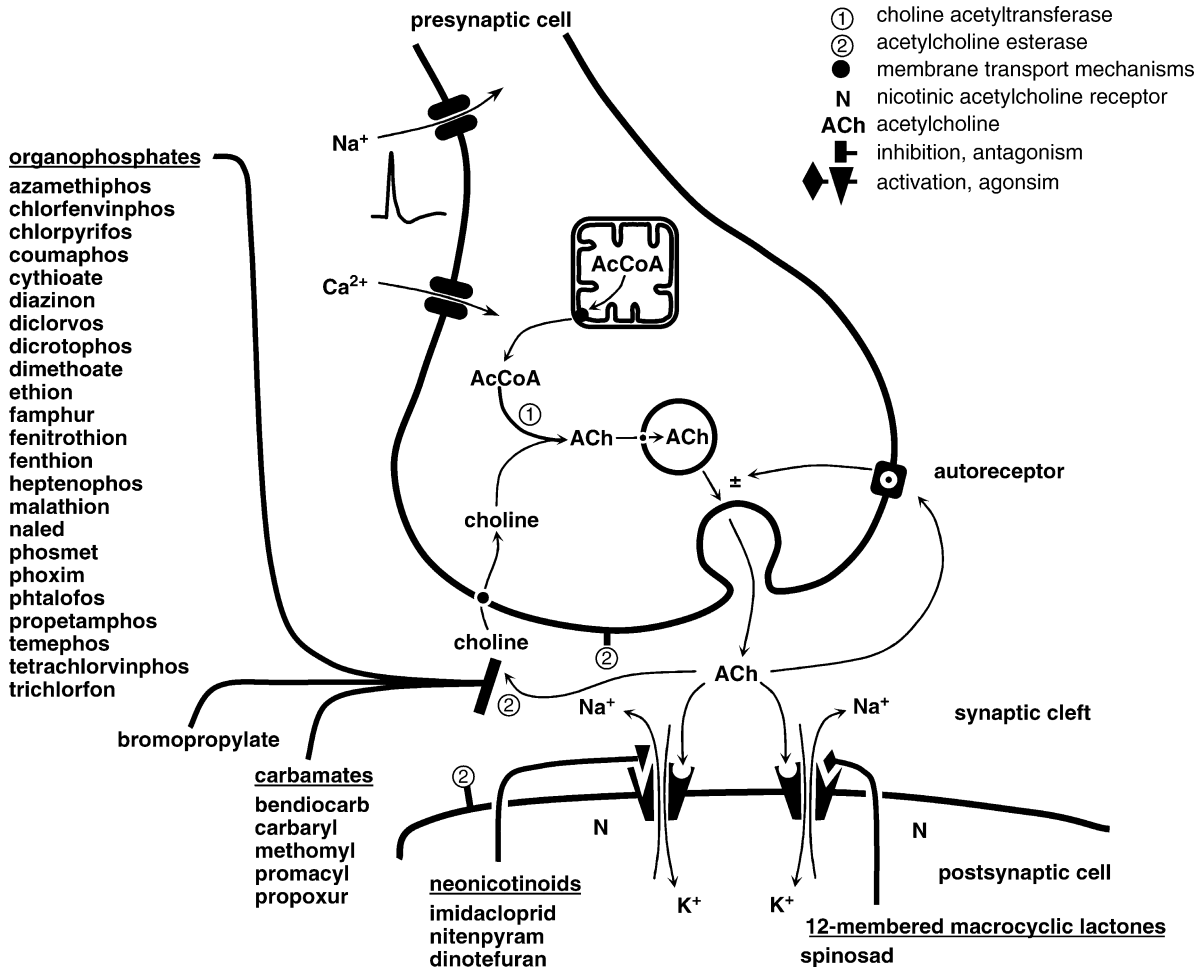
Organohalogenides (Fig. 2).

Important Compounds

Bromopropylate.

General Information

Bromopropylate (phenisobromolate) [isopropyl 4,4′-dibromobenzilate] acts similar to organophosphorous or carbamate compounds and is a weak inhibitor of the insect acetylcholine esterase. Additionally, the compound has a measurable effect on voltage sensitive



Ectoparasiticides – Agonists and Antagonists of Cholinergic Transmission. Figure 1 Model of the action of drugs interfering with acetylcholine mediated neurotransmission.

sodium channels of insect neurones. Despite its structural similarity with DDT or methoxychlor this effect is not comparable to that of DDT.

Bromopropylate is a non-systemic acaricide with contact action and long residual activity. The compound is used against ectoparasites for diagnosis and control of mite infestations in bees. LD_{50} acute oral toxicity for rats is >5,000 mg/kg (acute percutaneous LD_{50} > 4,000 mg/kg). The compound is toxic to fish. In mammals bromopropylate is rapidly and efficiently eliminated. Metabolism occurs mainly by cleavage of the isopropyl ester and to a minor extent by oxidation. Metabolites of the oxidation products are 3-hydroxybenzilate and conjugates.

Resistance

Resistance of ectoparasites against Bromopropylate is based on sequestration by enhanced hydrolytic activities (carboxylesterases) as well as on oxidation by mono-oxygenases. Bromopropylate-resistant varroa →mites have not yet been reported.

Organophosphorous compounds

Important Compounds

Organophosphates, Organophosphonates, Monothiophosphates, Dithiophosphates.

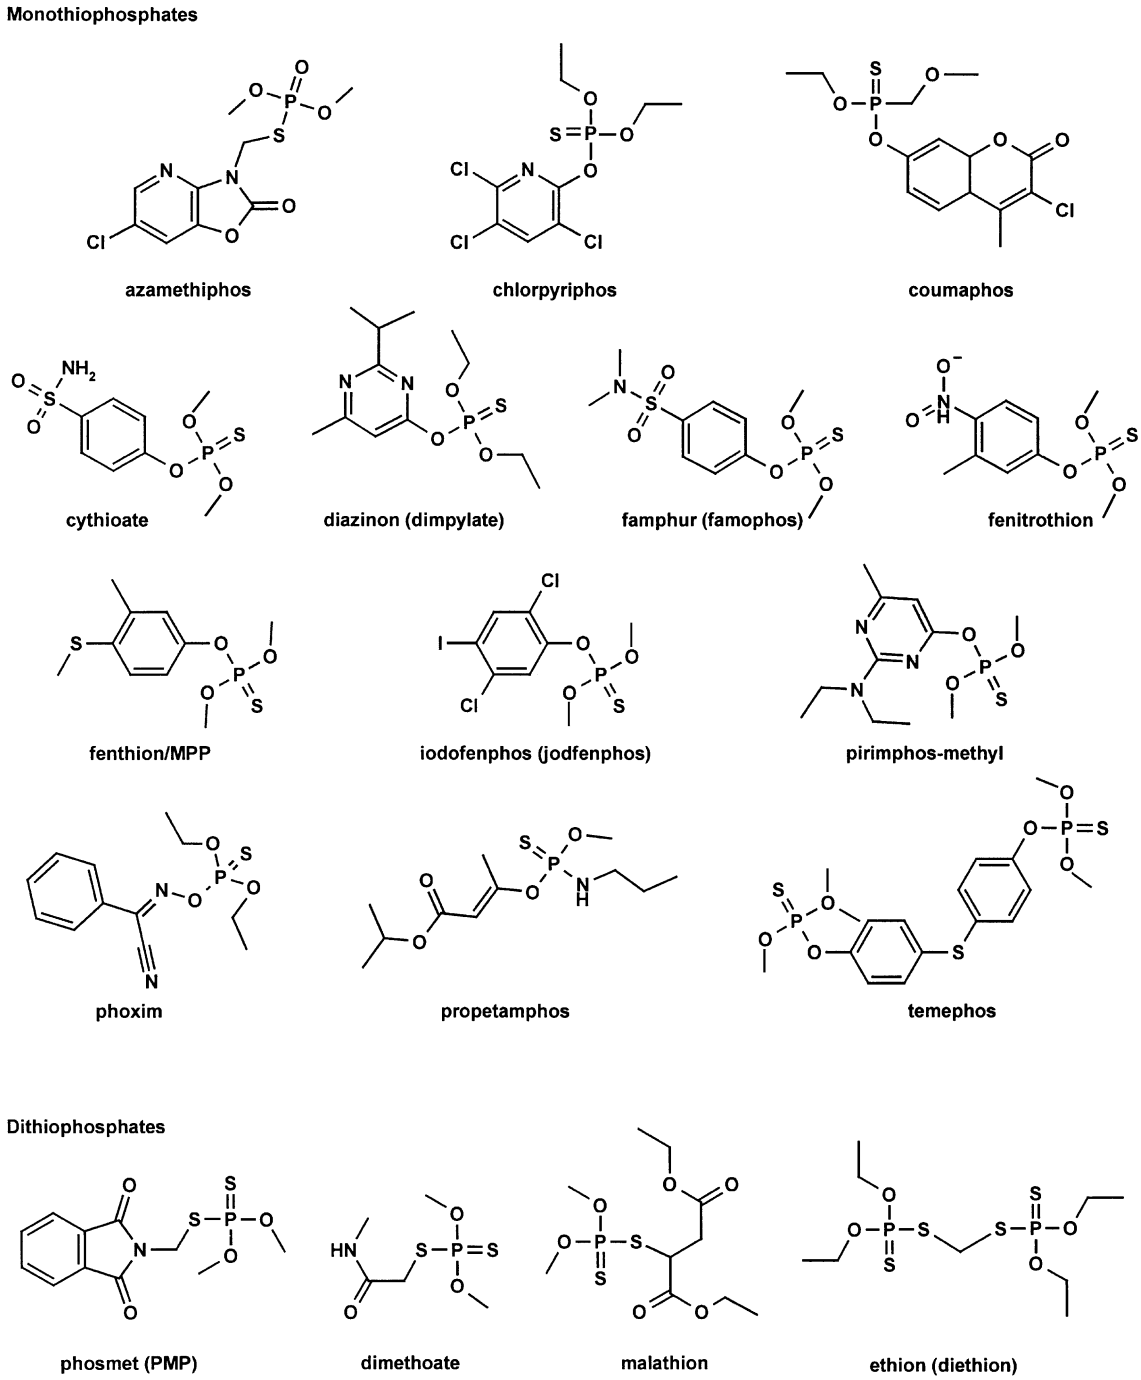
General Information

Insecticidal organophosphorous compounds were synthesised for the first time by G. Schrader nearly 60 years ago. Organophosphates are inhibitors of hydrolases, e.g., carboxyl esterases (ali-esterase), acetylcholine esterases. Several different isoforms of acetylcholine esterases have been identified in the insect central nervous systems which are differentially inhibited by organophosphates. The reaction mechanism of organophosphates with acetylcholine esterase resembles that of the endogenous substrate acetylcholine. The hydroxyl group of a specific

serin residue of the acetylcholine esterase is acetylated by acetylcholine, phosphorylated by organophosphates and carbamylated by carbamates. This indicates a competitive →mode of action. Since the inhibition constant of organophosphate compounds is small the compounds occupy the active site thus reducing hydrolysis of acetylcholine in the synaptic cleft. Neuronal transmission is influenced by stimulation of cholinergic →synapses followed by depression and paralysis.

Resistance

Tolerance or resistance occurs against all of the organophosphates currently on the market. However, resistance is still restricted to limited areas and specific



Ectoparasiticides – Agonists and Antagonists of Cholinergic Transmission. Figure 2 Structures of drugs affecting cholinergic neurotransmission.

Ectoparasiticides – Agonists and Antagonists of Cholinergic Transmission. Figure 3 Enzymes involved in detoxification of malathion.

ectoparasites. Reported resistance factors for ectoparasites like cattle tick or cat flea are in the range of 1.5-fold (which in fact should be called biological variability or at the most tolerance) to >100-fold. Organophosphate-resistant tick strains of the southern cattle tick *Boophilus microplus* have been identified in Australia, South Africa, Argentina, Brazil, Colombia, Ecuador, Costa Rica and Uruguay. Laboratory tests demonstrated different degrees of resistance from tolerance (1– to 4-fold reduced susceptibility) via slightly resistant (5– to 20-fold) to resistant strains (>20-fold). Field testing revealed that organophosphate resistance was widespread among Australian strains of *B. microplus*. Several organophosphate and carbamate →insecticides have been tested against a resistant flea strain (*Ctenocephalides felis*) from Florida and compared to a susceptible strain. Malathion (Dithiophosphates) and carbaryl (Carbamates) have been used in flea control at the Florida strain origin for about 30 years. The results indicated a <10-fold tolerance for organophosphates other than malathion which had a 25-fold higher LC_{50} than with susceptible control →fleas. Under laboratory conditions a 12-fold resistance against malathion has been observed upon continuous selection of adult fleas for 8 generations. In a organophosphate-resistant field strain of the cat flea *C. felis* two possible resistance mechanisms have been identified: detoxification by glutathion-S-transferases and target site insensitivity of acetylcholine esterase. Hence, it is speculated that rotation with carbamate insecticides would not control this flea strain.

Resistant strains of the housefly showed reduced →cuticle adsorption of organophosphates, reduced formation of biologically highly active oxon derivatives, accelerated formation of phosphates from thiophosphate derivatives, and reduced sensitivity of choline esterases.

For decades, organophosphates have been the only products for sheep treatment against blowfly strike and →lice in Australia. Resistance against, e.g., diazinon was detectable in 1965 in 20% of the adult blowflies at a low level. In 1970 about 95% of the flies were diazinone resistant. In 1995 this value had stabilised at about 97%. In case of blowfly control the occurrence of resistance did not mean a total control failure. For diazinon the protection period was reduced from about 12 weeks to 4–6 weeks. The actual resistance factors for more than hundred field populations of blowfly are in the range between 2-fold (tolerance) and 42-fold in laboratory trials predominantly concentrating at the higher range.

For diazinon (Monothiophosphates) and fenthion a delayed cuticular adsorption was observed with resistant housefly strains. For most ectoparasites resistant or tolerant against organophosphates one or more of the following resistance mechanisms have been identified: hydrolysis by carboxylesterases (ali-esterases), thus quenching the inhibitor, oxidation by microsomal enzymes (e.g., cytochrome P450 mono-oxygenases), dealkylation by glutathion-S-transferases and target enzyme insensitivity towards organophosphates. By molecular biology techniques additional resistance mechanisms have been demonstrated, e.g., multiple alleles of choline esterases with altered specificity, enhanced enzyme expression levels.

Organophosphorous compounds play an ongoing important role in the treatment of ectoparasitic diseases. Resistance has been encountered with synergistic additives inhibiting metabolic enzyme activities, e.g., piperonyl butoxide (PBO) as mixed function oxidase inhibitor, S,S,S-tributyl phosphorotrithioate (TBPT) and triphenyl phosphate (TPP) asinhibitors of detoxifying esterases, and diethyl maleate (DEM) as an inhibitor of glutathione-S-transferase mediated detoxification.

Organophosphates and Organophosphonates

Important Compounds

Chlorfenvinphos, dichlorvos (DDVP), dicrotophos, heptenophos, naled, tetrachlorvinphos (CVMP), trichlorfon/metrifonate.

General Information

Chlorfenvinphos is a broad spectrum insecticide and acaricide with contact and stomach action. It has a long residual activity and requires withdrawal periods of 3–21 days (depending on the respective formulation) for meat producing animals treated with the compound.

It is used against blowfly strike and also for control of →ticks, lice, →keds and screw worm. Chlorfenvinphos shows fish toxicity and only slight bee toxicity. Among the organophosphorous compounds it shows a relatively high acute oral toxicity against rats (9.6–39 mg/kg LD_{50}). On the other hand the compound is metabolised quickly in mammals by de-esterification to give 2-chloro-1-(2,4-dichlrophenylvinyl ethyl hydrogen phosphate. Excretion products are glucuronic acid conjugate and monohydrolysed metabolites. **Dichlorvos (DDVP)** is a rapid knockdown insecticide and acaricide with respiratory, contact and stomach action which rapidly decomposes in soil. Besides applications onpets and cattle dichlorvos has been used also against ectoparasites on salmon and trout. Because of its ability to act systemically dichlorvos is also used in animal treatment against →nematodes, →trematodes or →cestodes. It is metabolised in mammals by hydrolysis and O-methylation. Acute oral toxicity for rats is IC_{50} mg/kg (LD_{50}, acute percutaneous 90 mg/kg). High toxicity to birds and bees has been observed. The metabolism of DDVP in mammals occurs rapidly with a half-life of 25 minutes by hydrolysis and O-methylation in the liver. It is non-persistent in the environment. **Dicrotophos** is a systemic insecticide and acaricide with contact and stomach action and moderate persistence. Acute oral toxicity for rats is 17–22 mg/kg (LD_{50}, acute percutaneous 110–180 mg/kg). Very toxic to honey bees but due to rapid decline of compound on surfaces with little effect in practice. Dicrotophos is completely metabolised and eliminated in rats and dogs a few days after oral administration. **Heptenophos** represents a systemic insecticide with contact, stomach and respiratory action with fast initial activity and short residual effect. Acute oral toxicity for rats is 96–121 mg/kg (LD_{50}). In mammals the compound is excreted to 96% within 6 days in metabolised form in urine and faeces. **Naled** is a fast-acting non-systemic insecticide and acaricide with contact and stomach and some respiratory action. The biological activity may be due to *in vivo* debromination forming dichlorvos (q.v.). The compound is used against →hygiene pests and in animal houses and against ticks and fleas on pets. Acute oral toxicity for rats is 430 mg/kg (LD_{50}). The compound causes skin irritation and eye burns on rabbits at an acute percutaneous LD_{50} of 1100 mg/kg. **Tetrachlorvinphos (CVMP)** is a non-systemic insecticide and acaricide with contact and stomach action. The compound is active against, flies, fleas ticks and lice on pets and cattle, swine and poultry and in animal houses. LD_{50} acute oral toxicity for rats is 4,000–5,000 mg/kg. Low toxicity for birds and high toxicity for bees have been observed. In mammals tetrachlorvinphos is metabolised and eliminated quickly. Major metabolites found in urine of rats and dogs were glucuronic acid derivatives,mainly 2,4,5-trichlorophenyllethandiol glucuronide, 2,3,5-trichloromandelic acid, and 2-chloro-1-(2,4,5-trichlorophenyl)-vinylmethyl hydrogen phosphate. **Trichlorfon** is an insecticide with contact and stomach action. It is used to control fleas flies, keds, lice, warble flies and →mange mites on farm animals. It is also active against a variety of fish ectoparasites. Acute oral toxicity for rats is 560–630 mg/kg (LD_{50}; acute percutaneous >2,000 mg/kg). Toxicity to fish and bees is moderate. In mammals the compound is rapidly degraded in the blood. Trichlorfon excretion in the urine is complete within 6 hours. Major metabolites are dimethylphosphoric acid, monomethylphosphoric acid and dichloroacetic acid. As metrifonate the compound is used as an anthelmintic against nematodes, trematodes or cestodes.

Monothiophosphates

Important Compounds

Azamethiphos, chlorpyrifos, coumaphos, cythioate, diazinon (dimpylate), famphur (famophos), fenitrothion, fenthion (MPP), iodofenphos, phoxim, propetamphos, temephos.

General Information

Azamethiphos is an insecticide and acaricide with predominantly contact action that shows quick knockdown and good residual activity. The acute oral toxicity for rats is low (LD_{50} 1,180 mg/kg; percutaneous >2,150 mg/kg) but bee toxicity has been observed and it was classified as highly toxic to fish (rainbow trout). However, the compound has been tested against fish lice on salmon with positive results (efficacy at 0.01 ppm) and good tolerance by salmon. Major metabolite in mammals is the glucuronic acid conjugate of 1-amino-3hydroxy-5-chloro-pyridine. Azamethiphos is mainly used for control of public hygiene pests and insect pests in animal houses. **Chlorpyriphos** is a non-systemic compound with contact, stomach and respiratory action and efficacy against fleas, ticks and sarcoptic mite. Acute oral toxicity for rats is 135–163 mg/kg (LD_{50}; acute percutaneous >2,000 mg/kg) but it shows bee toxicity and high fish toxicity (0.003 mg/l LC_{50} for rainbow trout). Its slow degradation in soil to 3,5,6-trichloro-pyridin-2-ol with a half-life of 80–100 days is responsible for the long persistence in environment. Metabolism in mammals following oral administration is rapid and leads to the same major metabolite which is excreted via urine. **Coumaphos** is a broad spectrum insecticide and acaricide with predominantly contact action. Coumaphos (as 25% WP) has been approved APHIS-USDA-permitted pesticide for treatment of screw-worms, →scabies and ticks in federal eradication programmes. Systemic action in the host animal is directed against warble flies. Withdrawal periods for meat are 15 days to 3 weeks depending on formulation. LD_{50} acute oral toxicity in rats is 16–41mg/kg

(LD_{50} percutaneous 860 mg/kg) Because of its relatively low toxicity for bees it is also used as a miticide against *Varroa* mites in bee hives. Because of its ability to break existing resistance interest in the →varroatosis treatment with coumaphos has recently grown especially in the southern part of the United States. Coumaphos is also used in animal treatment against nematodes, trematodes or cestodes. **Cythioate** is rapidly absorbed from the gastro-intestinal tract after oral dosing with maximum drug effect for up to eight hours after administration. Fleas and other ectoparasites like ticks and mange mites are killed when they ingest the body fluids of the host. LD_{50} acute oral toxicity for rats is 107–246 mg/kg. The compound is rapidly eliminated from the body. **Diazinon (dimpylate)** is a broad spectrum insecticide and acaricide with contact, stomach and respiratory action. Withdrawal times for meat range from 3 to 14 days depending on formulation and host species. Acute oral toxicity for rats has LD_{50} from 240–480 mg/kg body weight, The compound shows a pronounced bee toxicity. The bird toxicity is impaired with bird repelling properties. Major metabolites in mammals are diethyl thiophosphate and diethyl phosphate. **Famphur** is used as ectoparasiticide against horn flies, grubs and lice in cattle and reindeer. LD_{50} acute oral toxicity for rats is 27–62 mg/kg for rats. **Fenitrothion** is a non-systemic insecticide with contact and stomach action and ectoparasiticidal activity against fleas. It is used as apublic health insecticide and for control of flies in animal houses. LD_{50} acute oral toxicity for rats is between 250 and 800 mg/kg (acute percutaneous LD_{50} 890 mg/kg). Fenitrothion is rapidly excreted in the urine and faeces (90% after three days in rats). Major metabolites are dimethylfenitrooxon and 3-methyl-4-nitrophenol. **Fenthion** is a systemic broad spectrum insecticide with contact, stomach and respiratory action against a variety of ectoparasitic insects and hygiene pests. Acute oral toxicity for rats is 250 mg/kg (LD_{50}; acute percutaneous 700 mg/kg). After oral administration the compound is eliminated in mammals mainly in the form of hydrolysis products in the urine. The major metabolites are fenthion sulfoxide, fenthion sulfone and their oxygen analogues. These metabolites are further hydrolysed to the corresponding phenols. **Iodofenphos** is a non-systemic insecticide and acaricide with contact and stomach action used as a premise ectoparasiticide in poultry houses. It shows low toxicity to mammals and is non-toxic for birds. **Phoxim** is a broad-spectrum insecticide and acaricide with contact and stomach action and a short-term activity. It controls mange mites, lice, keds, flies, fleas and fly larvae. Acute oral toxicity for rats is 1,976–2,170 mg/kg (LD_{50}; acute percutaneous > 1,000 mg/kg). The compound is toxic for fish and bees (contact and respiratory action). In mammals it is rapidly metabolised to diethylphosphoric acid and desethylphoxim. The nitrile is metabolised to phoxim carboxylic acid and metabolism of the oxon is also unusually fast. As much as 97% is secreted within 24 hours in the urine and faeces. **Propetamphos** is an insecticide and acaricide with contact and stomach action and long residual activity. Acute oral toxicity for rats is 60–119 mg/kg (LD_{50}; acute percutaneous 2,825 mg/kg for male rats). In mammals, propetamphos is completely metabolised and rapidly excreted mainly via urine and exhaled air. It is detoxified through hydrolytic reactions involving the phosphorus and carboxylic ester bonds followed by →Conjugation and through oxidation processes leading ultimately to CO_2. **Temephos**, a non-systemic insecticide is used in mosquito larvae control and for treatment of pets against fleas and treatment of humans against lice. The compound shows a low toxicity against mammals (LD_{50} acute oral toxicity for rats 4,204–>10,000 mg/kg; LD_{50} acute percutaneous toxicity for rats >4,000 mg/kg), birds and fish but is highly toxic to bees. In mammals, temephos is mainly eliminated unchanged in the urine and faeces.

Dithiophosphates

Important Compounds

Dimethoate, ethion (diethion), malathion, phosmet (PMP, phtalofos).

General Information

Dimethoate is a fast acting insecticide and acaricide which quickly penetrates the insect cuticle. High initial penetration rate and slow detoxification rate have been observed with the housefly →*Musca domestica*. The oxon compound shows highest insecticidal activity but is more toxic to mammals. Acute oral LD_{50} of dimethoate for rats is 250 mg/kg, acute oral LD_{50} of the dimethoxon is 30 mg/kg. Dimethoate is toxic to bees, fish and arthropod aquatic organisms. **Ethion** is a non-systemic acaricide with predominantly contact action. Only combinations with pyrethroids (deltamethrin, permethrin) or other organophosphorous compounds (dichlorvos) are marketed. Acute oral toxicity for rats is 208 mg/kg (LD_{50}). The compound is toxic to fish and bees. **Malathion** is a non-systemic pro-insecticide and acaricide with contact stomach and respiratory action. The compound is activated by metabolic desulfuration to the corresponding oxon. It is extensively used for →vector control in public health and against ectoparasites of cattle, poultry, dogs and cats. Malathion is also active against human head and body lice. The lice and their eggs are killed quickly upon treatment with 0.003% and 0.06% malathion in acetone. Acute oral toxicity for rats is 1,375–2,800 mg/kg. Malathion shows low toxicity to birds and is toxic for fish and bees. In mammals the major part of the dose is excreted in the urine and faeces 24 hours after oral administration. Microsomal liver enzymes start detoxification by formation of malaoxon that is subsequently

hydrolysed by carboxylesterases. **Phosmet** is a non-systemic insecticide and acaricide with predominantly contact action. Phosmet controls lice, horn flies, mange mites and ticks. The compound has also been formulated to act systemically against →warble fly larvae and mange mites. Acute oral toxicity for rats is 113–160 mg/kg (LD_{50}). It is toxic to fish and bees. In mammals it is metabolised rapidly to phthalamic acid and phthalic acid (and derivatives) which are excreted in the urine.

Resistance

Malathion: Organophosphorous compounds.

Carbamates

Important Compounds

Bendiocarb; carbaryl; methomyl; promacyl, propoxur.

General Information

Insecticidal **carbamate** compounds are inhibitors of acetylcholine esterases and have been synthesised in 1954 at the first time. The kinetic of acetylcholine esterase inhibition with carbamates compoundshas a half-life of about 20 minutes for the carbamylated enzyme complex which is more reversible than with organophosphates. The more potent carbamates are structurally closely related to acetylcholine. Their weaker reactivity at the active site is compensated by more pronounced enzyme-binding abilities. The signs of intoxication are similar to those of organophosphates. Stimulation of cholinergic synapses is followed finally by paralysis of the →ectoparasite.

Bendiocarb is an insecticide with contact and stomach action that gives rapid knockdown and has good residual activity. LD_{50} of acute oral toxicity in rats is 40–156 mg/kg (LD_{50} acute percutaneous toxicity 566–800 mg/kg). The compound is toxic to bees and fish. In mammals bendiocarb is rapidly absorbed after oral administration or inhalation. It is rapidly detoxified and eliminated almost completely after 24 hours as sulphate or glucuronide conjugate of 2,2-dimethyl-1,3-benzodioxol-4-ol its major metabolite. **Carbaryl** is a widely used insecticide with slightly systemic properties and contact and stomach action. The compound was introduced onto the market in 1956. Due to its relatively low toxicity to mammals it is used against ectoparasites. It shows weak inhibition of cholinesterase. Acute oral toxicity for rats (LD_{50} 500–850 mg/kg; acute percutaneous LD_{50} >4,000 mg/kg). The compound is toxic to adult bees but carbaryl is not transferred to the breed. The compound shows moderate toxicity to fish if applied as aqueous solution. Carbaryl has very low toxicity for birds (>2,000 mg/kg for young pheasants) and has been developed for treatment of ectoparasitic diseases on poultry and other cage birds. Carbaryl does not accumulate in mammals body tissues and is rapidly metabolised to non-toxic substances, particularly 1-naphthol. This metabolite and its glucuronic acid conjugate is eliminated in the urine and faeces. **Methomyl** is a mixture of (Z) and (E) isomers, the former predominating. It is a systemic insecticide and acaricide with contact and stomach action. It is used for control of flies in animal houses. Today, direct application is being replaced more and more by bait formulations, reducing the risk of mammalian intoxication. The acute oral toxicity for rats is 17–24 mg/kg (LD_{50}; acute percutaneous toxicity for rabbits >5,000 mg/kg). **Promacyl** wasused until recently as a special tickicide with contact and stomach action against a variety of tick species on cattle in Australia. Since 1997 the compound has not been produced any more. It has favourable withdrawal periods of 24 hours (meat) and no withdrawal period for milk. Acute oral toxicity for rats is 1,220 mg/kg (LD_{50}; acute percutaneous toxicity >4,000 mg/kg). **Propoxur** is a non-systemic insecticide with contact and stomach action. It gives rapid knockdown and long residual activity. The compound is active against fleas ticks, lice and biting lice in dogs and cats. LD_{50} acute oral toxicity for rats is 95–104 mg/kg (acute percutaneous LD_{50} for male rats is 800–1,000 mg/kg). The compound is highly toxic to adult bees but shows low toxicity for birds. In rats main metabolites are 2-hydroxyphenyl-N-methylcarbamate and 2-isopropoxyphenol that are rapidly excreted in the urine. The carbamic acid residue is decomposed and carbon dioxide is exhaled.

Resistance

Several different resistance mechanisms have been demonstrated in resistant hygiene pests and ectoparasites. Besides observations of reduced cuticle permeability of carbamates in resistant housefly strains detoxification through metabolising enzymes is the dominating mechanism of resistance against carbamates. Other than for organophosphates carbamate resistance depends more on oxidative metabolism. O-dealkylation, N-dealkylation, and N-methylhydroxylation and to a lesser extent hydroxylation are responsible for detoxification of carbamates like propoxur or carbaryl. In addition, turnover of these reactions is elevated by factors 2–3 in resistant strains compared to susceptible populations. Furthermore, for carbamate resistant strains of cattle tick (*Boophilus microplus*), sheep blowfly (*Lucilia cuprina*), and housefly (*Musca domestica*) choline esterases insensitive to carbamates have been identified. Carbamate insecticides have been extensively used in flea treatments in Florida. Several flea strains have been isolated that showed tolerance or resistance to carbamates and to organophosphates. Resistance factors for propoxur, carbaryl, and bendiocarb are 4-, 20- and 28-fold, respectively. Other authors reported strains of *Boophilus microplus* being resistant against carbamate ectoparasiticides.

Neonicotinoids

Important Compounds

Imidacloprid, nitenpyram.

General Information

Nicotine is not registered anymore for use against ectoparasites in countries with high registration standards for reasons of its intrinsic high mammalian toxicity. However, the natural product nicotine guided the discovery of a new class of insecticides. About 2,000 derivatives have been synthesised on the way to a group of 10 candidates with highest insecticidal activity finally leading to the synthesis of **imidacloprid**. In comparison to nicotine, the compound impairs a 9-foldlower acute mammalian toxicity and an average >900-fold higher insecticidal activity.

Available data on the mode of action of neonicotinoids predominantly have been generated with imidacloprid. In general, other neonicotinoids behave similarly. From several studies it can be concluded that potent insecticidal neonicotinoids are (partial) agonists of the postsynaptic acetylcholine receptors of motoneurones in insects. Imidacloprid induces slow depolarisation in cell bodies of motor-neurone from cockroach nerve cord preparations which is sensitive to nicotinic antagonists like dihydro-β-erythroidine. Imidacloprid is a more potent agonist than nicotine, however maximum depolarisation is slightly lower than with nicotine. Electrophysiological studies with mammalian nicotinic acetylcholine receptors from rat muscle expressed in *Xenopus*→oocytes revealed that imidacloprid acts as a 1,000-fold less potent agonist to mammalian nicotinic receptors compared to the naturally occurring agonist acetylcholine. Additionally, the open state phases are significantly reduced compared to acetylcholine. Binding studies with insect and mammalian brain tissue incubated with tritiated imidacloprid revealed high affinity binding sites in insect neuronal tissues but not in the mammalian brain. Hence, the favourable toxicity profile of neonicotinoids is also based on target specificity for the different subtypes of nicotinic acetylcholine receptors present in mammals and insects. Additional insecticidal benefit results from the reduced positive charge under physiological conditions at the receptor-binding nitrogen of neonicotinoid compared to nicotine alkaloids. The positively charged nicotine alkaloids are barely able to cross the lipophilic cuticle of insects, leading to poor contact activity of nicotine. Neonicotinoids show good and long-term systemic action in plants. They are also quickly distributed in mammals upon oral ingestion. However, this efficacy is a short term response due to rapid elimination with dramatic loss of efficacy after less than 4 days. Residual activity on animals for at least 4 weeks is achieved only through topical application (e.g., imidacloprid). **Dinotefuran** is the most recent addition to the neonicotinoide family. Instead of a chlorpyridyl or a chlorthiazolyl moiety a furanyl-residue has been introduced. Pharmacology at the nicotinic acetylcholine receptor and biological efficacy are comparable to the other members of the class of neonicotinoids. The compound is being developed for use against fleas on pets. Acute toxicity in rats gave an LD_{50} of 2,804 mg/kg and 2,000 mg/kg body weight for male and female, respectively. Acute dermal toxicity is >5,000 mg/kg in rats. The compound shows moderate eye irritation and no skin irritation in rabbits. Dinotefuran is not a skin sensitizer. It is non-toxic to birds and fish, NOAEC for Daphnia magna is 95 ppm. Dinotefuran is highly toxic to bees.

Imidacloprid is an insecticide with contact and stomach action introduced in 1992 as a new chemical entity insecticide in crop protection. Four years later imidacloprid was introduced as the active ingredient of a new and highly effective ectoparasiticide against adult fleas. In topical formulations imidacloprid has a long residual activity. Recently, a combination of imidacloprid was developed with an endectocide that is used against intestinal parasites including heartworm, diseases caused by mite infections as well as against lice and fleas (→Moxidectin). Acute oral LD_{50} for rats is 450 mg/kg (acute percutaneous LD_{50} >5,000 mg/kg). Very low toxicity for birds and fish was measured. In rats imidacloprid is quickly absorbed from the gastrointestinal tract and eliminated to 96% within 48 hours mainly via the urine. 15% was eliminated unchanged. The most important metabolic steps were hydroxylation at the imidazoline ring, hydrolysis to 6-chloronicotinic acid, loss of the nitro group with formation of the guanidine and conjugation of 6-chloronicotinic acid with →glycine. **Nitenpyram** is an insecticide with contact and stomach action similar to imidacloprid. It has been very recently introduced in selected markets as an oral formulation for acute treatment of fleas on pets. Upon oral administration ectoparasiticidal activity lasts not more than 3 days due to the quick elimination and excretion of the compound via urine. Nitenpyram is marketed only in combination with longer acting compounds. Acute oral LD_{50} for rats is 1,600 mg/kg (acute percutaneous LD_{50} > 2,000 mg/kg).

Resistance

More than 10 years after introduction of imidacloprid as a pet flea product, field resistance of ectoparasites against imidacloprid has not been reported. Laboratory trials with the multi-resistant (organophosphates, carbamates, pyrethroids, benzoylphenylureas, cyclodienes) field strain “cottontail” from Florida revealed no cross-resistance for imidacloprid to other flea insecticides. It can be speculated from data obtained with insects relevant to crop protection (aphids, whiteflies) that mechanisms of detoxification of neonicotinoids in fleas

will be based on similar mechanisms. For whitefly and aphids the dominant route of detoxification relies predominantly on oxidative processes, however some of the first step oxidation products retain insecticidal activity. To date, no target insensitivity was observed in insect ectoparasites collected from the field. Susceptibility to imidacloprid was not significantly different in housefly strains resistant against organophosphates or pyrethroids, respectively, compared to fully susceptible flies. Generally, the housefly is less susceptible to neonicotinoids. This could be due to fast detoxification by mixed function oxidases as can be concluded from experiments enhancing the efficacy of neonicotinoids against houseflies through →synergists like piperonyl butoxide. Additionally, slow penetration through the cuticle of the housefly is also discussed. Besides the metabolic detoxification a point mutation has been identified very recently in α1 and α3 subunits of nicotinic acetylcholine receptors from field strains of plant hoppers after further selection in the laboratory. After more than 15 years of use as crop insecticides in the field this is the first target site mutation. It turned out recently that this Y151S point mutation causes reduced agonist potency to the whole range of known neonicotinoids. Dinotefuran as the weakest agonist turned out to be the compound that is least affected by the mutation. However, this point mutation has yet to be identified in field populations of ectoparasites.

12-membered Macrocyclic Lactones

Important compounds: Spinosad.

Spinosad is the first product introducing a new class of 12-membered macrocyclic lactones, a mixture of spinosyn A and spinosyn D, isolated from extracts of Saccharopolyspora spinosa. The mode of action is similar to that of neonicotinoids though a different subtype of nicotinic acetylcholine receptors is agonistically targeted by these molecules. The compound is marketed as a wound dressing and insecticide against blowfly on sheep and against flies and lice on cattle. Efficacy against fleas is on the same level as with neonicotinoids. The acute oral toxicity LD_{50} for male and female rats is 3,738 mg/kg and >5,000 mg/kg bodyweight, respectively. Acute dermal toxicity is >2,000 mg/kg in rabbits. Acute inhalation LC_{50} rat is >5.18 mg/l. Spinosad technical (90%) is slightly irritant to rabbits but it is not a skin sensitizer.

At >2,000 mg/kg bodyweight no acute neurotoxicity has been observed. The compound has a half-life of approximately one day in aqueous solution under sunlight. No bioaccumulation has been found in fish. In rat spinosad is rapidly absorbed and extensively metabolised. The compound is slightly respectively moderately toxic to birds, fish and aquatic life and highly toxic to bees.

Resistance

No resistance of ectoparasites against spinosad has been described since the compound is relatively new to the market.

Ectoparasiticides – Antagonists and Modulators of Chloride Channels

Mode of Action

Fig. 1.

Structures

Fig. 2.

Organohalogenides

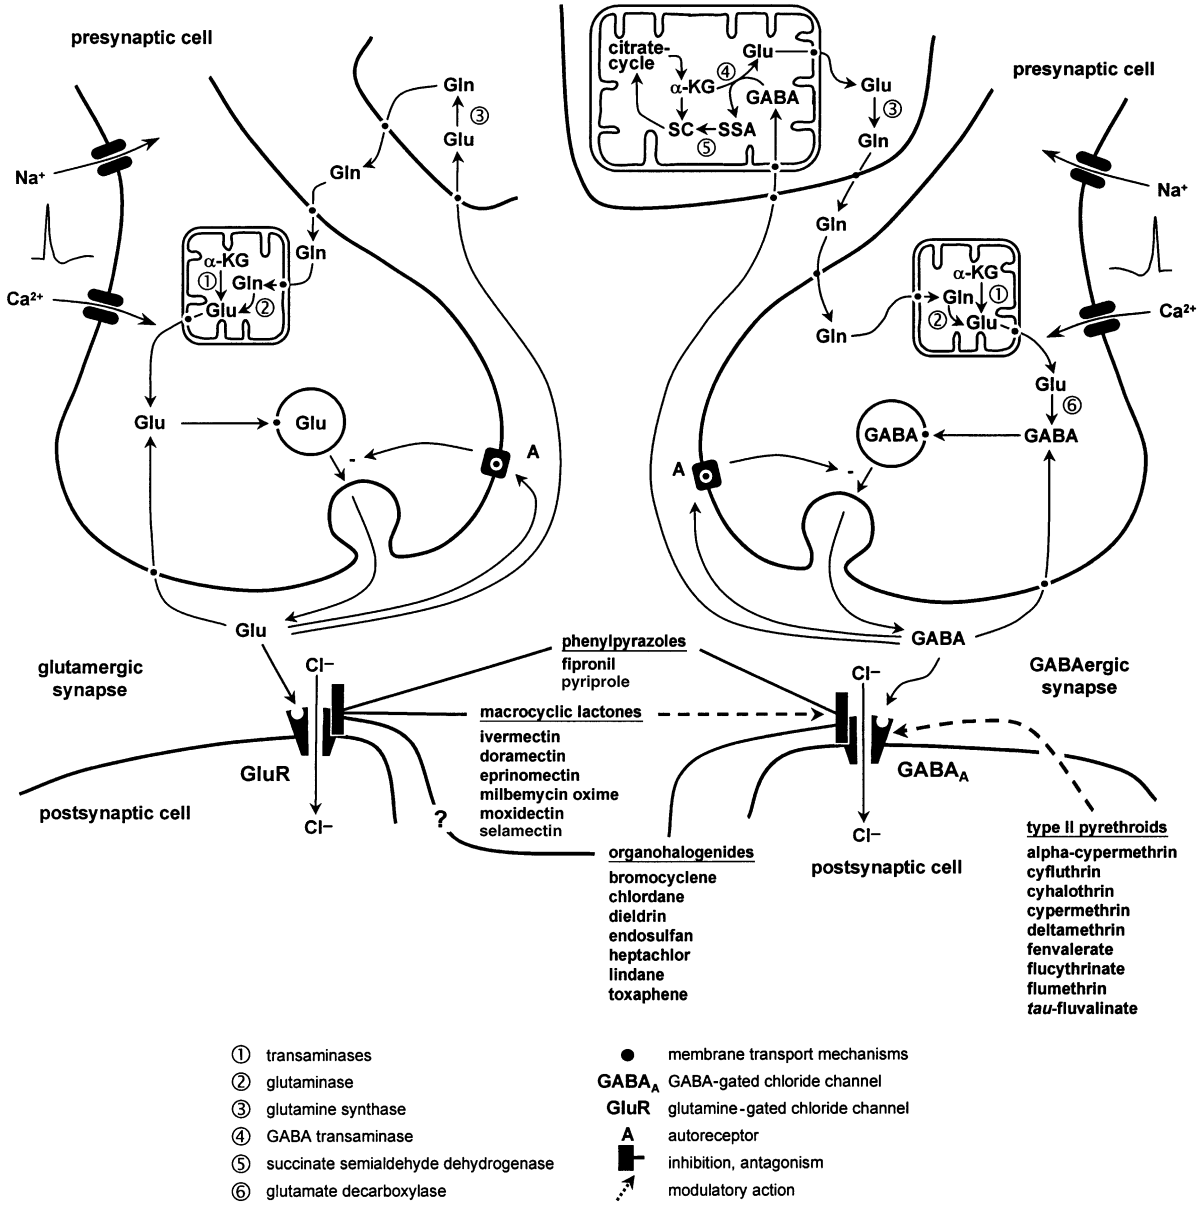
Important Compounds

Chlordane, Bromocyclene, Endosulfan, Lindane, Heptachlor, Toxaphene.

General Information

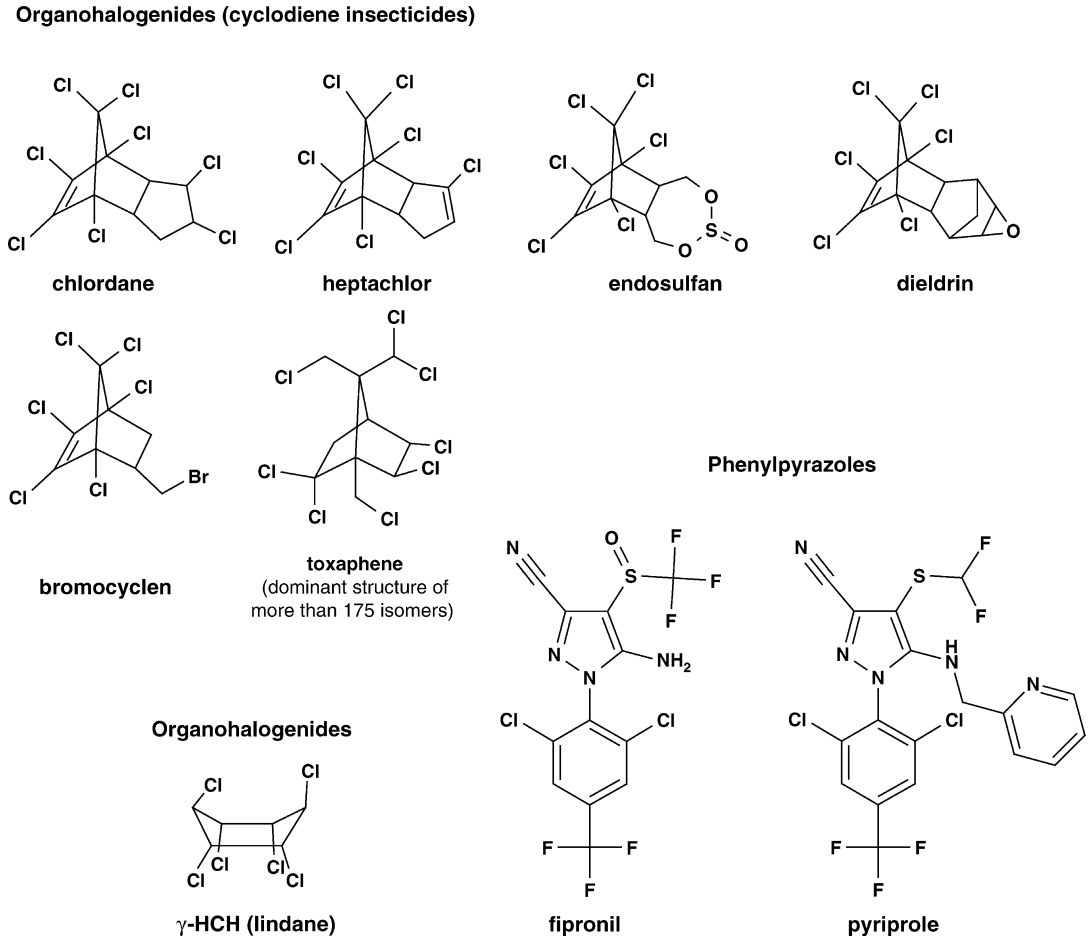
Lindane was isolated from the mixture of isomers in 1912. In 1943 lindane was identified as the insecticidal principle of hexachlorhexane. Insecticidal properties of chlordane, a cyclodiene, were at first identified in the 1940s. The action of lindane and cyclodienes to stimulate synaptic transmission was demonstrated 40 years ago. However, it was not until the early 1980s that the GABA-gated chloride channel complex was suggested to be their target site. In nerve and muscle preparations lindane and cyclodiene →insecticides antagonised GABA-stimulated ^{36}Cl uptake and competed with the TBPS (*t*-butyl-bicyclophosphorothioate) binding site at the GABA-gated chloride channel. Recent studies with cockroach neurones revealed that lindane and cyclodienes decrease the frequency of the GABA-gated chloride channel opening without changing the mean opening time. Dieldrin suppressed the GABA-induced current in a non-competitive manner. Since picrotoxin attenuates the inhibitory effect of dieldrin, it is speculated that cyclodienes bind to the picrotoxin/TBPS binding site. It follows that lindane and cyclodienes are antagonists at GABA-gated chloride channels directly responsible for excitatory symptoms in poisoning of mammals and insects.

Chlordane (cyclodiene compound) is a non-systemic insecticide with contact, stomach and respiratory action and long residual activity. It controls household insects as well as pests of domestic animals and man. The compound has impurities of different stereo-isomers and heptachlor. Acute oral LD_{50} for rats is 133–649 mg/kg (acute percutaneous LD_{50} 217 mg/kg). The compound accumulates in body fat and lipid-containing organs.



Ectoparasiticides – Antagonists and Modulators of Chloride Channels. Figure 1 Model of drugs affecting neuromuscular transmission by inhibitory →neurotransmitters.

It shows serious chronic and cumulative toxicity. The compound is toxic to fish and bees. In mammals chlordane is metabolised mainly to hydroxylated products. **Bromocyclene** is a non-systemic insecticide with contact and stomach action. It is used against ectoparasites in sheep and against →fleas on pets. **Endosulfan** (cyclodiene compound) is a non-systemic insecticide with contact and stomach action. In animal and public health applications it is used for the control of →tsetse flies. Acute oral LD_{50} for rats is 70–240 mg/kg depending on isomer and formulation (acute percutaneous LD_{50} > 4,000 mg/kg). Endosulfan is toxic to fish *in vitro* but no toxicity has been observed under field conditions. The compound shows no significant toxicity to bees. In mammals endosulfan is eliminated via the faeces within 48 hours. Residues accumulate in the kidney rather than in fat but are eliminated with a half-life of 7 days. The compound is rapidly metabolised to less-toxic metabolites and to polar conjugates. **Lindane (γ-HCH)** is one (>99%) isomer of the technically synthesised mixture of hexachlorhexane isomers. It is an insecticide with contact, stomach, and respiratory action and controls a broad spectrum of insects in public health and animal ectoparasites, e.g., →mites, sucking and biting →lice



Ectoparasiticides – Antagonists and Modulators of Chloride Channels. Figure 2 Structures of antiparasitic drugs affecting GABA-or glutamate-gated chloride channels (for structures of avermectins see →Nematocidal Drugs, Animals, →Nematocidal Drugs, Man).

and →ticks. Acute oral LD_{50} for rats is 88–270 mg/kg depending on the carrier (acute percutaneous LD_{50} 900–1,000 mg/kg). The compound shows toxicity to fish and to bees. In mammals lindane is found in the milk, body fat, and kidney after oral administration but rapid elimination occurs. Metabolites formed are less chlorinated compounds which are excreted as glucuronic acid conjugates.

Resistance

Most of the organohalogenide compounds have been withdrawn from the market for toxicological and environmental reasons. From 1948 to 1954 chlorinated hydrocarbons like DDT (→Ectoparasiticides - Blockers/Modulators of Voltage-Gated Sodium Channels/Organohalogenides) and dieldrin were extensively used for flystrike control. 1954 field monitoring detected no resistant blowfly populations whereas in 1958, the year of the withdrawal of aldrin/dieldrin insecticides for sheep treatment, 70% of the fly strains tested were resistant to dieldrin. The fast development of resistance against dieldrin was speculated to be pre-selected by the previous use of lindane, increasing the frequency of the rdl-gene (encoding for a dieldrin insensitive insect GABA receptor, see below). Resistance against this class of compounds is still present in the →ectoparasite populations. For dieldrin resistance, e.g., in blowfly populations 2–3% of the individuals still show the resistant phenotype. Therefore, application of selection pressure with new insecticides cross-resistant with this phenotype will favour the resistant individuals leading again to resistant populations in a few generations. Resistance against lindane was reported for Australian strains of the cattle tick *Boophilus microplus*.

Molecular biology techniques enabled the identification of the cyclodiene resistance mediating gene (rdl) that was identified as a member of the ligand-gated chloride channel gene family sensitive to GABA.

Macrocyclic Lactones

16-membered Macrocyclic Lactones.

Important Compounds

Doramectin, Eprinomectin, Ivermectin, Latidectin, Milbemycin Oxime, Moxidectin, Selamectin.

General Information

The class of 16-membered macrocyclic lactones comprises two families: the avermectins and the milbemycins. The avermectines have been discovered by Omura at the Kitasato Institute in Japan. The compounds are active against ecto-and endoparasites and thus defined as endectocides. The biochemical →mode of action is multifunctional. Recent reports established that the major target of the avermectins is the →glutamate-gated chloride channel. The compounds also exert modulatory agonistic activity at the GABA-gated chloride channel, thus causing paralysis. Detailed discussion of the mode of action of avermectins and target site identification has been described in →Nematocidal Drugs, Animals and →Nematocidal Drugs, Man. The following compilation concentrates on the ectoparasiticidal activities of the macrocyclic lactones.

Doramectin is a broad-spectrum insecticide and acaricide with contact and stomach action. The 25-cyclohexyl-avermectin B_1 compound was the fourth avermectin derivative introduced into the animal health market. It is a →fermentation product of a mutant Streptomyces avermitilis strain. The lipophilic cyclohexyl moiety seems to be responsible for the greater tissue half-life of doramectin. It is used as a systemic endectocide with ectoparasiticidal activity against →warble fly, screw worm, lice, mite and ticks including multi-resistant strains. **Eprinomectin** is an ivermectin derivative with an amino-modification of the bisoleandrosyl moiety resulting in enhanced insecticidal efficacy and favourable pharmacokinetics with no withdrawal periods for meat and milk. The compound retains the insecticidal and acaricidal properties of ivermectin. Eprinomectin was introduced into the market as an endectocide in 1997. **Ivermectin** is a potent insecticide and acaricide with stomach and contact action. The product is a semi-synthetic derivative of avermectin analogue of *Streptomyces avermitilis* and consists of 22,23-dihydroavermectin B_{1a} and 22, 23-dihydroavermectin B_{1b} (4:1 mixture). The compound is used in different formulations (injectable, pour-on, bolus) against ticks, sucking and biting lice, cattle grubs, mites, horn flies and bot flies. Withdrawal period for meat is 28 days. Ivermectin is not allowed for use with cattle producing milk for human consumption. Withdrawal period for dairy cows is 28 days prior to calving. Acute oral LD_{50} for rats is 10–50 mg/kg. The compound is toxic to fish and other aquatic organisms and toxic to honey bees. Excreted with faeces ivermectin is toxic to coprophagous insects.

Latidectin is a new semi-synthetic milbemycine derivative recently developed for treatment of intestinal nematodes and heartworm in pets. **Milbemycin-Oxime** is an insecticide, acaricide and nematicide with contact and stomach action. The compound is a mixture of milbemycin A3 and milbemycin A4 (3:7) produced by *Streptomyces hygroscopicus*. Subsequent derivatisation of the hydroxyl group at position 5 to a ketoxime resulted in a less potent compound with a favourable toxicological profile. The compound is predominantly active against →nematodes and shows only weak ectoparasiticidal activities at the concentrations used in animal treatment. In combination with an insecticide the compound is used against endoparasites and fleas in pets (→Lufenuron). **Moxidectin**, the third macrocyclic lactone introduced into the market of endectocides is produced by a combination of fermentation and chemical synthesis by 23-methoxime derivatisation of nemadectin, a milbemycin produced by *Streptomyces cyanogriseus noncyanogenus*. The efficacy against endo-and ectoparasite is comparable to that of ivermectin. Withdrawal periods are 28–49 days for meat depending on product. The compound is less toxic to coprophagous insects when compared to ivermectin. In combination with an insecticide the compound is used against endoparasites and ectoparasites like fleas and mites in pets (→Imidacloprid). **Selamectin** is a semi-synthetic doramectin analogue which has been introduced into the market of pet endectocides in 1999. The compound is active against fleas, some ticks, intestinal →hookworms, ascarids, and immature heartworms. The favourable toxicology profile was achieved through introduction of a 5-ketoxime group and cleavage of one sugar moiety.

Resistance

Broad resistance of parasitic arthropods against avermectins or milbemycins has not yet been reported. No cross-resistance has been found to other compounds. Reports of a milbemycin derivative breaking avermectin resistance of nematodes are under discussion. It is speculated that moxidectin has higher efficacy against specific nematodes compared to ivermectin leading to the control of ivermectin-resistant strains of these nematodes. A laboratory selection of sheep blowfly larvae with ivermectin was recently published. A pooled field strain was subjected to ivermectin treatment at a concentration producing more than 70% mortality. The larvae were selected over 60 generations, giving a 2-fold increase in the LC_{50} after the first selection and finally resulting in an 8-fold resistant strain. After relaxation of the selection pressure the selected strain reverted towards susceptibility fairly rapidly. Within 8 generations the LC_{50} values dropped from sevenfold to twofold compared to the parental strain.

Phenylpyrazoles

Important Compounds

Fipronil, Pyriprole.

General Information

Phenylpyrazole intoxication of blowfly causes hyperexcitability and elevates nerve discharge. Inhibitory effects of GABA on *D. melanogaster* motor neurone discharge are reverted in a manner similar to that of picrotoxin and cyclodienes. Phenylpyrazoles are antagonists of the GABA-gated chloride channel and there is evidence that these compounds share a common binding site with cyclodienes, TBPS, and picrotoxin on the GABA receptor.

Fipronil is a broad-spectrum non-systemic insecticide and acaricide with contact and stomach action and good residual activity. It is used for the control of ectoparasites of pets and livestock as well as an insecticide in public health. Acute oral LD_{50} for rats is 97 mg/kg (acute percutaneous $LD_{50} > 2{,}000$ mg/kg). Fipronil is harmful to some species of birds and fish and highly toxic to bees (direct contact and ingestion). In mammals fipronil is rapidly distributed and metabolised upon adsorption. Fipronil and its sulfone are eliminated mainly via the faeces. Urinary metabolites have been identified as conjugates of ring-opened pyrazole products. **Pyriprole** is a new broad-spectrum ectoparasiticide which has been developed very recently for use against ticks and fleas on dogs. The compound is less toxic than fipronil and is thought to be a pro-drug of the active compound with the free amine group. Acute oral LD_{50} for rats is >300 mg/kg. Pyriprole is a moderate eye irritant and shows no dermal irritation potential.

Resistance

Analysis of the *rdl* (resistant to dieldrin) gene isolated from cyclodiene-resistant →mosquitoes and flies showed a specific point mutation (A302S) responsible for the altered insecticide-susceptibility of the target. Cyclodiene-resistant fruit fly strains showed a more than 25-fold resistance against phenylpyrazoles. Phenylpyrazoletopical treatment of cyclodiene-resistant and gclodiene-susceptible *Blattella germanica* resulted in LD_{50} values of 40 µg/insect and 0.07 µg/insect, respectively, indicating a 570-fold cross-resistance. A cyclodiene-resistant housefly strain showing nearly 2,900-fold resistance to dieldrin had an LC_{50} value of 36 ppm for fipronil whereas LC_{50} of a susceptible reference strain was 0.4 ppm revealing a 90-fold cross-resistance. Perhaps more interestingly, despite the fact that the A302S mutation greatly reduces the rate of GABA receptor desensitisation, the fitness of resistant flies does not seem to be decreased. Recently molecular biology analyses of rdl-genes in several flea strains from different areas throughout the world revealed a

high prevalence of the point mutation conferring resistance to dieldrin. However, the practical relevance of this observation of potential phenylpyrazole cross-resistance on a molecular level has yet to be proven in *in vivo* trials on animal.

Ectoparasiticides – Blockers/ Modulators of Voltage-Gated Sodium Channels

Mode of Action

Fig. 1.

Structures

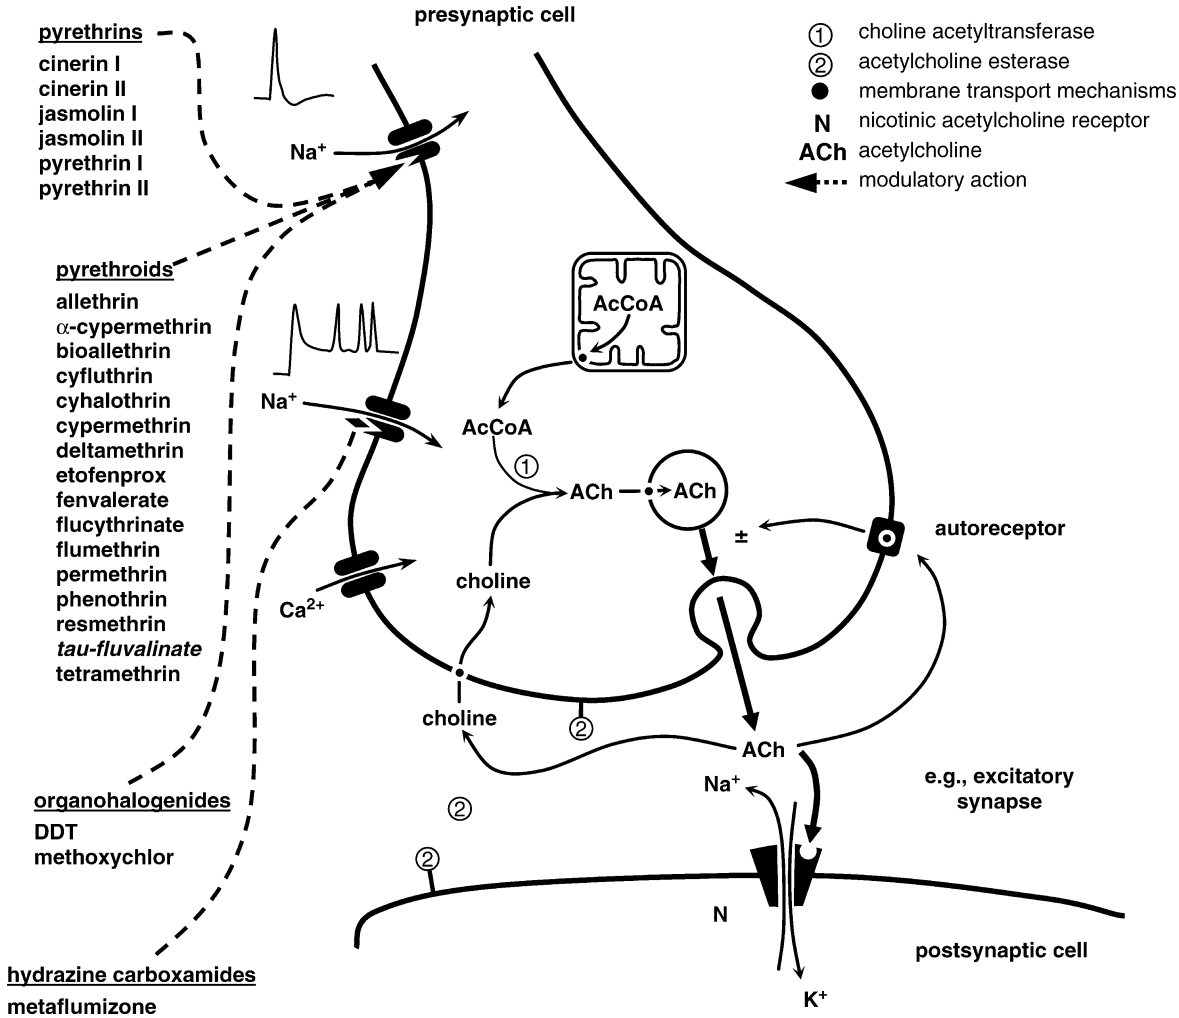
Organohalogenides, Fig. 2.

Important Compounds

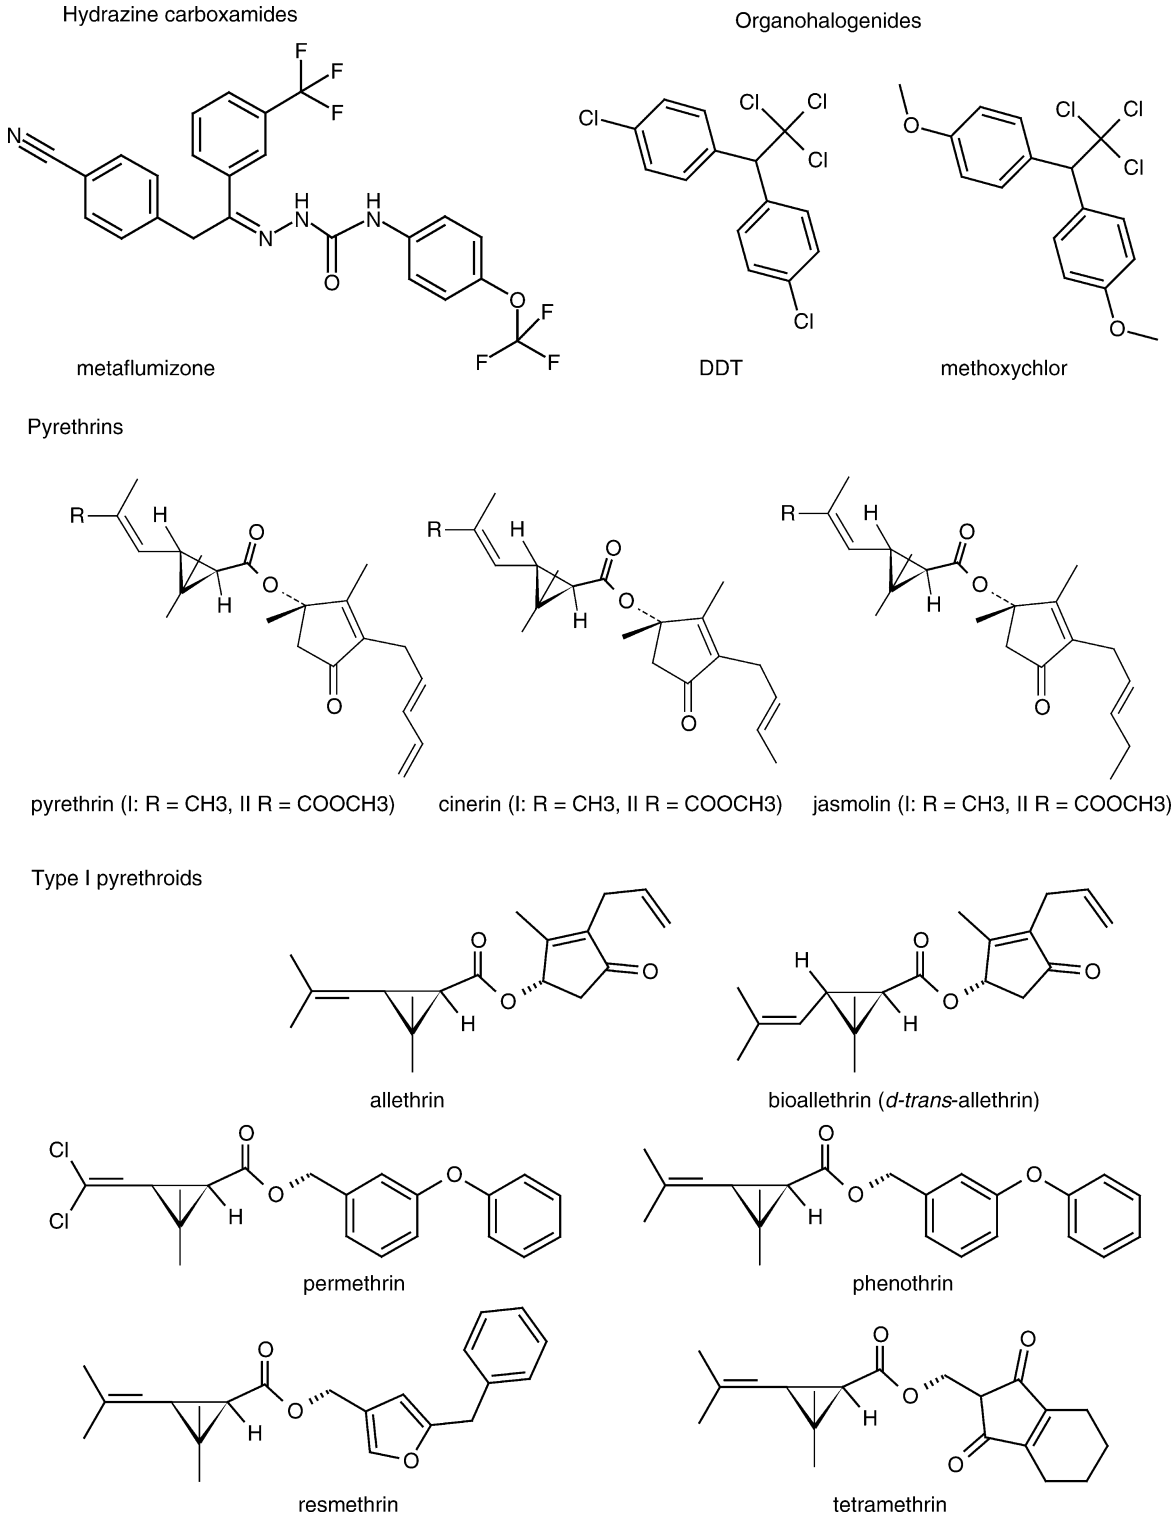
DDT, Methoxychlor.

General Information

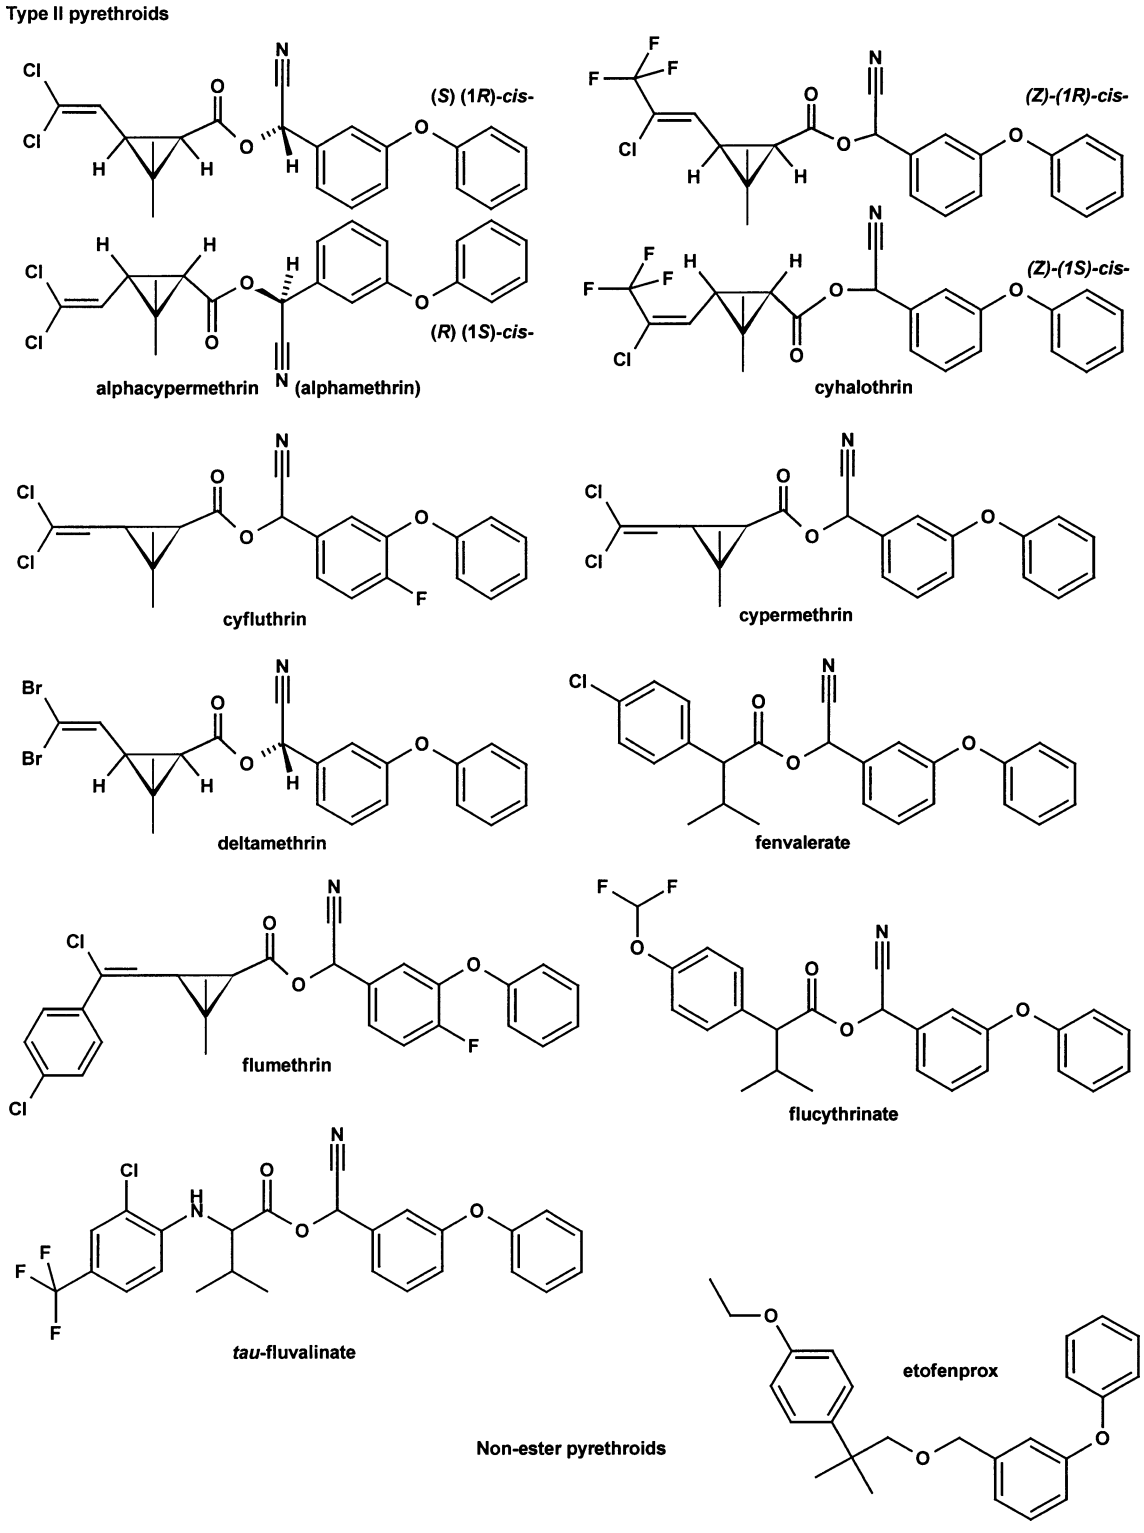
DDT is a broad-spectrum insecticide introduced onto the market in 1943. Nowadays, the compound has been replaced by less persistent →insecticides in nearly all countries. DDT is a persistent non-systemic insecticide with contact and stomach action. DDT acts on the voltage-gated sodium channel causing slow open and closing characteristics of the ion channel. This results in an increased negative afterpotential, prolonged action potentials repetitive firing after single stimulus,



Ectoparasiticides – Blockers/Modulators of Voltage-Gated Sodium Channels. Figure 1 Model of drugs affecting neural transmission at voltage sensitive sodium channels.



Ectoparasiticides – Blockers/Modulators of Voltage-Gated Sodium Channels. Figure 2 Structures of antiparasitic drugs affecting voltage sensitive sodium channels.



Ectoparasiticides – Blockers/Modulators of Voltage-Gated Sodium Channels. Figure 2 Structures of antiparasitic drugs affecting voltage sensitive sodium channels. (Continued)

and spontaneous trains of action potentials. Temperature has a profound effect on the insecticidal activity of DDT. Its potency to induce repetitive discharges from cockroach sensory neurones increases with lowering of the temperature with a Q_{10} of 0.2. While in most countries the use of DDT is prohibited by law, in some countries DDT is still used in mosquito eradication programs. Acute oral LD_{50} for rats is 113–118 mg/kg (acute percutaneous LD_{50} 2,510 mg/kg). DDT is toxic to fish and aquatic life. A side effect of DDT is the inhibition of a Ca-ATPase that is necessary for the calcification of egg shells. The compound accumulates in fatty tissues of mammals and is excreted in milk. The high potential for bioaccumulation and its long persistence has been discussed to be a major hazard to the environment. **Methoxychlor** is an insecticide closely related to DDT with contact and stomach action. It is used for the control of insect pests in animal houses, dairies and household. Acute oral LD_{50} for rats is >6,000 mg/kg The compound is toxic to aquatic life and fish. In mammals the compound is degraded by O-dealkylation to the corresponding phenol and diphenol, and by dehydrochlorination to 4,4′-dihydroxybenzophenone.

Resistance

Resistance of ectoparasites against DDT and methoxychlor is mainly of metabolic origin. Primarily, elevated levels of dehydrochlorinase activity together with mixed function oxidases are involved in detoxifying DDT. Reduced penetration of DDT through the cuticular layers is another resistance mechanism, e.g., in DDT-resistant flies. Furthermore, DDT susceptibility is reduced in target site mutant kdr and super-kdr housefly strains. Housefly strains resistant to DDT show reduced susceptibility for methoxychlor. However, methoxychlor-resistant flies are fully susceptible to DDT indicating a different mechanism for methoxychlor detoxification. A possible pathway could be demethylation and subsequent →Conjugation.

Pyrethrins

Important Compounds

Pyrethrin I, Pyrethrin II, Cinerin I, Cinerin II, Jasmolin I, Jasmolin II.

General Information

Pyrethrum comprises a mixture of naturally occurring pyrethrins (pyrethrin I, pyrethrin II, jasmolin I, jasmolin II, cinerin I, cinerin II) CNA; (Z)-(S)-2-methyl-4-oxo-3-(penta-2,4-dienyl)cyclopent-2-enyl (+)-trans-chrysantemate (cinerin I); (Z)-(S)-2-methyl-4-oxo-3-(penta-2,4-dienyl)cyclopent-2-enyl (+)-trans-chrysantemate (pyrethrin I); (Z)-(S)-3-(but-2-enyl)-2-methyl-4-oxo-cyclopent-2-enyl (+)-trans-chrysantemate (cinerin I); (Z)-(S)-2-methyl-4-oxo-3(pent-2-enyl)cyclopent-2-enyl (+)-trans-chrysantemate (jasmolin I);(Z)-(S)-2-methyl-4-oxo-3-(penta-2,4-dienyl)cyclopent-2-enyl pyrethrate (pyrethrin II); (Z)-(S)-3-(but-2-enyl)-2-methyl-4-oxo-cyclopent-2-enyl pyrethrate (cinerin II); (Z)-(S)-2-methyl-4-oxo-3(pent-2-enyl)cyclopent-2-enyl pyrethrate (jasmolin II)) isolated from *Tanacetum* (= *Chrysantemum* = *Pyrethrum*) *cinerariaefolium*. Pyrethrum is an ancient insecticide which was identified in China and spread to Dalmatia, France, USA, Japan in the 19th century (dried powdered flower heads were called Persian insect powder). Pyrethrum is a non-systemic insecticide with some acaricidal activity. It causes immediate paralysis with death occurring later and shows quick knock-down and short acting activities. The primary molecular target of pyrethrins is the neuronal presynaptic voltage-sensitive sodium channel. Pyrethrum is used in treatment of ectoparasites on companion and farm animals. The biological efficacy of pyrethrins and pyrethroids seems to be less pronounced in the larval stage of most insect species which might be due to the higher activity of the adult stages compared to larvae. Generally, it is combined with →synergists like piperonyl butoxide to encounter quick detoxification and to enhance potency. In mammals pyrethrins are rapidly degraded in the stomach by hydrolysis of the ester bond to non-toxic metabolites. The LD_{50} for acute oral toxicity in rats is 584–900 mg/kg (LD_{50} acute percutaneous toxicity >1,500 mg/kg in rats). Synergists seem not to enhance the toxicity of pyrethrins to mammals. Pyrethrins are highly toxic to fish and toxic to bees but show a repelling effect.

Pyrethroids

General Information

Pyrethrins served as a lead structure for the synthesis of the pyrethroids. The chemical class of pyrethroids is divided into structurally related subclasses. The type I pyrethroids are ester bond pyrethroids without α-cyano-residue, the type II pyrethroids include all ester bond pyrethroids containing a cyano-group at the α-carbon atom. An example for the class of non-ester bond pyrethroids is also given. A variety of structures were introduced onto the market during the 1970s and 1980s.

The insecticidal symptoms of type I pyrethroids are characterised by hyperexcitation, ataxia, convulsions and paralysis. Type II pyrethroids cause →hypersensitivity, tremors and paralysis. The primary target of pyrethrins and all pyrethroids is the voltage-sensitive sodium channel on the presynaptic side of insect neuronal →synapses.

The pyrethroids slow kinetics of both opening and closing of individual sodium channels resulting in delayed and prolonged openings. Pyrethroids also cause a shift of the activation voltage in the direction of hyperpolarisation. There then follows a membrane

depolarisation and an increase in depolarising after-potential. The latter reaches the threshold for excitation causing repetitive after-discharges. The membrane potential of sensory neurones increases discharge frequency, and that of nerve terminals increases the release of neurotransmitter and the frequency of spontaneous miniature postsynaptic potentials. The corresponding symptoms of mammalian or arthropod intoxication are hyperexcitation, hypersensitivity, convulsions and tremors. As described for DDT, pyrethroids also show a negative temperature coefficient for their activity on voltage-sensitive sodium channels revealing a Q_{10} value of 0.18 for tetramethrin between 25°C and 35°C. Type II pyrethroids also show some modulatory activity at a secondary target site identified as GABA-gated chloride channel.

Type I Pyrethroids

Important type I pyrethroids are allethrin, bioallethrin, permethrin, phenothrin, resmethrin, and tetramethrin.

Allethrin [(1R)-isomers] is a non-systemic insecticide with contact, stomach and respiratory action. It gives rapid knock-down and paralysis before killing. It is used for insect control in animal houses and as an animal ectoparasiticide. LD_{50} of acute oral toxicity for rats is 900–2,150 mg/kg. In mammals the compound is detoxified after oral administration in the liver by oxidation of one terminal methyl group of the chrysantemic acid moiety to a carboxyl group via an alcohol group. The compound is eliminated via urine and faeces within 2–3 days after treatment. **Bioallethrin**; d-trans-allethrin [≥93% (1R)-, ≥90% trans, ≤3% cis-isomer] is a potent contact non-systemic, non-residual insecticide producing rapid knock-down. It is used mainly in household and public health and in some countries is marketed for →ectoparasite treatment of companion animals. Mammalian toxicity is slightly higher than with allethrin. Detoxification and elimination occurs as described for allethrin. Cis/trans isomerisation has not been observed in soil. **Permethrin** is a non-systemic insecticide with contact and stomach action and slight repellent effect. It is used for repellence and control of biting flies and is also active against biting and sucking →lice on cattle. Recently the repellence and acaricidal efficacy of permethrin have been used in a combination product against ticks and fleas, flies and mosquitoes on dogs (→Imidacloprid). Acute oral LD_{50} for rats is 4,000 and 6,000 mg/kg for a cis:trans isomer mixture of 40:60 and 20:80 respectively (acute percutaneous LD_{50} > 4,000 mg/kg). Permethrin is toxic to fish and bees. In mammals hydrolysis of the ester bond occurs and the compound is eliminated as the glycoside conjugate. **Phenothrin** [(1R)-isomers]is a non-systemic insecticide with contact and stomach action that gives rapid knock-down. It is used in public health against a variety of injurious and nuisance insects and as a combination product with allethrin or tetramethrin for control of →fleas and →ticks on dogs and cats. Acute oral LD_{50} for rats is >10,000 mg/kg (acute percutaneous LD_{50} >10,000 mg/kg). The compound is toxic to fish and bees. **Resmethrin** is a non-systemic insecticide with contact action, acting in a similar manner to the natural pyrethrins but is not synergised by pyrethrum synergists. It is often used in combination with more persistent insecticides. Acute oral LD_{50} for rats is >2,500 mg/kg (acute percutaneous LD_{50} > 3,000 mg/kg). The compound is toxic to fish and to bees. Metabolism in hens was principally by ester hydrolysis and oxidation, followed by conjugation. **Tetramethrin** is a non-systemic insecticide with contact action that gives rapid knock-down. It is used as flea insecticide for pets. Tetramethrin is often combined with synergists or other pyrethroid insecticides. Acute oral LD_{50} for rats is >4,640 mg/kg (acute percutaneous LD_{50} > 5,000 mg/kg). The compound is toxic to fish and to bees. Tetramethrin seems to be metabolised in a similar way to the natural pyrethrins. In mammals, following oral administration, about 95% of the metabolised tetramethrin is eliminated in the urine and faeces within 5 days. The principal metabolite is 3-hydroxycyclohexane-1,2-dicarboximide.

Type II Pyrethroids

Important type II pyrethroids are alpha-cypermethrin, cyfluthrin, cyhalothrin, cypermethrin, deltamethrin, fenvalerate, flucythrinate, flumethrin and *tau*-fluvalinate.

Alpha-cypermethrin (formerly also known as alphamethrin) is a non-systemic α-cyano-pyrethroid with contact and stomach action. It is used mainly to control body lice and blowfly strike on sheep with no withdrawal period required. Acute oral LD_{50} for rats is 474 mg/kg (acute percutaneous LD_{50} > 2,000 mg/kg; tech. grade). The compound is toxic to fish and bees under experimental conditions but no toxic effects could be observed under field conditions. **Cyhalothrin** is a non-systemic insecticide and acaricide with contact and stomach action and repellent properties. It is mainly used for control of animal ectoparasites on sheep and cattle. Acute oral LD_{50} for rats is 114–166 mg/kg (acute percutaneous LD_{50} 200–2,500 mg/kg). The compound is toxic to fish and other aquatic organisms. In mammals the orally administered compound is hydrolysed at its ester bond and polar conjugates are formed from both moieties. Cyhalothrin is rapidly eliminated via urine and faeces. **Cyfluthrin** is a non-systemic insecticide with contact and stomach action with rapid knock-down efficacy and long residual activity. The compound is used in public health, against stored product pests and against flies in animal health. Acute oral LD_{50} for rats is 590 mg/kg (acute percutaneous LD_{50} > 5,000 mg/kg). Toxicity to bees and fish has been observed. Cyfluthrin was largely

and quickly eliminated in mammals. 98% of the administered amount was eliminated within 48 hours via urine and the faeces. **Cypermethrin** is a non-systemic insecticide and acaricide with contact and stomach action. It also deters ovipositioning blowflys on treated sheep. It has a broad activity against ectoparasites on farm animals. Withdrawal periods are 7 days for meat and at least 6 hours for milk. Acute oral LD_{50} for rats is 200–800 mg/kg (acute percutaneous LD_{50} > 1,600 mg/kg). The compound is toxic to fish and bees. **Deltamethrin** is a non-systemic fast acting insecticide and acaricide with contact and stomach action. It is used against a variety of ectoparasitic species on livestock. Acute oral LD_{50} for rats is 128–139 mg/kg (acute percutaneous LD_{50} > 5,000 mg/kg in aqueous solution). The compound is toxic to fish and bees under experimental conditions, but exhibits a repellent effect. **Fenvalerate** is a non-systemic insecticide and acaricide with contact and stomach action. It controls a broad-spectrum of parasitic arthropods and exhibits repellent activity. Acute oral LD_{50} for rats is 451 mg/kg (acute percutaneous LD_{50} > 2,500 mg/kg). The compound is toxic to fish and bees. In mammals fenvalerate is rapidly metabolised. Up to 96% of the compound administered orally is excreted in the faeces within 6–14 days. **Flucythrinate** is a non-systemic insecticide with contact and stomach action. It is registered for the control, of flies, fleas and other insects. Acute oral LD_{50} for rats is 67–81 mg/kg. The compound is moderately toxic to fish and toxic to bees but shows a repellent effect. In mammals flucythrinate is eliminated within 24 hours (60–70%) to 8 days (>95%) in the faeces and urine. Major metabolic pathways are hydrolysis followed by hydroxylation of the hydrolysis products. **Flumethrin** is a non-systemic insecticide and acaricide with contact and stomach action. It is used for the control of ticks, biting and sucking lice, →mites and for diagnosis and control of →varroatosis in beehives. At sub-lethal doses a sterilising effect of the pour-on formulation has been demonstrated for →*Hyalomma* ticks. Specific formulations have been granted nil withdrawal periods for meat and milk. Acute oral LD_{50} for rats is mg/kg (acute percutaneous LD_{50} mg/kg). The compound is moderately toxic to fish and shows low toxicity to bees which enables selective treatment against *Varroa* mites. ***tau*-fluvalinate** is a non-systemic broad range insecticide and acaricide. In animal health applications it is marketed as for the control of the *Varroa* mite in beehives. Acute oral LD_{50} for rats is >3,000 mg/kg (acute percutaneous LD_{50} > 20,000 mg/kg). *tau*-Fluvalinate is toxic to fish and other aquatic organisms.

Non-ester Pyrethroids

Etofenprox is a non-ester pyrethroid insecticide with contact and stomach action. The compound is mainly used in crop protection but is also used to control public health pests and on livestock against insects. Recently the compound has also been registered for use against ectoparasites on cats. Acute oral LD_{50} for rats is >42,880 mg/kg (acute percutaneous LD_{50} > 2,140 mg/kg). The compound is slightly toxic to fish.

Resistance

Pyrethroid resistant strains of the cattle tick *Boophilus microplus* have been isolated in countries in Central and Southern America, Southern Africa and Australia. Resistance of Australian strains of *B. microplus* against pyrethroids has been reviewed by J. Nolan. Monitoring of →horn fly control measures with pyrethroid dips, sprays or pour-ons revealed significantly reduced susceptibility. The period of spray efficacy fell from 30 to 20 and even to 5 days in some areas of Argentina. Dips regularly able to control horn flies for 15 days protected animals ranging from 0 to 6 days. Pour-ons of deltamethrin, cypermethrin, cyhalothrin or cyfluthrin experienced a decline in efficacy from 45–60 days down to less than four weeks during the study. Knock-down resistant *(kdr)* and *super kdr*(skdr) phenotypes have been described in several housefly strains of different origin. Recently, point mutations responsible for pyrethroid and DDT resistance have been identified in the coding region of the *para* sodium channel gene (the insect analogue of the vertebrate voltage sensitive sodium channel) from *kdr* and *skdr* strains of the housefly as well as kdr strains of the German cockroach.

Since 1981 pyrethroids have been used as ectoparasiticides against sheep lice as pour-on or wet-dip formulations. By mid 1985 reports of failures of the pour-on pyrethroids were becoming more frequent. About 7 years later a lice strain was isolated in New South Wales (Australia) that was found to be 642× resistant to cypermethrin and able to survive pour-on and full immersion dips. Addition of piperonyl butoxide to the formulation resulted in 81% reduction of lice number again.

Hydrazine carboxamide

Important Compounds

Metaflumizone.

Metaflumizone is the first compound used for animal health applications from a new class of chemicals acting as blocker of voltage sensitive Na+-channels in insects. The binding site and channel subtype is distinct from DDT or pyrethroid binding sites. The oxadiazine compound indoxacarb was the first member of a closely related chemical class with the same mode of action but is currently used only in crop applications. These type of carboxamides are insecticides mainly with stomach and contact action. While indoxacarb

requires esterolytic activation, metaflumizone already presents the active secondary amine group. Metaflumizone has been developed recently for use against fleas on cats as a single active application and against ticks and fleas on dogs in combination with an acaricide (→Amitraz). The acute oral and dermal LD_{50} in rat is >5,000 mg/kg bodyweight. Inhalation toxicity LC_{50} in rats is >5.2 mg/L. Metaflumizone is non-irritant to eyes or skin of rabbits. The compound is also not a sensitiser.

Resistance

Resistance to metaflumizone has not been reported yet since it will probably enter the first animal health markets in 2007. For indoxacarb that has the same mode of action esterolytic activities conferred high levels of resistance in leaf rollers. In housflies mixed function oxidases (MFO) were found to be responsible for a 118-fold laboratory selected indoxacarb resistance in houseflies. A cross-resistance against kdr or skdr pyrethroid resistance is not to be expected. Several authors found negative cross-resistance between pyrethroid resistance and elevated indoxacarb efficacy in lepidopteran species.

Ectoparasiticides – Inhibitors of Arthropod Development

Mode of Action

Chitin synthesis inhibitors (Fig. 1).

Structures

Fig. 2.

Important Compounds

Diflubenzuron, Fluazuron, Lufenuron, Triflumuron.

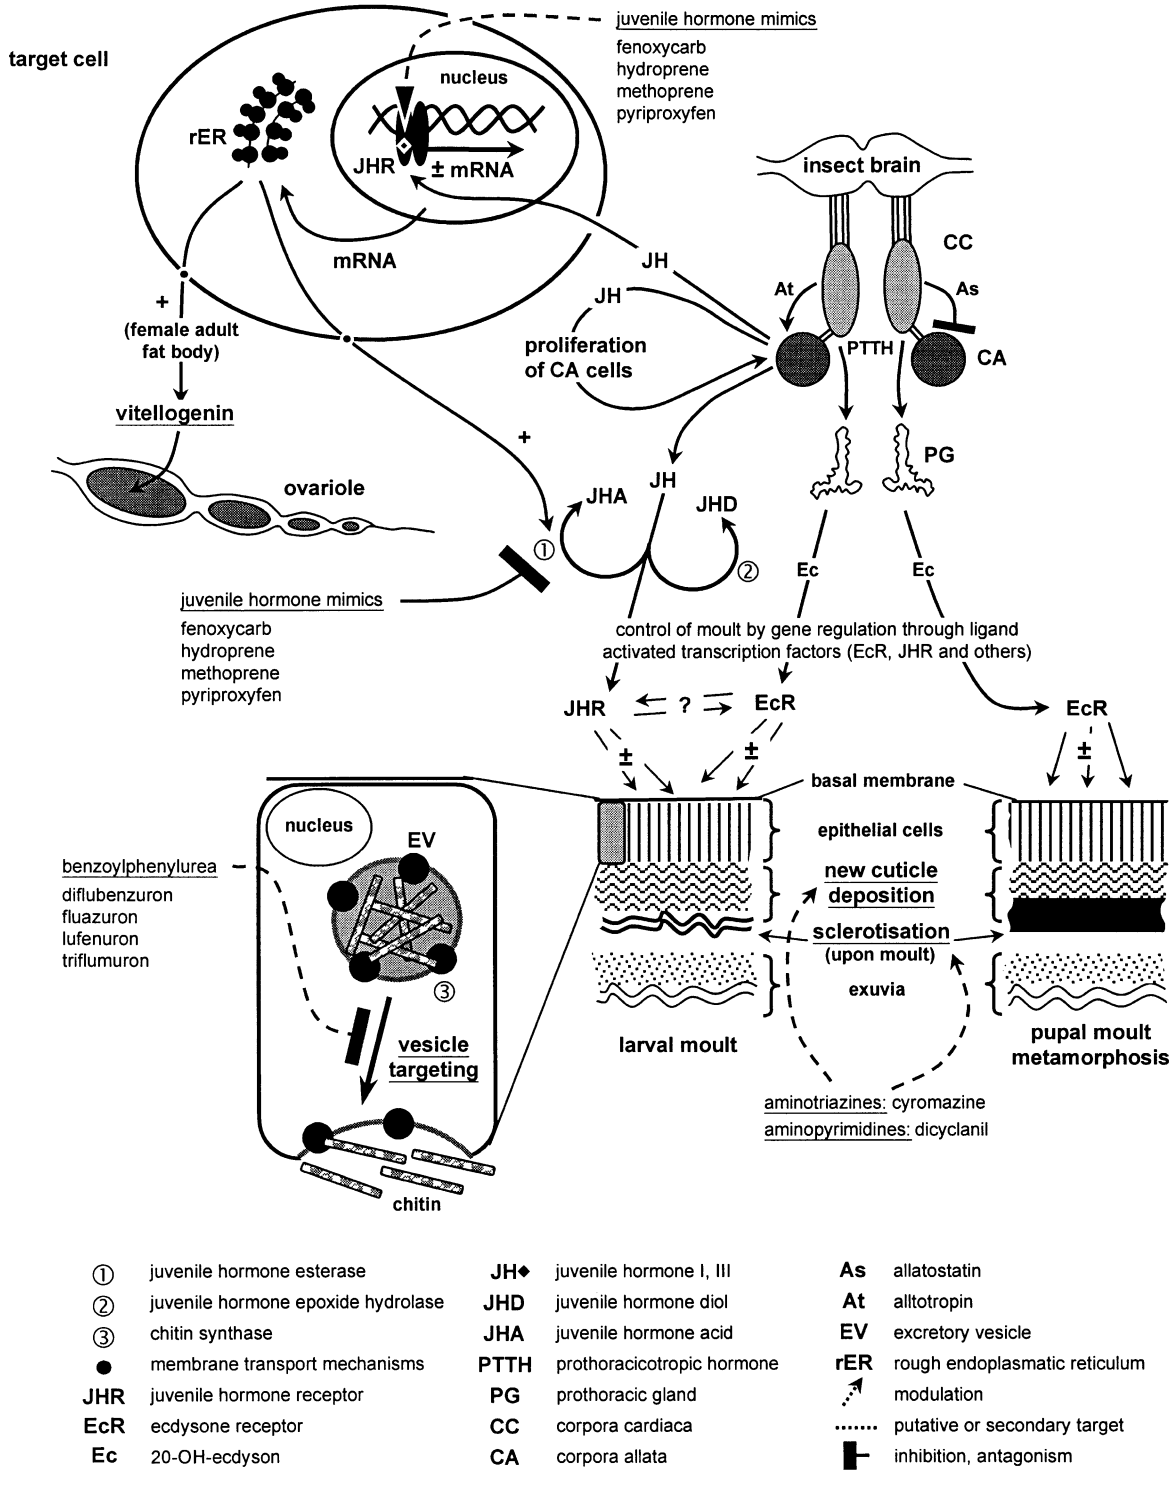
General Information

The chemical class of benzoylphenylurea (BPU) compounds is widely used as an insecticide also in animal health applications. The BPU compounds are inhibitors of chitin synthesis thus interfering with the formation of the insect →cuticle. There is no inhibition of other poly-sugar synthesis pathways (e.g., hyaluronic acid synthesis) by BPU compounds indicating high specificity. The biochemical target within the chitin biosynthesis pathway has not yet been clearly identified. Recent findings showed interference of BPUs with GTP-mediated Ca-transport in intracellular vesicles in chitin depositing →integument cells from American cockroaches. Chitin synthase itself is not inhibited by BPU compounds. Inhibition of chitin synthesis by BPU compounds depends on intact cells.

Diflubenzuron is a non-systemic insect growth regulator with contact and stomach action. It shows activity against moulting larvae or hatching eggs. The acute oral LD_{50} for rats is >4,640 mg/kg (acute percutaneous LD_{50} >10,000 mg/kg). The compound shows very low toxicity for fish and is not toxic to bees and predatory insects. In mammals diflubenzuron is partly eliminated as the parent compound with the faeces following oral administration. The other part is excreted mainly as hydroxylated metabolites. **Fluazuron** is a non-systemic ixodid growth regulator with contact and stomach action. The compound was recently launched for strategic tick control in Australia. It shows activity against all developmental stages of the cattle tick *Boophilus microplus* including all resistant strains. The acute oral LD_{50} for rats is >5,000 mg/kg (acute percutaneous LD_{50} > 2,000 mg/kg). Acatak has a withdrawal period of 42 days and treatment of dairy cows and sucking cattle is not allowed. The compound is harmful for fish but not toxic to bees. In mammals the compound is virtually not metabolised following oral administration. **Lufenuron** is an insect growth regulator that mostly acts by ingestion. The compound has been introduced in the pet market as a systemic flea growth regulator. Adult →fleas feeding from blood of systemically treated animals lay non-fertile eggs. Larvae feeding from faeces produced by treated adult fleas will be unable to moult and also cease feeding. The compound is also used in combination with macrocyclic lactones against endoparasites and fleas in pets (→Milbemycine Oxime). The acute oral LD_{50} for rats is >2,000 mg/kg (acute percutaneous LD_{50} > 2,000 mg/kg). The compound shows very low toxicity for fish and is only slightly toxic to adult bees. In mammals lufenuron is mainly eliminated as the parent compound with the faeces following oral administration. **Triflumuron** is a non-systemic insect growth regulator with stomach action. It shows activity against moulting larvae and causes infertility of eggs. The compound is used against blowfly, fly larvae in animal houses, cockroaches and flea larvae. The acute oral LD_{50} for rats is >5,000 mg/kg (acute percutaneous LD_{50} > 5,000 mg/kg). Triflumuron shows very low toxicity for fish and is not toxic to predatory insects. In mammals the compound is metabolised by hydrolytic cleavage-forming conjugated or partly hydroxylated metabolites containing the 2-chlorophenyl ring and correspondingly the 4-trifluormethyl-methoxyphenyl ring.

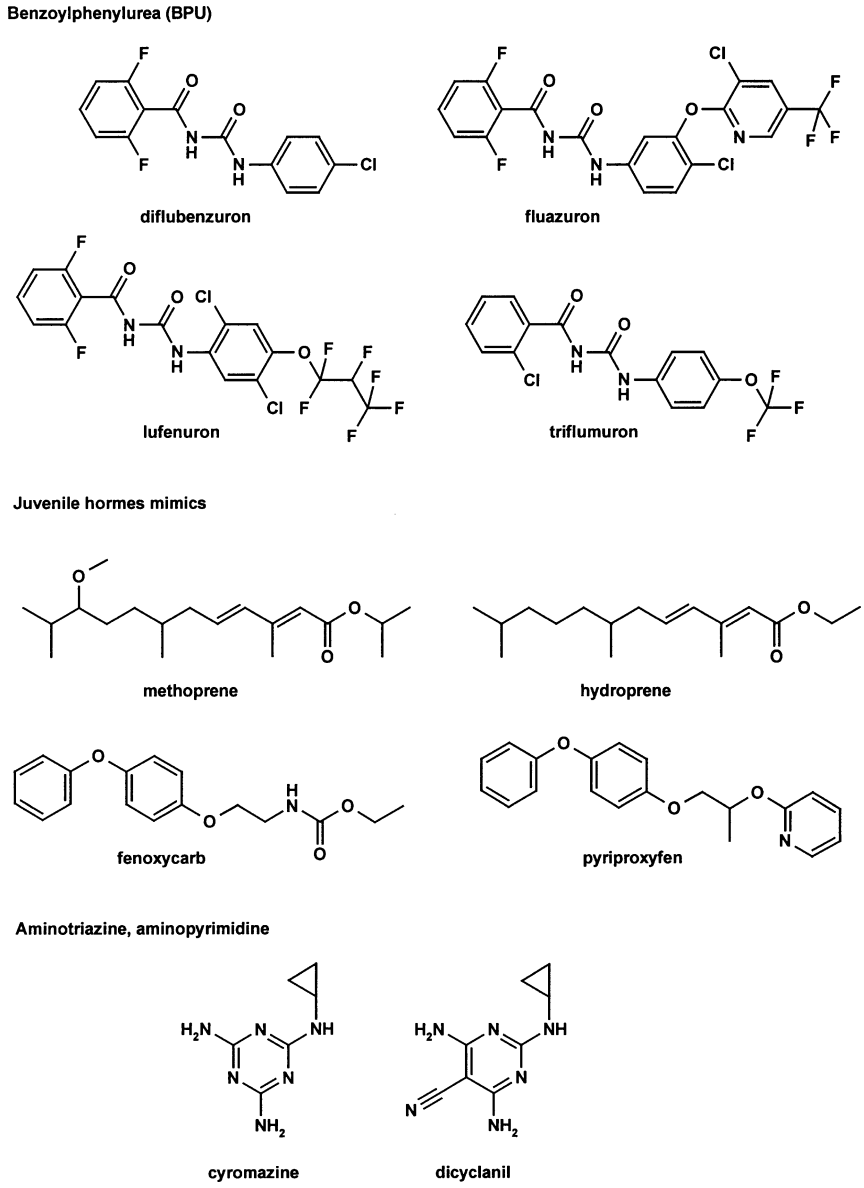
Resistance

In animal health, resistance of ectoparasites against BPU is still rare. This might change with the growing market



Ectoparasiticides – Inhibitors of Arthropod Development. Figure 1 Model of drug interaction with arthropod development.

share of BPU as a sheep ectoparasiticide. In diflubenzuron-resistant strains of the housefly *Musca domestica* oxidation seems to be the predominant route of detoxification. Another mechanism of detoxification of BPUs are hydrolases as could be demonstrated by the synergising effect of esterase inhibitors. Metabolic resistance against BPU has been demonstrated for a multi-resistant housefly population. Glutathion-S-transferase and mixed



Ectoparasiticides – Inhibitors of Arthropod Development. Figure 2 Structures of ectoparasiticidal drugs interfering with arthropod development.

function oxidase enzyme activities were determined and showed elevated levels. A multi-resistant flea strain collected from Florida showed resistance to some BPU compounds in laboratory *in vivo* trials.

Juvenile Hormone Mimics

Important Compounds

Methoprene, Hydroprene, Fenoxycarb, Pyriproxyfen.

General Information

The class of →insecticides comprises different chemical classes causing similar phenotypic damage to treated insects. They are mimics of the endogenous juvenile hormone of insects, preventing →metamorphosis to viable adults when applied to larval stages. Juvenile hormone mimics also exert ovicidal effects when applied to adults. Up to now, two primary targets of juvenoids have been identified. The compounds fulfil a dual function by inhibiting the juvenile hormone esterase from degrading endogenous juvenile hormone as well as by their weak agonistic effect on juvenile hormone receptors. This adds to the endogenous juvenile hormone effects thus compensating for the naturally occurring degradation of the juvenile hormone producing →corpora allata glands. In adult

insects →juvenile hormones are involved in regulation of vitellogenesis of the eggs. Altering homeostasis in this developmental stage could cause infertile eggs. The complete cascade of effects remains to be established. Several candidates for the endogenous juvenile hormone receptor - in all probability a member of the ligand-activated nuclear transcription factor family - are currently under discussion in *Drosophila*, e.g., the gene products of *ultraspiracle* and *methoprene tolerant*. Juvenile hormones and juvenile hormone mimics act as suppressers and stimulators of gene expression depending on the developmental stage and type of regulated protein. Several genes under the control of juvenoids have been identified. This explains the variety of effects observed with juvenoid treated insects.

Fenoxycarb is an insect growth regulator with contact and stomach action. The compound exhibits a strong juvenile hormone activity, inhibiting metamorphosis to the adults stage and interfering with the moulting of early instar larvae. The acute oral LD_{50} for rats is >10,000 mg/kg (acute percutaneous LD_{50} > 2,000 mg/kg). The compound shows low toxicity for fish and is non-toxic to adult bees. In mammals, the major metabolic path for fenoxycarb is ring hydroxylation to form ethyl-[2-[p-(p-hydroxyphenoxy)phenoxy]ethyl]-carbamate. **Hydroprene** is an insect growth regulator closely related to methoprene, predominantly used against →hygiene pests. **Methoprene** is an insect growth regulator (juvenile hormone mimic) preventing metamorphosis to viable adults when applied to larval stages. The compound is also used for the control of public health pests as well as in combination products against fleas on pets (→Fipronil). The acute oral LD_{50} for rats is > 34,600 mg/kg. The compound shows very low toxicity for fish and is non-toxic to adult bees. In mammals, methoprene is metabolised to simple acetates and also cholesterol has been identified as a secondary metabolite. The metabolites were present in milk and blood but have not been detected in tissues. Upon oral administration methoprene is not metabolised and excreted via the faeces and the urine. **Pyriproxyfen** is an insect growth regulator acting as a suppresser of →embryogenesis and adult formation (juvenile hormone mimic). The compound has been introduced in the pet market as a potent flea growth regulator and is used for the control of public health insect pests. The compound is also used for the control of flea development in combination with adulticides against fleas on pets (→Imidacloprid). The acute oral LD_{50} for rats is >5,000 mg/kg (acute percutaneous LD_{50} > 2,000 mg/kg).

Resistance Against Juvenile Hormone Mimics

No resistance has occurred against juvenile-hormone-related ectoparasite treatments. In Drosophila the methoprene-tolerant (Met) mutation results in a high (100-fold) level of resistance to the synthetic juvenile hormone analogue methoprene. The expressed Met-gene product has a high binding affinity to juvenile hormone in the nM range. Though JH regulation is disrupted and associated with fitness cost in Met-mutant flies, the Met-alleles have been shown to persist in wild type populations. Methoprene resistance that could not be reversed by different synergists has also been found in mosquito strains from different locations in the USA.

Aminotriazines/Aminopyrimidines

Important Compounds

Cyromazine, Dicylanil.

General Information

Currently, two structurally closely related drugs are marketed as insect growth regulators against larvae causing myiasis in animals and developing fly larvae in manure. The first of them, **cyromazine**, entered the market in 1979. The biochemical →mode of action remains unclear. Cyromazine has been tested in dihydrofolate reductase and tyrosinase assays but showed no inhibition of these enzymes while another study demonstrated an inhibition of dihydrofolate reductase. The compound is definitely not involved in inhibition of chitin synthase. There are strong hints on involvement of cyromazine in **sclerotization** of the cuticle. Cyromazine has its highest efficacy against first instar larvae and leads to changes in the elasticity of the cuticle which might cause physical instability and lesions in the cuticle, finally preventing further development. Cyromazine treated *Lucilia cuprina* larvae do not show signs of cuticle →apolysis. There was evidence of an abnormal continuous deposition of cuticle material by the epidermal cells. This also holds true for cuticle deposition in the foregut. The sum of observations is indicative of a fundamental interference with insect moulting at the hormonal level. However, recent results from positional cloning of a cyromazine resistance gene (achieved by chemical mutagenesis) and RNAi gene product disruption in *Drosophila melanogaster* supports the hypothesis that cyromazine interfere with nucleic acid metabolism.

Cyromazine is an insect growth regulator with contact action interfering with moult and pupation. The topically applied compound has a pronounced residual effect and protects sheep against blowfly strike for 8 weeks. There is a withdrawal period of 7 days for meat. Acute oral LD_{50} for rats is 3,387 mg/kg (acute percutaneous LD_{50} > 3,100 mg/kg). Cyromazine is non-toxic to fish and adult honey bees. The compound is efficiently excreted in mammals, mainly as the parent compound. **Dicyclanil** is an insect growth regulator

recently introduced into the market. The compound prevents development of larvae into pupae or adults when incorporated into the insect-breeding substrate. Dicyclanil shows a high specificity against developing flies and fleas. Its biological efficacy is higher compared to that of cyromazine.

Resistance against Cyromazine

Although 20 years of cyromazine treatment has passed, no proven resistance has been reported from the Australian blowfly. From all field strains assayed only three strains had a few survivors at the discriminating dose, but these flies were unable to reproduce successfully. Cyromazine was able to control even a high level multi-resistant housefly strain with a slightly higher LC_{50} (tolerance factor 1.7). There seems to be no cross-resistance to other insecticides. The cyromazine-resistant Drosophila obtained by chemical mutagenesis also is cross-resistant to Dicyclanil. While laboratory-selected *Musca domestica* strains showed cyromazine resistance levels of more than 100-fold, current field populations of the housefly found in Denmark, Brazil, and the USA show only low resistance levels and can be called less susceptible at best.

Ectoparasiticides – Modulators/Agonists of Aminergic Transmission

Structures

Amidines.

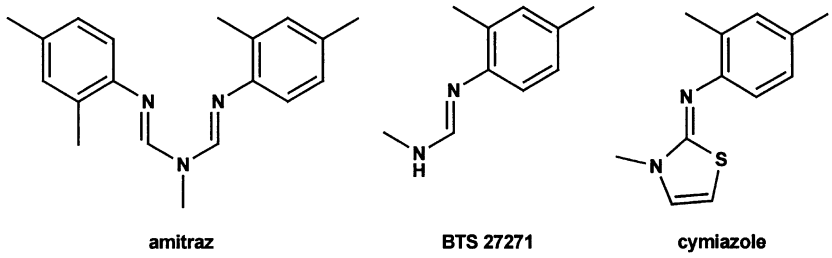
Important Compounds

Amitraz, Cymiazole.

General Information

Formamidines are agonists of the octopamine receptors in the arthropod nervous system, causing an increase in nervous activity, reduction of feeding and disruption of reproductive behaviour. Octopamine can act as a neurotransmitter, neuromodulator or even as a circulating neurohormone in insects. Octopamine is involved in energy mobilisation and stress responses. It has a function as a modulator of muscle contraction and controls the release of adipokinetic hormone. Formamidines have been shown to exert ovicidal effects in insects and acari. Additionally, formamidines of the chlordimeform type have been shown to efficiently inhibit monoamine oxidase from rat liver. Chlordimeform was withdrawn from the market in the late 1980s. General side effects of formamidines in mammals are possible alterations in the animals ability to maintain homeostasis for at least 24 hours after treatment. A symptom often observed with formamidine treated mammals is a reversible sedative effect.

Amitraz is a non-systemic acaricide and insecticide with contact and respiratory action. It has been shown that amitraz is rapidly metabolised in arthropods and that one metabolite (BTS-27271) shows a biological activity superior to that of amitraz itself. Therefore, it is thought that amitraz acts as a pro-insecticide and pro-acaricide. The tickicidal effect comes with an expelling action causing →ticks to withdraw mouthparts rapidly and fall off the host animal. The compound is used as an animal ectoparasiticide for the control of ticks, →mites and →lice on cattle, dogs, goats, pigs and sheep. Recently, the compound has also been developed for use in dogs against fleas and ticks in combination with a sodium channel modulator (→Metaflumizone). The acute oral LD_{50} for rats is 650 mg/kg (acute percutaneous LD_{50} > 1,600 mg/kg). The compound is toxic to fish and other aquatic organisms but rapid hydrolysis makes it unlikely that toxicity will be observed in natural aquatic systems. Amitraz shows low toxicity to bees and predatory insects. Withdrawal period for the compound in meat is 24 hours (7 days for sheep). In mammals rapid breakdown occurs and 4-amino-3-methylbenzoic acid and to a lesser extent N-(2,4-dimethylphenyl)-N′-methylformamidine are excreted as conjugates. **Cymiazole** (CGA 50439) is a non-systemic ectoparasiticide with contact and respiratory action. It shows a good killing-effect as well as inhibition of viable egg production and has a pronounced detaching effect on ticks. Cymiazole is also used as a



Ectoparasiticides – Modulators/Agonists of Aminergic Transmission. Figure 1 Structures of amidines.

systemic compound against varroa mites feeding on bees carrying the compound in their body fluid. The compound has a three-day withdrawal period for meat and can be used in milk producing cattle without restrictions. Cymiazole has an acute oral LD_{50} for rats of 725 mg/kg (acute percutaneous LD_{50} > 3,100 mg/kg). The compound shows only weak toxicity to fish and shows no significant toxicity to bees.

Resistance

Resistance against amitraz has been observed in several strains of the southern cattle tick in Australia. No resistance against amidine acaricides was found in multi-host ticks so far with the exception of one case of moderate resistance against amitraz in a multi-resistant *Rhipicephalus sanguineus* strain recently isolated from a large quarantine kennel.

Ectoparasitocidal Drugs

→Arthropodicidal Drugs, →Ectoparasiticides.

Ectopic Infections

Infections of other than the usual organs, e.g., →*Paragonimus* may occur not only in the lung but also in the brain, ommentum, skin, and liver of their hosts.

Ectoplasm

The peripheral, electron-lucent part of the →cytoplasm of many protozoans (→*Entamoeba histolytica*).

Ectospermatophore

→Ticks/Spermatogenesis and Fertilization.

Edema

Symptom of parasitized tissues, the accumalation of watery substances leads to swellings, e.g., →chagom, →trypanosomiasis.

Edhazardia Species

Microsporidian species of insects proceeding meiosis and change of ploidy.

Eflornithine

Difluormethylornithine (DFMO), agent against →trypanosomiasis. →Trypanocidal Drugs.

EGF

Epidermal growth factor.

Egg-Reappearance Period (ERP)

Time from oral infection with helminthic eggs until excretion of new ones by fertilised females. →Prepatency.

Eggshell

→Acanthor, →Cestodes, →Nematodes.

Egg-Sorting Apparatus

→Acanthocephala.

Ehrlich, Paul (1854–1915)

German physician, creator of chemotherapy, inventor of the first drug against syphilis (Salvarsan) and developer (together with Behring) of the vaccine against diphtheria. Winner of the Nobel prize in 1908.

Ehrlichia

Name

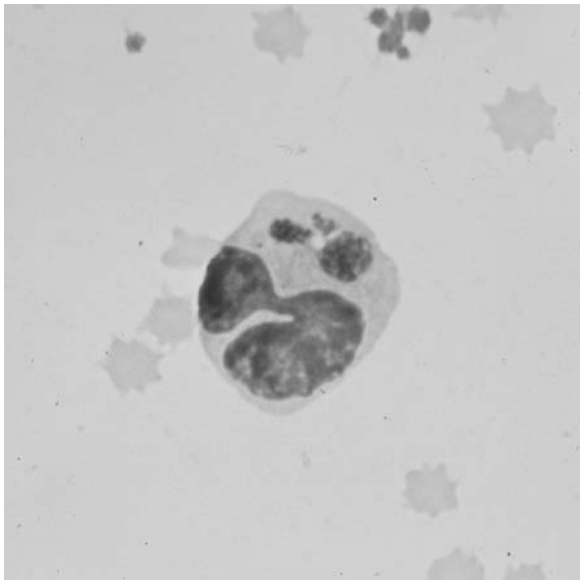
Honoring Paul Ehrlich (→Ehrlich, Paul), a German Nobel Prize winner and co-worker of Robert Koch (→Koch, Robert).

General Information

Ehrlichia is a genus of bacteria being transmitted by ticks. *E. phagocytophila* (transmitted by *Ixodes* ticks) introduces the granulomatous Ehrlichiosis in humans, horses, mice, and ruminants (Fig. 1); *E. canis* is the agent of the monocytic Ehrlichiosis in dogs (transmitted by *Rhipicephalus sanguineus*), while *E. chaffeensis* introduces this disease in humans being transmitted by *Amblyomma*-ticks in USA. *E. phagocytophilus* is synonym to *Anaplasma phagocytophylum*.

Ehrlichiosis

Anaemian disease in sheep, cattle, cats, and dogs due to the rickettsian agents (e.g., *Ehrlichia canis*, *Haemobartonella felis*, and *Anaplasma* spp.) transmitted by →ticks (→Tick Bites: Effects in Animals). These rickettsial stages are spherical (genera *Anaplasma*, *Haemobartonella*) and are found on the surface of erythrocytes (*Haemobartonella*) or appear ovoid (genus *Ehrlichia*) and are situated inside monocytes. In particular the intraerythrocytic stages of *Anaplasma marginale* of cattle may become misdiagnosed as →piroplasms.



Ehrlichia. Figure 1 Giemsa-stained blood smear showing the morula-like stage of *E. phagocytophila* besides the curved nucleus of a white blood cell.

Therapy

Haemobartonella: Tetracyclines; *Anaplasma*, *Ehrlichia*: Imidocarb (Imizol*). In humans *Ehrlichia sennetsu* (Japan, South-East Africa) and *E. chaffeensis* (USA) may occur and are apparently also tick transmitted. They cause fever, →vomiting, nausea, which may, however, be self-limiting.

EIA

Enzyme immunoassay.

Eichler's Hypothesis

Hosts belonging to a large taxonomic group will harbour a greater diversity of parasites than hosts belonging to a smaller systematic group.

Eimer, Theodor G. H. (1843–1897)

Swiss zoologist and physician, professor at Tübingen, discoverer of many protists, honored by →Eimeria.

Eimeria

Classification

Genus of →Coccidia.

Important Species

Table 1, Figs. 2–4.

Life Cycle

Fig. 1.

Diseases

→Eimeriosis, →Coccidiosis, Animals.

Eimeriosis

Intestinal infection of many plant eaters due to oocysts of the genus →*Eimeria* (Fig. 1); the disease is also named coccidiosis (→Coccidiosis, Animals).

Eimeria. Table 1 Most important species of the genus *Eimeria*

Species	Host/Habitat	Oocyst size (μm)	Prepatent period (days)	Pathogenicity
	Cattle			
E. bovis	Posterior small intestine	23–34 × 17–23	15–21	+

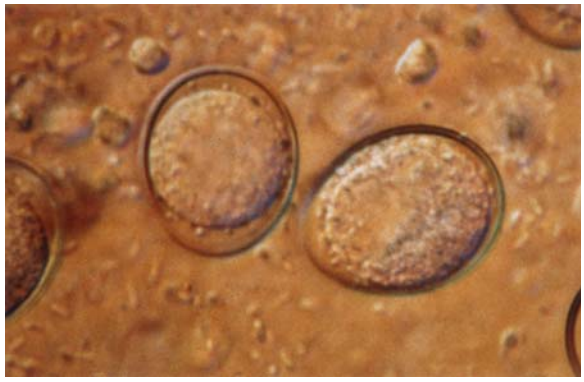
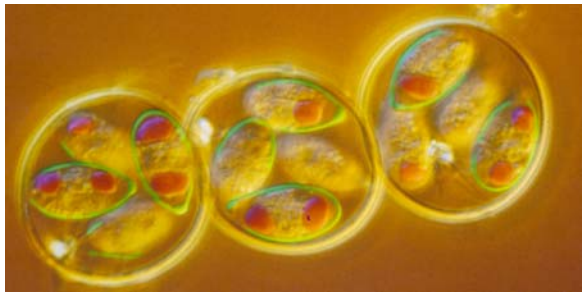
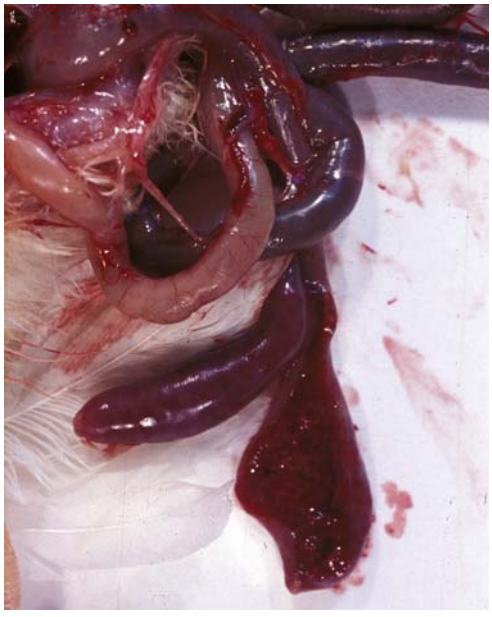
Eimeria. Figure 1 Life cycle of *Eimeria* spp. in chicken. For species and other hosts see Table 1. *1* After oral uptake of sporulated oocysts the sporozoites hatch in the small intestine from the sporocysts. *2–6* After penetration, multinucleate →schizonts are formed (3) inside a →parasitophorous vacuole (*PV*). The schizonts produce motile →merozoites (*DM, M*), which may initiate another generation of schizonts in other intestinal cells (**2–5**) or become gamonts of different sex (**7, 8**). *7* Formation of multinucleate →microgamonts, which develop many flagellated →microgametes (7.1–7.2). *8* Formation of uninucleate macrogamonts, which grow to be macrogametes (**8.1**) that are characterized by the occurrence of 2 types of →wall-forming bodies (WF_1, WF_2). *9* After fertilization the young →zygote forms the →oocyst wall by consecutive fusion of both types of wall-forming bodies (*FW*). *10* Unsporulated oocysts are set free via feces (exceptions are reptile- and fish-parasitizing *Eimeria* spp.). *11–13* →Sporulation (outside the host) is temperature-dependent and leads to formation of 4 sporocysts, each containing 2 sporozoites (*SP*), which are released when the →oocyst is ingested by the next host. *DG*, developing →microgametes; *DM*, developing →merozoite; *DW*, developing wall-forming bodies; *FW*, fusion of WF_1 to form the outer layer of OW; *M*, merozoite; *N*, nucleus; *NH*, nucleus of host cell; *OW*, oocyst wall; *PB*, polar body (granule); *PV*, →parasitophorous vacuole; *R*, refractile (= reserve) body; *SB*, →sporoblast; *SP*, →sporozoite; *SPC*, →sporocyst; *SPO*, sporont; WF_1, wall-forming bodies I; WF_2, wall-forming bodies II; *Z*, →cytoplasm of zygote (= young oocyst).



Eimeria. Figure 2 LM of unsporulated (= freshly excreted) *Eimeria* oocysts.



Eimeria. Figure 3 LM of 3 sporulated *Eimeria tenella* oocysts.



Eimeria. Figure 4 Bloody caeca of chicken infected with *Eimeria tenella*.

EIP

→Extrinsic Incubation Period.

Elaeophoriasis, Elaeophorosis

Elaeophora (→Filariidae) infects deer, elk, and sheep. The adult parasites live in the common carotid and internal maxillary arteries and produce microfilariae which are found in the capillaries of the face and the head. In sheep the →microfilariainduce a granulomatous reaction in the capillaries of the skin, and a dermatitis. The lesions on the head, feet, and abdomen are characterized by intense →pruritus resulting in erythrema, →alopecia, excoriations, ulcerations, crusts, and haemorrhage. Stomatitis, rhinitis, and keratitis also occur.

Therapy

→Nematocidal Drugs, Animals.

Elaphostrongylosis

Name

Greek: *elaphos* = red deer; *strongylos* = cylindric, and Latin: *cervus* = red deer.

Disease of deer or other ruminants due to infections with the 5–6 cm long (females) or the 3–4 cm long (males) of *E. cervi*. →Lungworms.

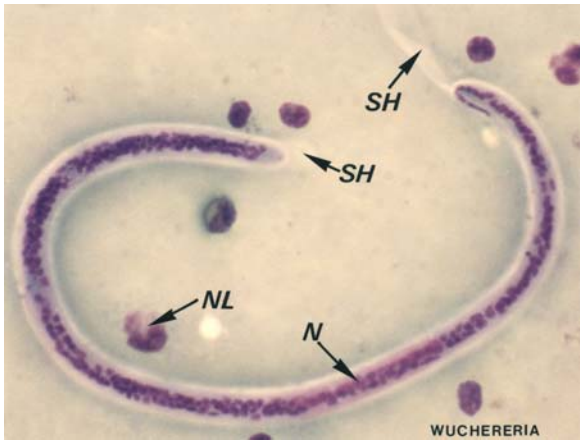
Electron Transport Chain

→Energy Metabolism.

Elephantiasis tropica

→Filariidae, →Filariasis, Lymphatic, Tropical; →Lymphatic Filariasis, →*Wuchereria*, →*Brugia*.

Main clinical symptoms: Lymphangitis, unfeelingness of skin portions; later: chylurie, elephantiasis, i.e., giant swelling of organs.



Elephantiasis, tropica. Figure 1 LM of the microfilaria of *Wuchereria bancrofti* (Giemsa stained).

Incubation period: 3–16 months.
Prepatent period: 7–24 months.
Patent period: 8–10 years (adults live for 18–20 years).
Diagnosis: Microscopic analysis of smear preparations or of membrane filtered material; microfilariae are found mainly at 10 p.m. in the peripheral blood (Fig. 1).
Prophylaxis: Avoid bites of vector →mosquitoes in endemic regions.
Therapy: Treatment see →Nematocidal Drugs, Man.

ELISA

Synonym
Enzyme-linked Immunosorbent Assay.

Kind of indirect →immunoassay frequently used, e.g., in →Serology. It needs only minor quantities of reagents and can equally be used for →antigen and →antibody detection.

Elokomin

Agent of disease, →Nanophyetus.

Embden, Gustav Georg (1874–1933)

German physiologist, discoverer of the pathway of degradation of polysaccharids (together with Otto Fritz Meyerhof, 1884–1951).

Embryogenesis

→Cestodes, →Nematodes.

Embryophore

Thick wall surrounding the larva (→Oncosphaera) of →cestodes inside eggs. Since in several tapeworm eggs the outer eggshell is smooth and becomes ruptured, the embryophore is the only cover to protect the larva (e.g., →*Taenia*, →*Echinococcus*).

Emetine

Alkaloid out of *Cephalis ipecacuana* being used against amoebiasis or as vomitory means.

Encephalitis

Inflammation of the brain. Often caused by the viral genus →Flavivirus (→Tick-Borne Encephalitis, →Russian Spring-Summer Encephalitis, →Powassan Encephalitis, →Colorado Tick Fever).

Encephalitozoon

Name
Greek: *en* = into, *kephale* = head, *zoon* = animal.

Classification
Genus of →Microspora.

Important Species
Table 1.

Life Cycle
Figs. 1, 2 (pages 450, 451).

Disease
→Encephalitozoonosis.

Encephalitozoon. Table 1 Important species of the genus *Encephalitazoon*

Species	Host	Habitat	Size of spore (µµm)	Geographic distribution
Encephalitozoon lacertae	Lizards (*Podarcis* sp.)	Epithelium of intestine	3.5 × 1.5	France
E. cuniculi	Rabbits, rats, mice *Mastomys* spp., guinea pigs, hamsters, goats, sheep, dogs, foxes, felids, mustelidae, monkeys, **humans**	Intestine + many organs; tissue cultures	2.5 × 1.5	Worldwide
E. helleri	**Humans** (AIDS)	Many organs	2.4 × 1.5	Worldwide
E. intestinalis	**Humans** (AIDS)	Many organs	2.0 × 1.5	Worldwide

Encephalitozoon cuniculi

→Encephalitozoonosis, →Nervous System Diseases, Carnivores, →Opportunistic Agents.

Encephalitozoonosis

Synonym

→Microsporidiosis, Encephalitozooniasis.

General Information

Encephalitozoonosis is a nervous system disease caused by the obligate intracellular microsporidian →*Encephalitozoon cuniculi*. The disease has been described in rodents, lagomorphs, primates, and several species of carnivores. Asymptomatic infection usually occurs in rodents and lagomorphs. In carnivores the neurological signs include repeated turning and circling movements, especially after disturbance, dysmetria, dysergia, →blindness, and a terminal semi-comatose state. Lesions described are →encephalitis and segmental →vasculitis. The course of the illness is usually 5–12 days. This parasite is also found in immunodeficient people as pathogen with a generalized spreading over many organs (→Opportunistic Agents).

Therapy

→Treatment of Opportunistic Agents, see also →Drugs Against Microsporidiosis.

Enchelys parasitica

→Ciliophora.

Encystation

Process found in many parasitic protozoans which involves formation of a →cyst wall either outside or inside the →cell membrane. Worm stages may also become encysted to survive inside or outside hosts.

Endectocides

→Arthropodicidal Drugs; →Ectoparasiticides.

Endemic Zone

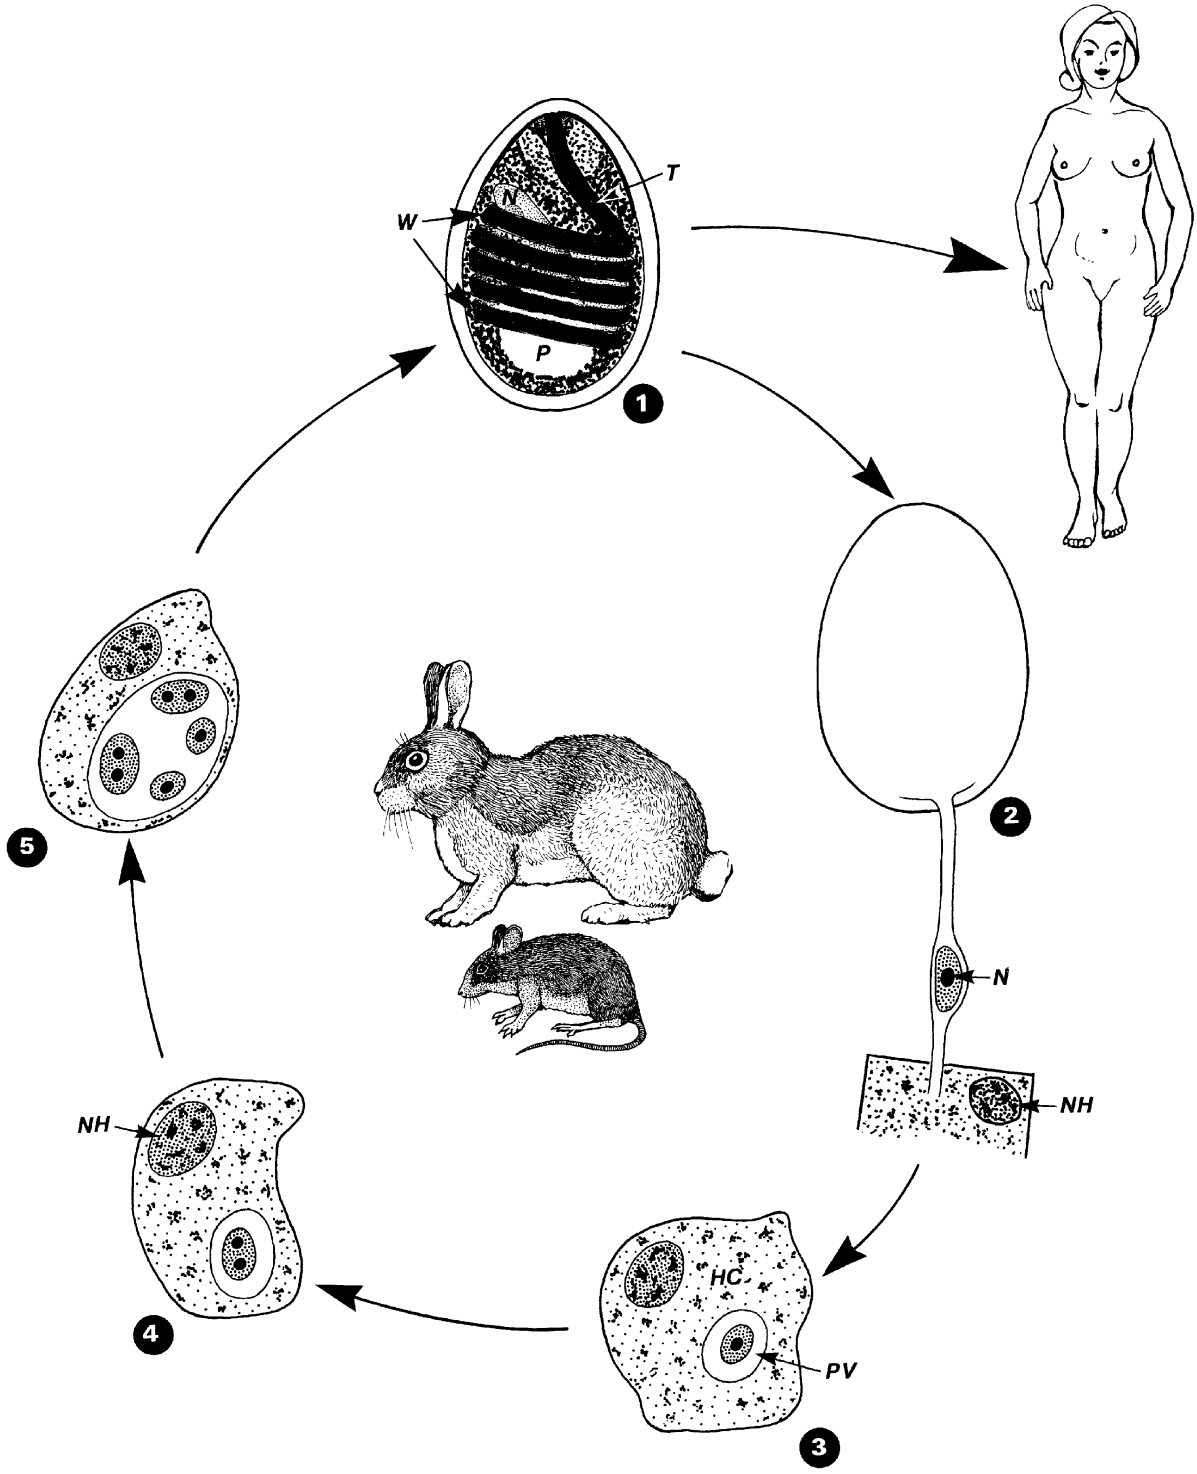
→Geographic Zones of Occurrence of Diseases: infections are always present.

Endemy

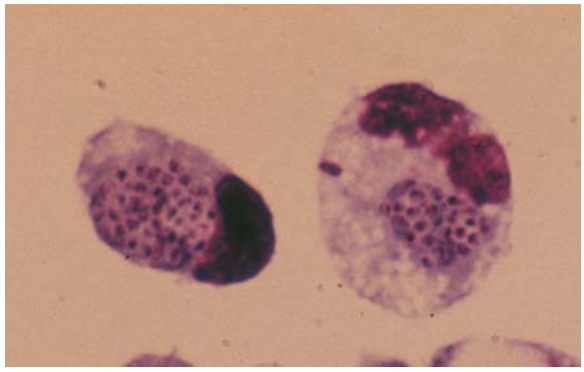
From *Greek*: endon = inside, demos = people. Persistent occurrence of parasites/agents of disease in a defined region.

Endocytosis

In addition to the direct transport of molecules through the →cell membrane (→Membrane Transport), other mechanisms exist for internalization of materials by cells. For example, relatively large organic materials may be internalized by endocytosis, i.e., by the formation of endocytotic vesicles. This process is termed →pinocytosis for the uptake of liquids and

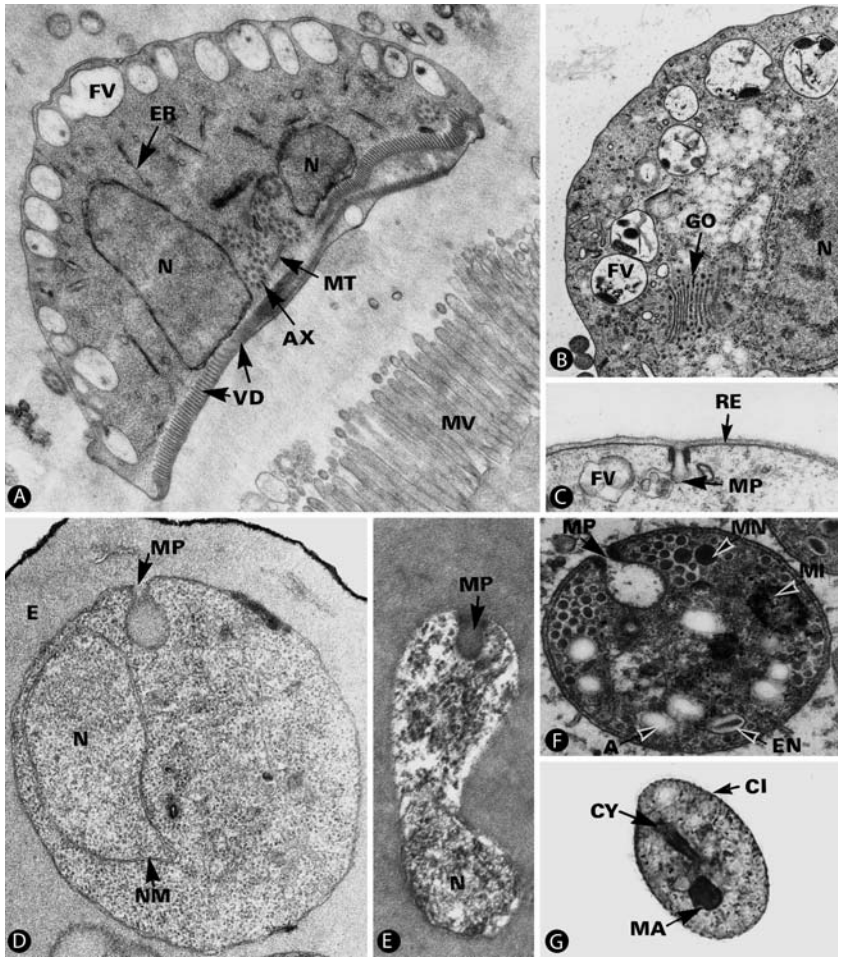


Encephalitozoon. Figure 1 Life cycle of →*Encephalitozoon cuniculi*, which may parasitize within a variety of hosts including immune depressive humans. *1* The infection of →AIDS patients occurs via oral uptake of →spores that derive from urine of animals (via contaminated food or via touching of furs). The mature uninuclear spore is characterized by 5 windings of the →polar tube (1) and the occurrence of a posterior vacuole (P). *2, 3* In human intestine the spore extrudes the polar tube being injected into a host cell. The uninuclear →sporoplasm creeps through the tube in the →cytoplasm of the host cell, where it is included within a →parasitophorous vacuole. *4, 5* Reproduction by repeated →binary fissions. The last binary fission (5) leads to 2 uninuclear →sporoblasts, which each grow up and differentiate into an infectious →cyst. The latter are freed when the host cell is used up and bursts. Thus these spores may become distributed in the whole body or set free in human stool. *HC*, host cell; *N*, nucleus; *NH*, nucleus of host cell; *P*, posterior vacuole; *W*, windings of the polar tube; *T*, →polar tube.

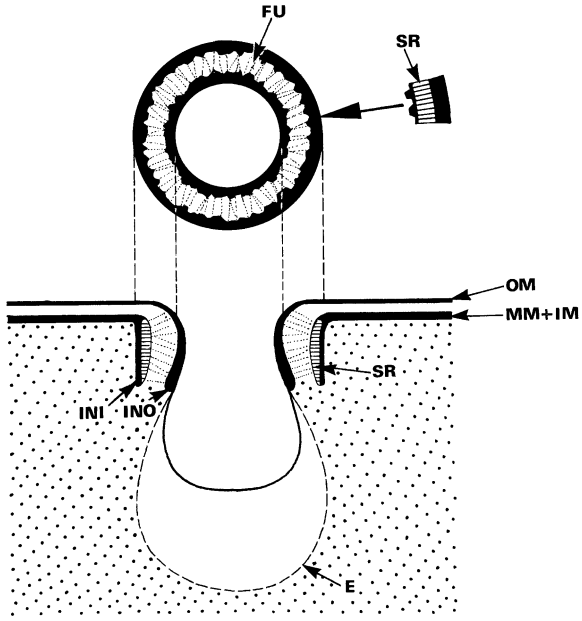


Encephalitozoon. Figure 2 Giemsa-stained blood smear showing enlarged human monocytes filles with large amounts of sporoblasts of *Encephalitozoon* sp. (courtesy Professor Dr. Heydorn, Berlin).

phagocytosis for the uptake of solid particles. Within the →vacuoles the material is degraded and then transported into the →cytoplasm by mechanisms similar to those used by the cell membrane. Alternatively, it may be released by dissolution of the membrane. Some →Protozoa have developed special places for the uptake of food, called cytostomes (Fig. 1). Endocytosis may occur at any point on the cell membrane (Fig. 1B) or is restricted to predisposed places. For example, in *Giardia* →trophozoites, endocytosis occurs only in the dorsal region, the region opposite the ventral sucker, which is the site of attachment (Fig. 1A); in trypanosomes, endocytosis occurs in the →flagellar pocket (→Pellicle/Fig. 2E); and in sporozoans it is found at small cytostomes called →micropores (Figs. 1C–F). While motile stages such



Endocytosis. Figure 1 A–G Transmission electron micrographs of feeding systems in protozoans. **A** Dorsal endocytosis in →*Giardia lamblia* (× 10,000). **B** General phagocytosis in →*Trichomonas vaginalis* (× 8,000). **C–E** Micropore in erythrocytic stages of →*Hepatozoon aegypti* (C × 7,000), →*Plasmodium falciparum* (D × 22,000), and →*Theileria annulata* (E × 44,000). **F** Micropore in a cross-sectioned cyst →merozoite of →*Besnoitia jellisoni* from mice. Acid phosphatase activity was shown in →mitochondria (× 25,000). **G** Cell mouth (→Cytostome) in a ciliate (× 500). *A*, →amylopectin; *AX*, →axoneme; *CI*, →cilia; *CY*, cytostome; *EN*, enigmatic body; *ER*, endoplasmic reticulum; *FV*, food vacuole; *GO*, →Golgi apparatus; *MA*, →macronucleus; *MI*, mitochondrion; *MN*, microneme; *MP*, micropore; *MT*, microtubule; *MV*, →microvilli of intestinal host cell; *N*, nucleus; *NM*, nuclear membrane; *RE*, remnants of erythrocyte; *VD*, →ventral disk.



Endocytosis. Figure 2 Diagrammatic representation of a sporozoan micropore in longitudinal and tangential sections. *E*, possible enlargement of the eytostomal invagination; *FU*, filamentous elements; *IM*, inner membrane of the →pellicle; *INI*, interruption of IM (forms outer ring in tangential section); *INO*, densification along the inner ring (formed by the invaginated outer membrane); *MM*, middle membrane of the pellicle; *OM*, outer membrane of the pellicle; *SR*, solid densification between IM and MM.

as merozoites and sporozoites possess only one micropore, gamonts, schizonts, and/or growing stages develop several such →cytostomes due to their need of a quick uptake of nutrients. Large endocytotic elements (cytostomes or cell mouths) are characteristic of many ciliates, too (Fig. 1G). Cytostomes may be reinforced by various structures, for instance by bundles of →microtubules in trypanosomes and ciliates or by cylinder-like structures in coccidians (Figs. 1C, 2). After the →phagosomes have entered the cytoplasm, the contents are digested and resorption of the necessary molecules occurs. The residue may be voided to the outside (→Exocytosis) or stored as an inclusion.

Many cells contain clathrin-coated pits that are involved in the receptor-mediated endocytosis of macromolecules, but our knowledge of →coated pits in Protozoa remains limited.

Endodyogeny

A peculiar longitudinal division of those →Coccidia (e.g., *Toxoplasma*, →*Sarcocystis*) that form →tissue-cysts (→Cell Multiplication).

Endolimax nana

→Amoebae.

Endoparasite

Organism living parasitically within another animal or man.

Endoparasites of Humans

Some important human endoparasites are listed in Table 1 (pages 453–459).

Endophagic

→Mosquitoes (e.g., *Anopheles gambiae*, the principal vector of →malaria in Africa) that bite predominantly indoors (rooms, buildings).

Endoplasm

The dense central part of the →cytoplasm which contains the cell organelles and the nucleus.

Endoplasmatic Reticulum

The endoplasmic reticulum (ER) is a large system of tubes and sacs that runs throughout the cell. It connects the perinuclear space with the cell interior and with the cell surface. There are 2 types of ER: rough ER (rER) and smooth ER (sER). The rER is characterized by the presence of →ribosomes (→Pellicle/Fig. 1B, →Trichomonadida/Fig. 1C) along its outer surface, whereas these are lacking in the sER. The rER and the sER may be interconnected.

Endoparasites of Humans. Table 1

Species	Human cases[1]	Stage used for diagnosis	Inter-human transmission[2]	Incubation period[3] (days)	Prepatency period[4] (weeks)	Patency (weeks)[5]	Prophylaxis[6]	Treatment[7]	Other/additional therapies[8]
Acanthamoeba spp.	Hundred thousands	Amoebae/ liquor	+	2–14	<1	<3 or lethal	No bathing in contaminated rivers/lakes	Amphotericin B + Sulfadiazine (or Tetracycline)	Keratitis: Neomycine, Clotrimazole
Acanthocheilonema (= Dipetalonema) perstans	50–60 million	Microfilariae	−	120	16–52	>52	Avoid bites of insects	Diethylcarbamazine	Antiallergical drugs
Ancylostoma duodenale	500 million	Eggs/feces	Free larvae +	14–28	5–7	~1000	Use of shoes	Albendazole, Mebendazole, Pyrantelpamoat	Antianaemic measurements
A. braziliensis, A. caninum	Many thousands	Migrating	Larvae	1–3	0	0	Use of shoes	Tiabendazole	?
Angiostrongylus cantonensis	Many thousands	Larvae/liquor	−	7–21	0 (no adults)	Larvae: months	No raw food	Tiabendazole	?
Angiostrongylus costaricensis	Many thousands	Eggs/biopsy of intestinal wall	−	1–4	3–4	>52	No raw snails	Tiabendazole, Ivermectin	?
Anisakis spp.	Thousands	Eggs/biopsy of intestinal wall	−	1 h - 7 d	0	Larvae: weeks	No raw fish	?	Surgical removal
Armillifer armillatus	Many thousands	Larvae/biopsy	−	?	0	0	Avoid feces of snakes	?	Surgical removal
Ascaris spp.	1.2 billions	Eggs/feces	+	4–7	6–11	>52	Avoid green salad, feces of pigs	Mebendazole, Abendazole	?
Babesia spp.	Some thousands	Merozoites/ blood smear	−	5–28	1	50	Avoid tick bites	Clindamycine, Chinine	Blood exchange
Balantidum coli	Many thousands	Veg. stages/ feces	+	4–14	<1	>20	Avoid pig feces	Metronidazole, Nitroimidazoles	Tetracyclines, Paronomycine
Blastocystis hominis	30–40 million	Cysts/veg. stages	+	1–3 ?	<1	2–3	Avoid feces	Metronidazole, Cotrimoxazole	Substitution of electrolytes
Brugia malayi, B. timori	100 million	Microfilariae/ blood	−	84–400	52	1000	Avoid bites of mosquitoes	Macro- + Microfilariae: Diethylcarbamazine	Antiallergical drugs
Capillaria hepatica	Few	Eggs/liver biopsy	−	?	?	Larvae: 50–100	Avoid green salad	Tiabendazole	?
Capillaria philippinensis	Thousands	Eggs/larvae/ feces	+	?	?	?	Avoid green salad	Mebendazole, Tiabendazole	?

Endoparasites of Humans. Table 1 (Continued)

Species	Human cases[1]	Stage used for diagnosis	Inter-human transmission[2]	Incubation period[3] (days)	Prepatency period[4] (weeks)	Patency (weeks)[5]	Prophylaxis[6]	Treatment[7]	Other/additional therapies[8]
Cercarial-dermatitis	Hundred thousands	Cercariae/skin	−	Minutes	0	0	No bath in contaminated water	Antiallergical compounds	?
Clonorchis sinensis	30–30 million	Eggs/feces	−	14	2–3	∼1000	Avoid raw fish	Praziquantel	?
Creeping eruption	Many thousands	Migrating/ larvae/biopsy	−	1–3	Larvae: weeks	Larvae: weeks	?	Tiabendazole	Icing, surgical removal
Cryptosporidium spp.	Hundred thousands	Oocysts/feces	+	1–12	2–4	1–2 up to 52	Avoid feces	?	Substitution of electrolytes
Cyclospora spp.	Thousands	Oocysts/feces	+	2–7	1	2–9	Avoid human feces	Cotrimoxazole	?
Cysticercus cellulosae	Hundred thousands	Cysticercus/ serology/CT	Eggs of adult tapeworm	70–90	0	0	Avoid human feces	Praziquantel, Albendazole	Symptomatical; mechanical remove
Dermodex folliculorum	Many millions	Skin probe	+	14	2	Years	Avoid contact to infected animals	Hexachlorcyclohexan; Crotamiton (10%), Neem	Symptomatical therapy
Dicrocoelium dendriticum	Thousands	Egg/feces	−	14–28	7–8	>250	Avoid unwashed green salad	Praziquantel	?
Dioctophyme renale	Few thousands	Egg/urine	−	30	12–24	150	Avoid raw fish	?	Mechanical removal
Diptalonema perstans	50–60 million	Microfilariae/ blood	−	120	>36	>52	Avoid bites of insects	Diethylcarbamazine	Antiallergical compounds
Diptalonema streptocerca	4–10 million	Microfilariae/ skin	−	120	>52	>52	Avoid bites of insects	Diethylcarbamazine	Antiallergical compounds
Diphyllobothrium latum	13–5 million	Proglottids/ eggs/feces	−	>21	3	520	Avoid raw fish	Niclosamide, Praziquantel	Substitution of vitamines
Dipylidium caninum	Many thousands	Proglottids/ feces	−	10–21	2–3	52	Avoid fleas	Niclosamide, Praziquantel	Protect pets against fleas
Dirofilaria spp.	Thousands	Larvae/biopsy	−	90–270	28	Larvae: years	Avoid bites of insects	Diethylcarbamazine	Surgical removal
Dracunculus medinensis	10 million	Adult worm/ skin	−	90–200	40–56	♀ dies days after excretion of larvae	Avoid uncooked water	Mebendazole, Tiabendazole	Remove worm from skin
Echinococcus granulosus	Hundred thousands	Cyst/CT/ biopsy	−	>360	Years	Years	Avoid dog feces	Mebendazole, Albendazole	Surgical removal of cyst

Echinococcus multilocularis	Thousands	Cyst/CT	−	>360	Years	Years	Avoid fox, dog feces	Mebendazole, Albendazole	Do not touch the cyst
Echinostoma ilocanum	Thousands	Egg/feces	−	?	3	?	Avoid uncooked snails	Praziquantel	?
Encephalitozoon cuniculi	Hundred thousands	Spore/urine	+	7	?	?	Avoid human urine	Cloroquine, Oxytetracycline, Albendazole	?
Entamoeba histolytica (a) Intestinal stages	400–500 million	Cyst/feces	+	2–21	>1	Years	Avoid any uncooked food/ human feces	Diloxanide furoate, Nimorazol, Paromomycin, 8-Hydroxychinoline	Antibiotica (Tetrazyklines, Erythromycine)
(b) Tissue stages		Amoebom/ biopsy/CT/ endoscopy/ sonography	−	2–28, up to years	1–2	Years/ recidives		Metronidazole, Tinidazole, Ornidazole, Dehydroemetin	Remove fluid from the liver abscess
Enterobius vermicularis	1.2 billions	Eggs/anal grove	+	7–28	4–5	9–12	Clean anal region	Mebendazole, Albendazole, Pyrantelpamoat	Repeat treatment at least 2 times in 3 weeks intervals
Enterozytozoon bieneusi	Thousands	Spore/feces	+	7	1	20	Avoid human feces	Albendazole	?
Enteromonas hominis	200 million	Veg. stages/ feces	+	?	?	?	Avoid feces	Not needed	?
Fannia-species (flies)	Thousands	Larvae/urine	−	−	0	0	Keep skin clean	Mechanical remove	Clean urine bladder
Fasciola hepatica	Thousands	Egg/feces	−	21–90	8–13	>250	Avoid eating plants from cow meadow	Dehydrometin, Praziquantel	?
Fasciolopsis buski	15–20 million	Egg/feces	−	21–90	9–14	>250	Avoid eating of chest nuts	Niclosamide, Praziquantel	?
Fly larvae	Hundred thousands	Larvae/biopsy	−	2–10	0	0	Keep skin clean	Mechanical removal	Use antibiotics
Gastrodiscoides hominis	Thousands	Egg/feces	−	21–90	9–14	>250	Avoid eating waterplants	Niclosamide, Praziquantel	?
Giardia lamblia	450 million	Cyst/feces	+	3–21	3–4	Years	Avoid human/dog feces	Tinidazole, Metronidazole, Ornidazole, Nimrorazole	Reduce uptake of carbohydrates
Gnathostoma spinigerum	Thousands	Larvae/biopsy	−	?	0	100	Avoid raw fish	Albendazole	Corticosteroids

Endoparasites of Humans. Table 1 (Continued)

Species	Human cases[1]	Stage used for diagnosis	Inter-human transmission[2]	Incubation period[3] (days)	Prepatency period[4] (weeks)	Patency (weeks)[5]	Prophylaxis[6]	Treatment[7]	Other/additional therapies[8]
Haemonchus spp.	Few	Egg/feces	+ via free larvae	28–35	12–24	>52	Avoid contaminated plants	Tiabendazole, Mebendazole, Albendazole	?
Hartmannella spp.	see Acanthamoeba (= synonym)								
Heterophyes heterophyes	10 million	Egg/feces	−	7–21	1–3	24–40	Avoid raw fish	Praziquantel	?
Hymenolepis diminuta	Thousands	Eggs/ proglottids/ feces	−	7–14	2	8–12	Avoid larvae in beetles	Niclosamide, Praziquantel	?
Hymenolepis nana	75 million	Eggs/ proglottids/ feces	+	7–28	4	2–50	Avoid self-infection	Niclosamide, Praziquantel	?
Isospora belli	Hundred thousands	Oocyst/feces	+	2–13	1	4–7	Avoid human feces	Sulfonamids	?
Lamblia (= Giardia) intestinalis	Old name for *Giardia lamblia*								
Leishmania braziliensis	10–15 million	Veg. stage/ skin smear	−	14–21 up to 1 year	1	Years	Avoid bites of sand flies	Amphotericin B, Antimon-V-compounds, Metronidazole, Pentamidine	Antibiotics, Sulfonamids
Leishmania donovani, L. chagasi, L. Infantum	20–40 million	Veg. stage/ smear	−	10–120	1–3	>52	Avoid bites of sand flies	Pentamidin, Antimon-V-compounds, Diamidine	Support immune system
Leishmania tropica-group	60 million	Veg. stage/ skin scrape	−	14–21	1–3	40	Avoid bites of sand flies	Natriumstibogluconate	Antibiotics, Sulfonamids
Linguatula serrata	Few	(a) Egg/saliva (b) Larvae/ biopsy	+ (eggs)	a/b 5–10	(a) 3 at ♀ (b) 0 at larvae	(a) 50–100 at ♀ (b) 0 at larvae	Avoid raw meat	?	Mechanical removal
Loa loa	40 million	Microfilariae/ blood	−	60–360	52–200	17 years	Avoid bites of tabanids	Diethylcarbamazine	Mechanical removal of adults.
Macaracanthorhynchus hirudinaceus	Many hundred thousands	Larvae/ intestinal biopsy	−	14–80	0	No adults	Do not eat raw insects	Loperamid	Surgical removal

Malaria-agents	see *Plasmodium* spp.								
Mansonella-species	see *Dipetalonema* spp.								
Mansonella ozzardi	12–15 million	Mikrofilariae/ blood	−	?	?	?	Avoid bites of insects	Diethylcarbamazine	
Metagonismus yokogawai	Hundred thousands	Egg/feces	−	?	?	?	Avoid raw fish	Praziquantel	
Metorchis conjunctus	Thousands	Egg/feces	−	?	4–5	250	Avoid raw fish	Praziquantel	
Microsporidia	see *Encephalitozoon* sp. and *Enterocytozoon bieneusi*								
Myiasis-agents (fly larvae)	Hundred thousands	Larvae/biopsy	−	10–14	Larvae: 5–10	Larvae: 5–10	Use of repellents	Subcutaneously: symptomatical Eye: 1% Mintacol	Mechanical removal
Nanophyetus salmincola	Few thousands	Egg/feces	−	6–10	1–2	>50	Avoid raw fish	Praziquantel	?
Naegleria spp.	Thousands	Amoebae/ liquor	−	2–7	>1	>3, possibly lethal	Avoid bath in contaminated water	Amphotericin B + Sulfonamids + Tetracyclines	?
Necator americanus	500 million	Egg/feces	− (free larvae)	14–28	4–17	∼1000	Use shoes	Albendazole, Mebendazole, Parantelpamoat	Antianaemic treatment
Oesophago-stomum spp.	Few	Egg/feces	+/+ (free larvae)	5–7	5–8	>52	Avoid raw food	Tiabendazole	?
Oestrus ovis	Thousands	Larvae/biopsy	−	−	0	0		Subcutaneously: symptomatical therapy Eye: Mintacol (1%)	Extraction
Onchocerca volvulus	40–45 million	Microfilariae/ skin	−	90–120	36	∼750	Avoid bites of simulids	Ivermectin, Diethylcarbamazine	Removal of nodules
Opisthorchis felineus	1–2 million	Egg/feces	−	14	2–3	>250	Avoid raw fish	Praziquantel	?
Opisthorchis viverrini	2–5 million	Egg/feces	−	14	2–3	>250	Avoid raw fish	Praziquantel	?
Paragonimus spp.	30 million	Eggs/saliva	−	63–84	12	∼1000	Avoid raw crabs	Praziquantel	?
Philophthalmus spp.	Few thousands	Adult worms/ eye	−	?	?		?		Surgical removal
Plasmodium falciparum	200–300 million	Gamonts/ rings/blood smear	− (blood transfer)	8–24	5 days	50	Chemoprophylaxis and use of repellents	Compounds according to countries	Symptomatical therapy
P. malariae		Schizont/ blood smear	−	20–40	13–16 days	∼1000			
P. ovale		Schizont/ blood smear	−	10–15	8 days	∼200			
P. vivax		Schizont/ blood smear	−	9–16	8 days	250			

Endoparasites of Humans. Table 1 (Continued)

Species	Human cases[1]	Stage used for diagnosis	Inter-human transmission[2]	Incubation period[3] (days)	Prepatency period[4] (weeks)	Patency (weeks)[5]	Prophylaxis[6]	Treatment[7]	Other/additional therapies[8]
Plerocercoids (Spargana)	Thousands	Larvae/biopsy	−	?	0	0	Avoid raw fish and uncooked water	Praziquantel, Cotrimoxazole	Surgical removal
Pneumocystis carinii	Acute: hundred thousands latent: 400 million	Cysts/saliva	+	7	1	Years	Avoid feces	Pentamidin-Isothionate, Trimethonrim + Sulfonamids	Symptomatical therapy
Sarcocystis spp. • Intestine • Tissue	Hundred thousands Few	Sporocysts/ feces Tissue cysts	− −	4–8 hours ?	5–10 days ?	6–18 1 year	Avoid raw meat ?	Sulfonamids ?	Substitution of electrolytes ?
Sarcoptes scabiei	5–10 million	Mite in skin + scrape	+	7	2	>250	Avoid contact with hosts/unproper clothes/beds	Hexachlorcyclohexan, Crotamiton, Neem extracts	Symptomatical therapy
Schistosoma haematobium	100 million	Egg/urine	−	28–600	10–12	>750	Do not bathe in contaminated rivers and lakes	Praziquantel	Use shoes in field work
S. intercalatum	Hundred thousands	Egg/feces	−	28–49	5–8	>250

Endospore

Inner layer of spore wall in microsporidians.

Endosulfan

Chemical Class

Organohalogenide (organochlorine compound, cyclodiene).

Mode of Action

GABA-gated chloride channel antagonist. →Ecto-parasiticides – Antagonists and Modulators of Chloride Channels.

Endotrypanum

E. schaudinni and *E. monterogeii* are parasites of Neotropical tree sloths being transmitted by phlebotomids. These species are unique among →Trypanosomatidae in that they enter the erythrocytes of their vertebrate hosts.

Endozoites

→Bradyzoites, →Tachyzoites.

Energetic Trade-Off

→Behavior.

Energy Metabolism

Synonym

Bioenergetics.

General Information

The generation of chemical energy for the cell (usually in the form of ATP) can be accomplished by either aerobic or anaerobic strategies. Aerobic generation of energy is defined as the complete oxidation of substrates to carbon dioxide and water via the combined action of the tricarboxylic acid (TCA) cycle and a mitochondrial respiratory chain. In this pathway, in which oxygen acts as the final electron acceptor to reoxidize reduced coenzymes, the major portion of ATP is produced by a process known as oxidative phosphorylation. In parasitic protozoa and helminths, the occurrence of this conventional type of energy metabolism is rather limited. It is mainly the free-living and some larval stages of helminths that are supposed to possess a functional TCA cycle and an aerobic mitochondrial respiratory system. A special category of organisms are the trypanosomatids, such as the bloodstream form of *Trypanosoma brucei*, whose energy metabolism is dependent on a plantlike alternative terminal oxidase. These organisms use oxygen as terminal electron acceptor, but this oxidative process via the alternative oxidase is not coupled to phosphorylation. Most parasites use, in the stages inside their hosts some kind of fermentation process for the production of ATP. Fermentations are defined as energy generating processes that produce their own oxidants to balance the production and consumption of coenzymes (NADH) without the use of oxygen as final electron acceptor. In some cases, this strategy is linked to an electron transport chain and oxidative phosphorylation (anaerobic "respiration"). Suitable substrates for fermentations are carbohydrates, because both oxidation and reduction of these compounds can occur, which is not possible using fatty acids as substrate. During lactate or ethanol producing fermentations these redox reactions are accomplished in the linear process of glycolysis. An alternative strategy, which is widely found in helminths involves a branched pathway (malate dismutation), in which a portion of the substrate is oxidized while another portion is reduced. Fermentations are widespread in endoparasites and are the sole or major ATP-producing routes in many protozoan and adult helminth parasites.

In all living cells, nutrient molecules are broken down to provide the energy required for the generation of ATP. This ATP can be synthesized from ADP via 2 basically different processes: substrate-level phosphorylation and oxidative phosphorylation. Substrate-level phosphorylation is the formation of ATP by the

direct phosphorylation of ADP via the transfer of a phosphoryl group from a high-energy intermediate to ADP. Oxidative phosphorylation is the process in which ATP is formed when electrons are transferred from the reduced coenzymes NADH or $FADH_2$ to oxygen via a series of electron carriers that make up the mitochondrial electron transport chain (also called respiratory chain). NADH and $FADH_2$ (produced in glycolysis, fatty acid oxidation, and the TCA cycle, from NAD^+ and FAD, respectively) are energy-rich compounds. They contain high-energy electrons obtained from metabolic intermediates. Transfer of these electrons from the reduced coenzymes to oxygen releases a large amount of free-energy that can be used to produce ATP. The transport of electrons through the electron transport chain leads to the pumping of protons across the mitochondrial inner membrane by 3 electron-driven proton pumps: NADH-ubiquinone reductase (Complex I), cytochrome reductase (Complex III), and cytochrome oxidase (Complex IV). The resulting proton gradient across the inner mitochondrial membrane is then used for the generation of ATP when electrons flow back into the mitochondrial matrix via ATP synthase. Oxidative phosphorylation provides most of the energy in aerobically functioning parasites, but is also connected to malate dismutation, the anaerobic fermentation variant operative in most adult helminths, where instead of oxygen, fumarate acts as terminal electron acceptor of the electron transport chain.

Inhibitors of the electron transport chain are often used to study the energy metabolism of parasites. These compounds bind to a component of the chain and block the flow of electrons, which results in a decreased ATP production, as electron transport and energy production are tightly coupled. Examples of frequently used inhibitors are: rotenone and amytal (inhibitors of Complex I), antimycin A (an inhibitor of electron flow through Complex III), and cyanide, azide, or carbon monoxide (inhibitors of Complex IV). Oligomycin and other unrelated compounds block the proton channel of the ATP-synthase, thereby directly inhibiting ATP synthesis. As some components of the electron-transport chain in parasites are often structurally slightly different from those in their hosts, the electron transport chain is also a suitable target of antiparasitic drugs. The antimalarial drug atovaquone, for instance, acts on complex III of the electron transport chain of *Plasmodium*; ascofuranone is a potent inhibitor of the alternative oxidase of trypanosomes, and nafuredin shows selective inhibition of complex I in helminth mitochondria.

In the energy metabolism of endoparasites, several biochemical reactions exist which have either no parallel in other eukaryotes or are a result of a modification of rather universal pathways. The energy metabolism of endoparasites is a fascinating and extensively studied research area of parasite biochemistry. Its vital function and divergence from that of their hosts makes the energy metabolism of parasites an interesting target for antiparasitic drug design.

Closely related to bioenergetics is the function of molecular oxygen in living organisms. Most of the oxygen consumed by animal cells is utilized by the cytochrome oxidase-linked mitochondrial respiration. In many parasitic protozoa and helminths this metabolic capability often does not exist or is considerably reduced. On the other hand, many endoparasites unequivocally have an aerobic requirement, if not for energy generation, then for specialized oxidative reactions such as eggshell tanning in helminths. These other functions of oxygen vary greatly between different species and their developmental stages, and have not yet been very well studied.

Adaptations

The major functions of the metabolism of animals are (1) to catabolize organic substances and to couple these processes to the conservation of chemical energy; (2) to assemble distinct, low-molecular weight precursors that are derived either directly from external sources or via metabolic interconversion of absorbed nutrient molecules into species-specific polymeric components (nucleic acids, proteins, polysaccharides, and lipids); and (3) to form and degrade the biomolecules required in specialized functions. Endoparasites are no exception to this universal concept but obviously, as a consequence of their parasitic way of life, they have evolved a variety of specific modifications, extensions, or simplifications to the metabolic pattern observed in most other forms of life.

As in many habitats, the major nutritional requirements for parasites are supplied by the host. Many synthetic pathways in parasites were abandoned during their evolution. These reduced biosynthetic capabilities have resulted in the elaboration of efficient mechanisms for substrate absorption and in specific pathways for interconversion and modification of substrate molecules. Additional features relate to the sophisticated adaptive mechanisms which enable parasites to evade the host's immune response and other defense systems. In many cases, unique metabolic structures and processes are maintained by parasites to cope with the extreme physical and chemical conditions often prevailing within their host environments. Still other metabolic peculiarities may be related to the distinct morphological organization of parasites, such as the lack of a circulatory system in helminths or the absence of a digestive tract in cestodes. Next to the adaptations in metabolism related to their opportunistic way of living as a parasite, helminths show a second type of

adaptations, i.e., those connected to the environmental changes that occur in their life cycle. During their complex developmental cycles, these organisms live alternating periods as free-living and parasitic stages. Usually, the free-living stages cannot obtain substrates from the environment. They have to live on the endogenous reserves that they obtained in their previous host. In the environment of parasitic stages, on the other hand, substrates are plentiful, and their only concern is to produce offspring and avoid being destroyed by the host's immune system. These changes in the environmental conditions are accompanied by metabolic adaptations. Unusual adaptive processes are found particularly in the strategies of energy metabolism, in the various routes of purine and pyrimidine salvage, and in the synthesis of numerous other molecular structures serving specialized functions.

Kinetoplastid Flagellates

The energy metabolism of kinetoplastid flagellates is better characterized than that of any other group of protozoan parasites. Most of the knowledge of the bioenergetics in these organisms has derived from studies on *Trypanosoma brucei, T. cruzi*, and a few *Leishmania* spp. This work has uncovered a variety of metabolic properties unique to the kinetoplastids, although large differences in metabolism also exist between the different species and stages of these organisms.

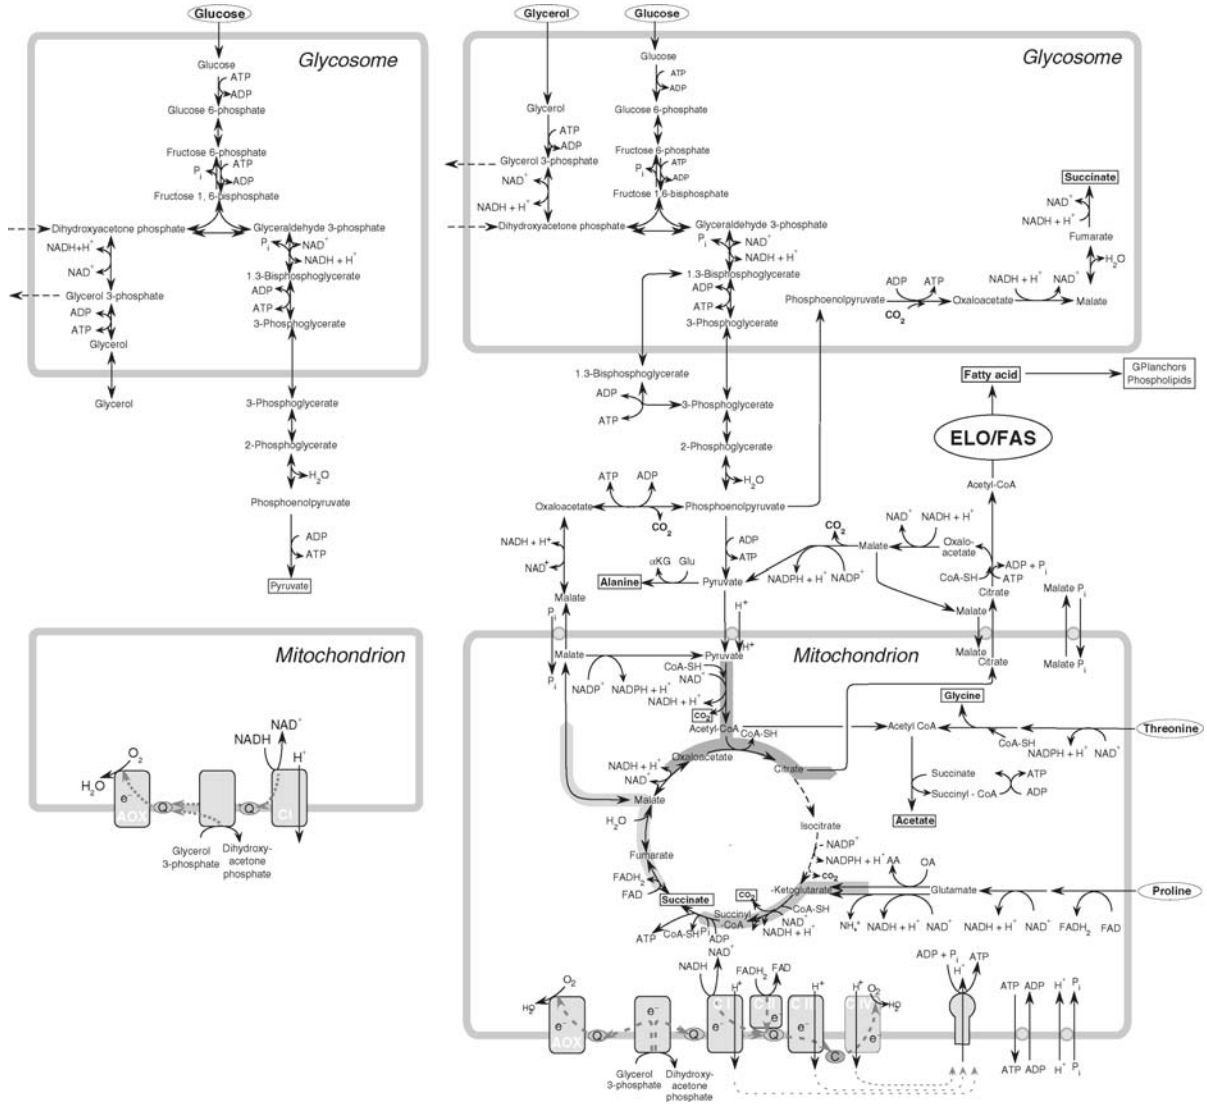
The long slender bloodstream trypomastigotes of *T. brucei* rely entirely on glycolysis for their energy production, with pyruvate being the sole end product (Fig. 1). In this pathway one molecule of glucose is converted to 2 molecules of pyruvate with a net synthesis of 2 molecules of ATP. Glucose is first degraded to 3-phosphoglycerate within membrane-bounded microbody-like organelles, called glycosomes, that are unique to the order Kinetoplastida. The 3-phosphoglycerate formed is then further degraded in the cytosol to pyruvate. Unlike in anaerobic lactate fermentation, in which the reducing equivalents generated by glyceraldehyde 3-phosphate oxidation are finally transferred to pyruvate (resulting in the formation of lactate), in *T. brucei* molecular oxygen serves as terminal electron acceptor, resulting in the formation of water as catalyzed by a plantlike alternative oxidase that is present in the inner membrane of the trypanosome's single mitochondrion (Fig. 1).

All of the glycolytic enzymes necessary to convert glucose into 3-phosphoglycerate are localized within the glycosomes (Fig. 1). These organelles, that are related to the peroxisomes in other eukaryotes, are unique to the trypanosomatid flagellates, such as *Trypanosoma*, *Leishmania*, *Phytomonas* and *Crithidia*. Glycosomes are bounded by a single membrane, extremely homogeneous in size, measure about 0.3 μm in diameter and represent more than 4% of the total cell volume. In *T. brucei*, more than 200 glycosomes are present per organism while in other genera these organelles are not as abundant.

The possible functional advantage of the extreme subcellular compartmentation and enzyme association within the trypanosome cell is still debated. About 90% of the glycosomal protein content consists of glycolytic enzymes which appear to be in close association. Originally it was suggested that compartmentalization of glycolysis in the glycosome enables the parasite to sustain its high rate of glycolysis because of the high concentration of substrates and enzymes which provided some kind of channeling in the pathway. There is, however, no experimental evidence for metabolite channeling in trypanosomes. Furthermore, calculations performed during modelling of glycolysis in bloodstream trypanosomes indicated that compartmentation of the enzymes in glycosomes is not necessary to obtain the observed glycolytic flux. Even if the glycolytic enzymes were not sequestered in a single compartment, diffusion should not be controlling the glycolytic flux in *T. brucei*. In addition, *T. brucei* indeed has a fairly high glycolytic flux when compared to mammalian tissues, but similar and even higher fluxes are also observed in other microorganisms, which do not possess glycosomes. Furthermore, all kinetoplastids possess glycosomes, including those that are not solely dependent on glycolysis for energy generation. Recent kinetic modelling suggested that concentrating the enzymes in glycosomes protects the trypanosome from phosphate depletion or osmotic shock caused by an unrestricted accumulation of sugar phosphates, and that it protects the cell from a failure to recover from glucose deprivation. Glycosomal metabolism is also involved in CO_2 fixation and in the biosynthesis of purine and pyrimidine nucleotides and ether-lipids.

Under anaerobic conditions, bloodstream trypomastigotes convert glucose to equimolar amounts of pyruvate and glycerol (Fig. 1). Under these circumstances, high concentrations of glycerol 3-phosphate and ADP are expected to accumulate inside the glycosomes. This allows the glycerol kinase (which is present in extremely high specific activities in trypanosomes capable of producing glycerol under anaerobiosis) to proceed in the unusual direction of ATP formation. As shown in Fig. 1, anaerobic glycolysis yields 1 ATP per glucose, via pyruvate kinase, but this is apparently not sufficient for growth. Incubation of bloodstream form *T. brucei* under anaerobic conditions leads to cell death, while attempts to knock out the alternative oxidase were unsuccessful and a 95% depletion of the alternative oxidase by RNAi led to a serious growth defect.

Transformation of bloodstream form *T. brucei* into the procyclic insect stage is accompanied by striking



Energy Metabolism. Figure 1 Schematic representation of pathways involved in carbohydrate and amino acid metabolism in bloodstream (left panel) and procyclic (right panel) form *Trypanosoma brucei*. Substrates are shown in ovals and end products in boxes. The shaded broad arrows in the background of the TCA-cycle represent functions of those parts of the cycle that are active in procyclic forms. The dark-shaded arrow indicates the flux from pyruvate and oxaloacetate to citrate in the transport of acetyl-CoA units from the mitochondrion to the cytosol, the intermediate shaded one represents that part of the cycle that is used for the degradation of proline and glutamate to succinate, whereas the lightly shaded one indicates the part of the cycle that is used during glyconeogenesis. Of the glycerol-3-phosphate shuttle only the components are shown and the travel of dihydroxyacetonephosphate and glycerol-3-phosphate between the glycosomes and the mitochondrion is not shown. *AA*, amino acid; *AOX*, plantlike alternative oxidase; *CI*, *II*, *III*, and *IV*, complex I, II, III, and IV of the respiratory chain; *c*, cytochrome c; *FAS*, fatty-acyl synthesis; *Glu*, glutamate; *α-KG*, α-ketoglutarate; *OA*, oxoacid; *PPP*, pentose phosphate pathway; *Q*, ubiquinone.

changes in energy metabolism (Fig. 1). Upon transformation into the procyclic insect stage, the glycosomal metabolism is extended, and part of the produced phosphoenolpyruvate is imported from the cytosol and subsequently converted into succinate via phosphoenolpyruvate carboxykinase, malate dehydrogenase, fumarase, and a soluble glycosomal NADH:fumarate reductase. Furthermore, in this procyclic insect stage the end product of glycolysis, pyruvate, is not excreted but is further metabolized inside the mitochondrion, in which it is mainly degraded to acetate. Acetate production occurs by acetate:succinate CoA-transferase

and involves a succinate/succinyl-CoA cycle that generates extra ATP. Surprisingly, under all conditions studied so far, the TCA cycle does not function as a cycle in procyclic *T. brucei* for the complete oxidation of acetyl-CoA to carbon dioxide. It was shown that parts of the TCA-cycle machinery are used in other processes, such as partial degradation of amino acids, but also for biosynthetic purposes, such as fatty acid biosynthesis and gluconeogenesis (Fig. 1). In addition to carbohydrate degradation amino acids, mainly proline and threonine, are thus important substrates for the production of ATP in procyclic insect stage *T. brucei*. Utilization of amino acids correlates well with the change in the trypanosome's environment. Under resting conditions, proline is present in tsetse hemolymph in excessively high concentrations, and the midgut of the fly is deficient in carbohydrates but rich in amino acids and peptides.

The reducing equivalents (NADH), generated by substrate oxidation, are in all trypanosomatids delivered to a respiratory chain that uses oxygen as the final electron acceptor, but essential differences in respiratory chains exist among the various species and developmental stages. The long-slender bloodstream stage of *T. brucei* lacks cytochromes and a classical respiratory chain, but contains instead a plantlike alternative oxidase. Reducing equivalents produced in the glycosomes are transferred to the mitochondrion via the classical mammalian-type glycerol 3-phosphate/dihydroxyacetone phosphate shuttle (Fig. 1). The mitochondrial FAD-linked glycerol-3-phosphate dehydrogenase donates electrons to the ubiquinone/ubiquinol pool, and the reduced ubiquinol is then the electron donor for the alternative oxidase. This process of electron transfer via the alternative oxidase is not linked to ATP production, does not involve cytochromes, is insensitive to cyanide and antiycin A, but is susceptible to inhibition by aromatic hydroxamic acids like salicylhydroxamate (SHAM) and the antifungal agents ascofuranone and miconazole.

The procyclic insect stages of trypanosomes, in contrast, possess not only the alternative oxidase system, but also a classical, cyanide-sensitive cytochrome-containing respiratory chain, coupled to oxidative phosphorylation (Fig. 1). Apart from complex I, this part of the respiratory chain of trypanosomatids strongly resembles the mammalian type respiratory chain, as no dissimilarities have been found yet. It is unknown yet, what physiological advantage the multiple oxidase assembly may offer to trypanosomes. Under the conditions of the midgut of the tsetse fly where oxygen concentrations are low, expression of the alternative oxidase system would be downregulated, but the cytochrome aa_3-linked respiratory chain would be induced and become functionally operative. As the latter system is coupled to oxidative phosphorylation, the economic efficiency of the overall energy generating metabolism of procyclic trypanosome stages would by far exceed that of the bloodstream forms. This would well reflect the environmental transition from the vertebrate blood with its abundant supply of nutrients and oxygen to the insect midgut, where limited substrate and oxygen concentrations may have forced the parasite to develop a more efficiently functioning and versatile energy-generating system. Intermediate and short stumpy bloodstream forms of *T. brucei* have better-developed mitochondria than the long-slender forms and are not dependent only on glycolysis for energy generation. Apparently, the transition in energy metabolism between the glycolysis-dependent long-slender form and the mitochondrion-dependent procyclics occurs already in the bloodstream. The transitional bloodstream forms are thus pre-adapted to functioning in the insect vector if ingested with a blood meal. Substrate availability and/or energy metabolism seem to have a function in the induction of differentiation processes during the trypanosomal life cycle, but the underlying mechanisms are not yet fully understood.

The substrates and metabolic pathways utilized for energy generation by other kinetoplastids are similar to those observed in the procyclic culture forms of *T. brucei*. The differences in energy metabolism between the two main morphological forms of *Leishmania* spp. are less pronounced than those of *T. brucei*. The glycolytic enzymes are present in glycosomes, and the cristate mitochondria of *Leishmania* possess TCA-cycle enzymes and a cytochrome-oxidase-linked respiratory chain, just like *T. brucei*. The relative importance of carbohydrates and amino acids as an energy source is not completely clear, however, and may vary with the stages, species, and phase of growth.

Leishmania promastigotes have an energy metabolism in which a small part of the carbohydrate is completely oxidized to carbon dioxide via the TCA cycle, but in which large amounts of partly oxidized products, like acetate, pyruvate and succinate, are also produced as end-products of glucose metabolism. A small part of the pyruvate is transaminated to alanine, which is then excreted. In *Leishmania* promastigotes, the partly oxidized end products are the result of an aerobic metabolism involving an electron-transport chain, with oxygen as final electron acceptor, as in procyclic trypanosomes. *Leishmania* promastigotes, like the insect stage of *T. brucei*, have a classical respiratory chain but lack the alternative oxidase that is present in the other Trypanosomatidae. *Leishmania* promastigotes are strongly dependent on this classical respiratory chain for their energy generation, which is in agreement with the observation that *Leishmania* promastigotes possess an energy metabolism in which

most of the carbohydrate is degraded to partially oxidized end products, a process concomitantly producing NADH that is reoxidized by the respiratory chain.

Leishmania amastigotes most likely have an energy metabolism very similar to that of the promastigotes, both stages being dependent on TCA-cycle activity and a mammalian-type respiratory chain, although fatty acids probably are a more important substrate in the insect stage, at least in *L. mexicana*. This would correlate with the nutritional conditions of their intracellular habitat, the macrophage, in which a sufficient supply of lipids is likely to be available.

The energy metabolism *of T. cruzi* strongly resembles that of *Leishmania*, i.e., all stages of this parasite possess TCA-cycle activity and a mammalian-type respiratory chain linked to the generation of ATP. However, like *Leishmania*, *T. cruzi* catabolizes glucose only partially to carbon dioxide and produces, in addition, various organic compounds as metabolic end products, including acetate and succinate.

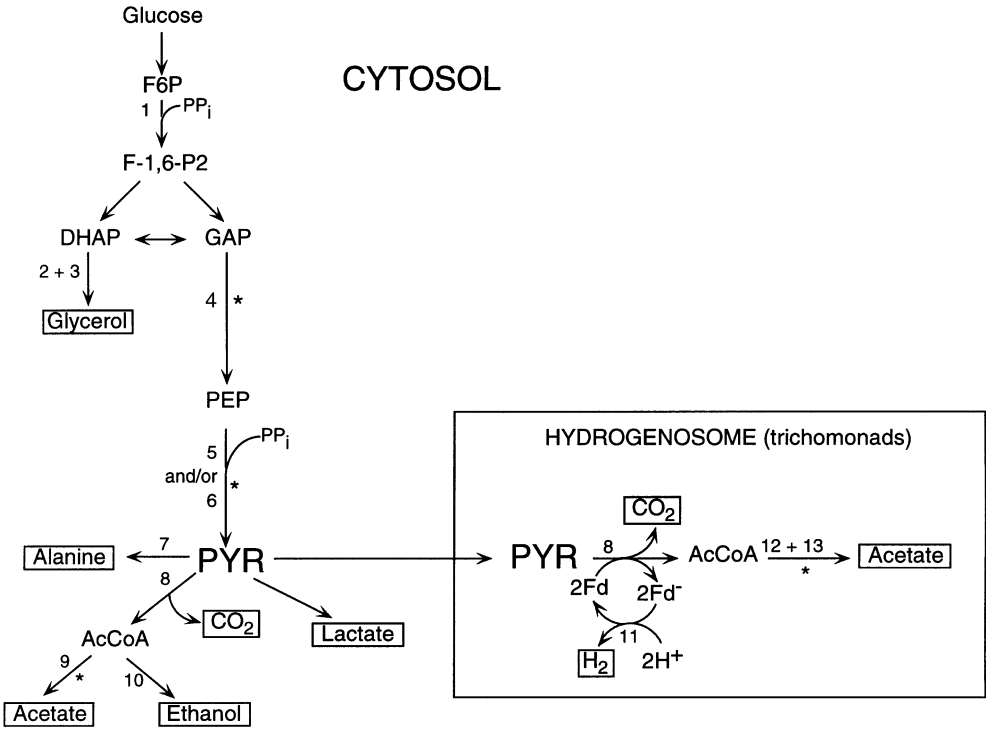
Anaerobic Protozoa

Protozoan parasites which have been classified as anaerobes occur in the taxonomic groups of trichomonad flagellates, and *Entamoeba* and *Giardia* spp. These organisms differ from most other eukaryotes in that they lack morphologically recognizable mitochondria (amitochondriate) and such biochemical attributes as the tricarboxylic acid cycle, cytochromes, and oxidative phosphorylation. They do not require oxygen for their survival and multiplication, but can tolerate low oxygen concentrations. As a consequence of this metabolic organization, energy generation in these organisms functions anaerobically and is exclusively associated with substrate-level phosphorylations. An important source of energy for anaerobic protozoa are carbohydrates which are stored in large amounts in the form of glycogen and degraded via an extended glycolytic pathway to different organic end products and CO_2. On the other hand, these organisms do consume O_2 when it is available, but the mechanism of this oxygen utilization process is unclear (see below).

Recently, mitochondrion-related organelles, called mitosomes, have been identified in a number of amitochondriate parasitic protozoa, including *Entamoeba histolytica*, *Giardia*, *Cryptosporidium parvum*, and microsporidians. Like mitochondria, mitosomes are double-membrane-bounded and contain some mitochondrial-type proteins, including chaperonin 60 (Cpn60), heat shock protein 70 (Hsp70), and the protein machinery responsible for iron-sulfur cluster assembly, but in contrast to mitochondria, mitosomes have not retained an organellar genome. The presence of mitosomes in parasitic protozoa lacking typical mitochondria provides evidence that these organisms are not primary amitochondriate, but have diverged from other eukaryotes after the mitochondrial endosymbiosis event.

Trichomonad flagellates distinguish from *Entamoeba* and *Giardia* in their ability to eliminate substrate-derived reducing equivalents in the form of molecular hydrogen by a pathway resembling that observed in some anaerobic eubacteria. As illustrated in Fig. 2, catabolism of carbohydrate in these parasites proceeds by classical glycolysis up to the step of pyruvate which is further metabolized to acetate, CO_2, and hydrogen. *Trichomonas vaginalis* and *Tritrichomonas foetus* show the same metabolic pattern, except that the former trichomonad produces lactate and the latter succinate as additional end products. The process of acetate formation in trichomonads is highly unusal for a eukaryote in that it is achieved by oxidative decarboxylation of pyruvate via a ferredoxin-linked step catalyzed by pyruvate:ferredoxin oxidoreductase. In a subsequent reaction, catalyzed by the iron-sulfur enzyme hydrogenase, the electrons are transferred from ferredoxin to protons to form molecular hydrogen. The ferredoxins involved in pyruvate oxidation of anaerobic protozoa are 12 kDa iron-sulfur proteins that differ in their structural properties among different species. The trichomond ferredoxin possesses only a [2Fe-2S] cluster similar to mitochondrial iron-sulfur proteins, whereas the ferredoxins of *Entamoeba* and probably *Giardia* contain 2 clusters of 4 iron atoms bound to 4 acid-labile sulfur atoms (2[4Fe-4S]). The characteristic trichomonad ferredoxin-dependent metabolic properties account for the selective toxicity of 5-nitroimidazole antiprotozoal drugs.

Another feature unique to the trichomonads is that the enzymes involved in pyruvate oxidation are carried in a separate organelle, the hydrogenosome, which is bounded by 2 closely apposed unit membranes and thus represents a metabolic compartment separate from the cytosol. The exact evolutionary position of the hydrogenosome is still debated, but functional and morphological considerations leads to the suggestion that hydrogenosomes and mitochondria are related organelles. The presence of hydrogenosomes is not restricted to trichomonad flagellates since they have been discovered also in anaerobic rumen ciliates, in fungi and in free-living protozoans of anaerobic sediments. The establishment of these organelles appears to be one of the various evolutionary approaches to adapt to an anaerobic mode of life. The advantage achieved with this strategy over that evolved in other anaerobic systems is that substrate-derived reducing equivalents can be directly eliminated in the form of molecular hydrogen and that substrate oxidation beyond the pyruvate step increases the economic efficiency of the energy generating system over that observed in simple lactate or ethanol



Energy Metabolism. Figure 2 The pathways of energy metabolism in anaerobic protozoa. *1*, PP_i-dependent phosphofructokinase; *2*, glycerol-3-phosphate dehydrogenase; *3*, glycerol-3-phosphatase; *4*, 4 glycolytical enzymes; *5*, pyruvate phosphate dikinase (not present in trichomonads); *6*, pyruvate kinase; *7*, alanine aminotransferase; *8*, pyruvate:ferredoxin oxidoreductase; *9*, acetate thiokinase (not present in trichomonads); *10*, acetyl CoA reductase/alcohol dehydrogenase; *11*, hydrogenase; *12*, acetate:succinyl CoA transferase; *13*, succinyl CoA synthetase. Glycerol formation occurs only in trichomonads and lactate formation only in *T. vaginalis*. In *Giardia* and *Entamoeba*, acetate formation occurs in the cytosol and is not coupled to hydrogen production. Metabolic end products are boxed. Asterisks indicate sites of ATP formation. *AcCoA*, acetyl coenzyme *A*; *DHAP*, dihydroxyacetonphosphate; *Fd*, ferredoxin; *F6P*, fructose-6-phosphate; *F-1,6-P_2*, fructose-1,6. bisphosphate; *GAP*, glyceraldehyde-3-phosphate; *MAL*, malate; *OAA*, oxalacetate; *PEP*, phosphoenolpyruvate; *PP_i*, pyrophosphate; *PYR*, pyruvate.

fermentation. The conversion of acetyl CoA, the primary product of anaerobic pyruvate oxidation in trichomonads, to free acetate can be coupled to substrate-level ATP synthesis, a process catalyzed by the combined action of 2 enzymes involving a CoA transferase and succinyl CoA synthetase.

Like trichomonad flagellates, the energy metabolism of *Giardia* and *Entamoeba* is entirely fermentative (Fig. 2), irrespective of whether oxygen is present or not, which is in accordance with the lack of mitochondria and the functions associated with these organelles. The utilization of carbohydrate results in the formation of a mixture of acetate, ethanol, and CO_2. Anaerobically, more ethanol and less acetate are produced, whereas in the presence of oxygen the catabolism switches to produce more acetate. In this pathway, the major fate of glycolytically formed pyruvate is its oxidative decarboxylation to acetyl CoA, catalyzed by an enzyme analogue to the ferredoxin-linked oxidoreductase of trichomonad flagellates. However, unlike trichonomads, *Giardia* and *Entamoeba*, because of the lack of a ferredoxin-linked hydrogenase, are not able to form molecular hydrogen. As an alternative, in these anaerobes reduced ferredoxin is utilized in the formation of ethanol as catalyzed by the bifunctional enzyme, acetyl CoA reductase/alcohol dehydrogenase. Oxygen may also act as terminal acceptor for the reducing equivalents removed from pyruvate, which would explain the aerobic requirement for acetate formation, but the precise steps involved in this pathway of electron flow are still unclear. As in trichomonads, hydrolysis of the acetyl CoA in these parasites can also be linked to energy generation by substrate level phosphorylation, but this step is catalyzed by a single enzyme, a novel type of acetate thiokinase (Fig. 2), which is known to occur only in some prokaryotes.

A notable feature of glycolysis in anaerobic protozoa is its dependency on pyrophosphate (PP_i) as a phosphate donor rather than on adenine nucleotides (Fig. 2). In a first step, a phosphofructokinase (PP_i-PFK) utilizes PP_i to phosphorylate the glycolytic intermediate fructose 6-phosphate to form the corresponding

l,6-bisphosphate. The second PP_i-dependent enzyme, pyruvate phosphate dikinase (PPDK), is located in lower glycolysis, where it replaces the pyruvate kinase (PK). In *T. vaginalis*, only the phosphofructokinase is PP_i-specific, whereas in *Entamoeba* and in *Giardia* both PP_i-PFK and PPDK are present. Recently, the coexistence of PPDK with PK in *Giardia* and the occurrence of a glycosomal PPDK in addition to cytosolic PK have been reported for *Giardia* and *T. brucei*, respectively. Other parasitic protozoa, including some apicomplexans, were also found to contain PP_i-PFK instead of the corresponding ATP-dependent enzyme, though these species are not considered to be anaerobic. A third PP_i-linked enzyme, phosphoenolpyruvate (PEP) carboxyphosphotransferase, is a constituent of a three-enzyme system functioning in *Entamoeba* as an alternative route for PEP utilization (Fig. 2). In this step, the high-energy phosphate bond of PEP is transformed into a PP_i bond with simultaneous fixation of CO_2. *Entamoeba* appears to be the only eukaryotic cell in which this enzyme is present. The possible physiological roles of inorganic PP_i, utilization may be to conserve the energy of the PP_i generated during anabolic processes and, as the PP_i-linked enzymatic reactions are reversible under physiological conditions, they may have functions not only in catabolic but also anabolic routes.

Anaerobic protozoa experience sometimes aerobic conditions within their natural environments and consume oxygen when provided, at rates comparable to those observed for aerobic protozoa and can tolerate surprisingly high concentrations of this gas *in vitro*. *T. vaginalis* has even been shown to grow optimally in the presence of small amounts of oxygen, and therefore these organisms may be classified as microaerophiles rather than anaerobes. Although the trichomonads, *Giardia* and *Entamoeba*, are devoid of any heme-containing proteins, reducing equivalents can be transferred from substrates to molecular oxygen. This reaction is catalyzed by NAD(P)H oxidoreductases which are located in the cytosol and apparently produce water as the reaction product. As an alternative, electrons to oxygen may be also donated through a succession of electron carriers containing flavins, non-heme iron, and other high potential carriers of an unknown nature. The precise architecture and physiological role of these presumptive respiratory systems of anaerobic protozoa, which are not associated with energy generation, remain to be elucidated. The fact that, with the exception of the large intestine, neither of the tissues colonized by these parasites are notably deficient in oxygen suggests that aerobic processes may be operative *in vivo*, and it was suggested that the respiratory systems may have a role in protecting the cell against oxygen damage.

Apicomplexans

Detailed knowledge of the bioenergetics of apicomplexan protozoa is limited to the intraerythrocytic stages of *Plasmodium* and *Eimeria*, while this aspect in the case of other genera has received only little attention. Generally, carbohydrates serve as the main energy source throughout the life cycle of apicomplexans. The erythrocytic stages of the malarial parasite lack energy stores and, consequently, use blood glucose as the primary nutrient. *Eimeria* spp. and *Toxoplasma gondii* bradyzoites store carbohydrate in the form of amylopectin, a known reserve polysaccharide of plants and some free-living protozoa and rumen ciliates. Like most other endoparasites, apicomplexan protozoa have a limited capacity to oxidize substrates completely to CO_2 and water but instead satisfy their energy requirements by fermentative mechanisms. The erythrocytic forms of mammalian malarial parasites convert glucose almost quantitatively to lactate, regardless of whether oxygen is present or not. Carbohydrate metabolism of the intraerythrocytic stages of *Babesia* seems to parallel that of human malarial parasites in that glucose is primarily or solely degraded to lactate. *Eimeria*, *Toxoplasma*, and *Cryptosporidium* also ferment carbohydrate to lactate with minor formation of acetate and glycerol. In common with anaerobic protozoa, glycolysis of various apicomplexans is unusual in that it contains PP_i-PFK instead of the conventional ATP-dependent enzyme. Another unique feature of these protozoans is that their lactate dehydrogenases, including those of *Plasmodium*, *Eimeria*, and *Toxoplasma*, contain a five-amino-acid insert around the active site, which may explain, at least in part, the unusual specificities of these enzymes in apicomplexans. A common feature of coccidian parasites is also the accumulation of mannitol, a carbohydrate previously known to be present only in fungi. The presence of mannitol in *Eimeria*, and probably also in *Toxoplasma* and *Cryptosporidium*, is associated with a cyclic pathway (mannitol cycle) that involves a synthetic and catabolic part and is linked to glycolysis via fructose 6-phosphate. The function of mannitol in coccidial parasites is still unclear, but suggested possibilities are its role as an energy reserve or osmoregulator, or it may act as a mechanism for dealing with oxygen radicals.

The lack of a full complement of the tricarboxylic acid cycle (TCA-cycle) enzymes in the apicomplexan parasites investigated has left a classical mitochondrial function involving complete substrate oxidation doubtful. Furthermore, in *Toxoplasma gondii* and *Plasmodium* spp. pyruvate dehydrogenase is only present inside the apicoplasts and not inside the mitochondria. This implies that acetyl-CoA, the substrate for the TCA-cycle, cannot be generated from pyruvate inside the mitochondria. On the other hand, several apicomplexans, notably

all life cycle stages of *Eimeria* and *Toxoplasma*, contain distinctive, cristate mitochondria. The presence of various cytochromes have been detected in these parasites and their respiration is sensitive to inhibition by cyanide and other mitochondrial electron transport inhibitors. For *Eimeria* it was suggested that during the processes of sporulation and excystation, which are associated with high respiratory activities, but also within those parasite stages preparing for an extracellular phase of life, a more aerobic type of metabolism may be established using the TCA cycle and cytochrome-linked substrate oxidation. As oxygen is required for optimal growth *in vitro* and inhibitors of respiration have significant effects on the survival of malarial and other apicomplexan parasites, a function of the mitochondrion in a capacity other than energy generation must be crucial. A possible functional significance of respiration in apicomplexans could be its coupling to the pyrimidine biosynthetic pathway as appears to be the case for blood stage *P. falciparum*. The observation that the anticoccidial quinolones and pyridinols inhibit respiration in *Eimeria* sporozoites and oocysts rather selectively suggests major differences between the coccidial and mammalian type of mitochondrial electron transport systems. Avian malarial parasites seem to have rather different bioenergetic capacities. Their cristate mitochondria appear to possess a functional TCA cycle, and in accordance with these properties, free erythrocytic stages of these species are able to oxidize a significant portion of the carbohydrate utilized to CO_2. *C. parvum* seems to lack mitochondria suggesting that oxygen is unimportant and glycolysis is the major strategy of energy generation in this apicomplexan.

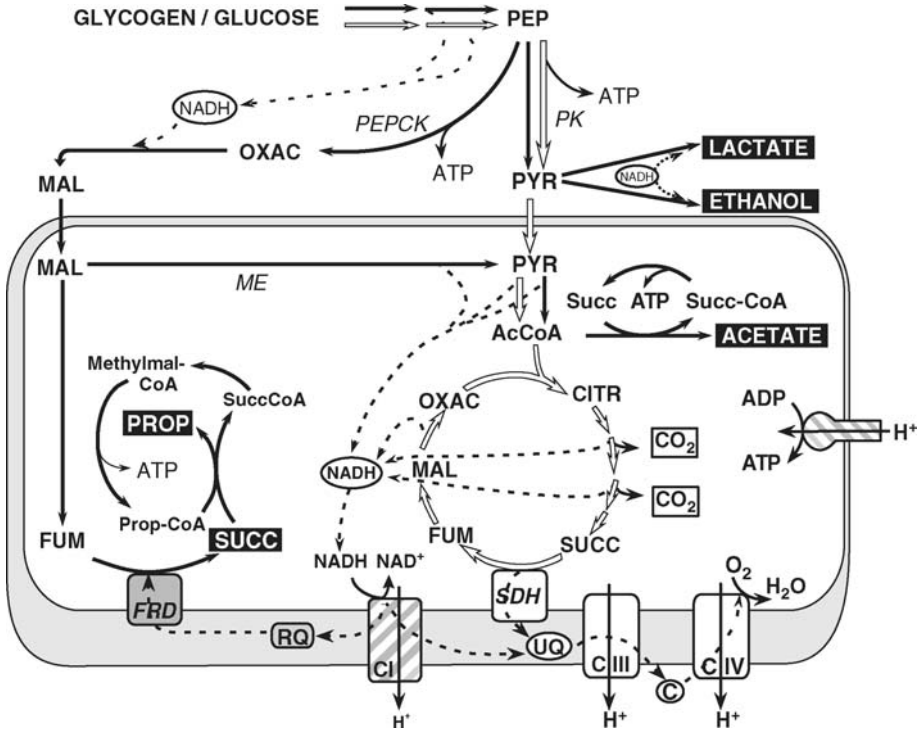
Helminths

Adult Helminths

As substrate for energy conservation the adult stages of most helminths use primarily carbohydrate, of which glycogen is the main storage polysaccharide, consisting in many cases of as much as l0% of the worm's wet weight. The catabolism of amino acids does not seem to be of particular importance for energy generation with the exception of glutamine, whose co-utilization with carbohydrate was shown to be energetically advantageous for some helminth species. Generally, the bioenergetic pathways found in adult helminths function primarily anaerobically. Effective terminal oxidative processes, such as the TCA cycle and a conventional type of respiratory chain, are very often absent or of limited activity, which precludes the utilization of fatty acids as an energy source. For the same reason, the degradation of carbohydrates and amino acids beyond the acetyl-CoA stage is only hardly feasible. As a consequence, most adult helminths are not capable of oxidizing organic compounds to a significant extent to CO_2 and water. More pronounced oxygen-dependent routes, however, appear to exist in small helminth species and in the outermost tissue layers of larger worms.

Although the pattern of end products varies greatly between different species of adult helminths, none of them degrades carbohydrates completely to carbon dioxide, as the free-living stages do. As helminths in general do not use oxygen as final electron acceptor, they must have a fermentative metabolism instead and excrete organic substances as metabolic end products. When oxygen cannot function as terminal electron acceptor, the degradation of substrates has to be in redox balance. Two approaches are pursued by helminths to fulfil this requirement. Some species, including adult schistosomes and filarial nematodes, use the classical adaptation to anaerobic metabolism by degrading carbohydrates to lactate or ethanol. This so-called anaerobic glycolysis yields 2 molecules of ATP per molecules of glucose degraded. Although most adult parasites use this strategy to some extent, the majority uses a different approach (malate dismutation), in which carbohydrates are degraded to phosphoenolpyruvate (PEP) via the conventional Emden-Meyerhof pathway. PEP is then carboxylated by phosphoenolpyruvate carboxykinase (PEPCK) to form oxaloacetate, which is subsequently reduced to malate (Fig. 3). The fate of PEP at the pyruvate kinase/PEPCK branch point will depend on the activity ratios and kinetics of the 2 enzymes involved, but is also determined by substrate concentrations, the rate of subsequent reactions and other factors. This part of the pathway occurs in the cytosol and is comparable to the formation of lactate or ethanol in being redox balanced and yielding 2 molecules of ATP per mol of glucose degraded. However, the malate produced in the cytosol is, unlike lactate, not excreted but transported into the mitochondria for further degradation. In a branched pathway, a portion of malate is oxidized to acetate and another portion of it is reduced to succinate. The oxidation occurs via 2 consecutive steps of oxidative decarboxylation, first to pyruvate via malic enzyme and subsequently to acetyl CoA via pyruvate dehydrogenase. The pyruvate dehydrogenase complex of *Ascaris suum* was shown to be specifically adapted to anaerobic functioning. The acetyl CoA formed is converted to acetate via a succinate/succinyl-CoA cycle. In the other part of the pathway, reduction of malate occurs in 2 reactions which reverse part of the TCA-cycle. Many helminths metabolize succinate further to propionate, which is then excreted. This so-called malate dismutation is in redox balance when twice as much propionate is produced as compared to acetate.

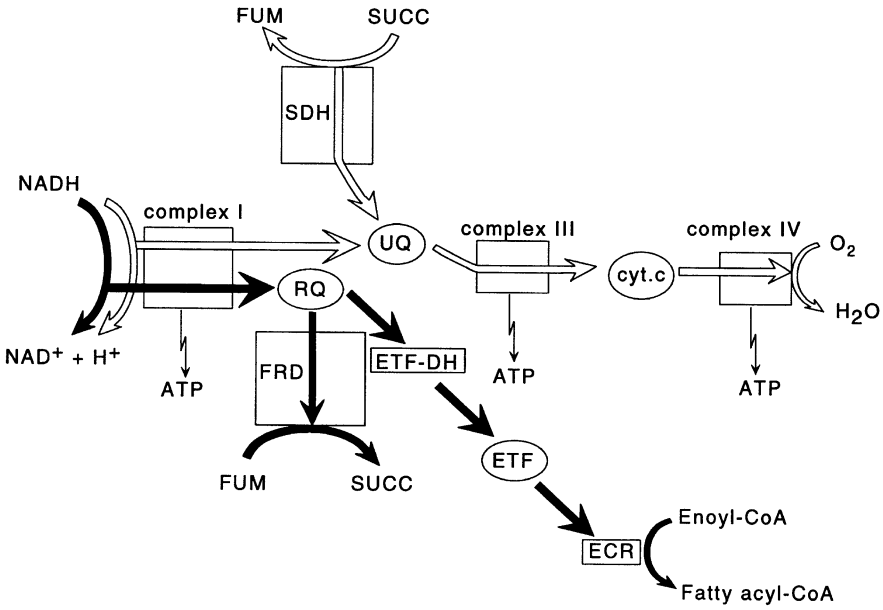
Apart from the electron-transport-associated ATP formation in the reduction of fumarate (see below), malate dismutation is also accompanied by substrate-level phosphorylations (Fig. 3). Formation of acetate from acetyl-CoA occurs via 2 consecutive enzymatic



Energy Metabolism. Figure 3 Generalized pathways of carbohydrate degradation by parasitic helminths. The aerobic metabolism of free-living and larval stages is shown in open arrows and the anaerobic fermentation pathways of adults in closed arrows. End products are in black boxes. *AcCoA*, Acetyl-CoA; *CI*, *III* and *IV*, complex I, III and IV of the respiratory chain; *CITR*, citrate; *FRD*, fumarate reductase; *FUM*, fumarate; *MAL*, malate; *Methylmal-CoA*, methylmalonyl-CoA; *ME*, malic enzyme; *OXAC*, oxaloacetate; *PEP*, phosphoenolpyruvate; *PEPCK*, phosphoenolpyruvate carboxykinase; *PK*, pyruvate kinase; *PROP*, propionate; *Prop-CoA*, propionyl-CoA; *PYR*, pyruvate; *RQ*, rhodoquinone; *SDH*, succinate dehydrogenase; *SUCC*, succinate; *Succ-CoA*, succinyl-CoA; *UQ*, ubiquinone.

steps with the concomittant production of ATP. The presence of the first enzyme of this reaction, acetate: succinate CoA-transferase, has now been unequivocally demonstrated in *F. hepatica*. The formation of propionate from succinate occurs through a sequence of metabolic reactions required for propionate utilization in animal tissues but working in reverse (Fig. 3). This cyclic pathway involves a set of enzymatic reactions which require deoxyadenosylcobalamin and biotin and accomplish the loss of a carboxyl group as CO_2. Each pass of the sequence promotes the synthesis of one molecule of ATP through coupling of ADP phosphorylation with the decarboxylation of methylmalonyl CoA. In total, the anaerobic production of propionate and acetate yields approximately 5 molecules of ATP per molecule of glucose degraded.

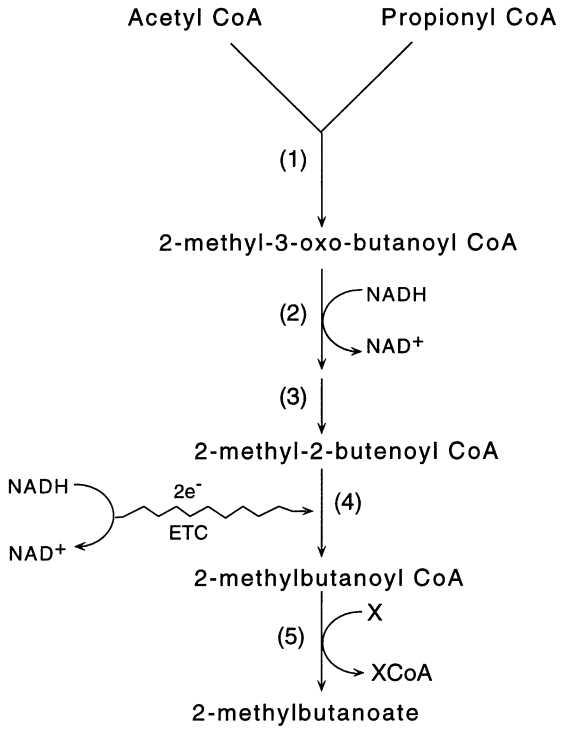
In the anaerobically functioning mitochondria of helminths capable of malate-dismutation, the electron-transport chain is different from the one present in mammals in that endogenously produced fumarate functions as the terminal electron acceptor instead of oxygen. In this case, electrons are transferred from NADH to fumarate via complex I and fumarate reductase (Fig. 4). Free-living stages of helminths, however, possess an aerobic energy metabolism with a classical mammalian type respiratory chain (see below). This implies that during the development of free-living into the parasitic stages, a transition occurs from succinate oxidation via succinate dehydrogenase in the TCA cycle to the reverse reaction, reduction of fumarate to succinate. Bacteria contain 2 homologous but distinct enzyme complexes to catalyse these reactions, one to oxidize succinate (succinate dehydrogenase) and one to reduce fumarate (fumarate reductase). Different enzymes are needed for these 2 reactions because the electron flow through the 2 complexes is in opposite direction, which implies differences in the affinity for electrons (standard electron potential) of the electron-binding domains of these enzyme complexes. Distinct enzyme complexes have now also been described in the parasitic nematodes *Haemonchus contortus* and *A. suum*. These complexes were shown to be differentially expressed during the life cycle of the parasites and are suggested to function either as a succinate dehydrogenase or as a fumarate reductase. In addition to customary enzyme complexes for succinate oxidation and fumarate reduction, also distinct quinones are involved in these processes in helminths.



Energy Metabolism. Figure 4 Schematic representation of the electron-transport chain in parasitic helminths. Electron flow to oxygen is shown in open arrows and the flow through fumarate reductase and to enoyl CoA reductase (*ECR*) in closed arrows. *Cyt. c*, cytochrome *c*; *ETF*, electron-transferring flavoprotein; *ETF-DH*, ETF-dehydrogenase (ETF:rhodoquinone oxidoreductase); *FRD*, fumarate reductase; *FUM*, fumarate, *SDH*, succinate dehydrogenase, *RQ*, rhodoquinone; *SUCC*, succinate, *UQ*, ubiquinone.

In many helminths, the primary products of anaerobic malate metabolism, acetate, succinate and propionate, accumulate as major excretory products. Some other helminths metabolize these compounds further to branched-chain fatty acids. In *A. suum*, the branched-chain fatty acids, 2-methylbutyrate and 2-methylvalerate, are the predominant end products of anaerobic carbohydrate metabolism. As demonstrated in Fig. 5, these acids arise from the condensation of acetyl CoA with propionyl CoA or of 2 propionyl CoA units, with subsequent conversion of the condensation products to the saturated fatty acids. This pathway is also located inside the anaerobically functioning mitochondrion and is similar to the reversal of β-oxidation of fatty acids, although some of the enzymes involved in branched-chain fatty acid production of helminths differ in their kinetics and regulatory properties from the corresponding mammalian β-oxidation enzymes. There is evidence to suggest that 2 sites of ATP generation may be operative in this reductive process (Fig. 4). One is associated with the penultimate step in which the dehydroacyl CoA compound is reduced to the saturated CoA ester and involves phosphorylation linked to electron transport, in a way similar to that occuring during fumarate reduction. NADH is reoxidized and the electrons are used for enoyl CoA reduction. A second site of energy generation is thermodynamically feasible in the final step of free branched-chain fatty acid formation which occurs with a large drop in free energy upon hydrolysis of the CoA thioester bond. Probably ATP formation proceeds either by a thiokinase or by the combined action of 2 enzymes, analogous to acetate formation from acetyl CoA. The production of these branched-chain fatty acids does not generate more energy than the production of acetate and propionate but functions as an alternative electron sink. More rarely occuring pathways of glucose utilization, such as those leading to propanol in *H. contortus*, have not yet been elucidated and thus their relevance to energy conservation is unknown.

The anaerobic energy generation in helminths can apparently be associated with several sites of ATP formation. At the substrate level, these are coupled to glycolysis, PEP carboxylation, methylmalonyl-CoA decarboxylation (in the formation of propionate) and succinyl CoA synthetase (in the formation of acetate), while NADH-coupled reductions of fumarate and enoyl CoA compounds serve to produce ATP via electron-transport-associated phosphorylation. Energy generation in helminths mediated by mixed fermentations and anaerobic electron transport would thus display a clear advantage over simple lactate or ethanol fermentation. The latter pathways yield only 2 ATP per molecule of glucose catabolized, whereas for an organism like *F. hepatica*, which degrades glucose almost solely to acetate and propionate in a ratio of 1:2, approximately 5 molecule ATP is produced per mol of glucose catabolized. In spite of the obvious advantage of multiple anaerobic catabolic systems over simple



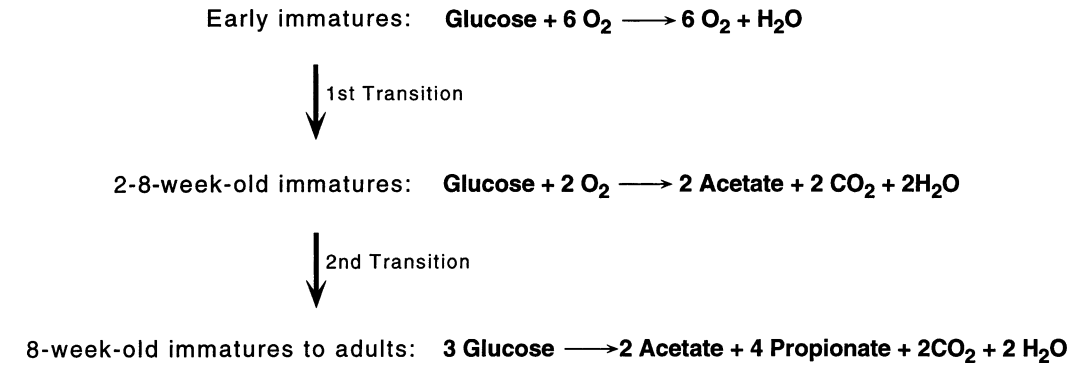
Energy Metabolism. Figure 5 Formation of branched-chain fatty acids by *Ascaris suum*. (After Komuniecki and Harris (1995)) 1, propionyl condensing enzyme; 2, 2-methyl acetoacyl CoA reductase; 3, 2-methyl-3-oxo-acyl CoA hydratase; 4, 2-methyl branched-chain enoyl CoA reductase; 5, acyl CoA transferase; *ETC*, electron-transport chain (see Fig. 4). The synthesis of 2-methylpentanoate (2-methylvalerate) proceeds in a similar way, except that 2 propionyl CoA units are used in the condensing reaction then.

lactate fermentation, the economic efficiencies of these pathways are still very low compared to that obtained from complete substrate oxidation to CO_2 and water, which generates approximately 30 molecules of ATP per molecule glucose degraded.

Free-Living and Larval Stages of Helminths

Most free-living stages of helminths are self-supporting, i.e., they do not obtain food or substrates other than oxygen from their environment. They are completely dependent on the endogenous food stores that they have obtained in their previous host. Glycogen is present in many free-living stages and is used to span the gap in food supply until the next host is entered. The free-living and parasitic developmental stages of helminths have, unlike the adult parasites, usually an aerobic energy metabolism. Many of them, such as the free-living infective eggs of *A. suum*, eggs and developing larvae of *Nippostrongylus brasiliensis* and *H. contortus*, juvenile liver flukes and young schistosomula, and various free-living cercariae, have a high oxygen requirement, mainly for energy generation, with high TCA-cycle and mitochondrial respiratory chain activities. These organisms thus are capable of completely oxidizing substrate carbon to CO_2 and water. In addition, smaller amounts of oxygen are needed for synthetic purposes, such as the formation of collagen and fatty acid desaturation. Another feature of the developmental stages of helminths is that the diversity of energy sources that can be utilized is, in many cases, greater compared to that of the respective adult forms. For instance, the free-living stages of many parasitic nematodes and some cercariae rely heavily on lipids for their energy generation, implying that a functional β-oxidation sequence is present in these stages. Generally, there is, however, great variation in the oxygen requirements and the capabilities for substrate utilization in the developmental stages of helminths, and the situation in one species may not be necessarily relevant for another species.

If the metabolism of helminths differs between larval and adult stages, then the developmental cycle of these organisms must involve, at some stage, a transition from one metabolic strategy to another, triggered by appropriate environmental and physiological conditions. In the development of *A. suum*, the transition from aerobic to anaerobic energy metabolism is likely to occur during the third molt when larvae develop in the small intestine from the third to the fourth stage. In contrast to the adult, which lacks a functional TCA-cycle and cyanide-sensitive respiration, the earlier larval stages of this parasite rely on aerobic strategies for energy conservation resembling those functional in mammalian cells. A similar adaptation is exhibited in the life cycle of *F. hepatica* (Fig. 6). While the early liver-parenchymal stages of this parasite possess a predominantly aerobic metabolism and are capable of complete substrate oxidation, these oxidative capacities decline gradually during development. In flukes between 2 and 8 weeks old, TCA cycle activity is already largely suppressed, but aerobic reactions still remain functional as characterized by the oxygen-linked formation of acetate. In this pathway, most of the chemical energy may still be conserved by mitochondrial oxidative phosphorylation, but the reducing power necessary to drive respiration is not derived from the TCA-cycle but from the formation of acetate. Compared to complete substrate oxidation, the relative efficiency of this energy-generating pathway is much lower, resulting in approximately 14 molecules of ATP per molecule of glucose catabolized to acetate and CO_2. After arrival of the flukes in their definitive environment, the bile ducts, a further drop in oxidative capacities and relative efficiency for energy generation occurs. From this stage on, anaerobic redox-processes, resulting in the formation of acetate and propionate,



Energy Metabolism. Figure 6 Changes in the energy metabolism of *Fasciola hepatica* during its development in the final host. Contribution of the 3 pathways of glucose breakdown to ATP synthesis is shown. (After Tielens 1994).

remain functional throughout adult life. In the development of the liver fluke, therefore, 2 pronounced shifts in energy metabolism seem to occur: one being characterized by the transition from complete substrate oxidation to aerobic acetate formation, and the other by a change from aerobic to anaerobic metabolism as is observed during the development of the late immature worms into the adult stage.

Also in schistosomes such a switch occurs from an aerobic metabolism in the free-living stages to an anaerobic one in the parasitic stages. The free-living cercariae and miracidia of *Schistosoma mansoni* possess an aerobic energy metabolism in which their endogenous glycogen reserves are degraded, mainly to CO_2. Adult schistosomes, on the other hand, live in the bloodstream of their host and despite their small size and life in an aerobic environment, they have a fermentative metabolism and degrade glucose, mainly to lactate. When cercariae penetrate the skin of the final host and transform into schistosomula, they switch rapidly from TCA-cycle activity to lactate production via glycolysis. This metabolic switch was shown to be initiated by the sudden presence of external glucose when the free-living stages penetrate the new host, and is not linked to a decreased availability of oxygen, as in *F. hepatica*. The mere presence of external glucose results in an increased glycolytic flux, probably caused by the rapid uptake of glucose that occurs upon expression at the surface of a specific schistosomal glucose transporter protein, SGTP4. This increased glycolysis is maintained as a result of the specific kinetic properties of schistosomal hexokinase, the first enzyme in glucose catabolism. The observed rapid switch to lactate production occurs only in cercarial heads, the region of the larvae that develops into the mature parasite. The tail of the cercaria, which only propels the organism through the water, is fully dependent on the degradation of endogenous glycogen reserves as it contains little or no SGTP4 and hexokinase, and it degenerates following the separation from the penetrating schistosomulum. In contrast to *Ascaris*, *F. hepatica* and several other helminth species, no significant changes in the energy metabolism occur during the further development of schistosomes. Lactate remains the main end product, although TCA-cycle activity and oxidative phosphorylation also contribute significantly to ATP production, even in adults.

The reason for the more pronounced oxidative capacities in developmental stages of helminths than in adults is not completely understood, but may be due to their smaller body size, which causes less oxygen diffusion problems than in adults, in conjunction with a sufficient availability of oxygen in the habitats of free-living and many parasitic larval stages. Both circumstances are likely to be essential for the establishment and function of the processes responsible for complete substrate degradation, i.e., the tricarboxylate cycle, β-oxidation route and a conventional type of phosphorylating respiratory chain. Upon increasing in body size which, for a migrating parasite, is often accompanied by a decreasing access to oxygen and changes in other environmental conditions, a marked drop in oxidative capacities often occurs in the adult, where anaerobic strategies are becoming the major ATP-generating sites. While in the latter stage these pathways cannot be reversibly replaced by aerobic processes, most developmental aerobic stages can survive anaerobically by utilizing anaerobic energy-conserving strategies which often coexist with aerobic routes. An example is *F. hepatica*, in which the ability of the adult to catabolize glucose anaerobically to acetate and propionate is present immediately after excystment and persists in all stages until the mature parasite. The interesting question of how the metabolic transitions occurring during the developmental cycle of helminths are regulated remains largely to be determined.

Rotenoids

General Information

Rotenone is a natural product isolated from the roots of *Derris* spp. and *Lonchocarpus* spp. The derris root has long been used as a fish poison among the Malaysian natives. The insecticidal properties of derris extracts were known in China long before isolation of the active principle in 1895 by Geoffrey. Rotenone

represents the most toxic and abundant member of about 13 rotenoids. Three other members also have been reported to show insecticidal activity but are less potent than rotenone: deguelin, tephrosine, toxicarol with 10%, 2.5%, and 0.25% of the rotenone activity, respectively (Fig. 2). In the last 40 years rotenone has been intensively used. The world production is in the range of 10–20t.

Molecular Interactions

Rotenone acts as an inhibitor of the electron transport system (site one) of the →mitochondrial respiratory chain. It inhibits the oxidation of NADH to NAD via coenzyme Q (reducing quinone to hydroquinone), thus also blocking the oxidation by NAD of substrates such as →glutamate, a-ketoglutarate, and pyruvate.

Rotenone is a nonsystemic selective insecticide with secondary acaricidal activity with contact and stomach action. It is used for the control of →lice, →ticks, and warble flies and against fire ants in premises as well as mosquito larvae (ponds). Today, its primary use as an ectoparasiticide is against ear →mites and demodectic mange and in combination with other ectoparasiticides like organophosphates and pyrethroids against sheep ectoparasites. Inactivation by photo-oxidation limits the use of rotenone as a single product when long residual activity is required. The LD_{50} of acute oral toxicity for rats is 132–1500 mg/kg. The estimated lethal dose for oral application of rotenone for humans is 300–500 mg/kg. Rotenone is highly toxic for mammals upon injection (LD_{50} 0.1–4 mg/kg). Rotenone is highly toxic to pigs but shows no toxicity to bees. The compound is also used as fish toxicant in fish management. Rotenone is metabolized in the rat liver or insect by enzymatic opening and cleaving of the furan moiety or, alternatively, by oxidation of the methyl group of the isopropenyl residue.

Resistance

Resistance of ectoparasites against rotenone has not yet been described.

Iodoquinol

Synonyms

5,7-diiodo-8-hydroxyquinoline, SS578, Diodoquin, Di-Quinol, Disoquin, Floraquin, Dyodin, Dinoleine, Searlequin, Diodoxylin, Moebiquin, Rafembin, Ioquin, Direxiode, Stanquinate, Quinadome, Yodoxin, Zoaquin, Enterosept, Embequin.

Cells and Cellular Interactions

Iodoquinol is active against →*Entamoeba histolytica* and against facultative pathogenic *Entamoeba* spp. such as *Dientamoeba fragilis*. The activity of iodoquinol is directed against →trophozoites (minuta forms) in the intestinal mucosa and cysts in the feces (→DNA-Synthesis-Affecting Drugs I/Table 1).

Molecular Interactions

The mechanism of action is unknown. It is tempting to speculate from some structural similarities with hydroxyquinolines that iodoquinol may interfere with the energy metabolism (→oxidative phosphorylation, inhibition of ATPase) in amoebes.

Nitazoxanide

Synonyms

2-acetoloxy-N-(5-nitro-2-thiazolyl)benzamide.

Clinical Relevance

The drug was first described in 1984 as a human cestocidal drug against *Taenia saginata* and *Hymenolepis nana*. In 1994 development of nitazoaxanide was re-initiated as a antiprotozoal agent. It is active against anaerobic protozoa and bacteria (*Trichomonas vaginalis*, *Entamoeba histolytica* and *Clostridium perfringens*) (→DNA-Synthesis-Affecting Drugs I/Table 1). However, nitazoxanide possesses broad-spectrum antiparasitic activities against protozoa, cestodes, and nematodes with modest to high cure rates depending on the degree of infection (light, moderate, heavy). Thus, the drug is effective against *E. histolytica, Giardia intestinalis, Isospora belli, Balantidium coli, Blastocystis hominis, Hymenolepis nana, Ascaris lumbricoides, Ancylostoma duodenale, Trichuris trichiura* and *Strongyloides stercoralis*.

Moreover, nitazoxanide had resolved diarroea caused by *Cryptosporidium parvum* in more than 80% of patients 7 days after beginning therapy. 67% of patients treated with the drug did not produce *C. parvum* oocysts. There are also studies in AIDS patients conducted in Africa and Mexico with favorable results.

Molecular Interactions

Experiments in the anaerobic protozoa *T. vaginalis* and *E. histolytica* as well as in the bacteria *C. perfringens* and *Helicobacter pylori* have shown that nitazoxanide inhibits pyruvate ferredoxin oxidoreductase (PFOR), the vital enzyme of the central intermediary metabolism. By contrast to the nitroimidazoles, nitazoxanide seems to interact directly with PFOR and the products of nitazoxanide activation do not induce mutations in DNA. This different mechanism of action is important in explaining the therapeutic efficacy of this drug

against metronidazole-resistant protozoa. The molecular mechanism of nitazoxanide in helminths is unclear at present.

Suramin

Synonyms

Bayer 205, 309F, Antrypol, Germanin, Moranyl, Naganol, Naganin, Naphuride Sodium.

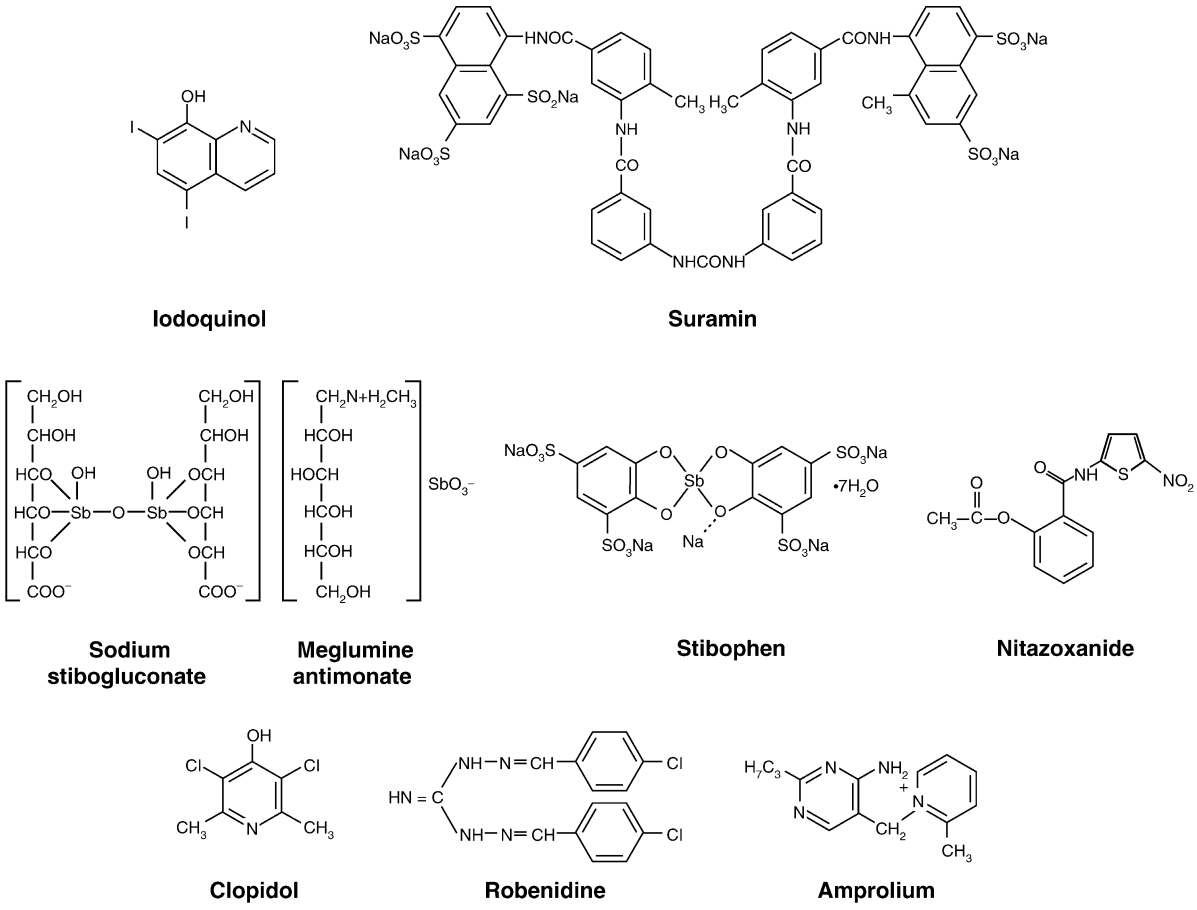
General Information

Suramin was explored in 1916 and originally introduced in 1922 as a trypanosomicidal drug in cattle.

Molecular Interactions

Suramin is chemically a sulfonic acid and structurally related to dyes such as trypanred, eboliblue, or trypanviolet. The six negative charges at physiological pH may be of great importance for the proposed →mode of action. The action of suramin is directed against →trypomastigotes of *Trypanosoma brucei gambiense* and *T. b. rhodesiense* in the blood dividing by →binary fission. The drug is taken up by trypanosomes via receptor-mediated →endocytosis in presence of serum proteins 18-fold higher compared to the normal fluid endocytosis alone. Intracellular suramin concentrations (about 100 μM) are equivalent to exogenous drug concentrations. Suramin is bound to albumin and low density lipoprotein (LDL) resulting on the one hand in reduced host toxicity but on the other hand leading to an inhibition of intralysosomal proteolysis in the host cell. The complexation of suramin to albumin is also responsible for a reduced total amount of free drug in the →cytoplasm of host cells.

The antitrypanosomal action of suramin on the molecular level is relatively unclear. There are reports on the inhibition of a variety of kinases and dehydrogenases from mammalian, bacterial, and fungal cells. In trypanosomes glycerol-3-phosphate oxidase and glycerol-3-phosphate dehydrogenase become inhibited, resulting in a disturbed redox balance within the trypanosomal cell and a decreased ATP-synthesis rate (Fig. 3). In addition, other enzymes of *T. brucei* such as DHFR, thymidine kinase, and a number of glycolytic enzymes (hexokinase, phosphoglucoisomerase, phosphofructokinase, triosephosphate isomerase, aldolase, glyceraldehyde-3-phosphate dehydrogenase, phosphoglycerate kinase, glycerol-3-phosphate dehydrogenase, and →glycerol kinase) become inhibited. The IC_{50} values of suramin on trypanosomal glycolytic enzymes (between 10 and 100 μM) are much lower compared to the corresponding enzymes from mammalian cells.



Energy-Metabolism-Disturbing Drugs. Figure 1 Structures of drugs affecting →energy metabolism.

The reason for the selective toxicity may be explained by the unusually high isoelectric points (between 9 and 10) for most of the glycolytic enzymes from *T. brucei*. The basic properties of the trypanosomal glycolytic enzymes resulting in additional positive charges on their surfaces may facilitate the binding of the highly negatively charged suramin. Thus, there are likely to be potentiated inhibitory effects by electrostatic interactions between positively charged trypanosomal enzymes and negatively charged suramin, and there is no direct inhibition of trypanosomal glycolytic enzymes in →glycosomes.

A further hypothesis for the suramin action on the molecular level is as follows. The nine glycolytic enzymes are synthesized on free →polysomes in the parasite's cytoplasm. These enzymes are then imported into the glycosomes post-translationally without any proteolytic modification within 3–5 minutes and become thus protected from suramin by compartmentalization in the glycosomes. Suramin possibly binds to the glycolytic enzymes in the cytoplasm on their way to the glycosome and/or interferes with their import into the glycosomes (Fig. 3). The inhibition of glycosomal protein import is followed by a gradual decrease of enzyme concentrations in the glycosomes. The average half-life of glycolytic enzymes is about 48 h inside the glycosomes. By this action suramin induces a slowing down of energy metabolism in suramin-treated trypanosomes. The inhibition of the import of glycosomal protein is either partially or totally with disruption of →glycolysis in the trypanosomes.

An additional hypothetical action of suramin is the indirect interaction with the DNA/RNA-replication resulting in retarded trypanocidal activity after 24–36 h corresponding to 4–7 divisions.

The antifilarial activity of suramin is directed against →macrofilariae and to a minor degree against microfilariae of →*Onchocerca volvulus* (→River Blindness). For a long time it was the only drug against adult *O. volvulus* in man, but today the use of suramin is limited. The antifilarial mechanism against *O. volvulus* is delayed (4–7 weeks after treatment). An inhibition of the cAMP-independent protein kinase I in *O. volvulus* is discussed. This protein is also the target

of suramin and stibophen against →*Ascaridia galli in vitro*. Suramin further exerts curative effects against →*Wuchereria bancrofti* filariasis and in addition shows effectivity against all stages of *Litomosoides carinii*. There is a requirement for intravenous injection which is accompanied by severe side effects. Suramin leads to a sterilisization of adult filariae. *L. carinii* in *Mastomys coucha* are killed within 6 weeks. Despite great chemical-synthetical efforts there is no possibility for improvement of better tolerability without loss of filaricidal activity. In general there is no correlation between filaricidal effects of suramin derivatives and trypanosomicidal activity.

Additional Features

Suramin has additional activities against a wide variety of pathogens. Thus it is a potential anti-AIDS drug, due to a potent inhibitory effect on the reverse transcriptase from a variety of retroviruses. In addition, an inhibitory effect on DNA polymerase activity is discussed.

Clinical Relevance

The main indication of suramin relies on the activity against early stages (bloodstream forms) of human African trypanosomes (*T. b. gambiense* and *T. b. rhodesiense*) (→DNA-Synthesis-Affecting Drugs III/Table 1). Suramin is usually given with five intravenous injections at a dosage of 20 mg/kg b.w. once every 5–7 days. In veterinary medicine the drug exerts efficacies against *T. b. brucei* (→Nagana), *T. b. evansi* (→Surra), and *T. equiperdum* (→Dourine). In addition, suramin has experimental activity against *Entamoeba histolytica*, →*Eimeria* spp., and avian →malaria.

Resistance

The mechanism of resistance of suramin on the molecular level is unclear. Generally the resistance to suramin is rare even after 70 years of application in trypanosomiasis field clinics. This might be an indirect support for the hypothetical action on multiple targets in trypanosomes.

Antimonials

Important Compounds

Sodium-stibogluconate, Meglumine-antimonate, Stibophen.

Synonyms

Sodium-stibogluconate: Antimony sodium gluconate, Pentostam, Myostibin, Solustibosan, Solyusurmin, Stibanate, Stibanose, Stibatin, Stibinol.
Meglumine-antimonate: N-methylglucamine antimonate, glucantime.
Stibophen: Sodium antimony bis(pyrocatechol-2,4-disulfonate), Sdt 91, Fuadin, Fouadin, Pyrostib, Corystibin, Trimon, Fantorin, Repodral, Neoantimosan, Sodium Antimosan.

Cells and Cellular Interactions

The antiprotozoal activity of the antimonials sodium-stibogluconate and meglumine-antimonate is directed against cutaneous, visceral, and mucocutaneous leishmaniasis (→DNA-Synthesis-Affecting Drugs II/Table 1). They have no activity against cultured leishmanial →promastigotes Stibophen shows besides the activity against *Leishmania tropica* and *L. mexicana* also activity against →*Schistosoma haematobium*.

Molecular Interactions

The mechanisms of antiprotozoal action of the pentavalent antimonials sodium-stibogluconate and meglumine-antimonate rely on their reduction to the corresponding trivalent antimonials by host metabolism. The activity is directed against those stages dividing by repeated binary fissions such as *L. donovani* and *L. chagasi* in spleen, liver, and skin stages, intracellular →amastigotes of *L. tropica*, *L. major* in the skin and *L. brasiliensis* and *L. mexicana* in mucous tissues of nose and mouth. Thereby, presumably those enzymes with sulfhydryl groups become inactivated by trivalent antimonials. Thus, the inhibition of cytoplasmic pyruvate kinase and other kinases with reactive sulfhydryl groups at their active sites results in a decreased flow of glucose into the citrate cycle in *L. tropica* promastigotes in presence of trivalent antimonials, in addition, there is an accumulation of glycolytic metabolites and a disturbance of energy production within the parasites. As an alternative hypothesis a disruption of

trypanothione reductase (TR) by antimonials is discussed. The real mode of antileishmanial action of the antimonials is yet unknown.

The antitrematodal action of stibophen may be explained by the inhibition of phosphofructokinase of →*Schistosoma mansoni*.

Resistance

Resistance against pentavalent antimonials is an increasing problem varying between 5%–70% of patients in some endemic areas. Resistant →*Leishmania* isolates tolerate concentrations of antimonials, which are 100-fold higher than the maximal achievable serum levels of drugs in humans.

The real mechanism of resistance against antileishmanial antimonials is still unknown. Biochemical studies indicate that there is a decreased accumulation of sodium-stibogluconate in resistant cell lines. It remains, however, unclear whether there is a decreased uptake or an increased efflux of drug. The resistance of *Leishmania* spp. against pentavalent antimonials can be reversed *in vitro* and *in vivo* by verapamil indicating a P-glycoprotein-mediated resistance mechanism.

In addition, it was proposed that the resistance mechanism in *Leishmania* spp. against antimonials is based on gene amplifications. Such a mechanism is proposed for the resistance against different compounds such as methotrexate, arsenite, tunicamycine, DFMO, mycophenolic acid, and vinblastine.

Clopidol

Synonyms

Meticlorpindol, Clopindol, Coyden; in combinations: Lerbek (= Meticlorpindol + Methylbenzoquate).

Cells and Cellular Interactions

The antiprotozoal activity of clopidol is directed against *Eimeria* spp. in chicken (→DNA-Synthesis-Affecting Drugs IV/Table 1). Clopidol leads to an inhibition of the development of sporozoites and trophozoites.

Molecular Interactions

Clopidol is a pyridone-derivative structurally related to the →quinolones. Its real mode of action is unclear to date. There is no interference with mitochondrial respiration of *E. tenella*. Synergistic effects between clopidol and methylbenzoquate indicate that the action of clopidol may be similar but not identical to that of quinolones. The differences are probably due to an alternative pathway of electron transport in coccidial →mitochondria with specific sensitivity to clopidol.

Resistance

There is cross-resistance between methylbenzoquate and clopidol in strains of *E. maxima.* The resistance against clopidol in a methylbenzoquate-resistant strain appears after many passages in chicken.

The mechanism of resistance against clopidol is unclear.

Robenidine

Synonyms

Robenzidene, Cycostat, Robenz.

Cells and Cellular Interactions

The antiprotozoal activity of robenidine is directed against all five economically important *Eimeria* spp. in poultry (*E. acervulina*, *E. maxima*, *E. necatrix*, *E. tenella*, and *E. brunetti*) (→DNA-Synthesis-Affecting Drugs IV/Table 1). Furthermore Robenidine exerts activity against →*Neospora caninum* →tachyzoites in cell cultures.

Molecular Interactions

Robenidine acts against developing first generation schizonts by possible interference with the oxidative phosphorylation and ATPase in mitochondria of *Eimeria* spp. and rat liver mitochondria. In chicken erythrocytes there is an induction of efflux of K^+-ions observable.

Amprolium

Synonyms

1-((4-amino-2-propyl-5-pyrimidinyl)methyl)-2-picolinium chloride, Corid, Amprol, Amprovine; in combinations: Amprol Plus, Amprol Hi-E, Amprolmix, Pancoxin, Supracox.

Cells and Cellular Interactions

Amprolium has been used for the therapy of coccidiosis in poultry, zoo birds, and mammals since 1960. It has activity against *Eimeria tenella, E. maxima*, and *E. necatrix* (→DNA-Synthesis-Affecting Drugs IV/Table 1). The action of amprolium is directed against →wall-forming bodies II of schizonts of the first and second generation.

Molecular Interactions

Amprolium is structurally related to thiamine, but lacks the hydroxymethyl group of this vitamine. Thus, the phosphorylation to the corresponding thiamine pyrophosphate analogue is abrogated. Thiamine is an essential cofactor for →pyruvate dehydrogenase activity, which is interestingly also the site of inhibition by antiprotozoal arsenicals. Amprolium competitively inhibits the transport of thiamine across the cell membranes of second generation schizonts. Amprolium possesses a high therapeutic index which may be explained by differences of thiamine transport rates between chicken epithelial cells and *Eimeria* spp.

Resistance

The mechanism of resistance against amprolium is explained by a modification of the target receptor

resulting in a decreased sensitivity to inhibition. The K_i-value for amprolium is increased nearly 15-fold to 115 μM in the resistant *E. tenella* strain.

Arsenicals

Important Compounds

Carbasone, Glycobiarsol, Melarsoprol, Thiacetarsamide, Mel PH, R7/45.

Synonyms

Carbasone: N-carbamoylarsanilic acid, Amebevan, Ameban, Amibiarson, Arsambide, Carb-O-Sep, Histocarb, Fenarsone, Leucarsone, Aminarsone, Amebarsone.
Glycobiarsol: Bismuth glycoloylarsanilate, Broxolin, Dysentulin, Milibis, Viasept, Wintodon.
Thiacetarsamide: Arsenamide, Thioarsenite, Caparsolate, Caparside, Arsphenamide, Filicide, Filaramide.

Clinical Relevance

The great interest in arsenicals at the beginning of the 20th century relied on their antibacterial activities. Thus, 4-arsanilic acid sodium (**Atoxyl**) and Salvarsan were the first drugs to be active against syphilis. **Carbasone** as one of the antiprotozoal arsenicals was introduced in 1931 against infections with →*Trichomonas vaginalis* and *Entamoeba histolytica*. **Glycobiarsol** introduced in 1938 exerts activities against *T. vaginalis*, *E. histolytica*, and →*Giardia lamblia*. **Melarsoprol** is still one of the drugs of choice for the treatment of late stage →sleeping sickness caused by *Trypanosoma brucei gambiense* or *T. b. rhodesiense*. Arsanilic acid and roxarsone exhibit activity against *E. tenella* sporozoites. **Acetarsone** in combination with arecoline was used as an anticestodal drug in small animals. In addition, sodium arsanilic acid in combination with copper sulfate has antinematodal activities against →nematodes in ruminants. The macrofilaricidal efficacy of arsenicals is also known for a long time. Interestingly, all arsenicals obtain almost exclusively adulticidal effects which is clinically proven in man. **Thiacetarsamide** potassium is a drug routinely used against →*Dirofilaria immitis* in the dog (→Inhibitory-Neurotransmission-Affecting Drugs/Table 1). Another arsenical is **melarsomine** used as adulticide against *D. immitis* in dogs. The main disadvantage of the arsenicals are their severe side effects, such as the arsenical encephalopathy. In the meantime new and less toxic organic arsenicals such as **Mel PH** and **R7/45** have been developed. In general, there are no marked reductions of microfilariaemia levels until day 7 p.i. and the adulticidal efficacy of drugs varies with the parasite species. Thus, thiacetarsamide is much more active against *Brugia* spp. than other arsenicals; →*Acanthocheilonema viteae* is more resistant to Mel PH and **R7/45** than *Litomosoides carinii* and *B. malayi*. Arsenicals exert better activity against female *L. carinii* and *B. malayi* than against males whereas both worm sexes of A. viteae are equally sensitive to arsenicals.

Molecular Interactions

The mechanism of action of antiprotozoal arsenicals is presumably due to an inhibition of glycolytic enzymes and/or protein kinases with SH-groups. Also trypanothione reductase may be a target of some arsenical compounds such as melarsoprol (→DNA-Synthesis-Affecting Drugs III/Fig. 1).

The antifilarial arsenicals lead to an *in vitro* and *in vivo* inhibition of →glutathione reductase as shown in *L. carinii* adults. Thereby, the parasitic enzyme is more susceptible to inhibition than the corresponding mammalian enzyme.

Clorsulon

Synonyms

L-631,529, MK-401, Curatrem, in combinations: Ivomec Plus.

Clinical Relevance

Clorsulon belongs to the fasciolicidal drugs (Table 1) with good activity against →liver flukes (→*Fasciola hepatica*) from the age of four weeks. It has low toxicity and is excreted rapidly. Clorsulon is suitable for the use in meat-producing animals. Now clorsulon is used in combination with ivermectin (Ivomec F).

Molecular Interactions

It is the only one of the most commonly used fasciolicides whose action is directed against glycolysis on the level of 3-phosphoglycerate kinase and phosphoglyceromutase. There is no great disruption of glycolysis *in vivo* by clorsulon. At a concentration of 500 μg/ml for 1 hour the glucose utilization is decreased by 60%, formation of acetate and propionate is inhibited by 54% and 85%, respectively, and ATP levels are reduced by 67%. The motility of the →flukes is gradually suppressed ending in a flaccid paralysis which may be explained by the slow depletion of energy reserves and cessation of feeding. Until now there are no reports about clorsulon resistance.

Isothiocyanates

Important Compounds

Bitoscanate, Nitroscanate.

Synonyms

Bitoscanate: Jonit, Bitovermol, Sicur.
Nitroscanate: Lopatol, Cantrodifene, Canverm.

Clinical Relevance

Nitroscanate was introduced in 1973. Its anticestodal activity is directed against →*Taenia* spp., →*Dipylidium caninum* and *Echinococcus granulosus* in dogs (→Membrane-Function-Disturbing Drugs/Table 1). Furthermore, nitroscanate is used in dogs against →hookworms and →*Toxocara* spp. Bitoscanate exerts activities against →*Ancylostoma* and *Necator*.

Molecular Interactions

There are no data about the mode of action of nitroscanate in →cestodes. There is one report showing that the →ATP synthesis in the trematode *Fasciola hepatica* is inhibited (Fig. 4).

Halogenated Monophenols

Synonyms

Disophenol: Ancylol, DNP, Iodophene, Syngamix.
Nitroxynil: Fasciolid, Dovenix, Trodax.

Clinical Relevance

Disophenol and nitroxynil are two members of monophenols with antitrematodal activity against *Fasciola hepatica* (Table 1). Moreover, disophenol exerts antinematodal activity against →*Haemonchus contortus*.

Halogenated Bisphenols

Important Compounds

Bithionol, bithionol sulfoxide, Meniclopholan.

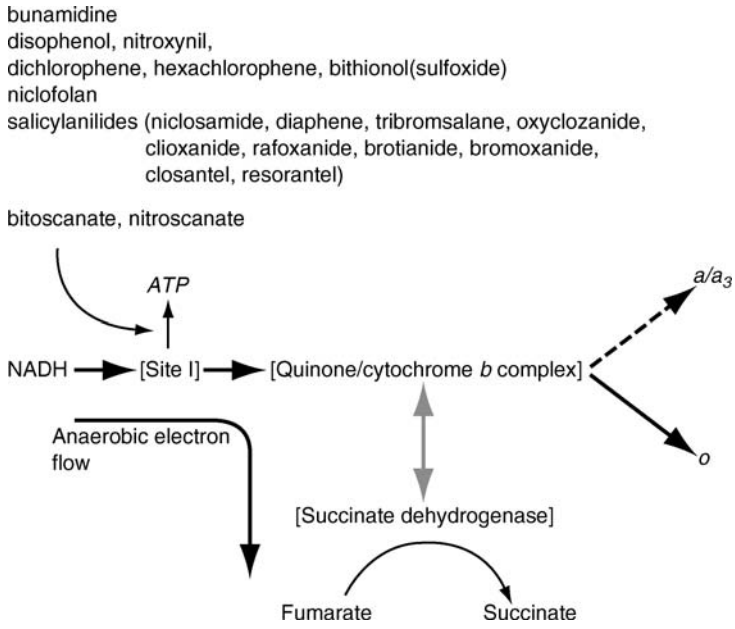
Synonyms

Bithionol: Actamer, Bitin, Lorothidol.
Bithionol sulfoxide: Bitin-S, Disto-5.
Meniclopholan: Niclofolan, Bayer 9015, Me 3625, Bilevon-M, Dertil, Distolon.

Clinical Relevance

Bithionol and bithionol sulfoxide (so-called thiobisphenols) were the first members of the class of halogenated bisphenols discovered in the 1930s. Dichlorophene was introduced in 1946 and hexachlorophene in the late 1950s. The anticestodal activity of these drugs is directed against *Taenia saginata*, →*T. solium*, *Diphyllobothrium latum*. They have some effects against *Hymenolepis nana*. These compounds are now replaced by more active drugs.

Hexachlorophene has some additional antitrematodal activity against mature *Fasciola hepatica*, →*Dicrocoelium dendriticum*, adult paramphistomes (Table 1). Dichlorophene shows activity against →*Fasciolopsis buski* (Table 2) and bithionol against →*Paragonimus* spp. (Table 2). Furthermore, bithionol is active against immature and adult paramphistomes (Table 1). However, it is toxic at the effective antitrematodal dose rate. Another member of the bisphenols, menichlopholan (= niclofolan) has fasciolocidal activity and high effectivity against immature paramphistomes in sheep (Table 1), but not against immature and adult flukes in cattle. Niclofolan exhibits additional activity against →*Metagonimus* spp. (Table 2).



Energy-Metabolism-Disturbing Drugs. Figure 4 Action of anthelmintics by uncoupling of oxidative phosphorylation.

Characteristics

The structure-activity relationships for the fasciolocidal activity of bisphenols are similar to that for monophenols. The safety index of monophenols and bisphenols is generally rather low between 1 and 4. Disophenol and nitroxynil obtain as electron-withdrawing substituents halogen, nitro, or cyano groups, which are necessary in at least the ortho- and/or parapositions of the phenol for the fasciolocidal activity. Nitroxynil, niclofolan, bithionol, and hexachlorophene have structural similarity to 2,4-dinitrophenol, a known uncoupler of oxidative phosphorylation in mammalian systems (Fig. 4).

Molecular Interactions

The mode of action studies with mono- and bisphenols have been carried out in isolated cestodal or mammalian mitochondria but not in liver flukes. Nevertheless, it is proposed that the action of monophenols and bisphenols relies on the decrease of ATP synthesis.

Salicylanilides

Important Compounds

Niclosamide, Oxyclozanide, Clioxanide, Rafoxanide, Brotianide, Bromoxanide, Closantel, Resorantel.

Synonyms

Niclosamide: Mansonil-P, Lintex-M, Mansonil-M, Yomesan, Bayluscid, Cestocid, Devermin, Fenasal, Radeverm, Sagimid, Tredemine, Vermitin.
Oxyclozanide: 3,3',5,5',6-Pentachloro-2'-hydroxysalicylanilide, Zanil, Diplin, Metiljin.
Clioxanide: 2-Acetoxy-4'-chloro-3,5-diiodobenzanilide, Tremerad.
Rafoxanide: 3'-Chloro-4'-(p-chlorophenoxy)-3,5-diiodosalicylanilide, MK-990, Bovanide, Duofas, Flukanide, Ranide, Ursovermid.
Brotianide: 3,4'-Dibromo-5-chlorothiosalicylanilide acetate, Bay 4059, Dirian.
Bromoxanide: none.
Closantel: Flukiver, Seponver.
Resorantel: Resorcylan, Terenol.

Clinical Relevance

The first salicylanilide niclosamide was discovered in 1958 and introduced in the early 1960s as anticestodal drug. The fasciolicidal activity of diaphene was discovered in 1963.

Niclosamide exerts anticestodal activity (→Membrane-Function-Disturbing Drugs/Table 1). It was the drug of choice in cestodiasis before the discovery of praziquantel. It has high curative efficacy against *Taenia saginata*, *T. solium*, *Diphyllobothrium latum*, *Hymenolepis nana*, →*Mesocestoides* spp., and *Dipylidium* spp., but only low activity against *Echinococcus granulosus*. Its absorption from the intestinal tract is poor (only 2%–25% absorption in the first four days), and it is not accumulated in any organ. More than 70% of the drug is excreted via feces and the excretion is completed within 1–2 days. Resorantel, another salicylanilide, exhibits anticestodal activity against →*Moniezia expansa* in ruminants.

In general, the antitrematodal activities are the main actions of salicylanilides. Niclosamide exerts activity against immature paramphistomes. It is regarded as the most effective and safe compound for the control of an outbreak of paramphistomiasis (Table 1). However, it has no effectivity against adult paramphistomes in ruminants. In general, drugs with high efficacy against the adult flukes are not active enough for elimination of pasture contamination. Furthermore Niclosamide has activities against intestinal flukes (*Fasciolopsis*, *Metagonimus*, *Heterophyes*, *Echinostoma*, *Gastrodiscoides*, *Watsonius*, *Nanophyetes*) (Table 2), but it is not active against *Fasciola hepatica*.

Diaphene is a mixture of 3,4,5'-tribromosalicylanilide (**tribromsalane**), the main component and fasciolicidal compound, and 4',5-dibromosalicylanilide used as a germicide. Tribromsalane was a new lead structure in the 1960s for a variety of salicylanilides such as **oxyclozanide**, **clioxanide**, **rafoxanide**, **brotianide**, **bromoxanide**, and **closantel**. Salicylanilides show an increased potency against adult and particularly also against immature flukes. They possess a greater therapeutic index between 4 and 6 compared to the halogenated phenols with a therapeutic index between 1 and 4. With salicylanilides mass treatment of sheep and cattle is possible for the first time, because they have good activity against 4–6 week old immature flukes.

Resorantel, a 4'-bromo-γ-resorcylanilide-derivative, is a specific and the most effective drug against immature and adult paramphistomes in sheep, goats, and cattle with slightly erratic, but good efficacy. In addition it has some activity against *Gastrodiscoides* (Table 2).

Oxyclozanide is probably the most suitable drug for the control of an outbreak of acute intestinal paramphistomes in calves, especially in concurrent *Fasciola*-infections.

Besides their anticestodal and antitrematodal activity, salicylanilides are also active against some nematodes. Thus, rafoxanide and closantel are active against the blood-ingesting nematode *Haemonchus contortus* (Table 1).

Molecular Interactions

The mechanism of the anticestodal action of niclosamide is the uncoupling of oxidative phosphorylation from electron transport in cestodes (Fig. 4). Thereby, protons are translocated through the inner

mitochondrial membrane. There is a measurable decrease of ATP synthesis in →*Ascaris* muscle mitochondria. The selective toxicity of niclosamide is explained by its poor absorption from the host intestine resulting in a protection of host cells against the uncoupling properties of this drug.

The fasciolicidal salicylanilides possess highly lipophilic groups like iodine, chlorophenoxy, tert-butyl-substituents which are responsible for prolonged plasma half-lifes between 2–4 days. Rafoxanide and bromoxanide have even longer half-lifes of 5–6 days. Moreover, there is slow excretion resulting in persistent drug residues. Therefore, several weeks of withdrawal periods before slaughter are necessary and most of the phenol-type fasciolicides are not used for treatment of milk-producing ruminants.

For rafoxanide, oxyclozanide, and closantel there is more direct evidence for an uncoupling action within the fluke (Fig. 4). An increased end-product formation by 32% and decreased ATP-synthesis by 29% by rafoxanide can be detected. Furthermore, there is an increased glucose uptake, decreased →glycogen content, enhanced end-product formation (succinate), increased mitochondrial ATPase activity, reduced ATP levels by closantel. A probable correlation between death of the flukes and reduced ATP levels is discussed. A deformation of mitochondria in many fluke tissues is observable. The →Golgi apparatus in the tegumental and gastrodermal cells is reduced in size and contains vacuolated cisternae. The basal infolds of the →tegument are swollen and ion pumps associated with the tegumental membranes are inhibited. There is as a result a general induction of rapid spastic paralysis of the adult flukes by the action of the presumptive uncoupler-type fasciolicides such as rafoxanide, oxyclozanide, nitroxynil.

Resistance

A selection of resistant strains of *Fasciola hepatica* in Australia has occurred by prolonged use of rafoxanide and closantel. There is cross-resistance between salicylanilides and the halogenated phenol nitroxynil. The resistance is manifest against immature but rarely against adult flukes. There is no side resistance in rafoxanide- and closantel-resistant liver flukes to oxyclozanide. It is assumed that selection for resistance in the case of rafoxanide and closantel is favored by possible differences in the mode of action and pharmacokinetic properties between oxyclozanide on the one hand and rafoxanide/closantel on the other hand. Thus, quick peak concentrations in the blood and quick elimination are seen with oxyclozanide in contrast to the strong binding to plasma proteins with rafoxanide and closantel resulting in long-lasting persistance in the blood at therapeutic concentrations for more than 90 days.

Cyanine Dyes

Important Compounds

Pyrvinium, Dithiazanine iodide.

Synonyms

Pyrvinium pamoate: Pyrvinium embonate, Viprynium embonate, Alnoxin, Molevac, Neo-Oxypaat, Pamovin, Poquil, Povan, Povanyl, Pyrcon, Altolat, Tolapin, Tru, Vanquil, Vanquin, Vermitiber.
Dithiazanine iodide: Abminthic, Anelmid, Anguifugan, Delvex, Dejo, Deselmine, Dilombrin, Dizan, Nectocyd, Partel, Telmicid, Telmid.

Clinical Relevance

Pyrvinium exerts antinematodal activity against *Enterobius*, *Trichuris vulpis*, dithiazanine iodide against *T. vulpis*. In addition, dithiazanine iodide has experimentally antifilarial activity against *Litomosoides carinii*.

Molecular Interactions

The antinematodal action against *T. vulpis*, a nematode residing in a more anaerobic environment, is probably the inhibition of glucose uptake by dithiazanine and also by pyrvinium. Responsible for the antifilarial action of dithiazanine is presumably the irreversible inhibition of oxygen uptake of adult *L. carinii*, an oxygen requiring nematode.

Entamoeba coli

→Amoebae.

Entamoeba histolytica

Classification

Species of →Amoebae, Table 1.

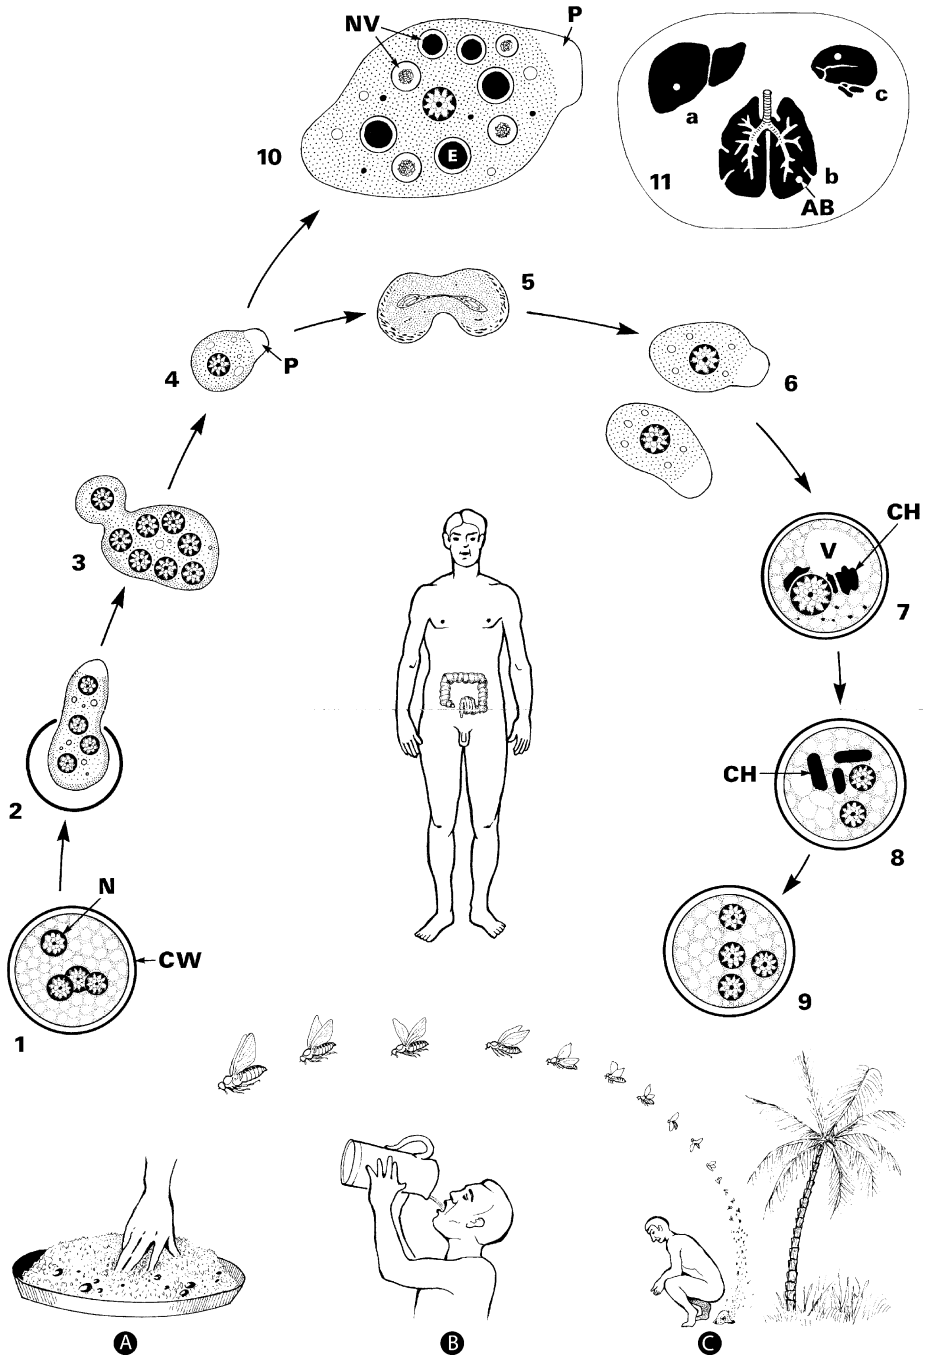
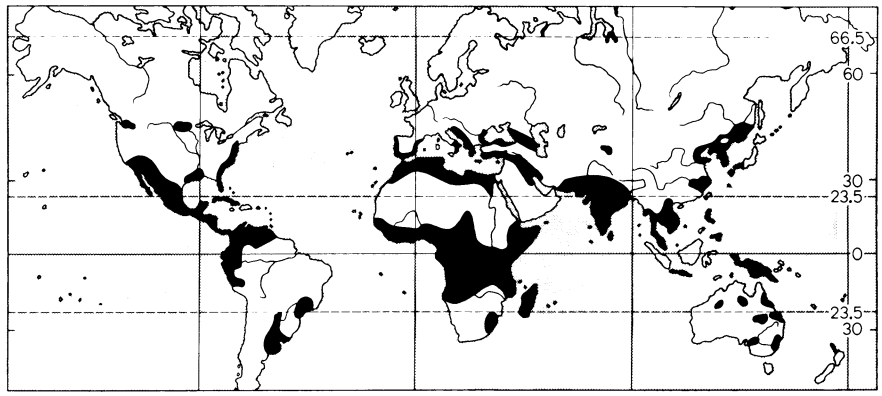
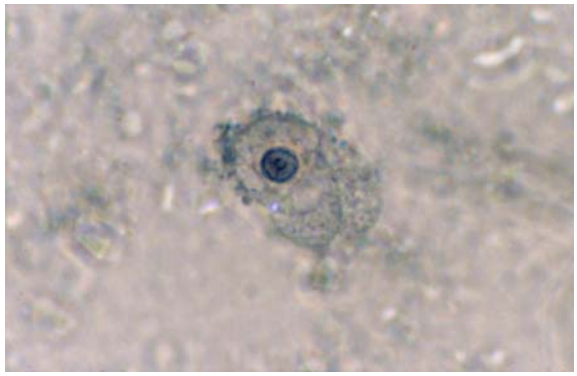
→Amoebiasis, →Entamoebiasis.



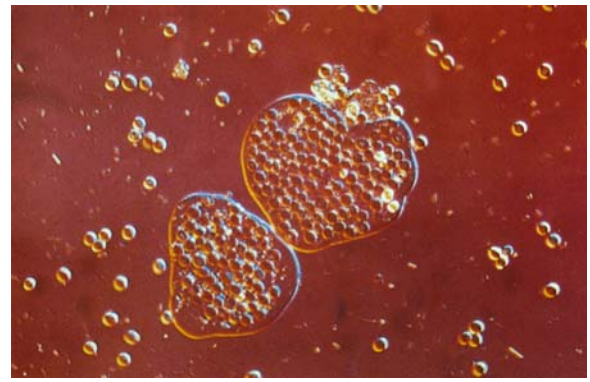
Entamoeba histolytica. Figure 1 Life cycle of *Entamoeba histolytica*. *1* Cysts with 4 nuclei (i.e., metacysts) are ingested orally with contaminated food or drinking water (**A–C**). *2–4* After excysting in the small intestine, both the →cytoplasm and nuclei divide to form 8 small amoebulae (i.e., metacystic →trophozoites). *5, 6* Mature trophozoites (i.e., minuta forms) reproduce by constant →binary fission. *7* Uninucleate cyst (i.e., →precyst) contains →chromatoid bodies and (often) a large →glycogen vacuole. *8* Cysts with 2 nuclei and chromatoid bodies. *9* Cysts with 4 nuclei (metacysts) are set free with the feces and become infectious when ingested by man. *10–11* Some of the minuta forms may grow to magna forms, which enter the intestinal wall and, via the bloodstream, other organs such as liver, lung, and brain (11 a–c), where they lead to →abscesses (i.e., →Amoebomae). Living amoebas are only found at the periphery of these amoebomae. *AB*, →abscess; *CH*, chromatoid body; *CW*, cyst wall; *E*, erythrocyte; *P*, single, pale pseudopodium; *N*, nucleus with central →nucleolus (karyosome); *NV*, food vacuole; *V*, →glycogen vacuole of young →cysts (for further species see →Amoeba/Table 1).



Entamoeba histolytica. Figure 2 Distribution map of amebic dysentery.



Entamoeba histolytica. Figure 3 Unstained minuta-stage of *Entamoeba histolytica*; note the nucleus with the centrally located nucleolus.



Entamoeba histolytica. Figure 4 LM of 2 magna-forms as seen with the Nomarski-technique.

Entamoeba Species

From Greek: *entos* = inside; *amoibos* = changing. →Amoeba.

Entamoebiasis

Disease due to the protozoan. →*Entamoeba histolytica*, →Alimentary System Diseases, Carnivores.

Main clinical symptoms in humans: →Abdominal pain, bloody-slimy →diarrhoea, liver dysfunction in case of liver →abscess.
Incubation period: 2–21 days.
Prepatent period: 2–7 days.
Patent period: Years.
Diagnosis: Microscopic determination of cysts in faecal samples.

Prophylaxis: Avoid uncooked food/water in endemic regions.
Therapy: Treatment see →Antidiarrhoeal and Antitrichomoniasis Drugs.

Enterobiasis

Pathology

Enterobiasis is a human infection with the ubiquitous →pinworm, →*Enterobius vermicularis*. This small nematode has a simple life cycle in the intestinal lumen (→Pathology/Fig. 22A). The adult female deposits eggs in the anal canal and on the perianal skin, causing irritation leading to itching. The adults are sometimes found in the lumen and even the mucosa of the vermiform appendix, but their role in causing appendicitis is in doubt. Ectopic worms may be found in the vagina, uterus, migrating up the fallopian tubes into the peritoneum, and occasionally elsewhere, where they tend to die and become

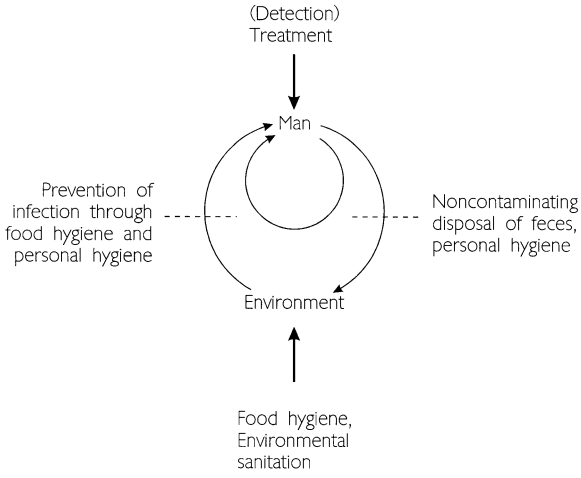
surrounded by small granulomas containing eosinophils (→Pathology/Fig. 27B-D). It has been speculated that eggs of *Enterobius* spp. transmit *Dientamoeba fragilis*, which may cause diarrhea, sometimes with blood and mucus.

Targets for Intervention

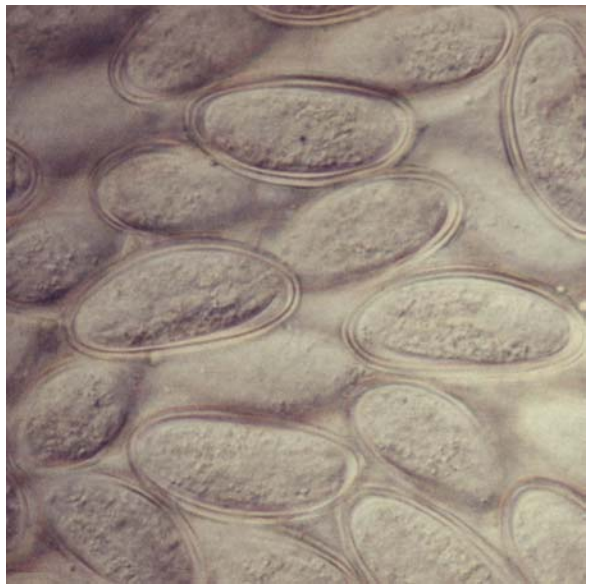
Infections with the nematode →*E. vermicularis* tend to be transmitted directly from man to man (anus-hand-hand-mouth), and self-reinfection is frequent since the worm eggs are immediately infective. However, some infections are also indirectly transmitted through contaminated material. Figure 1 shows potential targets and approaches of intervention.

The main targets will be infective reservoir and transmission from man to man. The approaches to control consist of detection and treatment of infections, and improving personal →hygiene and food hygiene. Blanket presumptive treatment campaigns without prior diagnosis have been successfully conducted, especially in populations of children with high infection rates. The best results were obtained with repeated treatment at an interval of 2–4 weeks.

Main clinical symptoms: →Pruritus analis, →diarrhoea, disturbances of sleep.
Incubation period: 1–4 weeks.
Prepatent period: 4–6 weeks.
Patent period: Years due to repeated autoinfections.
Diagnosis: Microscopic determination of eggs attached at the skin of the outer anal region (Fig. 2).
Prophylaxis: Repeated cleaning of toilets and daily cleaning of perianal skin; treatment of the whole family.
Therapy: Treatment see →Nematocidal Drugs.



Enterobiasis. Figure 1 Targets and approaches for the control of enterobiasis.



Enterobiasis. Figure 2 Eggs of *Enterobius vermicularis*.

Enterobius vermicularis

Synonym

→Pinworm of man, →*Oxyuris*.

Morphology

The adult female worms reach a length of 8–13 mm, are 0.3–0.6 mm in width, and have a long pointed tail (Fig. 2). The male is smaller (2.5 mm), its hind end is curved and contains a single copulatory spicule.

Classification

Species of →Nematodes.

Life Cycle

Figs. 1–3 (pages 488, 489).

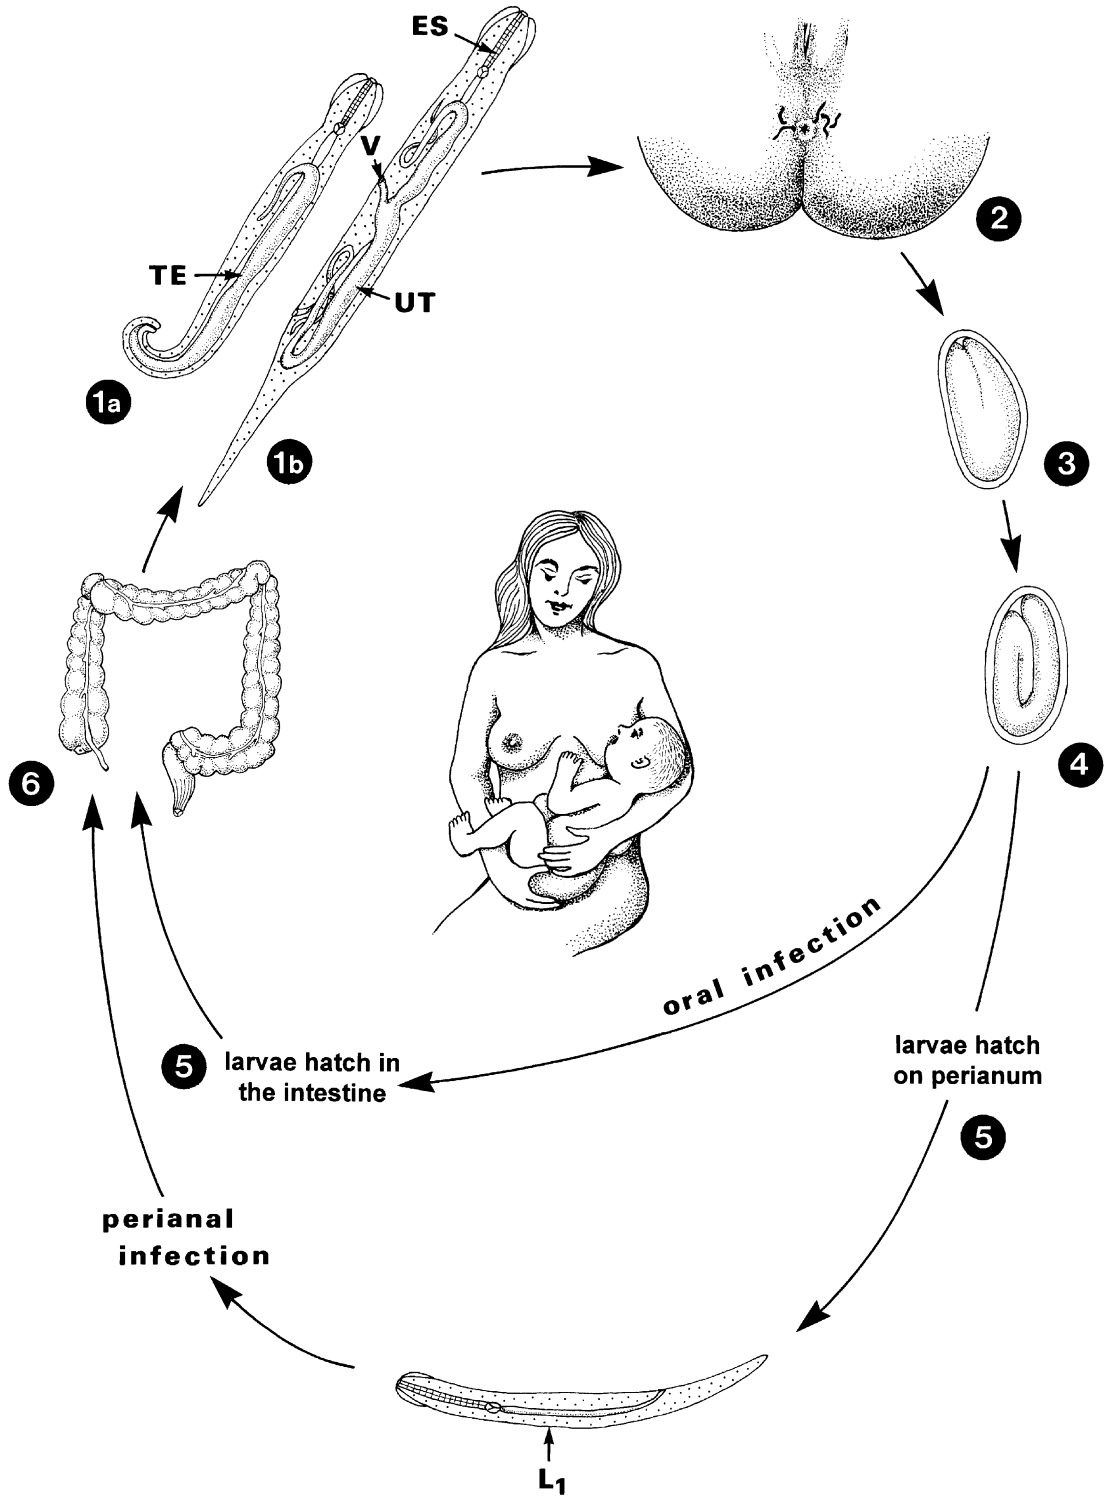
Disease

→Enterobiasis.

Enterocytozoon

Classification

Genus of →Microsporidia.



Enterobius vermicularis. Figure 1 Life cycle of *Enterobius vermicularis*. *1a/b* Whitish adult males (1a: 2–5 × 0.6 mm) and females (1b: 8–13 mm in length) live in the colon and rectum of man (especially children). *2/3* After copulation females migrate (at night) through the anus onto the perianal region, lay numerous (10,000) eggs and die. *4* Eggs embryonate within 6 h, forming the infectious first larval stage. *5* These eggs may be swallowed, or hatched larvae may enter the intestine directly via the anus, or erroneously via the vagina of women. *6* Inside the intestine the life cycle is completed within 4–6 weeks, leading to mature adults inside the colon. *ES*, esophagus; *L*, larva; *TE*, →testis; *UT*, uterus; *V*, vulva.

Enterobius vermicularis. Figure 2 LM of an adult female of *Enterobius vermicularis*.

Enterobius vermicularis. Figure 3 Higher magnification of the anterior pole of a female of *Enterobius vermicularis* with many excreted eggs; the anterior bulbus is characteristic.

Enterocytozoon bieneusi

This most common microsporidian in →AIDS patients (leading to chronic diarrhea with wasting syndrome) has recently been found in pigs, macaccas, dogs, and rabbits, thus underlining its zoonotic properties. →Microsporidia, →Opportunistic Agents.

Enteromonadina

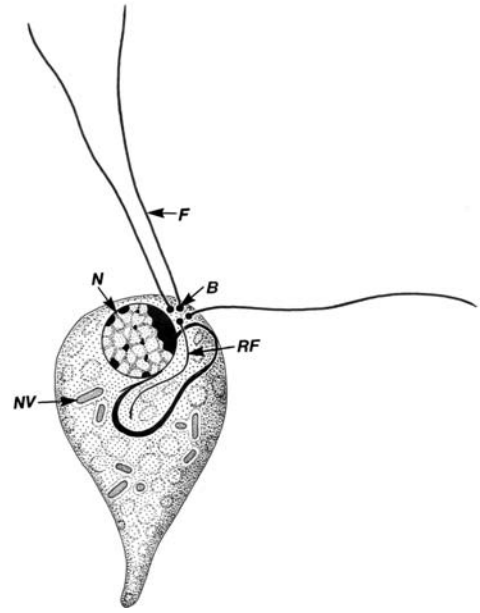
Group of diplomonadid protozoans. →Diplomonadida/Table 1.

Enteromonas hominis

Flagellated human intestinal parasite (Fig. 1). →Diplomonadida/Table 1.

Enteromyiasis

From Greek: *endon* = inside; *myia* = fly. Due to fly larvae, that parasitize in the gut system (e.g., →*Gasterophilus*).



Enteromonas hominis. Figure 1 Drawings of a trophozoite (a) and of an encysting stage (b) of *Enteromonas hominis*.

Entobdella

→Monogenea.

Entodiniomorphids

Group of ciliates that occur in the stomach of cattle, sheep, and goats (e.g., *Diplodinium dendatum* in cattle).

Entopolypoides

Genus of blood parasites that is now considered to belong to the genus. →*Babesia*. Two human cases had been described due to *E. macaci*.

Envelope

Locke proposed the name envelope for all such extracellular structures which have dimensions similar to those of plasma membranes and which are formed at membrane surfaces. Such envelopes (e.g., 3 in →*Trichinella spiralis*) occur in a variety of organisms, from bacteria to vertebrates. More information is needed about their biochemical and functional properties, since they allow many different transport processes and are apparently resistant towards hosts' digestive enzymes as well as cellular attacks.

Environmental Conditions

It is well known that parasites are more detrimental to their hosts when environmental conditions make the latter more vulnerable, principally because resources are limited and, as a consequence, immune defences weakened. In humans for instance, periods of famine are often aggravated by epidemics.

This happens also in the wild. De Lope et al. write: "It is inherent in the definition of parasitism that parasites are costly to their hosts. Costs can be measured in absolute terms, but may vary in relative magnitude as a consequence of variation in access by hosts to essential resources. If parasites are costly to their hosts in terms of fitness, they should be so to a larger extent under stressful environmental conditions."

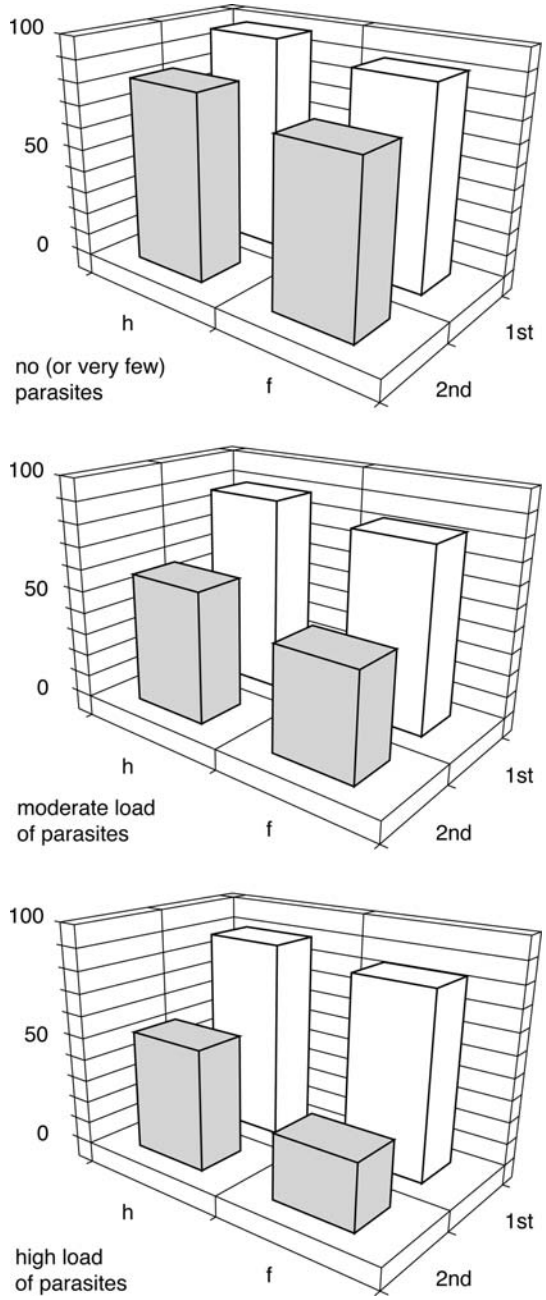
De Lope et al. have tested this prediction by comparing the impact of the →ectoparasite →*Oeciacus hirundinis* on its bird host, the house martin *Delichon urbica*. (The parasite feeds on the blood of nestlings and can cause their death.) All nests under study were fumigated in order to kill the parasites, then: (a) First third of nests were left without parasites, (b) 10 →bugs per nest were added in the second third, and (c) 100 bugs per nest were added to the last third. The authors then studied various parameters of bird reproduction, especially hatching success and fledging success (In the area -southern Spain- where the study was carried out, usually 2 broods are reared each year.) They showed that (Fig. 1):

- in the nests without (or nearly without) parasites, hatching and fledging successes are close to 100% in both clutches;
- in the nests with few bugs, there is little decrease in hatching and fledging successes in the first clutch, but in the second clutch the success goes down to ∼50%;
- in the nests with a high parasite load, the first clutch is still little affected, but the second clutch experiences a dramatic decrease of reproductive success.

Fledging and fledging success of second broods thus decreased considerably with increasing parasite intensity. In other words, parasites were more costly to house martins in the second clutch. The explanation is that the second clutch is reared when food (*D. urbica* is a strictly insectivorous passerine) is less abundant: the negative effects of parasites on their hosts increase as external conditions become worse. One may conclude that, when food is readily available, the negative effects of parasites are compensated on the part of the hosts to such an extent that decrease of host fitness is virtually absent or at least difficult to detect. In contrast, the impact of parasites on host fitness increases dramatically when environmental conditions are poor.

Environmental Management

→Disease Control, Methods.



Environmental Conditions. Figure 1 Hatching (H) and fledging (F) successes of house martin in first (1st) and second (2nd) clutches (original, data from de Lope et al.).

Environmental Parasitology

Parasites can be used as sentinels or biomarkers for the occurrence of pollution and/or presence of toxic substances, e.g., parasites were shown to accumulate metal ions, etc. from the food of their hosts, thus allowing conclusions on the food and/or on the situation of the habitat of the host.

Enzyme Linked Immunosorbent Assay (ELISA)

This is a type of sandwich-test for the diagnosis (e.g., of parasites) using antigen or antibodies that were marked with enzymes. In case of **antigen-ELISA** a specific antibody (directed against the antigen) becomes attached at a plate. Then the test substance (with the antigen) is filled onto the plate thus giving rise to antibody-antigen-complexes. As next step a second antigen specific antibody, which is marked with an enzyme, is added. If then the test substrate as added, the antigen can become qualitatively and quantitatively determined.

Eoacanthocephala

→Acanthocephala.

Eocollis arcanus

→Acanthocephala.

Eomenacanthus

Genus of →Acanthocephala.

Eosinophilia

As effect of the occurrence of some parasites in peculiar organs (e.g., →*Ascaris* during lung passage, schistosomal eggs in liver etc.) the general number of eosinophilic cells may become considerably increased. This increase is often used as help in diagnosis.

Eosinophilic Granulomas

→*Angiostrongylus cantonensis*, →Schistosoma, →Pathology.

Eosinophilic Meningoencephalitis

Disease in humans, e.g., due to infections with →*Angiostrongylus cantonensis* (L 3 enter the brain and die there). Such infections were reported from more than 30 countries in South East Asia, Africa, Australia and America.

Eosinophilic Reaction

→Pathology.

Eperythrozoon

Genus of rickettsiales (e.g., *E. suis* in pigs), transmitted mechanically by blood suckers.

EPG

Eggs per gram of feces. Method to measure the intensity of an infection using the techniques of the McMaster chambers or of the Kato-Katz smears.

Epicuticle

The outermost layer of the →cuticle in →nematodes. It is between 6 and 60 nm thick and consists mainly of 2 dark lamellae separated by a lighter interspace (→Nematodes/Fig. 7B, 8E, →Nematodes/Integument).

Epidemia

From Greek: *epi* = over, above; *demos* = people. Occurrence of diseases in different groups of hosts.

Epidemic Spotted Typhus

Disease of humans due to infection with the spherical, 0.3–0.5 µm-sized *Rickettsia prowazekii* stages transmitted by the feces of →lice (*Pediculus humanus corporis*) via inhalation or skin scratching. After an →incubation period of 10–14 days high fever occurs leading to death in 20% of (untreated) cases.

Therapy

Tetracyclines.

Epidemic Zone

→Geographic Zones of Occurrence of Diseases; infections occur at intervals.

Epidemiology

Epidemiology (expression in medicine) or →epizootiology (expression in veterinary medicine) is a science dealing with occurrence, distribution, prevention, and control of disease, injury, and other health-related events (e.g., influence of climatic conditions) in a defined animal or human population.

Epidermal Growth Factor (EGF)

Apical addition of this factor may block the activity of →*Giardia*-trophozoites to disrupt the tight junction-zone of their host cells.

Epieimeria

→Eimeria species, →Coccidia.

Epimastigotes

Developmental stage of →Trypanosomatidae mostly found in the intestine of the vectors. The single flagellum is anchored in the mid of the cell body (beyond the nucleus), →flagella.

Epimerite

→Gregarines.

Epistylis

→Ciliophora, →Flagella.

Epitheliocystidia

→Digenea.

Epizootiology

Epizootiology (expression in veterinary medicine) or epidemiology (expression in medicine) is a science dealing with occurrence, distribution, prevention, and control of disease, injury, and other health-related events (e.g., influence of climatic conditions) in a defined animal or human population.

EPM

Equine **p**rotozoal **m**yeloencephalitis described as result of infections with *Sarcocystis neurona* in horses (→Sarcocystis). The pathway of transmission remains unclear.

Eprinomectin

Chemical Class

Macrocyclic lactone (16-membered macrocyclic lactone, avermectins).

Mode of Action

Glutamate-gated chloride channel modulator. →Nematocidal Drugs, →Ectoparasiticides – Antagonists and Modulators of Chloride Channels.

Epsiprantel

→Cestodocidal Drugs.

Equine Protozoal Encephalomyelitis (EPM)

Disease of horses due to cerebral infection with the coccidian parasite *Neurospora*. Another often fatal viral disease is called equine encephalomyelitis (EEM).

Equine Protozoal Myeloencephalitis

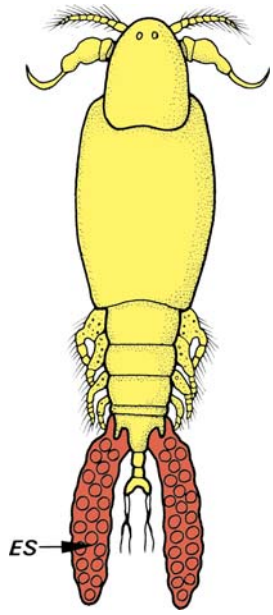
→EPM.

Ergasilus

Fig. 1 (page 494); →Crustacea.

Eridication

Trial to eliminate a vector of agents of diseases from a certain region.



Ergasilus. Figure 1 DR of an adult female with two egg-bags (ES).

Erpobdella octuculuta

→Leeches.

Erysipeloid

→Fleas.

Erythema

Clinical and pathological symptoms of infections with skin parasites (→Skin Diseases, Animals, →Tick Bites: Effects in Animals, →Tick Bites: Effects in Man, →Ticks as Vectors, →Lyme Disease).

Erythema chronicum migrans

→Lyme Disease.

Erythrocyte-Binding Antigens (EBA)

→Apicomplexa.

Escape Behavior

→Behavior.

Espundia

→Cutaneous Leishmaniasis.

Esthiopterum crassicorne

Species of Mallophaga of chicken.

Ether-Lipids

→Energy Metabolism.

Ethion (Diethion)

Chemical Class

Organophosphorous compounds (dithiophosphate).

Mode of Action

Acetylcholine esterase inhibitor. →Ectoparasiticides – Agonists and Antagonists of Cholinergic Transmission.

Etofenprox

Chemical Class

Pyrethroid (non-ester pyrethroid).

Mode of Action

Open state voltage-gated sodium channel blocker. →Ectoparasiticides – Blockers / Modulators of Voltage-Gated Sodium Channels.

Eubothrium

→Eucestoda.

Eucestoda

Classification

Subclass of →Cestodes.

General Information

The adult members of the Eucestoda are extremely dorso-ventrally flattened, appear mostly white-opaque, and inhabit the alimentary system of vertebrates (except for *Archigetes* spp., which may also reach sexual maturity in freshwater oligochaetes; Table 1). Most →tapeworms are polyzoic animals (Fig. 1, page 498) characterized by the repeated occurrence of sets of reproductive organs (exceptions are members of the orders Caryophyllidea (→*Caryophyllaeus laticeps*/Fig. 1) and Spathebothriidea). With the exception of the members of the order Dioecocestidae (parasites of the grebe and ibis), the tapeworms are protandric →hermaphrodites (monoecious animals) which cover a size range from 1 mm up to 25 m. Apart from the caryophyllideans, which are considered as sexually mature larvae (→Progenesis, →Neoteny) of pseudophyllideans, members of the Eucestoda show a characteristic body differentiation into →scolex, →neck, and →strobila consisting of a few to up to 4000 →proglottids (Figs. 1–3, pages 498–500).

The scolex is very small (mostly less than 1 mm) and endowed with specific holdfast systems such as →rostrum, acetabula, suckers, bothria, grooves, and hooks (Fig. 4, page 501; →Cestodes/Fig. 1). The small neck region is the continuously differentiating zone that produces immature proglottids; the cytological processes are only poorly understood. The strobila, representing the main bulk of the body, consists of a more or less long chain of proglottids. The latter contain, in a species-specific pattern, 1 or 2 sets of sexual organswhich, however, do not mature at the same time. Just behind the neck proglottids are immature, then further posteriad there are proglottids with mature male organs, then those with mature female organs, and finally those whose uterus contains fertilized eggs; the latter proglottids are thus described as gravid. Copulation occurs before egg formation; a given proglottid can copulate with itself, with others in the same strobila, or with those in other worms. When a gravid proglottid reaches the end of a strobila, it detaches (→Apolysis) and passes out intact with the feces (e.g., →*Taenia* spp.) or partly disintegrates before reaching the anus (→*Vampirolepis*/*Rodentolepis* = *Hymenolepis*). In cases where the uterus has an opening, the proglottids release the eggs and become detached when exhausted (→Pseudoapolytic, →Anapolytic; e.g., →*Diphyllobothrium*). Besides the sexual organs (repeated in each proglottid), some systems (such as excretory canals, nerve fibers, body wall with →tegument, longitudinal muscles) are common to the whole worm and run from the scolex to the posterior end (Fig. 1).

In general, ontogenesis of members of the Eucestoda proceeds as a →metamorphosis using different larval stages in alternating hosts (→Cestodes/Fig. 2, Table 1). The first and most common larva is the 6-hooked →oncosphaera, which is infectious to intermediate hosts and develops into other larval stages (→Cestodes/Fig. 2). In some species some of these later larval stages give rise to an asexually produced generation (e.g., →*Echinococcus*, →*Taenia multiceps*, →*Mesocestoides* sp.), thus initiating a →metagenesis, which is characterized by alternating sexually and asexually reproducing generations.

Important Species

Table 1.

Life Cycle

→Archigetes Species, →Dipylidium caninum/Fig. 1, →Echinococcus/Fig. 1, →Hymenolepidae/Fig. 1, →Mesocestoides/Fig. 1, →Pseudophyllidea/Fig. 1, →Taenia/Fig. 1.

Eucoccidium

Genus of the →Protococcidia; →Grellia.

Eucoleus

Synonym

→*Capillaria contorta*, the females reach a length of 2 cm, the males 12 mm; they live in the esophagus of goose, duck, chicken.

Eucestoda. Table 1 Some common species of the Eucestoda

Order/Species	Length of adult worm (m)	Egg size (μm)	Final host	Prepatent period	Intermediate host (i.h.)/ Habitat	Stage inside intermediate host (i.h.)

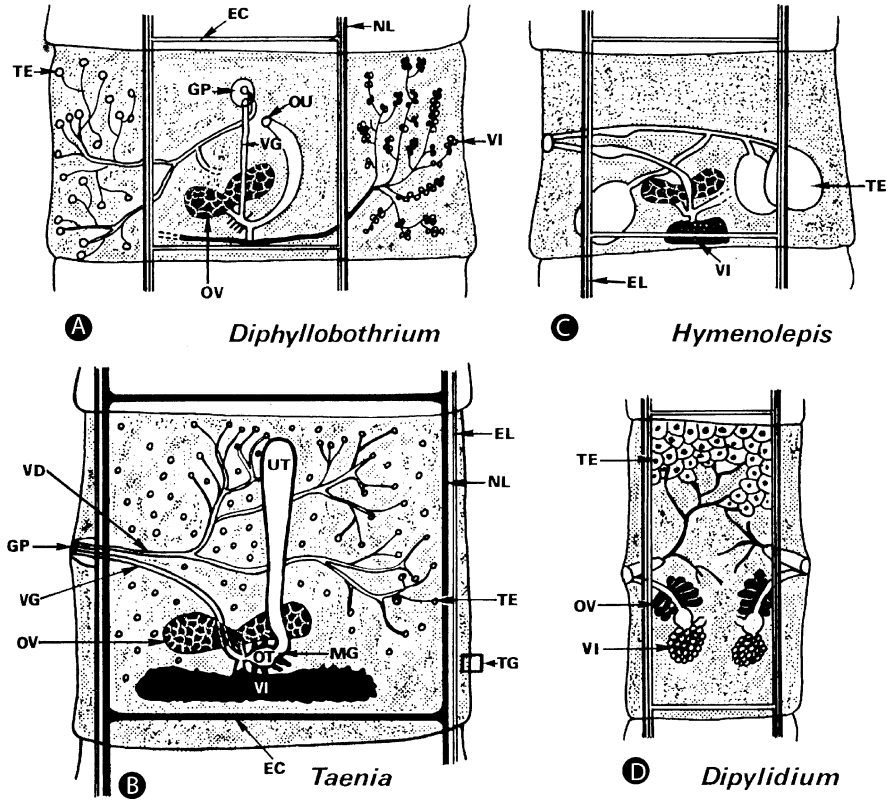
Eucestoda. Figure 1 A–C Diagrammatic representation of the organization of an eucestodean tapeworm (e.g., *Hymenolepis* sp.) showing the repeated reproductive organs and the common systems (nerves, excretory channels). Note the folded surface leading to the aspect of separate proglottids. Parenchymal muscles are left out. *EC*, cross-running excretory canal (connecting the ventral longitudinal vessels); *EG*, egg (containing the oncosphera); *EL*, longitudinally running excretory canals (2 on each side); *NL*, nerves running longitudinally; *PR*, proglottis; *OV*, ovary; *RS*, receptculum seminis; *SC*, scolex; *ST*, subtegumental cells and muscle layer (circular, longitudinal); *TE*, testis; *TG*, tegument; *UE*, uterus filled with eggs; *VD*, vas deferens; *VG*, vagina; *VI*, vitellarium.



Eucestoda. Figure 2 A–D Diagrammatic representation of the reproductive organs within proglottids of different genera of tapeworms. Note the different size and number of testes, the occurrence of an uterus opening, and the position of the genital porus. In **A** (*Diphyllobothrium* spp.) only 1 of the 2 vitellaria and half of the branched male system is drawn. *Dipylidium caninum* **(D)** has 2 sets of reproductive organs per proglottis. *EC*, cross-running excretory channel; *EL*, longitudinal excretory channel; *GP*, genital porus; *NL*, nerve running longitudinally; *OT*, ootype; *OU*, opening of the uterus; *OV*, ovary; *TE*, testis; *TG*, tegument (details not drawn); *UT*, uterus; *VD*, vas deferens; *VG*, vagina; *VI*, vitellarium.

Euglenozoa

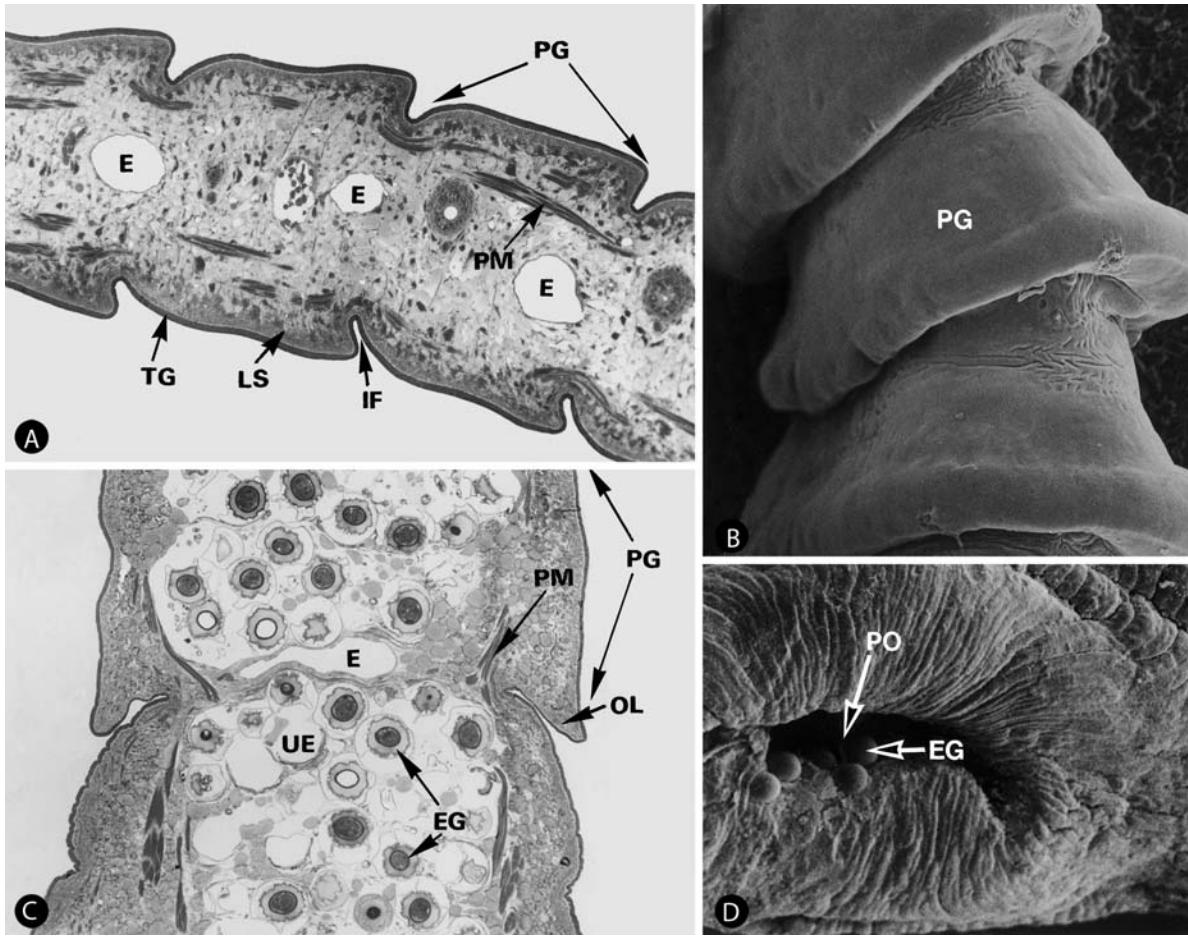
Phylum of protozoans (e.g., it contains the →Kinetoplastida, with specimens of the genus →*Trypanosoma*. →Classification.

Eukaryonts

Old name for →Eukaryota. See also →Nuclear Division.

Eukaryota

Eukaryotes may consist of a single cell or they may be multicellular organisms – termed →Metazoa – made up of differentiated (specialized) cells. They may be unicellular in all their developmental stages (→Protists), or unicellularity may be limited to certain developmental stages, such as the sexual stages (→Gametes) of plants and animals. Even highly differentiated →Metazoa retain vestiges of their unicellular origin, as shown by their development from unicellular "eggs," some of which may develop even if they are not fertilized. They also have the ability to reconstruct their whole bodies from a single cell, as do easily the sponges, but also the fertilized →oocytes of vertebrates. Eukaryotic



Eucestoda. Figure 3 A–D *Hymenolepis nana*: organization of the strobila. **A, C** Light micrographs of semithin sections, **B, D** scanning electron micrographs. *A* Longitudinal section of young proglottids (PG). Note the formation of infoldings at the distal end of proglottids (× 250). *B, C* Typical aspects of mature craspedote proglottids in longitudinal section (C) and surface view (B). Note the overlapping region (OL) and the absence of a definite border between the proglottids in C. (B × 80, C × 100). *D* Pore at the end of the terminal proglottid, through which eggs (EG) may pass (× 80). *E*, Excretory channel (connecting the longitudinal vessels); *EG*, egg; *IF*, infolding of the tegument; *LS*, layer of subtegumental cells; *OL*, overlapping part of the preceding proglottid; *PG*, proglottid; *PM*, parenchymal muscles (here running longitudinally); *PO*, pore; *TG*, tegument; *UE*, uterus filled with eggs.

cells consist of a membrane-bound →cytoplasm (containing 1 or more nuclei and various organelles that are also often membrane-bound, their compartments and membranes acting as sites) where reaction processes can occur. The most significant differences between the components of eukaryotic and prokaryotic cells are listed in Table 1.

Eumitosis

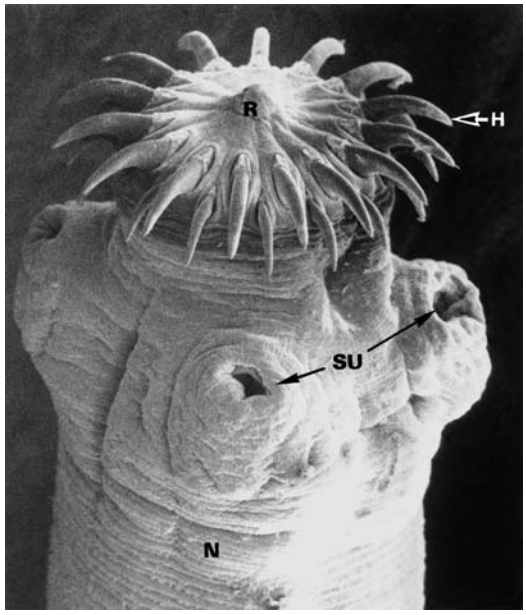
→Nuclear Division of the metazoans during which the nuclear membrane disappears.

Euparyphium melis

Species of the trematode order Echinostomatida.

Eurytrema

Genus of the trematode family Dicrocoeliidae. *E. pancreaticum* (8–16 × 5–8 mm, Fig. 1, page 502) is found in the pancreas of ruminants, pigs, camels, and monkeys in Asia and South America. Related species of birds are found occasionally in humans.



Eucestoda. Figure 4 Scanning electron micrograph of typical platyhelminthic →holdfast organs: *Taenia* spp. scolex with rostellar hooks (H) and suckers (SU) (× 150). *N*, →neck region; *R*, →rostellum.

Euryxenie

Greek: *euris* = wide/large; *xenos* = foreign; species with a large spectrum of possible hosts.

Euschongastia indica

Species of the mite family Trombiculidae, the larvae of which live as parasites.

Eutely

Absence or strict reduction of all divisions, e.g., →cell multiplication in →nematodes after last hatching is very restricted (if not entirely absent) -except within the reproductive system, midgut, epidermis, and somatic muscles.

Evasion

From Latin: *evadere*. Active slip out of parasites (e.g., →*Oxyuris*). →Immune Responses.

Evasion Mechanisms

Mechanisms of parasites to avoid the attacks of the immune system. →Amoebiasis, →Cysticercosis, →Giardiasis, Man, →Sleeping Sickness; →immune Responses.

Eukaryota. Table 1 Differences between prokaryotes and eukaryotes

Attributes	Prokaryotes	Eukaryotes
Cell nucleus	−	+
DNA-amount	Low (up to 1.4×10^{-2} pg/cell)	High (1.6×10^{-2} – 96 pg/cell) (in haploidity)
Organization	Circular	Linear (chromosomes) plus circular elements
Recombination	Conjugation	Meiosis and syngamy
Introns	−	+
Cell division	+	+
– Speed	Quick (20 minutes)	Slow (hours)
– Mode	By formation of septa	By mitosis and cytokinesis
Ribosome type (subunits)	70S (30S + 50S)	80S (40S + 60S)
Membrane bound organelles (mitochondria, plastids, Golgi etc.)	−	+
Mictotubules	−	+
Membrane bound flagella (9 × 2 + 2 pattern)	−	+
Use of actomyosin for movement	−	+
Endo- and exocytotic activity (i.e., movement)	−	+

+ Present, − Not present

Eurytrema. Figure 1 Adult from pancreas duct of a pig.

Exacerbation

From Latin: *acerbare*. Increase of the intensity of symptoms of disease.

Excoriation

Clinical and pathological symptoms (loss of surface layers) of infections with skin (Latin: *corium*) parasites (→Skin Diseases, Animals, →Demodicosis, Man).

Excretion

The process of eliminating waste materials (→Exocytosis).

Excretory Gland

Some →Nematodes possess paired glands to drain their body cavity, others have the so-called H-cell-system running as channels inside the lateral chords. Crustaceans developed similar excretory systems at the bases of antennae and/or their coxae (= first segment of leg).

Excyzoite

Stage that hatches from the 4-nucleated cyst of →*Giardia*, as soon as the cyst has reached the small intestine a few hours after oral ingestion.

Exflagellation

Formation of microgametes of →*Plasmodium* species in the gut of female anopheline mosquitoes.

Exocytosis

The process of →excretion similar to →endocytosis but in reverse. It may occur anywhere on the surface or, as in ciliates, at a specialized place called the →cell anus or →cytopyge.

Exophagic

→Mosquitoes that bite mainly outdoors (e.g., *Anopheles albimanus* in Central America).

Exospore

Outer layer of spore wall in microsporidians.

Exposition

Period during which hosts are exposed to possible transmission of agents of disease or time that have blood suckers for engorging parasitic stages.

Expression Associated Genes (ESAG)

At the plasma membrane of trypanosomes the transferring receptor is encoded by →VSG gene expression site associated genes (ESAG) no. 6 and 7 (with several alleles). However, only one form is expressed at a time.

Expulsion

Name

Latin: *expulsare* = eject.

Some drugs paralyse intestinal worms, which then are expelled and may start creeping in the feces: Living worms are also ejected during vomitory process.

Extended Phenotype

The notion of extended phenotype is due to Richard Dawkins, who defined it as "all the effects of a gene upon the world." In parasitology and more practically, it is the expression of a parasite's genotype into the phenotype of its host.

Many species of parasites manipulate the morphology and/or the behaviour of their hosts with the aim of facilitating their transmission to the next host in the life cycle. This is specially true when parasites have a life cycle involving an →intermediate host. Dawkins writes: "Parasites that have a life-cycle involving an intermediate host, from which they have to move to a definitive host, often manipulate the behaviour of the intermediate host to make it more likely to be eaten by the definitive host."

One of the first experimental demonstrations of an extended phenotype was achieved by Bethel and Holmes who showed that uninfected freshwater amphipods *Gammarus lacustris* tend to avoid light and remain close to the bottom of the lakes, whereas individuals infected by the acanthocephalan →*Polymorphus paradoxus* stay close to the surface and cling to surface debris. This behaviour makes them more vulnerable to surface-dabbling ducks, and thus facilitates parasite transmission. Dawkins regards the altered behaviour of the amphipods as an adaptation on the part of the parasite: "We may, therefore, talk of worm genes having phenotypic expression in shrimp bodies, in just the same sense as we are accustomed to talking of human genes having phenotypic expression in human bodies." Since the publication of a chapter by Bethel and Holmes in 1973, a great number of host phenotype manipulations by parasites have been reported. Poulin has drawn attention to the fact that energy spent on host manipulation is not available for other functions, which means that manipulation has a cost and must be optimized by selection as any adaptive trait. Maybe one of the most extraordinary examples of extended phenotype concerns immune avoidance by Strepsiptera, a group of insects which parasitize other insects. When penetrating a new host, the larva of the strepsipteran manipulates host epidermal tissue so that it may wrap within it; the larva is thus dissimulated to host immune defense; it is the manipulated host epidermis which constitutes a barrier to the host hemocytes.

The expression of parasite genes into the host phenotype might exist in humans. The best-documented case is that of *Toxoplasma gondii* which establishes persistent infections within the central nervous system of rodents but also in humans (20–80% of infection, depending on the country). In rats, *T. gondii* provokes an increase in activity, a decrease in neophobic behaviour, and an alteration of the perception of risk; as a result infected rats are easily preyed upon by cats, in which *T. gondii* completes its life cycle. While in humans, although the parasite is in a "dead end host," it provokes various disorders, including changes in the personality; even the risk of car accidents seems significantly increased in infected people.

Although the question of host manipulation must be regarded with a "critical eye" and the fact that the demonstration of the adaptive value of the host morphological and/or behavioral changes has not always been achieved, it is now widely accepted that the "extended phenotype" is one of the major adaptations facilitating parasite transmission.

Extrinsic Incubation Period (EIP)

This term (EIP) describes the period that is needed for a biting organism (e.g., insect, tick) to transmit an agent of disease after its uptake during a preceding blood meal. The **minimal EIP** is the time until the first female of a vector group transmit the agent of disease. The **middle EIP** is the period needed until 50% of the once infected blood suckers transmit. The EIP depends on the outer temperature, e.g., in the case of the transmission African horse sickness virus or bluetongue by →*Culicoides variipennis* respectively by *C. imicola* the virus replication starts only at an outer temperature of 9.9°C. At 15°C the EIP was 12.4 days, which was

shortened to 3.4 days, when the temperature arose to 30°C. The rise of temperature, however, shortens on the other hand the lifespan. Thus there must be found an optimum mixture of both in addition with other outer factors like rain, wind, etc., which influence the feeding activity of potential vectors.

Extrusome

→Flagella.

Exuvis

From Latin: *exuviae* = detached clothes. This term describes the empty chitinous or horny cover, which is left by, e.g., arthropods or reptiles after molt.

Eye Gnat

The chlorpid fly *Hippelates pusio*, which is only 2 mm long, bears yellow legs, eyes, and antennae, makes minute lesions in the conjunctival epithelium and may transmit the agents of contagious conjunctivitis, thus introducing the "sore- or pink-eye disease."

Eye Parasites

Parasites may enter each organ of the body. Several parasitic stages, however, have developed a special favor for this organ, which of course is especially sensible with respect to human welfare. Table 1 summarizes the parasites found in the different regions of the human eye. The life cycles, morphology, reproduction modes, and the pathological effects are described in the entries on the respective organisms). Figures 1–4 show some of the most common aspects of

Eye Parasites. Table 1 Ophthalmologic manifestation of parasitic infections

Ocular regions and ophthalmologic signs	Genera of parasites
Eyebrows and eyelids	*Pediculus, Phthirus, Ixodes*
Eyelid edema	Ixodids, *Pulex*, fly larvae, *Giardia, Trypanosoma, Plasmodium, Schistosoma, Paragonimus, Taenia*, spargana, *Ancyclostoma, Gnathostoma, Toxocara, Trichinella*, filariae
Chalazion and pseudochalazion	*Demodex*, fly larvae, *Trypanosoma, Schistosoma, Onchocerca, Leishmania*
Ptosis	*Taenia solium* (cysticercus)
Inflammations of the eyelid margin (blepharitis)	*Demodex, Pediculus, Phthirus, Plasmodium*
Ophthalmomyiasis	Fly larvae
Lacrimal ducts and glands	
Dacryocanaliculitis and dacryocystitis	Fly larvae, *Plasmodium, Ascaris, Mammomonogamus, Trypanosoma, Thelazia*
Dacryoadenitis	*Schistosoma, Plasmodium*
Orbit	
Exophthalmos	*Echinococcus*, coenurus, *Taenia, Schistosoma*, spargana, *Ascaris, Trichinella, Trypanosoma, Plasmodium, Entamoeba, Loa, Dracunculus, Dirofilaria, Gnathostoma*
Ocular muscles	
Diplopia	*Trichinella, Parastrongylus, Ancyclostoma*, spargana, *Taenia, Plasmodium*
Conjunctiva	
Parasites in the cul-de-sac	Fly larvae, *Enterobius, Thelazia*
Subconjunctival parasites	Fly larvae, *Thelazia, Loa, Wuchereria, Brugia, Dracunculus, Porocephalus*

parasites in eyes (pages 506, 507). For eye parasites of animals →Nervous System Diseases, Animals.

Eye Spot

Several →trematodes and especially their larvae possess an optical system to register light and dark in order to find suitable hosts. Since dense →pigment surrounds the optic cells, which are protrusions of ganglia of the anterior region or of the midbody and contain microtubuli →aberrant cilia, the developmental stages appear with dense spots. The number and arrangement of such spots are species-specific.

Eye Worm

Nematodes of the genus →Thelazia parasitize in the lachrymal ducts of horses and cattle. Transmission occurs by means of flies of the genus *Musca* that take up larvae 1 from the conjunctiva and introduce finally larvae 3. The mass of larvae 1 block the excretion of the lachrymal fluid. See also →Filariidae, →*Loa loa*, →*Thelazia*.

Facultative Anaerobes

Name

Greek: *aer* = air, *bios* = life.

These animals may survive also in absence of oxygen; e.g., *Toxocara* worms obtain most of their energy from glycogen degradation.

Facultative Pathogens

→Opportunistic Agents.

FAD

Flea **a**llergy **d**ermatitis: a reaction in sensitive dogs/cats or some other hosts on saliva of biting →fleas.

Fahrenholz' Hypothesis

The common ancestors of modern parasites were themselves parasites of the common ancestors of their present hosts.

Fahrenholz' Rule

Hypothesis that →Mallophaga and their bird hosts passed through the same →co-speciation and co-evolution, and that thus their phylogeny reflects this.

Falcipain

→Thiolproteinases.

Falciparum Malaria

Famphur (Famophos)

Chemical Class

Organophosphorous compounds (monothiophosphate).

Mode of Action

Acetylcholine esterase inhibitor. →Ectoparasiticides – Agonists and Antagonists of Cholinergic Transmission.

Fannia

Genus of flies, e.g., *Fannia scalaris* and *F. canicularis* (= i.e., smaller houseflies) look very similar to *Musca domestica*. However, the larvae of *Fannia* spp. have characteristic lateral branches (Fig. 1, page 510). The adults fly without zigzag movements mostly horizontally close to the ceiling of rooms. Larvae of these flies may be found in the rectum, vagina, or bladder of humans (→Myiasis).

Fannia. Figure 1 Larvae of *Fannia scalaris* (left) flies and *F. canicularis* (so-called small houseflies) or toilette.

Fasciola gigantica

This species which reaches a length of 75 mm is endemic in Africa (south of the Sahara), in subtropical and tropical Asia, and in countries along the East Coast of the Mediterranean Sea. Like →*Fasciola hepatica* it is found in the bile ducts of cattle. Recently it was proven that →hybridization is possible with *F. hepatica*.

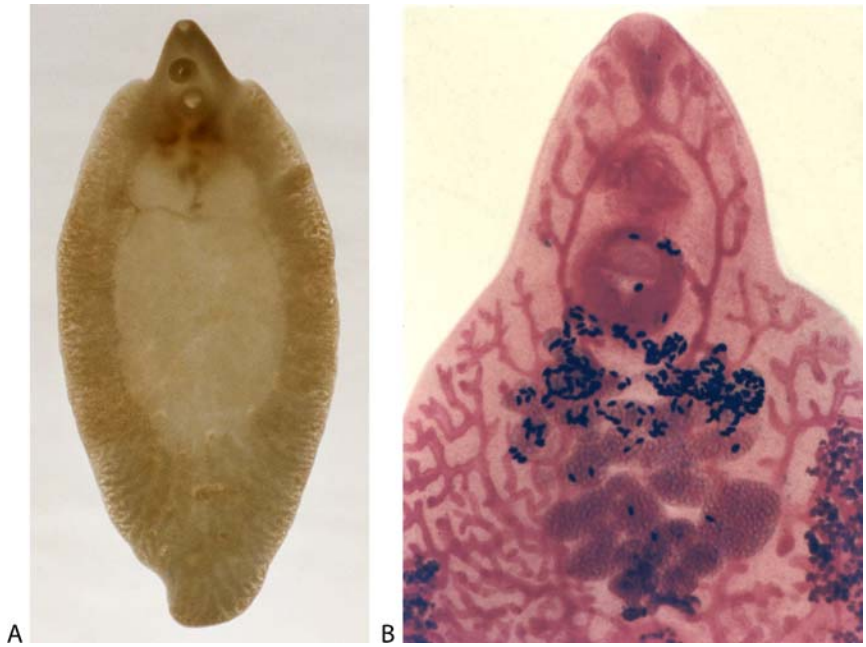
Reported prevalence rates reach from 3% in Southern Spain to 72% in some regions of China. Inside the large eggs the miracidium develops within 17 days after appearance, if the temperature is high (26°C) and the eggs are included in water. Inside the intermediate snails (*Lymnaea* spp.) the development of cercariae (via sporocysts and rediae) occurs within 4–7 weeks. Within minutes up to 2 hours after leaving the snails, these stages shed their tail and fix themselves at the leaves of water plants. Being covered by excretions of their cystogenous glands they become metacercariae, which are infectious to the final hosts.

As soon as they are swallowed by the final host, they hatch in the upper small intestine, penetrate the intestinal wall, and are found after 24 hours in the body cavity. From there they enter the liver within 4–6 days and migrate for 9–12 weeks, until they reach the bilary ducts and obtain maturity.

Fasciola hepatica

Name

Latin: *fasciola* = small band; Greek: *hepai* = liver.

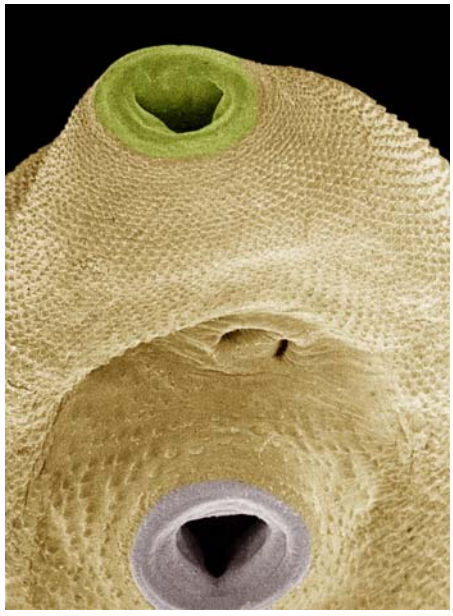


Fasciola hepatica. Figure 1 Light micrograph (LM) of an adult fluke and higher magnification of the anterior end.

Classification
Genus of →Digenea.

Morphology
Adult worms are characterized by an apical protrusion and a tegument with many toothed hooks (Figs. 1, 2). The eggs are very large, have an operculum, and can be isolated by the sedimentation technique (Fig. 3).

Life Cycle
Details see →Digenea/Table 1, →Digenea/Fig. 3.



Fasciola hepatica. Figure 2 Scanning electron micrograph (SEM) of the anterior portion of an adult fluke; note the numerous tegumental spines, 2 suckers and 2 genital openings.

Fasciola hepatica. Figure 3 LM of an egg obtained from faeces by flotation technique, note the slightly opened operculum.

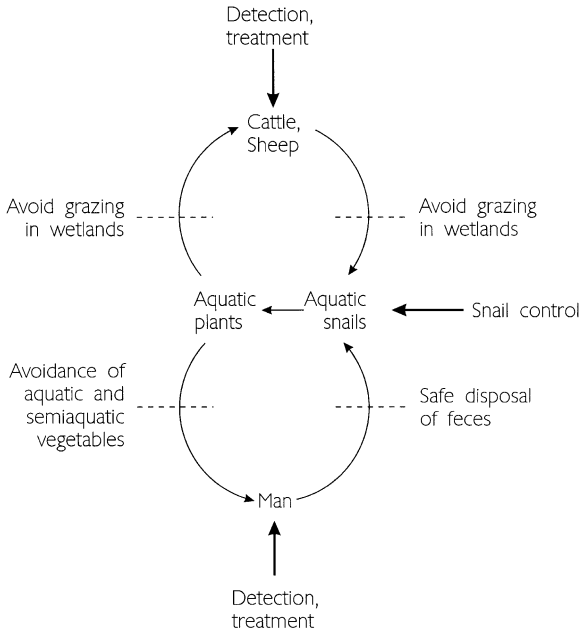
Disease
→Fascioliasis, →Fasciolosis.

Fascioliasis, Man

Fascioliasis describes an infection of the bile ducts with →*Fasciola hepatica*, the liver fluke of sheep, cattle, and man. After the ingestion of the metacercaria encysted on water plants (water cress salad), the larvae wander through the wall of the gut, into the liver →parenchyma, and into the bile ducts. The migration tracts are accompanied by an intense →inflammatory reaction with prominent eosinophils and Charcot-Leyden crystals, resolving ultimately by fibrosis (→Pathology/Figs. 3A,B, 21A,C). The liver may be enlarged and show abnormal function. Blood leukocytosis with →eosinophilia and fever are prominent. After long-standing infection with →flukes, bile duct →hyperplasia, pericholangitis, periportal fibrosis, and obstruction of the bile duct may develop. *F. hepatica* eggs are shed in the stools.

Targets for Intervention
Among the food-borne zooanthroponotic parasites, *F. hepatica* deserves attention as its control, seemingly simple, may pose major practical problems, foremost the relatively poor response to treatment and the high probability of reinfection. Upon reaching water the eggs release miracidia which infect aquatic snails. After completing development in the snail host, the infective →metacercariae leave the snail and attach themselves to plants and so reach their vertebrate hosts, especially sheep, cattle, and humans. Figure 1 shows the targets of intervention which consist of the elimination of infection and the interruption of the infection cycle. The practical approaches to control include the detection and treatment of vertebrate carriers, the safe disposal of human feces, the avoidance of raw aquatic vegetables and of those grown in wetlands, and as far as livestock is concerned, the avoidance of grazing in wetlands. The control of aquatic snails is a hypothetical possibility rather than a practical proposition.

Main clinical symptoms: Liver infection, fever, dyspepsy, ascites, eosinophilia.
Incubation period: 3–12 weeks.
Prepatent period: 3–4 months.
Patent period: 1–20 years.
Diagnosis: Microscopic determination of eggs (→Fasciola hepatica/Fig.3) in fecal samples by sedimentation method. →Serology.
Prophylaxis: Avoid eating raw freshwater plants.
Therapy: Treatment see →Trematodocidal Drugs.



Fascioliasis, Man. Figure 1 Targets and approaches for the control of fascioliasis.

Fasciolopsiasis

Fasciolopsiasis is an infection of the duodenum and jejunum of humans with adults of →*Fasciolopsis buski*/ Figs. 1, 2. It is usually asymptomatic when small numbers of worms are present. However, the multiple attachment sites that become ulcerated, can lead to appreciable blood loss and →abscess formation. Intestinal obstruction by large numbers of worms has been reported.

Main clinical symptoms: →Diarrhoea, nausea, →vomiting, →oedema, →anaemia, ascites.
Incubation period: 1–2 months.
Prepatent period: 2–3 months.
Patent period: 1 year.
Diagnosis: Microscopic determination of eggs (→Fasciolopsis buski/Fig. 3) in faecal samples (by sedimentation technique).
Prophylaxis: Avoid eating uncooked tropical vegetables or fruit.
Therapy: Treatment with praziquantel, see →Trematodocidal Drugs.

Fascioloides magna

8 cm long agent of Fasciolosis in North American sheep, cattle, and game animals.

Disease

→Fasciolosis, Animals.

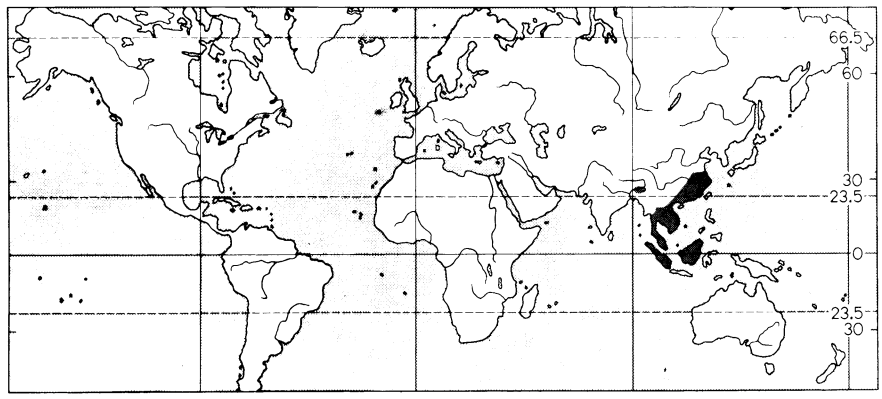
Fasciolopsis buski

Classification

Species of →Digenea.

Distribution

Fig. 1.



Fasciolopsis buski. Figure 1 Distribution map of *Fasciolopsis buski* endemic in Asia.

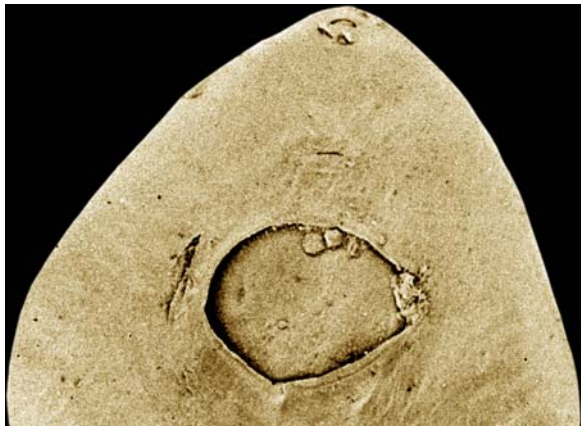
Morphology

The giant intestinal fluke is characterized by a very big ventral sucker and a smooth tegument without hooklets (Figs. 2, 3). The eggs are very large and possess an operculum (Fig. 4).

Life Cycle

→Digenea/Fig. 8.

Fasciolopsis buski. Figure 2 Light micrograph of an adult fluke.



Fasciolopsis buski. Figure 3 SEM of the anterior part of a fluke, note the very large ventral sucker.

Fasciolopsis buski. Figure 4 LM of an egg obtained by faeces flotation method.

Disease

→Fasciolopsiasis.

Fasciolosis, Animals

General Information

Disease caused by the →liver fluke genus *Fasciola*. *F. gigantica* occurs in the tropics. →*F. hepatica*, the common liver fluke, is the most widespread and important of the group. It is found mainly in sheep and cattle but a patent infection can develop in horses, pigs, wild animals, and in humans (→Fascioliasis, Man). The pathogenesis of fasciolosis is attributable in part to the invasive stages in the liver and in part to the blood-feeding by the adults in the bile ducts (Fig. 1). The process in all hosts shows close similarities, but considerable variation in severity occurs.

Fasciolosis, Animals. Figure 1 Sheep liver with adults of *Fasciola* in the calcified bile ducts (artificially opened).

Pathology

Ruminants

The pathological manifestations depend on the number of metacercaria ingested. The disease may follow acute or chronic courses. Acute fasciolosis is less common than the chronic entity and is almost invariably seen in sheep. It is essentially a traumatic hepatitis produced by the simultaneous migration of large numbers of adolescaria. It is towards the end of this development phase, about 6 weeks after infection, that the signs are apparent, with the major losses occurring 7–8 weeks after infection. Death may occur rapidly or after several days. Animals are disinclined to move, are anorexic, and show a distended abdomen which is painful to the touch. This is also the stage of parasitism in which "→black disease" occurs (*Clostridium novi* Type B).

Fasciolosis is most commonly a chronic disease, with no characteristic clinical signs. Loss of appetite and paleness of the mucous membranes appear to be constant features, and submandibular and udder →oedema are occasionally seen. Jaundice is hardly ever a sign in the living animal. Chronic debility with vague digestive disturbances are common. There is a substantial effect on milk production, and a reduction in food conversion efficiency with reduced weight gain. A reduction in wool production may occur in sheep, without symptoms of fasciolosis being apparent. Fasciolosis in sheep also has an adverse effect on conception and/or establishment of the fetus.

Changes in serum protein generally take the form of a depression in albumin compared with the globulins. They develop in 2 stages. The first stage coincides roughly with the period of fluke migration and is characterized by a progressive but usually mild →hypoalbuminaemia, with a more pronounced hyperglobulinaemia of variable severity. The second stage, which is associated with the presence of adult parasites in the bile ducts, is attended by further deterioration of albumin as well as a progressive reduction in globulin concentrations. There is little disagreement on the cause of the hyperglobulinaemia, which is generally considered to reflect increase synthesis of immunoglobulins in response to parasitic antigens. On the contrary a more complex nature of the different processes and inter-relationships are involved in the pathogenesis of hypoalbuminaemia. During the migratory stage hypoalbuminaemia is brought on by a combination of reduced albumin synthesis and plasma volume expansion. During the biliary stage of the disease the severity of hypoalbuminaemia is related to the loss of albumin into the intestine and to the rate of albumin synthesis and the fractional and total rates of albumin catabolism. These, in turn, are related to the levels of nutrition, appetite, and fluke burden. The increased synthesis of albumin probably diverts available amino acids away from other protein metabolism (muscle, milk, wool), thus accounting for the lowered levels of productivity seen in animals infected with *F. hepatica*.

The →anaemia is of the normocytic normochromic type, though some macrocytosis has been reported. The anaemia is well-recognized but its etiology is controversial.

Several factors may account for the anaemia:

- anaemia in the migratory phase is caused by accidental damage to hepatic vessels and haemorrhages.
- intrabiliary haemorrhage and consequent loss of red blood cells occur when adults arrive in the bile ducts. The ultimate degree of anaemia is not related to the severity of biliary haemorrhage, but rather to the animal's erythropoietic capacity which is influenced by levels of dietary protein and iron.

Good correlation between the bromsulphtalein excretion test, serum →glutamate oxalo-acetate transaminase and gamma glutamyl transferase determinations for the assessment of liver damage are found in infected sheep (liver function test).

Horses

F. hepatica is occasionally found in the equine and camel liver. Heavy infections are rare, and are usually only discovered during post-mortem examination.

Swine

F. hepatica has been found in pigs, but infections are very rare.

Targets for Intervention

→Fascioliasis, Man/Targets for Intervention.

Therapy

→Trematodocidal Drugs.

Fatigue

Symptom of clinical babesiosis in humans. →Babesiosis.

Favorisation

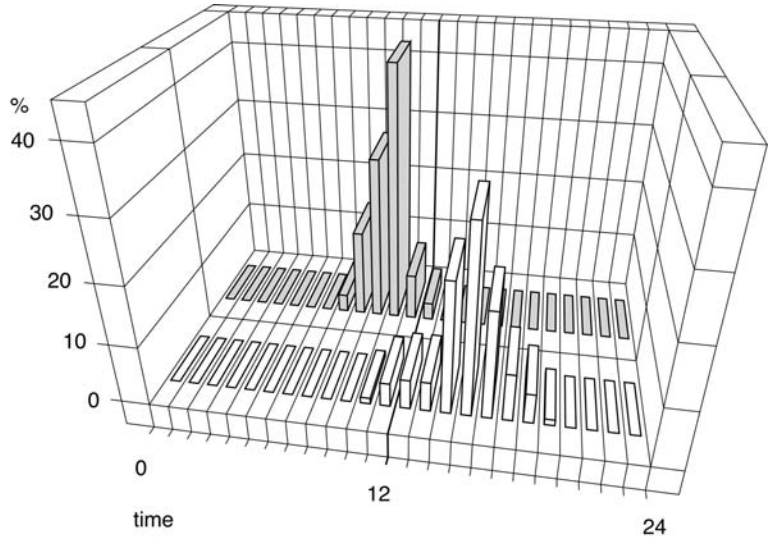
Favorisation was defined as an adaptation which gives the meeting of a host by a parasite a higher probability

than it would have only by chance (i.e., by causes unrelated with transmission). For instance, any process of chemical attraction which provokes the encounter between a larval stage of a parasite and its target host is a favorisation process.

Favorisation plays a variable role in parasite life cycles but is rarely absent. Although some parasite species invest principally in the production of a great number of infective stages which meet the host by chance, probably a majority of parasites have selected favorisation processes in the course of evolution.

The main aspects of favorisation are as follows:

- There is a free-living stage which disperses in the environment and exhibits some capacity to "find" the host. This is a simple process and the one most widely used by predators to "find" the prey. However, larval stages of parasites have, in general, limited capacities to localize a suitable host at distance. As exceptions, one must mention the numerous studies carried out on the larval stages of monogeneans and →trematodes. These researches demonstrate that aquatic larval stages may, to a certain extent, detect chemical gradients of substances emitted by the target hosts. It is surprising that the specificity of the attraction is wider that the specificity of development, with the result that a number of larval stages attach themselves to or penetrate into unsuitable hosts. The loss of infective stages known as "decoy effect" has been envisaged as a method of biological control (introduction of decoy organisms) but without any real success until now. The capacity of locating a host is much more developed when it is the adults, not the larvae or juveniles, which infect the host, as is the case of insect parasitoids. To a high degree, the parasitoids possess all the sensory organs common in →arthropoda. Some species detect their hosts, mainly lepidopterans, by odour (sometimes by the odour of the plant on which they feed), by vibrations (sometimes through several centimeters of wood), etc. The capacities of parasitoid insects to localize their hosts are sometimes surprising; possibly the most amazing of all is the wasp *Ichneumon eumerus*, which lays its eggs in a caterpillar (of the genus *Maculinea*) which lives itself in the depth of *Formica* nests. The wasps penetrate only into the nests which do harbour a caterpillar. It is supposed that the wasp listens at the entrance of the nest and is capable of detecting the noise made by the mandibles of the caterpillar. Let us add that the wasp emits a substance which make the ants fight between themselves instead of attacking the wasp, whilst the latter makes its way to the caterpillar.
- There is a coincidence between the presence of the parasite and the presence of its host in space and/or time. This has been particularly studied in aquatic →cercariae of trematodes and microfilariae of nematodes. The coincidence in space is achieved by a particular behaviour: in a same aquatic environment not all the species of cercariae swim at the same depth. Certain species swim rapidly towards the surface, others remain at the bottom, others scan the water column, etc. These different behaviours increase the probability of meeting the convenient target hosts. The coincidence in time is achieved through the emergence of cercariae from the snail →intermediate host. In most species, there is a very precise pattern of emergence (see Combes 2003) which is correlated with the activity rhythms of the host. Théron has shown that "→chronobiology" of cercariae can be selected rapidly with the result of increasing continuously the probability of meeting the host: in Guadeloupe for instance, →*Schistosoma mansoni* has 2 different hosts; humans and the black rat *Rattus rattus*: in transmission sites where humans are the main hosts, cercariae emerge from snails in the morning or around midday; in transmission sites where rats are the main (sometimes the unique) hosts, cercariae emerge later, at the end of the afternoon (Fig. 1). Microfilariae of →nematodes which live in the blood of vertebrates must be taken by →Mosquitoes or other biting arthropods to pursue their development. Most species aggregate in peripheric vessels at a period of the day corresponding to the time of biting activity of the vector. For instance, 80–100% of microfilariae of →*Wuchereria bancrofti* are found in the peripheric blood of humans during the night (i.e., when the principal vector →*Culex fatigans* is active) whereas they are virtually absent there during the day. A difference between microfilariae and cercariae is that microfilariae have a long lifespan (several weeks) and migrate to the peripheric vessels every day, whereas cercariae live only a few hours and have only "one chance" to find a host. The rhythm of microfilarial migrations is determined by the variation of physiological parameters of the human body; people working at night show the highest peripheral microfilaremy during the day and constitute probably dead ends for transmission. The rhythm of peripheral microfilaremy is not the same in areas where the vectors have different activity rhythms; in Polynesia, for instance, where the vector *Aedes pseuscutellaris* bites during the day, the rhythm is reversed.
- The parasite manipulates the behaviour of its "upstream" host. At any transmission event in the life cycle, the "upstream" host is the host where the parasite comes from. The most astonishing example of a manipulation of the behaviour of the upstream host is that of the trematode *Gynaecotyla adunca*. The snail intermediate hosts live normally at a certain distance from the shore. The presence of larval stages



Favorisation. Figure 1 Patterns of emergence of *Schistosoma mansoni* cercariae in foci where humans are the main hosts (grey bars, at the back) and in foci where rats are the main hosts (white bars, at the front). Confidence intervals are omitted. [Original, data from several papers by A. Théron].

of *G. adunca* provokes an alteration of the snail behaviour, which move towards the nearest beach where the second intermediate hosts (various crustaceans) live, and where the cercariae are emitted.

- The parasite manipulates the behaviour of its "downstream" host. The "downstream" host is the host to which the parasite moves during a transmission event. In contrast with the previous case, this process of manipulation is extremely frequent and intervenes when the parasite is transmitted from a prey to its predator. The parasite provokes various changes in the prey's behaviour (the upstream host), which make it either debilitated, or more conspicuous, or both. However, it is the behaviour of the downstream host which is manipulated since it is attracted by a prey which is easier to catch, but carries the infective stage of the parasite. A striking and well-known example is that of various species of the trematode →*Diplostomum*. To become an adult, the parasite must be transmitted from a freshwater fish to a piscivorous bird: the larval stages (→Metacercariae) of the parasites encyst in the eye of the fish, making it blind, and incapable of detecting the predator. In other life cycles, the presence of the parasite provokes an increase of the activity of the intermediate host, which makes it more conspicuous to the predator. Several studies show that the alteration of the behaviour appears only when the larval stage is actually infective. This is the case for the cestode →*Schistocephalus solidus*, which develops successively in a copepod, a fish (which ingests the copepod) and a piscivorous fish. Both the copepod and the fish exhibit a particular behaviour which makes them more susceptible to predation, but this occurs only when the corresponding larval stages of the parasite are mature. Another example is that of shore crabs whose hiding behaviour at low tide is modified by an acanthocephalan; crabs exposed are at a greater risk of predation by definitive bird hosts. A study demonstrates a different strategy on the part of the parasite: the tapeworm →*Hymenolepis diminuta* which infects the rats when they ingest the beetle *Tenebrio molitor*, impairs the chemical defense of the insects, which make them more palatable to the rats.

Filariasis, Lymphatic Tropical

Synonyms
Filariosis, Brugiasis, Wuchereriasis, LF.

General Information
→Lymphatic filariasis is an infection with one of several mosquito-borne filarial worms of the species →*Wuchereria bancrofti*, →*Brugia malayi* or *Brugia timori*, which live in the subcutaneous lymphatics or lymph nodes, with larvae circulating in the bloodstream. About one-fifth of the world's population live in areas where lymphatic filariasis is endemic. The disease is worldwide, 110 million people are estimated to harbour such infections. *W. bancrofti* is widely distributed throughout the tropics. *B. malayi* is restricted to parts of Southeast Asia and *B. timori* shows an even more restricted distribution in the Malay Archipelago. Adult *W. bancrofti* is restricted to man, while domestic and wild animals may serve as alternative hosts of *B. malayi* and *B. timori*. *W. bancrofti* is transmitted by →*Culex*, →*Anopheles*, and →*Aedes* spp., *B. malayi* and *B. timori* predominantly by →*Mansonia* spp.

Clinical manifestations of filariasis are almost exclusively due to the microfilariae shed by the adult female worms. The symptoms include initial filarial fever and lymphangitis which later gives rise to recurring lymphoedema. High adult wormload, and consequently high microfilarial density, favours the development of lymphangitis and elephantiasis.

Pathology
The larvae are injected intradermally with a mosquito bite and find their way to the large lymphatics, where they mature and mate. Swelling of lymph nodes containing adults is a common feature. However, when

an adult worm dies severe →lymphadenitis with chronic inflammatory to granulomatous reaction results, including eosinophils which ultimately leads to fibrosis. In some multiply infected individuals this may lead gradually to chronic lymphatic obstruction, which in a small percentage of cases progresses to the lymphedematous complication of elephantiasis, usually in an extremity. The newborn larvae circulate in the bloodstream within the internal organs, such as the spleen, and sometimes they migrate cyclically to the peripheral circulation, coincident with the biting/feeding habits of the prevalent transmitting mosquito. Tropical eosinophilic fever with pulmonary infiltration is often attributed to this infection.

Immune Responses

Because of the very long periods of survival of the →macrofilariae (=adult worms) in their hosts (5–15 years), it is obvious, that these parasites must have developed complex mechanisms to evade killing by the host immune defenses. In addition, the host's immune response significantly contributes to the different pathological manifestations of the disease.

There is a broad range of immune reactivity with considerable individual variation. In lymphatic filariasis, microfilaremic individuals (MF) who are clinically asymptomatic have high parasite burdens and little or no parasite antigen-specific cell-mediated responses. In contrast, patients with chronic lymphatic disease, e.g., elephantiasis, typically are amicrofilaremic and vigorous T cell responses against the parasite can be detected.

As for most of the other parasitic diseases, models of filarial infection in inbred mice significantly contributed to the understanding of the disease-influencing immunoregulatory events. Since laboratory mice are not permissive for filarial species found in infected humans, immunity to different stages of these filariae (3rd-stage larvae, adults, and microfilariae) has been analyzed separately as a surrogate approach. On the other hand, in the mouse model of *Litomosoides sigmodontis* infection, the full developmental cycle can be established in inbred mice, allowing to study immunity during maturation of infective larvae into adult worms.

Innate Immunity

Information on the role of components of →innate immunity in the early control of filariae is limited. Innate immune responses to *Brugia malayi* and *Onchocerca volvulus* are interestingly initiated by endosymbiotic *Wolbachia* bacteria and are dependent on TLR2, TLR6, and MyD88. In chronic infections however, the observed diminished expression and function of TLR is a likely consequence of chronic Ag stimulation and could serve as a novel mechanism underlying the dysfunctional immune response in filariasis. In a study by Babu et al. an unexpected role of NK cells was described. Comparisons of *B. malayi* worm survival in strains of mice with different levels of NK cell activity showed, that host NK cells are required for the growth of this human filarial parasite. While NOD/LtSz-SCID mice with diminished or absent NK cell activity were non-permissive to worm growth, C.B17 SCID mice with normal NK cell activity were highly permissive. Furthermore, transfer of NK cells into NK-deficient mice rendered these animals permissive. Although the mechanisms by which NK cell allow the growth of filariae is enigmatic so far, these findings clearly point to an interesting role of the innate immune system in the establishment of this parasitic disease. The most compelling evidence for a role of eosinophils in immunopathology of filarial infections comes from analysis of onchocercal dermatitis and keratitis. There is a consistent presence of eosinophils and eosinophil granule proteins at the site of tissue damage, either after parasite death or direct injection of parasite antigens. However, the role of IL-5 and other chemoattractant mediators for the recruitment and activation of eosinophils has yet to be established.

B Cells and Antibodies

High levels of parasite-specific IgE and IgG4 are produced in filariasis patients, generally accompanied by →eosinophilia. A reciprocal expression of these 2 isotypes has been found in lymphatic filariasis patients, with asymptomatic patients having much higher ratios of IgG4:IgE than found in elephantiasis patients, suggesting either that IgE is an antifilarial antibody, and/or that high IgE is involved in the pathogenetic pathway of the disease. High quantities of IgG4 can be frequently found in sera of microfilaremic patients, where sometimes up to 95% of the filarial-specific antibodies are of this subclass. In contrast, in elephantiasis patients IgG1, 2 and 3, dominate the filaria-specific antibody response. It seems likely that these antibodies may contribute to the pathology through →ADCC or →immune complex formation.

In mice infected with *B. malayi* the clearance of microfilariae was found to be clearly antibody-dependent. CBA/N mice which carry the Xid defect have a pronounced impairment of the B1 cell subset and are therefore unable to develop certain T-cell-independent IgM antibodies. The findings that microfilaremia can not be controlled in these animals after i.v. injection of *B. malayi* or implantation of *A. viteae* gravid females strongly suggest that T cell-independent IgM antibodies to the microfilariae's surface are involved in the clearance of microfilariae.

T Cells

Immunity to most filarial infections is clearly T cell dependent. Nude mice and rats are susceptible to infection with a number of species (*A. viteae, B. pahangi, B. malayi*) to which their normal, immune competent littermates are resistant, and infection against *B. pahangi* can be established in normally resistant CBA mice when these are deprived of T cells. The resistance of mice to *B. malayi* can be probably mediated by either $CD4^+$ T cells or $CD8^+$ T cells: Resistance to the maturation of infective larvae (L3) was not abrogated in either β2-microglobulin knockout mice, which lack MHC class I molecules and class-I-restricted $CD8^+$ T cells, or in anti-CD4-treated or CD4-deficient mice.

Important clues for the contribution of Th1 or Th2 cells to pathology or control of the parasite came from analysis of onchocerciasis patients. In individuals with generalized infections characterized by high microfilarial loads, low proliferative T cell responses to parasite antigens is accompanied by a production of Th2 cytokines. On the other hand, a minority of patients able to prevent maturation of L3 displays an immune response characterized by the predominance of IFN-γ producing Th1 cells. Several experimental studies have been performed to analyze the relative contributions of Th1 and Th2 cells and their products (cytokines) to the control of filarial parasites in mice. Following infection with L3 or immunization with L3 there is a strong expansion of parasite-specific Th2 cells and of associated immune responses such as IgE production and eosinophilia. In infections with both →*Brugia* and *O. volvulus* the Th2 responses appear to be protective, since antibodies against IL-4 or IL-5 resulted in longer survival of larvae. However, resistance to maturation of L3 into adults was not abrogated in IL-4 knockout mice, arguing for compensatory mechanisms in these gene-deficient mice. Infection of BALB/c mice with adult *B. malayi* worms, especially females, also induced strong IL-4 production by splenocytes.

The Th cell response to microfilariae has been most extensively investigated using *A. viteae, B. malayi, O. volvulus,* and *O. lienalis*. Interestingly, a dominant Th1 response has been observed during the first 2 weeks of infection, which is followed by an enhanced induction of IL-4 and IL-5 in addition to IFN-γ during the subsequent weeks. Thus, the time of exposure to microfilarial antigens seems to drastically influence the type of Th cell response. Both Th cell subsets may significantly contribute to the control of microfilariae, since both IFN-γ-stimulated macrophages as well as IL-5-dependent eosinophils are operative against microfilariae. Activated macrophages are able to damage microfilariea by releasing NO. In addition, microfilariae of some species (e.g., *O. lienalis*) but not of others (*B. malayi*) are sensitive to H_2O_2 which may be produced by eosinophils.

Filaria nematode infection is associated with a profound downregulation of the host immune system. When mice are infected with *B. pahagi*, natural T_{reg} expand and suppress excessive Th2 responses. In a model of murine filarial infection, the infection and subsequent immunosuppression is associated with accumulation of T_{reg} in the thoracic cavity.

Shaping of the Immune Response by the Parasite

Recent reports suggest that filarial parasites have the capacity to actively shape their immunological environments in their host. For example, secreted products of the →nematodes have been found to differentially modulate the expression and activation of protein kinase C isoforms in B lymphocytes. Furthermore, the expression of CD23 on human splenic B and T cells and Th2 responses are enhanced by soluble products of the parasite. Pastrana et al. cloned homologues of the mammalian migration inhibitory factor (MIF) from *B.malayi, W. bancrofti*, and *O. volvulus*. The effects of recombinant forms of the parasite MIF and human of inflammatory and T cell responses by filarial MIF could provide the parasite with a survival advantage.

Planning of Control

The approaches to the control of lymphatic filariasis were formerly based on the elimination of infection by treatment (diethylcarbamazine = DEC) and →vector control for the prevention of infection. Both approaches were only marginally effective due to the poor macrofilaricidal activity of DEC and constraints of controlling *Culex* spp. in urban areas and *Anopheles* spp. in the rural environment. Moreover, the first dose of DEC may cause severe and even fatal adverse reactions in persons infected with →*Loa loa*, a tissue-dwelling filaria occurring in tropical Africa.

The control of lymphatic filariasis has been revolutionized by the finding that a single dose of ivermectin or DEC or both will eliminate microfilaraemia for several months due to an action against microfilariae and embryonic stages. Although recurring, microfilaraemia will stay below 1% of the initial level for a year or more. With repeated dosing, once a year, microfilaraemia will not reach the level at which it could cause lymphoedema or elephantiasis.Essentially the same applies to onchocerciasis with regard to the prevention of irreversible ocular lesions. The reduction of microfilarial rates and densities will also lead to a rapid reduction of disease transmission, more effective than it could ever be expected from vector control.

Based on these findings, the WHO has embarked on the global elimination of lymphatic filariasis through the annual single dose administration of a combination of ivermectin and DEC to all persons (approximately 1,100 million) residing in areas where the disease is endemic. There is still the caveat of adverse reactions to

DEC in people infected with *Loa loa* (→Loiasis), but this only applies to tropical Africa and can be overcome by using ivermectin alone. The other, yet unknown, factor is the potential role of animal reservoir as an obstacle to the ultimate elimination of human brugian filariasis.

Targets for Intervention

The infective larvae of →*W. bancrofti* leave the arthropod vector at the time of a blood meal, slide along the outer surface of the →proboscis stem, and actively enter the bite wound. After reaching the lymphatic target organ, they will become adults and mate. The females will produce microfilariae which will periodically or sub-periodically enter the blood stream from where they can be taken up by the vector. Figure 1 shows that the detection and treatment of infected persons, suppression of microfilaraemia, vector control, and the interruption of contact between man and vector are potential approaches to the control of →bancroftian filariasis.

Main clinical symptoms: Lymphangitis, unfeelingness of skin portions; later: chylurie, elephantiasis, i.e., giant swelling of organs.
Incubation period: 3–16 months.
Prepatent period: 7–24 months.
Patent period: 8–10 years (adults live until 18–20 years).
Diagnosis: Microscopic analysis of smear preparations or of membrane filtered material (Figs. 2, 3); microfilariae are found at 10 p.m. in the peripheral blood, →Serology.
Prophylaxis: Avoid bites of vector →mosquitoes in endemic regions.
Therapy: Treatment see →Nematocidal Drugs, Animals, →Nematocidal Drugs, Man.

single pair of central microtubules) that is anchored to a basal body (→Kinetosome) that resides inside the cortical →cyto-plasm of the cell (Fig. 1C, →Trypanosoma/Fig. 5B). The →basal bodies are similar to centrioles in having 9 sets of 3 microtubules arranged in a ring-like pattern. The basal bodies may be connected to filamentous elements such as the kinetodesmal filaments of cilia. Several species of Protozoa have a rod-like structure consisting of a network of protein filaments inside the flagellum (Fig. 1D, E). These rods lie beside the axoneme, probably adding to the thickness and stability of the flagellum. This enhancement may be particularly important for Protozoa living in viscous media such as blood or intestinal fluids. Although flagella and cilia are

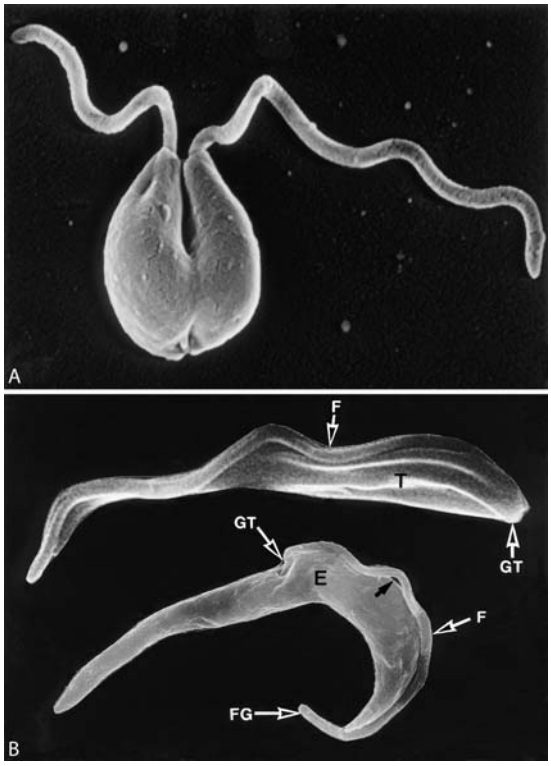
Flagella. constructed according to a general blueprint, in different Protozoa the paired outer microtubules in the flagella and cilia may differ in shape. The A-tubule, which is furnished with 2 dynein arms, typically possesses 13 protofilaments, whereas the B-tubule has only 9 protofilaments and shares 3 or 4 of the protofilaments of the A-tubule. The dynein arms act as enzymes for breaking down ATP and are assumed to represent the motor system in the gliding-filament theory. This theory postulates that the movement of flagella and cilia is



Flagella. Figure 2 SEM-micrographs of flagella of trypanosomatids. **A** *Leishmania major* promastigote in division. × 10,000. **B** Trypomastigote and epimastigote stage of →*Trypanosoma* sp. Flagellata

Synonym

→Mastigophora.

Classification

Subphylum of →Sarcomastigophora.

Flame Cell

Synonym

→Terminal Cell, →Cyrtocyte, →Platyhelminthes/Fig. 24.

Flatworms

Synonym

→Platyhelminthes.

Flaviviridae

Classification

Family of RNA viruses, transmitted by arthropods →Arboviruses.

General Information

Positive-sense single-stranded →RNA viruses (spherical, with envelope); about 60 species.

Important Species

→*Flavivirus*.

Flavivirus

Classification

Genus of Viruses including some →arboviruses.

General Information

Positive-sense single-stranded →RNA viruses (spherical, with envelope). Altogether about 60 virus species (some of them with several types/subtypes) described. Presently these species are assigned to 3 main divisions: Tick-borne viruses (with 2 groups), mosquito-borne viruses (with 7 groups), and viruses with no known arthropod vector (with 3 groups).

Important Species

Table 1.

Flavivirus. Table 1 Arboviruses V. Positive sense, single-stranded RNA viruses: Family Flaviviridae, genus Flavivirus

Serogroup (no. of known members)	Species (selected)	Arthropod host	(Main) vertebrate hosts	Distribution	Disease in man	Disease in animals
Tick-borne group (14)	Tick-borne encephalitis, European, Siberian, Far Eastern subtype	Ixodidae (*Ixodes ricinus, Ixodes persulcatus* and other species and genera)	Rodents	Northern and Central Europe, Northern Asia	Tick-borne encephalitis, Central European encephalitis, Russian Spring Summer encephalitis (fever, encephalitis)	Neurological disease

1. A humoral reaction (= immediate hypersensitivity reaction of type I) occurs within a few minutes after the bite due to intensive histamine excretion.
2. A delayed cell-mediated reaction (= hypersensitivity of type IV), which causes heavy pruritus, loss of hair and (occurrence) various lesions.

Flea Bites

Fleas can be easily disturbed during their blood meal. Thus they bite again in close neighbourhood to the first bite leading to "rows or chains" of bites (Figs. 1, 2). Scratching may inoculate bacterial superinfections (Fig. 2). In some persons/animals flea bites may introduce severe flea allergy dermatitis (→FAD).

Flea Bites. Figure 1 Three flea bites in a row.

Flea Bites. Figure 2 Flea bites with bacterial superinfections.

Fleas

Classification
Order of →Insects.

Synonym
→Siphonaptera, Aphaniptera.

Morphology
Figs. 1–7.

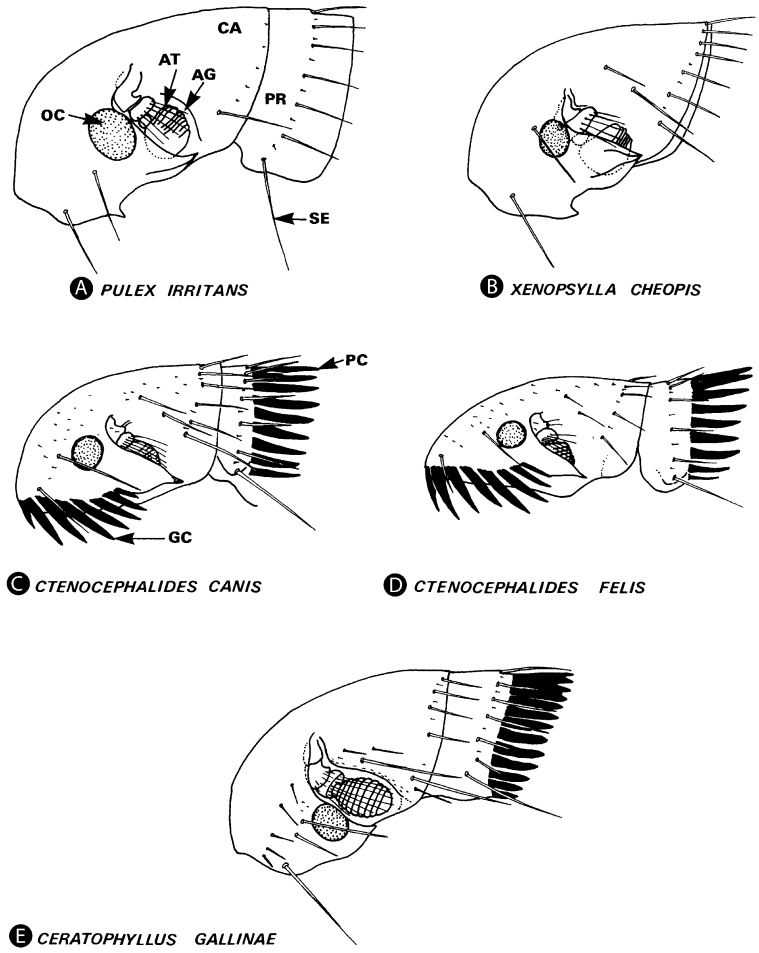
General Information
Of the approximately 2,500 species of fleas, about 94% suck on mammals, the remaining on birds. If they are hungry, many species probe on any warm-blooded vertebrate. Whereas larvae feed on organic material in the nest or lair of the host, adult males and females are obligate bloodsuckers and may live upto 12 months. Fleas can transmit various pathogens due to their repeated sucking activity on different hosts (Table 1), but are mainly known as vectors of →plague.

The life cycle proceeds as →holometabolous development (Fig. 2), including 3 detritus-feeding larval stages and a →pupa in a →cocoon, within which the finally formed adult fleas can rest for a long time (6 months), e.g., until a bird's nest is settled again or the material re-used. Adults are brown, wingless, laterally flattened, and about 1–6 mm long, jumping away if there is a risk of being caught. Since fleas react super-sensitively, several punctures are usually made by a single flea in the course of blood meal.

Important Species
Table 1.

Distribution
Fleas occur worldwide.

Morphology
The relatively small, rounded head of fleas has often ventral, heavily sclerotized outgrowths, the ctenidia and in some nest fleas no eyes or lateral ocelli. The antennae are very short (3 main segments), recessed in deep grooves. The ventral mouthparts consist of 3 stylets, a pair of maxillary laciniae, and the unpaired epipharynx, held by the 5-segmented labial palps. The →cuticle is tough and difficult to rupture. The dorsal sclerites of the 3 thoracic segments overlap the respective following one, and there they often possess many spinelets, the first of which is often a comb of



Fleas. Figure 1 Diagrammatic representation of heads of some important fleas (Table 1). The occurrence of →combs (*PC, GC*), the arrangement of setae (*SE*) and the shape of the antenna (*AT*) are specific. *AG*, antennal grove; *AT*, antenna; *CA*, caput; *GC*, genal comb (with several spines); *OC*, ocellus; *PC*, pronotal comb (with several spines), *PR*, pronotum; *SE*, →seta.

ctenidia. The legs are long, well- developed for jumping, and bear strong claws. Each of the 8 abdominal segments also overlaps the following one, often possessing many spinelets there which help to anchor the flea in the fur. In addition to the ctenidia, species can be identified by the genital organs, visible through the cuticle of the last segment, especially in specimens that were cleared chemica and mounted on microscope slides. Males and females can be separated according to the shape of the abdomen, genital organs, and the copulatory apparatus of males. The larvae are elongated and worm-like, without eyes and with legs possessing long setae on the body. Mature larvae are 4–10 mm long. Pupae develop in a cocoon, which is spun by the larvae, and to which dust adheres (Figs. 2, 5).

The female sand flea (*Tunga penetrans*) penetrates into the skin (→Jigger).

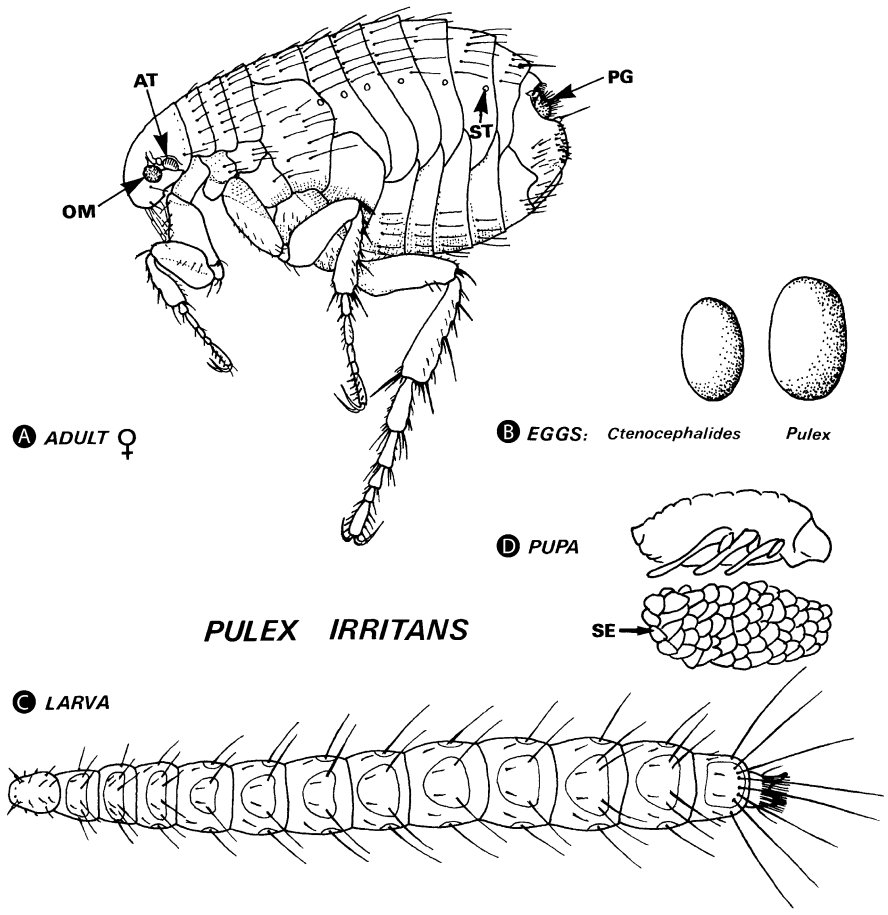
Genetics

Variations in the biology of different populations of *Pulex irritans* indicate that it is not a single species, but a species complex.

Reproduction

Breeding in the laboratory is possible for many species, especially for fleas of cats and rodents, but labour-intensive. Usually the living host is necessary, exept for a strain of the cat flea which has adapted to artificial feeding with cow blood.

Adults copulate immediately after emergence from the cocoon. Beginning 1 or 2 days later, females lay several hundred eggs (0.3–0.5 mm long), a cat flea 700–900 within 3 to 4 weeks. Most species need blood for the development of eggs (anautogeneous). Fertility



Fleas. Figure 2 A–D Life-cycle stages of fleas; the larva (**C**), which hatches from a 0.3–0.5 mm egg (**B**), has no eyes and reaches a length of 4–10 mm when fully grown. There are usually 3 larval instars, but only 2 in →*Tunga penetrans*. Larvae feed on organic debris and on undigested blood from the feces of adults. The differentiated third-stage larva constructs a loosely woven cocoon (3 × 1 mm) which may become encrusted by sand (**D**). Inside, the flea pupates (pupa shows anlagen of extremities (**D**), and remains quiescent until it emerges as an adult (females emerge 3–4 days before the males). Both males and females feed exclusively on blood and may live up to 12 months. *AT*, antenna; *OM*, →ommatidium (ocellus); *PG*, →pygidium (sensilium); *SE*, sand-encrusted cocoon; *ST*, stigma (spiracle).

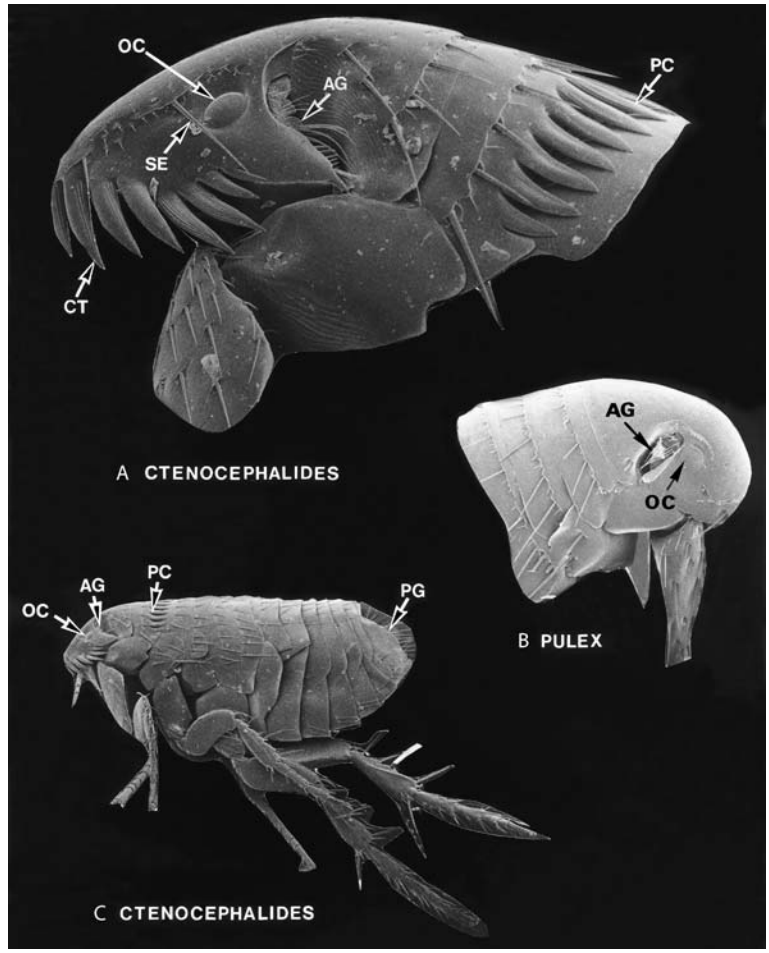
is reduced if the typical host is not present and if females have fed on other hosts. In some species more than 1 mating is necessary to fertilize all eggs. In the rabbit flea reproduction is regulated by the hormones of the host, i.e., maturation of adults is induced by blood meals from pregnant rabbits or newborn progeny (→Insects/Fig. 2).

Biochemical/Molecular Data

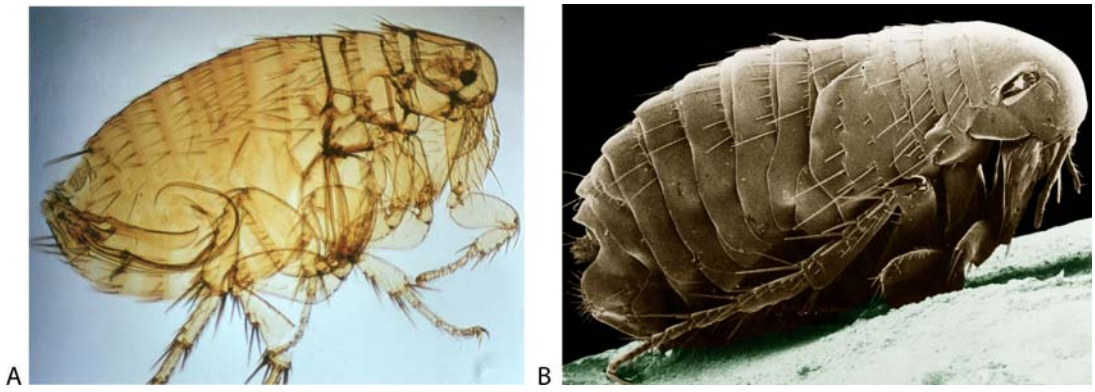
Biochemical investigations focus on the cat flea, e.g., components of the saliva. Other allergens are also considered in mRNA investigations. PCR is used to find pathogen-infected fleas and 18S rDNA sequencing for phylogenetic studies.

Life Cycle

After a temperature-dependent, low-humidity-sensitive (>70% necessary) embryonic development of about 5 days, the 1st-→instar larvae (1 mm long) hatch. The larvae live in the nest or lair of the host – in houses preferably in carpets – feeding organic material, but mainly remnants of digested blood and drops of undigested blood, both deposited by the adults during feeding. After 2 moults within 2–3 weeks, mature larvae spin cocoons from silk produced by the salivary glands. Dust adheres to the freshly spun silk in which the larva moults to the pupa within 2–3 days, the latter usually completing its development within 1 or 2 weeks. They die if humidity is <45%. The adult flea



Fleas. Figure 3 A–C Scanning electron micrographs of fleas of dogs, cats and man **A, C** *C. felis*, **B** →*Pulex irritans* (A × 150, B × 50, C × 20). *AG*, antennal groove; *CT*, →ctenidium (genal comb); *OC*, ocellus; *PC*, pronotal comb; *PG*, pygidium; *SE*, setae.



Fleas. Figure 4 **A** LM of *Pulex irritans*. **B** SEM of *Pulex irritans*.

remains in the cocoon and can wait long periods of time (6–12 months) until vibrations indicate the presence of a host. (Therefore, after holidays the dog or cat should be the first entering a room.) Adult fleas live several months, sometimes more than a year and can survive long periods of starvation. Under optimal conditions, the whole developmental cycle (egg to egg) lasts about 4 weeks. The majority of species are univoltine.

Fleas. Figure 5 LM of larvae of fleas containing blood excreted by adult fleas (black inclusion).

Fleas. Figure 6 SEM of a male sand flea (*Tunga penetrans*).

Whereas the majority of fleas irregularly sucks blood and rests near the host or in its fur, the adults of the sand fleas penetrate the skin and develop there, growing to the size of a small pea.

Transmission

Fleas jump from one host to a neighbouring one, the rat and the human flea covering 31 cm in a single jump. Nest-dwelling species do not jump as far. The energy for the jumps cannot be supplied by direct muscle action, but fleas possess a pad of resilin, a protein that can store and release energy like rubber.

Clinical Relevance

Main fleas of medical importance are especially the tropical rat flea →*Xenopsylla cheopis*, the →sand flea →*Tunga penetrans*, the cosmopolitan human flea *Pulex irritans* – all possessing no combs – and the cat flea *Ctenocephalides felis*. During the last years especially cat fleas have occurred more often, also on dogs. However, the incidence of the major transmitted disease, plague, has decreased markedly during the last 80 years. Since the rodent hosts cannot be eradicated, outbreaks of plague will regularly occur in many parts of the world, e.g., India and Russia. Fleas may introduce dermatitis in man and animals, too. Recently it was proven that fleas may transmit a wide range of viruses and bacteria by regurgitation of freshly fed blood and via excretion of faeces.

Feeding Behavior and Transmission of Disease

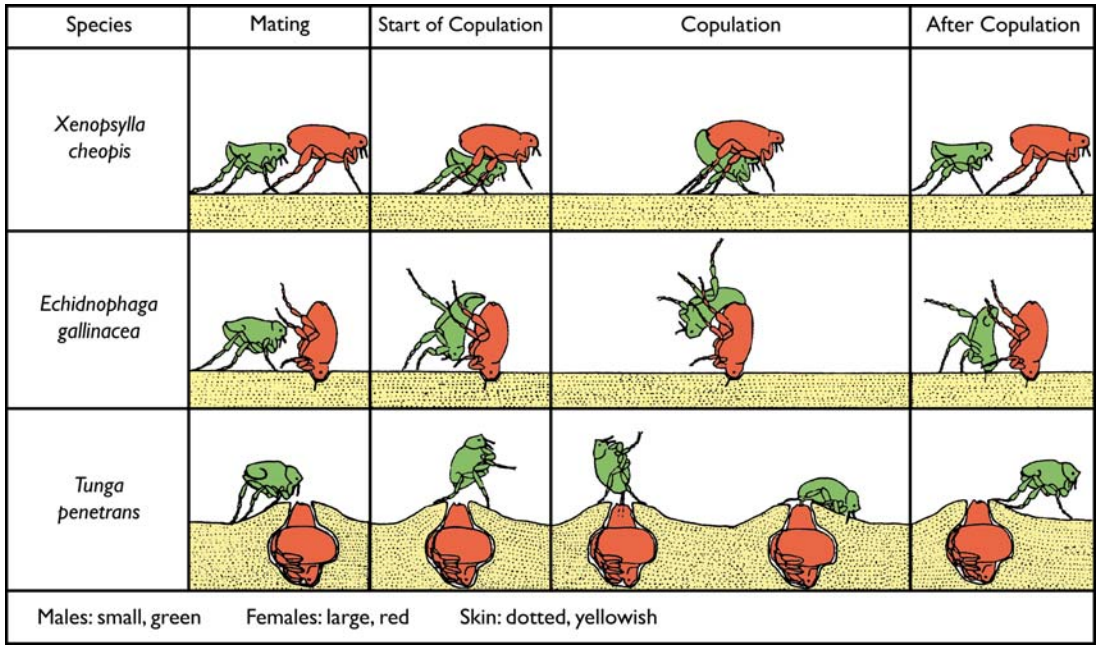
Fleas are attracted to the host by vibrations, warmth, carbon dioxide and shadowing. The natural main host is recognized by specific odours. Fleas are capillary feeders, some species →pool feeders, needing 2–10 minutes for a blood meal. Pumps transport the blood directly to the midgut in which it is stored and digested. The rupture of erythrocytes is achieved by many series of spines in the →proventriculus. The saliva of fleas causes itching and the resulting scratches secondary bacterial infections. The itching reaction is stronger if the fleas feed on an occasional, not the natural host.

Different flea species of rodents, especially the rat flea *Xenopsylla cheopis*, can transmit classic plague. Usually this occurs if many rats have died of the disease and the infected fleas attack other available hosts, e.g., human. Fleas also transmit →tapeworms to cats and filarie to dogs (→Dirofilaria, →Acanthocheilonema) and →murine typhus to man, the latter showing similarities in development and transmission to classic epidemic typhus transmitted by →lice (→Pediculus). Recent experiments have clearly shown, that fleas may also transmit viruses not only during engorging blood but also via faeces. This was proven for the Calici viruses of cats and Feline leucemia virus of cats. Thus it can be expected that many viruses of a similar stability may be transmitted to animal and human hosts.

Interaction of Vector and Parasite

If the fleas suck blood of a plague-infected host, the causative agent →*Yersinia pestis* is transmitted and multiplies in the lumen of the gut, especially in the foregut, initially resulting in a plug of bacteria which later is partly reduced. The blockage is stronger in the more virulent strains of bacteria which adhere stronger to each other. From the foregut or contaminated mouthparts the bacterium is transmitted to the vertebrate host.

Y. pestis is pathogenic to fleas due to the blockage of the proventriculus by a plug. Since only reduced volumes of blood can be ingested, infected fleas attack hosts more often. If the plug is reduced, more blood can be ingested. The infection not only disturbs blood ingestion, but especially the total blockage reduces longevity.



Fleas. Figure 7 Diagrammatic representation of the mating behavior of 3 flea types, which occur free or partly, respectively, fully attached on the skin of their hosts.

Fleas. Table 1 Some common fleas

Species	Length (mm)	Hosts	Main transmitted pathogens
Ceratophyllus gallinae	m 3.0 f 3.5	Chickens, turkeys, **humans**	Mechanically many pathogens

m = male, f = female

Diagnosis of Bites

Since disturbed fleas interrupt blood ingestion, usually several neighbouring bites occur.

Control

Information should emphasize the other feeding and infestation paths by larvae and thus the importance of

treatment of the house and not only the pet bedding. Pets should permanently wear an anti-flea collar. In regions with foci of sylvatic plague, the rats, ground squirrels, prairie dogs and marmots should be controlled or fed in bait boxes treated with →insecticides which then also act in the lair.

Infestations of pets with adult fleas can be reduced with insecticide collars. In infestations of homes, insect growth regulators, which are nearly non-toxic to vertebrates, can be used against larvae, e.g., methoprene, and insecticides against adults (→Ectoinsecticides, →Arthropodicidal Drugs).

Flight Speed

To attack their hosts parasitic mosquitoes and flies reach a considerable speed: e.g., mosquitoes (3.2 km/h), *Musca* spp. (0.4 km/h), *Calliphora* spp. (11.0 km/h), tabanids (22.4 km/h), Oestridae (*Cephenemyia stimulator* of deer, 40.0 km/h).

Floating Ovaries

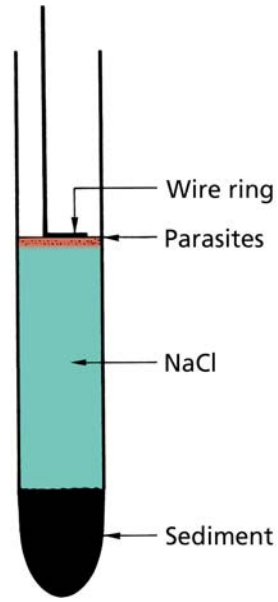
→Acanthocephala.

Flotation

Method to obtain small-sized cystic parasites from faeces probes (Fig. 1).

FLP

FMRF amide-like peptides (FLPs) play a central role in nematode motor and sensory capabilities. Since they are widely preserved in their sequence in many species of nematodes, they might be candidates for new parasiticides.



Flotation. Figure 1 Zonation in the tube after centrifugation.

Fluazuron

Chemical Class
Benzoylphenyl urea.

Mode of Action
Insect growth regulator (IGR, chitin synthesis inhibitor). →Ectoparasiticides – Inhibitors of Arthropod Development.

Flucythrinate

Chemical Class
Pyrethroid (type II, α-CN-pyrethroids).

Mode of Action
Open state voltage-gated sodium channel blocker. →Ectoparasiticides – Blockers / Modulators of Voltage-Gated Sodium Channels.

Flukes

Synonym
→Digenea.

Flumethrin

Chemical Class
Pyrethroid (type II, α-CN-pyrethroids).

Mode of Action
Open state voltage-gated sodium channel blocker. →Ectoparasiticides – Blockers / Modulators of Voltage-Gated Sodium Channels, →Arthropodicidal Drugs, →Ectoparasitocidal Drugs.

FMRF-Amide-Like Peptides (FLP)

These peptides of parasites are targets of new designed antiparasitic drugs (due to their motor and sensory capabilities in signalling).

Focus

Due to the complexity of the synecological systems in which →arboviruses circulate, preconditions for the maintenance of the virus cycle are usually fulfilled in limited areas only. These areas are called foci to which the viruses are endemic. →Arboviruses/Distribution.

Folic Acid

Folate derivatives are important cellular cofactors in the synthesis of nucleotides and a variety of amino acids. Like higher eukaryotes other than plants, most parasites lack the biosynthetic folate pathway. An exception are the apicomplexan parasites, including →*Eimeria*, *Toxoplasma*, and →*Plasmodium* sp., that are capable of and dependent on the *de novo* synthesis of folate cofactors from GTP, p-aminobenzoate (PABA) and →glutamate. This route initially involves the conversion of GTP to dihydroneopterin triphosphate by GTP cyclohydrolase, an enzyme that is considerably different in plasmodia compared to the mammalian homologue. Dihydroneopterin triphosphate can then be utilized by apicomplexans in a biosynthetic pathway leading to dihydrofolate. Conversion of this product to tetrahydrofolate and other folate derivatives occurs in both parasites and their vertebrate hosts, but the homologous enzymes involved in these reactions can differ remarkably in their properties. These unique metabolic features of plasmodia and related protozoans explains the selective toxicity of →sulfonamides and folate antagonists against malaria and other apicomplexan-derived diseases and may continue to provide a source for the development of new drugs and novel therapeutic strategies.

Food Uptake

→Acanthocephala.

Foraging Behavior

→Behavior.

Forest Yaws

Common name of the disease due to infections with *Leishmania guyanensis* (= cutaneous leishmaniasis), also called pian-bois and bosch-yaws.

Formol-Ether-Fecal Concentration

Method of preparation of feces to diagnose parasitic stages (cysts, oocysts, worm eggs).

Fortification

Formation of a primary →cyst wall inside a host cell or more general the strenghthening.

Fosmidomycin

→New Drugs.

Francisella tularensis

Agent of →tularemia being transmitted by contaminated mouthparts of various ectoparasites (e.g., →fleas, ceratopogonids = →Culicoides).

Therapy

Streptomycine, Gentamycine.

Frenkelia

Genus of tissue-cyst-forming →Coccidia, named in honor of Prof. Jack Frenkel, Kansas City, USA.

Fülleborn, Friedrich Georg Hans (1866–1933)

German physician (Fig. 1) and 1930–1933 director of the Hamburg Tropical Institute, important reports on →filariidae, leader of Filaria expedition (1908/1909).

Fumagillin

Insecticide to be used against →*Varroa* mites.

Fülleborn, Friedrich Georg Hans (1866–1933). Figure 1 Professor Dr. Friedrich Fülleborn just prior to his death.

Fungi

→Microsporidia, →Pneumocystis.

Furazolidone

Drug used for treatment of giardiasis and *Blastocystis* infections. →Antidiarrhoeal and Antitrichomoniasis Drugs.

Furcocercous Cercariae

→*Alaria canis*.

GAE

Granulomatous **a**moebic →**e**ncephalitis of man due to infection with →opportunistic agents, amoeba of the genera →Acanthamoeba and →Balamuthia, which also may penetrate and thus destroy the cornea of the eyes.

Galactogenic Transmission

Transmission to next host generation via milk. →Arboviruses, →*Toxocara*, →*Toxoplasma gondii*, →*Filariidae*.

Galenus, Claudius (129–199)

Greek-Roman physician, besides Hippocrates the most famous physician of the Antique.

Galleria mellonella

Species of the butterfly group, a moth, that parasitizes inside stocks of bees.

GALT

Gut **A**ssociated **L**ymphoid **T**issue, →Immune System.

Galton-Watson Process

→Mathematical Models of Vector-Borne Diseases.

Gambusia

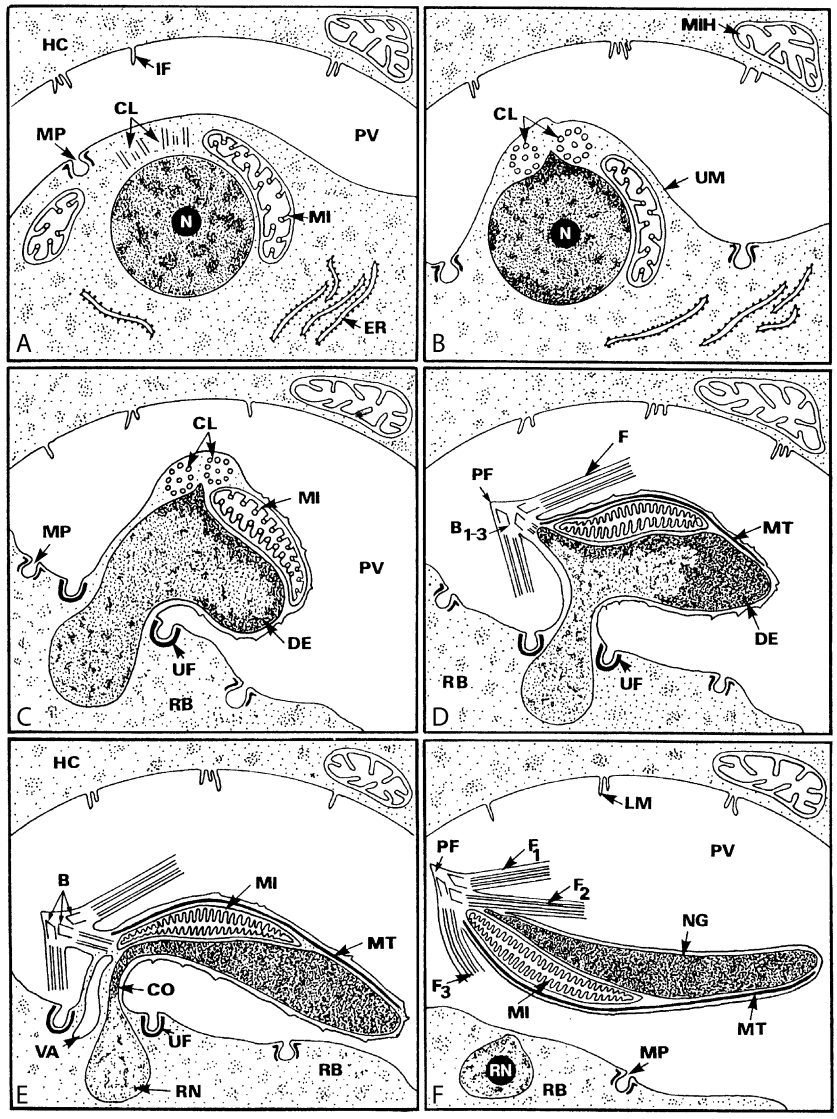
Genus of fish to be placed into ponds to control →mosquitoes by eating their larvae.

Gametes – Insects

The male gametes (sperms) of insects are in most cases flagellated with a species-specific size ranging from 20 µm until often 10 mm. The sperms include a nucleus, mitochondria, and an axoneme, which contains microtubules either in a 9 × 2 pattern or in a 9 + 9 + 2 pattern, terminates in single microtubules at the posterior end. At the top of the sperm a pointed fortified acrosome is formed (with a species-specific structure). The female gametes (oocytes) are spherical or ovoid and often rather large in comparison to the female insect.

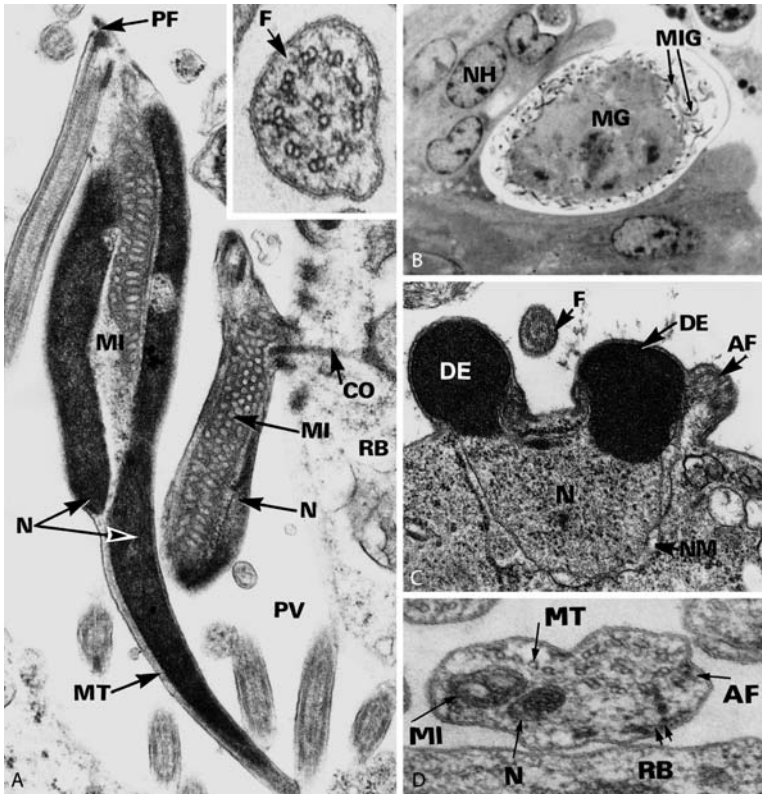
Gametes – Protozoa

Formation of sexual stages in →Protozoa is known for sporozoans including the →piroplasms, Ciliata, →Opalinata, →Hypermastigida (Fig. 8), and recently for trypanosomes (Fig. 7), but definite gametes are not always present (cf. →Platyhelminthes/Gametogenesis, →Nematodes/Gametogenesis). In the other groups the formation and fusion of gametes may be hidden. This may occur especially in those cases where the number



Gametes – Protozoa. Figure 1 A–F Diagrammatic representation of the formation of male (micro-) gametes of eimerian Coccidia (*E. maxima*) along the surface of →microgamonts. Other species have only 2 free →flagella. *B*, basal body; *CL*, →centriole-like structures (9 + 1 →microtubules); *CO*, connection; *DE*, densification; *ER*, endoplasmic reticulum; *F*, flagellum; *HC*, host cell; *IF*, intravacuolar folds; *LM*, limiting membrane of PV; *MI*, mitochondrion; *MIH*, mitochondrion of HC; *MP*, micropore; *MT*, microtubules; *N*, nucleus; *NG*, nucleus of the microgamete; *PF*, perforatorium; *PV*, →parasitophorous vacuole; *RB*, residual body; *RN*, residual nucleus; *UF*, underlying →fortification; *UM*, unit membrane; *VA*, vacuolization.

of gametes is low and where no clear differences between the fusing gametic partners are recognizable. Such →isogametes that look similar light microscopically, are found in the Opalinata, some →*gregarines*, *piroplasms*, and apparently in trypanosomes, where a true fusion of →epimastigotes is postulated to occur just before entering the salivary glands. In some gregarines, →anisogametes are described where both types of gamonts undergo divisions. In classic →Coccidia (e.g., →*Eimeria* spp., →*Isospora* spp.), tissue-cyst-forming coccidians (→*Sarcocystis* spp., →*Toxoplasma gondii*, etc.), classic →Haemosporidia →(*Plasmodium* spp., *Leucocytozoon* spp., etc.), and adeleideans (e.g., *Klossia*), micro- and macrogametes are formed (Figs. 1, 2). The whole process is called →oogamy, since here only the microgamont is divided, whereas the macrogamont develops into a large single →macrogamete (looking like an ovum). In no case, however, is the question of the chronological order of meiotic reduction definitively solved; so the distribution of haploidy and diploidy is not yet quite clear (→Chromosomes). In piroplasms (e.g., →*Babesia* spp. and →*Theileria* spp.), gamete formation



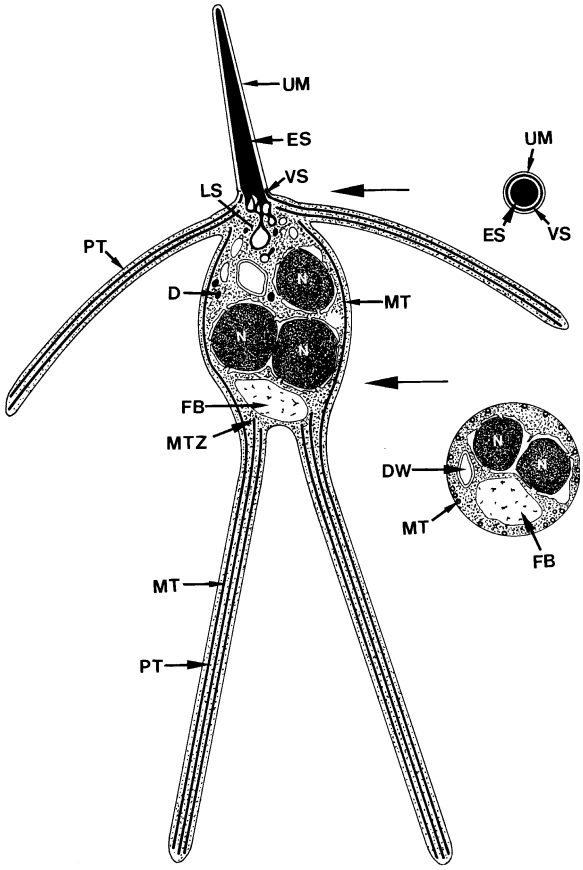
Gametes – Protozoa. Figure 2 TEM (A, C, D) and light (B) micrographs of developmental stages of microgamonts and microgametes. **A** →*Sarcocystis suihominis*: longitudinal section of microgametes connected to the residual body of the →gamont (RB) by a short bridge (CO). The microgametes consist of the nucleus (N) forming a groove, within which the mitochondrion (MI) is situated, 2 free flagella (F) with a typical cross-section (inset) and some microtubuli (MT) running below the →cell membrane. At the gamete's tip, a stiff perforatorium (PF) is formed that helps to enter into the macrogamete. *PV*, →parasitophorous vacuole. × 20,000. **B** Microgamont of →*Eimeria stiedai* during formation of migrogametes (MIG). *NH*, nucleus of the host cell. × 1,000. **C** →*Isospora* sp. from sparrow's intestine; formation of 2 microgametes from a single nucleus (N) in a microgamont. *AF*, →attached flagellum; *DE*, densification = later nucleus a microgamonts; *F*, flagellum; *N*, nucleus (remnant); *NM*, nuclear membrane. **D** Cross-section through the anterior tip of a microgamete of *Eimeria maxima*. Note the presence of the nuclear tip (N), the mitochondrion (MI), the attached flagellum (AF) and two rows of microtubules (MT, arrows). × 40,000. *RB*, residual microgamont.

and fusion differ from those in other sporozoans and need still more investigation (Figs. 3–5, pages 544, 555).

In all specimens of parasitic protozoans with typical gametes, a complete →syngamy can be observed, i.e., the differently determined gametes fuse completely, whether they include large (iso- or anisogametes) or only small (→Microgametes) amounts of cytoplasmic material. Syngamy always starts with the fusion of the limiting membranes (Figs. 4–6, pages 544–546), thus leading to a unicellular diplokaryon. Although karyogamy may be more or less delayed depending on the species, no further fertilization can occur along the surface of such zygotes, whether a fertilization membrane (as in some eimerian species) is formed or not.

In ciliates (e.g., *Balantidium*) no typical gametes are produced, but 2 similar looking individuals (→Conjugants) join temporarily for an exchange of a "wandering" nucleus during →conjugation. Similar processes may occur in other groups where sexual interchange has not yet been found or is reduced to a fusion of sister nuclei (→Myxozoa), which is called autogamy. Other hidden sexual processes are known from →Microsporidia, where so-called →meiospores may occur (e.g., →Amblyospora). More sophisticated methods, however, will surely contribute to the knowledge of this neglected, but extremely important phase of the parasite's life cycle.

In some groups of protozoans apparently, exchanges of DNA occur without a definite proof of fusion processes, which, however, may exist in low numbers and are thus not registered. Exchange experiments between different clones showed that in →*Trypanosoma*



Gametes – Protozoa. Figure 3 *Theileria* spp.; diagrammatic representation of a microgamont (= ray body) in cross- and longitudinal sections. *D*, dense granules; *DW*, double-walled organelle (mitochondrion); *ES*, spine; *FB*, fibrillar body; *LS*, labyrinthine structure; *MT*, microtubules; *MTZ*, microtubules are interrupted in drawing; *N*, nucleus; *PT*, protrusion (ray); *UM*, unit membrane.

haploid, diploid, and hybrid stages occur in the life cycle, a fact which underlines the suggested fusions (Fig. 7, pages 547). In →*Entamoeba histolytica* DNA measurements proved that the tissue-invading magnaforms possess at least twice as much DNA as the intestinal minuta forms – is this fact an indication for a preceeding fusion process?

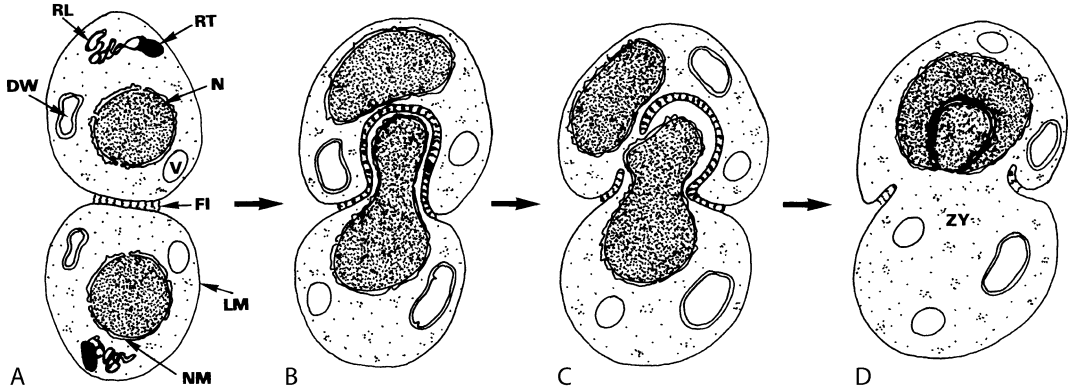
Gametes – Ticks

The male ticks develop 500 µm long prospermia which mature via a complicated process (called capacitation = differentiation) within 24 hours (after transfer to the female system) into a fertile stage (spermiophore). However, when having got contact to the female gamete (oocyte), only the nucleus of the male gamete enters, while the remainder of the sperm disintegrates. The prospermia of argasid ticks may measure up to 1 mm in length, those of ixodid ticks are shorter. Below the outer border of the prospermia many microtubule are arranged to guarantee shape and motility.

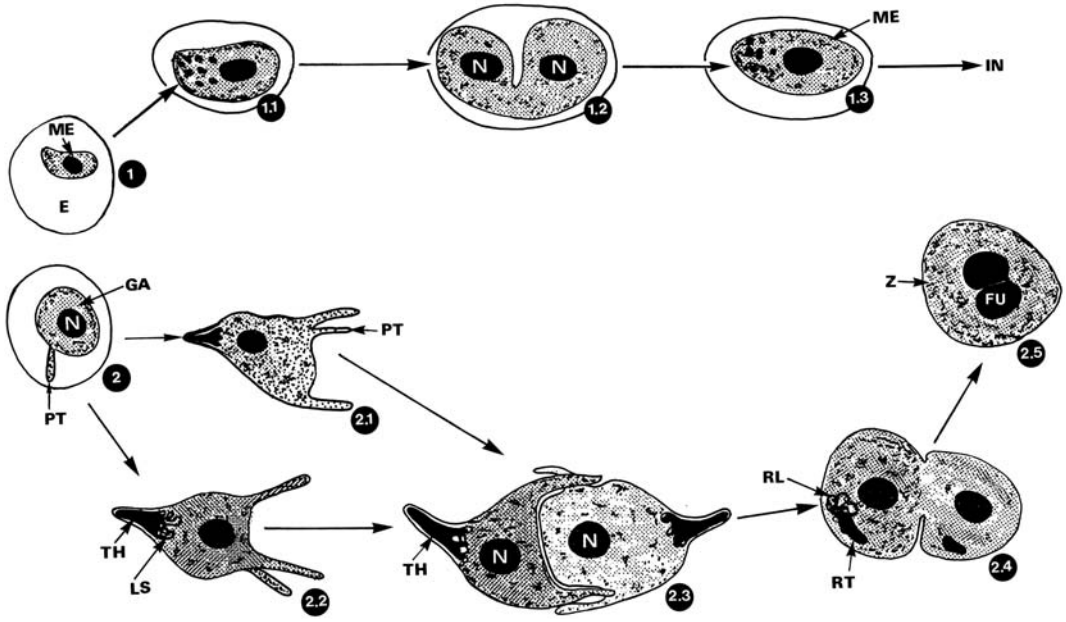
Gametes – Worms

Trematodes

The sperms of schistosomes are different from those of other trematodes. They possess a head-like thickening, which contains the electron dense nucleus. At the basis of the nucleus, a mitochondrion occurs and a basal body



Gametes – Protozoa. Figure 4 A–D Fusion of gametes in →*Theileria* spp. in 4 steps as seen *in vitro* and *in vivo*. *DW*, double-walled organelle; *FI*, filamentous elements; *LM*, limiting membrane (single); *N*, nucleus; *NM*, nuclear membrane; *RL*, remnants of labyrinthine structure; *RT*, remnants of the thorn; *V*, vacuole; *ZY*, →zygote.



Gametes – Protozoa. Figure 5 →*Babesia* spp.; formation and fusion of gametes. *1–1.3* Formation of merozoites by →binary fission (depending on the presence of fresh red blood cells in culture); this process does not occur in the tick's gut, where merozoites are dissolved. *2–2.5* Sexual processes. *2* Ovoid-spherical stages become gamonts and form protrusions (even in the vertebrate host blood). *2.1–2.2* Two types of ray bodies occur (one is more electron lucent than the other) after probable divisions. This process starts after disruption of the erythrocyte. *2.3* Syngamy of gametes. *2.4* Opening along the attached membranes. *2.5* Fusion of the nuclei. *E*, erythrocyte; *FU*, fusing nuclei; *GA*, gamont; *IN*, in culture indefinite repeated division occur; *LS*, labyrinthine structure; *ME*, →merozoite; *N*, nucleus; *PT*, protrusion; *RL*, remnants of the labyrinthine structure; *RT*, remnant thorn; *TH*, thorn; *Z*, zygote.

gives rise to a single axoneme which enters a long filament-like tail. The center of the axoneme only contains none, 1, or 2 microtubules (Figs. 1–3, pages 548, 549). Beneath the single cell membrane 25–115 microtubules are lining the inner surface of the gamete. In other digenetic trematodes (e.g., in *Clonorchis*) 2 axonemes are formed instead of 1 in schistosomes (Figs. 4, 5, page 549). In *Paragonimus*-sperms 2 mitochondria occur. The female gametes of most trematodes are ovoid or spherical.

Cestodes

The male gametes of the cestodes are filament-like reaching a length of often 0.2 mm. They are limited by a single cell membrane, which is lined inside by 25–40 microtubules (Fig. 6, page 550). The nucleus is situated in the central portion and is accompanied by the single axoneme, which has only a single central element. Mitochondria were not seen, acrosomal structures are lacking, too. The female gametes are in general spherical.

Nematodes

The gametes of nematodes are described and pictured in the keyword →nematodes.

Gametocyte

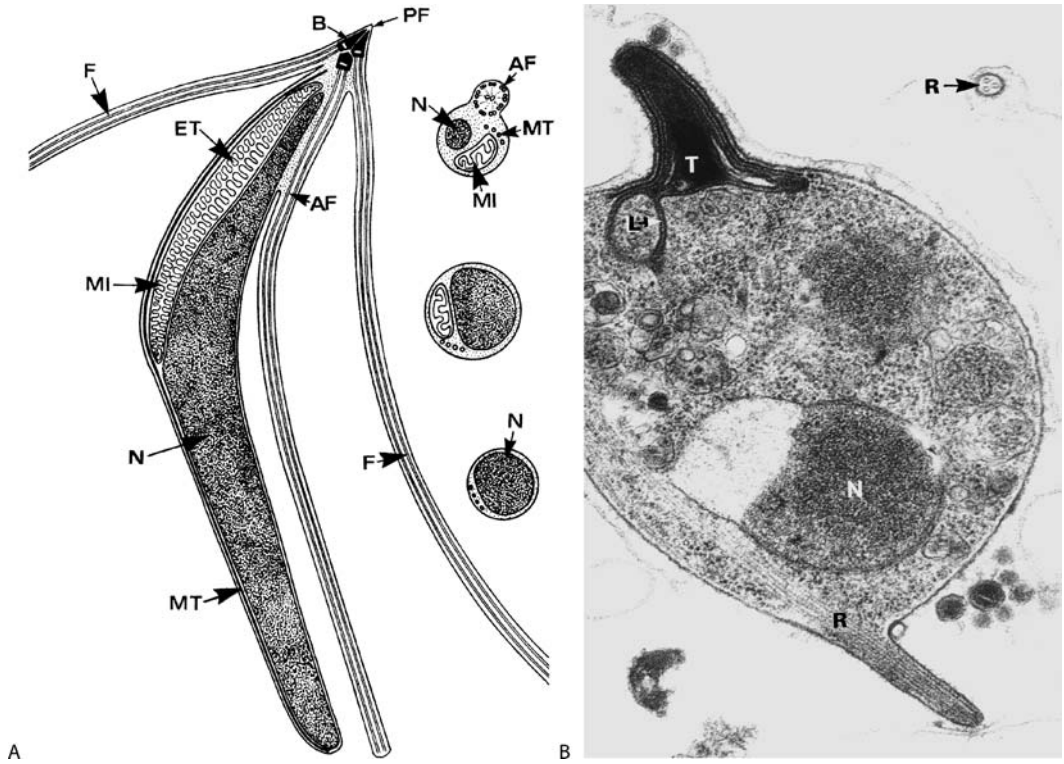
Other word for →gamont, i.e., stage proceeding →gametes.

Gamma-Amino Butyric Acid

→Nervous System of Platyhelminthes.

Gamogony

Sexual phase in the life cycle of →Coccidia which proceeds in general as →oogamy with macrogametes and →microgametes (→Gametes, →Eimeria, →Mitochondria/Fig. 1E).



Gametes – Protozoa. Figure 6 **A** Diagrammatic representation of a microgamete of *Eimeria maxima* in logitudinal and cross-section. *AF*, attached flagellum; *B*, basal body; *ET*, enlarged tubule (sacculus); *F*, free flagellum; *MI*, mitochondrion; *MT*, microtubule; *N*, nucleus; *PF*, perforatorium. **B** *Babesia canis*, longitudinal section through a microgamont inside a vector tick. Gamont

Stage preceding the →gametes (in Protozoa).

Gamontogamy

→Gregarines.

Gasterophilosis

Disease due to infestation with →*Gasterophilus* species, see Table 1 (page 550).

Gasterophilus

Name

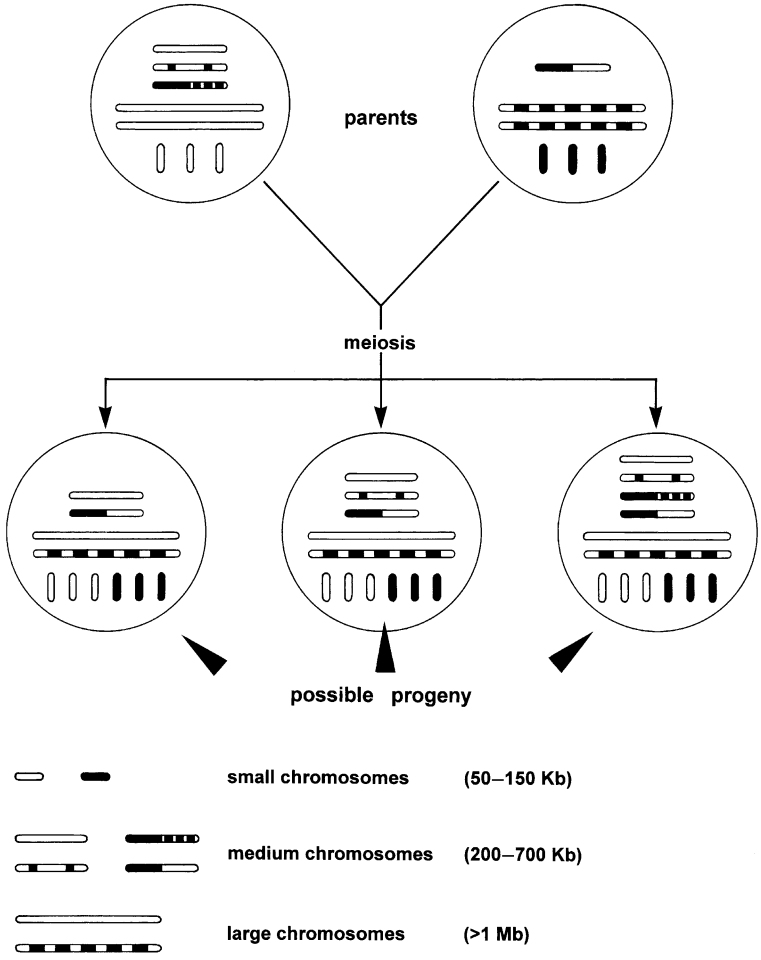
Greek: *gaster* = stomach, *phil* = loving it.

Important Species

- *G. intestinalis* (eggs are deposited all over the host's (equids) body), about 900 in 3 hours
- *G. haemorrhoidalis, G. nasalis* (eggs are found at lips)
- *G. inermis* (eggs on the hair of cheeks)
- *G. pecorum* (eggs are deposited on host's food), up to 2,000 per female

Adults do not feed, larvae hatch in the case of *G. intestinalis* within 7–14 days.

Human infections may occur after contact with infested horses with *G. nasalis, G. intestinalis* and



Gametes – Protozoa. Figure 7 Diagrammatic representation of the genealogy of the different →chromosomes of trypanosomatids during meiotic processes (after Tait and Turner, 1990).

G. haemorrhoidalis. The larvae penetrate human skin and migrate in a serpentine causing a line. Thus this myiasis is called *myiasis linearis*. Adults of *G. intestinalis* (syn. *G. equi*) reach a length of 1.8 cm (Figs. 1, 2; page 551) and appear reddish-yellow, brown-black. As adults they do not feed anymore. After mating the females, which possess a pointed terminal end being bended below the abdomen, clue up to 5,000, 0.2 mm long eggs at the hair of horses. After 5–10 days the larvae hatch from the egg and enter the mouth actively or are transported there during the licking of the horse. In the stomach the larvae molt twice and grow up to 2 cm as larva III; this stage appears red and is excreted 8–10 months after infection with the faeces. Pupation occours immediately on/in the soil. After 3–8 weeks the adult flies hatch from the puparium (during June). Their time of activity is July and August in Europe. →Diptera.

Gastritis chronica hyperplastica

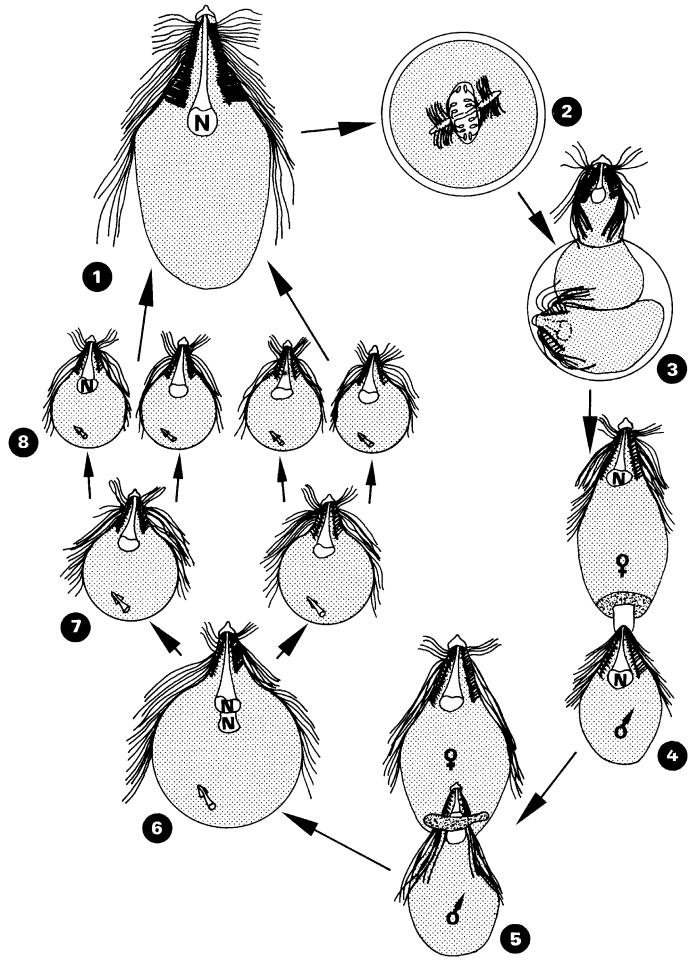
→Trichostrongylosis, Animals.

Gastrodiscoides hominis

→Digenea.

Gastrodiscus aegyptiacus

→Alimentary System Diseases, Horses.



Gametes – Protozoa. Figure 8 Diagrammatic representation of the modes of reproduction of the hypermastigine →*Barbulanympha* sp. from the intestine of the cockroach *Cryptocercus punctulatus*. **1** Trophozoite; **2, 3** division in a cyst; **4–6** fusion of gametes to form a zygote (6); **7, 8** formation of →trophozoites by repeated →binary fissions. *N*, nucleus.

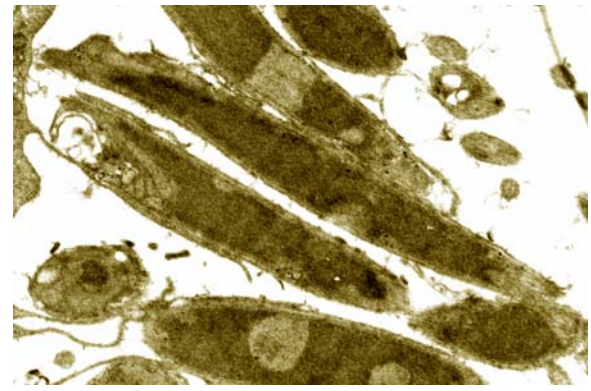
Gastrointestinal Hormones

General Information

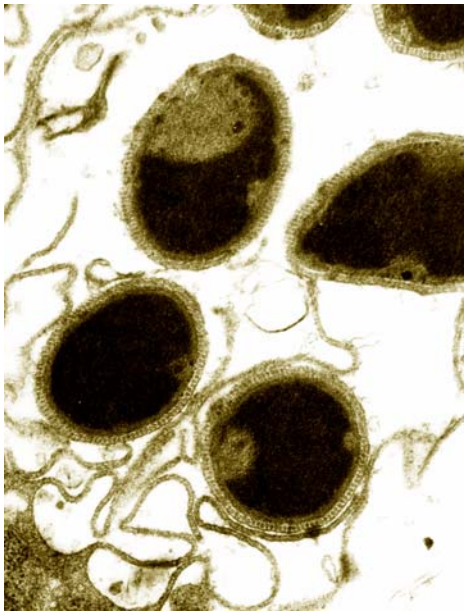
Gastrointestinal hormones like gastrin, cholecystokinin (CCK) and vasoactive intestinal peptide (VIP) are small peptides of 4–58 amino acids. Most of these hormones are sulfated.

Physiological Function

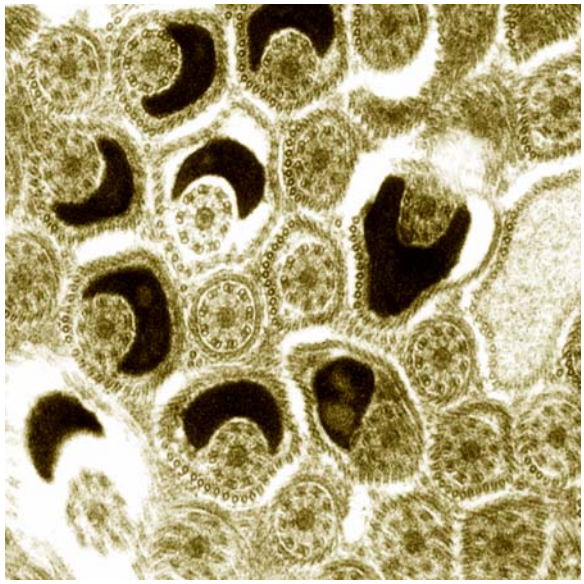
Gastrointestinal hormones are not part of a hierarchical system like the hypophyseal-gonad or -thyroid, or -adrenal gland axis. They are released by →neurotransmitters, other hormones of the gastrointestinal tract and by components of the food. Interestingly,



Gametes – Worms. Figure 1 Longitudinal section through the anterior end (head) of schistosomal sperms.

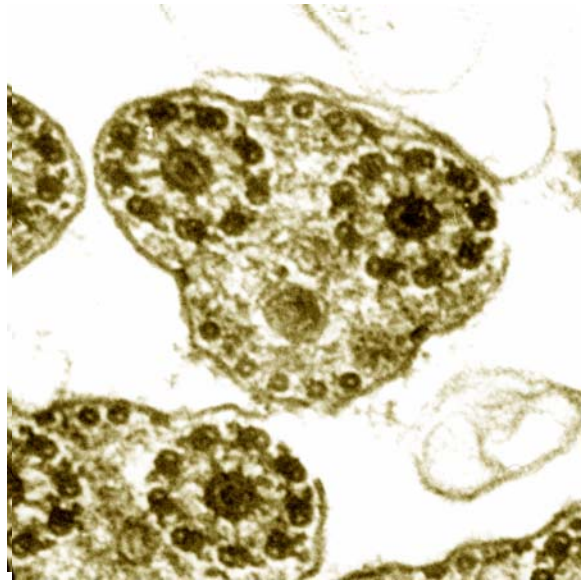


Gametes – Worms. Figure 2 Cross-section through the head of schistosomal sperms showing the nuclei and the peripheral microtubuli.

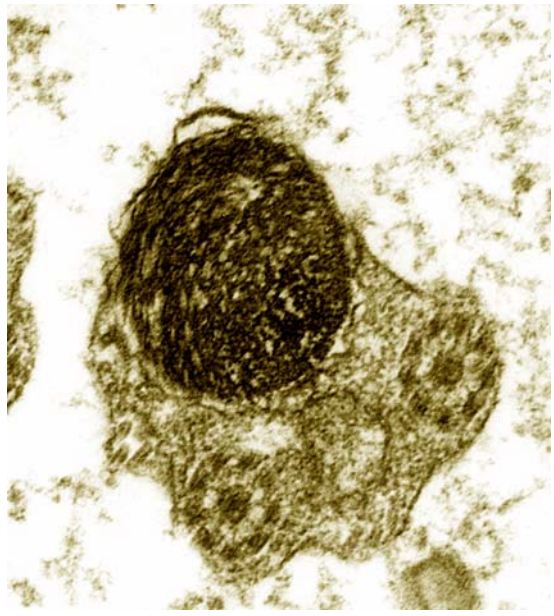


Gametes – Worms. Figure 3 Cross-section through sperms of schistosomes at different levels of the axoneme. Note the terminal portion of the nucleus (black).

these hormones are also produced in the central nervous system and their functions are different, depending on the localisation. For example, CCK increases the release of hormones and enzymes from the pancreas and also contracts the gall bladder, but in the brain it is an important sensor for satiety.



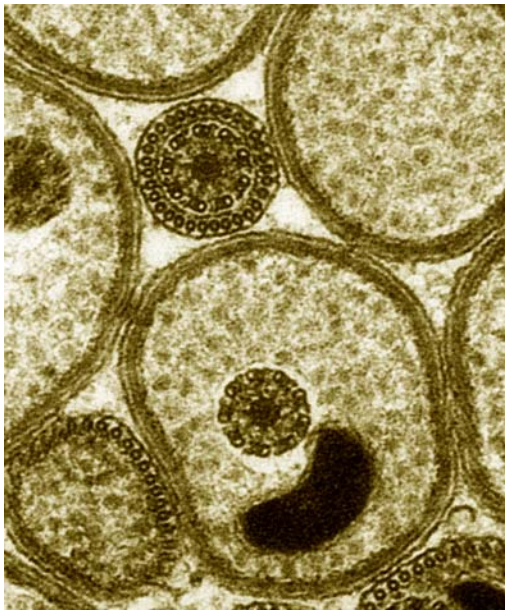
Gametes – Worms. Figure 4 Cross-section through sperms of *Clonorchis* in a non-nuclear region.



Gametes – Worms. Figure 5 Cross-section of sperms of *Clonorchis* in a nuclear region.

Clinical Relevance

Infection with gastrointestinal →nematodes is an important cause of impaired productivity in all domestic ruminants (→Alimentary System Diseases, Ruminants). Changes in feed intake and gastrointestinal functions are essential mechanisms for these losses. Gastrin levels increase after infection, as well as the pH in the abomasum. Quite often, but not regularly, there is also an increase in serum pepsinogen. These different



Gametes – Worms. Figure 6 Cross-section through the sperms of *Hymenolepis nana* (Cestoda) at different levels.

effects finally lead to →hyperplasia and hypergastrinemia. In some gastrointestinal helminths, gastrointestinal hormones have been demonstrated by immunocytochemistry but the function of these parasitic hormones is unknown so far, with the exception of a vasoactive intestinal peptide (VIP) from the nematode →*Nippostrongylus brasiliensis*. This hormone is part of the excretory/secretory material and it inhibits the amplitude of contractions of the intestinal tract as efficiently (in the pM range) as the corresponding vertebrate hormone. Since VIP is known to inhibit food intake and to stimulate ACTH and growth-hormone release in the brain, the nematode VIP might therefore have additional advantages for the parasite.

Pathology

Infection of ruminants with adult worms (→*Haemonchus contortus*, resp. →*Ostertagia circumcincta*) leads to rapid responses (increase in serum pepsinogen and gastrin as well as abomasal pH) within less than a day, whereas with larval stages there is a lag phase of four to five days, though finally there is the same degree of response and also of hypergastrinemia. It is speculated that excretory/secretory products of adult worms lead to this cascade of events. Removal of the adult worms by treatment with antihelminthic agents rapidly normalises gastrin, pepsinogen and abomasal pH. The role of CCK for sensoring satiety was demonstrated by the application of CCK which depressed short-term feed intake only in infected animals and also by a CCK antagonist which, after central infusion, increased short-term feed intake. The effect was more pronounced in infected animals than in controls.

Gasterophilosis. Table 1 *Gasterophilus* species and Control Measurements

Parasite	Host	Symptoms	Country	Therapy		
				Products	Application	Compounds
Gasterophilus haemorrhoidalis (Nose or lip bot)	Horse		Worldwide	Eqvalan™ Paste 1.87% (Merial)	Oral	Ivermectin
Gasterophilus inermis	Horse		Europe, Africa, Asia			
Gasterophilus intestinalis (Common bot)	Horse	Most of the time asymptomatic; stomatitis, eating and chewing problems, erosions, ulcera, and dilatation of the stomach, chronic duodenitis, proctitis	Worldwide	Eqvalan™ Paste 1.87% (Merial) Quest Gel (Fort Dodge)	Oral	Ivermectin
Gasterophilus nasalis (Throat bot)	Horse		Worldwide	Eqvalan™ Paste 1.87% (Merial) Quest Gel (Fort Dodge)	Oral	Ivermectin
Gasterophilus nigricornis	Horse		Europe, Africa, Asia		Oral	Moxidectin
Gasterophilus pecorum	Horse		Europe, Africa, Asia			

Gasterophilus. Figure 1 Diagrammatic representation of the dorsal side of an adult female of *Gasterophilus intestinalis*. The pointed posterior end is bended below the abdomen.

Gasterophilus. Figure 2 Larvae of *Gasterophilus intestinalis*, that are attached to the stomach wall of a horse.

Gastrotaenia

Genus of the tapeworm family Hymenolepididae. *Gastrotaenia* sp. reaches a length of 13 mm and is found in the muscular stomach of ducks and swans. Intermediate hosts are copepods.

GBD

Global burden of disease. Life time lost due to disease. All →DALY added results in the GBD-value of a distinct region.

Gedoelstia Species

Flies of the family Oestridae, the larvae 1 of which penetrate occasionally into the conjunctival sac of cattle leading to a →conjunctivitis. In addition the larvae 2 and 3 are found in the sinus frontalis, in brain and in heart muscles (→Nervous System Diseases, Ruminants, →Uitpeuloog).

Gehyrolina paragonopora

Species of →Cestodaria.

Géné's Organ

Géné's organ is common to all female →ticks. It is found just above the position at which the capitulum is joined to the idiosome, in the camerostomal fold of ixodid ticks, the camerostomal depression of argasid ticks, or anterodorsally ventrad of the pseudoscutum in nuttalliellids. During →oviposition, Géné's organ emerges through an aperture to give each egg a waxy surface, as a final waterproofing. The →porose areas of female ixodid ticks (→Ticks/Fig. 6), whose function was not known for a long time, appear to act in conjunction with Géné's organ by producing inhibitors of the autoxidation of the unsaturated egg wax lipids (→Ticks/Reproduction). Terminal portion of the ixodid tick ovipositor system. Here the eggs were covered by a clueing layer, which protects the egg from drying when deponed onto the floor. This layer enables the rather undisturbed development of the larvae inside.

Genital System Diseases, Animals

Parasitic infections of the genital tract are of major economic importance (Table 1), particularly those caused by the widely distributed protozoan parasites →*Toxoplasma gondii*, →*Neospora caninum* (syn. →*Hammondia heydorni*?) and →*Tritrichomonas foetus* which are major causes of reproductive failure in ruminants.

Genital System Diseases, Animals. Table 1 Parasites affecting the Genital System of Domestic Animals (according to Vercruysse and De Bont)

Parasite	Host	Location	Clinical presentation	Principal lesions
Protozoa				
Besnoitia besnoiti	Cattle	Testicles	Infertility	Orchitis
Neospora caninum	Cattle, sheep, goat, horse, dog, cat	Neural tissues	Abortion, neuromuscular signs in congenitally infected calves	Encephalitis in transplacentary-infected fetuses
Sarcocystis spp.	Cattle, sheep, goat, pig	Vascular endothelium of placenta, fetus	Abortion	Placentitis
Toxoplasma gondii	Sheep, goat	Placental cotyledons, fetus	Abortion	Necrosis in villous part of cotyledons, leukoencephalomalacia in congenitally-infected lambs or kids
Tritrichomonas foetus	Cattle	Vagina, cervix, uterus, oviduct, preputium	Early abortion, sterility	Vaginitis, endometritis, balanoposthitis
Trypanosoma equiperdum	Horses	Genitalia, skin, nerves	Genital phase: mucoid, vaginal or urethral discharge, nymphomania, micturition, rarely abortion	Oedema and inflammation of genitalia with ulcera, pigmentation of vulva or penis

T. gondii infections are ubiquitous throughout the world and are an important cause of →abortion in small ruminants. In fact, the parasite may invade many different organs in nearly all warm-blooded animals, and the clinical picture in a particular host species depends on the particular involvement of any one or more of these organs. However, in the vast majority of cases, infections remain asymptomatic. During initial exposure of pregnant ewes and does, the parasite primarily invades the placenta and may, at any gestational age, lead to fetal infection, with or without fetal death. Therefore, exposure of susceptible animals may lead to a wide range of clinical manifestations, including early embryonic death, mummification, abortion, stillbirth, neonatal death or birth of weak offspring. Abortion is generally caused by →necrosis of the cotyledons of the placenta. Congenital infection mainly affects the brain of the fetus, and lambs or kids born alive may show signs of →encephalitis. In pigs and dogs, cases of congenital toxoplasmosis have been reported, and clinically affected animals often show respiratory signs. *T. gondii* is apparently not a significant fetal pathogen in cattle and horses.

→*Sarcocystis* spp. are common, ubiquitous, sporozoan parasites of herbivores, but they rarely cause clinical signs or abortions in infected animals. Acute forms of →sarcocystosis are associated with the massive development of schizonts in endothelial cells of blood vessels. The clinical signs include high fever, →anorexia, anemia, ataxia and loss of weight, sometimes with high mortality rates. *Sarcocystis* spp. have occasionally been reported as causing abortion in cattle, sheep, goats and pigs. In some cases, the absence of schizonts from the fetus suggest that the abortion is caused by maternal failure. In other cases, where the aborting mother may be otherwise normal, the extensive development of schizonts in the endothelial cells throughout the fetal tissues and within the placenta suggest that abortion is directly caused by the parasitic infection. It is uncertain whether some reported cases of *Sarcocystis* abortion in cattle, in fact, are *Sarcocystis* or possibly, *Neospora* infections.

N. caninum, which has long been misidentified as *T. gondii*, is now known to occur in a wide range of host species, including dogs, cats, horses, cattle, sheep and goats. Dogs have been identified as definitive hosts. Clinical manifestations of →neosporosis have mainly been observed in cattle and dogs. Transmission occurs orally, and via the transplacental route. *N. caninum* has a predilection for the central nervous system and skeletal muscles, generally leading to encephalomyelitis and polymyositis. In cattle, neosporosis is regarded as a major cause of abortion, particularly among dairy cattle. Although fetal death probably occurs throughout the gestation period, cows only abort from 3 months of gestation to term. It is likely that 1- to 2-month-old fetuses are killed *in utero*, resorbed, and the cow returns to heat again. Fetuses which die *in utero* may be

resorbed, mummified, aborted or stillborn. *N. caninum* is most often demonstrable in the brain and heart of the fetus, and rarely in other organs, including the placenta. Some congenitally infected calves may be born with signs of neuromuscular dysfunctions, while others may be born clinically normal but chronically infected. In aborted fetuses, the major lesion is a multifocal, necrotising, non-suppurative encephalomyelitis. *Besnoitia besnoiti* occurs in cattle in Southern Europe, Africa and Southeast Asia. Lesions, if any, are mainly confined to the skin and mucosa of the upper respiratory system, however, orchitis and subsequent infertility has been reported in bulls.

Trichomonosis is an important venereal disease of cattle caused by the flagellated protozoan *T. foetus*. In bulls infections usually go unrecognised. However, they remain chronically infected and transmission of the parasite to heifers or cows occurs at coitus. In the female, a primary infection invariably causes a vaginitis of varying intensity, with swelling of the vulva and vaginal discharge. Thereafter the parasites migrate upward through the cervix and invade the uterus. The inflammatory changes in the endometrium and cervix are relatively mild and non-specific, although the exudate, mucopurulent in character, may be rather copious. *T. foetus* does not prevent conception as such, but endometritis and uterine catarrh prevent proper fertilization, and result in aberrant →oestrus cycles and repeat breeding. Trichomonal abortion may occur at any time, but usually takes place early in gestation. Embryonal or fetal death may be followed by retention and sometimes pyometra, which occasionally result in permanent infertility. Unlike bulls, infections are self-limiting in females, with clearence of parasites after approximately 95 days.

→Dourine is a chronic venereal disease of horses caused by *Trypanosoma equiperdum*. The infection occurs in all species and breeds of Equidae, but not with the same intensity. Donkeys and mules are more tolerant to the infection than horses, while among the latter thoroughbreds and imported horses tend to be more susceptible to the disease than native horses. Unlike other species of trypanosomes, *T. equiperdum* is transmitted by coitus. It may take several months before clinical signs appear, by which time the infection may have spread significantly over the horse population. *T. equiperdum* is a tissue parasite and infects primarily the mucosa of the genital organs, the skin and nervous tissues. The disease which is insidious in nature, affects both stallions and mares. It usually progresses through three distinct phases. A first phase marked by swelling of the external genitalia is followed by an urticarial phase visible on the skin. These two phases may last several months to several years, during which time the animal gradually becomes cachectic. A third, invariably fatal nervous phase characterised by incoordination and paralysis occurs in some horses. The genital phase is initiated by a mucoid vaginal or urethral discharge, →nymphomania and a mild fever with →oedema of the genitalia. Abortion in cattle associated with *T. brucei* or *T. congolense* infection (Nagana, African trypanosomosis) has been reported and this disease may also reduce fertility by altering testicular steroid production and sperm quality in bulls and causing atrophy of the ovaries in cows.

In horses, larvae of the →nematodes →*Strongylus vulgaris* and *S. edentatus* have occasionally been found migrating into the testes, leaving such lesions as inflamed, haemorrhagic migratory tracts. In warm climates, larvae of *Draschia megastoma, Habronema muscae*, and *H. majus* deposited near the prepuce by the →intermediate host flies (housefly *Musca domestica* and the →stable fly *Stomoxys calcitrans*) burrow into the dermis and cause extensive granulomatous inflammation. The infestation known as 'summer sores' is more common in geldings (accumulation of smegma) than in stallions.

Therapy

See treatment of the various species, →Chemotherapy, →Drugs.

Genome Sizes

→Nucleic Acids, →Chromosomes. The genome of parasites is much larger/bigger than that of bacteria. While *Escherichia coli* has 4.2 Mb, reach protozoans 9.4 (*Babesia bovis*), 12 Mb (*Giardia*), 20 Mb (*Trypanosoma brucei brucei*), or even 80 Mb (*Toxoplasma gondii*). Worm genomes become even much bigger, i.e., 150 Mb are reached in the case of *Onchocerca*, 270 Mb in schistosomes. The same size range is found in mosquitoes (280 Mb), while small mammalia (like mice) have 2,700 Mb.

Geographic Distribution

Like all living species, parasites have adapted to particular →environmental conditions. No parasite species exists everywhere on earth. For a parasite to exist at any one place, there needs to be a suitable host and a suitable environment for transmission.

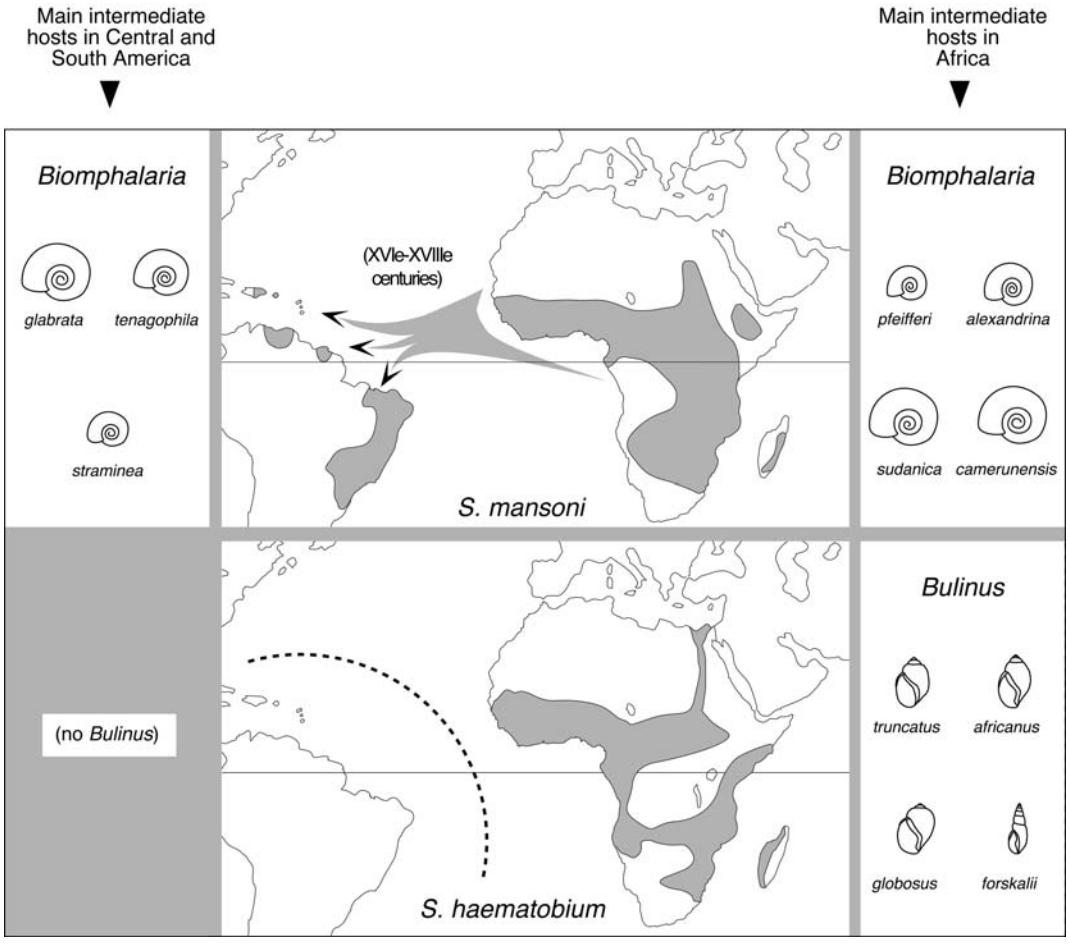
The expression "suitable host" implies several constraints: not only must the host be "qualitatively" present (i.e., a susceptible population), but also quantitatively (i.e., a density of hosts allowing sufficient production of larval stages and transmission); in heteroxenous life cycles, the constraints are multiplied by the number of different host species necessary for the completion of the cycle.

The expression "suitable environment for transmission" implies other constraints, because (with very few exceptions like *Trichinella*), parasites spend a part of their life outside the hosts and have, like all organisms, particular requirements such as range of temperature, presence of water, etc.

The geographic range of a particular parasite is usually constrained by a limiting factor, which is not always easy to identify (cf. maps added to several life cycles). When several host species are required for the development of a parasite species, this species can exist only where all these host species coexist. This explains why parasites with simple life cycles adapt themselves to new environments better than parasites with complex life cycles. In the latter case, it is rare that all the conditions are met. For instance, when schistosomes were transported into America with the slave trade (Fig. 1), only one species of African schistosome found a convenient mollusc vector and became established (→Specificity).

Geographic Zones of Occurrence of Diseases

Agents of disease are found in different numbers in 4 different zones:



Geographic Distribution. Figure 1 Current distribution of →*Schistosoma mansoni* and →*S. haematobium*, as explained by their vector distribution: *S. mansoni* and *S. haematobium* were both introduced into the New World during the 16th and 17th centuries but only the first one was compatible with local snails and became established (from Combes, 1995, modified).

a) **Endemic zone:** infections are found the whole year.
b) **Epidemic zone:** outbreaks occur at different intervals.
c) **Incursive zone:** disease and its agents are only found occasionally.
d) **Exterior zone:** here the agents of disease were not yet found.

Germ Balls

→Digenea/Reproduction.

Germ Theory of Disease

→Mathematical Models of Vector-Borne Diseases.

Germarium

Ovary of →Platyhelminthes →Digenea.

Giant Cells

A granulomatous reaction is introduced by multinucleated giant cells in human brain infected with *Acanthamoeba* or *Balamuthia* amoebae (→GAE). This reaction may not be present in cases of immunosuppressed patients. A similar reaction occurs in the liver of patients with schistosomiasis. There the remnants of the eggs of the schistosomes are finally engorged by such giant cells, which occur at the end of a strong granulocytic reaction in the liver. →granulomes/pathology.

Giardi, Alfred (1846–1908)

French zoologist and describer of many protists.

Giardia lamblia

Synonym

Lamblia intestinalis, Giardia duodenalis.

Classification

Species of →Diplomonadida.

Life Cycle

Fig. 1.

Giardia lamblia (named after the scientists Giardi and Lambl) was already seen by van Leeuwenhoek in 1681 but not described till 1859 by Lambl. However, in recent years many new molecular biological results showed that the species situation is rather complicated, since many hosts are involved in human and animal →giardiasis (Table 1). The trophozoites of *G. lamblia* are pear-shaped, about 10–20 μm long with a width of about 5–15 μm, and possess 2 nuclei and 8 flagella (Figs. 2A, 4). Since the trophozoites are attached with their ventral disc (Figs. 2, 4) to the surface of epithelial cells (Fig. 5), they disturb the normal way of food uptake. The reproduction occurs by →binary fission. Finally, ovoid cysts of about 10–15 × 7–10 μm are formed. When excreted via feces they contain 4 nuclei (Fig. 3A). The fine structure of trophozoites and cysts is shown in Figs. 2–4.

Morphology

Figs. 2, 3, see also →Flagella/Fig. 3.

Species Relations

Giardia lamblia, that was described in papers until 2004 is apparently a mixture of several species and so-called genotype assemblages, which now were combined to *G. duodenalis* with several subtypes and different zoonotic properties (Table 1). Thus species names such as *G. cati, T. canis, T. bovis* are now invalid, and only a few other species of none or reduced anthropozoonotic importance are recorded (Table 1). The finding that *G. duodenalis* (Assemblage A) may infect a wide spectrum of mammals besides man is of high epidemiologic importance. In humans also mixed populations of different genotype assemblages may occur.

Disease

Giardiasis, Animals

Pathology

Giardia species occur in dogs and cats, and giardiosis may represent an important problem in these hosts. It causes →anorexia, depression, and a mild recurring →diarrhoea consisting of soft, light-coloured stools with a characteristic "oatmeal" texture, frequently containing mucus. Growth retardation and cachexia may occur. The mechanism by which giardial →malabsorption and diarrhoea occurs is unclear. Epithelial damage, increased turnover of epithelial cells, villous shortening, and disaccharidase deficiency have all been reported as manifestations of giardiosis.

Giardia spp. are usually non-pathogenic inhabitants of the intestine of horses, cattle, sheep, and goats. However, they may cause diseases under certain circumstances, such as in animals which are immuno-compromised, malnourished, or very young.

Giardiasis, Man

Pathology

→*Giardia lamblia* is a binuclear, pear-shaped flagellate which lives in the duodenum and upper small intestine, where it is closely applied or attached to the epithelium by means of a suction disk. Ultrastructural examination of a biopsy of the small intestine often shows the epithelial →microvilli to be destroyed at the attachment sites of the flagellates. Acute infections are usually of short duration with →diarrhoea and epigastric distress which subsides with the development of immunity. →Chronic infections occur in patients with low or absent IgA, IgG, or IgM. In these patients the intestinal villi are often blunted from loss of epithelium which regenerates inadequately. The lamina propria is heavily infiltrated with lymphocytes and granulocytes. Diarrhoea, →weight loss, and intestinal →malabsorption with flatulence accompany chronic infections. The →trophozoites can be found in diarrhoeic stools, by duodenal aspiration or biopsy. The 4-nucleate →cysts (→Giardia lamblia/Fig. 3) are found in stools.

Immune Responses

The establishment of animal models and the production of the whole life cycle of the parasite *in vitro* have greatly facilitated the characterization of stage-specific antigens as well as of analyzing the contribution of humoral and cell-mediated immune responses in the control of the infection. Most ofthe current knowledge comes from 4 different sources: (1) *in vitro* studies with axenically grown *G.* →*lamblia* trophozoites and immune cells from different hosts; (2) studies with *G. lamblia*-infected mice or gerbils; (3) experiments with *G. muris*-infected mice; and (4) the analysis of immune responses in *Giardia*-infected humans.

Innate Immunity

Since neutrophils are circulating blood cells, they are generally considered to play only a minimal role in intestinal infections. However, these cells are able to migrate like →amoebae through small cracks in vessel linings to the exterior, where they eventually infiltrate tissues such as epithelial layers of the intestinal tract. It has been shown that certain products of neutrophils, cryptidins, and cationic neutrophil peptides, possess anti-giardial activity. The content of granules together with antibodies reduces parasite infectivity and antibody-dependent cytotoxicity (→ADCC) was demonstrated with human peripheral blood neutrophils *in vitro*. Since all these anti-giardial effects of neutrophils have been analyzed only *in vitro* so far, the functional role of these cells *in vivo* remains to be elucidated. Although in mice infected with *G. muris* there was only a small rise in mucosal mast cell numbers, inhibition of mast cell products by cyproheptadine enhanced the infection.

B cells and Antibodies

An important function of antibodies in the control of giardiasis is suggested by more severe infections in patients with hypogammaglobulinaemia. In B-cell-deficient mice, unable to mount an anti-Giardia Ig response, the infection with *G. lamblia* could not be resolved and antigenic diversification within the parasite population occurred in an unusually slow manner. Several studies have additionally demonstrated antibody-mediated killing of *Giardia* trophozoites *in vitro*, which is not in all cases complement dependent. The most important Ig for the control of giardiasis is IgA. The appearance of secretory IgA in the intestine correlates with the elimination of the parasite from the small intestine, but the effect of Ig subclass is complement-independent since IgA lacks C1q-binding sites in its Fc region required for the activation of the classical complement pathway. IgA may thus mediate its function in a complement-independent manner, e.g., by binding to trophozoite surface proteins thereby causing detachment and aggregation of the parasite. However, a functional role of complement should not be ruled out since (1) proteins of the complement cascade are synthesized by epithelial cells of the intestinum and (2) the alternative pathway of complement activation may be operative. Certain surface molecules, e.g., in the sucking disc of the parasite as well as metabolites released by trophozoites are able to activate the alternative pathway.

T cells

There are few studies on the role of specific T cells in the defense against *Giardia*. The latent and acute phases of *G. lamblia* infection are accompanied by an increase of $CD8^+$ cells among IELs while in the elimination phase this population decreases and $CD4^+$ cells increase significantly. Since trophozoites are killed by oxidative-burst mechanisms stimulated in macrophages via IFN-γ, it was tempting to speculate that T cells producing this cytokine might be involved in the control of parasite replication.

In addition, IFN-γ leads to enhanced phagocytosis of *Giardia* trophozoites by macrophages. Comparing the antibody and cytokine response in relatively resistant B10 mice and more susceptible BALB/c mice it was found that B10 mice produced IgG2a while BALB/c mice produced IgG1 after *G. muris* infection, suggesting differential involvement of Th1 and Th2 cells. When lymphocytes from mesenteric lymph nodes were stimulated *in vitro*, only those of B10 mice produced measurable amounts of IFN-γ. The application of neutralizing antibodies against IFN-γ to B10 mice resulted in an enhanced intensity of infection, arguing for a protective role of Th1 cells in this parasitic infection.

Immunopathology

The killing of the parasite can lead to injury as shown, for example, in co-culture experiments with enterocytes and activated macrophages from the gut of mice infected with *G. lamblia*. It is not clear, however, if villus atrophy and crypt →hyperplasia observed in response to infection with *Giardia* as well as the phenomena of maldigestion and →malabsorption are direct consequences of the parasite load or caused by the host's immune response. Antigenic extracts of *G. lamblia* containing proteins of 32–200 kDa transiently suppressed the activity of dissaccharidases when gerbils were challenged with this fraction. It has been speculated that this short-lived effect could be mediated by lymphokines and/or mediators released by mast cell, neutrophils, or macrophages.

Evasion Mechanisms

Only recently has the possible involvement of antigen-variation in establishing a *Giardia* infection been noticed. The antigens involved belong to a family of variant-specific surface proteins (VSGs), which are unique, cysteine-rich zinc-finger proteins. After inoculation of a single *G. lamblia* clone expressing one →VSG into mice or humans, the original VSP is gradually replaced by many others beginning 2 weeks post-infection. Selection by immune mechanisms is suggested because (1) switching occurs at the same time that antibodies are first detected and (2) the antigenic switching does not occur in SCID mice.

The →antigenic variation of *Giardia* parasites may increase the chance of successful initial infection or reinfection.

Main clinical symptoms: →Abdominal pain, Slimy non-bloody, diarrhoea, malabsorption.
Incubation period: 3–21 days.
Prepatent period: 3–4 weeks.
Patent period: Years.
Diagnosis: Microscopic determination of trophozoites and cysts in faecal samples.
Prophylaxis: Avoid contact with human or animal faeces.
Therapy: Treatment see →Antidiarrhoeal and Antitrichomoniasis Drugs.

Giemsa, Berthold Gustav Carl (1867–1948)

German chemist and chemotherapeut at the Hamburg Tropical Institute, inventor of the famous blood-smear stain, which made it possible to diagnose →malarial stages, →Trypanosoma, →Filariidae, etc. Inventor of apparatuses to disinfect whole ships.

Giemsa Stain

Peculiar staining to demonstrate blood parasites (e.g., →*Plasmodium*, →*Trypanosoma*) or stages in tissue cultures; nuclei appear blue, the plasma reddish.

Gigantism

When parasitized, several snail species grow up considerably in order to compensate losses due to parasites (e.g., in the mud snails *Hydrobia ulvae* and *H. ventrosa* when parasitized by trematode stages).

Gigantobilharzia

In contrast to its name this genus includes very thin (filament-like) schistosomes of gulls. They are about 1.2 cm long, look similar as males and females, and have reduced mouth and ventral suckers. Their cercariae may initiate dermatitis in humans.

Gigantocotyle

Genus of the digenetic trematode family Paramphistomatidae (→*Paramphistomum cervi*).

G. explanatum reaches a size of 8–13 mm × 3–4 mm and lives as adult in the bile ducts of cattle and buffaloes in Southeast Asia.

Gigantolina magna

Species of →Cestodaria.

GI-Nematodes

Abbreviation for gastrointestinal →nematodes, e.g., trichostrongylids.

Gland Cell Secretion

→Platyhelminthes.

Glossina. Figure 3 SEM of the anterior portion of a tsetse fly.

ion content, growth and differentiation processes, and on the immune system. It is therefore difficult to define the mechanism of action of glucocorticoids on parasites and to clarify whether these are direct or indirect effects.

Pathology

It is impossible as yet to give a coherent picture of the influence of glucocorticoids on parasites and vice versa. In some instances there are even contradictory results: for example, corticosteroid hormones can increase or decrease the infection rate within the same systematic group. One possible explanation is the finding that the

→fecundity of adult parasitic →nematodes increases at lower glucocorticoid levels but decreases at higher concentrations of hormone.

Clinical Relevance

Due to their immunosuppressive action glucocorticoids usually have a deleterious effect on the host and may lead to higher degrees or to prolonged parasitemia. Glucocorticoid therapy may therefore be risky, especially, e.g., if a patient suffers from →cerebral malaria.

→Energy Metabolism, →Reserve Granules.

Glycolysis

Metabolic process to use glucose, →energy metabolism.

Glycophorin A

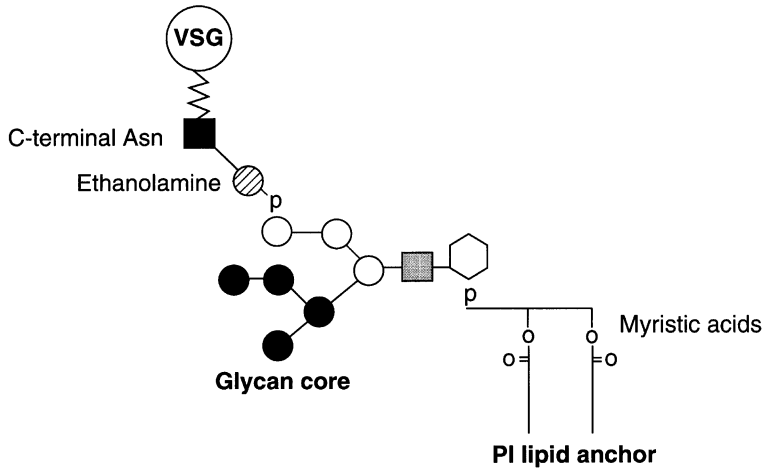
→Apicomplexa.

Glycosomes

These →microbodies are specific organelles of kinetoplastic →Trypanosomatidae. They are ovoid and membrane-bound, appear electron-dense and reach about 0.25 µm in diameter (→Trypanosoma/Fig. 5). They are rather numerous and contain 7 glycolytic enzymes, which in other cells normally occur in the →cytoplasm. In trypanosomes, however, this energy-delivering process of degrading sugar proceeds exclusively in these organelles, which thus play an important role in metabolic compartmentation. The bloodstream forms (i.e., trypomastigote stages) degrade glucose into pyruvate, which is finally excreted. During this process they need 50–100% of their dry-weight per hour. Since they are not able to store any polysaccharide internally, they have to take up glucose constantly. If this is not possible (e.g., in cultures), they will die. Therefore these glycosomes are extremely important for the survival of trypanosomes in the bloodstream of their hosts, and thus they have become targets for drug development. *T. cruzi* is an exception and may survive several days without the presence of glucose. This may be due to the activation of the proteins within so-called →reservosomes and/or due to the initiation of the respiratory chain-elements, which are present in the blood stages of *T. cruzi*. Several authors found hints that the glycosomes are evolutionarily related to →peroxisomes, which are absent in trypanosomes (→Energy Metabolism).

Glycosylphosphatidylinositols

Glycosylphosphatidylinositols (GPIs) are a family of glycolipids that are widespread in nature implying an important biological role. The major function of these molecules is to anchor proteins to →cell membrane surfaces. The occurrence of GPI anchors is particularly abundant in protozoan parasites, where they serve as the predominant mechanism for integrating glycoproteins and phosphosaccharides into membrane lipid bilayers. Examples are the variant surface glycoproteins (VSGs) of African trypanosomes, which have played a major role in the discovery of →GPI membrane anchors, the →promastigote surface protease of →*Leishmania* spp., the →merozoite surface proteins of →*Plasmodium falciparum* and the surface antigens of *Toxoplasma gondii* tachyzoites. In higher eukaryotes, GPI-anchored proteins constitute only a minor proportion of cell surface proteins. GPI anchors are composed of a common core structure of →phosphatidylinositol



Glycosylphosphatidylinositols. Figure 1 Protein GPI anchor structure of the *Trypanosoma brucei* variant surface glycoprotein. ●, Galactose; ○, mannose; ▩, glucosamine; hexagonal ring structure, inositol; *P*, phosphate.

(PI), a mannose-containing glycan chain and ethanolamine phosphate, which is linked to the C-terminal end of the protein (Fig. 1). The alkyl or acyl chains of the phospholipid provide the attachment of the protein to the membrane from which they can be released by PI-specific phospholipases. The core structure of the GPI is conserved, but marked differences are found in the side chains attached to the core glycolipid. Heterogeneity also exists in the lipid composition. In *Trypanosoma brucei*, the VSG anchor of bloodstream forms contains exclusively dimyristoyl-PI, while the anchor of the →procyclic acidic repetitive protein (PARP) of the insect stage contains 1-stearyl-PI and is palmitoylated on the inositol. The lipid moiety of *trans*-sialidase of metacyclic *T. cruzi* is a →ceramide The →GPI anchor is synthesized in the endoplasmatic reticulum by the sequential glycosylation of the PI followed by the addition of ethanolamine phosphate. GPI anchoring proceeds via a transamidation reaction, in which the GPI moiety is attached to the protein via an amide linkage between the GPI ethanolamine and the protein's C-terminal amino acid. GPIs and GPI-related glycolipids of protozoan parasites contribute to a protective →glycocalyx formed over the plasma membrane, such as glycosylinositolphospholipids (GIPLs) of mammalian and insect stage *Leishmania* and the PARP of *T. brucei*. The GPI-anchor of the latter protein is heavily substituted with galactose, *N*-acetylglucosamine and sialic acid. GPIs may also serve specific roles in intracellular trafficking, protein targeting, membrane signalling and, in →malaria, as toxins by upregulating host endothelial cell surface molecules.

GPIs are also found in →protozoa as mature surface glycolipids which are not linked to protein, such as the →lipophosphoglycan (LPG) and GIPLs of leishmanial parasites. These structures have no analogs in higher organisms and appear to represent recent evolutionary adaptations to a parasitic mode of life. GIPLs are structurally closely related to the phosphosaccharide core PI region of LPG (Fig. 2) and form a dense surface →glycocalyx above the plasma membrane of about 10 million copies in both →amastigotes and promastigotes of *Leishmania* spp. They consist of small mannose- and other hexoses-containing glycans that are glycosidically linked to alkylated or alkylated-and-acylated PI. The detailed structure of the GIPLs varies among different leishmanial species and developmental stages of the same species. GIPLs have been suggested to play critical roles in *Leishmania* amastigote survival and virulence.

Glycosylphosphatidylinositols. GMP

Good medical praxis: defined activities in treatment.

Gnathobdellida

→Leeches.

Gnathostoma spinigerum

Classification

Species of →Nematodes.

Morphology

Adult male worms have a length of 10–30 mm, while females reach up to 50 mm; both are characterized by an anterior bulbus and defined rows of spines (Figs. 2, 3, page 568).

Further species with different numbers of hooklets at the anterior bulbus are:

1. *G. hispidum* (in pigs in Europe and Asia; occasionally in humans). The adults reach a length of 25 mm.
2. *G. doloresi*, which is found in pigs in the Philippines, India, and Asia. The females obtain a length of up to 35 mm. →Creeping eruption in humans was seen after eating raw fish.
3. *G. nipponicum*; this species lives in groups or single in a hard tumor of the esophagal wall of the weasel in Japan. Adult males are 20–23 long, females 29–34 mm.

→Creeping eruption in humans occurred after eating loaches or various fresh water fish containing larvae.

Life Cycle

Fig. 1 (page 567).

Disease

→Gnathostomiasis.

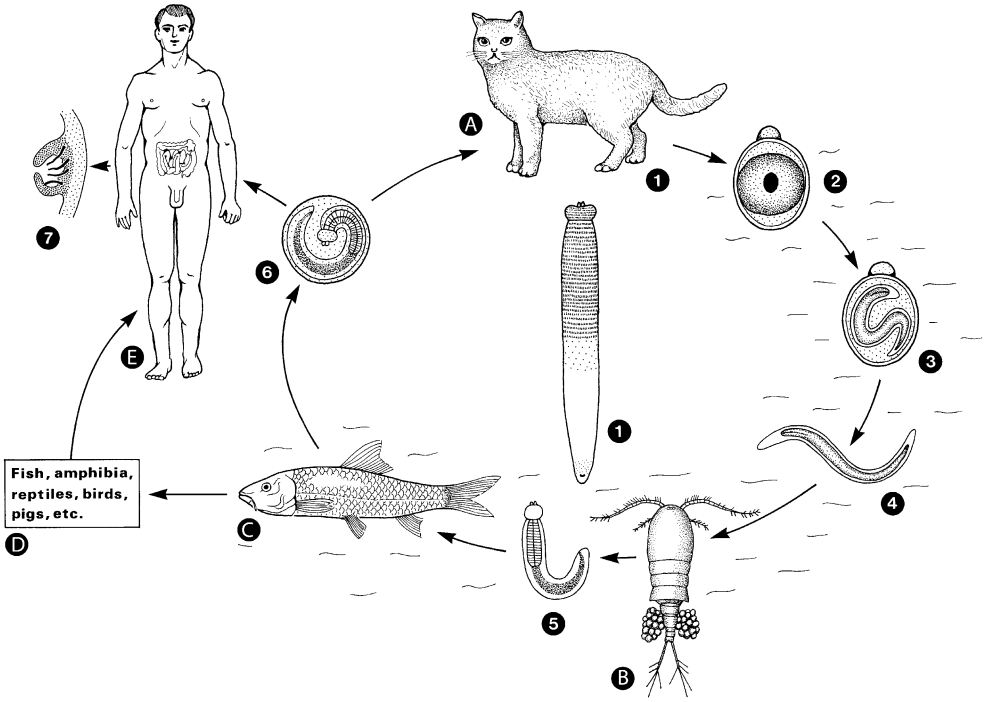
Gnathostomiasis

Gnathostomiasis is an aberrant infection of man with larvae of →*Gnathostoma spinigerum* of felines and dogs. It is acquired from contact with meat of infected intermediate hosts (fish, amphibians, reptiles, birds). The larvae from the intermediate hosts enter human tissue and may migrate slowly through many tissues, giving rise to the intermittent subcutaneous swellings and (very often) to intestinal nodules. The worm is surrounded by an →inflammatory reaction with many eosinophils.The larvae are especially destructive when they die in the brain or eye.

Main clinical symptoms: Eosinophilic encephalomyelitis due to wandering larvae in brain, leucocytosis, blood →eosinophilia, intestinal nodules.
Incubation period: 3–7 days.
Prepatent period: There is no reproduction in man.
Patent period: Months.
Diagnosis: Serodiagnostic methods.
Prophylaxis: Avoid eating raw meat or undercooked fish and crabs.
Therapy: Treatment see →Nematocidal Drugs.

Golgi Apparatus

→Dictyosomes are composed of flat sacs with swollen peripheral regions (→Endocytosis/Fig. 1B, →Merozoite/Fig. 1, →Trypanosoma/Fig. 5), from which vesicles are formed. Several dictyosomes together form the Golgi apparatus of a cell. However, many protozoans (e.g., merozoites of coccidians) have only 1 dictyosome which then represents the Golgi apparatus, while other



Gnathostoma spinigerum. Figure 1 Life cycle of *Gnathostoma spinigerum* using different types of hosts (**A**–**E**). *1* Adults (male 10–30 mm; female up to 50 mm), which are characterized by a spiny anterior bulbus and many body rows of spines, live in the stomach wall of the final hosts (cats) leading to tumorlike growths. *2–4* The eggs (65–70 × 40 μm) are unembryonated when passed by feces (2). After 1 week of embryonation the first-stage larva (4) hatches in water and swims actively. It remains covered by a thin sheath representing the inner egg shell. *5* The first →intermediate host (**B**) is a cyclopoid copepod, where the L_1 penetrates the hemocoel and develops further into a second-stage larva (L_2) within 7–10 days. The L_2 already has a swollen head bulbus covered with 4 transverse rows of spines. *6* Fish act as second intermediate hosts when they eat infected copepods. The L_2 penetrates the intestine of its new host and migrates to muscles or connective tissues, where it molts to form the L_3 which becomes encapsulated. The L_3, measuring about 4 mm, is infective to the final host, where it reaches maturity. However, the encapsulated L_3 is also infective to other hosts (**D**) including humans (**E**). *7* If L_3 are eaten by other than the final hosts (including man), they wander in that host's tissues without further development; in humans and animals this leads to symptoms of *gnathostomiasis externa* or *interna*, depending on the infected tissues. If humans eat such uncooked paratenic hosts (**D**), they may become infected but no further development occurs, although the ingested L_3 remain infective for final hosts within such paratenic hosts (arrow not drawn to **A**). In the intestine of humans, worm stages lead to →nodule formation (7).

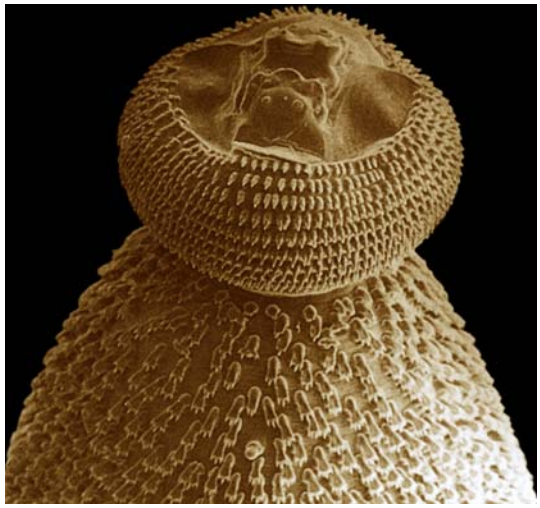
parasites (e.g., →*Trichomonas*) include several dictyosomes per cell. These organelles are always situated close to the rER and the 2 organelles act together as functional units in the production and transport of membrane and in the formation and transport of all types of macromolecular proteins and lipids. The dictyosomes are never covered by ribosomes. The principal function of the Golgi apparatus is the transport of secretions and excretions formed on the rER. These reach the dictyosomes at its cis-side and are transported within →vacuoles that are cut off at its periphery (the trans-region). Endocytotic vesicles such as food vacuoles also come into contact with the Golgi apparatus and the rER system at points where they fuse with enzyme-containing vacuoles produced by the Golgi apparatus; this is how digestive enzymes and other products enter the endocytotic vacuoles.

Golgi, Camillo (1844–1926)

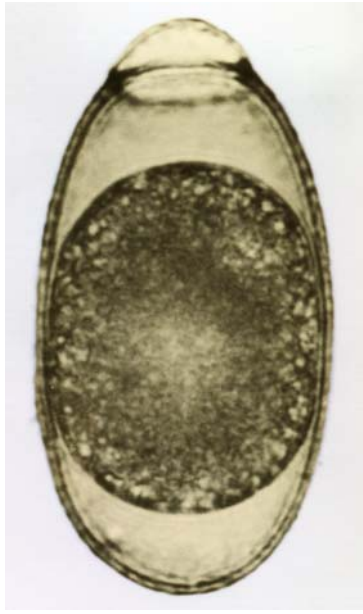
Italian anatomist, discoverer of the Golgi apparatus. Winner (1906) of the Nobel Prize (together with Ramon y Cajal).

Golgi-Less-Secretory-System

In →*Giardia* encystation occurs via a unique secretory apparatus, which is not a typical Golgi-apparatus, but very probably a primordial Golgi or new secretory system composed of "encystation-specific vesicles"



Gnathostoma spinigerum. Figure 2 SEM of the anterior end of *Gnathostoma spinigerum* showing the spiny cuticle.



Gnathostoma spinigerum. Figure 3 LM of the typical egg of *Gnathostoma spinigerum* being characterized by a single terminal plug.

(ESV), the surface of which is covered with clathrin and dynamin. These ESV's become fragmented and form the cyst wall outside of the cell membrane.

Gomori's Silver Impregnation

→Pneumocystis.

Gongylonematidae

Nematode family of the suborder Spirurina, which is characterized by the fact that the males enrol their posterior end.

From Greek: *spira* = winding, *ura* = tail. *Gongylomema* spp. are found in mammalians and birds parasitizing the wall of the esophagus. Their life cycle includes intermediate hosts such as beetles and cockroaches. Related groups are worms of the genus →*Camallanus*.

GPI

Synonym

→Glycosylphosphatidylinositol, →Apicomplexa.

GPI Anchor

→Apicomplexa, →Glycosylphosphatidylinositols.

Granulomatous Amebic Encephalitis (GAE)

Brain

Human brain disease due to infection with free-living amoeba (→*Acanthamoeba castellanii*, →*Balamuthia mandrillaris*). While *Acanthamoeba*-GAE is mainly found only in immunocompromized persons, GAE due to *Balamuthia* occurs in both immunocompetent and immunocompromized ones. *Balamuthia*-trophozoites reach a size of 12–60 (mean 30) µm. *Acanthamoeba* is smaller (25–40 µm).

Granulomes

Name

Latin: *granulum* = grain, granule.

This term describes parasitic stages that are surrounded by defense cells of the host. →Schistosoma, →Pathology.

Graphidium

Genus of trichostrongylid stomach worm of rodents and rabbits, e.g., *G. strigosum* (hare); *G. neoplasticum* (rat), up to 2 cm in length.

Grassi, Giovanni Battista (1854–1925)

Italian physician and biologist, describer of the life cycle of →*Ascaris* and many details of →*Plasmodium*.

Gregarina

Genus of →Gregarines, →Chromosomes.

Gregarines

Classification

Subclass of →Sporozoa.

General Information

The gregarines exclusively parasitize invertebrates (Table 1). Because they are in general large cells, reaching up to 10 mm in some species, they are useful models for teaching. General features are:

- Sexual reproduction begins with the mating of gamonts (→Syzygy, →Gamontogamy).
- Gamonts of both sexes carry out →multiple fissions.
- Fusion of iso- or →anisogametes occurs inside the common gamontocyst.
- →Sporogony consists of 1 →nuclear division sequence (no →oocyst occurs, but only sporocysts which produce the infectious sporozoites).

System

Among the gregarines there are extra- and intracellular parasites which belong to the following systematic orders (Figs. 1–3, pages 571, 572):

- Order: Archigregarinida
  - Extracellularly attached to host cells
    - Genus: *Selenidium*
- Order: Eugregarinida
  - Extracellular development prevailing, no →schizogony (Fig. 1B, C)
  - Family: Aseptinata
    - Body consists of a single unit (acephaline forms)
    - Genera: *Monocystis* (Fig. 2), *Lecudina*, →*Lankesteria*, *Rhynchocystis*, →*Gonospora*
  - Family: Septatina
    - Body is divided by a septum (formed by ectocytoplasm) into an anterior →protomerite (possibly bearing an anterior anchoring apparatus, the →epimerite) and a posterior →deutomerite containing the single large nucleus (Fig. 1)
    - Genera: →*Gregarina* (Fig. 3), →*Leidyana*, →*Neoschneideria*, *Stylocephalus*, →*Actinoc- ephalus*
- Order: Neogregarinida

Gregarines. Table 1 Some common gregarines

Species	Size of trophozoites (μm)	Host/Habitat
Order Eugregarinida		
Family Aseptatina		
Monocystis agilis	200 × 65	Earthworm/Seminal vesicle
Nematocystis vermicularis	1000 × 100	Earthworm/Seminal vesicle
Lankesteria ascidiae	240 × 60	Ascidia (*Ciona intestinalis*)/Gut
L. culicis	200 × 40	Mosquitoes (*Aedes aegypti*)/Gut
L. planariae	100 × 30	*Planaria* spp./Gut, ceca
Ascogregarina taiwanensis[b]	500 × 30	*Aedes albopictus* Malpigh. Tubules
Gonospora beloneides	800 × 80	Polychaetes/Body cavitiy
Family Septatina		
Gregarina polymorpha	350 × 100	Larvae of flourbeetle (*Tenebrio molitor*)/Gut
G. blattarum	1100 × 400	Cockroaches/Gut
G. queni	65 × 25	Bees/Gut
Neoschneideria douxi	70 × 45	Bees/Gut
Leidyana sp.	125 × 40	Bees/Gut
Stylocephalus longicollis	100 × 20	Beetles (*Blaps mortisaga*)/Gut
Actinocephalus parvus	80 × 20	Larvae of fleas/Gut
Coleorhynchus heros	3000 × 300	*Nepa cinerea*/Gut
Order Neogregarinida		
Schizocystis gregarinoides	400 × 15	Larvae of ceratopogonid gnats/Gut
Lipocystis polyspora[a]	Sporozoites 9 × 2	Mecoptera (*Panorpa* sp.)/Fat body
Ophryocystis mesnili[a]	Sporozoites 9 × 2	Larvae of flour beetle (*Tenebrio* sp.)/Malpighian tubules
Mattesia dispora[a]	Sporozoites 9 × 2	Mealmoths (*Ephestia kuehniella*)/Fat body

[a] Live as intracellular parasites in all developmental stages
[b] Syn. *Lankesteria*

- Development primarily intracellular with schizogony (Fig. 1A)
  - Genera: →*Mattesia*, →*Schizocystis*, *Lipocystis*, →*Ophryocystis*

Important Species

Table 1, Figs. 2, 3.

Life Cycle

Fig. 1.

Grellia (syn. Eucoccidium) dinophili

Protococcidian within the body cavity of the Archiannelid *Dinophilus gyrociliatus*. There is no →schizogony, only trophonts grow up to gamonts that form male and female →gametes. After →syngamy, the →oocyst gives rise to sporoblasts (sporocysts) containing the sporozoites.

Grocer's Itch

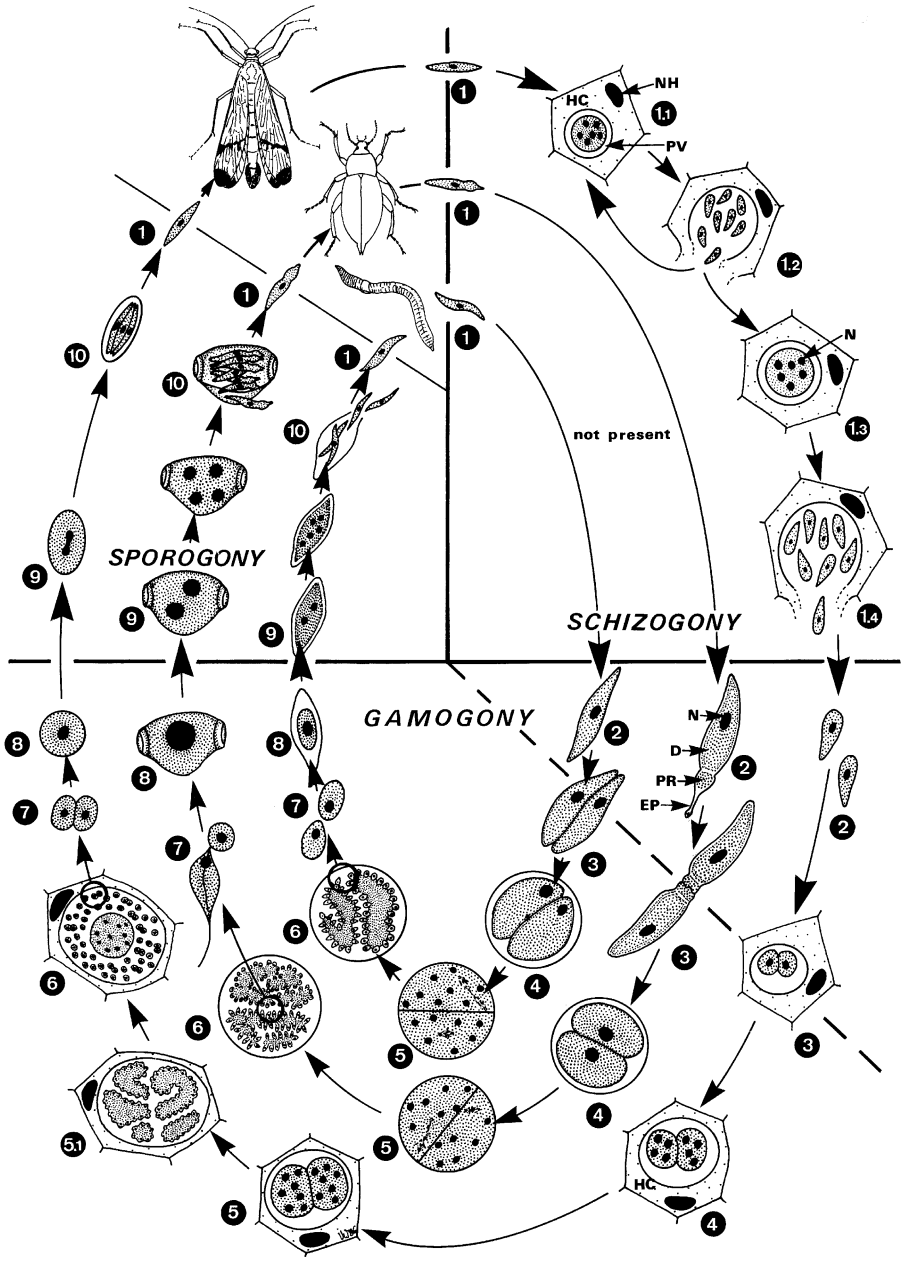
Allergic reaction due to contact with dust or harvest →mites.

Grocott's Modification

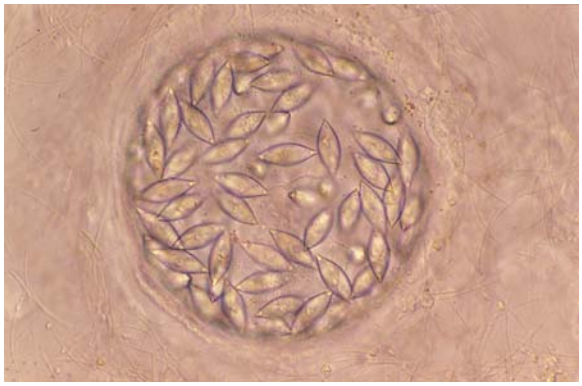
→Pneumocystis.

Grooming Behavior

→Behavior.



Gregarines. Figure 1 Life cycle of different types of gregarines. **A** →*Lipocystis polyspora*; the whole development (1–10) takes place within the fat body cells of the scorpion fly *Panorpa communis* (type of schizogregarines). **B** →*Stylocephalus longicollis*; development takes place partly in the gut lumen of the beetle *Blaps mortisaga* (**1**–**4**), partly outside the host in its feces (type of eugregarines, Polycystidae, i.e., the gamonts are subdivided, and a septum is present). **C** →*Monocystis agilis*; main development (**1**–**8**) takes place within the lumen of the seminal vesicle of earthworms (*Lumbricus terrestris*, etc.), sporogony outside the host (type of eugregarines, Monocystidae, i.e., gamonts have no inner septum). ***1*** Sporozoites are orally ingested within sporocysts and set free in the lumen of the gut. **A** *1.1–1.4* In *L. polyspora* repeated production of differently shaped merozoites occurs by schizogony in the cells of the fat body. ***2*** Sporozoites (B, C) or merozoites (A) become →trophozoites which grow to be gamonts. ***3, 4*** Pairs of gamonts (B, C) excrete a cyst wall (i.e., form a gamontocyst). In *L. polyspora* the paired gamonts are situated in a →parasitophorous vacuole of their host cell. ***5–7*** After repeated nuclear multiplications many iso- (A, C) or anisogametes are formed, which start fusing and thus lead to numerous zygotes. ***8–10*** The zygotes are surrounded by a wall and thus obtain their characteristic shapes; they may then be considered as sporocysts, within which 8 sporozoites are finally formed (in all 3 species). New infections of hosts start after swallowing the infectious sporocysts with contaminated food. *D*, deutomerite; *EP*, epimerite; *HC*, host cell; *N*, nucleus; *NH*, nucleus of the host cell; *PR*, protomerite; *PV*, parasitophorous vacuole (for further species see Table 1).



Gregarines. Figure 2 Gamontocyst of *Monocystis agilis* (with numerous sporocysts) inside the seminal vesicles of *Lumbricus* annelids (earthworm).

Gregarines. Figure 3 Motile gamont of a septate gregarine (*Gregarina polymorpha*) from gut of the flour beetle (*Tenebrio*).

Growth Factors

General Information

Epidermal growth factor (EGF) and insulin-like growth factor I (IGF-I) stimulate cell proliferation; IGF-I is also involved in metabolic functions. Their corresponding receptors are tyrosine kinases phosphorylating intracellular proteins.

Certainly all parasites living in vertebrate hosts come into contact with growth hormone, growth factors, and cytokines from the host, either circulating in the blood or being locally expressed like e.g., insulin-like growth factor I (IGF-I) in the skin. Cytokines of the host are primarily involved in immune responses whereas growth hormone and growth factors are signalling substances regulating, e.g., differentiation and proliferation in parasites.

Pathology

Infection with parasites usually changes titres and cytokine profiles in the host, independently of whether →Protozoa or helminths are involved. Interestingly, the infective-stage larva of →*Brugia malayi* produces a cytokine which resembles the host macrophage migration inhibitory factor (MIF) and which is able to modulate the host immune response and to promote parasite survival. Another example of a substance produced by the parasite and mimicking a host hormone is the →plerocercoid growth hormone-like factor from spirometrid →tapeworms. This factor circulates in the blood, binds to the host growth hormone receptor and mimics many of the biological actions of growth hormone.

IGF-I of the host is recognized by *Leishmania mexicana* →vacuoles and →amastigotes and this external host signal is converted into a parasite signal. First, IGF-I binds to both promastigotes and amastigotes, it stimulates growth in both cell types and leads to a rapid tyrosine phosphorylation of parasite proteins. The pattern of phosphorylated proteins is dependent on the developmental stage. In another protozoan parasite, *Trypanosoma brucei*, EGF of the host is able to stimulate growth and to activate the signal transduction cascade in the parasite, leading finally to GTP-hydrolysis via small G-proteins. EGF is active at physiological concentrations. In the same species, bombesin, a peptide hormone from the brain and the gastrointestinal tract, also hydrolyses GTP.

Growth Retardation

The presence of specimens of several species of worms hinders the normal growing of their human or animal hosts: *Ascaris, Strongyloides, Ancylostoma, Necator*, etc.

GSH

Synonym

→Glutathione.

Gubernaculum

Portion of male copulatory apparatus in →nematodes.

Guide RNA

Guide RNAs (gRNAs) are small RNA molecules that are encoded in the →mitochondrial DNA of kinetoplastid flagellates. These gRNAs have a template-like function during the →RNA editing process and specify the site and number of uridylate residue (U) additions to and occasional deletions from precursor mRNA. gRNA sequences have been identified in more than 10 different kinetoplastid species, several hundred kinetoplastid gRNAs have been sequenced, and for some of them secondary structures and 3-dimensional working models have been proposed. The total number of gRNAs varies greatly between species and even between different strains of the same species. The greatest number is found in the trypanosomatids. The →minicircle kDNA contains the majority of the gRNA genes that are localized at specific sites within the variable region. In *Trypanosoma brucei*, each minicircle can encode 3–5 gRNAs, whereas *Leishmania tarantolae* contains only a single gRNA per minicircle, reflecting less extensive editing as compared to the former species. The →maxicircle kDNA also contains a small number of gRNA genes in addition to protein-coding genes, rRNA genes and cryptogenes. *T. brucei* possesses the greatest kDNA complexity with over 200 minicircle classes that can encode more than 1000 different gRNAs.

Guinea Worm

→*Dracunculus medinensis*.

Gula

Morphological structure of the Heteroptera (bugs). The head capsule is closed ventrally by a bridge behind the rostrum, so that the rostrum arises not at the hind margin of the head but some distance in front of it. Often the rostrum is brought further forward by a considerable elongation of the head.

Gyalocephalus capitis

Small strongylid nematodes of equids (male 7–10 mm, female 8–13 mm).

Gymnophallidae

Trematode family, the members of which mostly occur in birds. Only one genus (*Gymnophalloides*) includes a very small parasite of humans, which may occur in large numbers in the intestine or in the bilary system. This worm is characterized by the pecularities, that the ventral sucker occurs in the posterior quarter of the body and that many tegumental hooks are formed. Intermediate hosts are marine oyster and clam.

Gymnophalloides

Species

G. tokiensis, *G. seoi*.

Morphology

0.5 × 0.3 mm sized trematodes, which are found in the small intestine of birds (oyster catchers) and humans in Korea/Asia. The adults possess a large oral and a small ventral sucker. In addition, there occurs an unique ventral pit, which is situated (as the ventral sucker) in the posterior third of the spiny tegument (with many scales). The first intermediate host is unknown, but oysters are the second one containing the infectious metacercariae. In Korean villages infection rates of up to 46 % were found when diagnosing the thin eggs 25 µm × 15 µm in the faeces.

Symptoms of Disease

Gastrointestinal troubles, fatique, weight loss, diarrhoea.

Therapy

→Trematocidal Drugs.

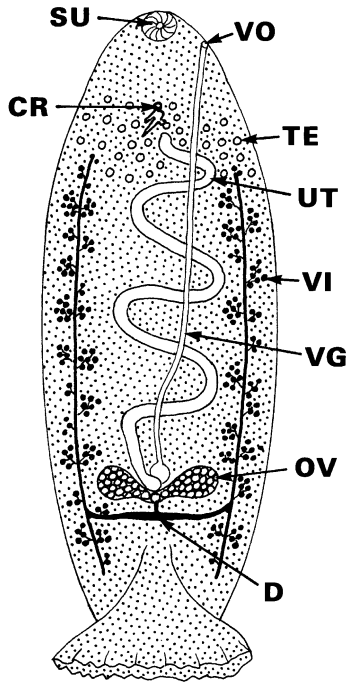
Gynandry

From *Greek*: gynandros = bisexuell. →Hermaphroditism.

Gyrocotyle

Classification

Genus of monozoic →Cestodes.



Gyrocotyle. Figure 1 DR of the adult monozoic tapeworm *Gyrocotyle* spp. (3 cm) from the stomach and intestine of chimaerorid fish; the characteristics of gyrocotylids are the (not drawn) ruffled body margins and the terminal posterior →rosette; intermediate hosts are unknown. *AH*, adhesion zone; *CR*, →cirrus; *D*, duct of vitteline glands; *DB*, →dense bodies in the vitelline system; *GA*, genital atrium (joint pore of UT and VE); *OV*, ovary; *PB*, →proboscis; *SU*, sucker; *TE*, testes; *UO*, opening of the uterus; *UT*, uterus; *VD*, vas deferens; *VG*, vagina; *VI*, →vitelline glands; *VO*, opening of vagina; *Z*, interruption (animals are longer).

Life Cycle

See also →Gyrocotylidea, →Cestodes/Life Cycle. Fig. 1.

Gyrocotyle fimbriata

Cestodarian parasite of chimaeroid fish.

Gyrocotyle urna

Species of →Cestodaria (→*Amphilina foliacea*).

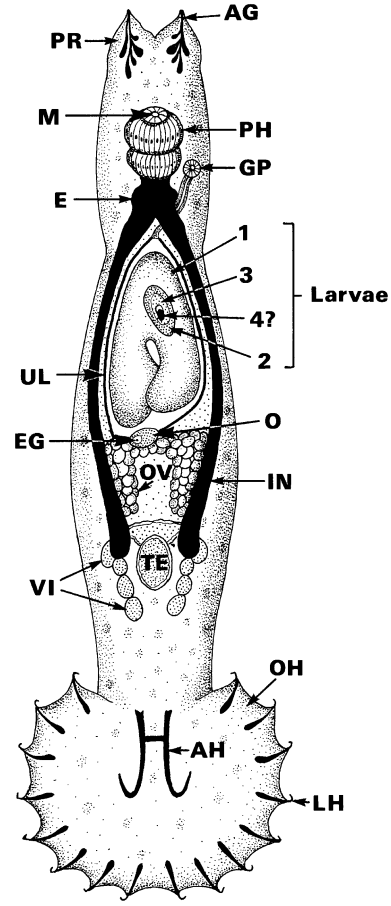
Gyrocotylidea

→Cestodaria.

Gyrodactylus

Classification

Genus of →Monogenea.



Gyrodactylus. Figure 1 Gyrodactylus: Organization of an adult monogenean: *Gyrodactylus* spp. containing several generations which were produced by →polyembryony (i.e., mitotic division of germ cells at a very early stage). *AG*, adhesion gland; *AJ*, anchoring central hooks; *E*, esophagus; *EG*, egg; *GP*, genital pore; *IN*, intestinal branch; *LH*, lateral hooklets; *M*, mouth; *O*, oviduct; *OH*, →opisthaptor; *OV*, ovary; *PR*, →prohaptor; *TE*, →testis; *UL*, uterus containing larvae 1–4; *VI*, vitellary gland (→Vitellarium).

Gyrodactylus. Figure 2 SEM of the dorsal side of an attached monogenean fluke (*Gyrodactylus aculeati*).

Morphology

Fig. 1.

Reproduction

After copulation a larva develops inside the uterus which is retained until grown up into a functional preadult already containing larvae of the second, third, and eventually fourth generation. This polyembryogeny (Figs. 1–3) is only poorly understood, but enables the parasite to establish quickly many offsprings on a new host (fish), →Platyhelminthes/Fig. 14.

Gyrodactylus aculeati

→Platyhelminthes/Fig. 14, 17B.

Gyrodactylus. Figure 3 LM of an adult *Gyrodactylus* fluke on the skin of a fish. Note that this animal already contains the next 2 generations in its brood chamber.

Gyrodactylus elegans

→Monogenea.

Gyrostigma

Genus of the fly family Gasterophiliidae inducing myiasis in the stomach of rhinos in Tropical Africa.

Habitat

Name

Latin: *habitare* = dwelling.

This term – often used as a synonym of biotope – is the place/region, where a species lives, e.g., where ecological factors allow survival.

Habitat Selection

Name

Latin: *habitatio* = dwelling.

Habitat comprises all ecologic factors of the surroundings of an animal (often used as synonym to biotope).

Parasites which actively find and invade their hosts accumulate in favourable habitats, responding to very different environmental stimuli. Short-living stages such as trematode miracidia and →cercariae prefer mainly habitats frequented by their potential hosts, whereas many long-living stages such as some nematode infective larvae and →ticks primarily select habitats which support their survival. Such stages shift to habitats where an encounter with their hosts is increased when the conditions for their survival are favourable. For mechanisms of habitat selection see →host finding, miracidia of →trematodes, cercariae of trematodes (→Digenea), →nematodes, ticks.

Habronema

From Greek: *habros* = fine, *nema* = filament. Genus of →Nematodes, →Stomach worms.

Habronemiasis, Habronemosis

The larvae of →*Habronema* spp. and *Draschia* (→Filariidae) cannot penetrate normal skin. However, cutaneous invasion and lesions occur when larvae are deposited near open wounds by their vectors. Areas frequently involved include the withers, the lower limbs, the medial canthus of the eye, and the urethral process and prepuce of the male. The gross lesions rapidly become progressive and proliferative in nature, comprising ulcerated tumorous masses of red-brown granulation tissue. The sore is already painful before the development of →granuloma. This causes an intense →pruritus, and infected animals exacerbate the condition by biting and rubbing the lesion.

Therapy

→Nematocidal Drugs, Animals.

Haemabartonella

Genus of rickettsiales, transmitted by blood suckers.

Haemadipsa

→Leeches.

Haemagogus

Genus of mosquitoes, which may transmit the virus of Yellow fever.

Haemaphysalis

Name

Greek: *haima* = blood, *physa* = bladder; English: Red sheep tick.

General Information

Genus of hard →ticks comprising worldwide about 150 species (mostly in Africa, South Asia). In West and Middle Europe 3 species occur: *H. punctata, H. concinna,* and *H. inermis*. *H. punctata* is a small (female 3–3.5 mm, male 2.8 mm) 3-hosts tick, the adults of which attack sheep, cattle, goats, and horses, cervids, hare, hedgehog, mice. One generation needs about 3 years. This species transmits *Babesia*- and *Theileria* spp. The 2 other European *Haemaphysalis* ticks: *H. concinna* (Relict tick) and *H. inermis* (Winter tick) are of lower importance. On the other hand the tropical species *H. leachi*, which is able to develop all stages within 123 days, is an important vector of diseases in Africa especially of carnivores and ruminants. In America only a few species occur (e.g., *H. leporis* on rabbits).

Haematobia

Genus of the fly family Muscidae, synonym to *Liperosia* (*L. irritans*) and *Siphona irritans*. *H. irritans* (small meadow biting fly, 3–5 mm long) occurs worldwide, sucks blood up to 20 times per day, and develops 4–5 generations per year. *H. stimulans* (synonym: *Stomoxys stimulans* and *Haematobosca stimulans*) is the so-called large meadow bite fly with a length of up to 7 mm. Its activity is mainly in late summer and autumn. While *H. irritans* practically lives on the host, *H. stimulans* leaves the host for the night. →Ectoparasiticides.

Haematobia irritans

Small biting fly (3–5 mm), which occurs worldwide and appears grey, green-brown, or black with brown legs. It feeds up to 20 times per day at cattle sitting head down. The larvae develop in faeces of cattle – in Europe up to 5 generations occur (→Tabanids/Fig.1). Related species are *Haematobia (Stomoxys) stimulans* = large biting fly (5–7 mm), *Hydrotaea irritans* (head and udder fly (5.5–7 mm), and →*Stomoxys calcitrans*.

Haematoloechus

Life Cycle

→*Prosthogonimus macrorchis*/Fig. 1.

Haematoloechus medioplexus

→Digenea, →*Prosthogonimus macrorchis*/Fig. 1.

Haematophagous Animals

Name

Greek: *haima* = blood, *phagein* = feeding.

Arthropods (→Insect), →Leeches, →Vampire Bats, →Vampire Fish that feed blood at the surface of their host.

Haematopinus suis

Name

Greek: *haimo* = blood, *pinein* = drinking.

This is the louse of pigs. The females measure 4–6 mm in length, the males are only 3.5–4.7 mm in size (Fig. 1). Their body appears brown and the neck is rather long. The eggs (1 mm) become clued at the hair. The whole development takes 20–26 days. The females lay about 60 eggs. Besides pigs also man is attacked. Related species are *Haemotopinus eurysternus* (cattle), *Haemotopinus asini* (horses, donkeys). →Lice.

Therapy

→Ectoparasiticidal Drugs.

Haematopinus suis. Figure 1 Two swine lice (*Haematopinus suis*) – note the rather long and slender neck.

Haematopota

→Diptera (Tabanids).

Haementeria

Giant leech, which may grow up to 30 cm. →Leeches.

Haemodipsus

Genus of lice of rabbits and hare (female 1.5 mm, male 1.2 mm). *H. ventricosus* (Fig. 1) and *H. lyriocephalus* may transmit of agents of tularaemia.

Haemodipsus ventricosus

→Lice.

Haemoglobinpathies

Defects of haemoglobin formation such as HbS, HbE, HbF, HbC, G 6 PD-defiencies or λ-thallassaemia reduce or hinder the growth of →*Plasmodium falciparum* and thus provide some resistance to malaria.

Haemoglobinuria

Urine appears bloody, symptom in infections with babesial and malarial diseases.

Haemogregarina

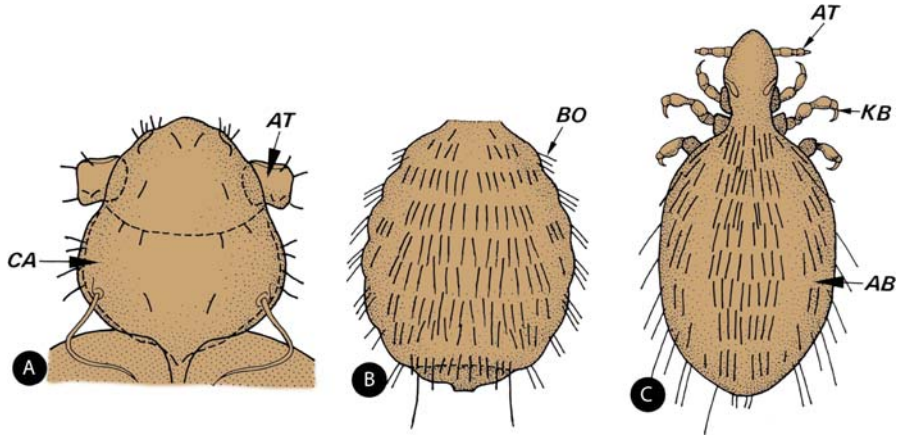
→Apicomplexa, →Coccidia.

Haemolysis

Lysis of red blood cells, symptom of infection with →*Babesia* species.

Haemonchosis

Haemonchosis is a common and severe disease of the ruminant abomasum in many parts of the world. →*Haemonchus contortus* infects mainly sheep and goats, while *Haemonchus placei* occurs mainly in cattle. The pathogenesis of *Haemonchus* infection is the result of →anaemia and hypoproteinaemia caused by the bloodsucking activity of the parasite. Large



Haemodipsus. Figure 1 DR of the characteristics of the rabbit louse *H. ventricosus* (**A, B**) and the hare louse (*H. lyriocephalus*, **C**). **A** head of ♂; **B** abdomen of ♀; **C** female; *AB*, abdomen; *AT*, antenna; *BO*, spines; *CA*, caput, head; *KB*, leg with claws.

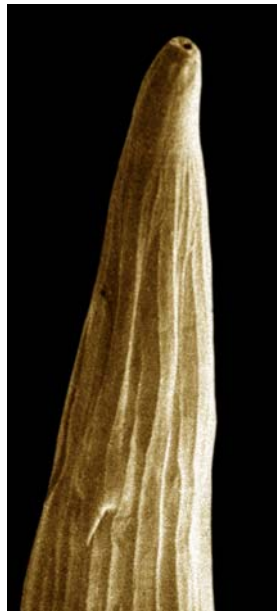
numbers of *Haemonchus* administered to sheep cause changes resembling those occurring in →ostertagiosis, including rises in abomasal pH and increased plasma pepsinogen. However, the latter 2 effects do not contribute to the spontaneous disease. The following description is mostly based on studies on ovine haemonchosis. The hyperacute form occurs in animals exposed over a short period of time to thousands of parasites, and is rare. The animal bleeds to death within a week, loosing 200–600 ml of blood/day. In many cases there are no preliminary signs and death is sudden. In others there is an extreme anaemia and black faeces. Death occurs before compensatory erythropoiesis can take place, within 7 days. In the acute disease animals of all ages show anaemia, bottle jaw, and dark faeces. There are conflicting reports as to whether →anorexia occurs and it has even been reported that sheep eat more than they normally do. Animals lose weight, are weak and lethargic, and lose wool. Ewes suffer agalactia, so that their lambs may become emaciated and die from malnutrition. The anaemia of acute haemonchosis develops in 3 phases. The first phase which occurs during the pre-patent period is characterized by a fairly dramatic fall in packed cell volume, although serum iron at this stage is normal. This is considered to be the result of blood loss caused by immature worms, at a time when the haemopoietic system of the host is not fully mobilised to compensate it. In the second stage (from about 1–2 months) the packed cell volume does not decrease any further, because of the mobilisation of the haemopoietic system and the high serum iron concentrations. However, since the capacity of the sheep infected with *H. contortus* to reabsorb haemoglobin iron is limited, the iron reserves rapidly become depleted, which progressively leads to the third stage of the anaemia i.e., a low serum iron accompanied by a marked drop in packed cell volume. This indicates a dyshaemopoiesis due to iron deficiency and possibly to reduction in the availability of amino acids. →Hypoalbuminaemia occurs. Chronic haemonchosis may last for 2–6 months. Only a few adult worms (100–1,000) can cause a seepage of blood into the abomasum accounting at most for 50 ml/day. Anaemia is not present as compensatory erythropoiesis takes place, which depletes serum iron. The animal looks malnourished, with progressive loss of weight and wool-peeling in adult animals, and stunting of growth in lambs. The condition is aggravated by poor quality grazing as occurs in Africa and other tropical regions. A marked anaemia develops in terminal cases when iron and protein for erythropoiesis are depleted.

Therapy

→Nematocidal Drugs, Animals.

Haemonchus contortus

Trichostrongylid nematode of ruminants (Figs. 1, 2) of 20–30 mm in length (female). →Nematodes, →Trichostrongylidae/Fig. 1.



Haemonchus contortus. Figure 1 SEM of anterior end of *Haemonchus contortus*. Note the presence of a lateral hooklet at the cuticle.

Haemonchus contortus. Figure 2 LM of an egg of *Haemonchus contortus* after M.I.F. concentration.

Disease

→Haemonchosis.

Haemopis sanguisuga

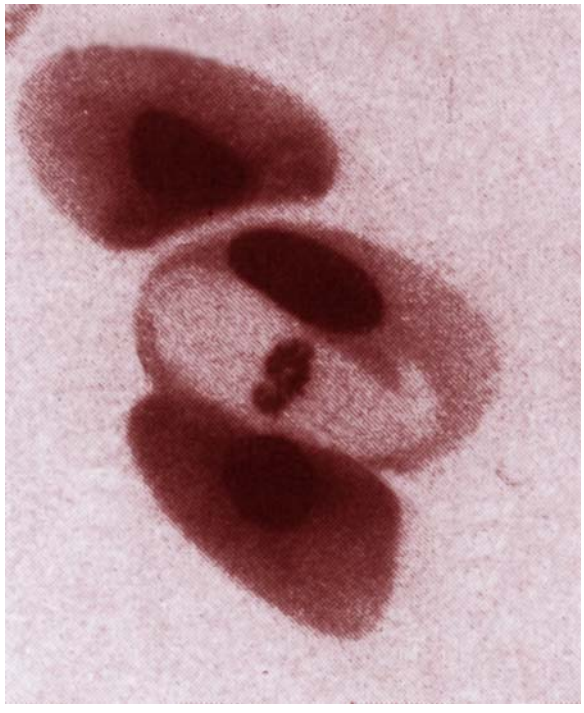
→Leeches.

Haemoproteus

Genus of coccidian blood parasites of reptiles and birds (e.g., *Haemoproteus columbae*). Vectors are louse flies (→Hippoboscidae) or midges (→*Culicoides*). The schizogony occurs inside endothelial cells of the blood vessels, while the gamonts are found in red blood cells. In general there are low or no clinical symptoms of disease.

Haemoproteus columbae

Parasite of red blood cells of doves (Figs. 1, 2), *H. nettionis* is found in ducks, geese, *H. meleagridis* in turkeys. Vectors are louseflies, →*Pseudolynchia canariensis* (= syn. *Lynchia maura*). Symptoms of disease are described as pseudomalaria.
Prepatent period: 4–5 weeks, →Malariacidal Drugs.



Haemoproteus columbae. Figure 1 Blood smear of a gamont inside a red blood cell.

Haemoptysis

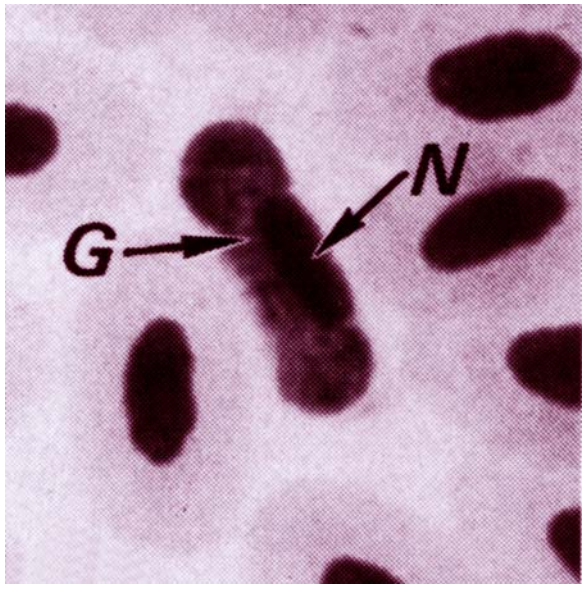
Sputum contains blood due to lung lesion in →*Paragonimus* infections and/or tuberculosis.

Haemorrhagic Effects

From Greek: *rhegnymie* = disrupt. Symptom of many parasitosis, when blood vessels become destroyed; e.g., →sarcosporidiosis.

Haemosporidia

→Apicomplexa.



Haemoproteus columbae. Figure 2 LM of a smear preparation of a gamont of *H. columbae* in the nucleated erythrocytes of a dove. *G*, gamont; *N*, nucleus of the parasite.

Haemozoin – Protein Complex

→*Plasmodium* degrade haemoglobin into such a complex appearing brown-black as pigment.

Halicephalobus

Name

Greek: *hyalinos* = transparent, clear, *kephalon* = head, *lobos* = lobe.

Synonym

Micronema.

General Information

Genus of free-living →nematodes of the family *Cephalobidae*, which are related to the members of →Rhabditidae. Some species such as *H. deletrix* (Latin: *deletio* = destruction), however, are able to penetrate the skin of vertebrates or enter them via food (as larvae or adults). The described, fully proven cases include horses, cattle, rabbits, and (even more rare) humans. In horses, brain, lung, ocular, and renal infections, granulomatous posthitis are described, while mastitis was found in addition, in cattle. Another species of horses is *H. gingivalis*. Up to now only females were found reaching a length of only 0.5 mm, while the larvae on the soil reach 120–220 µm, when hatching from the 40 × 12 µm sized eggs. All stages possess a rhabdoid oesophagus.

Therapy

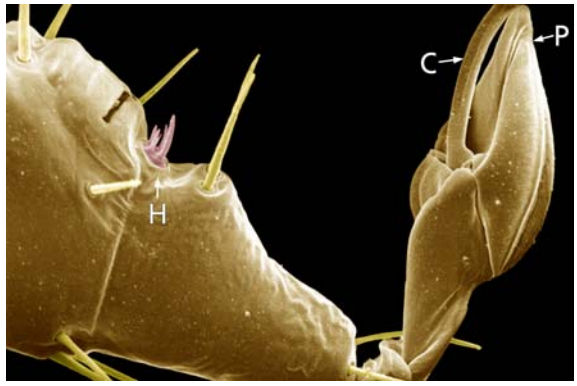
Ivermectin, →Nematocidal Drugs.

Haller's Organ

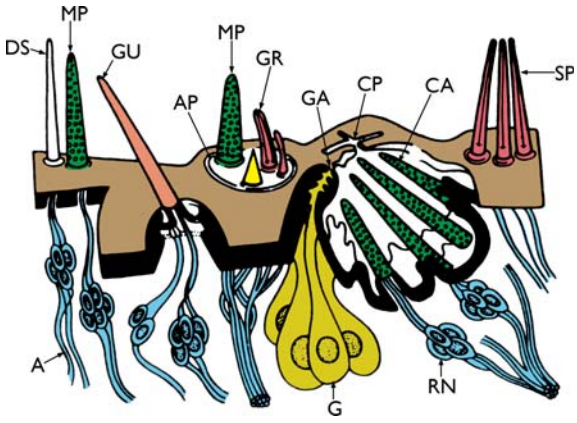
Housing some of the tick's olfactory chemoreceptors, itis part of the sensory structures on the dorsal surface ofthe tarsi on leg one of →ticks (Fig. 1, →Ticks/Host Recognition).

This organ (Figs. 1, 2) consists of several units:

1. **posterior capsule**: except for *Ixodes ricinus* and a few others it is covered and exposed only via a small slit.



Haller's Organ. Figure 1 SEM of the first right leg of *Ixodes ricinus* showing the external structures of the Haller's organ (H) and one claw (C) and the pulvillus (P).



Haller's Organ. Figure 2 Diagrammatic representation of the arrangement of the sensilla in the Haller's organ of an ixodid (redrawn and modified after Sonenshein 1991). *A*, axons; *AP*, anterior dorsal pit; *CA*, capsular sensillum; *CP*, capsular aperture; *DS*, distal precapsular sensillum; *G*, gland; *GA*, gland's aperture; *GR*, grooved sensillum; *GU*, gustatory hair; *MP*, multiporose sensillum; *RN*, receptor neurons; *SP*, sensilla of posterior capsule.

2. **anterior pit**, which represents a depression located distal to the posterior capsule, surrounded by a cuticular fold and containing a small number of sensilla.

Small groups of olfactory sensilla (slightly posterior to the capsule and distal to the anterior capsule) apparently also function in the same way as the sensilla of the Haller's organ (Figs. 1, 2).

The composition and number of the sensilla involved are genus- and species-specific, thus explaining that different ticks react differently onto host attractants and repellents.

Halofantrine

→Malariacidal Drugs.

Halofuginone

→Theileriacidal Drugs.

Halzoun Syndrome

Disease in humans due to infection with the dog pentastomid worm →*Linguatula serrata*, which block the nasal pathways and may thus introduce →oedema and unfeelingness of head regions.

Main clinical symptoms: Oedema, disturbances of organs.
Incubation period: 7 days to months.
Prepatent period: 6–7 months.
Patent period: 15 months.
Diagnosis: Microscopic determination of worm eggs in nasal mucus (Fig. 1).

Halzoun Syndrome. Figure 1 LM of a pentastomid worm (*Linguatula*).

Prophylaxis: Avoid contact with dogs in tropical regions.
Therapy: Provocation of sneezing, mechanical withdrawal of the worms.

Hamilton and Zuk Hypothesis

In 1982, Hamilton and Zuk published a paper whose consequences in the world of parasitologists and ecologists were considerable. It is well known that, in certain animal species, there is a marked dimorphism in size, ornamentation, and colours between males and females. This is the case especially in birds (although not only in them), where males are often brightly coloured and compete for females through complicated parades. Darwin explained →sexual dimorphism by natural selection: if there is a genetic diversity in, for instance, the length of feathers in males, and if females mate preferentially (sexual selection) with the males which have the longest feathers, then the genes responsible for long feathers increase their frequency in the population. If the genetic diversity of feather length is continually renewed, there is a runaway process which leads to extravagant ornamentation like that of pheasants and paradise birds.

This explains the possible mechanism of sexual selection, but it does not say why sexual selection exists. There are at least two difficulties: one is that these processes do not exist in all species (for instance, male and female magpies and many other birds look the same); another is that a price has to be paid for extravagant ornamentation (there is a metabolic price for constructing them and the bright colours make birds more prone to predation).

The Hamilton and Zuk hypothesis states that the brightness of colours and the quality of parades provide females with an indication of the "quality" of males, especially of their ability to resist parasites. The idea is that, if the male of a given species is brightly coloured, it may develop these colours fully only if it possesses resistance genes to parasites. The "interest" of the female to mate with such a resistant male is to associate her own genes with "good genes," thus giving her offspring the best chance of survival. If the hypothesis is correct, there must be a positive correlation between the mean parasite load of a species and the degree of sexual dimorphism. Since Hamilton and Zuk published their article, a number of studies (comparative analyses and experiments) have tried to confirm or to contradict the hypothesis. Logically, the more a species harbours parasites, the more the cost of extravagant colours and ornamentation is compensated by the benefits of sexual selection. In other words, being bright and colourful is meaningful only if selection of resistance genes is necessary.

The hypothesis has been the subject of many controversies, some authors being very negative. More than 20 years after the publication of Hamilton and Zuk's article, it seems that a majority of surveys and comparative analyses demonstrate that the hypothesis is at least partly correct.

Hammond, Datus (1911–1974)

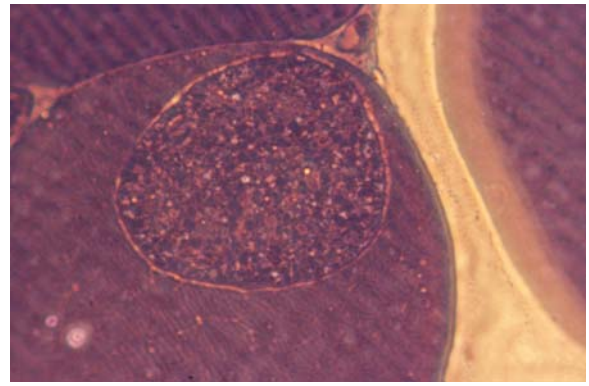
American protozoologist, Logan, Utah.

Hammondia hammondi

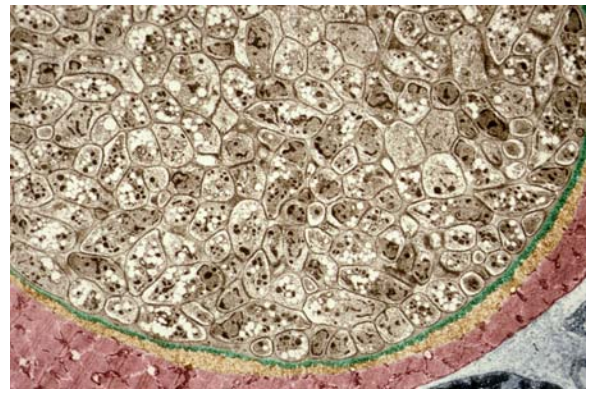
→Coccidia; final hosts are cats (like in →*Toxoplasma gondii*), however, the life cycle includes obligatorily intermediate hosts (such as mice, rats, pigs, goats, hamsters, dogs). *Toxoplasma*-like tissue-cysts (Figs. 1, 2) occur.

Therapy

Not needed since apathogenous to most hosts.



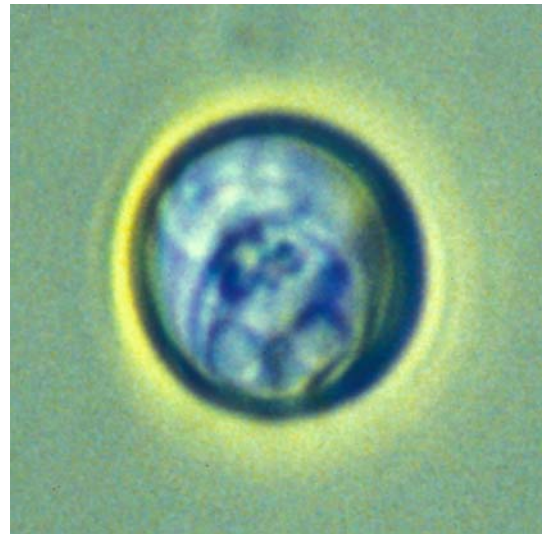
Hammondia hammondi. Figure 1 LM of a section through a muscle fiber of a mouse containing a cyst of *Hammondia hammondia*.



Hammondia hammondi. Figure 2 TEM of a section trough the cyst depicted in Fig. 1.

Hammondia heydorni

Tissue-cyst-forming species of the →Coccidia. Final hosts are dog, fox, or coyote, intermediate hosts may be cattle, sheep, goat, rodents, etc, which shed small ovoid oocysts (Fig. 1). This nonpathogenic species is probably identical with →*Neospora caninum* (being a pathogenic strain).



Hammondia heydorni. Figure 1 Sporulated oocyst of *Hammondia heydorni* with 2 sporocysts.

Hammondiosis

Disease due to →*Hammondia*, mostly symptomless. →Neosporosis.

Chemotherapy

→Coccidiocidal Drugs.

Hanging Groin

Symptom due to infection with →*Onchocerca* worms. Chronically enlarged lymph nodes may introduce a "mild local elephantiasis" due to superficial water influx.

Hannemannia

Genus of mites of amphibia.

Haplobothriidae

Family of cestodes in freshwater fish (e.g., genus *Haplobothrium globuliforme* of bowfin = *Amia* calva). These species are unique because they appear as intermediate forms between →Pseudophyllidea and →Trypanorhyncha, since their bothria are located at the tips of 4 tentacle-like projections known as proboscides.

Haplometra cylindracea

This is a rather common plagiorchiid digenetic trematode in the lungs of frogs already known since 1800 (cf. →*Paragonimus* species of humans).

Haplorchis

Genus of trematode flukes of the family Heterophyidae, which rarely may also occur in the intestine of humans. →*Heterophyes*.

Haplosporidia

Group of parasites probably belonging to a known phylum of Protozoa, mostly parasitizing clams (e.g., *Haplosporidium armoricanum* = *Minchinia armoricana* is found in clams such as *Ostrea edulis*). Recently they were included into protozoan phylum →Alveolata.

Haplosporidium nelsoni

Microsporidian of the American oyster, formerly named →MSX-body.

Happening

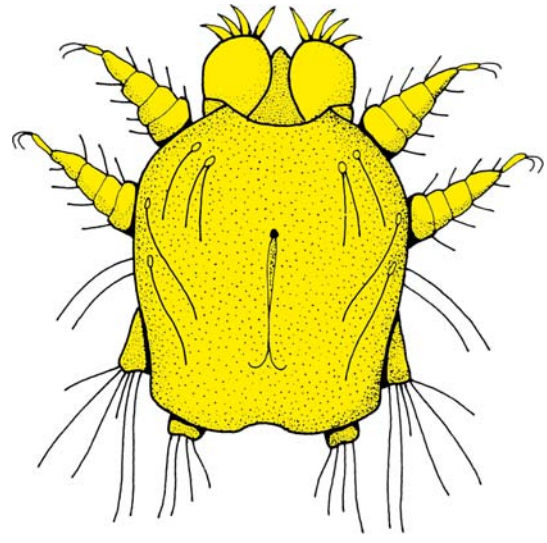
→Mathematical Models of Vector-Borne Diseases.

Hapyrhynchus

H. nidulans (syn. *Sarcopterinus nidulans* is a small mite that lives inside the feather shaft of doves and other birds (Fig. 1). →*Syringophilus*.

Hardy-Weinberg Equilibrium

→Population Genetics.



Hapyrhynchus. Figure 1 Adult male of *H. nidulans* (syn. *Sarcopterinus*).

Hartmanella

Genus of opportunistic →amoebae. *Hartmannella vermiformis* caused several human cases of fatal central nerve system disease.

Harvest Mite

→Neotrombicula autumnalis.

Haustellum

From Latin: *haurire* = take away; feeding apparatus of dipteran and hemipteran bloodsuckers.

H-Cell

→Nematodes/Excretory System.

Health Education

→Disease Control, Methods.

Heart-Lung-Trachea Passage

→Ancylostoma, →*Ascaris*/Life Cycle.

Heartwater

The significance of some rickettsial diseases is difficult to assess. This applies particularly to heartwater, a disease of domestic ruminants caused by →*Cowdria* (syn. *Ehrlichia*) ruminantium, which is transmitted by all African species of →*Amblyomma* found on susceptible hosts. Experimentally, it is also transmitted by the American *A. maculatum*, too, and the disease's recently discovered presence on Guadeloupe and other Caribbean islands (where *A. variegatum* has been introduced from Africa) poses a severe threat to the cattle and sheep industries in tropical and subtropical mainland America. Heartwater is an acute disease in susceptible animals such as introduced *Bos taurus* cattle but is less apparent in endemic situations which exist in most of sub-Sahelian Africa. After an →incubation period of 1–5 weeks following the bite of an infected tick, the first clinical signs are a rise in temperature to over 40°C; in many cases, few other signs appear until shortly before death. →Hypersensitivity and other nervous symptoms appear during the latter stages of the disease, culminating in central nervous effects. Many animals recover without showing any symptoms beyond fever. Definitive diagnosis is usually only possible at post mortem by demonstrating the causative organism in Giemsa-stained smears of brain tissues. Gross lesions commonly seen are pulmonary oedema, hydropericardium (from which the disease has its name), hydrothorax, and ascites. The mode of transmission may be through regurgitation of the midgut contents by the tick, but this has not been demonstrated. A crude and fairly inefficient form of immunization is available.

Therapy

Treatment is possible through tetracyclines, but frequently not practically possible because of inadequate diagnostic resources.

Heartworm

Synonym

→Dirofilaria immitis.

Disease

→Cardiovascular System Diseases, Animals.

Heartworm Disease

→*Dirofilaria immitis*, →Cardiovascular System Diseases, Animals.

Heat Shock Proteins

A family of ubiquitous polypeptic proteins also produced by parasites. Here they protect against stresses interacting with the host's immune system. The 70-kDa heat shock protein of *Toxoplasma gondii* (HSP 70) is able to allow tachyzoite production and cyst formation in rather virulent strains, while the specimens of apathogenic strains (without formation of HSP 70) will be killed by macrophages. In *Plasmodium falciparum* HSP genes are found on →chromosomes 7 and 8 (→Toxoplasmosis, Animals, →Toxoplasmosis, Man).

Hectospsylla

Genus of fleas (e.g., *H. psittaci* of birds), from Greek: *hektos* = attach, *psylla* = flea.

Heleidae

Other name →Ceratopogonidae.

Heligmosomoides polygyrus

Fig. 1, →Behavior, →Nematodes.

Heligsomum

Genus of nematodes with about 17 species parasitic in rodents.

Helminth

Synonym

Worm, from Greek: *helminthos*.

Heligmosomoides polygyrus. Figure 1 Photo of several adult worms being anchored in the intestinal wall of a mouse. The arrows point to the twisted posterior ends.

→Annelida, →Acanthocephala, →Platyhelminthes, →Cestodes, →Trematodes, →Nematodes, →Pentasto-mida, →Leeches.

Helminthic Infections, Pathologic Reactions

Lesions and inflammatory reactions accompanying →helminth infections are particularly complex and variable. Immunity against these large organisms is generally less effective than against protozoans and part of a worm's life cycle may be spent in an immunologically privileged state, as with the adult schistosomes, or in a privileged site, as with the helminths living in the lumen of the intestine. Because of the more prolonged infections with schistosomes, and the release of eggs over a long period of time, the histologic reaction to a recently arrived egg can often be seen side by side with reactions to eggs that have been present for a long time as shown by granulomas destroyed eggs and fibrosing (→Pathology/Fig. 1A-D). One of the hallmarks of the defense against helminths is the eosinophilic granulocyte which is toxic to many worms. This is accompanied by an acidic lysophospholipase of a molecular weight of 13,000 with a free sulfylhydril group which may crystallize as Charcot-Leyden crystals (→Pathology/Fig. 3B). These crystals have been obtained not only

from eosinophils but also from basophils. The role of the latter cells has been studied less frequently than that of the eosinophils. Because basophils and tissue mast cells require special staining for their demonstration, such as Alcian blue at pH 0.5, and are not shown on routine histologic sections, little is known of the role of basophils in the inflammatory and possibly defensive reaction against helminths. More information is available about their participation in the →inflammatory reaction evoked by →ticks.

Helper-Cells

T = cells (Th1, Th2) belong to the group of T-lymphocytes. Their response informs the B-lymphocytes and thus initiates the formation of antibodies or via other signals the activation of interleukines.

Hematuria

Name

Greek: *haima* = blood, *uron* = urin.

Symptom of infection with →*Schistosoma haematobium*, →pathology.

Heme Polymerase

→Hemozoin.

Hemelytron

Forewing of Heteroptera (bugs) consisting of a hard and membranous (hind) region.

Hemiclepsis marginata

Leech that reaches a length of up to 3 cm, sucks at the surface of fishes. Its mouth sucker is heart-shaped (upside down).

Hemidesmosome

Asymmetric (half-side) arrangement of desmosomes to be used for attachment of cells at different surfaces (e.g., →undulating membrane of trypanosomes).

Hemimetabolous Development

In some orders of parasitic insects (e.g., →lice, →bugs) the larvae hatching from eggs are very similar to the adults (→Imago) except for the absence of functional gonads and wings, if these are present at all in adults (→Bugs/Fig. 1, →Lice/Fig. 2). Furthermore theses types of larval instars, which are generally called nymphs, feed mostly in the same way as the adults. During growth several molts (→Ecdysis) occur, the number of which varies between species. The last →ecdysis during this gradual development leads to mature and fertile adults, which soon start reproduction.

Hemiptera

Synonyms

→Bugs, →Rhynchota.

Hem(oglobin) Interaction

Mode of Action

Figs. 1, 2.

Structures

Fig. 3.

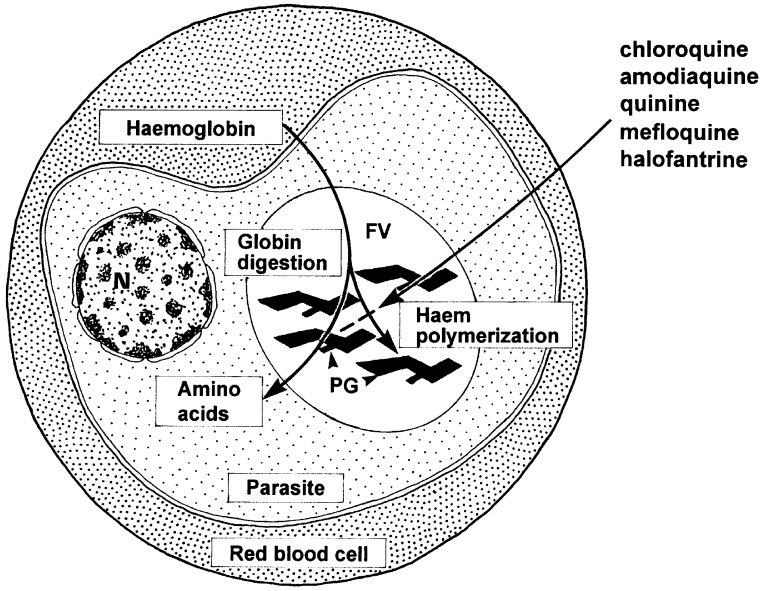
Artemisinin and -derivatives

Important Compounds

Dihydroartemisinin, Artemether, Arteether, Artesunate, Bicyclic trioxanes, Tetraoxanes, Tricyclic trioxanes, 11-alkyl,12-deoxy artemisinins, Arteflene.

Synonyms

Artemisinin: Qinghaosu.



Hem(oglobin) Interaction. Figure 1 Model of the formation of the noncovalent heme-chloroquine complex (Gutteridge (1993) In: Cox FEG (ed) Modern Parasitology, 2nd edition, Blackwell Science, pp. 219–242).

Combination: Artemether/Lumefantrine (Riamet®, Coartem®).

Clinical Relevance

Artemisinin has been used so far for the treatment of malaria in at least 3 million people. The advantage of this drug is its rapid action against →cerebral malaria (→Malaria).

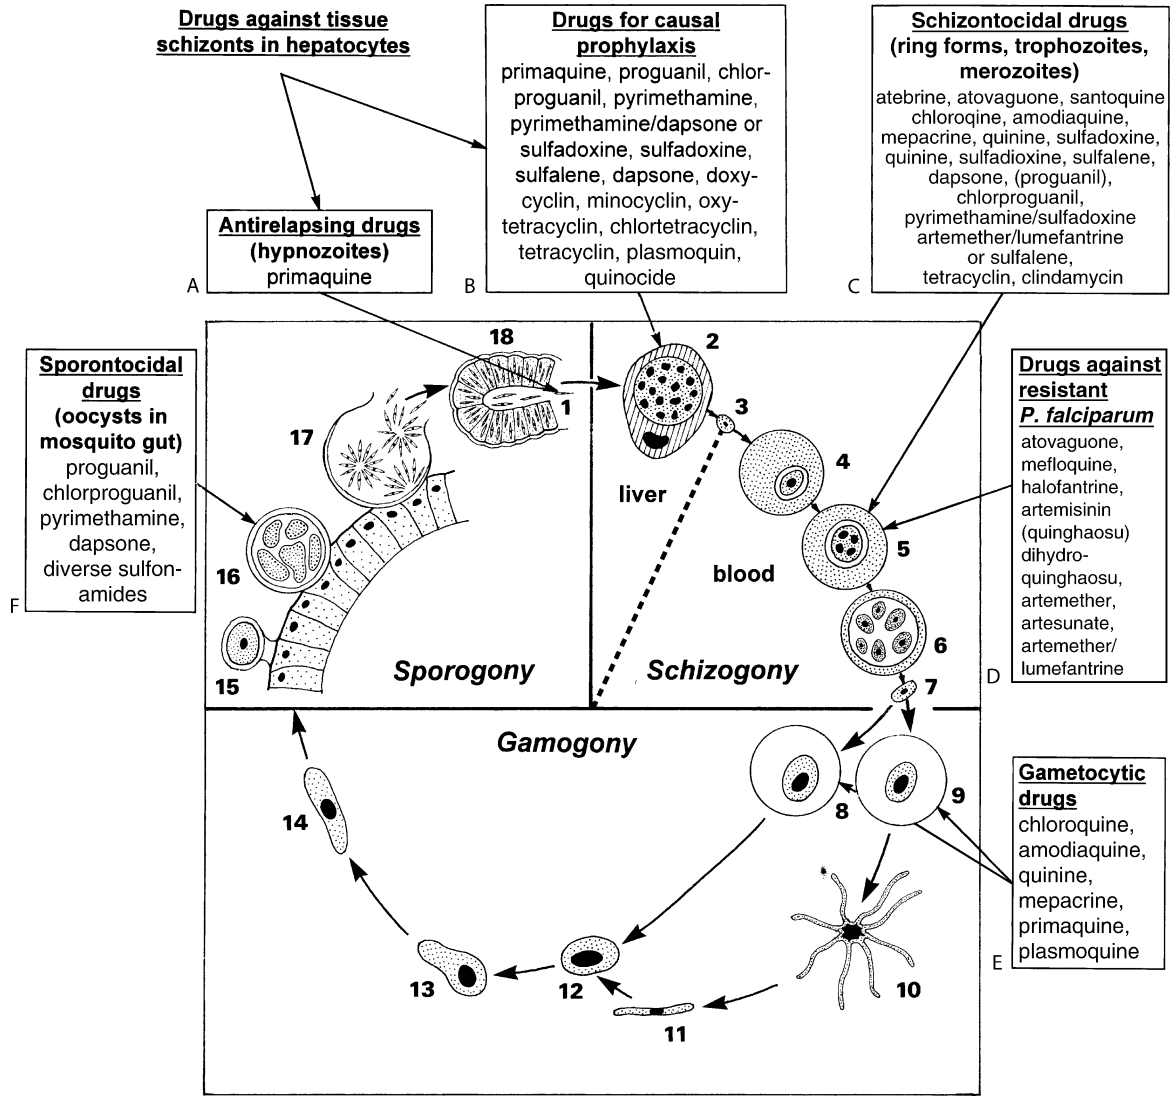
Artemisinin is isolated from the plant *Artemisia annua* and was originally developed in China. It is chemically related to 1,2,4-trioxanes. Among artemisinin and the so-called first generation compounds are esters or ethers obtained from the lactol, dihydroartemisinin.

The rediscovery of quinghaosu (artemisinin) in China in 1972 and the subsequent synthesis of artemether and artesunate have provided highly effective alternatives to quinine. The artemisinin derivatives are today the most rapidly acting and potent of all the antimalarial drugs. They can be given once daily and are safer and easier to administer than quinine. Artesunate or artemether given orally are an essential component of the combination treatment of uncomplicated falciparum malaria, which is now accepted as the treatment of choice. In the treatment of severe malaria, intravenous artesunate is more rapidly acting in terms of parasite clearance and simpler to administer compared to quinine. Mortality on artesunate recipients was 15% compared to 22% in quinine recipients with severe malaria. In addition, artesunate treatment was well tolerated, while quinine treatment was accompanied with hypoglycaemia. The combination artemether/lumefantrine (Riamet®, Coartem®) is not suitable for prophylaxis but is recommended for stand-by self-medication. The dosage is 80 mg/ 480 mg (= 4 tablets) initially, followed by further 4 tablets after 8 hours, and 4 tablets two-times daily on days 2 and 3 (in total 24 tablets).

The antischistosomal effect of artemether and other artemisinin derivatives has been described in the 1980s. During 1994 and 1996 seven large-scale clinical trials had been conducted in China showing 85% protection against *Schistosoma japonicum* infections, if the drug is taken every two weeks starting before the first contact with water containing infected snails. Thus, artemether can be used for prophylaxis against schistosome infections (→Membrane-Function-Disturbing Drugs/Table 2). Effects against *S. mansoni* and *S. hematobium* infections have been shown in laboratory experiments. Successful clinical trials against these two species have been conducted in Africa in the late 1990s. The combination of praziquantel and artemether would be effective against all stages of schistosomes. Praziquantel acts primarily against adult worms and artemether against juvenile stages. This approach is in clinical trial in China, Egypt, and the Philippines.

Molecular Interactions

Artemisinin is characterized by its new structure and new →mode of action unrelated to any other known antimalarial drug. Indeed, there is no cross-resistance against any of the known antimalarials. The activity of artemisinin and its derivatives is directed only against erythrocytic schizonts (Fig. 2). High drug concentrations are detectable in the region of membranes of

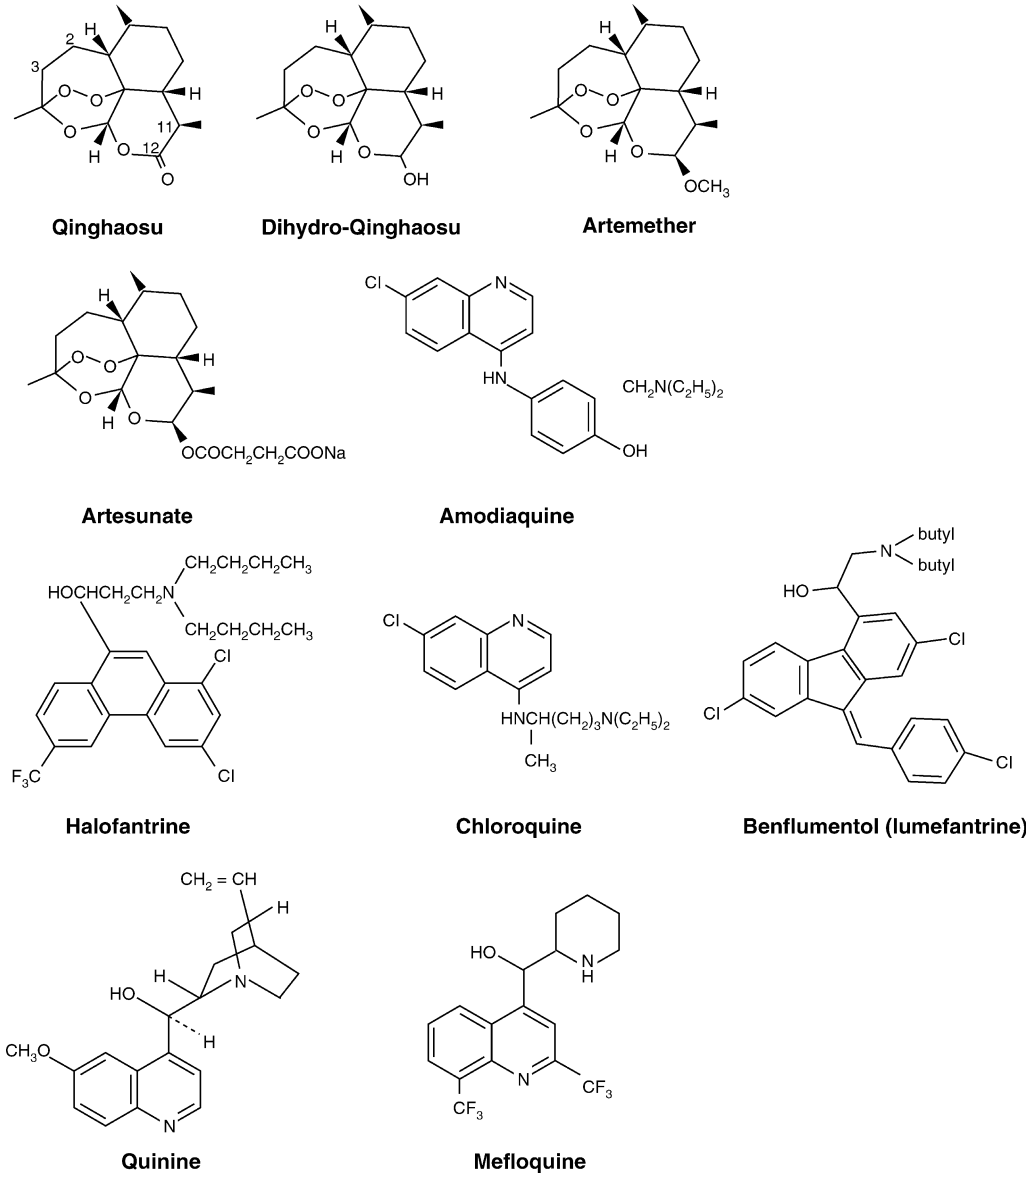


Hem(oglobin) Interaction. Figure 2 Action of antimalarial drugs on life cycle stages. For life cycle details see the legend →Plasmodium/Fig. 2.

intraerythrocytic →trophozoites. There are also other measurable artemisinin-induced metabolic alterations: an interference with the energy production, a reduction of →DNA synthesis, an inhibition of mRNA polymerase activity, and an inhibition of purine synthesis in *Plasmodium berghei* at the level of inosine monophosphate dehydrogenase.

The mode of action proceeds in two different steps. In the first step the endoperoxide bridge is cleaved (Fig. 4). This reaction is catalyzed by intraparasitic iron and heme, and leads to the generation of unstable free radical intermediates. The selective toxicity of artemisinin against malaria parasites is presumably due to this iron catalyzed generation of free radicals, and this is favored by the fact that just these intraerythrocytic parasitic stages are rich in iron and heme. In the second step of the reaction, specific malaria proteins with molecular masses of 25, 32, 42, 50, 65, and >200 kDa become alkylated. These alkylation reactions take place in parasitic ring forms and trophozoites. Proteins of uninfected red blood cells or of infected red blood cells pretreated with the inactive derivative desoxyarteether are not alkylated. Structure activity relationships of various tricyclic trioxanes reveal that certain rings in artemisinin are redundant. Thus, the high artemisinin-like activity is due to the structurally minimal bicyclic trioxane. A rapid rearrangement of active bicyclic trioxanes and spirocylane ring is induced by ferrous chloride.

It was recently reported that artemisinin may be involved in specific inhibition of plasmodial cysteine protease activity responsible for about 30% of hemoglobin degradation by *Plasmodium yoelii*.



Hem(oglobin) Interaction. Figure 3 Structures of antiparasitic drugs affecting hem degradation.

Resistance

So far there are no reports about resistance against artemisinin or its derivatives. However, the clinical trials of artemether and artemether-benflumetol have led to the observation that artemisinin is able to induce drug metabolizing enzyme and, thus, may contribute to its own clearance.

Amodiaquine

Synonyms

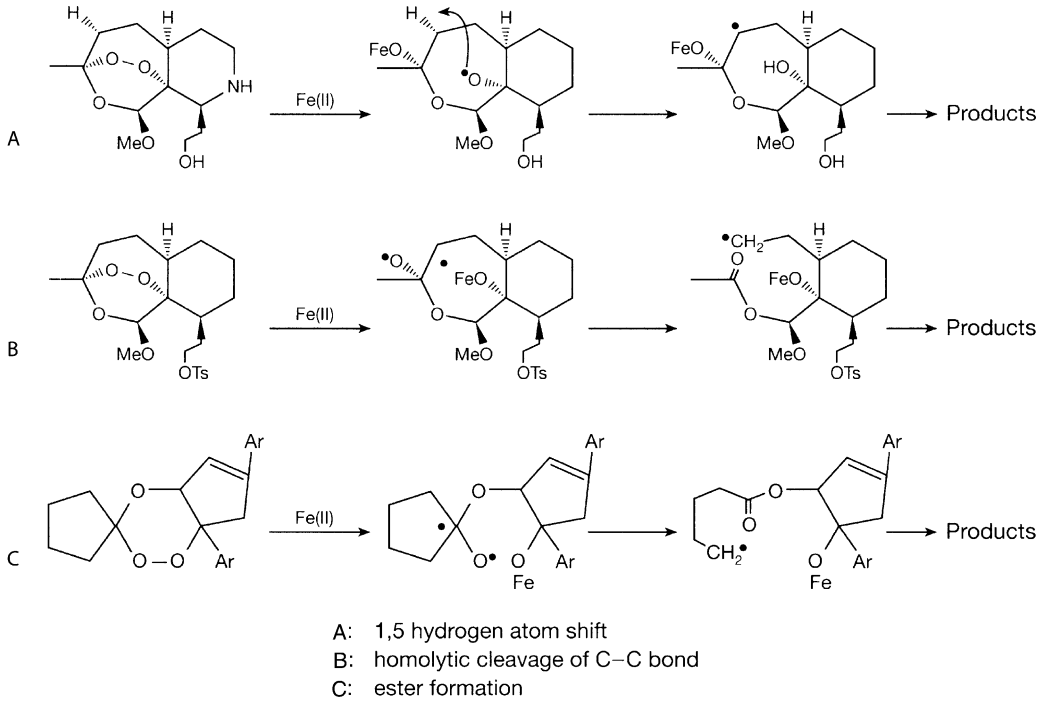
4-((7-chloro-4-quinolinyl)amino)-a-(diethylamino)-o-cresol, SN10751.

Clinical Relevance

Amodiaquine was invented between 1941 and 1945 as an antimalarial drug and was introduced in 1975. Its antimalarial activity is comparable to that of chloroquine.

Molecular Interactions

Amodiaquine is a member of the 4-aminoquinolines with an activity which is directed against erythrocytic schizonts and gametocyts of plasmodia (Fig. 2). Amodiaquine serves as a prodrug, which is converted to desethylamodiaquine responsible for the antimalarial activity. The mechanism of action is presumably identical to that of chloroquine (Fig. 1).



Hem(oglobin) Interaction. Figure 4 Cleavage of the Endoperoxide Bridge of Artemisinin by Hem-Iron (Meshnick SR, Jefford CW, Posner GH, Avery MA, Peters W (1996) Parasitol Today 12: 79–82).

Resistance

The mechanism of resistance against amodiaquine is also presumably identical to that against chloroquine which is assumed to be due to an impaired uptake mechanism. This is supported by the appearance of a general cross-resistance between amodiaquine and chloroquine. There are also a few hints of amdodiaquine activity against chloroquine-resistant →*Plasmodium* strains but in general resistance with this drug is no problem.

Halofantrine

Clinical Relevance

Halofantrine was developed within the Walter Reed Army Institute for Research (WRAIR) antimalarial drug development program in 1984. It had been introduced in 1988. However, because of severe cardiovascular side effects, halofantrine is no longer used. The antimalarial activity against →*Plasmodium falciparum* and *P. vivax* is much better documented than that against *P. malariae* and *P. ovale*.

Molecular Interactions

Halofantrine is a phenantrene methanol, and its activity is directed against erythrocytic schizonts (Fig. 2). The action of halofantrine on the molecular level is unknown. It is presumably different from that of quinine and mefloquine, but it may be otherwise similar to that of mefloquine (Fig. 1).

Resistance

First reports on resistance appeared in 1992. In Thailand there are mefloquine-resistant strains of *P. falciparum* which show simultaneously reduced sensitivity to halofantrine, thus indicating cross-resistance between mefloquine and halofantrine. On the molecular level, the resistance mechanism against halofantrine is suggested to be of the MDR phenotype similar to that against mefloquine and quinine, while it may be different from that against chloroquine.

Chloroquine

Synonyms

7-chloro-4-(4-diethylamino1-methylbutylamino)quinoline, SN7618, RP3377, Aralen, Nivaquine B, Sanoquin, Artrichin, Bipiquin, Reumachlor, Bemaphate, Resoquin, Resochin, Chlorochin.

Clinical Relevance

Chloroquine has been used in the treatment of malaria for some 60 years since its discovery in the 1930s. It exerts a wide variety of activities against different parasites.

The activity of chloroquine against →*Entamoeba histolytica* is directed only against liver abscesses. It has no effect against intestinal stages. Chloroquine especially is used in combination with emetine to improve the curative effects of the latter. Other combinations

with significant amoebicidal activity are chloroquine/dehydroemetine or chloroquine/diloxanide furamide.

As antimalarial drug chloroquine is mostly used as a diphosphate salt. It is effective against all four human malaria parasites. Thus, it has high activity against blood schizonts (asexual intraerythrocytic stages of *Plasmodium vivax* and *P. falciparum*) and against gamonts of *P. vivax* (Fig. 2). It has no significant effects against extraerythrocytic stages in the liver. Therefore, chloroquine cannot be used as a causal-prophylactic drug.

Molecular Interactions

The amoebicidal action of chloroquine is directed against trophozoites (magna forms) in the liver and other extraintestinal organs. The precise mechanism of action in →amoebiasis is unknown. Presumably it is different from the antimalarial action by intercalation into DNA or by inhibition of protein-synthesis.

There are different hypotheses for the mode of action of chloroquine. The uptake of host-derived hemoglobin and its digestion in the food vacuole by developing parasites plays a vital role in survival of these parasites, and this is therefore the Achilles' heel, which makes the plasmodia vulnerable to →quinoline compounds. During the degradation of globin ferrous heme is released and oxidized to a ferric form, which is toxic for the parasites by damaging parasitic membranes and inhibiting various parasitic enzymes including proteases. To circumvent these toxic effects of ferrous heme plasmodia have evolved specific detoxification mechanisms. These rely on the conversion of the ferric hem into an insoluble, unreactive crystalline material called →hemozoin (= malaria →pigment). Hemozoin is a polymer of the iron porphyrin ferriprotoporphyrin IX (hemin) residues linked by iron-carboxylate bonding β-haematin. It is at present controversial, whether the formation of this polymer is catalyzed by a →heme polymerase or proceeds spontaneously without protein. Despite these differences there is no doubt that just this important polymerization step is susceptible to inhibition by quinoline-containing antimalarial drugs (chloroquine, quinine, amodiaquine), Fig. 1. This is supported by a strong correlation among a series of quinoline compounds between inhibition of parasite growth and inhibition of the heme polymerization. In addition, the subcellular localization of the inhibition of heme polymerization correlates with the site of drug accumulation. Thereby, the heme substrate is probably converted into a noncovalent complex with the quinoline. This hemin-chloroquine-complex is assumed to be toxic to the parasite by lysing membranes or by inhibiting further aspartic protease-mediated hemoglobin degradation.

In the alternative model of chloroquine action by Warhurst 1995, in which the presence of a heme polymerase is not necessary for β-hematin formation, the formation of β-hematin can be inhibited by chloroquine, amodiaquine, and quinine just as they are reported to inhibit heme polymerase. The action of blood schizontocides is thus, according to this model, simply by binding to hemin monomers and preventing their polymerization and detoxification by sequestration with apohemozoin.

For all the known models of the chloroquine action it is proposed that the drug is taken up by the parasites by passive diffusion. However, recently a chloroquine-transporter in the plasma membrane of *P. falciparum* could be characterized. This transport protein is responsible for the accumulation of drug inside the parasite. The uptake mechanism is temperature-dependent, saturable, can be inhibited and follows the Michaelis-Menten kinetics in contrast to the chloroquine uptake into noninfected erythrocytes, which is by simple diffusion. It is proposed that the chloroquine-transporter works as a Na^+/H^+-exchange protein and is able to regulate the cytoplasmic pH. In contrast to other →eukaryonts *P. falciparum* appears not to possess other pH-regulatory systems beside this exchange protein. This is obviously an adaptation to the intracellular parasitism and may explain why this system is an Achilles' heel by which the plasmodia become vulnerable to the action of →quinolones. Corresponding exchange proteins from human cells do not bind or transport chloroquine. The energy for this process is gained via the Na^+-gradient which is built by the Na^+/K^+-ATPase. Chloroquine is able to stimulate the exchange protein, thus leading to an enhanced exchange of protons and Na^+-ions. As a result, pH and Na^+-ions are enhanced intracellularly and chloroquine is taken up and accumulated during the initial activation phase. The chloroquine uptake proceeds as long as there is a Na^+-gradient across the plasma membrane. The molecular mechanism of the activatory effect of chloroquine is unclear at present.

Besides the amoebicidal and antimalarial activity, chloroquine has also antibabesial and anticestodal activities. The mechanism of action of chloroquine in these indications is not yet known. In other nonparasitic indications chloroquine is used in rheumatoid arthritis, chronic polyarthritis and Lupus erythematodes. Here the membrane-stabilizing-effects of chloroquine may contribute to the anti-inflammatory effects. Thereby, the actions of lysosomal proteases become inhibited by this drug.

Resistance

Chloroquine resistance in *P. falciparum* was first observed in 1957. The greatest hindrance for the elucidation of the resistance mechanism was lack of knowledge of the mode of action of the quinoline-based antimalarials on *Plasmodium* spp., which is still discussed controversially. In chloroquine-resistant *P. falciparum* the release of chloroquine is 40–50 times more rapid compared to

wild-type strains. The efflux rates of chloroquine are different between sensitive and resistant strains. The accelerated chloroquine efflux in resistant strains can be inhibited by calcium-channel blocking agents such as verapamil. Thus, the chloroquine-resistance mechanism resembles that of multidrug-resistant cancer cells. Two genes in *P. falciparum*, pfmdr1 and pfmdr2, could be identified, which are homologous to MDR genes. The gene pfmdr1 encodes a 162 kDa homologue of the P-glycoprotein (Pgh1), located mainly at the membrane of the digestive vacuole of the parasite. Indeed, there is evidence for the involvement of Pgh1 in nucleotide-dependent transport across membranes. However, a correlation between amplification of pfmdr1 and chloroquine resistance remains doubtful.

In an alternative hypothesis, chloroquine-resistance may be linked to an impaired chloroquine-uptake mechanism. Indeed, it could be shown recently that resistant *P. falciparum* strains possess an altered Na^+/H^+-exchange protein which are continuously in an activated state, so that chloroquine cannot activate it furthermore. As a result, chloroquine cannot be taken up and accumulated by these cells. The molecular biological background for the constitutive activation of the exchange protein in resistant cells is, however, unclear to date.

Quinine

Synonyms

6-methoxy-a-(5-vinyl-2-quinuclidinyl)-4-quinolinemethanol, Aristochin, Aristoquin, Aristoquinine, Biquinate, Coco-Quinine, Dentojel, Diquine carbonate, Quinamin, Quinamm, Quinate, Quinbisan, Quine, Quinoform, Quinsan, Quiphile, Tasteless Quinine.

Clinical Relevance

Quinine is the main alkaloid of the Cinchona bark in Peru known as effective febrifuge against intermittent fever since the early 17th century. It has some activity against *Trypanosoma brucei*, but the main activity relies on the antimalarial activity. It is used especially for the therapy of chloroquine- and multidrug-resistant *Plasmodium falciparum* infections. The combination with tetracyclin is used in cases of severe resistance. Furthermore, quinine is used in combination with clindamycin against babesiosis. Another, nonparasitic indication is the usage as antiarrhythmic drug.

Molecular Interactions

The activity of quinine is directed against erythrocytic schizonts and gametocyts of all human *Plasmodium* spp., but gamonts of *P. malariae*, *P. ovale*, and *P. vivax* are also damaged (Fig. 2). The action of quinine on the molecular level is suggested to be identical to that of chloroquine (Fig. 1).

Resistance

Quinine has been used in the meantime for more than 350 years without loosing its general effectiveness. Formerly quinine was, however, probably never used at a high enough frequency against *P. falciparum* to induce resistance. The existence of cases of quinine resistance was reported for the first time in 1910 by Nocht and Werner in Brazil. The molecular basis of the mechanism of quinine resistance is assumed to be identical to that of mefloquine, but different from that of chloroquine.

Mefloquine

Synonyms

Larian, Laricur.

Clinical Relevance

Mefloquine was synthesized in 1971 and marketed since 1977. The activity is directed against chloroquine-resistant and mostly against multidrug-resistant *Plasmodium falciparum*.

Mefloquine acts against the erythrocytic schizonts of all 4 *Plasmodium* spp. (Fig. 2). It has additional activity against young gamonts of *P. malariae*, *P. ovale* and *P. vivax*.

Molecular Interactions

The mechanism of action of mefloquine may be similar to that of chloroquine or quinine, since mefloquine and chloroquine are believed to share the same drug receptor within the food vacuole of infected erythrocyte (Fig. 1). However, in contrast to chloroquine which has been shown to inhibit the activity of the hem polymerization by more than 80%, mefloquine does not cause such an inhibitory effect. There is another hypothesis that the antimalarial activity of mefloquine may be due to an interaction with parasite proteins by hydrogen-bond formation.

Resistance

There is occasional resistance against mefloquine. The first case of mefloquine resistance was reported in Thailand in 1982. In the meantime cure rates from eastern Thailand are reported to have dropped to only 41%. The molecular basis of resistance against mefloquine is presumably different from chloroquine resistance since mefloquine still exerts activity against chloroquine-resistant *P. falciparum*. Enhanced drug efflux as seen in chloroquine-resistant *P. falciparum* has not yet been shown with the class of the structurally related

compounds mefloquine, halofantrine, and quinine. The neuroleptic agent and calcium-channel-blocker penfluridol increases the susceptibility of mefloquine-resistant strains to mefloquine, and interestingly, there is no increase of mefloquine-activity in mefloquine-resistant strains by verapamil. By contrast penfluridol cannot increase the susceptibility against chloroquine in chloroquine-resistant strains of *P. falciparum*. Mefloquine resistance exhibits patterns more indicative of the MDR phenotype and is often associated with halofantrine and quinine resistance. The EC_{50} values for mefloquine, halofantrine, and artemisinin are decreased by penfluridol, but not by agents modulating chloroquine resistance. There are several reports on an association between mefloquine resistance and amplification of pfmdr1. Thus, a mefloquine-resistant clone selected by drug pressure exhibited a two- to four-fold increase in the copy number of pfmdr1 and a significantly higher level of corresponding mRNA compared to the sensitive clone. In 10 mefloquine-resistant strains with concurrently reduced susceptibility to halofantrine, pfmdr1 is present in multiple copies, whereas this amplification is not found in the only sensitive strain. A selection for mefloquine resistance in 2 clones generated amplification and overexpression of pfmdr1 and overexpression of its product, Pgh1. The overexpression of Pgh1 correlates with increased resistance to halofantrine and quinine and decreased resistance to chloroquine. Thus, there seems to be an inverse correlation concerning Pgh1 expression in chloroquine resistance and a MDR phenotype involving mefloquine, halofantrine, and quinine.

Lumefantrine

Synonym

benflumetol; Combination: artemether/lumefantrine (Riamet®, Coartem®).

Clinical Relevance

Lumefantrine is used in the drug combination with artemether and recommended for standby medication in uncomplicated malaria tropica.

Molecular Interactions

It is shown that lumefantrine interacts with synthetic phospholipid bilayers of dipalmitoyl- or dioleoylphosphatidylcholine, egg lecithin or mouse erythrocyte membranes, thereby provoking a condensing effect. Artemether and lumefantrine are shown to act synergistically against *P. falciparum in vitro*.

Resistance

The drug combination is active against multiresistant *Plasmodium* strains under field conditions.

Hemozoin

Hemozoin (→malaria pigment, beta-hematin) is the chemically inert crystalline substance produced in the digestive food vacuole of blood-stage malaria parasites. The pigment is visible microscopically in stages that are actively degrading hemoglobin, such as →trophozoites and schizonts. During proteolysis of host erythrocyte hemoglobin, monomeric, toxic heme (hematin, ferriprotoporphyrin IX) is released. In order to protect itself, the malaria parasite has evolved a distinct mechanism for detoxification of free heme through its conversion to hemozoin, originally described as a polymer of heme but more recently characterized as heme dimers that form chains linked by hydrogen bonds in the crystalline hemozoin. The mechanism of hemozoin formation is still not well understood. →*Plasmodium* histidine-rich protein-2 and a polymerase enzyme have been proposed to mediate heme aggregation into hemozoin. But this process may also occur spontaneously in the acidic environment of the food vacuole. The heme detoxification process is unique to *Plasmodium*, and there is now considerable evidence that interference with hemozoin formation is the mechanism of antimalarial action of →chloroquine and other 4-aminoquinolines.

Henneguya

Genus of →Myxozoa in fish.

Hepatic Stellate Cells

These cells are activated and multiplied in the wall of liver blood vessels in case of chronical diseases, which may be induced by parasitic infections (e.g., due to schistosomes, *Clonorchis, Echinococcus*, etc.).

Hepatitis interstitialis parasitaria multiplex

Syndrome due to infection with *Ascaris suum* in pigs. →Ascaris, →Milk Spots.

Hepatocystis

Genus of coccidian blood parasites, the species of which are transmitted by midges (→Ceratopogonidae, →*Culicoides*) mainly to monkeys (*H. kochi, H. simiae*) in Africa and to other hosts (including hippos). Inside liver cells giant schizonts = meronts of 4 mm are formed, while in red blood cells only gamonts occur.

Hepatomegaly

Name

Greek: *hepar* = liver, *megale* = large.

Enlarged liver due to infections with →schistosomes, →*Echinococcus*, →*Entamoeba*, opisthorchiasis, →visceral leishmaniasis (→Kala Azar), →Chagas' disease (hepatosplenomegaly).

Hepatoxylon

Genus of trypanorhynchid tapeworms in fish (→Trypanorhyncha).

Hepatozoon

Name

Greek: hepar = liver, zoon = animal.

Classification

Genus of →Coccidia.

Important Species

Table 1. In 2003 it was shown that within dogs two tick-transmitted *Hepatozoon*-species exist (perhaps another is transmitted by fleas):

1. *H. canis*, which is well adapted to its host (dogs) with low graded symptoms of disease.
2. *H. americanum*, which produces severe and frequently fatal myositis, is highly virulent. It has apparently recently crossed the species barrier from a wild host to pet dogs.

Life Cycle

Figs. 1–3 (pages 599, 600).

Disease

Infections with *H. canis* are (often) symptomless, but may be potentially fatal due to lethargy, cachexia, and anaemia. Often 1–5% of the neutrophils are infected and more than 50,000 gamonts may be found per µl blood of dogs. The infections emerging today due to *H. americanum*, however, lead to a debilitating and often fatal disease, starting with fever, muscle atrophy, fatal myositis (due to heart infections). The vector of *H. americanum* is *Amblyomma maculatum* (so-called Gulf Coast tick). Natural hepatozoonosis similar or identical to *H. canis* was reported also in coyotes (*Canis latrans*) as well as that due to *H. americanum.*

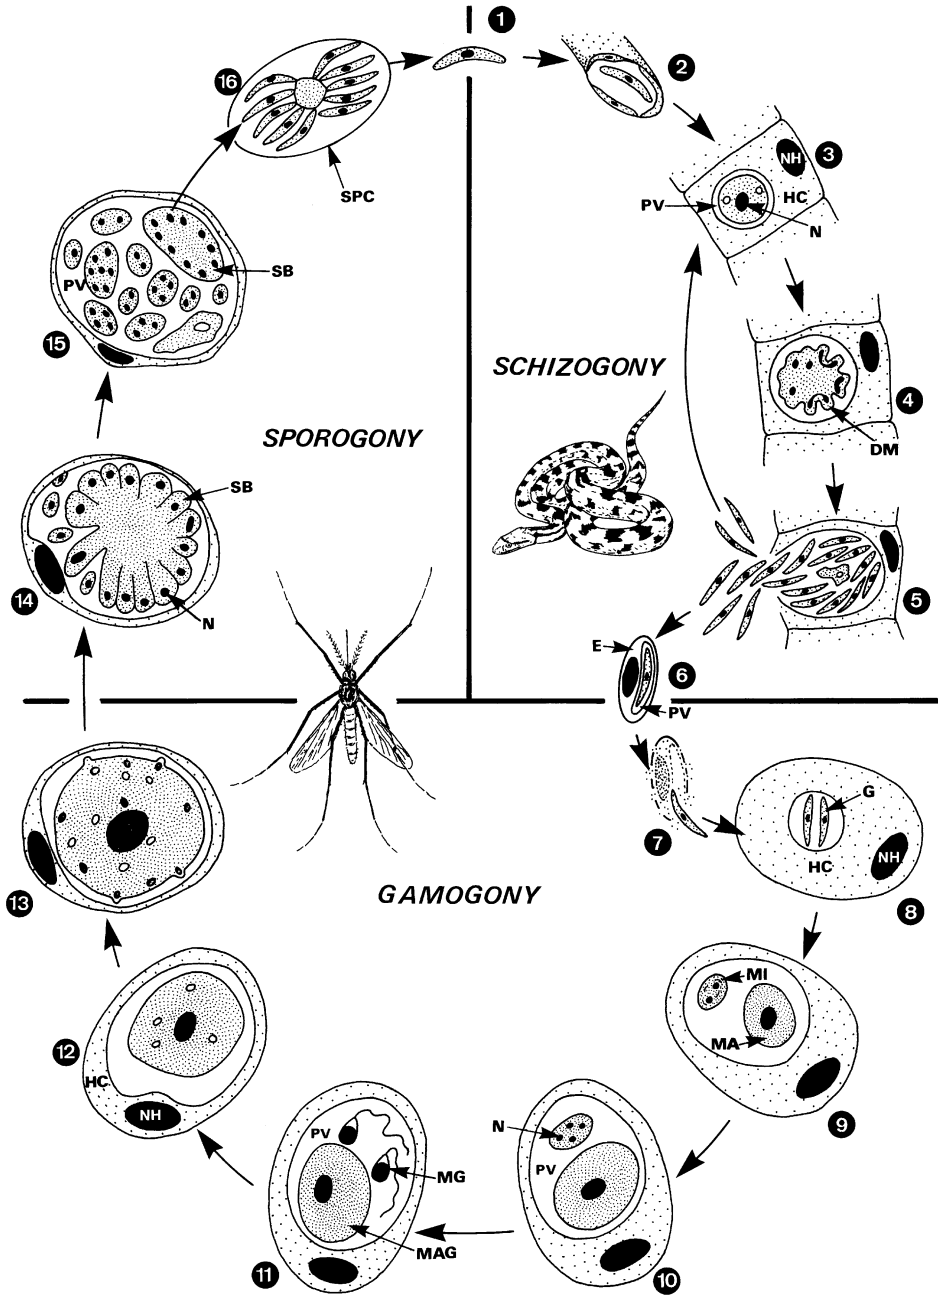
Heptachlor

Chemical Class

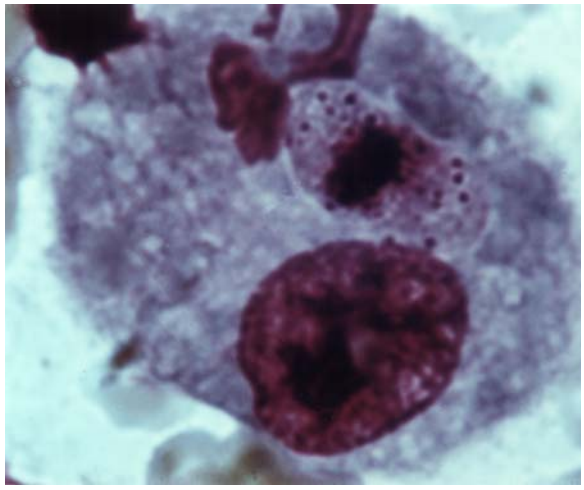
organohalogenide (organochlorine compound, cyclodiene).

Hepatozoon. Table 1 Important species of the genus *Hepatozoon*

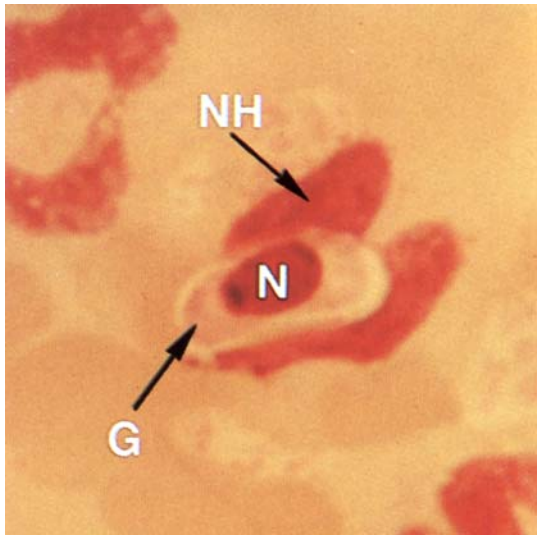
Species	Host	Hosts/Habitat	Vector/Habitat	Mode of infection/transmission
Hepatozoon muris (syn. *perniciosum*)	2	Rats, mice/Liver cells, leukocytes	Rat mites (*Echinolaelaps* sp.)/Hemocoel	Blood meal of vector
H. erhardovae	2	Bank voles (*Clethrionomys* sp.)/Lung, leukocytes	Rat fleas/Hemocoel	Blood meal of vector
H. canis	2	Dogs/Liver cells, Spleen leukocytes	Ticks *(Rhipicephalus sanguineus, Ixodes)* spp.	Blood meal of vector
H. aegypti	2	Snakes (*Spalerosophis diadema*)/*Lung*, erythrocytes	Mosquitoes (*Culex pipiens*)/Body cavity	Blood meal of vector



Hepatozoon. Figure 1 Life cycle of *Hepatozoon aegypti* inside snakes (*Spalerosophis diadema*; Colubridae) and →mosquitoes (*Culex pipiens*). *1, 2* Sporozoites are injected during bite of the female mosquito and enter the lung capillaries of the snake. *3–5* After penetration into endothelial cells (3) they grow to be schizonts (4) which form merozoites (5). *6* The free merozoites may enter other endothelial cells, where they repeat →schizont formation (3) *or* penetrate into erythrocytes and become gamonts of different sex. *7, 8* After sucking by a mosquito, the gamonts are set free (7), migrate into the hemocoel, and penetrate into host cells, where they associate in pairs within a →parasitophorous vacuole (8). *9* On day 2 after infection, differentiation to micro- and macrogamonts occurs. *10* Nucleus of →microgamonts divides. *11* Formation of the nonflagellated →microgametes on day 3 after infection. *12, 13* Fertilization on day 4 and growth of the young →oocyst during the following days. *14* Formation of sporoblasts on days 8–10. *15* Formation of 15–75 sporoblasts, the nuclei of which divide several times. Then the →sporoblast forms a smooth wall and thus becomes a →sporocyst. *16* These sporocysts become disrupted, leading to distribution of sporozoites inside the vector. The main method of infection is the bite, but in experiments oral infection of snakes was also possible. *DM*, developing →merozoite; *E*, erythrocyte; *G*, gamonts (of different sex); *HC*, host cell; *MA*, macrogamont; *MI*, microgamont; *MG*, microgamete; *N*, nucleus; *NH*, nucleus of the host cell; *PV*, parasitophorous vacuole; *SB*, sporoblast; *SPC*, sporocyst.



Hepatozoon. Figure 2 LM of a stage in a white blood cell of a Giemsa-stained smear.



Hepatozoon. Figure 3 LM of a Giemsa-stained blood smear of *H. muris* in a mouse lymphocyte. *G*, gamont; *N*, nucleus; *NH*, nucleus of the host cell.

Mode of Action

GABA-gated chloride channel antagonist. →Ectoparasiticides – Antagonists and Modulators of Chloride Channels.

Heptenophos

Chemical Class

Organophosphorous compounds (organophosphate).

Mode of Action

Acetylcholine esterase inhibitor. →Ectoparasiticides – Agonists and Antagonists of Cholinergic Transmission.

Hermaphrodites

→Cestodes, →Trematodes, →Leeches, →Nematodes (*Rhabdias*).

Hermaphroditism

Name

Greek: *hermaphroditos* = son of the god Hermes and the goddess Aphrodite (= a bisexual stage).

The parasitic stages may be monoecious (hermaphroditic) having male and female gonads in a single individual. Male and female gonads usually mature at different times, but are visibly present in the same individual. Most common is →protandry (→Androgyny), with maturation of the male gonads first; the inverse, →protogyny (→Gynandry), is relatively uncommon (e.g., in a few →tapeworms). In addition, a peculiar type of protandry is found in some →nematodes and arthropods, where individuals develop female gonads only after the complete disappearance of the male ones, thus leading to a misleading →dioecious appearance. Hermaphroditism (with cross-fertilization) is the rule in some groups (platyhelminths, with exceptions such as schistosomes), whereas nematodes, acanthocephalans, pentastomids, and arthropods are dioecious (again, with some exceptions or modifications).

Hermetia illucens

This co-called Black soldier fly (family Stratiomyidae) is often found in masses around poultry and swine houses. The adults are 2 cm long, with black legs and white-yellow tarsi. The antennae are long, project directly forward from the head, and the last segment (3rd) is tapered with no arista. The larvae reach a size of 2 cm, grow in manure of livestock and poultry. They induce the manure to become more liquified and thus suitable for the housefly larvae.

Herpetomonas

→Trypanosomatidae.

Herpobdella

Genus of leeches that may transmit trematodes of fish.

Heterakis

→Nematodes.

Heterobilharzia americana

Schistosoma spp. in dogs, which induces bloody diarrhoea, anorexia, loss of weight, and hypoalbuminaemia.

Heterogony

Name

Greek: *heteros* = different, *gone* = offspring.

Follow-up of generations that reproduce by →parthenogenesis or bisexual intercourse, e.g., →Strongyloides stercoralis.

Heterophyes heterophyes

Classification

Species of →Digenea.

Morphology

These worms are very small (only 1.7–2 mm long) and live attached at the wall of the intestine. Their body is covered with many spiny scales (Figs. 2, 3, page 603). Their ventral sucker lies laterally away from the median line.

Life Cycle

Fig. 1 (page 602).

Heterophyiasis, Animals

→*Heterophyes heterophyes*, →Alimentary System Diseases.

Heterophyiasis, Man

Disease due to infections with →*Heterophyes* species via oral uptake of uncooked infected fish.

Main clinical symptoms: →Diarrhoea, →abdominal pain.
Incubation period: 1–3 weeks.
Prepatent period: 1–2 weeks.
Patent period: 2–6 months.
Diagnosis: Microscopic determination of eggs in faecal samples (Fig. 1, 603).
Prophylaxis: Avoid eating raw fish.
Therapy: Treatment with praziquantel, see →Trematodocidal Drugs.

Heteroptera

From Greek: *heteros* = different, *pteron* = wing. →Bugs.

Heteroxenous Development

Name

Greek: *heteros* = the other, *xenos* = foreigner, guest.

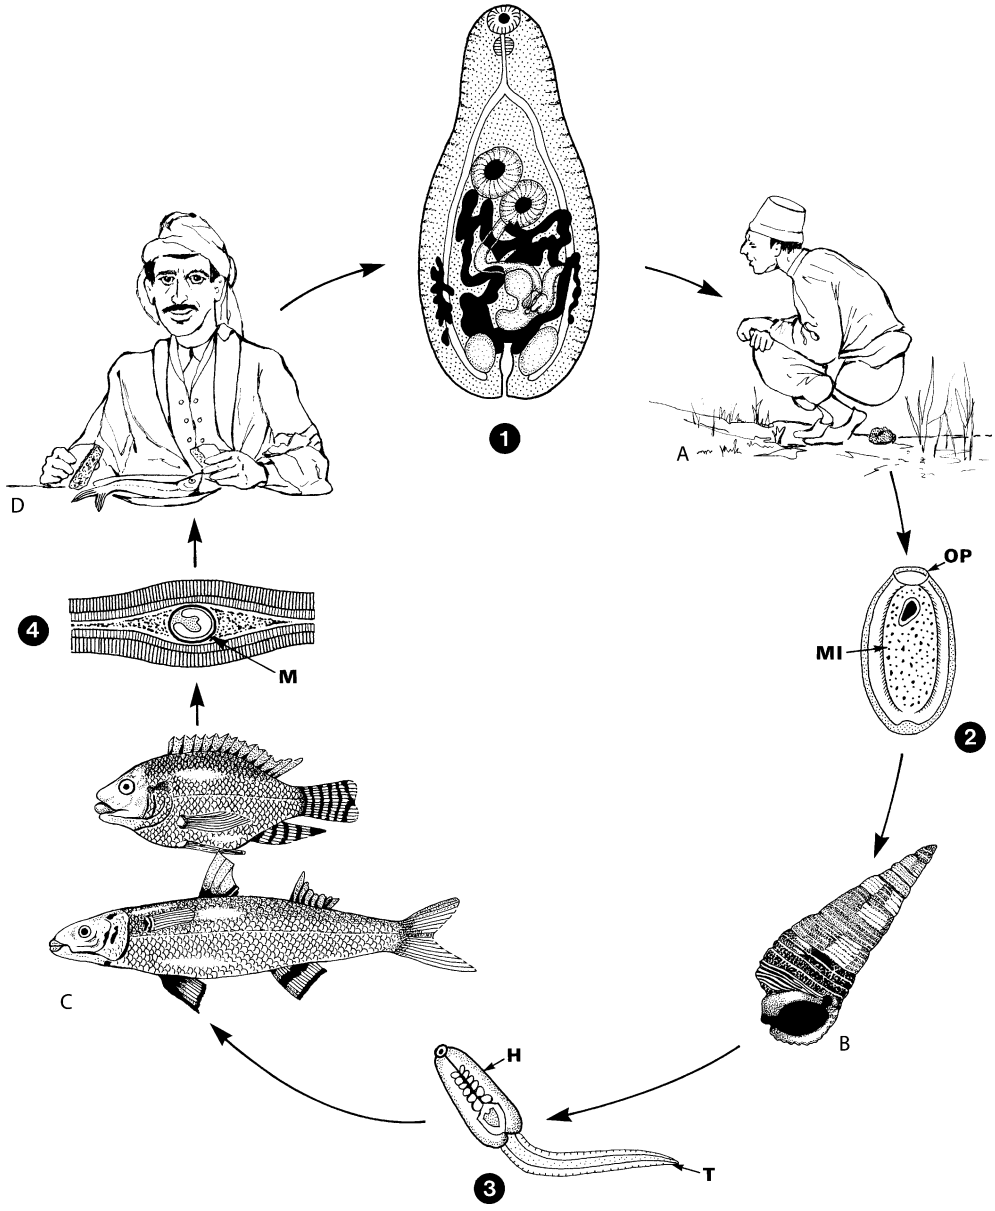
This term describes cycles with involvement of different hosts (e.g., →Schistosomes). →Dixenous Development.

Hexacanth

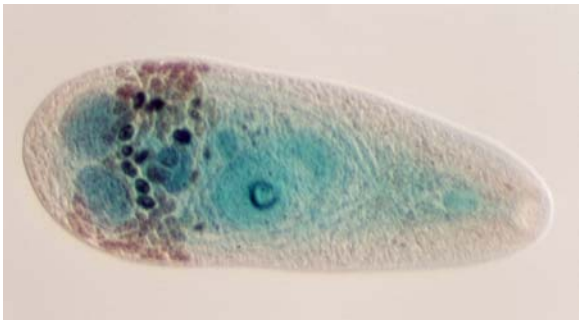
The larvae of the →Eucestoda have 6 hooks (3 pairs) and are thus described as hexacanth whereas the larvae of →Cestodaria form 10 larval hooks (→Decacanth).

Hexachlorcyclohexan

Lindan is the χ-isomer of this compound.



Heterophyes heterophyes. Figure 1 Life cycle of *Heterophyes heterophyes*. This fluke, which reaches a size of about 2–0.4 mm and is characterized by a large muscular bulbus (close to the ventral sucker) around the genital openings, lives in the small intestine and caecum of fish-eating mammals including man (**A, D**). It has snails (**B**, e.g., *Pirenella conica*) as first and various brackish species or freshwater fish (**C**, e.g., *Oreochromis* spp., *Tilapia* spp., *Mugil* spp.) as second intermediate hosts. *1* Adult worm, ventral side. *2* The small-sized (24 µm × 14 µm) eggs, which are operculated and contain a →miracidium larva, are set free within feces of the final host (**A**). They become ingested by snails (**B**) which are found in the Eastern Mediterranean Sea, Red Sea, Gulf, and may reach a length of up to 3 cm. *3* After several reproduction phases (like in →*Clonorchis*) including one →sporocyst generation and often 2 →rediae stages, tailed →cercariae are released from the snail and penetrate into the skin of fish (**C**). The cercariae reach a total size of 185 × 90 µm. *4* Only the head of the cercaria penetrates and becomes encysted as so-called metacercaria (size: 0.8 mm in diameter) under the scales or in the flesh of fish. Humans (**D**) become infected by eating raw, pickled, or insufficiently cooked contaminated fish. The →metacercariae excyst in the intestinal tract, become attached to its wall and reach maturity within 1–2 weeks. *G*, →gonotyl, sexual sucker; *H*, head of cercaria; *M*, metacercaria; *MI*, miracidium; *OP*, →operculum; *T*, tail of cercaria.



Heterophyes heterophyes. Figure 2 LM of an adult worm of *Heterophyes heterophyes* (ventral side, colored).

Heterophyes heterophyes. Figure 3 SEM of the ventral side of an adult *Heterophyes heterophyes*, note the scaly surface.

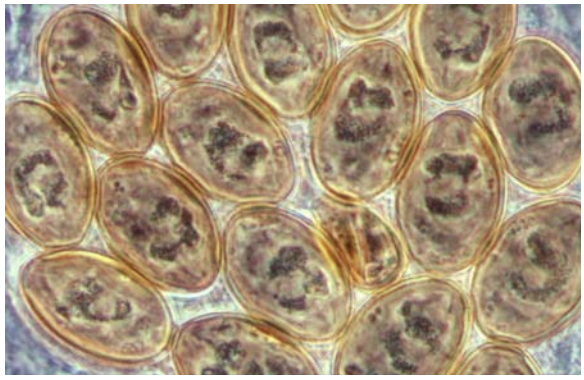
Hexaflumuron

Growth regulator in insect larvae (= acts as insecticide and hinders the molt of larvae →Diflubenzuron = Dimilin), →Methoprene.

Hexamita

Name

Greek: *hex* = six, *mitos* = filament.



Heterophyiasis, Man. Figure 1 LM of *Heterophyes heterophyes* eggs from feces.

Hexamita. Figure 1 LM of *Hexamita* – stages from fish intestine.

Morphology

The specimens of *Hexamita salmonis* and *S. symphysodonis* parasitize in the fish intestine reach a size of about 8–12 µm in length, possess 2 nuclei and in total 6 flagella, of which 4 become free at the anterior pole, 2 at the posterior (Figs. 1–3). Reproduction occurs by binary fision and transmission by cysts that are excreted with the feces (Figs. 2, 3, page 604).

Symptoms of Disease

Apathy, loss of weight, white feces, death (also hollow – sickness in discus – fish).

Therapy

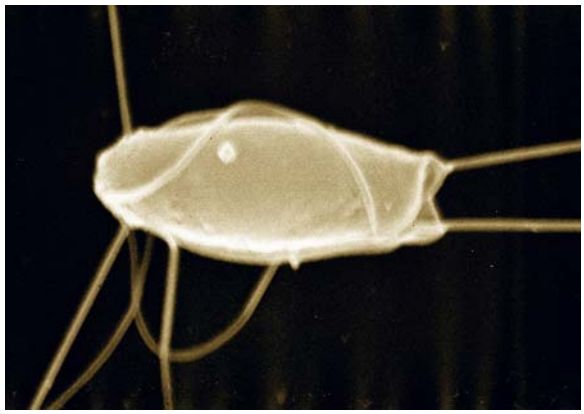
Flagellol™ (5-nitroimidazoles). →Diplomonadida.

Hexapoda

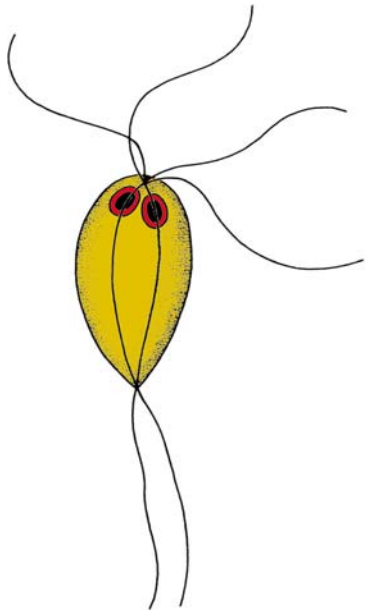
Animals with 6 feet (→Insecta), from Greek: *hexa* = six, *podos* = feet.

Hibernation

Overwintering, survival of developmental stages. In →ticks, e.g., all stages are capable to survive; in the →Culicidae *Anopheles maculipennis* and *Culex pipiens* fertilized females overwinter, while in many →*Aedes* species the eggs serve as anchor for the next generation.



Hexamita. Figure 2 SEM a *Hexamita*-stage.



Hexamita. Figure 3 Diagrammatic representation of a *Hexamita*-stage.

Himasthla

→Digenea.

Hippobosca equina

Name

Greek: *hippos* = horse, *boskein* = feeding on the meadow.

General Information

This "horse louse fly" reaches a length of 8 mm (Fig. 1), has yellow-red legs and reddish wings, while the thorax is black with yellow stripes. The female places 7–10 larvae onto the soil, where they pupate within 4–6 hours. Mostly after 4 weeks (range 3–20) the adults hatch.

Symptoms

The horses are restless due to the rapid movements of the adult flies within the hair and due to their painful bites. Humans are also attacked; the pain is intensive like that of bee bites.

Hippobosca equina. Figure 1 DR of an adult stage.

Hippoboscidae

Name
From Greek: *hippos* = horse, *boskein* = feeding at meadow. Horse louse flies.

Classification
Family of →Diptera.

Morphology
Figs. 1–4.

Hippoboscidosis

Disease due to infestation with hippoboscids, see Table 1 (page 607).

Hirnwurm

German term for →metacercariae of *Dicrocoelium* inside the brain of the second →intermediate host (ant). →Behavior.

Hirudo medicinalis

Synonym
Medical leech, from Latin: *hirudo* = leech.

Classification
Species of leeches (→Annelida).

General Information
For further information see →leeches.

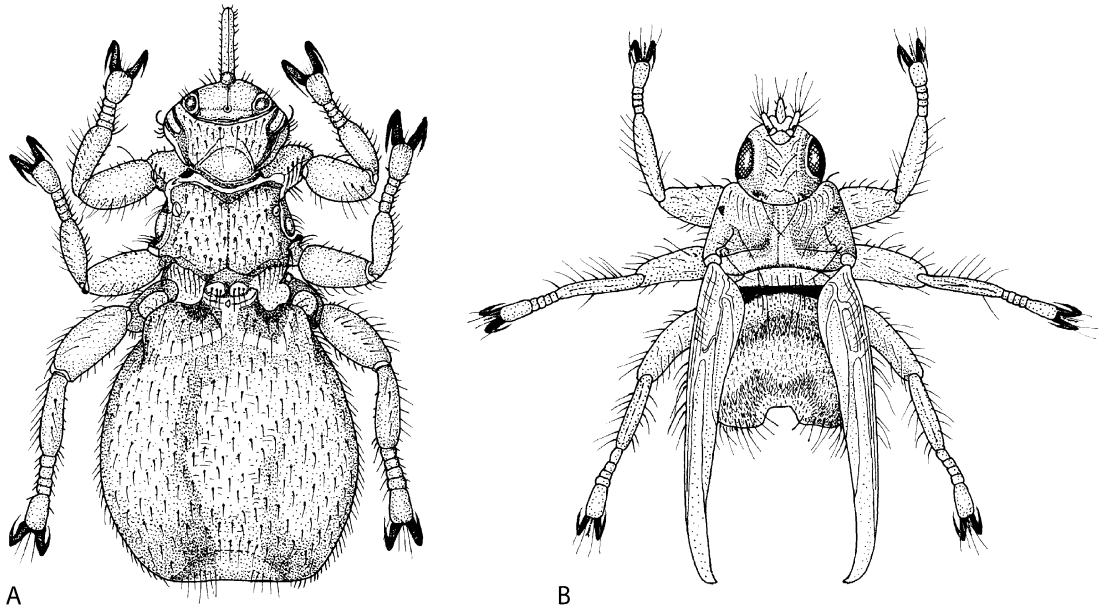
Morphology
Figs. 1–4 (pages 607–609).

Histamine

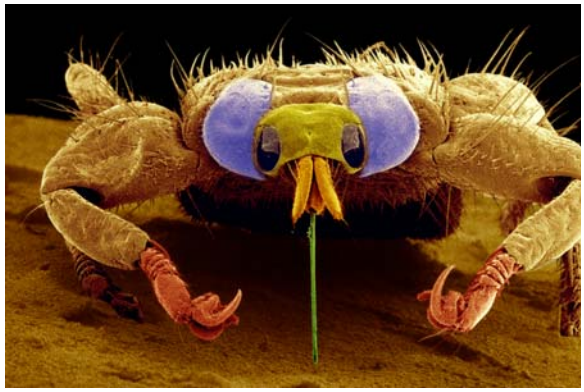
→Amino Acids, →Nervous System of Platyhelminthes.

Histiocytic Reactions

→Pathology.



Hippoboscidae. Figure 1 Species of the Family Hippoboscidae. **A** →*Melophagus ovinus*, sheep ked, without wings. **B** *Stenepteryx hirundinis* from swallows, with wings.



Hippoboscidae. Figure 2 SEM of *Lipoptena cervi*.

Hippoboscidae. Figure 3 LM of an adult *Melophagus ovinus* stage from dorsal.

Hippoboscidae. Figure 4 LM of a puparium of *Melophagus ovinus* from hair of sheep.

Histologic Reactions

→Pathology.

Histomonas meleagridis

→Black Head Disease.

Historical Landmarks

Parasites do not accept borderlines. Thus parasitology has been an international and interdisciplinary science from its beginnings in early human cultures. Philosophers, theologians, natural scientists, pharmacists, physicians, and veterinarians gave birth to deep insights into the world of parasites. Some of the highlights, the selection of which is, of course, an expression of personal taste, are listed below (Table 1, pages 610–613).

More recent findings are not listed, since several have to be confirmed and/or enlarged in their basic elements. Of course, many other discoveries – especially in the last decades – are surely worth citing. Their importance for the ongoing struggle against parasites will, however, become clearer in the future.

HIV

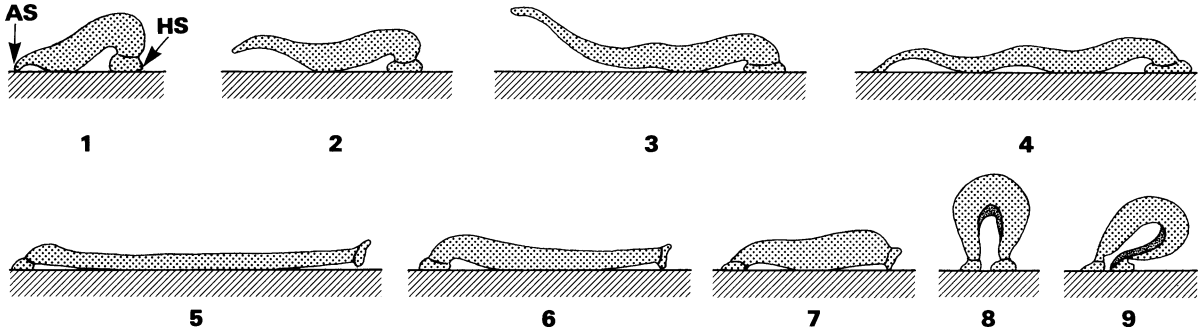
Human immunodefiency virus.

HIV-Interactions

Many parasites grow much better in hosts that are HIV-infected (→Opportunistic Agents). Some like →*Leishmania* spp. induce the activation of HIV in latently infected monozytic and T cells.

Hippoboscidosis. Table 1 Hippoboscids and Control Measurements

Parasite	Host	Vector for	Symptoms	Country	Therapy		
					Products	Application	Compounds
Hippobosca equina (Horse louse-fly)	Horse, Cattle		Anal-/pubic area, irritation through movement and bloodsucking, itching, wool loss or alopecia through rubbing	Europe			
Hippobosca variegata	Cattle		Tail, irritation through movement and bloodsucking, itching, wool loss or alopecia through rubbing	Europe	Ivomec 1% injection for cattle (Merial)	Injection	Ivermectin
Lipoptena capreoli	Goat						
Lipoptena cervi	Deer, Cattle, Goat		Ear, irritation through movement and bloodsucking, itching, wool loss or alopecia through rubbing	Europe			
Melophagus ovinus (Sheep ked, sheep "tick")	Sheep	*Trypanosoma melophagium* (nonpathogenic)	Blood loss, itching, wool loss	World-wide	Butox (Intervet)	Pour on	Delta-methrin



Hirudo medicinalis. Figure 1 Movements of *Hirudo medicinalis* along the skin of a host. *AS*, anterior sucker; *HS*, posterior sucker.

HIV-Protease-Inhibitors

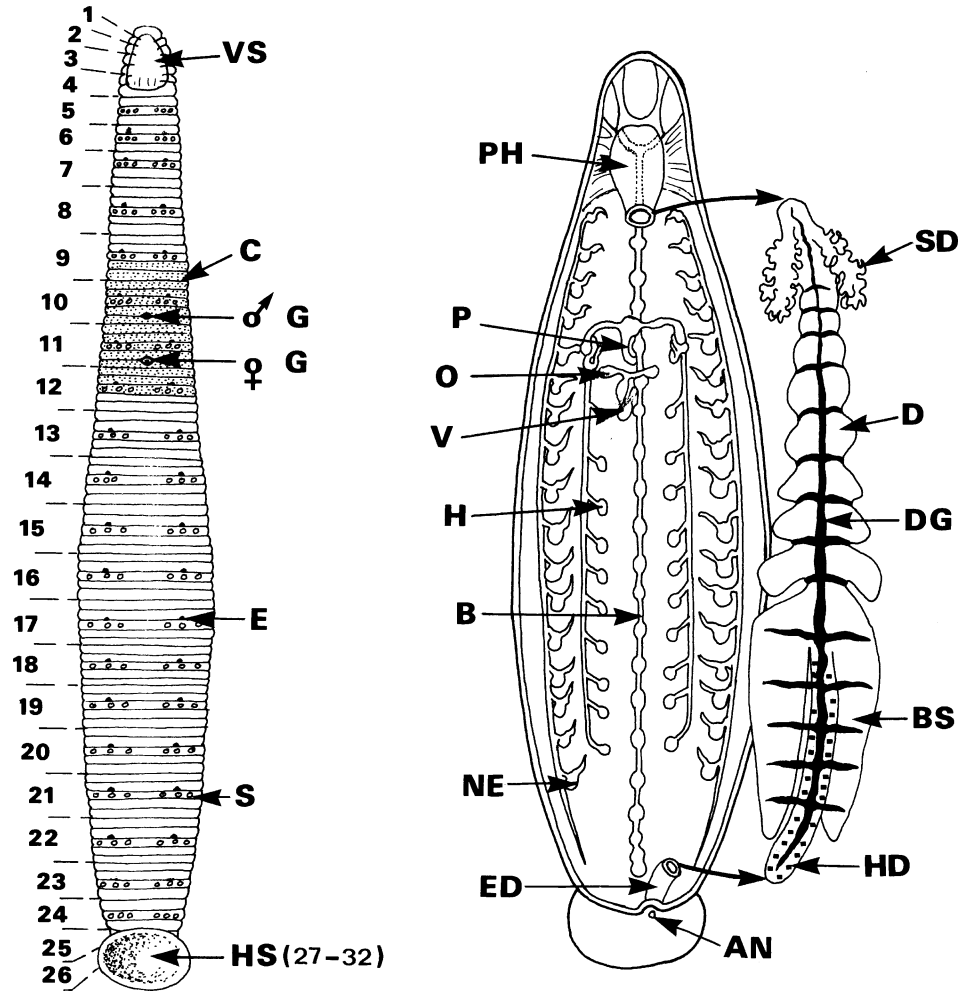
The highly active antiretroviral therapy (HAART) in HIV-patients has shown a significant parallel regression of diseases due to infections with opportunistic parasites. This is not only explainable by support of the immune system (e.g., Indovir may reduce *Cryptosporidium*-infections up to 100%, *Toxoplasma*-infections up to 63%).

Hoferellus

Genus of →Myxozoa of fish.

Hoferellus cyprini

Species of →Myxospora in carps.



Hirudo medicinalis. Figure 2 *Hirudo medicinalis*, the medical leech. **A**, ventral aspect; the outer annulation does not confer to the inner segments (1–32). **B**, inner structure. After copulation and transfer of so-called double spermatophores, fertilized eggs are packed together into slime (→Cocoon) deriving from the →clitellum and are deposited on plants. After a period depending on the temperature of the water, the young worms hatch from the eggs and reach maturity within 5–6 months. *A*, anus; *B*, ventral nerve cord; BS, last intestinal caecum; *C*, →clitellum; *D*, intestinal caeca; *DG*, dorsal blood vessel; *E*, →nephropores = openings of the 17 pairs of →metanephridia; *ED*, rectum; *G*, genital porus; *H*, →testis; *HD*, hind gut; *HS*, posterior →sucker; *NE*, nephridium; *O*, ovary; *P*, penis; *PH*, pharynx; *S*, sensory papillae; *SD*, salivary glands; *V*, vagina; *VS*, apical sucker.

Hohorstiella lata

Mallophagan species of doves.

Holarctis

Name

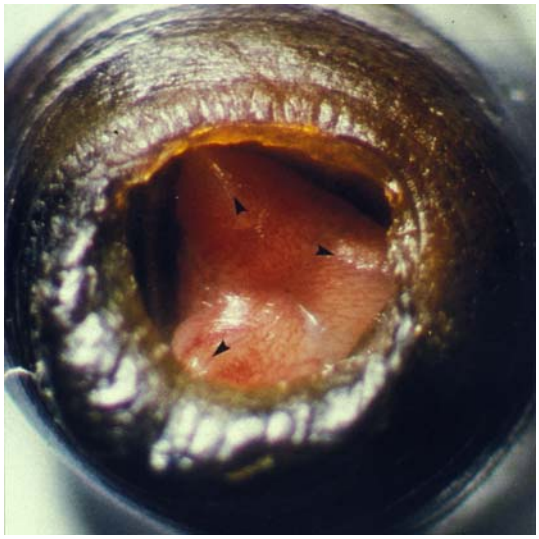
Greek: *holos* = total, *arctos* = north.

Zoogeographical region with typical animals and plants accommodated at moderate and cold climate around the northern pole.

Holarktikos crassiceps

Mallophagan species of goats.

Hirudo medicinalis. Figure 3 LM of an adult *Hirudo medicinalis* from dorsal.



Hirudo medicinalis. Figure 4 LM of the oral sucker of *Hirudo medicinalis*. Note the 3 cutters.

Holdfast Organs

→Acanthocephala, →Aspidogastrea, →Leeches, →Cestodes, →Argulus, →Ticks, →Lice, →Pentastomida.

Hologamy

From Greek: *holos* = total, *gamein* = mating. Total fusion of 2 individuals (e.g., in protozoans).

Hologonic Ovaries

In hologonic ovaries which are found in trichurid →nematodes the oogonia cover the entire wall of the ovarial tube. The germ cells develop via the various stages of oogenesis while moving from the wall towards the lumen of the ovary (→Nematodes/Reproductive Organs).

Hologonic Testes

The hologonic type of →testis where the spermatogonia line the wall of the testis is found in trichurid →nematodes; moreover, →spermatogenesis occurs during migration towards the lumen of the testis (→Nematodes/Reproductive Organs).

Holometabolous Development

This type of development, which is the most common in insects, is also found in large groups of ectoparasites (e.g., →Diptera, →Fleas, →Diptera/Fig. 1, →Fleas/Fig. 2, →Mosquitoes/Fig. 1). In general different types of developmental stages occur during a holometabolous life cycle: larva, →pupa, and adult →(imago). Larvae, which hatch from the egg and which may undergo a species-specific number of molts, are completely different from the adults. They feed on other substrates, in general lack the body appendages of adults (e.g., antennae, wings, mouthparts, legs), and often have only rudimentary eyes. The pupae are nonfeeding, very often remain quiescent (an exception are the motile pupae of →Mosquitoes, see →Mosquitoes/Fig. 1), and are in general in a thickened →cocoon or →puparium. Inside the puparial cover a complete reorganization of the insect's body occurs, leading to the final production of the adult male or female, which leave the pupa by typical opening mechanisms.

In general, the adults (imago) of ectoparasites feed on their hosts. In flies, tabanids, and fleas both sexes feed on the host's blood or body fluids, whereas in mosquitoes only the females take up blood (besides nectar) in order to produce viable eggs. The mouthparts (→Insects/Figs. 7–9) are species-specific as are the mating processes, which start soon after hatching from the puparial enclosure.

Historical Landmarks. Table 1 Historical landmarks (not complete)

1500 BC	The Egyptian papyrus Ebers reported on human worms and schistosomiasis.
500 BC	The Greek poet **Herodot** reported that the Egyptians use fine nets against mosquitoes.
430 BC	**Hippocrates** (460–399 BC) described *Ascaris, Oxyuris*, adult *Taenia*, and Malaria.
342 BC	The great Greek natural scientist **Aristoteles** (384–322 BC) established a first classification system for animals (*Historia animalium*).
62 AD	In his *Historia naturalis*, the Roman **Lucius Columella** (40–88 AD) reported on parasitic animal diseases. **Plinius Secundus** (23–79 AD) also wrote on this subject.
158 AD	The Roman physician **Claudius Galen** (129–199 AD) propagated the knowledge of Hippocrates.
480 AD	The Roman **Vegetius Renatus** (450–510 AD) published his Ars veterinaria with detailed descriptions of intestinal worms.
1000	**Avicenna** (Abu Ali El-Hosein Abdallah Ibn Sina, 980–1037). This Persian theologian and physician reported in his book *Liber canonis medicinae* on malaria and on many worms, especially on *Dracunculus*, which today in French is still called *fil d'Avicenne.*
1150	**Hildegard of Bingen** (1098–1179). This German nun published methods of treating worms in her *De causis et curis morborum.*
1220	**Albertus Magnus** (1193–1280). This German theologian and physician reported in his 26-volume opus *De animalibus* on Aristoteles' insights.
1498	**Savanorola** (1452–1498). In his *Tractatus de vermibus*, this Italian scientist described the occurrence and treatment (by mercury) of worm-infected humans.
1520	The German physician P.A.T. **Bombastus** von Hohenheim, called **Paracelsus** (1496–1541) introduced inorganic salts (e.g., zinc salts) as anthelminthica.
1552	The Belgian physician **Cornelius Gemma** (1534–1579) published the first picture of a human tape-worm.
1583	Discovery of quinine for malaria treatment by an unknown Peruvian (Indian) and the Augustinian monk **Antonio de la Calancha.**
1674–1681	The Dutch optician and autodidact **Antonie van Leeuwenhoek** (1632–1723) described oocysts of the later established genus *Eimeria* and several *Giardia* stages taken from its own feces.
1684–1698	The Italian physician and philosopher **Francesco Redi** (1626–1697) described in his book *Osservazioni interno agli animali viventi* about 108 different worms and published (in 1698) a detailed study on *Fasciola hepatica.* Due to his leadership he is considered the **Father of Parasitology** – the name rediae for special trematode developmental stages honors this.
1699	The Dutchman **Nicolaas Hartsoeker** (1656–1725) and the Frenchman **J. Andry** (1658–1742) proposed that helminth infections derive from oral intake of excreted worm eggs.
1717	The Italian **Lancisco** postulated that malaria is caused by bites from mosquitoes.
1739–1778	The Swedish physician **Carl von Linné** (1707–1778) created within the different editions of his book *Systema naturae* a comprehensive system of classification of animals and plants.
1756	The English physician **Alexander Russel** (1715–1768) discovered in Aleppo the skin leishmaniosis.
1766	The German physician and natural scientist **Peter Simon Pallas** (1741–1811) was the first to begin the experimental transmission of parasites to animals.
1782	The German theologian **J.A.E. Goeze** (1731–1793) initiated the taxonomy of helminths.
1790	The Danish pharmacist and veterinarian **P.C. Abildgaard** (1740–1801) experimentally transmitted *Diphyllobothrium*-larvae to chicken.
1801	The German physician and natural scientist **Carl Asmund Rudolphi** (1771–1832) published his *Entozoorum historia naturalis with* a taxonomy of all available parasites.
1801	The French natural scientist **Jean Baptiste Lamarck** (1744–1829) presented the first general theory of the evolution within his *Philosophie Zoologique.*
1820	The French scientists **Pierre Joseph Pelletier** and **Joseph Lavendou** isolated quinine from plants.
1835	The English medical student **J. Paget** (1814–1899) and his teacher **R. Owen** described trichines in human muscles. Since the name originally given, *Trichina*, was prefixed for an insect, the worm name was changed in *Trichinella* by Railliet (1895).
1838	The German scientists **N. Schleiden** and **Theodor Schwann** (1810–1882) formulated the **cell theory**, which became the dead end for the former *de-novo*-creation-theory.
1841	The Swiss scientist **G.G. Valentin** described the first trypanosomes in the blood of a salmonid fish.
1848	The American **Josiah Nott** postulated again that mosquitoes were vectors of malaria and yellow fever.
1849	The Swiss **G. Gross** discovered *Entamoeba gingivalis* as the first parasitic amoeba.
1853	The German **C.T.E. von Siebold** (1804–1885) showed the life cycle of *Echinococcus granulosus.*

Historical Landmarks. Table 1 Historical landmarks (not complete) (Continued)

1859	The Germans **Rudolph Virchow** (1821–1902) and **Rudolph Leuckart** (1822–1898) independently found the life cycle of *Trichinella spiralis.*
1859	The English philosopher, theologian and natural scientist **Charles Darwin** (1809–1882) published his *The Origin of Species* – another landmark of the evolution theory.
1865	The Bohemian monk **Gregor Mendel** (1822–1884) formulated the basic laws of genetics.
1869	The German physician **Otto Wucherer** (1820–1873) discovered in Brazil microfilariae and schistosome eggs in human urine.
1875	The German physician **F.A. Lösch** described at the Court in St. Petersburg (Russia) for the first time stages of *Entamoeba histolytica.*
1878	The Scottish scientist **Sir Patrick Manson** (1844–1922) working in China showed that *Wuchereria bancrofti* is transmitted by mosquitoes (*Culex* sp.).
1880	The French man **Charles L.A. Laveran** (1845–1922) showed malaria stages within erythrocytes.
1882	The Russian scientist **Ilja Metchnikoff** (1845–1916), working in Italy, was the first to describe the phenomenon of phagocytosis and to develop the concept of cellular immunity (Nobel Prize 1908).
1885	**A.L.J. Railliet** (1852–1930); this French zoologist described a large range of protozoans and helminthes.
1888	The French physiologist **Charles Richet** (1855–1935) formulated the basic concept of humoral immunity (Nobel Prize 1919).
1890	The German veterinarian **Robert von Ostertag** (**1**964–1940) described a large variety of parasitic nematodes in animals.
1893	The Americans **Theobald Smith** and **F.L. Kilbourne** identified the transmission of *Babesia bigemina* by ticks (*Boophilus annulatus*).
1895	The English military physician **David Bruce** (1855–1932) showed that the tsetse fly is the vector of animal trypanosomes.
1897	In India the English Army doctor **Sir Ronald Ross** (1857–1932) proved that avian malaria was transmitted by *Anopheles* mosquitoes (Nobel Prize in 1902). In the same year the Italians Bignami, Bastianelli and Grassi did the same for human malaria.
1898	The German physician and discoverer of the agent of tuberculosis (*Mycobacterium tuberculosis*) **Robert Koch** (1843–1910) described *Theileria parva*, the agent of East Coast fever (Nobel Price 1905).
1898	The French man **P.L. Simond** succeeded in demonstrating the transmission of plague by rat fleas.
1900	In Cuba an American group working with **Walter Reed** demonstrated the transmission of yellow fever by *Aedes aegypti.*
1903	The English scientists **W. B. Leishman** and **C. Donovan** independently described *Leishmania donovani*, the agent of Kala-azar disease.
1904	In Cairo the German helminthologist **Arthur Loos** (1861–1923) discovered the transmission of the hookworm.
1906	The American physician **Howard T. Ricketts** (1878–1910) recorded the tick *Dermacentor andersoni* as being a vector of the agents of the Rocky Mountain spotted fever.
1906	The German zoologist and discoverer of the agent of syphilis **Fritz Schaudium** (1871–1906) described *Entamoeba histolytica* as a human parasite.
1907	The American **E.E. Tyzzer** described stages of the genus *Cryptosporidium.*
1907	The German chemist **Paul Ehrlich** (1854–1925) – the father of chemotherapy – proposed the drug trypan red against trypanosomiasis (Nobel Price 1908).
1908	In North Africa the French military doctors **Charles Nicolle** (1866–1936) and **L.H. Manceaux** described *Toxoplasma gondii* in a rodent.
1909	The Brazilian **Carlos Chagas** (1879–1934) discovered the life cycle of *Trypanosoma cruzi* and described *Pneumocystis carinii.*
1909	Teams working with the Frenchman **Charles Nicolle** (1866–1936) (Tunis) and the American **H.T. Ricketts** (Mexico) proved that the louse *Pediculus humanus corporis* is a vector of the typhus-causing rickettsia.
1910	The Italian **Carini** discovers *Pneumocystis carinii* in rats.
1914	The Japanese scientists **M. Miyairi** and **M. Suzuki** worked out the life cycle of *Schistosoma japonicum.*
1916–1920	Development of Suramin (B205) against trypanosomiasis (Bayer Co., Germany).
1917	The Austrian psychiatrist **Julius Wagner Ritter von Jauregg** (1857–1940) tested a live vaccination using *Plasmodium vivax*-stages (Nobel Prize 1927).
1925	The English natural scientist **D. Keilin** elucidated the electron cascade (cytochrome) system while using parasitic insects and worms as models.

Historical Landmarks. Table 1 Historical landmarks (not complete) (Continued)

1934	Discovery of chloroquine as a malariacidal drug at Bayer Co. (Wuppertal, Germany).
1938	The German scientists **Helmut** and **Ernst Ruska** developed the transmission electron microscope at Siemens Co. (Berlin) (Nobel Prize 1985).
1939	Sulfonamides were introduced as anticoccidial drugs and the Nobel Prize was awarded to their discoverer **Gerhard Domagk** (1895–1964) (Bayer Co., Leverkusen, Germany).
1944	**Erich Reichenow** and **N. Mudrow** (Leverkusen, Germany) demonstrated the liver stages of avian malaria.
1950	In the USA **C. Bueding** demonstrated the carbohydrate metabolism in *Schistosoma mansoni.*
1953	The Americans **J.D. Watson** and **F.H.C. Crick** described the structure of DNA.
1955	DDT, which had been developed in 1939 by the Swiss **Paul Müller**, was introduced as an insecticide.
1956	The English scientists **P.C.C. Garnham** and **S. Short** demonstrated the liver stages *of Plasmodium* within humans.
1959	The English natural scientist **J.D. Smyth** and **J.A. Clegg** elucidated the egg shell formation in flatworms.
1960	**Erich Scholtyseck** (Bonn, Germany) and **Datus Hammond** (Logan, Utah) started systematical electron microscopic studies on Coccidia.
1961	The American **L.S. Diamond** cultured *Entamoeba histolytica* axenically.
1961	First reports on chloroquine resistance in Asia and Africa.
1963	The Americans **F.M. Fischer** and **R.M. Sanborn** demontstrated that the microsporidian *Nosema* produces juvenile hormones for its insect host.
1963	The Americans **C.P. Read, A.H. Rothman**, and **J.E. Simmons** demonstrated the basics of the membrane transport in cestodes.
1964	The American **R. Damian** proved molecular mimicry in schistosomes.
1965	The Australian **W.P. Rogers** discovered the role of enzymes in the moulting of nematodes.
1966	Introduction of benzimidazoles as broad spectrum anthelminthica.
1969	The American **Jack Frenkel** (Kansas) and the Indian **J.P. Dubey** together described the cat as final host of *Toxoplasma gondii.* **Work** and **Hutchinson** (Scotland) and **Overdulve** (Holland) independently achieved the same result.
1972–1977	German research teams led by **Micheal Rommel, Alfred Otto Heydorn**, and **Heinz Mehlhorn** discovered and described the life cycles of several *Sarcocystis* species and related cyst forming species.
1975	**Georg Köhler** and **J. Milstein** developed the hybridoma technique for the production of monoclonal antibodies (Nobel Prize 1986).
1975	The English biologist **C. Cross** characterized the glycoprotein surface coat of trypanosomes.
1975–1978	German research teams led by **Eberhard Schein, Karl Friedhoff**, and **Heinz Mehlhorn** discovered the complete life cycles of 10 *Theileria* and *Babesia* species.
1976	The Americans **Trager** and **Jensen** succeeded in establishing continuous *in vitro* cultures *of Plasmodium falciparum.*
1976	The American **C.H. Zierdt** and the Chinese **J. Tan** introduced *Blastocystis* as a parasite.
1978	The Scottish scientists **Keith Vickerman** and **G.A.M. Cross** demonstrated antigenic variation in the surface coat of trypanosomes.
1981	Introduction of ivermectin.
1981	The Swiss **Burgdorfer** recognized *Ixodes* ticks as vectors of *Borrelia* bacteria, the agent of Lyme disease.
1982	American scientists defined the first malaria antigen-circumsporozoite antigen.
1984	The threat of AIDS was growing and the importance of **opportunistic parasites** became recognized.
1985	Application of PFGE to parasitological problems.
1986	Recognition of the importance of zymodemes for the identification of strains of *Trypanosoma cruzi*.
1987	Use of DNA probes in the field.
1988	Application of DNA-amplification techniques in parasitology.
1988	The Colombian microbiologist **M.E. Pattarroyo** presented a synthetic vaccine against *Plasmodium falciparum.*
1989	RNA editing in parasites.
1989	RNA-editing was found to occur in trypanosomes.
1990	Possible role of transgenic mosquitoes in control measures.
1990	The reasons for sequestration in *Plasmodium falciparum* were detected.
1991	Cross-regulation of Th1 and Th2 subsets in parasitic infections.
1991	The function of nitric oxide in human malaria and other parasitic infections was detected.

Historical Landmarks. Table 1 Historical landmarks (not complete) (Continued)

1992	Potential of understanding genomes of parasites and vectors.
1993	Avermectins and management of arthropods of medical and veterinary importance.
1993	**M.E. Pattarroyo** reported on first successful malaria vaccine trials in South America (failures occurred later).
1994	HIV-AIDS and leishmaniasis.
1995	Trials of the SPf66 malaria vaccine in humans.
1996	Combination therapy for malaria.
1997	Global mapping of filariasis.
1998	Climate change and vector-borne diseases.
1999	Roll Back Malaria initiative.
2000	*Wolbachia* in filarial worms as a target for chemotherapy.
2000	*Plasmodium falciparum* genome completed.
2001	Apoptosis of intracellular protozoa.
2002	Genetic analysis of arthropod blood meals.
2003	Transgenic mosqzitoes and malaria control.
2003	Human genome completed.
2004	DNA microarray analysis of protozoan gene expression. Application of DNA fingerprinting to forensic science. Beginning of the Human Genome Project.

Homidium

Salt →Trypanocidal Drugs.

Homology

Common ancestry of 2 genes (characters, genes, positions, etc.)

Homoplasy

→Phylogeny.

Homoxeny

From Greek: *homos* = identical, *xenos* = foreign. Uniform development, development in 1 host-type.

Hooks

→Holdfast organs of →Acanthocephala, some digenetic Trematodes, →Cestodes, →Monogenea, →Pentastomida.

Hookworm Disease

Pathology

Hookworm disease is produced by →*Ancylostoma duodenale*, →*Necator americanus*, and several other species (→Hookworms). The larvae live in moist soil and enter the skin, giving rise to allergic dermatitis with a papular and sometimes vesicular focal rash that is intensely pruritic and is sometimes referred to as "ground →itch". The larvae enter the blood stream, get to the lungs where they may give rise to focal hemorrhages and to allergic →pneumonia. The larvae migrate up the bronchial tree to the pharynx and are swallowed. They reach adulthood in the upper small intestine where they attach to the mucosa with their powerful buccal capsule enclosing a tag of mucosa from which they draw blood. This may be accompanied by →abdominal pain after 35–40 days. From time to time the worm moves to another site, sometimes leaving the microscopic →ulcer to bleed until the vessels thrombose and the site heals. With heavy infection anemia develops.

Because the worms take in more blood than they assimilate; black stools, or melena, are common, but some of the iron lost is resorbed in the intestine.

Immune Responses

Data indicate that a Th2-dominated immune response acts to reduce the weight and →fecundity of →hookworms like *Ancylostoma duodenale* and *Necator americanus* in the human gut. Parasite specific IgE and →eosinophilia may be involved in host protection. In elder patients there is significant negative correlation between antilarval IgG antibodies and parasite burden. The fact that human hookworms nevertheless survive in an immunological hostile host for many years may be best explained by efficient escape mechanisms preventing the immune system from exerting its full effects. Several molecules secreted by hookworms have a potential to inhibit or antagonize the immune system of the host. In →*Ancylostoma* species, the neutrophil inhibitory factor (NIF), a glycoprotein of 41 kDa potently inhibits CD11b/CD18 dependent neutrophil activation and adherence to vascular endothelium. Since Necator americanus lacks NIF it may rely on acetylcholinesterase, glutathion-S-transferase, and superoxide dismutase to suppress inflammation. Acetylcholinesterase not only inhibits gut peristalsis but may also suppress the release of inflammatory cytokines by lymphocytes stimulated via their muscarinic receptors. Secreted glutathion-S-transferase, and superoxide dismutase may represent protective mechanisms of the hookworms against reactive oxygen intermediates produced by activated leukocytes in the gut. An IgA protease present in *Necator americanus* has the potential to produce IgA Fab fragments capable of blocking complement or phagocytic attack mediated by intact IgG or IgM. Since secretory IgA provides a potent signal for eosinophil degranulation, the secretion of an IgA protease would be beneficial to the parasite also on this level.

Targets for Intervention

Both *Ancylostoma duodenale* and *Necator americanus* require specific →environmental conditions for their larvae to hatch and become ensheathed, rhabditiform, infective organisms that will actively enter a new host through the skin, usually that of the feet or lower part of the legs. Most of the infections are contracted in the peridomestic environment. Figure 1 indicates the infected host, the contaminated environment, and the infection cycle as targets of intervention. Suitable approaches to control include the detection and treatment of infected persons, the safe disposal of feces, rigorous environmental sanitation, and wearing shoes as a means of avoiding skin contact with contaminated soil.

Main clinical symptoms: →Pruritus, bronchitis, eosinophilia, red-diarrhea, fever, →anemia, cachexia, breakdown of circulation
Incubation period: Dermatitis: 4 hours, intestinal symptoms: 2 weeks.
Prepatent period: 5–6 weeks.
Patent period: 20 years.
Diagnosis: Microscopic determination of eggs in fecal samples (Fig. 2).
Prophylaxis: Use solid shoes in endemic regions and avoid human feces.
Therapy: Treatment see Nematocidal Drugs.

Horse Bot Flies

→Gasterophilus.

Horse Flies

→Tabanus, →Tabanids.

Horse Leech

→Limnatis nilotica.

Horse Tick

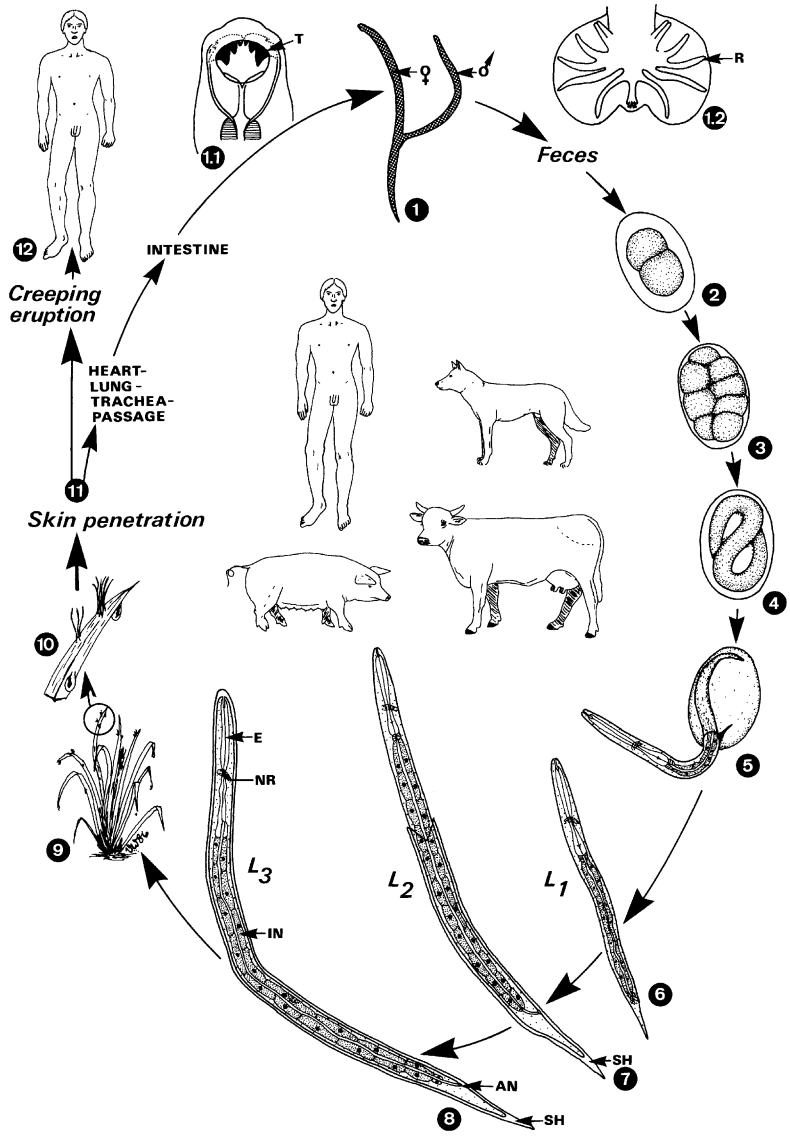
Dermacentor albipictus.

Host Behavior

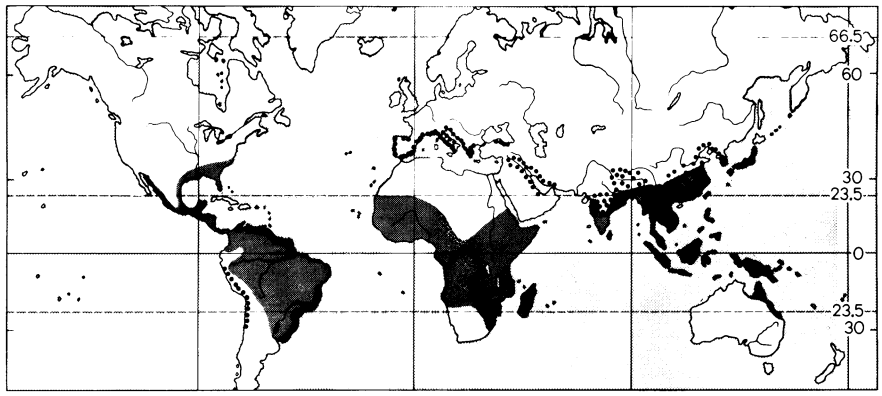
General Information
Host behavior can be modified in various ways by parasites, for instance just because of debilitation. However, the most interesting alterations are related to the →extended phenotype.

In the last 20 years, an increasing number of "manipulations" of host behavior by parasites have been reported. These manipulations increase the chances of the life cycle being completed.

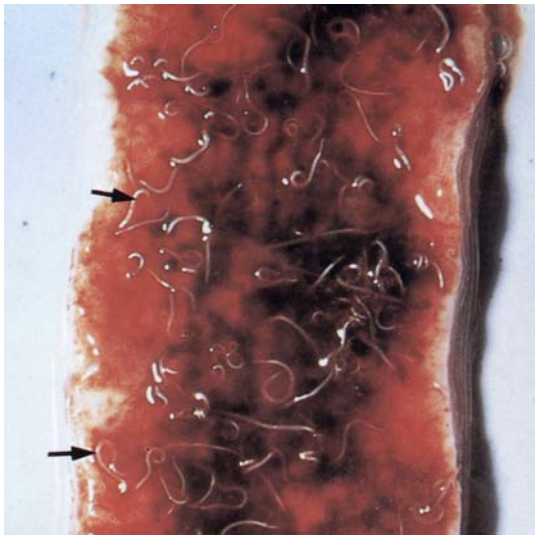
The case of the "brainworm" which manipulates ant behaviour was one of the first cases to be described in detail. →*Dicrocoelium dendriticum* is a trematode which develops in 3 successive hosts: a terrestrial gastropod, an ant, and a mammal (usually a sheep). →Cercariae are produced in the snail and emitted in small mucus balls which attract ants and are eaten by them. For the life cycle to be completed, the ant must be then ingested by a sheep. One of the ingested cercariae makes its way towards the brain of the ant and provokes a drastic change in the behavior of its host: "whereas an uninfected ant would normally retreat into its nest when it became cold, infected ants climb to the top of



Hookworms. Figure 1 Life cycle of hookworms (e.g., →*Ancylostoma duodenale*, *A. caninum, A. braziliense*, →*Necator americanus*, →*Globocephalus* sp., →*Bunostomum* sp.). *1* As shown here for *A. caninum*, the adults inhabit (in copula; 1) the small intestine of their hosts, attaching by means of their buccal cavity to the mucous layer and sucking blood using their species-specific teeth (1.1). By help of their copulatory bursa (fortified with specific rays; 1.2) the males are attached to the female vulva (location varies according to species) thus giving rise to the typical Y-shaped copulatory aspects. *2–4* Eggs are excreted unembryonated and develop the L_1 in the soil. *5–8* The L_1, which is called a rhabditiform larva (due to its esophagus), escapes from the →eggshell and feeds on organic material; it then undergoes the first molt, completely shedding its →cuticle. After a time spent feeding, the L_2 (still rhabditiform) molts to the infectious filariform L_3. The second-stage →cuticle may be retained (8) as a loose-fitting sheath or it may be lost earlier (7). *9–10* L_3 live in the upper few millimeters of soil, migrate to the surface, and are often found in groups of thousands on the soil or on plants (moving synchronously). *11* Infection of final hosts occurs when L_3 contacts the skin and burrows into it. After a →heart-lung-trachea passage the L_3 reach the intestine, →molt twice, and become sexually mature. (In some species transplacental transmission of L_3 or transmission in mother's milk is possible.) *12* If a human becomes invaded by L_3 of a species or strain that normally matures in animals (e.g., *A. caninum, A. braziliense*) the larvae migrate for months through the cutaneous layers, leading to a disease called →creeping eruption. *AN*, anus; *E*, esophagus; *IN*, intestine; *NR*, nerve ring; *R*, rays of →bursa copulatrix; *SH*, →sheath (originating from the molted cuticle of the preceding larval stage); *T*, tooth (here each with 3 peaks).



Hookworms. Figure 2 Distribution map of *Ancylostoma duodenale* (grey) and *Necator americanus* (black).



Hookworms. Figure 3 Dog intestine filled with numerous blood sucking *Ancylostoma* worms leading to an enormous bleeding.

grass stems, clamp their →jaws in the plant and remain immobile as if asleep." This "abnormal" behavior increases considerably the probability of the infected ants being eaten by sheep. It is also remarkable that the infected ant, if not eaten, goes down to its nest during the hot period of the day (which prevents it from dessication) and returns at night to its position at the top of stems.

Such adaptive processes, which increase the probability of a parasite completing its life-cycle by modifying host behavior, are part of a more general aspect of parasite adaptations, called →favorisation.

→Extended Phenotype.

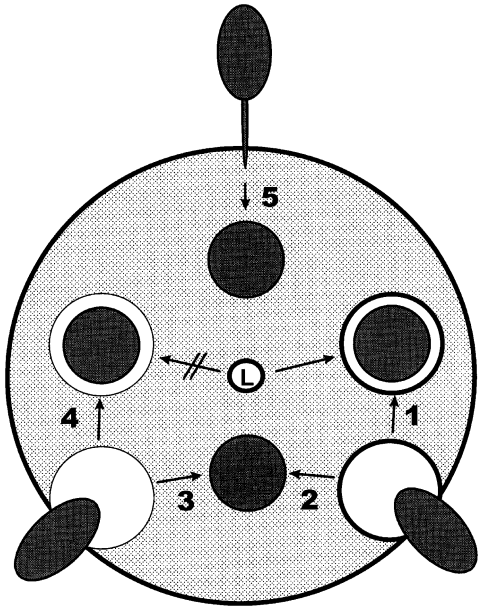
Host Cell Invasion

General Information

When a parasite comes into contact with a potential host cell, 2 series of events may occur which lead to intracellular parasitism. First comes a recognition step which enables a suitable close association between both partners, then comes the internalization of the organism within the host cell. The mechanisms of recognition are far from being entirely elucidated, as well as the ones by which entry occurs. Data have been obtained however, which show that the different parasite groups have evolved different strategies toward these goals.

A major question when dealing with host cell invasion by a pathogen is to decide whether this one actively enters a cell or whether it is engulfed by the process called phagocytosis. The matter is rather clear with those parasites which force their way through the plasma membrane of the host cell or fuse their membrane with it; it is more confusing when internalization occurs within a →parasitophorous vacuole, the membrane of which is continuous with the host cell →plasmalemma during the whole invasion process, as is the case with most protozoan parasites. Moreover, when a parasite uses phagocytosis to gain access into a cell, another important issue is its behavior facing the fate of a phagosome, i.e., fusion with a lysosome and exposure to a cocktail of lytic enzymes which are supposed to digest the phagosomal contents. Parasites seem to have also evolved various ways of escaping this fatal outcome, as will be described below. Different invasion processes which occur among intracellular eukaryotic pathogens are depicted in Fig. 1.

Because of their medical interest, host cell invasion by Apicomplexan zoites (e.g., →*Plasmodium*, *Toxoplasma*, →*Eimeria*, →Sarcocystis, or →Piroplasms) has



Host Cell Invasion. Figure 1 Invasion processes observed among different intracellular pathogens. *1* Invasion by phagocytosis, parasite development in →phagolysosomes (e.g., →*Leishmania* spp.). *2* Invasion by "phagocytosis," escape of the parasite into the host cell cytoplasm (e.g., *Trypanosoma cruzi*). *3, 4* Active invasion of →Apicomplexa, characterized by a →moving junction and the development of the parasitophorous vacuole. An originality of piroplasms (e.g., →*Babesia*) is the disintegration of the parasitophorous vacuole membrane soon after invasion, the parasite then lying directly within the erythrocytic stroma (*3*). Other Apicomplexa complete their →schizogony within a parasitophorous vacuole after inhibition of fusion with →lysosomes (*4*). *5* Invasion through the host cell plasmalemma (Microsporidia).

been studied to a great extent (→Apicomplexa/Host Cell Invasion).

In contrast, little morphological data are available on the invasion of host cells by kinetoplastids. More studies deal with the ways these organisms escape the phagosome lysosome fusion (→Trypanosoma/Host Cell Invasion, →Leishmania/Host Cell Invasion). Although rather poorly known, the mechanism of cell invasion by →Microsporidia has very peculiar characteristics. →Microsporidia self-inject into their host cell by devaginating a membranous organelle (→Polar Tube) which forces its way through the host cell plasmalemma and through which the parasite →cytoplasm moves into the recipient cell (Fig. 1). Invasion is thus intrusive: this is the only case known among intracellular parasitic →protozoa where parasite development may occur either in the cytoplasm of the cell or within a parasitophorous vacuole; but whether this →vacuole forms at invasion or later is not known.

Host Demography

The impact of parasites on host demography was underestimated by ecologists for a long time but, during the last 20 years, several studies have demonstrated that parasites play a prominent role in the regulation and sometimes even breakdowns of their host populations.

Among the studies on the relationship between the parasitic load and the demography of the hosts, the following are especially demonstrative.

In Scotland, important variations in the population densities of the grouse *Lagopus lagopus scoticus* depend at least in part on the abundance of the nematode *Trichostrongylus tenuis*, which lives by thousands in the caeca of the bird. The years when climatic conditions favour the survival of the larvae of the nematode in the open air, the grouse experience increased predation and loss of →fecundity.

Similarly, another nematode, *Obeliscoides cuniculi*, makes the snowshoe hare *Lepus americanus* vulnerable to its predators. Individuals which are treated by an anti-helminthic (ivermectin) are 2–3 times less often captured by predators than controls.

However, parasites are not always detrimental to their hosts. This happens when parasites interfere with competition between hosts. A parasite is capable of modifying the status of competition between free-living species, as soon as the species in competition are differently affected by this parasite. For instance, the fruit flies *Drosophila melanogaster* and *D. simulans*, species morphologically similar but genetically isolated, are attacked, at the larval stage, by the parasitoid wasp *Leptopilina boulardi*. Experiments by Boulétreau et al. have demonstrated that, when *D. melanogaster* and *D. simulans* are grown together in equal numbers at 25°C, *D. melanogaster* eliminates *D. simulans* in a few weeks. However, when the parasitic wasp is added to the system, an equilibrium becomes established, and the species of *Drosophila* coexist. Boulétreau et al. explained this result by a different receptivity of the 2 *Drosophila* to the parasitoid, which parasitizes *D. melanogaster* more frequently than *D. simulans*. Field studies in African oases have demonstrated that, the more abundant the wasp is, the more an equilibrium between the species of fruit flies is realised: the conclusion is that a parasite may be detrimental to individuals, but beneficial to the population (in this example, any individual of *D. simulans* which is infested by *Leptopilina boulardi* is finally killed by the parasite, but *D. simulans* can compete successfully with *D. melanogaster* only where the parasite is present).

Freeland thinks that a species may invade an ecosystem only if its susceptibility to the local parasites is lower than that of the related autochtonous species. This case is probably rather rare because the immigrant, being in contact with the parasite for the first time, may have limited defences. This means that certain parasites can contribute to maintaining the composition of faunas (biodiversity), by protecting them from invasions. A classical example is that of the nematode *Parelaphostrongylus tenuis*, a parasite of the North American white-tailed deer *Odocoileus virginiatus*, which reduces the competition of its host with other ungulates. For instance, the moose *Alces alces* is more susceptible to the parasite than the white-tail deer and experiences important mortality rates when it invades the territories of the white-tailed deer.

The same kind of "protection by parasites" can play a role within a given species, between populations of this species. It is probable that →malaria protected Africans from colonisation until the discovery of quinine and that, nowadays, trypanosomes protect native African ungulates from the introduction of alien species.

Because the impact of parasites on the competition between hosts is often unpredictable, the consequences of introduction of allochtonous species with their parasites can be dramatic: the Caspian sturgeon *Acipenser stellatus* was introduced 40 years ago in the Aral Sea with its monogenean parasite *Nitzchia sturionis* which passed onto the local sturgeon *A. nudiventris*. There this new parasite provoked disastrous mortality rates in the autochtonous species. It is not impossible that the extinction of some vertebrates in the course of geologic times were due partly to parasites.

Finally, the history of the conquest of Latin America is perhaps the best example of the impact of "new" parasites on host populations. Black estimates that more than 50 million native Americans died from pathogens introduced by the invaders. This recalls the sentence of Haldane: "a non-specific parasite to which partial immunity has been acquired, is a powerful competitive weapon."

Host Endocrine System

General Information

A possible strategy for a successful adaptation of a parasite to its host is the induction of conditions favourable for its own development and metabolism by manipulating the endocrine system of the host. This same goal can also be reached by producing hormones which are similar to host hormones and which mimic their actions (→Gastrointestinal Hormones, →Growth Factors). Modification of the endocrine system of the host by a parasite leading to favourable conditions has indeed been found in a variety of host–parasite interactions in both invertebrates and vertebrates and practically every hormone system in a host might be involved. Changes in hormone titres of the host may not only be seen under the aspect of favourable for the parasite but may also represent adaptations of the host to a disadvantageous condition. For example, the reduced level of thyroxine in severe →falciparum malaria patients is interpreted as an adaptation of men to accelerated catabolism. One also has to keep in mind, that one hormone might act in various ways, may be dependent on the parasite species. In the case of nematode-infected mammals thyroxine exerts its influence presumably via the immune system of the host.

Manipulation Mechanisms

Manipulation of the host's endocrine system in order to improve the living conditions for the parasite involves several mechanisms:

- Maintenance of an adequate food and energy supply (→Ecdysteroids, →Gastrointestinal Hormones, →Growth Factors, →Insulin, →Juvenile Hormones).
- Induction of immunosuppression, not only by interfering with immunomodulatory steroid hormones (→Sex Steroid Hormones, →Glucocorticoids), but also by the induction of specific defence molecules. A newly described Ig-superfamily member from the snail *Lymnaea stagnalis* is downregulated during the course of parasitosis with the trematode →*Trichobilharzia ocellata*.
- Induction of analgesia in the host (→Opioids).
- Control of the speed of development, an adequate body size and reproduction of the host. These diverse effects might be brought about by one and the same hormone. For example, higher juvenile hormone concentrations in larval stages of insects increase body size, prolong larval life and prevent reproduction, whereas in females →juvenile hormones induce vitellogenin synthesis in the fat body and facilitate vitellogenin uptake into →oocytes. Both processes are inhibited in females if they are infected by metacestodes. In the *Lymnaea-Trichobilharzia* system mentioned above, not only is immunosuppression induced by the →cercariae but also the synthesis and/or release of a peptide, called schistosomin, which has cytokin-like functions without being a cytokine and which leads to →castration and giant growth in the snail host (→Ecdysteroids, →Growth Factors, →Juvenile Hormones).

All these processes are under hormonal control and may be the result of a rapid and direct change in gene expression in the host, evoked by the parasite. Of course these processes can also be regulated by other factors and they may not be realised simultaneously. It is also not clear in all instances whether the changes in the host's hormonal system are specific or general stress reactions.

Host Finding

Many parasite stages reach and infect their hosts, and an increasing amount of research is concerned with the question of how the parasites find and recognize their hosts. In most cases where host-finding behavior has been analyzed in some detail, it has been found to consist of a series of different behavioral phases. In each of these phases the parasites may respond to different environmental or host signals, a fact which often complicates the experimental analysis of host-finding behavior. Most information on the complex nature of host finding is available in →helminth parasites for digenean miracidia and →cercariae (→Digenea), and →nematode larvae, and in bloodsucking arthropods for →mosquitoes, →tsetse flies and →ticks (for details see *host finding* in the entry of the respective group).

The mechanisms of host finding and host recognition in these better-studied parasite groups support the following views. Most parasites which actively reach and infect their hosts have evolved very complex behavior patterns for finding their hosts and most of them achieve a narrow range of host-specificity. This is also true for stages which are produced in very large numbers (e.g., trematode cercariae). Another typical characteristic of host finding is a high diversity of host recognition strategies. Normally, each species finds and identifies its host with mechanisms and in response to host signals that differ from those of other species, even when these attack the same host genera. The high complexity, specificity, and diversity of host recognition strategies suggest that host finding and host recognition are important determinants in the evolution of parasitism.

Host Hormone Effects on Parasites

Some parasites are considerably affected in their development by host hormones (Table 1).

Host Response

→Pathology.

Host-Parasite Interface, Protozoa

The protozoan parasites developed a great variety of contacts to their hosts. The origin of parasitism started surely from free-living stages, that entered the

Host Hormone Effects on Parasites. Table 1 Examples of host hormone effects

Parasite	Hormone	Parasite stage	Effects
Entamoeba histolytica	Cortisol	Trophozoites	↑ Reproduction, ↑ metabolic activity
Leishmania mexicana	GM-CSF	Promastigotes	↑ Growth
Trypanosoma cruzi	EGF	Amastigotes	↑ Growth, ↑ reproduction, ↑ metabolic activity
Plasmodium falciparum	Cortisol	Merozoites	↑ Growth, ↑ reproduction
Schistosoma mansoni	Cortisol	Adult worms	↓ Reproduction, ↓ oviposition

EGF: Epidermal growth factor

hollows of the host's body. Then more or less fixed attachments to inner surfaces occurred and finally penetration into cells took place. Once inside, the parasites became situated directly in the →cytoplasm or were included into parasitophorous →vacuoles (→Host Cell Invasion, →Coccidia). From the latter several genera (e.g., *Toxoplasma*, →*Sarcocystis*, →*Frenkelia*, →*Besnoitia*, →*Cystoisospora*, *Hammondia*, *Neospora*, *Caryospora*) formed so-called tissue-cysts by →fortification (= formation of a →primary cyst wall) and development of species-specific protrusions of the original membrane of the parasitophorous membrane (→Tissue-Cyst). The main features are summarized in Table 1.

House Fly

Musca domestica (→Diptera).

HRP-1 Protein

→Knobs, →*Plasmodium falciparum*.

HSC

→Hepatic Stellate Cells.

Human Botfly

→Dermatobia hominis.

Human Parasitic Diseases: Origins

Like other host species, humans harbour 2 kinds of parasites, from an evolutionary point of view. Some of them have been parasitic in the hominid lineage for a long time and have coevolved with our primate ancestors. Others are the result of lateral transfers (or "host-switchings").

The classical example of parasites which are probably inherited from our primate ancestors is the nematode →*Enterobius vermicularis*, simply because all other primates harbour species closely related to "our" parasite. This does not mean that lateral transfers of oxyurids did not occur between some species of primates but these transfers occurred inside the phylum.

The classical example of human parasites which are certainly the result of "true" lateral transfers is provided by schistosomes. There is no evidence that schistosomes evolved in primate hosts. On the contrary, a phylogeny based on DNA sequences showed that they have evolved in host phyla, rodents and ungulates. These studies led to the conclusion that the human parasite →*Schistosoma mansoni*, the agent of intestinal schistosomiasis, is close to a rodent parasite, whereas the human parasite →*S. haematobium*, the agent of urinary schistosomiasis, is related to ungulate parasites. It is probable that the schistosomes were acquired by hominids when they increased their contact with water sources in the African savannahs. The period of the host switching was tentatively suggested to be about 2 million years ago, on the basis of molecular comparisons. The origin of the genus *Schistosoma*, as deduced from molecular phylogny, is in Asia.

Similarly, on the basis of molecular studies, it has been proposed that →*Plasmodium falciparum* could be the result of a transfer from birds to humans, and also because the shape of the parasite ("*falciparum*") seems better adapted to the shape of an avian red cell (oval) than to that of a primate red cell (circular).

Anderson and Jaenike have considered →*Ascaris* from humans and pigs, which are morphologically closely related. Taking into account that domestication of pigs occurred between 7,000 and 20,000 years before the present time, the authors ask the question: did humans acquire the parasite from pigs or the contrary? Their study of the introns of several nuclear genes, of ribosomal DNA spacers, and of a part of →mitochondrial DNA, suggests that the pigs are the ancestral hosts and that all the *Ascaris* of present-day humans originate from a unique event of lateral transfer from pigs, which could have occurred in Asia.

Many other parasites of mankind are probably the result of lateral transfers due to the invasion of new ecosystems and the acquisition of new behaviours by humans, which put them in contact with infective stages of parasites which had evolved in other phyla. The transfer is of course sometimes impossible. For instance, swimmers are frequently infested in lakes by →cercariae of various bird schistosomes, but the disease is limited to a dermatitis (→"Swimmer's Itch") because the schistosomulae cannot mature into adult worms.

A lateral transfer is not necessarily followed by a →speciation process. Humans may simply become a new species in the host-spectrum of the parasite. This has consequences on pathogenicity: when parasites have a wide host-spectrum, the optimal pathogenicity (→Virulence) cannot be selected in every host species. The pathology may remain either sub-optimal or over-optimal. This causes a permanent maladaptation of the parasite to certain of its hosts, sometimes to humans.

Humoral Immune Response (HIR)

HIR is concerned with B-lymphocyte cell products (i.e., formation of immunoglobulin (Ig) antibodies. The IgA, IgG, IgM, and IgE occur in different situations and are effective against parasites in different ways (e.g., neutralization of invading stages, agglutination, complement activation, facilitated opsonization, etc.).

Hunterella

Genus of ichneumonid wasps, which parasitize as larvae in ticks. In some regions of West Africa *H. hookeri* kills about 90% of the nymphs of *Rhipicephalus sanguineus*.

Hyalomma

Name

Greek: *hyalos* = glass, *omma* = eye.

General Information

Genus of hard →tick species with two hyaline eyes (name); about 30 species are found in arid or semi-arid species in Africa, Asia, and southern Europe. Important as vector of →*Theileria* stages is *H. anatolicum anatolicum* on ruminants and horses, while *H. marginatum* occurs on birds and *H. aegypticum* on turtles. The life

cycle may be completed in less than 4 months, thus the infection risk is increased by this short period as well as by the fact that *Hyalomma* spp. may depone more than 10,000 eggs.

Hyaloplasm

Synonym
→Ectoplasm.

Hybridization

Formation of progeny between 2 different species (e.g., →*Schistosoma mansoni* and →*S. japonicum* or →*Fasciola hepatica* and *F. gigantea*).

Hydatid Disease

Synonyms
→Hydatidosis, cystic →echinococcosis.

Hydatidosis

→Echinococcus, →Echinococciasis.

Hydatids

Large (up to 20 cm in diameter), fluid-filled cysts formed by →Echinococcus granulosus inside intermediate hosts (e.g., sheep, humans). The aqueous fluid contains thousands of →brood capsules and protoscolices that are infectious to the final hosts (e.g., dogs, foxes).

Hydatigera taeniaeformis

Synonym of →*Taenia taeniaeformis*, →cestodes; tapeworm of cats and other felids reaching a length of up to 60 cm; intermediate hosts are rodents harbouring so-called →strobilocercus larvae.

Hydrocephalus

→Toxoplasmosis, Man/Pathology.

Hydrogen

→Energy Metabolism.

Hydrogenosomes

The →trichomonads, which are anaerobic, have →microbodies called hydrogenosomes. They are limited by mostly 2 closely attached membranes surrounding a granular matrix (→Trichomonadida/Fig. 1C, E). The enzyme system of these bodies differs from that of →mitochondria, as they metabolize pyruvate from →glycolysis into acetate, CO_2 and H_2. In ciliates, similar hydrogenosomes with double membranes are present, in addition to regular →mitochondria (→Energy Metabolism).

Hydropene

Chemical Class
Juvenile hormone agonist (juvenile hormone analogue).

Mode of Action
Insect growth regulator (IGR, juvenile hormone mimics). →Ectoparasiticides – Inhibitors of Arthropod Development.

Hydrotaea

Genus of the fly family Muscidae; important species are *H. irritans* (5.5–7 mm long) of cattle being called head and udder fly. The larvae live in the feces, highest

activity is in July and August. This fly is involved in the disease described as summer mastitis. On horses *H. albipuncta* occurs in addition to *H. irritans*. →Ectoparasiticides.

Hydroxychloroquine

→Malariacidal Drugs.

Hydroxyquinoline Derivatives

→Malariacidal Drugs.

Hygiene

Science of health and its preservation. →Disease Control, Methods.

Hygienic Behavior

→Behavior.

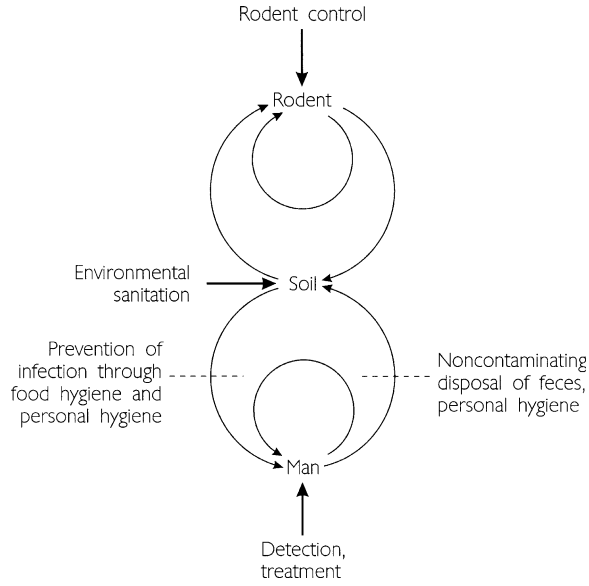
Hymenolepiasis

General Information

The cestode *Hymenolepis nana* (syn. →*Rodentolepis nana*) is primarily a parasite of rodents, but is also frequently found in man where it is autoreproductive, but in general not very pathogenic. Figure 1 shows the presence of man-man, rodent-rodent, man-rodent, and rodent-man cycles.

Targets for Intervention

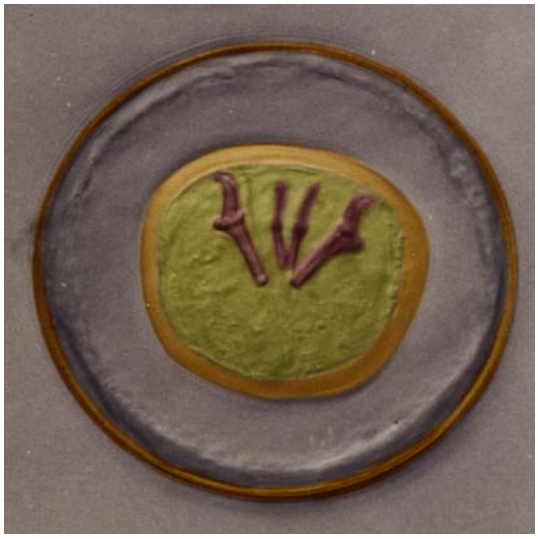
Possible targets are the rodent reservoir, the human cases, transmission both from and to man, and the environment where infective material may be encountered (Fig. 1). It is evident that one approach on its own will probably do very little to improve the situation.



Hymenolepiasis. Figure 1 Targets and approaches for the control of hymenolepiasis.

Hymenolepiasis. Figure 2 LM of an egg of *Hymenolepis nana*.

Main clinical symptoms: Malnutrition, →*diarrhoea*, →abdominal pain.
Incubation period: 1–4 weeks.
Prepatent period: 2 months.
Patent period: 2–4 weeks.
Diagnosis: Microscopic diagnosis of eggs in fecal samples (Figs. 2, 3).
Prophylaxis: Avoid contact with rodent and human feces.
Therapy: Treatment with praziquantel, →Cestodocidal Drugs.



Hymenolepiasis. Figure 3 LM of an egg of *Hymenolepis diminuta*.

Hymenolepidae

Name
Greek: *hymen* = fine membrane, *lepis* = scale.

Classification
Family of →Eucestoda.

Life Cycle
Figs. 1–6 (pages 626, 627).

Disease
→Hymenolepiasis.

Hymenolepis diminuta

From Greek: *hymen* = thin membrane, *lepis* = cover. →Cestodes, →Hymenolepidae.

Hymenolepis microstoma

→Cestodes, →Hymenolepiasis.

Hyostrongylus

Name
Greek: *hyo* = belonging to, *strongylos* = rounded.

Classification
Genus of the nematode family Trichostrongylidae.

General Information
This so-called red-stomach-worm of pigs reaches as female about 1.2 cm in length, the males are only 0.7 mm long. The worms suck blood in the stomach and after copulation the 70–85 mm × 40 mm sized eggs appear in the faeces. After some days the larva 1 hatches from the egg and develops into larva 2, which survives often for 1 year in the food. After oral uptake the larva 3 develops within 3 weeks (including 2 moults) into the adult stage.

Disease
→Alimentary System Diseases, Swine.

Hyostrongylus rubidus

→Nematodes.

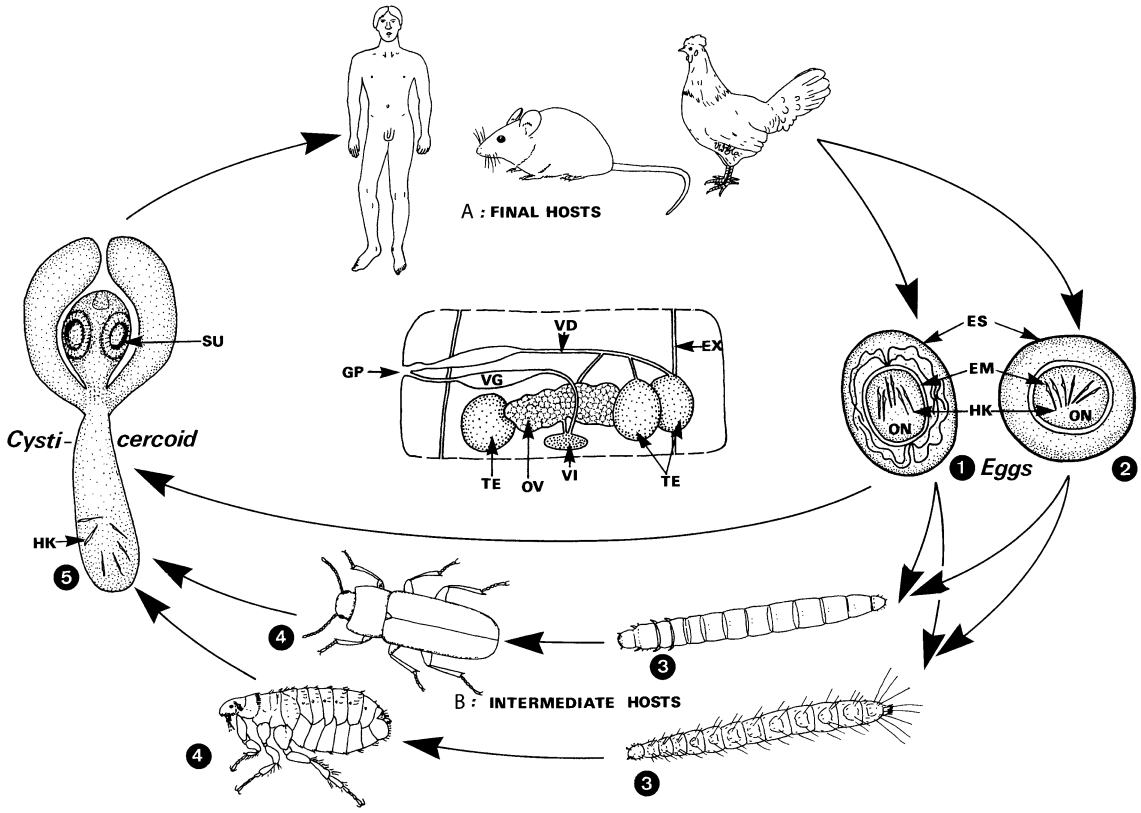
Hypergammaglobulinemia

Symptom of disease in cystic →echinococcosis and in →malaria being characterized by an enormous amount of gamma-globulines in the blood.

Hyperinfections

Name
Greek: *hyper* = over, Latin: *inficere* = infect.

Infections with enormous amounts of parasites, which then disseminate also in other than the normal organs, e.g., in →*Strongyloides stercoralis*, →*Capillaria philippiensis*. This often is the case, when →autoinfection is possible.



Hymenolepidae. Figure 1 Life cycle of →tapeworms of the family Hymenolepididae. **A** Species and final hosts (others see →Eucestoda/Table 1): →*Rodentolepis (Vampirolepis, Hymenolepis) nana (fraterna)* of mice and humans, 4–6 cm long and 1 mm broad, scolex with 24–27 rostellar hooks; →*Hymenolepis diminuta* of rats, mice, dog, and humans, up to 6 cm long and 3.5 mm broad, no rostellar hooks; *Echinolepis (Hymenolepis) carioca* of chickens and birds. →Strobila up to 8 cm long and 3–5 mm broad, scolex has no rostellar hooks. The sexually mature →proglottids are characterized by 3 spherical testes (TE); there is no distinct border wall between the proglottids *(dotted lines)*. **B** Intermediate hosts (→Eucestoda/Table 1). *1–4* Eggs containing the →oncosphaera larva (1 *H. nana*, 40–60 × 30–50 gm; 2 *H. diminuta*, 60–80 × 70 µm) are infectious to various insects (larvae, adults) as intermediate hosts (3, 4). *5* Inside the body cavity of these hosts a second larva (→Cysticercoid) is formed, which grows to be a mature tapeworm when the →intermediate host is swallowed by the final host. In *H. nana* the intermediate host is optional; when eaten by a man or a rodent, the egg (1) hatches in the duodenum, releasing the →oncosphaera, which penetrates the mucosa. Here it develops directly into a cysticercoid (5). In about 6 days the →cysticercoid emerges into the lumen of the small intestine, where it attaches and grows to be a mature worm. *EM*, →embryophore (layer surrounding the oncosphaera); *EX*, excretion system (longitudinal); *ES*, →eggshell; *GP*, genital pores; *HK*, hooks of oncosphaera; *ON*, oncosphaera; *OV*, ovary (→Germarium); *SU*, sucker; *TE*, →testis; *VD*, vas deferens; *VG*, vagina with enlarged seminal vesicle; *VI*, →vitellarium.

Hyperkeratosis

Symptom of diseases due to →*Onchocerca volvulus*. The microfilariae in the skin indroduce an immune reaction described also as “paper skin.”

Hypermastigida

Classification

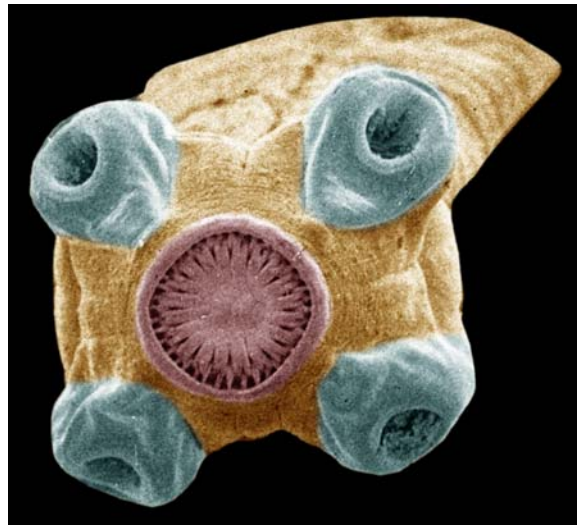
Order of →Mastigophora.

Hymenolepidae. Figure 2 SEM of an adult of *Hymenolepis nana*.

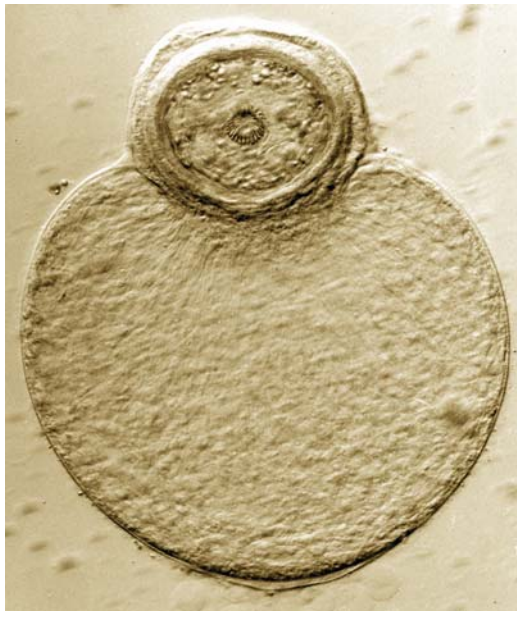
General Information

Members of the Hypermastigida (Fig. 1, page 628), like the →Oxymonadida, inhabit the intestine of wood-feeding insects and are involved in the digestion of cellulose; however, the question of whether they

Hymenolepidae. Figure 3 SEM of the scolex of *Hymenolepis nana*.



Hymenolepidae. Figure 5 SEM of the scolex of *Hymenolepis microstoma*.



Hymenolepidae. Figure 4 TEM of the cysticercoid of *Hymenolepis nana*.

Hymenolepidae. Figure 6 LM of *Hymenolepis diminuta* (this species has no hooks at the scolex).

produce the necessary enzymes themselves or whether they are obtained from endosymbiotic bacteria, has not yet been answered. Others are found in the intestine of cockroaches (e.g., →*Barbulanympha*, see →Gametes). This group is characterized by the occurrence of many repeated sets of 4 apical →flagella, which are arranged in a trichomonadid-like basal pattern, thus giving them the appearance of a wild tuft. Reproduction occurs by longitudinal division, while also sexual processes are unknown. During this process the flagella become resorbed except for a set of 4; their duplication initiates the →cell division and the final formation of other flagella sets. In some species transmission occurs by oral uptake of fecally passed cysts.

Hypermastigida. Figure 1 LM of a specimen of the order Hypermastigida from the intestine of cockroaches.

Hypermastigina

Order of flagellates with numerous apical →flagella, →Barbulanympha.

Hyperparasitism

A second type of parasite is hidden inside a parasite and thus is also fed indirectly by the host.

Hyperplasia

From Greek: *hyper* = over and above, *plasso* = formation. Some parasites introduce an enlargement of organs. →Pathology.

Hypersensitivity

→Pathology.

Hypertrophy

Enlargement of cells due to parasitism, e.g., →*Theileria* schizonts, →*Trichinella*.

Hypnozoites

Stages (sporozoites, merozoites of →malarial parasites) that stay within host cells (e.g., liver cells) and start reproduction only after a longer phase of inactivity. They are also called dormozoites (→Plasmodium/Fig. 2).

Hypoalbuminaemia

Clinical symptom in animals due to parasitic infections (→Alimentary System Diseases, →Clinical Pathology, Animals).

Hypobiosis

Delayed ongoing of development (→Trichostrongylidae/Life Cycle, →Lungworms, →Nematodes).

Hypodectes

Genus of mites in the nests of birds (e.g., *H. propus* of doves).

Hypoderaeum

→Digenea.

Hypoderma

From Greek: *hypo* = below, *derma* = skin. →Diptera.

Hypoderma bovis

Synonym

→Warble Fly.

Classification

Species of →Diptera.

Life Cycle

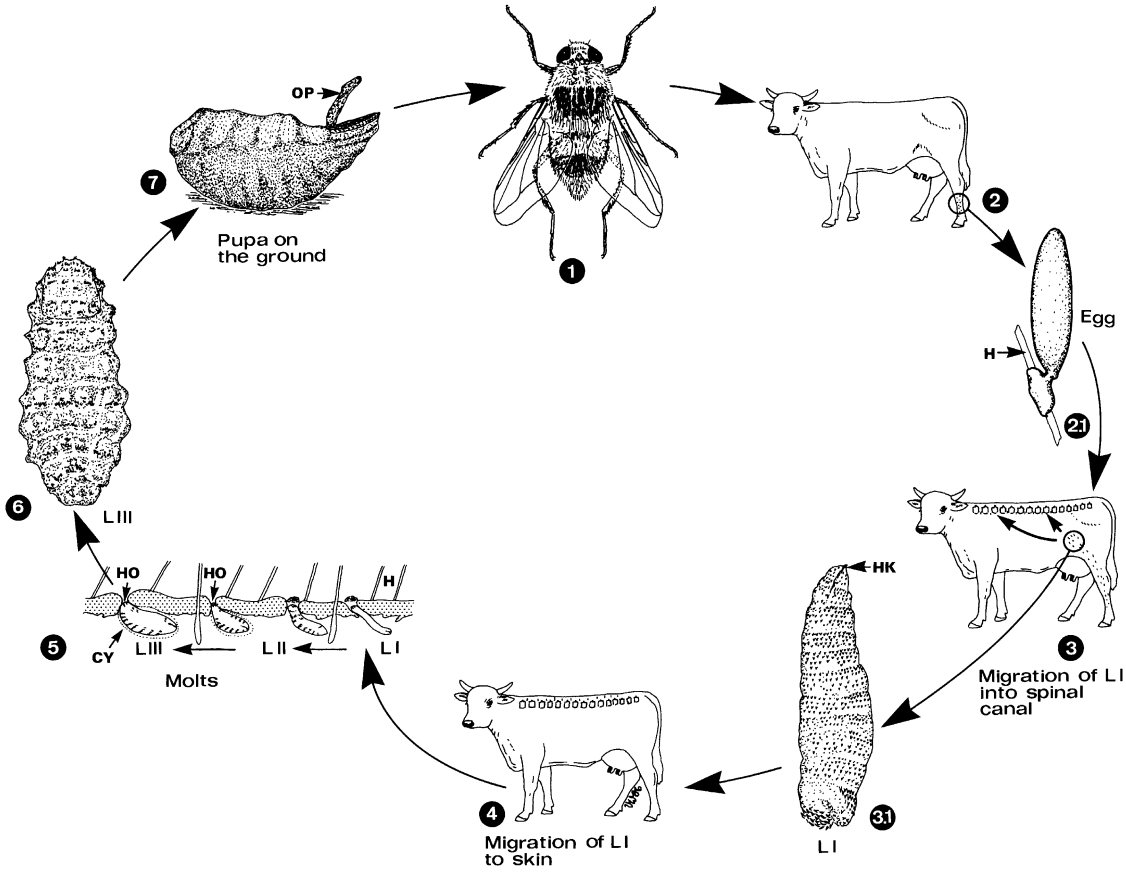
Figs. 1–4.

Diseases

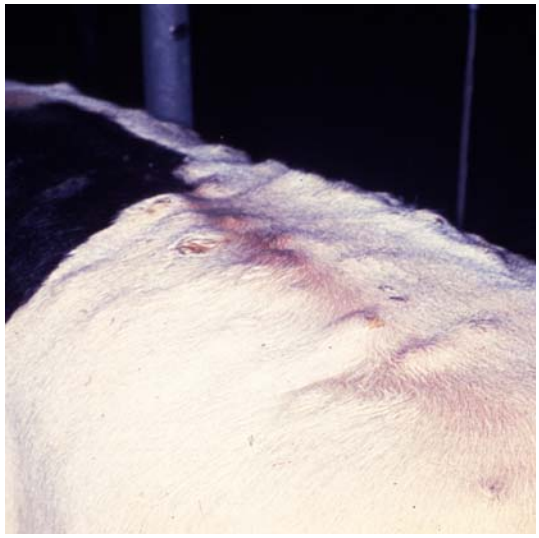
→Nervous System Diseases, Horses, →Skin Diseases, Animals.

Hypoderma lineatus

→Diptera, →Nervous System Diseases, Horses, →Skin Diseases, Animals.



Hypoderma bovis. Figure 1 Life cycle of *Hypoderma bovis* (warble fly). *1, 2* Adult females lay several hundred eggs which are singly deposited and become attached to the host's hair (2.1) by an attachment organ. The first-stage larva hatches from the egg in about 4 days, crawls down the hair, and penetrates the skin. *3* The exact route taken by migrating larvae in the host is not known, but after several months they reach the final site, the epidural fat of the spinal canal (3.1). *4–6* At the beginning of the year the L_1 leave the spinal canal and move to their final site on the back; this is an area of 25 cm on either side of the midline from shoulder to tail and is where the cysts (=warbles) are formed from March to July. The L_1 (3.1) measures about 10 mm in length just after arrival; it molts into the second-stage larva soon after reaching the skin and cuts a hole (HO) in it through which it respires by means of paired terminal →spiracles After →molt the third larval →instar appears and then develops into the 30-mm-long prepupa (6). After several weeks the yellowish-brown prepupa forces its way through the skin's opening, drops to the ground and moves actively seeking shelter. *7* The pupal stage needs 3–10 weeks depending upon external conditions (*H. lineatum* needs 4 weeks or less). Adults of *Hypoderma bovis* appear from June to mid-September, are unable to feed, and live for only 3–5 days; they emerge early in the day and mate within 1 h. *CY*, cyst, or warble; *H*, hair; *HK*, larval mouth hooks; *HO*, hole in the skin; *OP*, opening (for emergence) in the pupal →cocoon.



Hypoderma bovis. Figure 2 Cow with several nodules containing larvae of *Hypoderma bovis*.

Hypoderma bovis. Figure 3 Extraction of a larva 3 of *Hypoderma bovis*.

Hypodermis

→Arthropoda, →Body Cover, →Nematodes.

Hypodermosis

Disease due to infestation with grub flies (Table 1, page 631).

Hypoderma bovis. Figure 4 LM of an extracted larva 3 of *Hypoderma bovis*.

Hypoglycemia

A frequently encountered complication in *Plasmodium falciparum* →malaria, which is apparently based on increased use of glucose and impaired glucose production due to inhibition of gluconeogenesis.

Hypopus

In members of the Acaridida the →deutonymph is completely different from the preceding and the following stage with respect to morphology and behavior. This so-called hypopus stage has no functional mouthparts and is a facultative developmental route which may be present in the life cycle of a mite generation. This special phenotype of a deutonymph can survive bad environmental influences much better than the normal form. The hypopodes are able to attach themselves to animals by ventral suckers or claspers and are thus transported to new environments or hosts (→Phoresis). In the genus →*Glycyphagus* inert hypopodes occur, which remain within the exuvia of the protonymphs; they are not provided with organs to fix themselves and thus can be moved by air currents. In certain members of the family Glycyphagidae (e.g., *Rodentopus sciuri*) the hypopus also lacks organs for attachment. The hypopus forms of these →mites are found in the subepidermal tissues of various animals. →Mites/Ontogeny.

Hypodermosis. Table 1 Grub and warble flies and control measurements

Parasite	Host	Symptoms	Country	Therapy		
				Products	Application	Compounds
Hypoderma bovis (Northern cattle grub)	Cattle, (Horse)	Cattle have a panic fear of flying *Hypoderma* and try to escape; inflammation of skin with strong exsudation, then encapsulation, fistula; high economic loss through skin damages, loss of fattening performance (meat loss), milk loss	Europe, Former Soviet Union, North America, Africa, Asia	Neguvon (Bayer): No treatment during migration	Wash or Spray	Trichlorfon/ Metrifonate
				Warbex Famphur Pour-on for Cattle (Schering Plough)	Pour-on	Famphur
				Co-Ral 25% Wettable Powder (Bayer)	Dip or Spray	Coumaphos
				Ivomec 1% Injection for Cattle (Merial)	Injection	Ivermectin
				Dectomax (Pfizer)	Injection	Doramectin
				Cydectin (Bayer)	Injection	Moxidectin
Hypoderma lineatum (Common cattle grub)	Cattle, (Horse)	Creep on the cattle, no fear	In areas with an early spring, early drive to pasture	Co-Ral 25% Wettable Powder (Bayer)	Dip or Spray	Coumaphos
				Warbex Famphur Pour-on for Cattle (Schering Plough)	Pour-on	Famphur
				Ivomec 1% Injection for Cattle (Merial)	Injection	Ivermectin
				Dectomax (Pfizer)	Injection	Doramectin
				Cydectin (Bayer)	Injection	Moxidectin
Przhevalskiana silenus (syn. Grivellia)	Goat, rare Sheep	Inflammation of skin with strong exsudation, then encapsulation, fistula; high economic loss through skin damages, loss of fattening performance (meat loss), milk loss	Mediterranean area			
Dermatobia hominis (Tropical warble fly or torsalo)	Cattle, Dog, Humans, etc.	Inflammed skin pustules	Latin America	Co-Ral 25% Wettable Powder (Bayer)	Dip or Spray	Coumaphos
				Warbex Famphur Pour-on for Cattle (Schering Plough)	Pour on	Famphur
				Ivomec 1% Injection for Cattle (Merial)	Injection	Ivermectin
				Dectomax(Pfizer) Topline (Merial)	Injection Pour on	Doramectin Fipronil

Hypostome

Ventral part of the gnathosoma of →ticks (→Ticks/Alimentary System).

Hypoxia

From Greek: *hypo* = below, *oxys* = oxygen. Lack of oxygen. Endoparasites have to develop systems to survive this lack →Anaerobiosis.

Hysterosoma

From Greek: *hystera* = uterus, *soma* = body. This term describes the 3rd and the 4th, legless abdominal region of →Acari.

Hysterothylacium aduncum

Nematode species in the mesenteries and intestine of flat fish of Baltic sea.

Hystrichis tricolor

Species belonging to the family Dioctophymatoidea (→*Dioctophyme renale*). *Hystrichis tricolor* appears 3-colored, reaches a size of 40 mm in females, 25 mm in males, and lives in the digestive stomach of wild and domestic birds in Europe. Intermediate hosts are earthworms.

Icaridin (Bayrepel)

Chemical Class
Repellent.

Mode of Action
Olfactory reception.

Ichthyobodo necator

Synoym
Costia necatrix.

Classification
→Phylum Euglenozoa, Classis Trypanosomatidea, Order Bodonida.

Morphology
The spherical, free-swimming (10–20 µm × 6–10 µm) swarmer has 2 flagella (9 and 18 µm long) and a long typical mitochondrial kinetoplast (Fig. 1). The reproduction occurs by binary fission. The free-swimming stages become attached to the surface of a fish and then appear pear-shaped (Fig. 2, page 634) and develop a chitinous layer as outer cover.

Life Cycle
After feeding the fixed trophozoites (Fig. 2) detach from the skin, sink to the ground, close the feeding opening, and thus become a cyst, within which 256 so-called dinospores (or swarmers) are formed, which must find a host within 24 hours.

Therapy
Flagellol™ (Sera), (nitroimidazoles).

Ichthyonema

Name
Greek: *ichthys* = fish, *nema* = filament.

Synonym
→*Philometra* spp. of fish nematodes, which reach as females a length of 5 cm and a diameter of 1 mm (males 2–3 mm long). They parasitize inside blood vessels, body cavity, and in/on the gills. *Cyclops*-crustaceans are apparently the intermediate hosts.

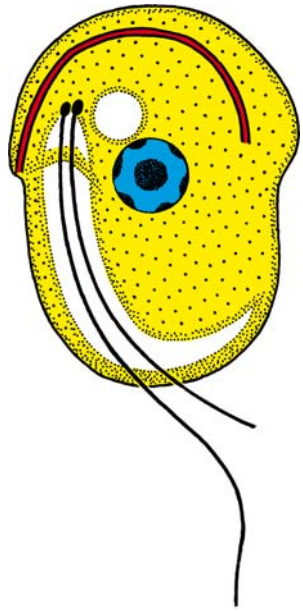
Ichthyophthiriasis

Disease of free freshwater and ornamental fish due to an infection with the holotrich ciliate →*Ichthyophthirius multifiliis*, which lives between the epidermis and the corium. Infection can be diagnosed by the occurrence of white dots on the skin (= other name for the disease: white-dots disease). Fish try to get rid of the apparently itching parasites by scrubbing at stones etc.; their fins are kept compressed. If gills are highly infected, fish show apathy, do not feed, are seen in a lateral upside-down position, do not show escape-reflexes and may die due to inflammation of the skin lesions within 4–5 days.

Therapy
Protazol™ (Sera/Alpha-Biocare).

Ichthyophthirius multifiliis

Name
Greek: *ichthys* = Fisch, *phtheiros* = louse; Latin: *multus* = much, *filia* = daughter.



Ichthyobodo necator. Figure 1 Diagrammatic representation (DR) of the swarmer of *Ichthyobodo necator.*

Ichthyobodo necator. Figure 2 DR of the skin-attached trophozoite of *Ichthyobodo necator.*

Classification
Species of →Ciliophora, phylum Alveolata.

Life Cycle
Figs. 1–3 (page 635).

Disease
→White Dot Disease; name: →Ichthyophthiriasis: fish appear with white spots (Fig. 2). Due to the feeding of the trophozoites in the skin (Fig. 3) superinfections with bacteria occur and the fish often die due to lack of oxygen.

Therapy
Protazol® as medical bath.

Ichthyosporidium

→Microsporidia.

Icterus

Symptom of infections with the yellow fever virus, A-hepatitis, or liver infections due to parasites.

Idiosoma

Main portion of the body of →Acarina, being subdivided into the podosoma (bearing the walking legs and the genital pore) and the opisthosoma. The latter is the region posterior to the leg coxae and the anal aperture.

Idiosyncrasia

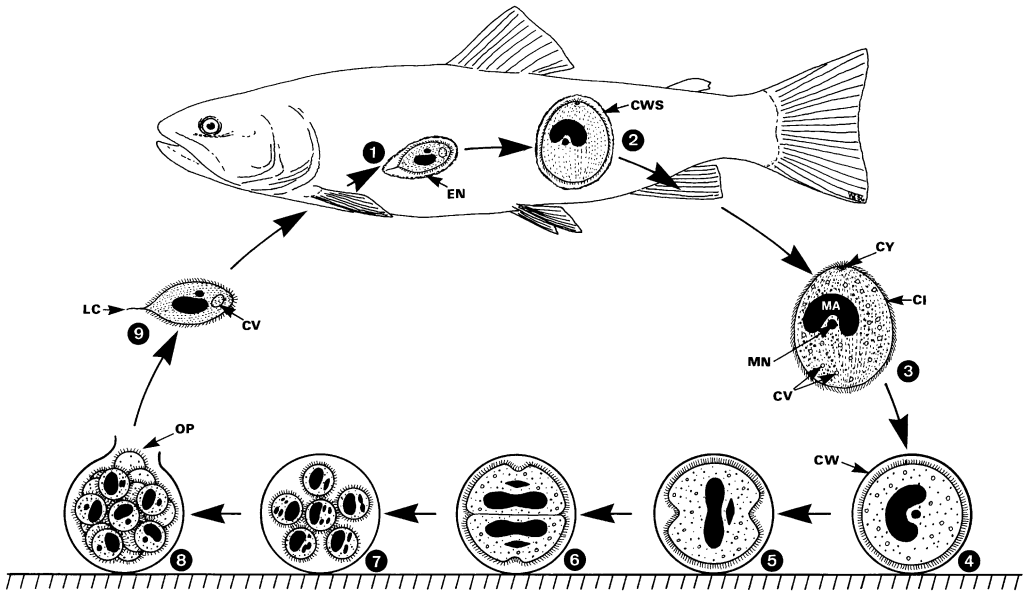
Effect of high dosages of chinin lead in malaria to black urine excretion.

IFA

Indirect fluorescent antibody assay.

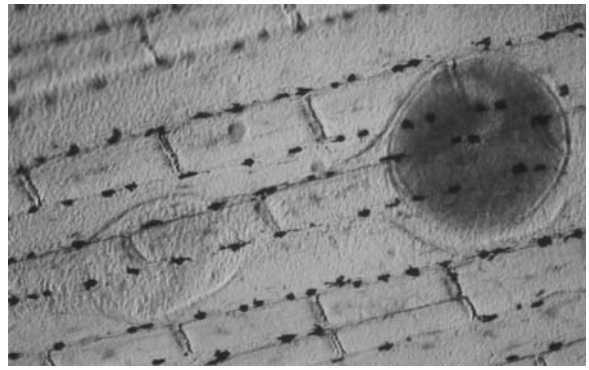
IFAT

Indirect fluorescent antibody test.



Ichthyophthirius multifiliis. Figure 1 Life cycle of *Ichthyophthirius multifiliis* parasitizing many species of freshwater fish. *1* →Swarmer penetrates the skin of a fish and becomes encysted (*EN*) by host tissues. *2* The encysted →swarmer grows to be a trophozoite, reaching a diameter of up to 1 mm; the skin then presents with a large grayish pustule at these places. *3* Upon rupture of the pustules the →trophozoites, which have numerous contractile →vacuoles, are liberated and swim about feebly. Upon coming to rest on the bottom of the pond the →trophozoite secretes a thick-walled gelatinous cyst wall about itself. *4–8* Within an hour of →Encystation the mother trophozoite starts reproduction by simple transverse division, this being repeated until up to 1,024, 30–50 μm long, pear-shaped swarmers (with a single →contractile vacuole) are formed. *9* After rupture of the cyst, the liberated swarmer attaches to the skin of fish within 1 day (unattached ones die during the second day). *CI*, →cilia; *CV*, contractile vacuole; *CW*, cyst wall of cysts on the bottom of the pond; *CWS*, cyst wall in skin; *CY*, →cytostome; *EN*, encysting swarmer; *LC*, long terminal cilium; *MA*, →macronucleus; *MI*, →micronucleus; *OP*, opening rupture of CW; *SW*, swarmer.

Ichthyophthirius multifiliis. Figure 2 Black molly fish with white dots of *Ichthyophthirius*.



Ichthyophthirius multifiliis. Figure 3 LM of the skin of a fish with a trophozoite of *Ichthyophthirius multifiliis* in a feeding tunnel.

IHA

Indirect hemagglutination assay.

IHAT

Indirect hemagglutination test.

Imago

An →insect in its final, adult, sexually mature, and often winged state.

Imidacloprid

Chemical Class
Neonicotinoide.

Mode of Action
Nicotinic acetylcholine receptor agonist. →Ectoparasiticides – Agonists and Antagonists of Cholinergic Transmission, →Insecticides, →Ectoparasitocidal Drugs.

Imidathiazoles

→Nematocidal Drugs.

Imidocarb

→Babesiacidal Drugs.

Immune Complex

Synonym
Antibody–Antigen Interaction.

General Information
The formation of immune complexes with subsequent clearance is a physiological process during the acute phase of an immune reaction. When antibody-antigen aggregates develop in rising quantities they become detectable in the peripheral blood as so-called circulating immune complexes (→CIC). The formation of CIC is a common event during chronic parasitic infection like schistosomiasis, filariasis, leishmaniasis, trypanosomiasis, toxoplasmosis, and quartan →malaria. Only the deposition of immune complexes may cause severe pathological changes in the host.

During parasitic infection various circulating antigens appear at different developmental stages. Due to a selective immune response only few of them are complexed by antibodies. The antibody–antigen interaction may lead to structural changes in the antigen. The clearance of immune complexes depends on the structure of the antigen and the quality (affinity) and quantity of the antibody.

Immune complexes are able to bind complement compounds and to activate the cellular immune response via Fc-receptors. Resulting pathological changes are either membrane proliferative →glomerulonephritis or, when the antigen is tissue bound, an →Arthur's Phenomenon.

CICs are a common phenomenon in the sera of →*Wuchereria bancrofti*-infected patients. Renal abnormalities like chronic progressive glomerulonephritis are reported for patients with malaria (*Plasmodium malariae*) and →Bancroftian filariasis. Also, a chronic *Leishmania infantum*-infection in dogs may cause glomerulonephritis.

Immune Evasion

Mechanisms developed by parasites to survive the attack of the host immune system (→Immune Responses).

Immune Responses

A general feature of many parasitic infections by →protozoa or helminths is their chronicity and several reasons contribute to this, e.g., weak →innate immunity and the capacity of parasites to withstand or to evade destruction by specific immune responses of the vertebrate host. General aspects of the various host immune responses are described in the following. Peculiarities of the immunological response to specific parasites are described in detail under the headwords of the respective diseases.

Innate Immunity
The skin and the linings of the respiratory, gastrointestinal, and urogenital tract present formidable physical and chemical barriers to infective organisms and represent a first line of defense. These barriers provide a →natural resistance, also called innate immunity, to infection, but they are not perfect. Protozoan and helminthic parasites, have evolved in such a way that

they either are able to penetrate the body's barriers directly or are transmitted by insect bites.

In the body the alternative pathway of complement activation provides a first line of defense against many parasites. The complement component C3 is cleaved spontaneously in plasma to produce C3b; once bound to the parasite surface and stabilized to form a C3 convertase, activation of the terminal complement components C5-C9 takes place, and the parasites are lysed by the major attack complex MAC. A second line of defense is provided by macrophages and neutrophilic leukocytes, which play a major role in all stages of host defense. These cells by means of their CR3-receptors are able to recognize microbial substances and thus ingest the parasites. In addition, Toll-like receptors (TLRs) have been defined as important transmembrane receptors that confer a certain degree of specificity to the cells of innate immune system. TLRs have been implicated in recognition of every known category of pathogen that causes infectious disease. TLRs can recognize minute concentrations of microbial components and orchestrate an early defense, largely dependent on the MyD88-dependent activation of NF-κB, which will trigger microbiostatic/microbicidal effector mechanisms and lead to the production of proinflammatory cytokines thereby also shaping the adaptive immune response. The importance of the TLR-mediated signaling pathways in the host resistance and pathogenesis during parasitic diseases has been demonstrated by experimental infections of MyD88-deficient mice with various protozoan parasites and helminths. The identification of a single TLR involved in the *in vivo* host responses to protozoan parasites has been a more difficult task, because protozoan parasites might be recognized by more than one TLR. Nevertheless, a number of distinct molecules derived from protozoan parasites have been shown to activate cells from the innate immune system via TLRs, e.g., glycosylphosphatidinositol anchors from parasite surface proteins are recognized by TLR2, nucleic acids by TLR3 and TLR9, and a profiling-like protein of *Toxoplasma gondii* by TLR11, respectively. As a result of the TLR-stimulation and the parasite uptake, the secretion of cytokines by phagocytes is initiated which include interleukin-1 (IL-1), IL-6, IL-8, IL-12, and tumor →necrosis factor (TNF). These factors recruit more phagocytes to the site of the infection and an increase in circulating neutrophils. Phagocytes also release other proteins with significant local effects, such as oxygen radicals, peroxides, →nitric oxide, prostaglandines, leukotriens, complement components, etc. Infection of cells with viruses, but also with parasites induced the production of interferon (IFN)-α and -β. These interferons contribute to the inhibition of natural killer cells (NK-cells), cells which are known to function in the initial phase of infection with intracellular pathogens, including parasites such as →Leishmania. Activated NK-cells secrete large amounts of IFN-γ. This IFN-γ is critical for the control of some parasitic infection before T cells have been triggered to liberate this cytokine. A further effect of IFN-α and -β is to augment the expression of MHC class I molecules, which favors the ability of host cells to present parasite antigenic peptides to $CD8^+$ cells (see below). Once parasites have survived the innate immune response, the →acquired immunity comes into effect.

Acquired Immunity

Acquired immunity is mediated by the humoral and cellular immune system, in which the B-lymphocytes are mediators of the humoral responses. Upon direct recognition of the parasites, i.e., antigen, they produce antibodies of different isotypes, that are specific for the antigen. A remarkable difference between bone marrow-derived B and thymus-derived T cells is the inability of T cells to recognize antigens directly as B cells do. T cells, on the other hand, need adequate presentation of antigens mostly by major histocompatibility complex (MHC) molecules expressed on antigen-presenting cells (APCs), such as dendritic cells, Langerhans cells, macrophages, B cells, and vascular endothelial cells. The →T-cells are distinguished according to their T cell-receptor (TCR) and accessory molecules. The TCR is composed of an α and β chain or an γ and δ chain. Accessory molecules are the CD4 or the CD8 marker.

Antigen Presentation

Before further discussing the functions of the T cells, interest will be focused on the MHC and →antigen presentation. MHC genes are organized in a gene complex of about 3.5 mb on chromosome 6 in man. Several classes of molecules are encoded in this gene complex, of which the MHC class I and class II molecules are central to antigen presentation. MHC class I molecules are formed by a variable polypeptide chain and a constant β-2 microglobulin. The MHC class II molecules represent heterodimers composed of variable α and β chains. Association of antigen with MHC molecules occurs inside the antigen-presenting cell and processing of foreign antigen to peptide fragments is an essential prerequisite for successful association and presentation. The complex of the MHC molecule and antigen peptide is transported to the cell surface and presented to T cells. MHC class I and II molecules can be subdivided into classical and nonclassical MHC molecules. Classical class I molecules are encoded in man by the HLA-A, -B, and -C genes. These highly polymorphic molecules present processed peptides to $CD8^+$ T cells. Nonclassical class I molecules are much less polymorphic and are encoded

by HLA-E, -F, and -G. Their function in man is still ill-defined. In the mouse, the related Qa-1 and Qua-2 molecules present a restricted set of peptide antigens, for instance a fragment of lysteriolysin, to $CD8^+$ T cells. Classical MHC class II molecules in man are encoded by HLA-DP, -DQ, and -DR. These molecules present processed peptides to $CD4^+$ T cells. Nonclassical class II molecules, such as DMA and DMB, appear to support classical class II molecules in antigen presentation.

CD1 molecules form a non-MHC-encoded family of molecules involved in antigen presentation. As class I molecules, they are composed of a polymorphic α chain and β2-microglobulin. So far, the isoforms CD1 a-e have been described in humans. Recently, it became apparent that CD1 molecules act as restriction elements in the presentation of several mycobacterial lipids, such as mycolic acid, and glycolipid antigens, such as lipoarabinomannan to T cells. Interestingly, CD1 molecules seem to present nonpeptide antigens not only to classical T cells but also to the recently described subsets of $CD4^+$ NKT 1. 1^+ and $CD4^-$ $CD8^-$ NK 1 . 1^+ T cells, that are also designated as natural killer T cells or NKT-cells. These NKT-cells, because of their capacity to produce interleukin 4 and other cytokines, can potentially influence the phenotype of the immune response to class II-restricted antigens. Their role in parasite infection, however, is still unclear.

Whether an antigen will be processed and presented with class I or class II MHC molecules appears to be determined by the route that the antigen takes to enter a cell. Exogeneous antigen is produced outside of the host cell and enters the antigen-presenting cells, which degrade the exogenous protein within the phagosome into peptides of 12-15 amino acids length. The peptides are loaded into the cleft within the MHC class II molecules. The MHC class II peptides complex is then exported to the cell surface, where it is recognized by T-cells displaying CD4. $CD4^+$ T cells recognize their antigen MHC class II restricted. Endogenous antigen is produced within the host cell itself. It is either of host cell or of parasite origin. In the cytosol, proteasomes degrade endogenously synthesized proteins to peptides, which are then transported by particular transport-associated proteins, so-called TAPs to the endoplasmic reticulum. Here the peptides bind to MHC class I molecules. Thereafter the complex is exported to the cell surface. T cells displaying CD8 recognize the complex and are thereby stimulated. Therefore, they are said to be MHC class I restricted.

The great →polymorphism of genes coding for MHC molecules allows man to bind and present a vast diversity of different peptides produced by the many parasite pathogens, to a large T cell repertoire, resulting in highly specific immune response.

T-Cell Mediated Responses

Next, the various T cells, to which antigen is presented will be discussed. In man, the T cell population in the periphery amounts to more than 10^{12} cells, of which more than 90% carry the α/β T-cell receptor (TCR) and less than 10% the g/d receptor. The TCR associates with the variable region of the MHC-molecule which carries the antigenic peptide and the CD4 or CD8 molecules bind to the constant regions of the MHC molecules. Binding of the antigen/MHC-complex to the TCR results in the engagement of the CD3-complex, with subsequent signal transduction and T cell activation. This signal transduction is modulated by costimulatory effects induced by the accessory receptor/ligand pairs CD40/CD40 ligand or B7/CD28. CD40-mediated signals seem to affect primariliy $CD4^+$ T cells of the Th1 subtype, whereas the B7 costimulis trigger T cells of the Th2 subtype. The $CD4^+$ T-cells according to their cytokine secretion pattern have been first subdivided by Tim Mossmann into the Th1 and Th2 family, Th1 cells producing IL-2 and IFN-γ, cytokines that serve as stimuli of T-cells or macrophages respectively, and Th2 cells producing IL-4, IL-5, and IL-10, that is T-cells that act as true helper cells for →B-cells. The Th1 cells, via IFN-γ, seem to act as classical cells of delayed type of →hypersensitivity, i.e., of cell-mediated immunity for instance in the tuberculin reaction. Thus, they are of prime importance in the control of intracellular microorganisms such as toxoplasma, leishmania, mycobacteria, and others. By virtue of their IFN-γ production Th1 cells also downregulate Th2 cells. The Th2 cells, on the other hand represent the classical T helper cells, which are involved in the allergic reaction and in humoral immune responses. IL-4 is central to IgE production and IL-5 to IgA production and IL-10 downregulates Th1 cells. The subdivision of $CD4^+$ T cells in Th1 and Th2 cells should however not be taken too strictly because during a developing immune response, T cells producing both Th1 and Th2 cytokines are found, and Th1 and Th2 cells might well coexist in the tissue.

Differentiation of Th0 cells into Th1 or Th2 is driven by cytokines produced by different cells of the immune system. IL-12 is the major player in the Th1 pathway and IL-4 driving the Th2 cells. Undoubtedly, the signals which in leishmaniasis are decisive for the initiation of a protective Th1 response versus a disease-promoting Th2 response, are by far not clear.

Besides $CD4^+$ T cells, $CD8^+$ cells are involved in →immune reactions to most if not all intracellular parasites including plasmodia, toxoplasma, and leishmania. $CD8^+$ cells function by their capacity to act as cytolytic killer cells as well as producers of cytokines such as IFN-γ, etc. $CD8^+$ T cells lyse infected target cells by cell-to-cell contact subsequent to the recognition of

the target peptide that is presented by class I molecules. Target cell lysis is mediated by 2 separate mechanisms. The first mechanism involves the secretion of perforins and granzymes by the killer cells, which both lead to osmotic lysis of the target cells. The second mechanism requires the cross-linking of the Fas-ligand and the cytolytic $CD8^+$ cells with the Fas-antigen on the target cells with subsequent chromatin condensation, DNA fragmentation, and cell rupture. This mechanism induces →apoptosis, also known as programmed cell death, in the target cells. Cytolytic activity is most prominent in $CD8^+$ T cells, however also some $CD4^+$ T-cells have been shown to act as killer cells as in the case of →*Toxoplasma gondii*-infected macrophages. $CD8^+$ cells may act in synergy with Th1 cells, when Th1 cells produce the cytokines IL-2 and IFN-γ and $CD8^+$ cells contribute their cytolytic activity to the pathogen-eliminating process. Another type of T cells involved in the regulation of antiparasitic immunity are regulatory T cells (T_{reg}). Several types have been described based on their origin, generation, and mechanism of action, with 2 main subsets identified: "natural" $Foxp3^+CD4^+CD25^+$ T_{reg}, which develop in the thymus and regulate self-reactive T cells in the periphery, and "inducible" T_{reg} (e.g., Tr1 or Th3 cells), which can develop in the periphery from conventional $CD4^+$ T cells. Both types of T_{reg}, by virtue of their capacity to control the intensity of effector responses, have been shown to play a major role in the control of various parasitic infections.

Specific Aspects of Immune Responses to Helminths

Worms such as nippostrongylus, filaria, →ascaris, and schistosomes induce high levels of specific IgE antibodies and eosinophilia. This characteristic response pattern is caused by the particular ability of helminths to preferentially stimulate the Th2 subset of $CD4^+$ cells, which secrete the cytokines IL-4 and IL-5, IL-4 involved in the production of IgE antibodies and IL-5 acting as growth factor for eosinophils. *In vitro* studies suggest that helminths opsonized with specific IgE antibodies are lysed by eosinophils that carry Fc receptors specific for IgE, the toxic product contained in the major basic protein of the eosinophils granules. This effector mechanism however does not relate to cell helminths infections as immunity to →schistosoma induces Th1 cells and the production of IFN-γ, which results in activation of macrophages that directly delete the schistosome larvae by means of →nitric oxide (NO).

Strategies of Evasion of Immune Mechanisms by Parasites

The capacity of parasites to survive and to persist in their hosts is a result of coevolutionary events that enable the parasites to evade immune effector mechanisms. Most parasites have developed multiple →evasion strategies to circumvent both innate and acquired defense mechanisms of the host, which will be discussed separately for each parasite.

Immunization

See Vaccination Chapters.

Immunoassay

General Information

Immunological assays are available for measuring the humoral immune response after parasitic infections. For the detection and quantitation of antibodies or antigens an immunoassay has to fulfill 3 basic requirements: highly specific, highly sensitive, and reproducible. The field of application and the quality of antigen/antibody available are the main variables which determine the choice for 1 specific assay. A test system may be adequate for population screening or for individual diagnosis. Ideally, it is a single definitive test which can equally detect antibodies in low-responders, in people with recently contracted infection or with high titers and clinical signs, and be suitable for a posttreatment follow-up.

The stability of the antigen-antibody complex (avidity) determines the success of all immunological assays.

IFA, EIA, WB

The indirect immunofluorescence (fluorescent antibody) assay (test) (IIFA, IFA, IIFAT, IFT) has long been the best choice in parasitology. By using cryosections from different developmental stages of helminths or free →protozoa as antigens the test provides a satisfactory discrimination between specific and nonspecific reactions. The differential binding of antibodies to different structures of the parasite or cell is used to distinguish between specific and nonspecific reactivity. Its disadvantage is subjective reading and labour intensiveness. Screening of a large population is practically impossible. The indirect haemagglutination test (IHAT, IHA) is applied for fast screening at low costs of several parasitic infections. A broad application of the indirect enzyme-linked immunosorbent (enzyme immunosorbent) assay (→ELISA, EIA) has long been delayed by the use of nondefined, crude parasite extract antigens, resulting in a high degree of cross-reactivity. This disadvantage is now partly overcome by the availability of secretory/excretory (E/S) antigens, synthetic peptides and recombinant antigens. Still, the sensitivity and specificity of the ELISA vary considerably but it is an easy and fast alternative especially for population and herd screening and epidemiological studies. The western blot (WB, enzyme immunoblot, EIB), which provides a species or stage specific diagnosis is a confirmation test and applied as the final diagnostic step when screening results are positive.

Other Test Systems

Today, only few laboratories still use immunodiffusion (ID), gel precipitation, complement fixation test (CFT), Sabin Feldman dye test (DT), counterimmunoelectrophoresis (CIE) or radioimmunoassay (RIA) in routine →serodiagnosis. These test systems consume much antigen in comparison to the ELISAs, are less sensitive or use radiolabelled conjugates. Other test systems like card agglutination test (CATT), direct agglutination test (DAT), latex agglutination test (LA), carbon immunoassay (CIA), dot blot, and dip stick antigen assay were developed for a rapid, low cost screening under field conditions.

The rapidly increasing knowledge on immunology and molecular biology may result in a large scale production of characterized parasitic antigens applicable in different test systems. However, the suitability of each product for diagnostic purposes depends on the dynamics of the hosts immune response to that particular antigen.

Characteristics

IIFAT results depend not only on the kind of antigen used but also on its processing. Fixation is one of the most important steps (unfixed, formalin, aceton, methanol, heat, and others) to enhance or decrease the sensitivity or specificity of the test. The reading of the IIFAT requires a specific microscope. Reading of the slides by inexperienced staff may lead to different end-point titers due to subjective impressions. A new generation of IHATs using selected red blood cells of the 0 Rh- type for antigen cross-linking reduces the non-specific agglutination of erythrocytes and improves the specificity of this fast test system. ELISA is a suitable test system for the detection of both antigen and antibody. It is very sensitive and economic for testing a large number of serum samples within a relatively short time. The test principle allows many variations in the performance of the assay and the use of detection systems. Direct and indirect, capture and dip stick and many other ELISA systems are described as efficient in different diagnostic fields. Reading of the test is normally by use of a photometer. In highly specific assays a discrimination between positive and negative results is also possible visually. Indirect ELISAs, which are predominately used in parasitology for →antibody detection, measure antibody binding and not antibody levels and therefore provide only a limited quantitative information. The WB analysis demonstrates serum reaction patterns with antigen fractions of either a complex mixture or predefined extracts of parasites. It is used to demonstrate either an individual stage specific antibody response in follow-up studies or species specific reaction for the discrimination of infection with closely related parasites. The CATT is an easily and fast to perform low-cost system which uses the surface antigen of different *Trypanosoma*-species for antibody detection. It is applied as a screening tool for the (West) African →sleeping sickness and animal trypanosomiasis caused by *T. brucei/congolense* and *T. evansi*.

Standardisation

Standardisation of immunological assays is a crucial problem in parasitology. The evaluation of the specificity, sensitivity, and negative/positive predictive value of an assay requires either a "gold standard" or a population based evaluation of numerous defined serum samples. Only the DT is an accepted "gold standard" for toxoplasmosis →serology. For other parasitic infections either parasite detection, disease, or some other immunological assay with proven diagnostic value are used as "gold standard." Many home made or commercial test systems still work with undefined antigens. Also, reference sera are not available for all parasitic infections. Hopefully, standardization will improve with the availability of defined antigens.

Clinical Relevance

The clinical value of an immunoassay depends on its ability to allow the identification of an infected individual on the results of single test. Ideally, the

producer provides information on the positive and negative predictive value for his immunoassay. Due to a comparatively low demand for parasitological immunoassays in the low incidence "developed" countries test systems are often produced in parasitological laboratories. At present, only the serodiagnosis of toxoplasmosis is to a high degree commercialized and, in Germany, submitted to an official, external quality control. The choice of a suitable test system is therefore essential for a good diagnosis. For individual diagnosis a quantitative and specific measurement of the serum antibody concentration is required. The approximate antibody concentration is given either by end-point titers (IIFAT, IHAT), units, or absorbances (ELISA). The WB pattern can provide only semiquantitative, but highly specific results. In any case, an interlaboratory comparison of test results is only possible when identical assays are performed. The application of intra- and interassay quality controls by use of defined reference material is obligatory. For screening purposes a sensitive assay is preferred for primary diagnosis, followed by a more specific test for definitive diagnosis. Qualitative test results (positive/negative) will be sufficient for population screening or herd control. When interpreting test results it has to be considered that there is not only a population-based variability of the antibody responses to parasitic infections but also a great variability of the individual response depending on the parasite load and stage of infection. Finally, antibodies show variation among different techniques due to differences in multivalent binding.

The use of different test systems for seroepidemiological studies may result in different rates of seroprevalence achieved. These differences may reflect basic differences in the sensitivity or specificity between test systems. However, when direct parasite detection as "gold standard" for test evaluation is used, the resulting sensitivity depends not only on the experience of the investigator but also the frequency of sampling and the parasite load of the individuals tested. When disease is used as "gold standard" for test evaluation, a comparatively high seropositivity will result when the infective parasite exhibits a long →incubation period and/or low →morbidity rate. The clinical outcome of parasitic infections depends also on the genetic predisposition of the infected individual. A positive test result in 1 immunoassay may therefore provide evidence for a yet unknown immunological recognition of the parasite, which is undetectable in other assays. Discrepant rates in the prevalence of *Toxocara canis*-antibodies in human serum were reported when either CIEP and IIFAT or E/S-ELISA was applied. The interpretation of unresolved positive values is carried out by considering the incubation period and possible pathological effect of each parasite.

Immunodiagnosis

→Serology.

Immunofluorescence Antibody Test (IFAT)

Diagnostic method.

Immunofluorescence Assay (IF)

Diagnostic method to detect parasitic cells.

Immunoglobins

Antibodies (IgA, IgE, IgM, IgG) that were produced by the B-lymphocyte system.

Immunoprophylaxis

→Vaccination.

Immunosorbant Agglutination Assay (ISAGA)

Diagnostic method.

Immunosuppression

Reduction of the activity of the immune system, e.g., due to HIV-infection, constant uptake of cortisone or co-infection with several parasites leads to the abnormal reproduction of some parasites. →Opportunistic Agents.

Incidence

Number of new cases of disease with respect to a defined population.

Incubation Period

Period up to the first appearance of clinical symptoms after an infection with →agents of disease. It is mostly not identical to →prepatency.

Incursive Zone

→Geographic zones of occurrence of diseases: agents of disease are only found occasionally.

Indoor Feeding

→Endophagy (e.g., mosquitoes, that take their blood meal inside of human dwellings).

Indoxacarb

Chemical Class

Carboxamide (oxadiazine carboxamide).

Mode of Action

Voltage-gated sodium channel modulator. →Ectoparasiticides – Blockers / Modulators of Voltage-Gated Sodium Channels.

Inermicapsifer madagascariensis

Small only 5 cm long tapeworm of humans in East Africa, Asia, Cuba, and South America.

Infection

Moment of invasion/introduction/transmission of →agents of disease, which reproduce inside the host. With respect to man there are main routes (e.g., eating plants infected with *Fasciola*→metacercariae or pig meat with →cysticercus of →*Taenia solium* or uncommon, but also highly effective ones (e.g., eating infected raw liver in the case of *Fasciola* or imported sweet potatoes covered with eggs of *Taenia solium*, as was shown in a Jewish population).

Infestation

Settlement of a parasite, in or on a host without local reproduction (e.g., sucking of a tick/flea).

Inflammatory Reaction

→Pathology.

Infracommunity

→Communities.

Infrapopulation

This term includes all individuals of a single species parasitic in a single host.

Inhibitors of the Electron Transport Chain

→Energy Metabolism.

Inhibitory-Neurotransmission-Affecting Drugs

Overview see Table 1.

Structures

Fig. 1.

Piperazine

Synonyms

75 different synonyms (Chemotherapy of parasitic diseases (Campbell WC, Rew RS (eds), Plenum Press, New York and London, p. 629).

Clinical Relevance

The antinematodal activity of piperazine is directed against →*Ascaris lumbricoides*, *Enterobius*, ascarids in dogs and cats, adult →*Oesophagostomum* in pigs, adult

Inhibitory-Neurotransmission-Affecting Drugs. Table 1 Drugs active against micro- and macrofilariae

Year of introduction or discovery	Drug	Effects against filariae	Effect on other parasites
Drugs with predominantly microfilaricidal effects			
Acetylcholine-Neurotransmission-Affecting Drugs			
1955	Metrifonate	*Onchocerca volvulus microfilariae*	*Ascaris*, *S. haematobium*, insects
1965	Levamisole	*W. bancrofi*, *B. malayi*	Intestinal nematodes
Inhibitory-Neurotransmission-Affecting Drugs			
1980	Ivermectin	*Onchocerca volvulus*, *W. bancrofti*, *Loa loa*; *Dirofilaria immitis*	Nematodes, arthropods
1980's	Milbemycin D	*Dirofilaria immitis***	Nematodes, arthropods
1990	Milbemycin A4 oxime	*Dirofilaria immitis*; microfilariae in rodent models*	Nematodes, arthropods
1990	Moxidectin	*Dirofilaria immitis*; microfilariae in man and rodent models*	Nematodes, arthropods
1993	Doramectin	Microfilariae in man and rodent models*	Nematodes, arthropods
1999	Selamectin	*Dirofilaria immitis*	Nematodes, arthropods
2005	Latidectin	*Dirofilaria immitis*	Nematodes, arthropods
Membrane-Function-Disturbing Drugs			
1947/48	Diethylcarbamazine	*W. bancrofti*, *Brugia* spp., *Onchocerca volvulus*, *Loa loa*	
Drugs with predominantly macrofilaricidal effects			
Energy-Metabolism-Disturbing Drugs			
1916	Suramin	*Wuchereria*, *Brugia* (macrofilariae); adult *O. volvulus*	Trypanosomes
1984	Arsenamide (Thiacetarsamide)	*Dirofilaria immitis* (dog)	
Microtubule-Function-Affecting Drugs			
1971	Flubendazole, Mebendazole, Albendazole	*Wuchereria*, *Brugia* (macrofilariae), *O. volvulus*, also embryostatic effects	Nematodes, cestodes, trematodes, Giardia
Drug combinations			
	Ivermectin/DEC	Lymphatic filariasis	Mites/microsporidia
	Ivermectin/Albendazole		
Drugs with macro- and microfilaricidal effects			
1980	Benzothiazoles	*Onchocerca*, *Brugia* spp., *Dipetalonema* spp.	Cestodes

** McKellar QA and Benchaoui HA (1996) J. Vet. Pharmacol. Therap. 19: 331–351

horse →nematodes, and *Ascaridia* in chicken. Piperazine is only effective against large intestinal nematodes.

Molecular Interactions

Piperazine (Fig. 1) induces a reversible paralysis of *Ascaris suum in vitro* by exerting hyperpolarizing effects, thus acting as a selective GABA agonist (Fig. 2). The average duration of piperazine-induced channel openings is 14 msec, and is thus shorter than the GABA-produced openings with 32 msec. Piperazine is about 100 times less potent than GABA in *A. suum*. The difference in potency correlates with the need for higher piperazine concentrations to achieve a similar opening rate to GABA. The →*Ascaris* GABA receptor is pharmacologically distinguished from the vertebrate $GABA_a$ receptors. The action becomes potentiated by the presence of a high pCO_2 probable by interaction of CO_2 with the heterocyclic ring of piperazine which partially substitutes for the carboxylgroup of GABA.

Macrocyclic Lactones

Important Compounds

Ivermectin, Abamectin, Doramectin, Eprinomectin, Latidectin, Milbemycin oxime, Moxidectin, Selamectin.

Synonyms

Ivermectin: Baymec, Ivomec, Ivomec-Premix Ivomec-S, Cardomec, Equell, Eqvalan, Furexel, Heartguard 30, Heartgard Chewable, Mectizan, Oramec, Rotectin, Strongid, Zymectrin; in: Ivomec-P, Heartgard Plus.
Abamectin: Avomec, Duotin, Enzec; in: Equimax.
Doramectin: Dectomax.
Eprinomectin: Eprinex.
Latidectin: Lifenal
Milbemycin oxime: Interceptor, Interceptor Flavor Tabs; in: Sentinel.
Moxidectin: Cydectin, Equest, Pro Heart, Quest.
Selamectin: Revolution, Stronghold.

Clinical Relevance

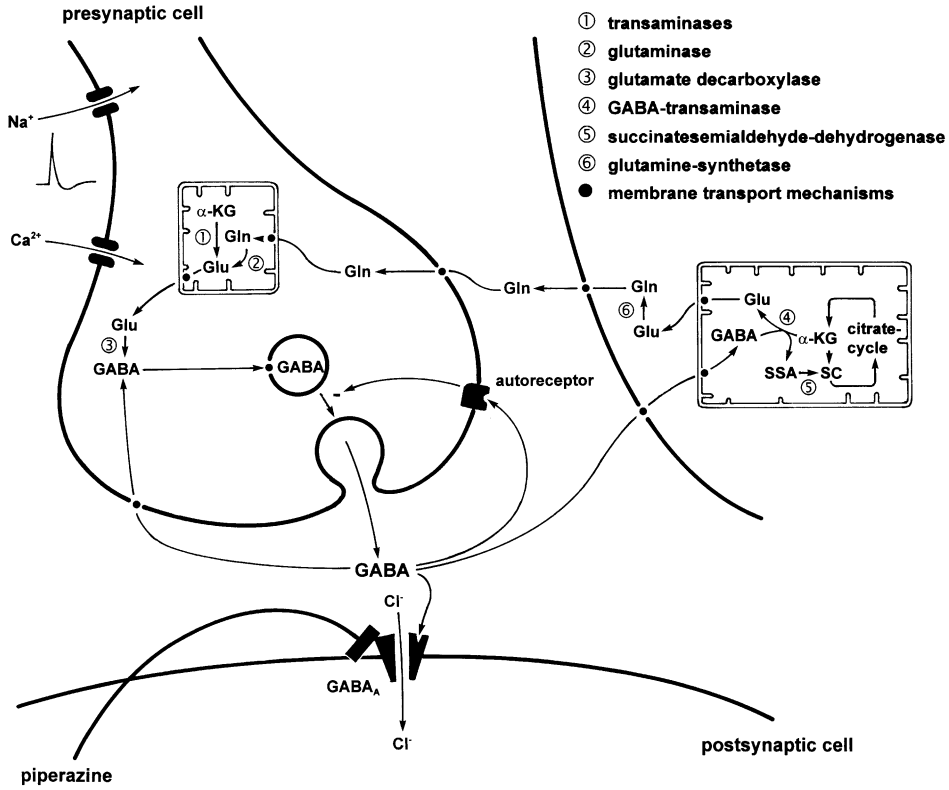
The group of these macrocyclic lactones is subdivided into 2 groups, the **avermectins** and **milbemycins**. To the avermectin anthelmintics belong avermectin (explored 1975), ivermectin (marketed 1980), abamectin (1980), doramectin (1993), eprinomectin (1996), selamectin (1999) and latidectin (2005). To the milbemycin anthelmintics belong milbemycin (explored 1973), milbemycin oxime and moxidectin (1993). Avermectin is produced by *Streptomyces avermitilis*, an actinomycete strain. Avermectin was isolated in 1975 and its antiparasitic activity discovered in mice infected with *Nematospiroides dubius*. The components avermectin B_{1a} and B_{1b} exert the highest anthelmintic activities. The chemical reduction leads to dihydro-derivatives with low toxicity. The mixture of 80% dihydro avermectin B_{1a} and 20% B_{1b} is named **ivermectin**.

Macrocyclic lactones are applied as broad-spectrum anthelmintics and ectoparasiticides in dogs, horses, cattle, sheep, pigs (Tables 1, 2, →Microtubule-Function-Affecting Drugs/Table 1, 2). Ivermectin is the drug of choice against →*Strongyloides stercoralis* infections in immunosuppressed patients. In addition, this drug is used for →heartworm →prophylaxis, in human onchocerciasis it is the drug of choice and it is of growing importance in →lymphatic filariasis (e.g., →*Wuchereria bancrofti* infections) as single drug or in combination with DEC or albendazole (Table 1). It has microfilaricidal effects and leads to a suppression of →embryogenesis in human onchocerciasis. It was introduced to Onchocerciasis Control Program of WHO in 1987 as Mectizan. In addition, ivermectin has some activity against male →*Onchocerca volvulus* in man as well as against microfilariae of *W. bancrofti*, →*Loa loa*. Ivermectin activity can be observed against *Litomosoides carinii* microfilariae in the circulating blood but not against microfilariae in the pleural cavity. Ivermectin has some *in vitro* activity against filarial parasites, e.g., →*Onchocerca* spp. There is generally a great discrepancy between the good *in vivo* efficacy and the minor *in vitro* effects. In general, treatment with ivermectin is not accompanied by severe side effects.

Molecular Interactions

Macrocyclic lactones act at the junction of ventral cord interneurons and motorneurons resulting in the immobilization of nematodes and at the neuromuscular junction of arthropods causing paralysis. Macrocyclic lactones are taken up by many gastrointestinal and filarial nematodes via the cuticula and presumably with equal importance by oral ingestion (→Acetylcholine-Neurotransmission-Affecting/Fig. 3), while in blood-sucking parasites (→*Haemonchus contortus*, arthropod ectoparasites) the oral absorption is by far more important. This view is supported by the observation that macrocyclic lactones exert greater activities against sucking →lice (*Haematopinus eurysternus*, *Linognathus vituli*) than biting lice (*Damalina bovis*). They also have high efficacy against →mites (*Sarcoptes scabiei var bovis*), which are known to be blood consumers.

The →mode of action of avermectins and milbemycins relies on the opening of the chloride ion channels in the neuronal membranes of nematodes and the muscle membranes of arthropods (Fig. 3). Thereby, cells become hyperpolarized and can no longer respond to incoming stimuli. All the physiological effects of avermectins and milbemycins can be reversed by picrotoxin, a specific blocker of the chloride ion channels. There is an ivermectin-induced increase of chloride permeability of nerve and muscles membranes of invertebrates observable. The structure and regulation of chloride ion channels of nematodes on the molecular level is unclear at present and also the identity of the target ion channel is controversial. Results from experiments with crayfish and *Ascaris suum* reveal that there is an interaction with receptors at chloride channels. The action is obviously not mediated by GABA-gated chloride channels. Expression experiments with *Xenopus*→oocytes lead to a proposed action of avermectins on a glutamate-gated chloride channel (GluCl). Genes encoding ivermectin-sensitive glutamate-gated chloride channel subunits could be isolated from →*Caenorhabditis elegans*. Moreover, the avermectin-binding site could be purified from *C. elegans*. A 1.8–2.0 kbp mRNA of *C. elegans* encoding a chloride channel with sensitivity to both ivermectin and →glutamate could be identified. The channel is presumably a pentamer similar to



Inhibitory-Neurotransmission-Affecting Drugs. Figure 2 Model of the action of piperazine on the GABAergic neurotransmission.

the nicotinic receptor and is selectively permeable for anions (chloride). The pentamer consists presumably of GluCl-α subunits with a glutamate-binding site and a GluCl-β subunit which contains the ivermectin-binding site. Molecularbiological experiments reveal that the GluCl-β subunit of the glutamate-gated channel is expressed in the pharyngeal muscle of *C. elegans*. There are considerable identities of α- and β- subunits of the glutamate-gated ion channels with the α- and β-subunits of mammalian GABA and →glycine receptors.

According to a hypothesis the pharyngeal pumping of nematodes is inhibited by ivermectin. In the pharyngeal muscle of *A. suum* a potentiation of the action of glutamate on glutamate receptors that gate chloride channels by ivermectin analogues could be observed. The hyperpolarization of the nerve and muscle membranes leads to a flaccid paralysis of the parasites. The CNS side effects of ivermectin are explained by the strong action on the receptors in rat brain through potentiation of GABA- and benzodiazepine-binding to open the channel. Nevertheless the relatively safe use of avermectins is due to the inability to cross the blood-brain barriers into the CNS in mammals with the exception of Collies. Moreover, the selectivity of macrocyclic lactones is due to different neurotransmitter functioning of glutamate in invertebrates (protostomes) where it acts as an inhibitory neurotransmitter in contrast to vertebrates where glutamate acts as an excitatory neurotransmitter.

Macrocyclic lactones like milbemycin oxime have only slight inhibitory and stimulatory concentration-dependent effects on the motility of filariae such as →*Dirofilaria immitis*. It is assumed that definite host factors are required, which are independent of a specific immune status of the host. In →*Acanthocheilonema viteae* an ivermectin-mediated cell adherence to the living microfilariae is observable and also cellular cytotoxicity by complement activation via the alternate pathway and/or antibodies. *L. carinii* microfilariae are killed without direct contact between cells and larvae. Here a very short-living mediator, which can be inhibited by the arginin-analogs such as N^G-monomethyl-L-arginine and L-canavanine, seems to be involved in the drug's action. Leucocytes are also required for the *in vitro* efficacy of ivermectin against microfilariae of *Dirofilaria immitis*. The immobilization of the larvae is necessary for cell adherence or cellular toxicity similar to ivermectin-induced paralysis of *Acanthocheilonema suum*. In addition, the paralysis of microfilariae of *O. volvulus* presumably facilitates the phagocytic

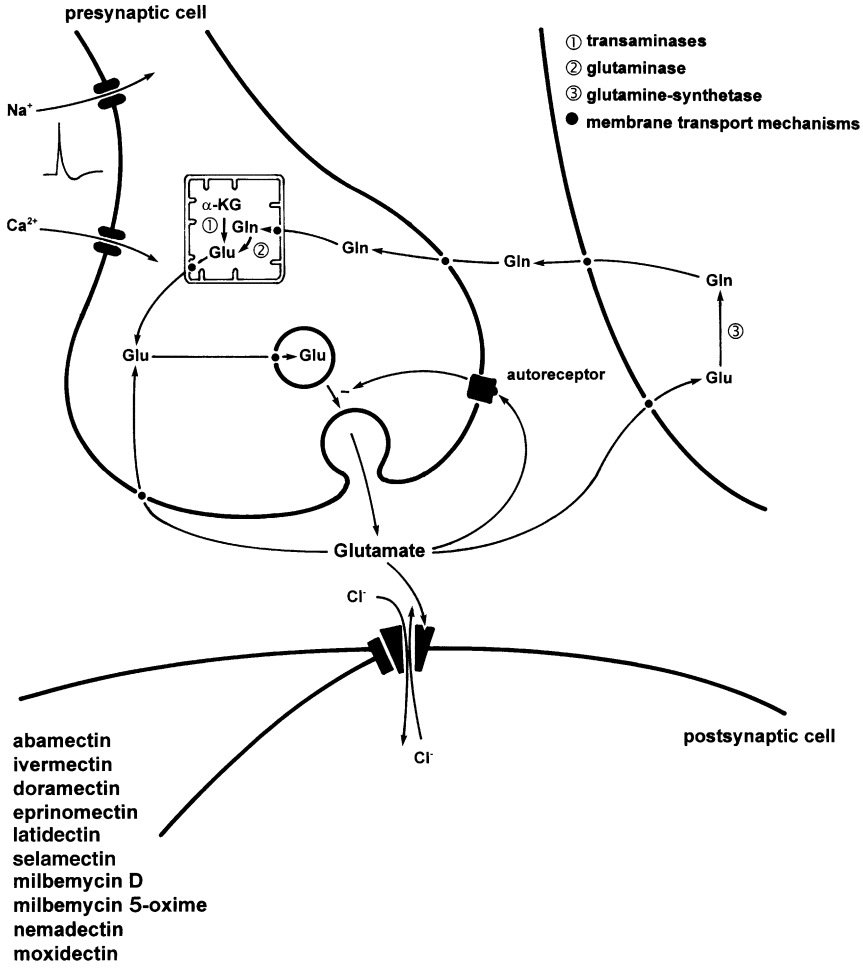
cell-trapping. The effects of ivermectin on adult worms are not fully understood to date. Electron microscopic studies on *Acanthocheilonema viteae* reveal a vacuolization and an increased electron density in all organs beginning 8 days after treatment. In *L. carinii* a degeneration of intrauterine stages and an extreme folding of the uterine wall can be observed accompanied by a generally increased electron density.



Inhibitory-Neurotransmission-Affecting Drugs. Figure 3 Model of the drugs affecting neuromuscular transmission by inhibitory neurotransmitters in protostomes.

Resistance

Resistance against macrocyclic lactones is probably inherited by a single dominant allele in *Haemonchus contortus*. The mechanism of ivermectin resistance on the molecular level is still unknown. Membranes of ivermectin-resistant and -susceptible larvae of *H. contortus* contain similar numbers of ivermectin-binding sites with the same affinity characteristics. It could recently be shown that ivermectin resistance may be caused by an altered P-glycoprotein homolog in *H. contortus*. Thereby the expression of P-glycoprotein mRNA is higher in the ivermectin-resistant *H. contortus* strain than in the susceptible strain. This multidrug-resistance mechanism can be reversed by verapamil and there is an increased efficacy of ivermectin and moxidectin against moxidectin-resistant *Haemonchus* in jirds (*Meriones unguiculatus*) in the presence of verapamil. The disruption of the mdr1a gene, which encodes P-glycoprotein in mice, results in →hypersensitivity against ivermectin. In another report an involvement of P-glycoprotein in ivermectin resistance in *H. contortus* was excluded. Now there exists a *Caenorhabditis elegans* mutant with a high level of ivermectin resistance, which can serve as a tool for further investigations of alterations in the glutamate/ivermectin chloride channel receptor and mechanism of ivermectin resistance in future.

Cyclic Octadepsipeptides

PF1022A

Synonyms.

Clinical Relevance

This compound has potent antinematodal properties against →*Toxocara canis*, *T. cati*, and →hookworms in dogs and cats and *Trichuris vulpis* in dogs. In addition, it has high efficacies against gastrointestinal →nematodes in horses, sheep, chicken, and rodents.

Molecular Interactions

PF1022A is a 24-membered cyclic depsipeptide isolated from *Mycelia sterilia*, a fungus which belongs to the →microflora of the plant *Camellia japonica*. Recently the chemical synthesis of PF1022A and also the radiolabelled compound have been reported. The anthelmintic action on the molecular level remains obscure to date. It appears that it exerts its activity by interfering with the neuromuscular transmission of nematodes. At low concentrations, the motility of →*Angiostrongylus cantonensis* is depressed, and picrotoxin, bicucullin, and Ca^{++} can antagonize the action. Thus, the action is explained by an antagonism of acetylcholine receptors and/or gabaergic mechanisms. It could also be shown that PF1022A has a high affinity binding to the $GABA_A$ receptor in *Ascaris suum*.

Recent experiments show that PF1022A and emodepside bind to a latrophilin-like receptor in the parasitic nematode *Haemonchus contortus* and the free-living nematode *Caenorhabditis elegans*.

Emodepside

Synonyms

PF1022-221, Bay 44-4400, emodepside as part of the anthelmintic combination emodepside/praziquantel in Profender Spot-On® for cats.

Clinical relevance

Anthelmintic research of the class of cyclic octadepsipeptides to which emodepside belongs started at the beginning of the 1990s. PF1022A, the starting material of emodepside, is a natural secondary metabolite of the fungus *Mycelia sterilia*, which belongs to the microflora of the leaves of *Camellia japonica*. PF1022A consists of four N-methyl-L-leucins, two D-lactic acids and two D-phenyllactic acids. These molecules build up a cyclic octadepsipeptide with an alternating L-D-L configuration. Emodepside is a semisynthetic derivative of PF1022A, which contains a morpholine attached in para-position at each of both D-phenyllactic acids.

Emodepside is effective against a wide variety of nematodes in cats, dogs, sheep, cattle, horse, poultry, mice, and rats. In cats after spot-on application of the all de-wormer Profender®, emodepside is highly efficacious against *Toxocara cati* and *Ancylostoma caninum* (→Microtubule-Function-Affecting Drugs/Table 2). In addition to its effects against gastrointestinal nematodes emodepside shows activities against lungworms in cattle, different larval stages of filariae in rodent models, and *Trichinella spiralis* larvae in mice.

Molecular Interactions

Emodepside binds to a presynaptic latrophilin-like receptor in the parasitic nematodes *Haemonchus contortus*, *Ostertagia ostertagi*, *Cooperia oncophora*, *Ancylostoma caninum*, and the free-living nematode *Caenorhabditis elegans*. Binding of drug to the latrophilin-like receptor is followed by the activation of a presynaptic signal transduction cascade (Fig. 4). The activation of Gqα protein and phospholipase-Cβ leads to mobilization of diacylglycerol (DAG). DAG then activates UNC-13 and synaptobrevin, two proteins which play an important role in presynaptic vesicle
